Diagnosis

The diagnosis of a periodontal abscess should be based on the overall evaluation and interpretation of the patient´s symptomatology, together with the clinical and radiographic signs found during the oral examination (Corbet 2004).

The case definition of a periodontal abscess, according to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Papapanou *et al*. 2018) was established based on two primary criteria as detectable signs/symptoms: ovoid elevation in the gingiva along the lateral part of the root and bleeding on probing. Other secondary signs/symptoms also listed were pain, suppuration on probing, deep periodontal pocket, and increased tooth mobility. This case definition was proposed based on the findings of the review paper presented at the Workshop (Herrera *et al*. 2018), which pooled together studies with a relevant number of cases and their comprehensive descriptions (Smith & Davies 1986; Hafstrom *et al*. 1994; Herrera *et al*. 2000a; Jaramillo *et al*. 2005; Chan & Tien 2010).

The most frequent sign of a periodontal abscess is the presence of an ovoid elevation in the periodontal tissues along the lateral side of the root (Fig. 19-2). Abscesses located deep in the periodontium may be more difficult to identify as they may manifest as a diffuse swelling or simply a red area (Fig. 19-3), rather than a prominent swelling of the soft tissues. Another common finding is suppuration either through a fistula or, most commonly, through the pocket opening (Fig. 19-4). This suppuration may be spontaneous or occur when pressure is applied to the outer surface of the lesion. Some studies found molars more frequently affected (Smith & Davies 1986; Herrera *et al*. 2000a), while others found equal distribution (Chan & Tien 2010) or predominance in anterior teeth (Jaramillo *et al*. 2005). One study reported a higher number of abscesses at the interdental area (Smith & Davies 1986), while others observed more frequent abscess formation at buccal sites (Herrera *et al*. 2000a; Chan & Tien 2010). The clinical symptomatology usually includes pain (from light discomfort to severe pain), tenderness of the gingiva, swelling, and sensitivity to percussion of the affected tooth. Other related symptoms are tooth elevation and increased tooth mobility (Fig. 19-5).

Fig. 19-2 Periodontal abscess associated with a lower right first molar. Note the association between the abscess formation and the furcation lesion in this molar.

Fig. 19-3 Periodontal abscess associated with a mandibular second molar. Note the diffuse swelling affecting the entire buccal surface of the molar.

Fig. 19-4 Periodontal abscess associated with a lower right first molar. Note the spontaneous suppuration expressed through the gingival margin.

Fig. 19-5 Periodontal abscess associated with an upper right third molar. Note how this lesion is associated with tooth extrusion and mobility.

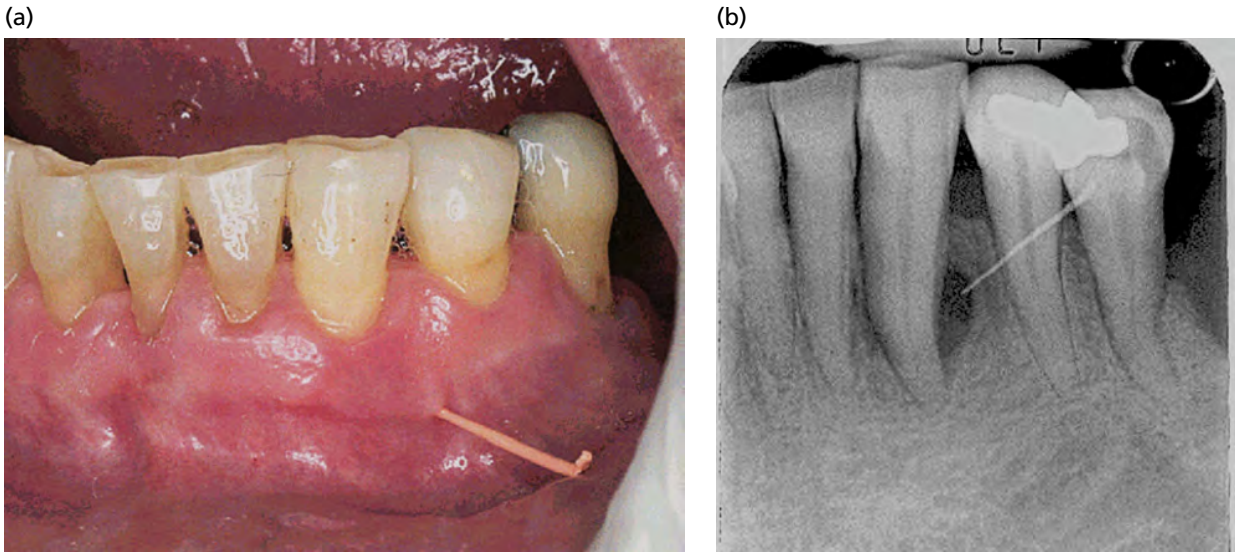

Fig. 19-6 (a) Periodontal abscess associated with a lower left canine. Note the fistulous tract opening demonstrated with a gutta-percha point. (b) Radiographic image of the lower canine shown in (a). Diagnosis of a periapical abscess was made from the positive tooth vitality and absence of caries or restoration in the canine, and the presence of a deep periodontal pocket in the lingual aspect of this tooth.

During periodontal examination, the abscess is usually found at a site with a deep periodontal pocket. Signs associated with periodontitis such as bleeding on probing, suppuration, and sometimes increased tooth mobility are also frequently present. The radiographic examination may either reveal a normal appearance of the interdental bone or evident bone loss, ranging from just a widening of the periodontal ligament space to pronounced bone loss involving most of the affected root (Fig. 19-6).

In some patients, the occurrence of a periodontal abscess may be associated with elevated body temperature, malaise, and regional lymphadenopathy (Smith & Davies 1986; Herrera *et al*. 2000a). Herrera *et al*. (2000a) studied samples from the blood and urine of patients, taken immediately after the diagnosis of a periodontal abscess, and reported that in 30% of the patients the number of blood leukocytes was elevated. The absolute number of blood neutrophils and monocytes was also elevated in 20–40% of the patients.

The patient history may also provide relevant information for the diagnosis of abscesses, especially in cases associated with previous treatments (scaling and root planing, periodontal surgery, intake of systemic antimicrobials or other drugs [e.g. nifedipine], and endodontic treatment), or in abscesses related to foreign body impaction. Most abscesses affect periodontitis patients, either untreated, in periodontal maintenance or undergoing active therapy.

Differential diagnosis

The differential diagnosis of periodontal abscesses should always consider other abscesses that may occur in the oral cavity (Ahl *et al*. 1986). Acute infections, such as periapical abscesses, lateral periapical cysts, vertical root fractures, and endo-periodontal lesions may have a similar appearance and symptomatology, although their etiology is different, and therefore, their appropriate treatment will depend on an accurate differential diagnosis. Signs and symptoms indicating a periodontal origin include: history of periodontitis or previous periodontal therapy, presence of deep periodontal pockets with suppuration when probed and, usually, tooth vitality. Radiographically, these affected teeth show crestal bone loss and frequently angular bony defects and furcation lesions. A likely periapical (endodontic) origin will include the following signs and symptoms: history of caries or presence of advanced caries lesions, presence of restorations or root canal treatment, questionable response or non-responsive to pulpal vitality tests, and presence of a sinus fistulous tract. Radiologically, there is usually evidence of a periapical radiolucency associated with a carious, restored, or endodontically treated tooth. From the radiograph, the quality of the root canal therapy and the existence of endodontic files or post perforations can be recognized.

The differential diagnosis should also consider other lesions that, although rare, may appear in the oral cavity and have a similar appearance to a periodontal abscess (Table 19-3). In cases where the abscess does not respond to conventional therapy, a biopsy and histopathologic diagnosis is always recommended:

- Tumor lesions, including metastatic lesions, odontogenic myxoma, non-Hodgkin´s lymphoma, squamous cell carcinoma, metastatic carcinoma.
- Other oral lesions: pyogenic granuloma, osteomyelitis, odontogenic keratocyst, eosinophilic granuloma.
- Self-inflicted gingival injuries.
- Sickle cell anemia.
- Abscesses after surgical procedures.

Table 19-3 Differential diagnosis of periodontal abscesses, as shown in different case reports.

Why periodontal abscesses are relevant

Prevalence

Periodontal abscesses represented approximately 7.7–14.0% of all dental emergencies, being ranked the third most prevalent infection demanding emergency treatment, after dentoalveolar abscesses and pericoronitis (Ahl *et al*. 1986). In an army dental clinic, 27.5% of periodontitis patients presented with periodontal abscesses, with clear differences between patients undergoing active periodontal treatment (13.5%) and untreated patients (59.7%) (Gray *et al*. 1994). Among 114 patients undergoing periodontal maintenance, periodontal abscesses were detected in 42 patients (37%) followed up for 5–29 years (McLeod *et al*. 1997). In the Nebraska prospective longitudinal study, 27 periodontal abscesses were observed for 7 years, and 23 of them occurred in sites that received coronal scaling (Kaldahl *et al*. 1996). Out of the 27 abscesses, 16 had an initial probing pocket depth >6 mm, while at eight sites, it was 5–6 mm.

Tooth loss

The rapid destruction of periodontal tissues, caused by a periodontal abscess, may negatively affect the prognosis of the affected tooth, and it has been considered the main cause of tooth extraction during periodontal maintenance (Smith & Davies 1986; Chace & Low 1993; McLeod *et al*. 1997; Silva *et al*. 2008). Similarly, teeth with repeated abscess formation were considered to have a "hopeless prognosis" (Becker *et al*. 1984), and 45% of teeth with a periodontal abscess found during periodontal maintenance were extracted (McLeod *et al*. 1997). The main reason for tooth extraction of teeth with a questionable prognosis, which had been followed up for 8.8 years, was the presence of periodontal abscess (Chace & Low 1993). Smith and Davies (1986) evaluated 62 teeth with

abscesses: 14 (22.6%) teeth were extracted as initial therapy, and nine (14.5%) after the acute phase and, out of the 22 teeth treated and subsequently monitored, 14 had to be extracted during the following 3 years. It has been suggested that early diagnosis and adequate therapy might be important in the management of a periodontal abscess in patients in supportive periodontal care, since under these conditions the prognosis of the affected tooth may not be affected (Silva *et al*. 2008).

Systemic dissemination of the infection

Periodontal abscesses may be associated with a systemic dissemination of the, initially, localized infection. Numerous case reports/series (Table 19-4) have described the occurrence of systemic infections resulting from a suspected source in a periodontal abscess, either through dissemination (via bacteremia or directly to adjacent tissues), occurring during the treatment of the abscess or related to an untreated abscess.

Necrotizing periodontal diseases

What are necrotizing periodontal diseases

Necrotizing periodontal diseases (NPDs) are a group of periodontal diseases with a characteristic clinical phenotype (papilla necrosis, bleeding, and pain) and associated with different degrees of host immune response impairment (Papapanou *et al*. 2018).

Classification

In the AAP International Workshop for a Classification of Periodontal Diseases in 1999, necrotizing ulcerative gingivitis (NUG) and necrotizing ulcerative periodontitis (NUP) were included in NPDs (Lang *et al*. 1999). Some studies suggested that they may represent different stages of the same disease, since they have similar etiology, clinical characteristics and treatment, and may even progress to more severe forms such as necrotizing stomatitis (NS) and noma (Novak 1999; Rowland 1999). The terminology "ulcerative" was

Table 19-4 Systemic complications of periodontal abscesses.

Reference	Country	Study design	Follow up	Patients (*n*)	Age	Name of the condition	Main results
Gallagher *et al*. (1981)	USA	Case report	2 months	1	54	Periodontal abscess	Brain abscess
Suzuki & Delisle (1984)	USA	Case report	18 months	1	62	Multiple periodontal abscess	Pulmonary actinomycosis

Duke *et al*. (2014)	USA	Case report	3 minutes	1	17	Periodontal abscess	Lemierre syndrome with respiratory distress

eliminated, since ulceration was considered to be secondary to necrosis (Feller & Lemmer 2005). NPD patients are frequently susceptible to future recurrence of disease (Johnson & Engel 1986; MacCarthy & Claffey 1991) and NPD could also become a "chronic condition", with a slower rate of destruction (Pindborg 1951). In cases of severe systemic involvement, progression of NPD into other oral lesions could occur (Williams *et al*. 1990; Felix *et al*. 1991).

NUG has been diagnosed for centuries with different names, including Vincent's disease, trench-mouth disease, necrotizing gingivo-stomatitis, fuso-spirochaetal stomatitis, ulcerative membranous gingivitis, acute ulcerative gingivitis, necrotizing ulcerative gingivitis, or acute necrotizing ulcerative gingivitis (Johnson & Engel 1986; Rowland 1999; Holmstrup & Westergaard 2008). NUP was defined both in the 1989 World Workshop (Caton 1989) and in the 1993 European Workshop (Attström & van der Velden 1993).

In the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Herrera *et al*. 2018; Papapanou *et al*. 2018), a new approach for classifying NPDs was suggested and accepted, since the previous concept did not take into account the huge differences in prevalence, risk of progression, and extent/severity of NPD among patients with different predisposing conditions. NPD in HIV/AIDS patients or in malnourished children in developing countries may represent a severe and even life-threating condition (in the latter case). Conversely, NPD in smokers/stressed adult patients in developed countries represented a relevant but normally non-threatening condition. Therefore, patients with a continuously and severely compromised systemic immune system (see previous examples) have a higher risk of suffering from NPD, and of presenting with a faster and more severe progression of the disease (from necrotizing gingivitis [NG] to necrotizing periodontitis [NP], and even to NS and noma). Conversely, in patients with a compromised systemic immune system for a limited duration (e.g. stressful situation in students or militaries), NG may not progress, although the lesions would be different if affecting a gingivitis or a periodontitis patient (Table 19-5).

Etiology, pathogenesis, and histopathology

NPDs are infectious conditions; however, predisposing factors, including a compromised host immune response, are critical in the pathogenesis.

The bacterial etiology of NPD, with the presence of spirochetes and fusiform bacteria, was previously demonstrated by Plaut in 1894, and Vincent in 1896 (reviewed in Rowland 1999). Moreover, clinical improvements observed after mechanical debridement and antimicrobial treatment further supported the bacterial etiology of these conditions (Socransky & Haffajee 1994). Earlier studies, using electron microscopy, suggested tissue invasion by spirochetes (Listgarten 1965; Courtois *et al*. 1983). Studies using bacterial culture identified *P. intermedia,* as well as *Treponema*, *Selenomonas*, and *Fusobacterium* species, which were considered "constant flora" in NPD lesions (Loesche *et al*. 1982). The role of spirochetes was confirmed by immunoassays (Riviere *et al*. 1991a,b) and polymerase chain reaction (PCR) targeting 16s rRNA (Dewhirst *et al*. 2000). Recent studies by phylogenetic analysis also suggested a role of *P. intermedia* and *Peptostreptococcus* genus in the etiology of NPD. The microbiota associated with NPD in HIV is similar to that of periodontitis in non-HIV patients, with some specific features, such as presence/invasion of *Candida albicans,* herpes viruses, or superinfecting bacterial species.

Necrotizing gingivitis lesions, observed with light microscopy (Listgarten 1965), showed the presence of an ulcer within the stratified squamous epithelium and the superficial layer of the gingival connective tissue, surrounded by a non-specific acute inflammatory reaction. Four regions have been described: (1) superficial bacterial area; (2) neutrophil-rich zone; (3) necrotic zone; (4) spirochaetal infiltration zone. Additional findings included plasma cells in the deeper parts and IgG and C3 between epithelial cells (Hooper & Seymour 1979). These observations have been confirmed by electron microscopy, adding areas of transition to a chronic stage of inflammation (Courtois *et al*. 1983).

Predisposing factors

The most relevant predisposing factors for NPD were shown to be those altering the host immune response and usually more than one factor was necessary to cause onset of the disease (Dufty 2014).

Human immunodeficiency virus infection and acquired immune deficiency syndrome (HIV/AIDS)

NPD in HIV patients may be more frequent and show faster progression, with an increased risk of evolving into more severe lesions (NP and NS), and an increased tendency for disease recurrence and poor response to therapy.

Other systemic conditions

Different reports have found NPD lesions associated with, or as a consequence of, different systemic conditions, or mimicking NPD, in which the lesions were part of the systemic pathology (Table 19-6 later in the chapter).

Malnutrition

Malnutrition could also be an important predisposing factor for NPD (Buchanan *et al*. 2006), especially in developing countries (Jimenez & Baer 1975;

Table 19-5 Classification of necrotizing periodontal diseases, based on the predisposing factors (2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions). (Sources: Herrera *et al*. 2018; Papapanou *et al*. 2018).

	Necrotizing periodontal diseases									
Category	Continuously and severely immunocompromised patients					Moderately and/or short-term immunocompromised patients				
Patients	In adults		In children			In gingivitis patients				In periodontitis patients
Predisposing factors	HIV+/AIDS with CD4 counts <200 and viral load	Other severe systemic conditions (immuno-suppression)	Severe mal-nourishment[1]	Extreme living conditions[2]	Severe (viral) infections[3]	Uncontrolled factors: psychological stress, nutrition, smoking, habits	Previous NPD: residual craters	Local factors: root proximity, tooth malposition	Common predisposing factors for NPD (see text)	
Clinical condition	NG, NP, NS, noma. Possible progression					Generalized NG. Possible progression to NP		Localized NG. Possible progression to NP	NG. Infrequent progression	NP. Infrequent progression

[1] Mean plasma/serum concentrations of retinol, total ascorbic acid, zinc, and albumin markedly reduced (very marked depletion of plasma retinol, zinc, and ascorbate) and saliva levels of albumin and cortisol, as well as plasma cortisol concentrations, significantly increased.
[2] Living in substandard accommodations, exposure to debilitating childhood diseases, living in close proximity to livestock, poor oral hygiene, limited access to potable water, and poor sanitary disposal of human and animal faecal waste.
[3] Measles, herpes viruses (cytomegalovirus, Epstein–Barr virus-1, herpes simplex virus), chicken pox, febrile illness.
NG, necrotizing gingivitis; NP, necrotizing periodontitis; NPD, necrotizing periodontal diseases; NS, necrotizing stomatitis.

Osuji 1990; Enwonwu *et al*. 2006). A marked reduction in key antioxidant nutrients and an altered acute phase response against infection ("protein energy malnutrition") (Enwonwu 1972; Melnick *et al*. 1988a) have been reported. Other consequences were an inverse proportion in the ratio of helper/suppressor T-lymphocytes, histaminaemia, increased free cortisol in blood and saliva, and defects in mucosal integrity (Enwonwu 1972; Enwonwu *et al*. 1999).

Psychological stress and insufficient sleep

Certain situations of acute psychological stress or stressful situations, some personality traits, or the ability to cope with a stressful situation, may predispose individuals to NPD. During stress periods, the immune response is altered, and the subject's behavior is changed. The biological plausibility of this assumption is based on the reduction of gingival microcirculation and salivary flow; increase in serum and urine levels of 17-hydroxycorticosteroid (17-OHCS) (Maupin & Bell 1975); change in the function of PMN and lymphocytes, and increase in periodontal pathogen levels (*P. intermedia)* (Loesche *et al*. 1982).

Inadequate oral hygiene, pre-existing gingivitis, and previous history of NPD

Plaque accumulation has been considered a predisposing factor for NPD, which may also be aggravated by limited tooth brushing because of pain (Johnson & Engel 1986; Taiwo 1993; Horning & Cohen 1995). NPD usually occurred secondarily to a previously existing periodontal disease: chronic gingivitis (Pindborg 1951; Wilton *et al*. 1971), previous NPD (Horning & Cohen 1995).

Tobacco and alcohol consumption

Most adult patients with NPD are smokers (Pindborg 1951; Giddon *et al*. 1964; Shields 1977; Stevens *et al*. 1984; Robinson *et al*. 1998; Lopez & Baelum 2009). Alcohol consumption has also been associated with the physiological and psychological factors favoring NPD (Horning & Cohen 1995; Magan-Fernandez *et al*. 2015).

Young age and ethnicity

Young people (15–34 years old) in the developed world are at a higher risk of suffering from NPD, frequently in combination with other predisposing factors (Skach *et al*. 1970; Stevens *et al*. 1984; Falkler *et al*. 1987; Horning & Cohen 1995). Children are at a higher risk in developing countries, and this is normally associated with malnutrition and other infections (Malberger 1967; Jimenez & Baer 1975). Some studies suggested that Caucasians suffered from NPD more frequently (Barnes *et al*. 1973; Stevens *et al*. 1984; Horning & Cohen 1995) than other ethnic groups. However, this finding needs to be confirmed.

Seasonal variations

Different studies have evaluated the hypothesis of the effect of seasonal variations on the prevalence of NPD: in central Africa, NPD peaked in the rainy season; less clear patterns were observed in military personnel, students or general populations, although winter months were normally peak periods, except in South Africa.

Other factors

Local factors, including decorative restorations (Flaitz & Agostini 2002) or orthodontic therapy (Sangani *et al*. 2013) may favor the onset of NG. Body geometry (Clark & Giddon 1971), thermoregulatory abnormalities (Giddon *et al*. 1969), allelic variants for complement factors and properdin factor B (Melnick *et al*. 1988b), or erythrocyte catalase activity (Nicol *et al*. 1971) have also been studied with inconclusive results.

Diagnosis

Diagnosis of NPD should be primarily based on clinical findings (Rowland 1999; Corbet 2004). Microbiological or biopsy assessments may be recommended in cases of atypical presentations or non-responding cases.

Necrotizing gingivitis

According to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Papapanou *et al*. 2018), a case of NG is primarily defined by the presence of necrosis/ulcer of the interdental papillae, gingival bleeding, and pain. Secondary signs/symptoms include halitosis, pseudomembrane formation, regional lymphadenopathy, fever, and sialorrhea (in children). This case definition was proposed based on the findings of the review paper presented at the Workshop (Herrera *et al*. 2018), which pooled together studies with a relevant number of cases (35 or more) (Barnes *et al*. 1973; Stevens *et al*. 1984; Falkler *et al*. 1987; Horning & Cohen 1995). In these studies, the most relevant clinical findings were: necrosis/ulcer in the interdental papilla (94–100%), gingival bleeding (95–100%), pain (86–100%), pseudomembrane formation (73–88%), and halitosis (84–97%) (Fig. 19-7). Extraoral signs included adenopathy (44–61%) or fever (20–39%). In children (Jimenez & Baer 1975), pain and halitosis were less frequent, while fever, adenopathy, and sialorrhea were more frequent.

Fig. 19-7 Necrotizing gingivitis in a 22-year-old woman: bleeding, necrosis, and pseudomembrane can be observed. (Source: Courtesy of Dr. Belén Retamal-Valdes.)

Necrotizing periodontitis

According to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Papapanou *et al*. 2018), a case of NP should primarily include necrosis/ulcer of the interdental papillae, gingival bleeding, halitosis, pain, and rapid bone loss (Fig. 19-8). Secondary signs/symptoms are pseudomembrane formation, lymphadenopathy, and fever. This case definition was proposed based on the findings of the review paper presented at the Workshop (Herrera *et al*. 2018), in which, in addition to the signs/symptoms observed in NG, periodontal attachment and bone destruction were considered as relevant, together with more frequent extraoral signs (Cobb *et al*. 2003). In severely immune-compromised patients, bony sequestra can occur (Umeizudike *et al*. 2011). NP could be the result of one or various episodes of NG (not always associated with pocket formation), or of NG occurring at a site previously affected by periodontitis (periodontal pocketing would be found) (Barr & Robbins 1996; Novak 1999).

Necrotizing stomatitis

According to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Papapanou *et al*. 2018), NS is primarily defined by the presence of soft tissue necrosis that extends beyond the gingiva, with bone denudation that may occur through the alveolar mucosa, with larger areas of osteitis and formation of bone sequestrum. It typically occurs in severely systemically compromised patients (HIV/AIDS patients, severe malnutrition). Atypical cases have also been reported, in which NS may develop without prior appearance of NG/NP lesions (Jones *et al*. 2000; Barasch *et al*. 2003; Salama *et al*. 2004; Feller *et al*. 2005).

It is mandatory to establish a differential diagnosis with vesicular–bullous diseases, primary or recurrent herpetic gingivostomatitis (Guggenheimer & Fletcher 1974; Lerman & Grodin 1977), oral manifestation mimicking NPD lesions, and toothbrush abrasion (Page *et al*. 1980) (Table 19-6).

Fig. 19-8 Necrotizing periodontitis: presence of necrosis/ulcer of the interdental papillae. (Source: Courtesy of Dr. Mauro Santamaria.)

Why necrotizing periodontal diseases are relevant

Epidemiology

Prevalence/incidence of NPDs has been reported for the overall population or for specific groups of individuals:

- In general populations attending dental clinics, the prevalence of NG ranged from 0.51 to 3.30% (Skach *et al*. 1970; Stevens *et al*. 1984; Falkler *et al*. 1987; Arendorf *et al*. 2001).
- In military personnel (Schluger 1949; Pindborg 1951; Grupe 1956; Shannon *et al*. 1969; Barnes *et al*. 1973; Horning *et al*. 1990; Minneman *et al*. 1995), the prevalence/incidence reported was higher close to the end of the Second World War (3.96–20.6%) than it was in more recent studies (0.19–6.19%).
- In African populations (Sheiham 1966; Malberger 1967; Enwonwu 1972; Osuji,1990; Taiwo 1993; Enwonwu *et al*. 1999; Kaimenyi 1999), highly variable results have been reported.
- In students (Giddon *et al*. 1963, 1964; Lopez *et al*. 2002; Lopez & Baelum 2004; Lopez & Baelum 2009), prevalence ranged from 0.9 to 6.7%.
- In HIV/AIDS patients data showed wide variations: children (2.2–5%), HIV adult patients (0.0–27.7% for NG and 0.3-9% for NP), and HIV/AIDS patients (10.1–11.1% for NG and 0.3–9% for NP) (Laskaris *et al*. 1992; Riley *et al*. 1992; Glick *et al*. 1994a,b; Robinson *et al*. 1998; Flaitz *et al*. 2001; Tappuni & Fleming 2001; Reichart *et al*. 2003; Sharma *et al*. 2006; Tirwomwe *et al*. 2007; Sontakke *et al*. 2011).

Severe destruction, sequalae, and risk of recurrence

NPD are considered among the most severe inflammatory conditions associated with oral biofilm bacteria (Holmstrup & Westergaard 2008), as they can progress rapidly and cause severe tissue destruction.

Table 19-6 Differential diagnosis of necrotizing periodontal diseases in case reports.

Reference	Country	Study	Patients (*n*)	Age	Gender	Periodontal condition	Other condition	Main results
Aker *et al*. (1978)	USA	Case report	1	17	Male	Initially "trench mouth" NUG	Acute lymphocytic leukemia	Disorders (leukemia) may share some of the clinical features of NUG
Page *et al*. (1980)	USA	Case report	1	35	Male	ARG	Unknown etiology, toothbrush abrasion	ARG is self-limiting and recurrent
Groot *et al*. (1990)	Netherlands	Cases series	3	44, 35, 42	Males	Initially generalized periodontitis with ANUG in AIDS patient	Primary oral malignant NHL	Striking resemblance to ANUG
Musa *et al*. (2002)	USA	Case report	1	9	Female	NUG	Oral cicatricial pemphigoid	Child with cicatricial pemphigoid, clinically manifested as NUG
Mucke *et al*. (2010)	Germany	Case report	1	76	Male	NG	Gingival angiosarcoma	Gingival angiosarcoma mimicking NG
Genuis & Pewarchuk (2014)	Canada	Case report	1	32	Female	Severe NG	Granulomatosis with polyangiitis (Wegener´s)	Granulomatosis with polyangiitis poses a significant diagnostic dilemma due its diverse presentations

ACPD, advanced chronic periodontal disease; AIDS, acquired immune deficiency syndrome; ARG, acute recurrent gingivitis; ANUG, acute necrotizing ulcerative gingivitis; ChP, chronic periodontitis; EBV-1 and EBV-2, Epstein-Barr viruses type 1 and type 2; GenP, generalized periodontitis; HCMV, human cytomegalovirus; HHV-6, human herpes virus; HIV, human immunodeficiency virus; HPV, human papilloma virus; HSV, herpes simplex virus; LPJ, localized juvenile periodontitis; NG, necrotizing gingivitis; NHL, non-Hodgkin's lymphoma; NUG, necrotizing ulcerative gingivitis; P, periodontitis.

It is, therefore, important to control predisposing factors, and once disease develops, to act quickly in order to limit its progression and exacerbation. Thus, these conditions should be managed promptly, and there is evidence that NPD can be controlled by means of an adequate periodontal treatment (Fig. 19-9), combined with effective oral hygiene measures and control of predisposing factors (Johnson & Engel 1986) (see Chapter 31).

NG patients, however, are frequently susceptible to future disease recurrence, mostly because of the difficulties in controlling predisposing factors as well as the challenge in achieving proper supragingival biofilm control. This is in part because of the sequelae of these diseases, mainly the presence of gingival craters (MacCarthy & Claffey 1991). NG can heal without clinical sequelae (Bermejo-Fenoll & Sanchez-Perez 2004), but often the necrotizing lesion extends laterally from the papilla to the gingival margin, affecting both the buccal and lingual sites and progresses to other sites in the mouth, progressing also from a localized into a generalized disease. It may also extend apically, leading to NP. As explained before, NP can be the result of one or more episodes of NG, or the result of an NPD affecting a site with periodontitis (Novak 1999). NPD can also become chronic, with a slow reduction in its symptomatology and progression, with ensuing destruction, although at a slower rate (Pindborg 1951; Holmstrup & Westergaard 2008).

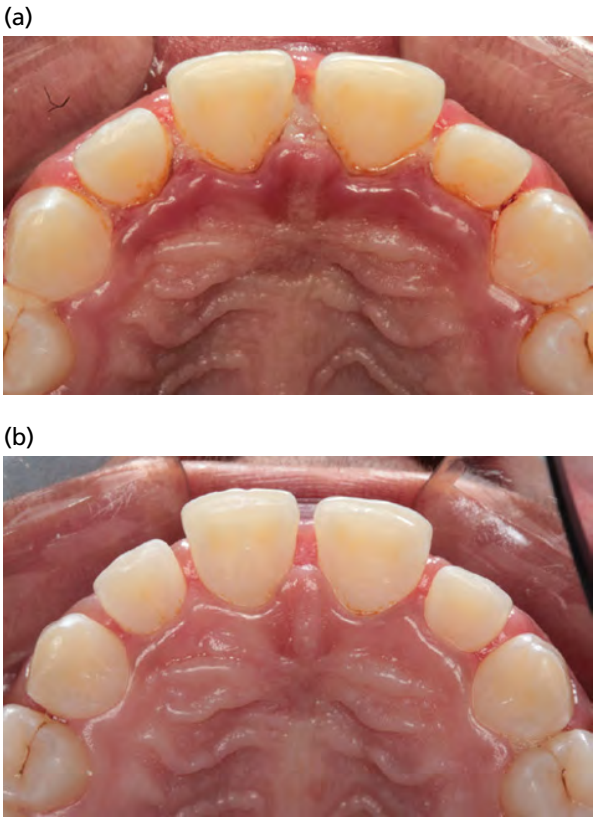

Fig. 19-9 Healing of necrotizing gingivitis lesions in the upper anterior sextant. (a) Active lesions with necrosis the interdental papillae. (b) Complete resolution after 60 days. (Source: Courtesy of Dr. Nidia Castro dos Santos and Dr. Mauro Santamaria.)

Life-threatening conditions

In cases of severe systemic involvement, such as in AIDS or severe malnutrition, NG and NP can progress further, with rapid involvement of the oral mucosae. The severity of these lesions is normally related to the severity of the systemic condition and the compromised immune host-response, leading to extensive bone destruction and presence of large osteitis lesions and oral-antral fistulae (Williams *et al*. 1990), with common features with *Cancrum oris* or noma. Some investigators suggested that noma is a progression of NP affecting the skin, whereas others believe that NS and noma are two distinct clinical entities. Noma is a destructive gangrenous disease affecting the facial tissues. It is associated with high mortality and morbidity rates (Enwonwu 1985; Baratti-Mayer *et al*. 2003; Enwonwu *et al*. 2006), and it is almost exclusively observed in developing countries, especially in children suffering from systemic diseases, including severe malnutrition. Noma is normally preceded by measles, malaria, severe diarrhea, and NG, which highlights the importance of prevention, early detection, and treatment during the first stages of the disease (Rowland 1999).

Endo-periodontal lesions

Under physiological conditions, the periodontal supporting tissues and the pulp/root canal complex exist in equilibrium. If the pulp or the periodontium suffer an injury, microorganisms and inflammatory products affecting one structure may also affect the other. Most of the time, these pathological communications are contained after effective periodontal or root canal treatment. For example, if the root canal is infected, even if a certain degree of cross-contamination with the periodontium occurs, in most cases this contamination would vanish after the proper root canal treatment. However, serious damage to the pulp/root canal complex and the periodontium in the same tooth, accompanied by a deep periodontal pocket and altered sensitivity test, is called an endo-periodontal lesion (EPL).

Classification

EPLs have been termed retrograde periodontitis, endodontic–periodontal lesions, or periodontal–endodontic lesions (Simring & Goldberg 1964; Simon *et al*. 1972; Al-Fouzan 2014). In 1972, Simon *et al*. published the first classification system for EPLs, which was widely used for decades and included five main categories: (1) primary endodontic lesions; (2) primary endodontic lesions with secondary periodontal involvement; (3) primary periodontal lesions; (4) primary periodontal lesions with secondary endodontic involvement; and (5) "true" combined lesions. The rationale behind this classification system, and a recent proposed amendment (Al-Fouzan 2014), is the assumption that lesions of periodontal origin have a worse prognosis than those of endodontic origin. However, it became clear that using "history of the disease" as the main criterion for diagnosis was not practical, because once the lesion is established, it is difficult to be sure whether the lesion was primarily endodontic, periodontal, or a combination of both (Herrera *et al*. 2018). In addition, determining the primary source of infection may not be so relevant for the treatment of EPLs, as both the root canal and the periodontal tissues would require treatment (Chapple & Lumley 1999; Meng 1999b). In 1999, the AAP included EPLs for the first time in its classification system, under the name "combined periodontal–endodontic lesions" (Armitage 1999; Meng 1999b). However, no categories were proposed, reducing the usefulness of this system. Ideally, classification systems should be based on signs and symptoms that can be assessed when the lesion is detected, and should provide categories able to guide the prognosis and treatment of the condition. In 2017, the World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Caton *et al*. 2018; Herrera *et al*. 2018; Papapanou *et al*. 2018) proposed a new classification for EPLs, based on the prognosis of the tooth involved and on the following signs and symptoms: (1) presence or absence of root damage; (2) presence or absence of periodontitis; and (3) the extent of the periodontal destruction around the affected tooth. This classification scheme is presented in Table 19-7. Three main prognostic categories for a tooth affected by an

Table 19-7 Endo-periodontal lesions classification. (Source: Herrera *et al*. 2018.)

Endo-periodontal lesion with root damage	Root fracture or cracking	
	Root canal or pulp chamber perforation	
	External root resorption	
Endo-periodontal lesion without root damage	Endo-periodontal lesion in periodontitis patients	*Grade 1* – narrow deep periodontal pocket in 1 tooth surface
		Grade 2 – wide deep periodontal pocket in 1 tooth surface
		Grade 3 – deep periodontal pockets in more than 1 tooth surfaces
	Endo-periodontal lesion in non-periodontitis patients	*Grade 1* – narrow deep periodontal pocket in 1 tooth surface
		Grade 2 – wide deep periodontal pocket in 1 tooth surface
		Grade 3 – deep periodontal pockets in more than 1 tooth surfaces

EPL were suggested: hopeless, poor, and favorable. The hopeless prognosis is normally associated with EPL accompanied by root damage (e.g. fracture or perforation), whereas the prognosis of a tooth with an EPL associated with endodontic and periodontal infections may range from favorable to hopeless, depending on the extent of the periodontal destruction around the affected tooth, and the presence and severity of periodontitis in the mouth (Herrera *et al*. 2018).

Etiology

EPLs are always associated with variable degrees of microbial contamination of the dental pulp and the periodontal tissues. However, the primary etiology of these lesions may be: a trauma and/or iatrogenic factor (non-infectious origin), or an endodontic and/or periodontal infection (infectious origin) (Herrera *et al*. 2018).

Endo-periodontal lesions associated with trauma and iatrogenic factors

These are EPLs of non-infectious origin. They normally have a hopeless or poor prognosis and are caused by trauma or iatrogenic events affecting the pulp and the periodontium. The most common lesions in this category are: (1) root/pulp chamber/furcation perforation (e.g. because of root canal treatment or tooth preparation for post-retained restorations) (Karabucak & Setzer 2009; Asgary & Fazlyab 2014; Tobón-Arroyave *et al*. 2004); (2) root fracture or cracking (e.g. because of trauma or tooth preparation for post-retained restorations) (Nicopoulou-Karayianni *et al*. 1997; Karabucak & Setzer 2009; Floratos & Kratchman 2012); (3) external root resorption (because of trauma) (White & Bryant 2002); and (4) pulp necrosis (because of trauma) draining through the periodontium (Tobón-Arroyave *et al*. 2004). The latter type of lesion has the best prognosis among all lesions in this category, because it is not associated with root damage.

Endo-periodontal lesions associated with endodontic and periodontal infections

These are lesions of infectious origin that may be initiated: (1) by a carious lesion that affects the pulp and, secondarily, affects the periodontium; (2) by periodontal destruction that secondarily affects the root canal; or (3) by both events concomitantly. The latter type occurs less frequently and it is usually referred to as a "true-combined" or "combined" lesion (Simon *et al*. 1972; Solomon *et al*. 1995; Singh 2011; Didilescu *et al*. 2012). Their prognosis varies, from favorable to very poor, depending on the extension of the lesion and the presence of periodontitis in the mouth.

EPLs may occur in subjects with periodontal health or disease, and the periodontal status was one of the main features in the new classification scheme of EPLs (Tables 19-7, 19-8, and 19-9). The periodontal condition has an important impact on the prognosis of these lesions because of the striking changes in the oral ecology of subjects with periodontitis (Socransky *et al*. 1998; Ximenez-Fyvie *et al*. 2000a,b; Mager *et al*. 2003; Socransky & Haffajee 2005; Faveri *et al*. 2006; Haffajee *et al*. 2008). Converting this ecology back into a healthy state is quite a difficult task (Teles *et al*. 2006; Soares *et al*. 2014; Feres *et al*. 2015; Tamashiro *et al*. 2016), especially in patients with advanced periodontitis and in teeth with deep pockets, as is the case in EPLs. Therefore, a detailed periodontal examination is a very important step for an accurate diagnosis, prognosis, and treatment plan of EPLs.

Microbiology

The microbiota of EPLs has been assessed by several investigators using different diagnostic tests (Table 19-10), such as microbial culture (Kipioti *et al*. 1984; Kobayashi *et al*. 1990; Pereira *et al*. 2011), PCR (Rupf *et al*. 2000; Pereira *et al*. 2011; Didilescu *et al*. 2012; Xia & Qi 2013; Li *et al*. 2014), checkerboard DNA–DNA hybridization (Didilescu *et al*. 2012), next generation sequencing (NGS) (Gomes *et al*. 2015), and denaturing gradient gel electrophoresis (DGGE)/cloning and sequencing (Xia & Qi 2013; Li *et al*. 2014). Taken together, the results of these studies suggested a marked similarity between the microbiota of root canals and periodontal pockets. Most of the species found in both niches are well recognized periodontal pathogens from the so-called red and orange complexes (Socransky *et al*. 1998), such as *P. gingivalis*, *T. forsythia*, *P. micra*, and species from the genera *Fusobacterium*, *Prevotella,* and *Treponema* (Rupf *et al*. 2000; Pereira *et al*. 2011; Didilescu *et al*. 2012). The studies using molecular techniques (Xia & Qi 2013; Aksel &Serper 2014; Gomes *et al*. 2015) observed high microbial diversity in both periodontal and endodontic samples and identified less common taxa, such as *Filicator alocis*, *Enterococcus faecalis*, and species from the genera *Desulfobulbus, Dialister*, and *Fretibacterium*. Incidentally, most of these species/genera have also been associated, recently, with the etiology of periodontitis (Griffen *et al*. 2012; Abusleme *et al*. 2013; Galimanas *et al*. 2014; Perez-Chaparro *et al*. 2014; Camelo-Castillo *et al*. 2015; Chen *et al*. 2015a; Kirst *et al*. 2015; Park *et al*. 2015; Dabdoub *et al*. 2016; Oliveira *et al*. 2016; Perez-Chaparro *et al*. 2018; Shi *et al*. 2018; Schulz *et al*. 2019; Feres *et al*. 2020; Ikeda *et al*. 2020).

It should be emphasized that with the exception of one study (Xia & Qi 2013), all the other studies evaluated the microbiota of EPLs in subjects with periodontitis, in teeth with advanced periodontal destruction, and without extensive restorations or cavities, suggesting that the primary source of infection was the periodontal microbiota. Therefore, one could argue that cases of EPLs of primary endodontic origin could harbor a different microbiota. Nonetheless, the studies that evaluated the microbiota associated

with different types of endodontic lesions (e.g. necrotic pulp, endodontic infection associated with pulp space exposed or unexposed to the oral cavity, acute or chronic apical endodontic lesions, and symptomatic irreversible pulpitis) also mainly identified those microorganisms normally found in the periodontal microbiota (Sassone *et al*. 2007; Siqueira & Rocas 2009; Siqueira *et al*. 2011; Santos *et al*. 2011; Sassone *et al*. 2012; Rocas *et al*. 2016).

Taken together, the abovementioned data suggest that there are no major differences between the microorganisms found in endodontic and periodontal lesions, or a specific microbial profile associated with the EPLs. This was somehow expected, as both sites of infection (root canal and periodontal pockets) are anaerobic environments exposed to similar nutrients.

Pathogenesis and histopathology

The dental pulp and the periodontium have different communication pathways, such as the apical radicular foramina, accessory (or lateral) canals, and dentinal tubules (Seltzer *et al*. 1963). The prevalence and location of accessory canals have been studied as they may influence the development of EPLs. Studies evaluating extracted teeth described a high prevalence of accessory canals, predominantly at the apical third of the roots. Nonetheless, they were also observed in high numbers in other portions of the roots, such as in the furcation regions of multirooted teeth (Seltzer *et al*. 1963; Rubach & Mitchell 1965). Under normal conditions, these paths between the pulp/canal complex and the periodontal tissues are aseptic and filled with capillaries, cells, fluids, and fibers (Seltzer *et al*. 1963; Rubach & Mitchell 1965). The pathological communication between these structures was first described in 1964 by Simring and Goldberg, and this may allow the migration of microorganisms or their by-products and/or inflammatory mediators from the root canal to the periodontium, or vice-versa, leading to an EPL (Lang & McConnell 1920;

Seltzer *et al*. 1963; Mazur & Massler 1964; Rubach & Mitchell 1965; Simon *et al*. 1972; Langeland *et al*. 1974; Zuza *et al*. 2012).

The influence of pulp disease in the periodontium is overall, well established, but the opposite route of contamination has been a topic of controversy. Granulomatous lesions or abscesses caused by infected/necrotic pulp can be formed around the root apex or in other parts of the root. It was demonstrated that the progression of this periradicular lesion may generate localized periodontal attachment loss, bone destruction, and may drain through the gingival sulcus/periodontal pocket (Seltzer *et al*. 1963; Rubach & Mitchell 1965; Hirsch & Clarke 1993). The influence of periodontal diseases in the pulp was reported by several histological studies that analyzed extracted teeth with periodontal destruction but free of carious lesions and/or extensive restorations. These studies consistently showed varying degrees of pulp alterations, such as altered nutritional supply, necrosis, atrophic, and degenerative changes (e.g. reduction/increase in number of pulp cells), and presence of calcifications, fibrosis, and reparative dentine (Lang 1920; Seltzer *et al*. 1963; Rubach & Mitchell 1965: Langeland *et al*. 1974: Zuza *et al*. 2012). Although most of these studies have suggested a positive association between the severity of periodontal destruction and the pulp alterations, a few histological (Mazur & Massler 1964; Bergenholtz & Lindhe 1978; Czarnecki & Schilder 1979) and animal studies (Hattler *et al*. 1977; Bergenholtz & Lindhe 1978) failed to show any correlation.

Risk factors

The main risk factors for the occurrence of EPL are advanced periodontitis, trauma, and iatrogenic events. Other reported risk factors were the presence of grooves, furcation involvement, porcelain-fused-to-metal crowns, and active carious lesions (Herrera *et al*. 2018) (Table 19-9). Several of these studies clearly specified that the teeth affected by EPLs had porcelain-fused-to-metal crowns, and thus, this type of crown was listed above as a risk factor for this condition. Nonetheless, in theory, any type of prosthesis could be considered as a risk factor for EPLs through different mechanisms: they may invade the biological width or favor the accumulation of biofilm, with consequent coronal leakage and recontamination of the endodontic filling.

Furcation involvement, severe bone destruction around the affected tooth, and anatomic problems (e.g. the presence of grooves) could worsen the prognosis of EPLs. Indeed, most of the single EPLs in non-periodontitis patients reported in the literature were associated with palatal grooves (Kerezoudis *et al*. 2003; Ballal *et al*. 2007; Attam *et al*. 2010; Gandhi *et al*. 2011; Coraini *et al*. 2013; Kishan *et al*. 2014; Castelo-Baz *et al*. 2015; Chen *et al*. 2015b; Sharma *et al*. 2015; Sooratgar *et al*. 2016).

Clinical presentation and diagnosis

According to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Caton *et al*. 2018; Herrera *et al*. 2018; Papapanou *et al*. 2018), an EPL is a pathologic communication between the pulpal and periodontal tissues at a given tooth that may occur in an acute (symptomatic) or a chronic (asymptomatic) form. The review paper presented at the Workshop to support the new classification of EPLs revealed that the most relevant clinical findings associated with EPLs are the presence of deep periodontal pockets reaching or close to the apex and negative or altered response to pulp sensitivity tests (Herrera *et al*. 2018). Normally, EPLs do not present evident symptoms, but if they are associated with a recent traumatic or iatrogenic event (e.g. root fracture or perforation), the most common manifestation is an abscess accompanied by spontaneous pain or pain on palpation and/or percussion. The other described signs and symptoms were: bone resorption in the apical or furcation region, purulent exudate, tooth mobility, sinus tract, presence of crown, and gingival color alterations (Table 19-8) (Herrera *et al*. 2018).

The diagnosis of EPLs should primarily comprise anamneses and clinical findings, including radiography (Meng 1999b; Herrera *et al*. 2018). Patient history is important for identifying the occurrence of trauma, and previous endodontic treatment/instrumentation or post preparation. If one or more of these events are identified, detailed clinical and radiographic examinations should be conducted to evaluate the presence of perforation, fracture, cracking, or external root resorption. Careful radiographic evaluation and clinical examination of the root anatomy is of great importance at this stage, to assess the integrity of the root and to help with diagnosis. A radicular groove, for example, might mimic a vertical root fracture in the radiograph (Attam *et al*. 2010).

If perforations and fractures are not identified, the diagnosis should proceed to a second stage, consisting of full-mouth periodontal assessment, including probing depth, presence of cavities, attachment level, bleeding on probing, suppuration and mobility, as well as tooth vitality and percussion tests. The sensitivity test is an essential step of the diagnosis, since an altered or negative test is required to define the presence of an EPL (Gupta *et al*. 2011). Even if a radiographic communication between the root canal and the periodontium through the apical foramen is detected, a vital pulp suggests that the host's defense system is being effective to protect the pulp tissue against the invasion of microorganisms (Yu & Abbott 2007; Zuza *et al*. 2012). Figure 19-10 presents

Table 19-10 Studies that evaluated the microbiota of endo-periodontal lesions. (Source: Herrera *et al*. 2018.)

Reference	Study design	Number of teeth studied	Technique	Periodontitis patient	Main finding
Kipioti *et al*. (1984)	Clinical study	16	Culture	Yes	The majority of isolates in periodontal pockets and root canals were *Bacteroides gingivalis* (currently *Porphyromonas gingivalis*) and *Bacteroides melaninogenicus ss intermedius* (currently *Prevotella intermedia*)
Kobayashi *et al*. (1990)	Clinical study	15	Culture	Yes	The predominant bacterial species in periodontal pockets and root canals were from the genera *Streptococcus*, *Peptostreptococcus*, *Eubacterium*, *Bacteroides*, *Fusobacterium*, *Actinomyces*, and *Streptococcus*
Pereira *et al*. (2011)	Clinical study	27	Culture/PCR	Yes	The most prevalent species in periodontal pockets and root canals were *Porphyromonas gingivalis*, *Prevotella intermedia,* and *Prevotella nigrescens*
Didilescu *et al*. (2012)	Clinical study	46	PCR/ checkerboard DNA–DNA hybridization	Yes	The predominant bacterial species in periodontal pockets and root canals were *Fusobacterium nucleatum*, *Campylobacter rectus, Eubacterium nodatum, Eikenella corrodens, Parvimonas micra*, and *Capnocytophaga sputigena*
Xia & Qi (2013)	Clinical study	13	PCR/DGGE, cloning, and sequencing	No	The similarity of bacteria in dental plaque and necrotic pulp ranged from 13.1% to 62.5%. The main genera identified in dental plaque were *Campylobacter*, *Fusobacterium*, *Neisseria*, *Peptostreptococcus, Veillonella, Aggregatibacter, Enterobacter*, and *Haemophilus,* and in necrotic pulps were *Mogibacterium*, *Corynebacterium, Neisseria and Actinomyces*
Li *et al*. (2014)	Clinical study	20	PCR/DGGE, cloning, and sequencing	Yes	The predominant bacterial species in periodontal pockets and root canals were *Filifactor alocis*, *Parvimonas micra*, *Porphyromonas gingivalis*, and *Tannerella forsythia*
Rupf *et al*. (2000)	Clinical study	31	Real-time PCR	Yes	The most prevalent bacterial species in periodontal pockets and root canals were *Aggregatibacter actinomycetemcomitans*, *Tannerella forsythia*, *Eikenella corrodens, Fusobacterium nucleatum, Prevotella intermedia, Porphyromonas gingivalis*, and *Treponema denticola*
Gomes *et al*. (2015)	Clinical study	15	Next generation sequencing	Yes	*Enterococcus faecalis, Parvimonas micra* **and** *Filifactor alocis* were among the most prevalent species in both root canals and periodontal pockets. Other species were also predominant in root canals (*Mogibacterium timidum*, *Fretibacterium fastidiosum*) or in periodontal pockets (*Streptococcus constellatus*, *Eubacterium brachy*, *Tannerella forsythia*).

DGGE, denaturing gradient gel electrophoresis; PCR, polymerase chain reaction.

the main steps for a proper diagnosis of an EPL in clinical practice.

Some EPLs are associated with a sinus tract, which are not always located in the exact direction of the affected root/tooth. In these cases, the clinician may use the gutta-percha tracing approach to help locate the tooth/root affected by the lesion. It consists of introducing a gutta-percha cone in the sinus tract in order to trace its path using x-rays. By inserting the gutta-percha cone in the periodontal pocket, the same strategy may be used to track the path of the pocket to the apex of the affected root/tooth.

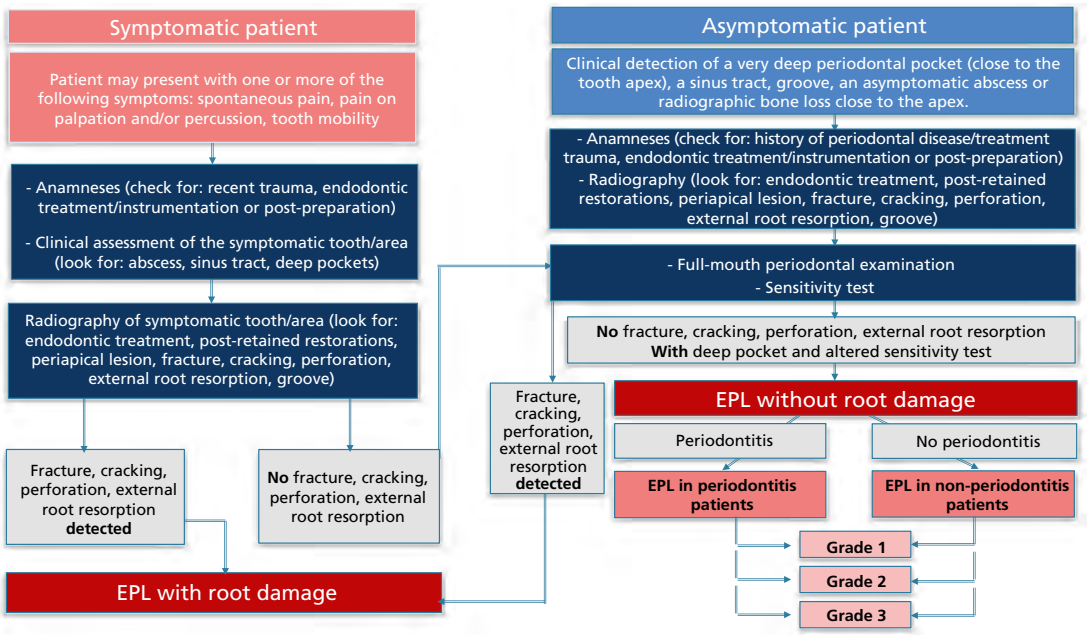

Fig. 19-10 Diagnostic tree for endo-periodontal lesions (EPL).

Summary

Periodontal abscesses should be classified according to the etiological factors involved in their development, since they can present distinct etiologies, commonly associated with reduced drainage of a deep periodontal pocket. Their relevance is based on rapid tissue destruction, which may compromise tooth prognosis, becoming one of the main reasons for tooth extraction in supportive periodontal care. In addition, relevant, but not frequent, systemic risks have been associated with periodontal abscesses.

NPDs typically show three main clinical findings, namely papillary necrosis, bleeding, and pain, and they are considered as the most severe biofilm-related periodontal conditions. A compromised host immune response is crucial to the onset, severity, extent, and progression of NPDs. As such, these diseases need to be classified according to the level of impairment of the immune system.

For EPLs, a pathological communication between the endodontic and periodontal tissues is established, and the lesion can show an acute or a chronic course. It is recommended that they should be classified according to the signs and symptoms that may have a direct impact on their prognosis and treatment, including the presence or absence of fractures and perforations, the presence or absence of periodontitis, and the extent of periodontal destruction around the affected teeth.

Part 7: Peri-Implant Pathology

Chapter 20

Peri-Implant Mucositis and Peri-Implantitis

Tord Berglundh[1], Jan Lindhe[1], and Niklaus P. Lang[2]

Introduction

Peri-implant disease is a collective term used to describe inflammatory processes in tissues that surround dental implants and includes two entities: peri-implant mucositis and peri-implantitis. A new classification of peri-implant diseases was proposed at the 2017 World Workshop on Classification of Periodontal and Peri-Implant Diseases and Conditions (Berglundh *et al*. 2018) and case definitions for peri-implant health, peri-implant mucositis, and peri-implantitis were presented. It is important in this context to distinguish between the terms *case definition* and *disease definition*. A disease definition is descriptive and provides information on the characteristics of the disease, whereas a case definition serves as a directive for the clinical assessment of the disease, that is, the diagnosis. While peri-implant mucositis and peri-implantitis will be described in detail in this chapter, the main characteristics of healthy peri-implant mucosa will also be reviewed to highlight important differences between peri-implant tissues and periodontal tissues (Fig. 20-1). The etiology and pathogenesis of peri-implant diseases including the transition from healthy peri-implant mucosa to peri-implant mucositis and from peri-implant mucositis to peri-implantitis are similar to that of periodontal diseases at teeth. Case definitions are fundamental for diagnosis of peri-implant diseases and the clinical assessment of bleeding on probing (BoP) is the key method to differentiate between healthy and inflamed tissue. Peri-implant mucositis and peri-implantitis, however, are distinguished by the assessment of peri-implant bone loss in radiographs. Bone loss represents an apical shift of the crestal bone level between two examinations and should, in addition, exceed bone level changes that may occur during a phase of initial bone remodeling after implant installation (see also Chapter 5). Case definitions and their role in the appraisal of the prevalence and risk factors for peri-implant disease are discussed in Chapter 7.

Healthy peri-implant mucosa

A healthy peri-implant mucosa is characterized by the absence of visible signs of inflammation, such as redness and swelling. While BoP should not occur during clinical examination, there is no defined range of probing depth compatible with healthy peri-implant mucosa.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

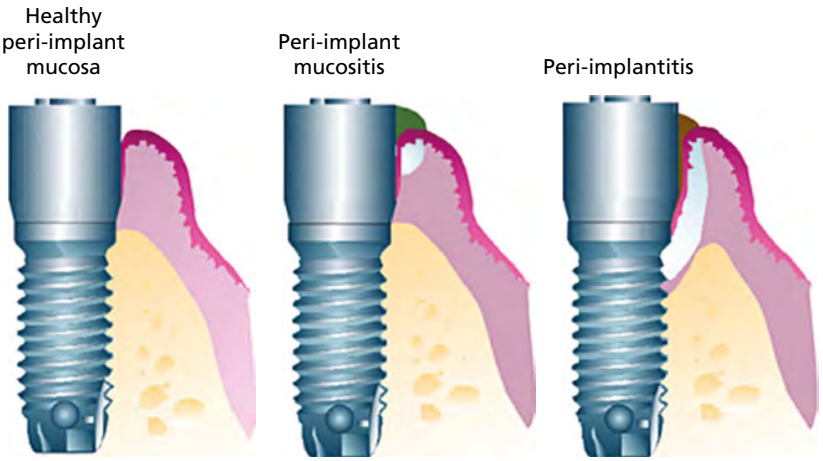

Fig. 20-1 Healthy peri-implant mucosa, peri-implant mucositis, and peri-implantitis.

Most information on histological characteristics of the healthy peri-implant mucosa are derived from pre-clinical *in vivo* studies (Araújo & Lindhe, 2018; Berglundh *et al*. 2018). Thus, following implant installation, a transmucosal passage is formed around the abutment portion of the device. The ridge mucosa at such sites adapts to the new functional demands and a peri-implant mucosa becomes established. The mucosa surrounding implants and the gingiva at teeth have many features in common (Berglundh *et al*. 1991). Both types of tissues are often lined with a keratinized oral epithelium; at clinically healthy sites, this is continuous with a thin non-keratinized barrier or junctional epithelium that faces the implant or the tooth surface. In the connective tissue immediately lateral to these thin epithelial linings, small infiltrates of inflammatory cells (neutrophils, macrophages, T cells, B cells) are frequently seen (Liljenberg *et al*. 1997; Tomasi *et al*. 2014, 2016). The inflammatory cells represent the host's defense against bacterial products and hence they may be considered as an integral component of the biologic seal that separates the peri-implant and periodontal attachment tissues from the oral cavity (see also Chapters 4 and 10).

In contrast to periodontal tissues, peri-implant tissues do not present with a root cementum and a periodontal ligament. In the connective tissue zone between the bone crest and the junctional epithelium of the peri-implant mucosa there are no inserting collagen fibers into the implant and the vascular density is lower than that in corresponding compartments of periodontal tissues (Araújo & Lindhe 2018; Berglundh *et al*. 2018). It is anticipated that this lack of a root cementum and a periodontal ligament entails an impaired capacity to encapsulate the progressing lesion of the developing peri-implant disease process.

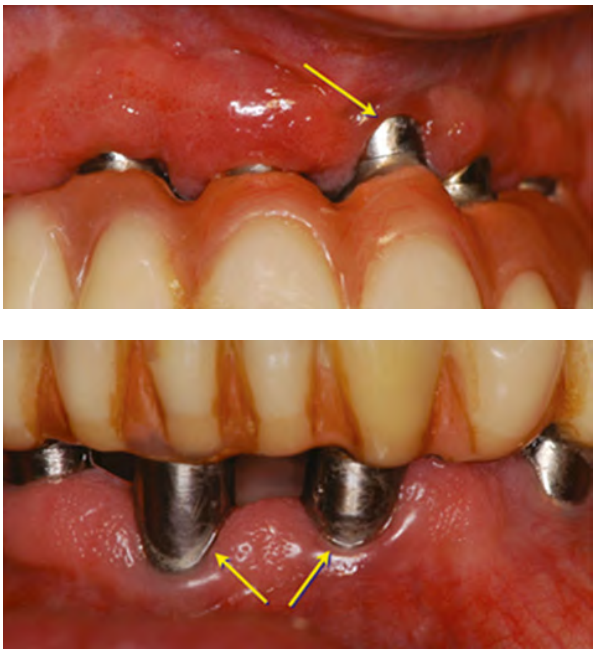

Fig. 20-2 Clinical symptoms of peri-implant mucositis, including varying signs of redness and swelling. Probing resulted in bleeding from the margin of the mucosa (arrows).

Peri-implant mucositis

Clinical features and diagnosis

Peri-implant mucositis is an inflammatory lesion of the soft tissues surrounding an endosseous implant in the absence of loss of supporting bone (Berglundh *et al*. 2018; Heitz-Mayfield & Salvi, 2018). Its clinical features are in many respects similar to those of gingivitis at teeth and include classical symptoms of inflammation, such as swelling and redness. It should be noted, however, that visible signs of inflammation may vary and be masked by the metal of the device or the crown restoration. The clinical assessment of peri-implant mucositis must therefore always include assessment of bleeding following probing (Fig. 20-2). While BoP is the main clinical characteristic in sites with peri-implant mucositis, an increase of probing depth may also occur due to swelling or decrease in probing resistance. Thus, the diagnosis of peri-implant mucositis is based on the observations of BoP and absence of bone loss (Fig. 20-3). Case definitions for peri-implant mucositis are discussed in Chapter 7.

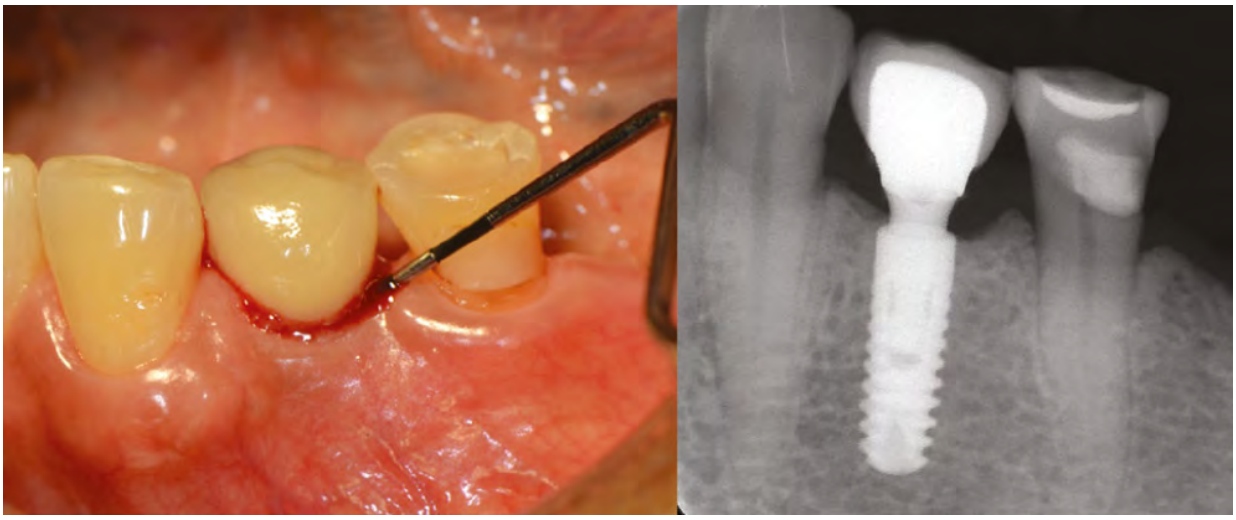

Fig. 20-3 Diagnosis of peri-implant mucositis indicated by the clinical finding of bleeding on probing and absence of radiographic bone loss.

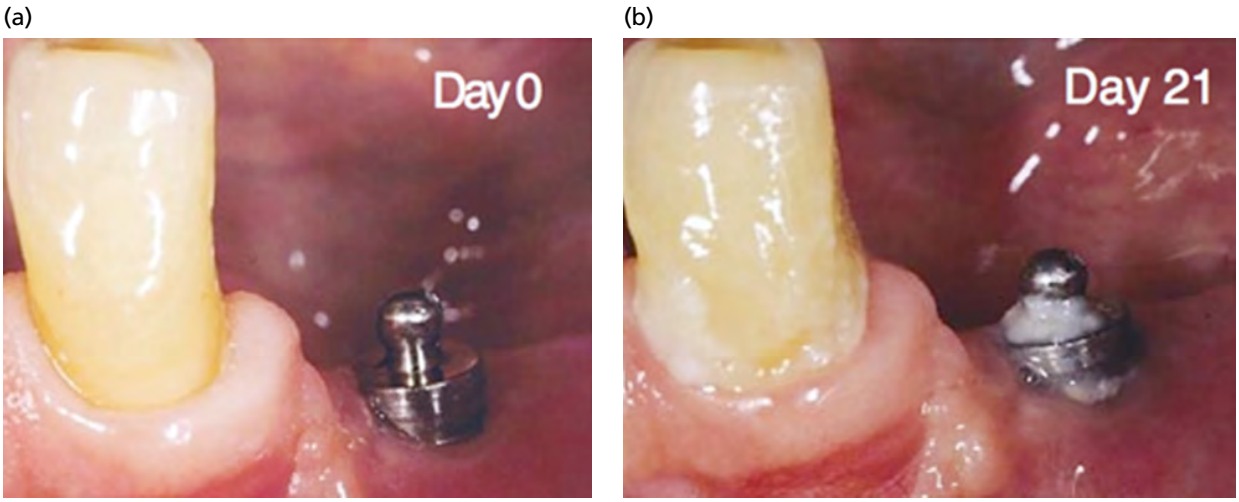

Fig. 20-4 (a) Healthy gingiva and peri-implant mucosa. (b) Same site following 3 weeks of plaque formation.

Clinical models

The response of the gingiva and the peri-implant mucosa to early and more longstanding periods of plaque formation was analyzed both in studies in humans and in preclinical models. Pontoriero *et al*. (1994) engaged 20 partially edentulous human subjects in a clinical "experimental gingivitis in man" (Löe *et al*. 1965) study. All subjects had been treated for advanced periodontal disease and thereafter had been restored with implants in one or several segments of the dentition. During a 6-month period following the prosthetic rehabilitation, the subjects were enrolled in a meticulous maintenance program that included regularly repeated supportive measures. A baseline examination was subsequently performed including assessment of plaque, soft tissue inflammation, probing pocket depth (PPD), soft tissue recession, and composition of oral biofilms. The participants refrained from all oral hygiene measures for 3 weeks. It was observed that during this interval, plaque build-up (amount and composition) and the soft tissue response to the microbial challenge, for example inflammation and PPD change, developed in a similar manner in the tooth and implant segments of the dentition.

Zitzmann *et al*. (2001) studied the response to plaque formation in the soft tissues at implant and tooth sites in humans. Twelve subjects with healthy periodontal and peri-implant conditions were asked to refrain from all oral hygiene measures for a period of 3 weeks (Fig. 20-4). Clinical examinations were performed and soft tissue biopsies were harvested prior to and at the end of the plaque accumulation period. It was demonstrated that plaque build-up was associated with clinical signs of soft tissue inflammation and also an increase in the scale of soft tissue infiltrate by inflammatory cells in tissues around teeth and implants.

Salvi *et al*. (2012) reported on the reversibility of experimentally induced gingivitis/peri-implant

mucositis in a study including 15 partially dentate subjects. Following an initial period of plaque formation to induce mucosal inflammation, oral hygiene procedures were re-instituted. The inflammation gradually resolved in the gingiva as well as in the peri-implant mucosa.

Untreated peri-implant mucositis may progress to peri-implantitis. Costa *et al*. (2012) reported that patients with peri-implant mucositis at baseline and not receiving regular supportive peri-implant therapy presented with an incidence of peri-implantitis of 44% during a 5-year period. In a parallel group of patients with peri-implant mucositis who attended a regular supportive therapy program, the incidence of peri-implantitis over 5 years was 18%. This observation underlines the importance of detecting and treating peri-implant mucositis to prevent progression to peri-implantitis.

Preclinical models

In an experiment in the dog, Berglundh *et al*. (1992) compared the reaction of the gingiva and the peri-implant mucosa with 3 weeks of *de novo* plaque formation. The mandibular premolars in one side of the mandible were extracted, leaving the premolars on the contralateral side as controls. After 3 months of socket healing, implants were inserted in the edentulous ridge. The animals were placed in a plaque-control program to allow for ideal healing of the mucosa at the implants and to prevent gingivitis from occurring in the tooth segments of the dentition. After this healing period, the dogs were examined and samples from the minute biofilms that were present on the implant and the tooth surfaces were harvested. The plaque-control program was terminated and the animals given a soft diet that allowed gross plaque formation. Re-examinations, including clinical assessment, sampling of plaque from teeth and implants, as well as biopsy, were performed after 3 weeks. During the course of the study, similar amounts and composition of plaque formed on teeth and implants. It was therefore concluded that early microbial colonization on titanium implants followed the same pattern as that on teeth (Leonhardt *et al*. 1992). Both the gingiva and the peri-implant mucosa responded to this plaque build-up with the establishment of overt

Fig. 20-5 Five months of undisturbed plaque formation on three different types of implants in a dog.

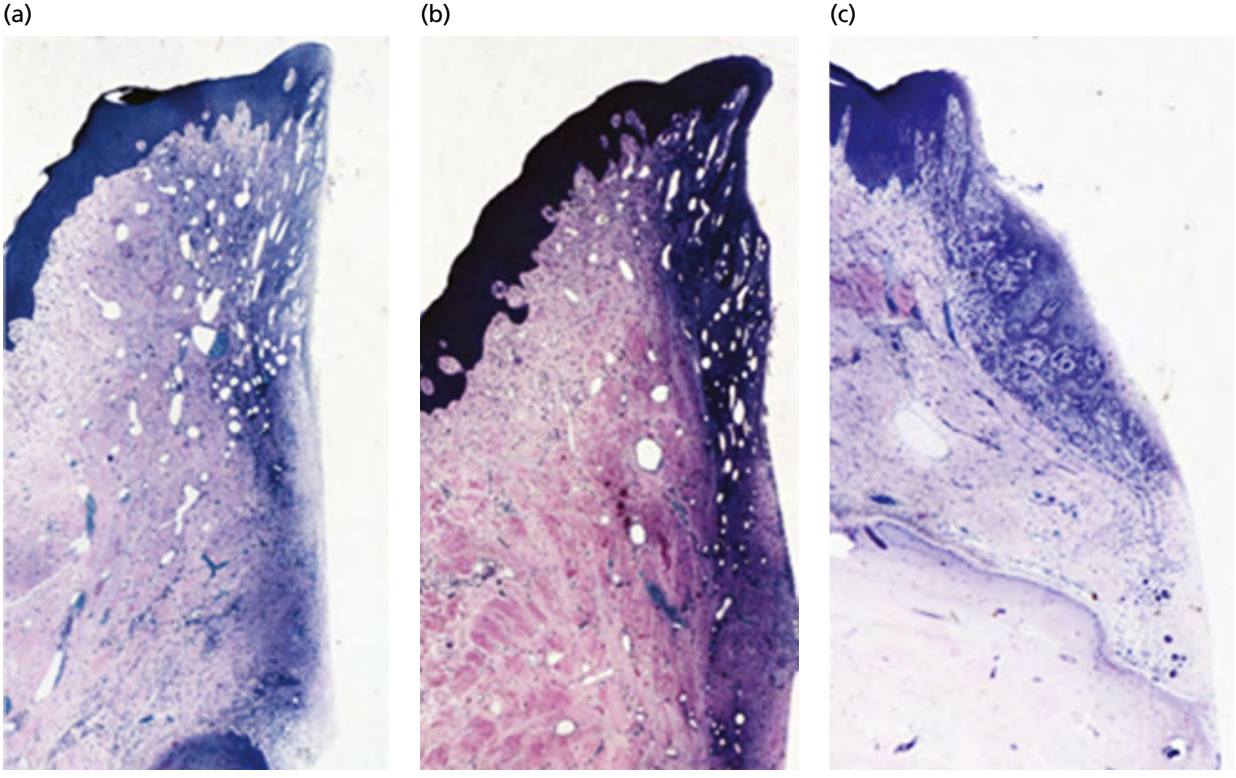

Fig. 20-6 (a–c) Photomicrographs illustrating inflammatory cell infiltrates (ICT) established in the peri-implant mucosa around the three implant types shown in Fig. 20-5. The apical extension of the ICT is consistently within the dimension of the barrier epithelium for all three implant types.

inflammatory lesions, that is infiltrates of leukocytes in the connective tissue. The lesions in the gingiva and in the peri-implant mucosa were similar both with respect to size and location. Hence, both lesions were consistently found in the marginal portion of the soft tissues and between the keratinized oral epithelium and the junctional or barrier epithelium.

With increasing duration of plaque build-up (3 months) in the dog model described above, the lesions in the peri-implant mucosa seemed to expand and progress further "apically", while the gingival lesions remained unchanged (Ericsson *et al*. 1992). Furthermore, the lesions in the peri-implant mucosa contained a much smaller number of fibroblasts than the corresponding infiltrates in the gingiva. In any inflammatory lesion of longstanding, periods of breakdown and periods of repair interchange. It was therefore suggested, that in the gingival lesion, the amount of tissue breakdown that occurred during the 3-month interval was more or less fully compensated for by tissue build-up during a subsequent phase of repair. In the lesions in the peri-implant mucosa, the tissue breakdown was not fully recovered by reparative events. This reduced build-up may have been the reason for the resulting additional propagation and spread of the lesion in the peri-implant mucosa.

In a similar dog experiment, Abrahamsson *et al*. (1998) studied soft tissue lesions after 5 months of plaque formation at three different implant systems (Fig. 20-5). They observed that the response of the peri-implant mucosa to longstanding plaque formation appeared to be independent of the implant system that harbored the biofilm and that the apical extension of the inflammatory lesion was consistently within the dimensions of the barrier epithelium for all three implant systems (Fig. 20-6).

Conclusion: Peri-implant mucositis and gingivitis have many features in common. The host response to bacterial challenge at teeth and implants includes the development of clinical signs of inflammation and the establishment of inflammatory lesions in the mucosal/gingival connective tissues. Since peri-implant mucositis represents the obvious precursor of peri-implantitis, as does gingivitis for periodontitis, prevention and treatment of mucositis appears to be an important prerequisite for the prevention of peri-implantitis (Lang & Berglundh, 2011; Jepsen *et al*. 2015).

Peri-implantitis

Clinical features and diagnosis

Peri-implantitis is a plaque-associated pathological condition occurring in tissues around dental implants. It is characterized by inflammation in the peri-implant mucosa and subsequent progressive loss of peri-implant bone (Berglundh *et al*. 2018; Schwarz *et al*. 2018). Therefore, diagnosis of peri-implantitis requires detection of both BoP and bone loss assessed on radiographs (Fig. 20-7). Peri-implantitis initially affects the marginal part of the peri-implant tissues and the implant may remain stable and in function for varying periods of time. Implant mobility is therefore not an essential symptom for peri-implantitis but may occur in the final stage of disease progression and indicates complete loss of integration.

As pointed out for the clinical characteristics of peri-implant mucositis, various factors such as the morphology of the peri-implant mucosa and position of the implant may also influence the clinical appearance of inflammation in peri-implantitis. Probing is therefore a prerequisite in the examination of peri-implant tissues and should include assessments of both BoP and PPD. Pus is a common finding in peri-implantitis sites (Fransson *et al*. 2008).

Hence, the clinical appearance of peri-implantitis may vary and is not consistently associated with overt signs of pathology. Two different cases are shown in Figs. 20-8 and 20-9. While plaque and calculus together with clinical signs of inflammation are present in the case shown in Fig. 20-8, the case shown in Fig. 20-9 does not disclose such symptoms. Probing the site shown in Fig. 20-9, however, revealed a PPD of about 10 mm, BoP, and suppuration.

Bone loss around implants observed in radiographs obtained from sites with peri-implantitis (Fig. 20-10) appears to be symmetric, that is there is a similar amount of bone loss circumferentially at the implants. The morphology of the osseous defect, however, may vary depending on the buccal–lingual (palatal) dimension of the alveolar ridge. Thus, in sites where the width of the ridge exceeds that of the

Fig. 20-7 Diagnosis of peri-implantitis indicated by the clinical finding of bleeding on probing and radiographic bone loss.

peri-implantitis lesion, a buccal and lingual bone wall may remain, and a contained, crater-formed defect occurs. Conversely, in sites with a narrow ridge, the buccal and lingual bone will be resorbed and lost during progression of peri-implantitis.

Progression of peri-implantitis occurs in a non-linear and accelerating pattern (Fransson *et al*. 2010; Derks *et al*. 2016) and appears to be faster than that observed in periodontitis (Berglundh *et al*. 2018). As the onset of peri-implantitis may occur early during follow-up, clinical examinations including assessments of PPD and BoP of peri-implant sites should be carried out on a regular basis to indicate the possible need for additional radiographic examinations for bone level assessments. While the diagnosis of peri-implantitis requires the detection of BoP and bone loss, it is assumed that previous examination data are available. In the absence of such data, however, the diagnosis of peri-implantitis is based on the combination of BoP, PPD ≥6 mm and bone levels located ≥3 mm apical of the most coronal portion of the intraosseous part of the implant periodontitis (Berglundh *et al*. 2018). Case definitions for peri-implantitis in day-to-day clinical practice and in epidemiological research are discussed in detail in Chapter 7.

Fig. 20-8 Clinical symptoms of peri-implantitis. Note the large amounts of plaque and calculus, and visible signs of inflammation in the peri-implant mucosa.

Conclusion: Symptoms of peri-implantitis relate to the infectious/inflammatory nature of the lesion. Thus, in addition to radiographic evidence of bone loss, there are clinical signs of mucosal inflammation, including swelling and redness of the mucosa as well as bleeding on gentle probing. Suppuration from the "pocket" may also occur. Progression of peri-implantitis occurs in a non-linear and accelerating pattern and appears to be faster than that observed in periodontitis. The implant may remain stable until only minute amounts of "osseointegration" remain.

Human biopsy material

While precise information exists on the histopathology of human periodontitis, the number of studies on peri-implantitis lesions in humans is increasing but remains small in comparison (Berglundh *et al*. 2011; Schwarz *et al*. 2018). Studies providing information on tissues harvested from peri-implantitis sites disclosed that the mucosa contained large inflammatory cell infiltrates. Sanz *et al*. (1991) analyzed soft tissue

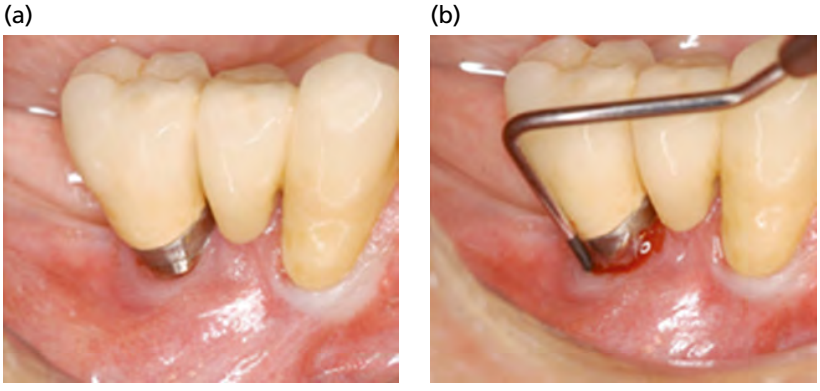

Fig. 20-9 An implant-supported crown in the premolar position in the right side of the mandible. (a) No or minor signs of inflammation in the surrounding mucosa. (b) Probing resulted in bleeding and suppuration from the implant site.

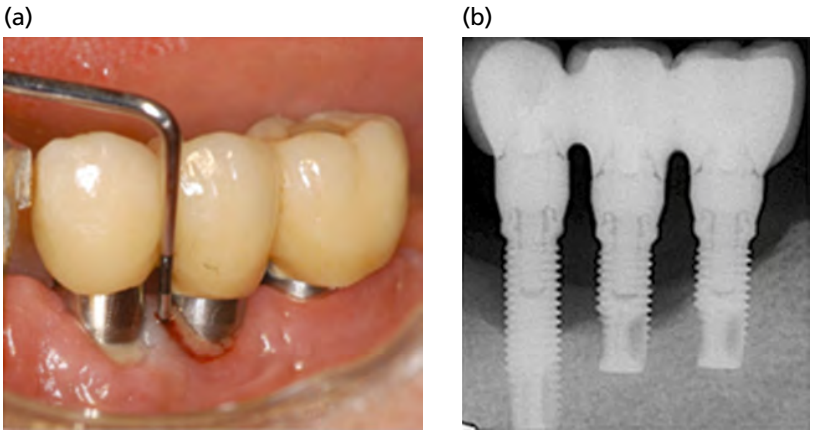

Fig. 20-10 Clinical (a) and radiographic (b) characteristics of three implant sites with peri-implantitis in the left side of the mandible. Note the presence of swelling and suppuration in the peri-implant mucosa (a) and the pronounced bone loss around the implants in the radiograph (b).

biopsies from six patients with peri-implantitis and reported that 65% of the connective tissue portion was occupied by inflammatory cells. Piattelli *et al*. (1998) described some pathologic features of tissues harvested from 230 retrieved implants: at sites where the implants had been removed due to peri-implantitis, "an inflammatory infiltrate, composed of macrophages, lymphocytes and plasma cells, was found in the connective tissue around the implants". In a study including 12 human peri-implantitis lesions, Berglundh *et al*. (2004) found that the mucosa contained very large lesions in which numerous plasma cells, lymphocytes, and macrophages were present (Fig. 20-11). It was furthermore observed that the inflammatory cell infiltrate consistently extended to an area apical to the pocket epithelium and that the apical part of the soft tissue lesion frequently reached the bone tissue. Berglundh *et al*. (2004) also reported that numerous neutrophil granulocytes (polymorphonuclear leukocytes) were present in the lesions. Such cells occurred not only in the pocket epithelium and associated areas of the lesions, but also in perivascular compartments in the center of the infiltrate, that is distant from the implant surface. In the apical part of the lesion, the inflamed connective tissue appeared to be in direct contact with the biofilm on the implant surface. Gualini and Berglundh (2003) used immunohistochemical techniques to analyze the composition of peri-implantitis in a study of six subjects. Neutrophils were found in large numbers in the central portions of the infiltrate. This finding was in agreement with that made by Hultin *et al*. (2002) who analyzed the exudate that could be harvested from implant sites in 17 patients with peri-implantitis and reported the presence of large numbers of neutrophils. Immunohistochemical techniques have also been used to evaluate differences between peri-implantitis and periodontitis lesions. Bullon *et al*. (2004) observed that both types of lesions contained T and B lymphocytes, plasma cells, and macrophages, while Konttinen *et al*. (2006) reported that the number of cells positive for interleukin-1 alpha (IL-1α) and IL-6 was larger and the number of tumor necrosis factor-alpha (TNF-α)–positive cells smaller in peri-implantitis than in periodontitis lesions. A more comprehensive evaluation of human peri-implantitis and periodontitis lesions was presented by Carcuac and Berglundh (2014). Soft tissue biopsies were collected from diseased sites (PPD ≥7 mm, BoP, and marked bone loss) in 40 patients with advanced peri-implantitis and 40 patients with severe periodontitis. The histological examination revealed that peri-implantitis lesions were more than twice as large as the periodontitis lesions (Fig. 20-12). In addition, the inflammatory cell infiltrate in peri-implantitis extended to a position that was apical of the pocket epithelium and was less walled-off in apical and lateral directions than the periodontitis lesions. The immunohistochemical analysis revealed that the density of plasma cells, neutrophil granulocytes, and macrophages was considerably larger in peri-implantitis than in periodontitis lesions.

Note the difference in size of the inflammatory cell infiltrate lateral to the pocket epithelium (left) between periodontitis (a) and (b) peri-implantitis.

Preclinical models

In order to study the response of the peri-implant mucosa to long-standing plaque exposure, an experimental periodontitis/peri-implantitis model was developed in the dog (Lindhe *et al*. 1992) and in the monkey (Lang *et al*. 1993; Schou *et al*. 1993). Although the experiments had somewhat varying designs, their outcomes were almost identical and, hence, only the result from the dog model will be reported.

In the dog model (Lindhe *et al*. 1992), the premolars were extracted on one side of the mandible, implants were inserted, and abutment connection performed 3 months later. During the healing phase, a strict plaque control regimen was maintained and healthy tissue conditions were thereby established in all tooth and implant sites to be monitored. On a given day, the periodontitis and peri-implantitis lesions were induced. This was accomplished by terminating the plaque control regimen and placing cotton ligatures around the neck of both the premolar teeth and the implants. The ligatures were forced into a position apical to the soft tissue margins. A "pocket" between the tooth/gingiva and implant/mucosa was thereby created, a submarginal biofilm rapidly formed, and inflammatory lesions developed in the neighboring tissues. Radiographs obtained after 6 weeks of the experiment revealed that a substantial amount of bone tissue had been lost at both teeth and implant sites. The ligatures were removed. After a further 4 weeks, the animals were re-examined, radiographs obtained, plaque sampled, and biopsies of tooth and implant sites harvested. It was observed that the plaque that had formed in the deep "pockets" had a similar composition at tooth and implant sites, and was dominated by Gram-negative and anaerobic species (Leonhardt *et al*. 1992). This observation is consistent with findings in humans indicating that the microbiota at teeth and implants shares many features, but also that the microbiota at healthy and diseased sites – tooth sites as well as implant sites – is very different. Thus, implants and teeth that are surrounded by healthy soft tissues are associated with biofilms with small numbers of Gram-positive coccoid cells and rods. Sites with extensive periodontal and peri-implant inflammation harbor biofilms with large numbers of Gram-negative anaerobic microorganisms (see Chapter 9).

Histopathologic examination of the biopsy samples from the dog study (Lindhe *et al*. 1992) revealed that there were marked differences in the size and location of the inflammatory lesions at periodontal and peri-implant sites. Thus, while the lesions in the periodontal sites were consistently separated from the alveolar bone by a 1-mm wide zone of non-inflamed connective tissue, the lesion in the peri-implant tissue in most situations extended to the alveolar bone. It was concluded that the pattern of spread of inflammation was different in periodontal and peri-implant tissues. It was suggested that the peri-implant tissues, in variance with the periodontal tissues, are poorly organized to resolve progressive, plaque-associated lesions. The validity of this

conclusion was substantiated in subsequent studies (Marinello *et al*. 1995; Ericsson *et al*. 1996; Persson *et al*. 1996; Gotfredsen *et al*. 2002), using similar models but allowing for different periods of tissue breakdown.

In the preclinical studies reported above, the experimental models used ligatures to disrupt the soft tissue seal around the implant and thereby allowing a biofilm to form in a submarginal location. The ensuing host response included an inflammatory lesion in the mucosa that over time became progressively larger. Cells in the lesion activated systems of reactions that promoted degradation of connective tissue and bone. The placement of a new ligature in a more "apical" position allowed the destructive process to continue. The size and type of ligature (e.g. cotton, silk), their corono-apical position in the pocket, as well as the number of replacements determined the rate and magnitude of tissue breakdown in this so-called experimental peri-implantitis model (Berglundh *et al*. 2011).

Zitzmann *et al*. (2004) used 21 sites in dogs to study experimental peri-implantitis. After the lesions had become established, the ligatures were removed, and the sites were monitored for an additional 12 months. It was observed that in 16 sites the destructive conditions persisted and caused progressive bone loss. In the remaining five sites, however, the lesions became encapsulated and no further breakdown of peri-implant bone took place.

This so-called "spontaneous progression model" (Zitzmann *et al*. 2004) was subsequently used by Berglundh *et al*. (2007). They examined the tissue reaction around custom-made implants with either a smooth, polished surface or a roughened SLA (sand-blasted, large grit, acid etched) surface. During the pre-experimental period of ligature-induced breakdown, similar amounts of bone loss occurred around the two types of implants. Evaluation 5 months after the removal of ligatures, however, revealed that bone loss had progressed and that the size of the inflammatory lesion in the connective tissue was larger at the implants with the rough than with the smooth surface. The area of plaque was also larger at implants with the rough surface. It was concluded that the progression of peri-implantitis, if left untreated, is more pronounced at implants with a moderately rough surface than at implants with a smooth/polished surface.

While the study by Berglundh *et al*. (2007) used implants with custom-made surfaces, Albouy *et al*. (2008, 2009) analyzed differences in spontaneous progression of experimental peri-implantitis between commercially available implants with SLA, TiOblast, TiUnite, and turned surfaces. Spontaneous progression occurred with all implant types during the 6-month period after ligature removal. The histologic examination revealed that all specimens presented with large inflammatory lesions that extended apical of the pocket epithelium. The pocket compartment was occupied by biofilm, calculus, and pus, and the uncovered apical part of the inflammatory cell infiltrate faced the biofilm. Osteoclasts in large numbers were detected on the surface of the crestal bone and other giant-like cells occurred in the soft tissue lesion, distant from the crestal bone.

Albouy *et al*. (2012) in a subsequent experiment in dogs repeated the spontaneous progression model using implants with a similar geometry and with two different surfaces (turned and modified). During the 6 months after ligature removal, a significantly larger amount of bone loss occurred around the implants with the modified than with the turned surface. In addition, the dimensions of inflammatory lesions, pocket epithelium, and biofilm were larger at the implants with a modified surface.

The spontaneous progression model was also used in an experiment aimed at evaluating differences between peri-implantitis and periodontitis. Thus, Carcuac *et al*. (2013) used the dog model and two kinds of implants. Experimental peri-implantitis and periodontitis were induced by ligature placement and plaque formation. The ligatures were removed after 10 weeks and bone level changes were evaluated in radiographs during the following 6 months. It was reported that the amount of bone loss that occurred following ligature removal was significantly larger at implants with a modified surface than at implants with a turned surface and at teeth (Fig. 20-13). The results from the histologic examination confirmed previous findings (Lindhe *et al*. 1992) and revealed that peri-implantitis sites exhibited inflammatory lesions that were larger and extended closer to the bone crest than those in periodontitis (Figs. 20-14,

(b) Close-up of outlined area in (a) showing the large infiltrate (ICT) apical of the pocket epithelium and in direct contact with the biofilm on the implant surface. Osteoclasts (arrows) are present on the bone surface. PE, pocket epithelium.

20-15). Carcuac *et al*. (2013) also reported that the lesions in peri-implantitis contained larger proportions of neutrophil granulocytes and osteoclasts than lesions in periodontitis.

A new approach of the spontaneous progression model was presented by Carcuac *et al*. (2020) in a study on experimental peri-implantitis in augmented and pristine bone. While a standard osteotomy preparation procedure was applied at pristine bone sites at implant placement, a modified osteotomy was used at test sites, resulting in a 1 mm wide and 5 mm deep circumferential gap following implant installation. The gap was filled with a bone substitute and was covered by a resorbable collagen membrane. After several months of healing, experimental peri-implantitis was initiated by placement of ligatures and plaque accumulation. In contrast to previous experiments using the spontaneous progression model, the ligatures were removed already after 4 weeks. Thus, spontaneous progression of experimental peri-implantitis was initiated without a preceding period of significant ligature-induced bone loss. Carcuac

et al. (2020) reported that differences in bone loss during the spontaneous progression period following ligature removal between pristine and augmented sites were small and that implants with turned, non-modified surfaces exhibited smaller amounts of bone loss than implants with modified surfaces. These observations indicate that the short-term disruption of the soft tissue barrier around implants promoted by the ligature together with plaque formation, initiated a host response with the formation of an inflammatory lesion in the mucosa that over time progressed in an apical and lateral direction. Thus, following the initial short period of ligatures, inflammation persisted in the peri-implant connective tissue together with continuous crestal bone loss during the subsequent 6-month period.

Data obtained from pre-clinical studies presented above (Berglundh *et al*. 2007; Albouy *et al*. 2008, 2009, 2012; Carcuac *et al*. 2020) indicate that the implant surface characteristics influenced the degree of spontaneous progression of experimentally induced peri-implantitis. It should be kept in mind, however, that in these studies, a limited number of implant types were evaluated. It is thus not possible to determine if any particular type of implant system or implant surface is associated with a greater risk for peri-implantitis. On the other hand, the experimental studies do demonstrate that continuous plaque formation at sites where a peri-implantitis lesion has become established and ligatures removed, may result in additional destruction of soft and hard tissue components of peri-implant tissues and that this progression of disease is influenced by implant surface characteristics.

Conclusion: Peri-implantitis lesions are poorly encapsulated, extend to the marginal bone tissue, and may, if allowed to progress, lead to the loss of the implant. The large numbers of neutrophils in the peri-implantitis lesion and the absence of an epithelial lining between the lesion and the biofilm, indicate that the peri-implantitis lesions have features that are different from those of periodontitis lesions. Progression of peri-implantitis is more pronounced at implants with modified surfaces than at those with smooth, non-modified surfaces.

Conclusion

Studies in man and experiments in animals have documented that *de novo* formation of a biofilm on the implant surface initiates a host response that involves the establishment of an inflammatory lesion in the peri-implant mucosa (peri-implant mucositis). This lesion is initially located in the connective tissue immediately lateral to the barrier epithelium and is, in many respects, similar to that which develops in the gingiva when plaque forms on adjacent tooth surfaces. In the continued presence of a submarginal biofilm, the lesion in the marginal mucosa around implants may occasionally spread in an "apical" direction to involve the hard tissue, compromise osseointegration, cause varying degrees of marginal bone loss (peri-implantitis), and, in the absence of treatment also cause the loss of the implant.

Introduction

The coordinated sequence of events involved in periodontal wound healing is critical for maintenance of intact, periodontally healthy tissues as well as in situations where the clinician employs therapeutic approaches to regenerate the periodontium when these tissues are lost or compromised. The structure and function of the periodontium is determined by the dynamic interactions and interfaces of four main tissues: periodontal ligament (PDL), tooth root cementum, alveolar bone, and gingiva. Collectively, these tissues provide a biologic and physical barrier to a multitude of external insults sustained by the teeth as a result of normal occlusal function and the complex microbial environment of the oral cavity. The most common reason that the integrity of the periodontium is compromised is due to chronic inflammation triggered by complex bacterial communities, namely periodontal pathogens. Nonetheless, the periodontium represents a resilient organ characterized by a dynamic structure being very responsive to a variety of mechanical and biochemical factors to maintain homeostasis (Burger *et al*. 1995; Duncan & Turner 1995; Marotti 2000; Marotti & Palumbo 2007; Bonewald & Johnson 2008). Its structure and function during remodeling and healing is determined by the orchestration of a sequence of events involving biological growth factors, namely: platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), fibroblast growth factor (FGF), bone morphogenetic proteins (BMPs), insulin-like growth factor 1 (IGF-1), transforming growth factor beta 1 (TGF-β1), among others (reviewed in Larsson *et al*. 2016). These factors play an important role in modulating the adaptive potential of the periodontium, which is responsible

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

for it protecting and maintaining the integrity of its four fundamental components (Fig. 21-1).

Clinically, following breakdown of the periodontium, detrimental changes undermine and disrupt the functional and structural integrity of the alveolar bone, gingiva, the PDL, and the cementum. The restoration of the original structure, properties, and function of these tissues is a major goal of regenerative periodontal therapies. Unfortunately, altered and delayed healing often disrupts the normal restoration of the periodontium and as a result, instead of full restoration of the tissue to its innate form and function, a varying degree of compromised outcomes commonly occurs.

Wound healing: Outcomes and definitions

Before exploring the mechanisms underlying the cellular and molecular events of wound healing, it is important to understand the cascade of healing patterns that have been recognized in the periodontal complex (Table 21-1).

From a histological standpoint, the following types of healing outcomes are observed in the periodontium: repair, reattachment, new attachment, regeneration, resorption, and ankylosis (Table 21-2).

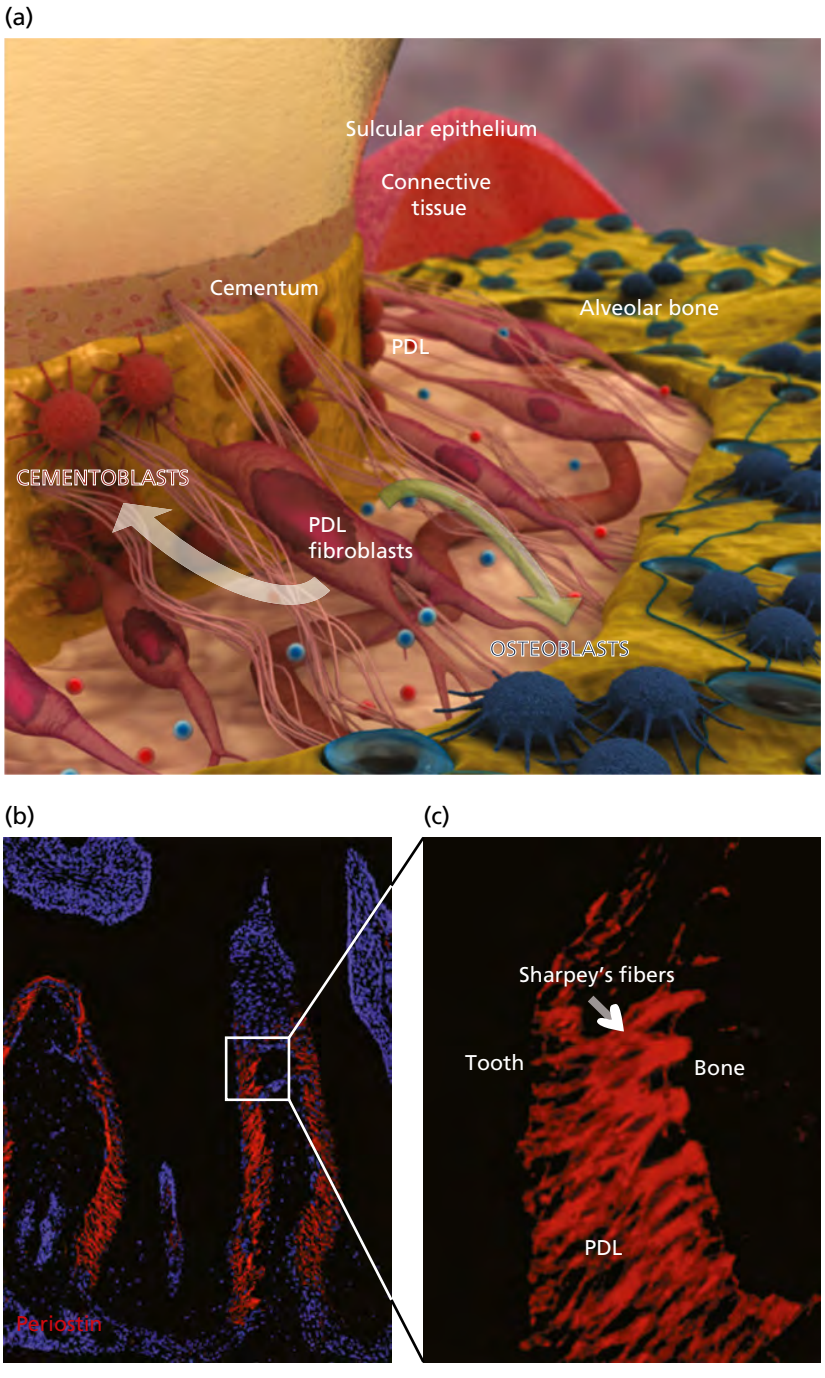

Fig. 21-1 (a) The tooth-supporting apparatus (i.e. periodontium) includes the alveolar bone, the periodontal ligament (PDL), the cementum, and the gingiva. Collectively, they represent a dynamic tissue complex with mechanical and biological functions that synergistically determine the tissue adaptive potential and its ability to sustain microbiological and mechanical challenges. (b) The functional periodontal system is characterized by distinct fibrillar structures known as Sharpey's fibers that connect the alveolar bone to the tooth surface cementum (red fluorescent immunostaining for periostin).

Table 21-1 Healing patterns in the periodontal tissues.

Healing by first intention	Healing through primary intention involves the wound edges being brought together using sutures. Primary intention wounds are associated with minimal tissue loss and regeneration predominates over fibrosis
Healing by second intention	Wound healing by secondary intention occurs in surgical wounds that are left to heal without approximating the edges. The wound then fills with granulation tissue from the bottom up. The epithelium then fills in over the top of the granulation tissue. Scarring is evident as there is significant fibrosis
Healing by third intention	Where there is great loss of tissue, the wound must heal by contraction of the wound edges and the formation of granulation tissue. In some cases, the presence of a foreign body or infection may be suspected, and these wounds are left open deliberately for several days until the potential complication has resolved. When resolution has occurred, the wound edges can be brought together (approximated) and the wound proceeds to heal
Partial-thickness healing	Occurs when a partial-thickness wound is closed primarily by epithelialization. This wound healing involves the superficial portion of the dermis (lamina propria). There is minimal collagen deposition and an absence of wound contraction

Table 21-2 Outcomes of periodontal wound healing.

Repair	Healing of a wound by tissue that does not fully restore the architecture or the function of the part. Within the periodontal wound, it refers to restoration of a normal gingival sulcus at the same level as the base of the previous pathologic periodontal pocket. Often repair is typified by the presence of a long junctional epithelium
Reattachment	Refers to the reattachment of the gingiva to areas from which it was mechanically removed
New attachment	Occurs when newly generated fibers are embedded in new cementum on a portion of the root that was uncovered by disease
Regeneration	Reproduction or reconstruction of a lost or injured part in such a way that the architecture and function of the lost or injured tissues are completely restored. This takes place by growing precursor cells replacing lost tissue
Resorption	Loss or blunting of some portion of a root, sometimes idiopathic, but also associated with orthodontic tooth movement, inflammation, trauma, endocrine disorders, and neoplasia
Ankylosis	Fusion of the tooth and the alveolar bone

Wound healing biology

The process of wound healing is the body's primary mechanism to restore tissue integrity following injury. If wound healing does not occur properly, chronic disruption of the protective barrier may lead to severe physiologic, immunologic, and metabolic abnormalities. Wound healing represents a dynamic process that involves several cell types and biologic mediators. Within the complex microenvironment of the periodontal wound, cell populations migrate, differentiate, and proliferate; epithelial and connective tissues interact; and a vast array of cytokines and extracellular matrix (ECM) molecules orchestrate these processes which take place in overlapping phases (reviewed in Sculean *et al*. 2015).

Phases of wound healing

The general principles of healing, and the cellular and molecular events observed in extraoral sites, also apply to the healing processes that take place following periodontal surgery. Traumatic injury causes capillary damage and hemorrhage, and, as a result, a blood clot is formed. The formation of a clot is the immediate response to any trauma. The clot has two functions: it temporarily protects the denuded tissues and it serves as a provisional matrix for cell migration. The blood clot consists of all cellular components of blood (including red and white blood cells and platelets) in a matrix of fibrin, plasma fibronectin, vitronectin, and thrombosporin. Beyond this, the process has been divided into three stages:

1. Inflammation phase
2. Granulation phase
3. Matrix formation and remodeling (maturation) phase.

Each of the steps of wound healing is essential to restoring tissue structure and function but the initial healing phases often determine the outcome (Susin *et al*. 2015).

Inflammatory phase

The growth factors which are present in the initial blood clot formation are responsible for recruitment of inflammatory cells and serve to regulate the granulation process. Within hours of injury, inflammatory cells (predominantly neutrophils and monocytes) populate the clot. These cells cleanse the wound of bacteria and necrotic tissue through phagocytosis and release of enzymes and toxic oxygen products. Within 3 days, the inflammatory reaction moves into its late phase. Macrophages migrate into the wound area and these macrophages contribute to the cleansing process by phagocytosis of used polymorphonuclear leukocytes and erythrocytes. Additionally, macrophages release a number of biologically active molecules such as inflammatory cytokines and tissue growth factors, which recruit further inflammatory cells as well as fibroblastic and endothelial cells, thus playing an essential role in the transition of the wound from the inflammatory into the granulation tissue formation phase and tissue resolution (Garlet *et al*. 2018).

Granulation phase

The neutrophil population is overtaken by macrophages within a few days. Macrophages also serve the purpose of wound decontamination. They play an important role in the formation of granulation tissue. Granulation tissue formation begins on approximately day 4. Macrophages constitutively release growth factors that promote the healing process. Growth factors and cytokines secreted by macrophages are involved in the proliferation and migration of fibroblasts, endothelial cells, and smooth muscle cells into the wound area. The cells in the wound proliferate around the radius of the wound site developing cell to cell and cell to matrix connections. Macrophages and fibroblasts continue to express growth factors that regulate the healing process, both in an exocrine and autocrine manner. Studies have shown that wound sites supplemented with growth factors have an accelerated rate of granulation tissue formation (Sporn *et al*. 1983). At 7 days after initiation of wound healing, granulation dominates the wound site and the initial collagen fibers are being formed. Eventually, cells and matrix form cell–cell and cell–matrix links that generate a concerted tension resulting in tissue contraction. This phase of granulation tissue formation gradually develops into the final phase of healing in which the reconstituted, more cell-rich tissue undergoes maturation and sequenced remodeling to meet functional needs.

Maturation phase

Fibroblasts responsible for the replacement of the provisional ECM produce a new collagen-rich matrix. Approximately 1 week following wounding, and once the collagen matrix has been synthesized, some fibroblasts undergo transformation into myofibroblasts and express α-smooth muscle actin. This transformation and synthesis is responsible for wound contraction. Endothelial cells, responsible for angiogenesis, migrate into the provisional wound matrix to form vascular tubes and loops, and as the provisional matrix matures, the endothelial cells undergo programmed cell death (apoptosis) and the number of vascular units is reduced. Maturation of the granulation tissue will lead to the regeneration or repair (scar formation) of the injured tissues. Whether the damaged tissues heal by regeneration or repair depends upon two crucial factors: the availability of cell type(s) needed and the presence or absence of cues and signals necessary to recruit and stimulate these cells.

Factors that affect healing

The periodontium is like most other tissues in the body in that its healing capacity is highly influenced by local and systemic factors.

Local factors

Healing after gingival and periodontal surgery can be delayed and altered by various local factors, the most critical of these factors being:

- Plaque microorganisms
- Excessive tissue manipulation during treatment
- Trauma to the tissues
- Presence of foreign bodies
- Repetitive treatment procedures that disrupt the orderly cellular activity during the healing process
- Inappropriate vascular perfusion to the surrounding area.

Healing is therefore improved by debridement (removal of degenerated and necrotic tissue), immobilization of the healing area, and pressure on the wound. The cellular activity in healing entails an increase in oxygen consumption. However, healing of the gingival tissue is not accelerated by artificially increasing the oxygen supply beyond the normal requirements (Glickman *et al*. 1950).

Systemic factors

Age has long been recognized as a variable which negatively impacts the wound healing capacity of most tissues of the body (Holm-Pedersen & Löe 1971). Healing is also impaired by inadequate food intake, systemic disorders that interfere with the uptake of nutrients, and deficiencies in essential vitamins (Barr 1965), proteins (Stahl 1962), and other nutrients.

Hormones also have an impact on healing. Systemically administered glucocorticoids such as cortisone hinder repair by depressing the inflammatory reaction or by inhibiting the growth of fibroblasts, the production of collagen, and the formation of endothelial cells. Systemic stress, thyroidectomy, testosterone, adrenocorticotropic hormone, and large doses of estrogen suppress the formation of granulation tissue and impair healing (Butcher & Klingsberg 1963).

Progesterone increases and accelerates the vascularization of immature granulation tissue (Lindhe & Brånemark 1968) and appears to increase the susceptibility of the gingival tissue to mechanical injury by causing dilation of the marginal vessels (Hugoson 1970).

Periodontal wound healing

For functional periodontal regeneration to occur, a series of temporal and spatial events must occur in a similar sequence to those involved in the natural formation and development of the periodontium (Chen *et al*. 2011). Most of the mechanisms underlying these cellular and molecular events have been identified with the first series of these events including cell migration and attachment to the denuded root surface. In using small animal models, it is clearly observed that a microenvironment is established which favors the proliferation, migration, and maturation of mesenchymal progenitors in the defective area of the PDL or the host bone (Lekic *et al*. 1996a,b). These processes are mediated and coordinated by soluble factors, other cells, and ECM. In the very early healing phases initiated by blood coagulation and migration of neutrophils and monocytes, the primary goals of these cellular events are to achieve wound debridement and bone resorption. Bone formation typically initiates from the bony margins of the lesions (Rajshankar *et al*. 1998). Within days after surgery, a thin cementum layer with a connective tissue attachment can be observed, particularly on the apical side of the teeth where the cementum is thicker compared with the narrow coronal region (King *et al*. 1997). Once mineralized tissues are established, PDL fiber orientation, directionality, and integration into both cementum and alveolar bone are mediated by appropriate mechanical loading (Mine *et al*. 2005; Rios *et al*. 2011). It is therefore highly critical that investigators, according to the timeline these processes follow, select the appropriate time point(s) to determine the therapeutic efficacy "window" of a candidate periodontal-engineered device or bioactive molecule (Fig. 21-2).

Periodontal wound healing is considered a more complex process compared with epidermal wound healing. The native periodontium includes cementum, a functionally oriented PDL, alveolar bone, and gingiva. The interfaces between these tissues as well as the transgingival position of the teeth represent a constant challenge during the restoration of the integrity of the native structures as they seek to create a new connection to the non-vascular and non-vital hard tissue of the root surface within the context of an open system that is permanently contaminated and under a significant "bacterial load". It is therefore not surprising that the healing results following all types of gingival and periodontal therapy can be quite variable.

The most basic requirement for successful periodontal treatment is a clean, biofilm-free, decontaminated root surface. Therapy includes both surgical and non-surgical modalities, which result in instrumentation of the affected tissue. This creates a wound in periodontal tissues that are stressed by inflammation. The results of therapy are dependent on the ability of the body to heal afterwards and the mechanisms that dictate these processes. It is important to understand that the order of events during wound healing after therapy depend on a complex set of biologic communications in the area of interest.

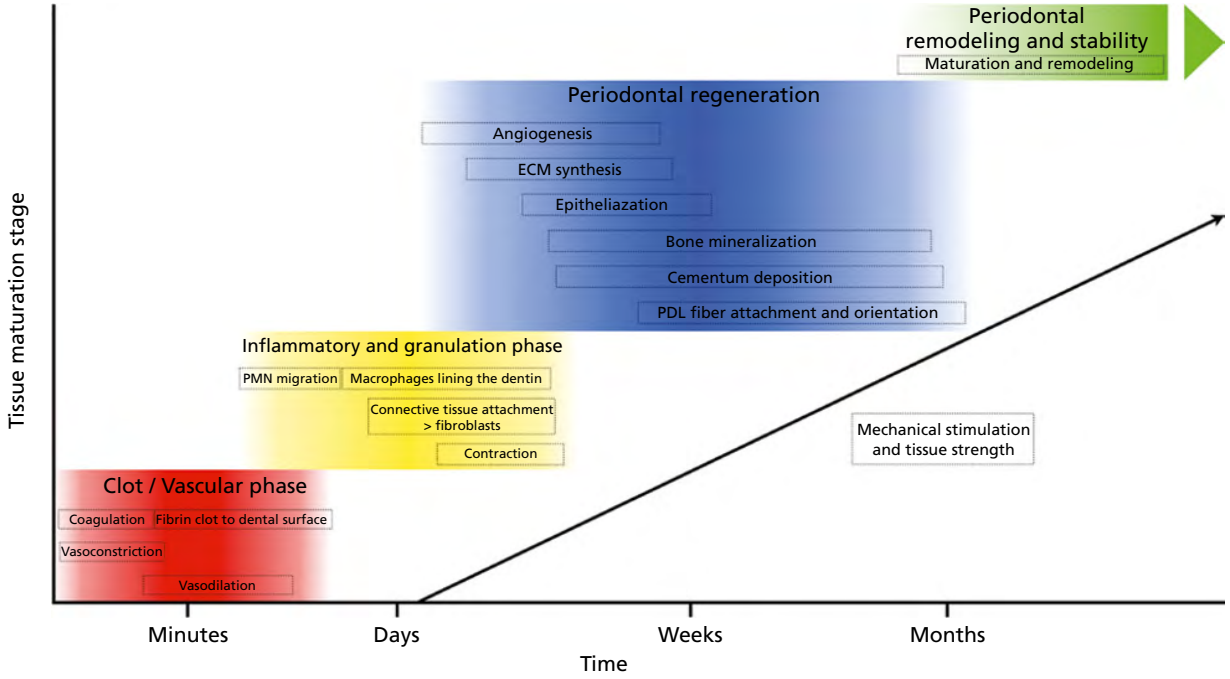

Fig. 21-2 Stages of periodontal wound healing. Optimal periodontal healing requires different processes in a sequential manner. After the initial coagulation phase, inflammatory reaction, and granulation tissue formation events, progenitor cells involved in multitissue regeneration are locally recruited and mediate the bioavailability of important growth factors. As the healing progresses, mechanical stimuli increase and promote an organized ECM synthesis as well as cementum and bone formation and maturation. Once those structures are established, PDL fibers are organized and oriented. Progressively, the tissues mature and ultimately increase its mechanical strength. Remodeling processes continue in the regenerated periodontium as an essential mechanism that monitors the adaptation potential to the challenging local and systemic environment. (Source: Padial-Molina *et al.* 2012.)

Research on periodontal wound healing in the past provided the basic understanding of the mechanisms favoring periodontal tissue regeneration. A number of valuable findings at both the cellular and molecular levels was revealed and subsequently used in the engineering of the regenerative biomaterials that are available in periodontal medicine today.

The morphology of a periodontal wound comprises the gingival epithelium, gingival connective tissue, PDL, and hard tissue components such as alveolar bone and cementum or dentin on the dental root surface. This particular composition affects both the healing events in each tissue component as well as in the entire periodontal site. While the healing of gingival epithelia and their underlying connective tissues concludes in a number of weeks, the regeneration of PDL, root cementum, and alveolar bone generally occurs over a number of weeks or months. With the aim of wound closure, the final outcome of wound healing in the epithelium is the formation of the junctional epithelium surrounding the dentition (Caton *et al*. 1980). The healing of gingival connective tissue, on the other hand, results in a significant reduction of its volume, thus clinically causing both gingival recession and reduction of the periodontal pocket depth. PDL is shown to regenerate on newly formed cementum created by cementoblasts originating from the PDL granulation tissue (Karring *et al*. 1985). Furthermore, alveolar bone modeling occurs following the stimulation of mesenchymal cells from the gingival connective tissue, which are transformed into osteoprogenitor cells by locally expressed BMP (Krebsbach *et al*. 2000; Sykaras & Opperman 2003).

A series of classical animal studies demonstrated that the tissue derived from alveolar bone or gingival connective tissue lacks cells with the potential to produce a new attachment between the PDL and newly formed cementum (Karring *et al*. 1980; Nyman *et al*. 1980). Moreover, granulation tissue derived from the gingival connective tissue or alveolar bone results in root resorption or ankylosis when placed in contact with the dental root surface. It should be expected, therefore, that these complications would occur more frequently following regenerative periodontal surgery, particularly following those procedures which include the placement of grafting materials to stimulate bone formation. The reason for root resorption is rarely identified; however, it may be that following the surgical intervention, the dentogingival epithelium migrates apically along the root surface, forming a protective barrier against the root surface (Bjorn *et al*. 1965; Karring *et al*. 1984). The findings from these animal experiments revealed that ultimately the PDL tissue contains cells with the potential to form a new connective tissue attachment (Karring *et al*. 1985).

Typically, the down-growth of the epithelium along the tooth root surface reaches the level of the PDL before the latter has regenerated with new layers of cementum and newly inserted connective tissue fibers. Therefore, in order to enable and promote the healing towards the rebuilding of cementum and PDL, the gingival epithelium must be hindered in

its creation of a long junctional epithelium along the root surface down to the former level of the PDL.

The principles of periodontal wound healing provide the basic understanding of the events that underlie the events responsible for wound healing following surgical interventions for periodontal therapy. In order to achieve new connective tissue attachment, the granulation tissue derived from PDL cells has to be given both space and time to organize and mature to new cementum and PDL.

Healing after periodontal surgery

Healing after gingival and periodontal surgery represents a more complex situation, particularly in cases where the periodontal tissue is juxtaposed to an instrumented root surface deprived of its periodontal attachment. In this situation, the wound margins are not two opposing vascular gingival margins but comprise the rigid non-vascular mineralized tooth surface on one side, and the connective tissue and epithelium of the gingival flap on the other (Fig. 21-3). Early healing events at the dentogingival interface have been examined using dentin blocks implanted in edentulous alveolar ridges, submerged under gingival flaps, in dogs (Wikesjo *et al*. 1991).

Clot formation at the interface between the tooth and a gingival flap is initiated as blood elements initiate the formation of a clot onto the root surface during surgery and at wound closure. This represents the very first healing event at the tooth–gingival flap interface (i.e. the absorption and adhesion of plasma proteins onto the root surface) (Wikesjo *et al*. 1991). Within minutes, a fibrin clot attached to the root surface is developed. Within hours, the early phase of inflammation may be observed as inflammatory cells, predominantly neutrophils and monocytes, accumulate on the root surface. After a few days, the late phase of inflammation dominates the healing picture as macrophages migrate into the wound followed by the formation of granulation tissue. After a week, a connective tissue attachment may be forming at the root surface as collagenous elements appear to be orientated in close proximity to the dentin surface. Resorptive remodeling of the dentin surface may be evident at this observation interval.

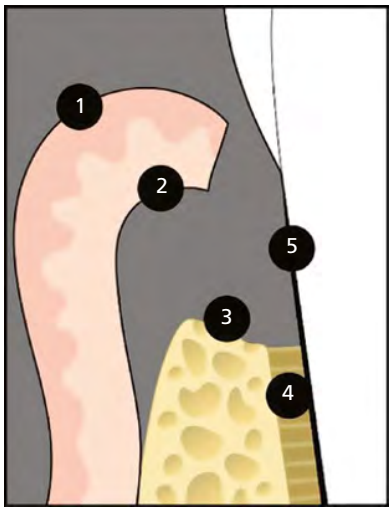

Fig. 21-3 Periodontal wound following flap surgery: (1) gingival epithelium; (2) gingival connective tissue; (3) alveolar bone; (4) periodontal ligament; and (5) cementum or dentin on the dental root surface

Within 14 days, the newly formed collagen fibers may show an arrangement indicative of physical attachment to the dentin (Selvig *et al*. 1988). Ramfjord *et al*. (1966) reported that collagen maturation of collagenous tissues and functional orientation of the connective tissue takes 3–5 weeks. In addition, new bone deposition starts to occur from days 10–21 (Wilderman 1964). Eventually, cementum formation may be initiated, but not until at least 3 weeks after wound closure (Hiatt *et al*. 1968).

Only a few experimental studies have evaluated the functional integrity of a maturing periodontal wound. Hiatt *et al*. (1968) examined the tensile strength of the tooth–gingival flap interface following reconstructive surgery of relatively small surgical dehiscence defects over the maxillary canine teeth in the dog. They found that the tensile strength increased from approximately 200 *g* at 3 days postsurgery to 340 *g* at 5–7 days postsurgery, and to >1700 *g* at 2 weeks postsurgery. In other words, they found that a relatively limited periodontal wound might not reach functional integrity until 2 weeks postsurgery. These data suggest that wound integrity during the early healing phase depends primarily on the stabilization of the gingival flaps achieved by suturing.

Histologic studies have shown that various surgical periodontal procedures can lead to different patterns of healing. Empirically, periodontal healing has generally been characterized by maturation of the gingival connective tissue, some regeneration of alveolar bone and cementum, and, most importantly, epithelialization of the root surface (Listgarten & Rosenberg 1979). Long junctional epithelium is commonly found on the root surface after traditional periodontal surgery and provides protection against bacterial invasion and ankylosis. However, downgrowth of epithelium from the gingival margin prevents the coronal migration of PDL cells, which are responsible for the formation of connective tissue attachment (Fig. 21-4).

Soft tissue management in early regenerative attempts adhering to the principle of epithelial exclusion has included repeated subgingival curettage during healing to control epithelialization of the root surface. More recent approaches have included the prevention of the gingival epithelium from contacting the root surface during the early healing phase by utilization of a cell-occluding membrane. Human as well as animal studies have reported the success with a membrane in facilitating the migration and proliferation of cells from the PDL and alveolar bone in the wound space (Nyman *et al*. 1982; Gottlow *et al*. 1984).

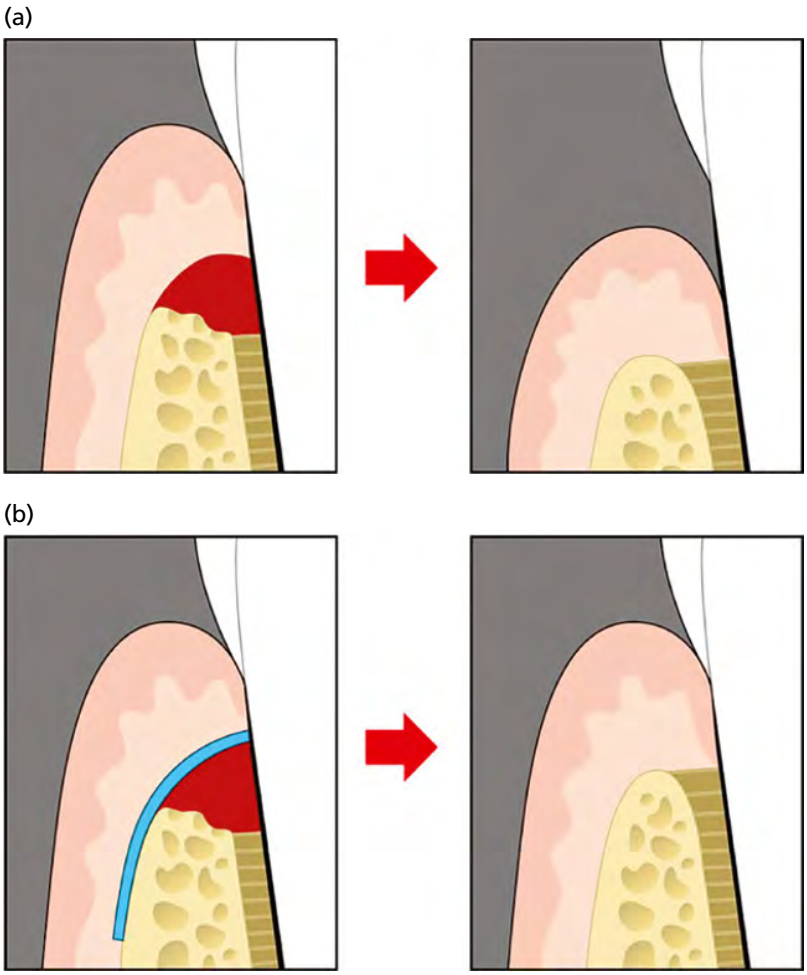

Fig. 21-4 (a) Regular healing process following the periodontal flap adaptation with significant reduction of the attachment apparatus. (b) In order to enable and promote the healing towards the rebuilding of cementum and periodontal ligament, the gingival epithelium must be prevented from creating a long junctional epithelium along the root surface down to the former level of the periodontal ligament (e.g. by placement of a bioresorbable membrane).

The general concepts of healing have been applied in the environment of periodontal tissues. Several investigations have been conducted in attempts to elucidate the exact mechanisms that guide the process and determine the final healing pattern.

Advanced regenerative approaches to periodontal tissue reconstruction

Periodontal regeneration is assessed by probing measures, radiographic analysis, direct measurements of new bone, and histology (Reddy & Jeffcoat 1999). Many cases that are considered clinically successful, including cases with significant regrowth of alveolar bone, may histologically still show an epithelial lining along the treated root surface instead of newly formed PDL and cementum (Listgarten & Rosenberg 1979). In general, however, the clinical outcome of periodontal regenerative techniques has been shown to depend on: (1) patient associated factors such as plaque control, smoking habits, residual periodontal infection, or membrane exposure in guided tissue regeneration (GTR) procedures; (2) effects of occlusal forces that deliver intermittent loads in axial and transverse dimensions; as well as (3) factors associated with the clinical skills of the operator, such as the failure of primary closure of the surgical wound (McCulloch 1993). Even though modified flap designs and microsurgical approaches have been shown to positively affect the outcome of both soft and hard tissue regeneration, the clinical success for periodontal regeneration remains limited in many cases. Moreover, the surgical protocols for regenerative procedures are demanding and may therefore may not be achievable for a number of clinicians. Consequently, both clinical and preclinical research continues to evaluate advanced regenerative approaches (Ramseier *et al*. 2012) using new barrier membrane techniques (Tsai *et al*. 2020), cell-growth stimulating proteins (reviewed in Larsson *et al*. 2016), or gene delivery applications (reviewed in Goker *et al*. 2019), respectively, in order to simplify and enhance the rebuilding of missing periodontal support (Fig. 21-5).

Regenerative surgery

Regenerative periodontal therapy comprises techniques that are particularly designed to restore lost parts of the tooth-supporting structures, including cementum, PDL, and bone. Classically, the most common periodontal indications for these procedures include deep infrabony defects, furcation defects of upper premolar and molar teeth, and localized gingival recession defects. The new classification of periodontal diseases recognizes the key role of

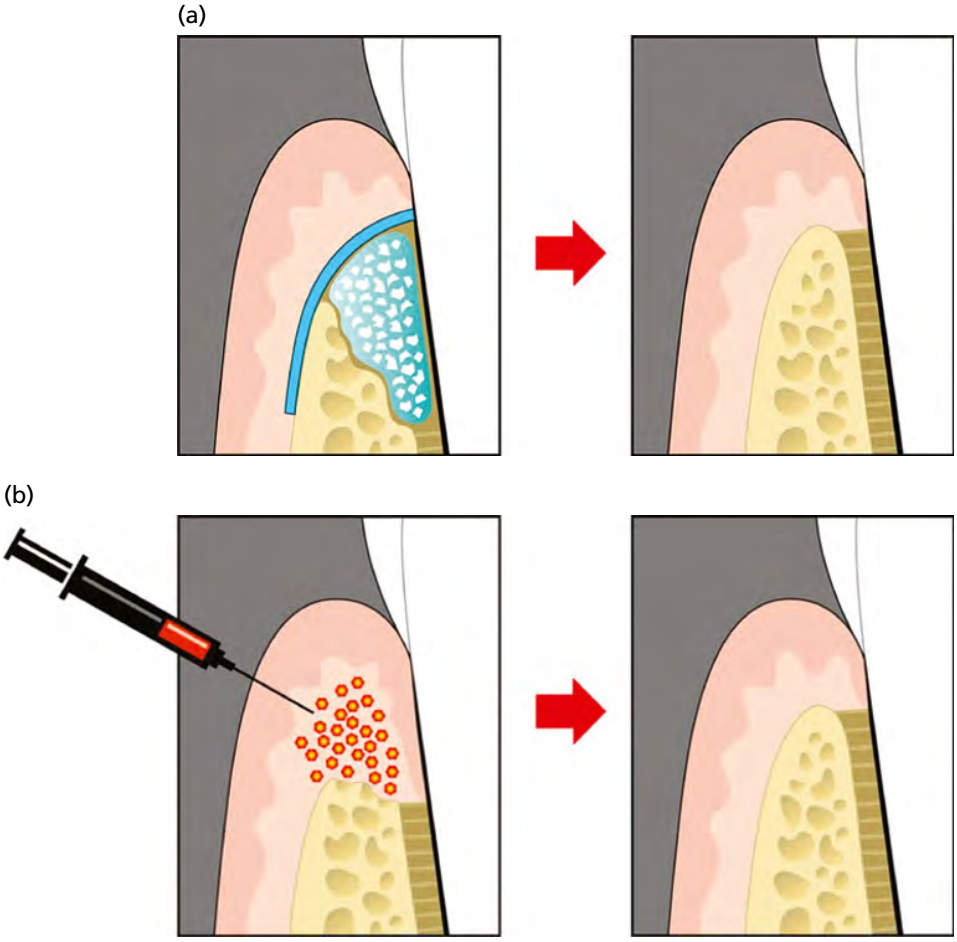

Fig. 21-5 Advanced approaches for regenerating tooth-supporting structures. (a) Application of a graft material (e.g. bone ceramic) and growth factor into an infrabony defect covered by a bioresorbable membrane. (b) Application of gene vectors for the transduction of growth factors producing target cells.

interdental clinical attachment level (CAL) for defining the periodontal status of and the severity (stage) of the periodontal disease (Tonetti *et al*. 2018). Thus, the prognosis (and the stage) of periodontal disease can be improved by regenerating the interdental clinical attachment. Interdental attachment is composed by the supracrestal attachment, which is measured from the cemento-enamel junction (CEJ) to the base of the pocket in the interproximal area. Interproximal bone loss can occur horizontally and/or vertically. This pattern of interdental bone and attachment loss has a major impact not only on patients' esthetic but also on the tooth prognosis. Several attempts have been made for predictably treating these conditions, and to develop new techniques and materials that should be recommended for regenerating the lost interproximal attachment (McGuire & Scheyer 2007; Zucchelli & De Sanctis 2008; Rasperini *et al*. 2013, 2020; Carnio 2014; Aslan *et al*. 2017; Trombelli *et al*. 2017; Zucchelli *et al*. 2017; Ausenda *et al*. 2019). The clinical success for periodontal regeneration may change the long-term prognosis of the tooth (Sculean *et al*. 2008; Nickles *et al*. 2009; Silvestri *et al*. 2011; Cortellini *et al*. 2017). Clinical and preclinical research continues to advance the field of periodontal regenerative therapy by evaluating innovative tissue engineering approaches that include optimized scaffold fabrication technology (Pilipchuk *et al*. 2015), new barrier membrane techniques (Tsai *et al*. 2020), cell-growth stimulating proteins (Dereka *et al*. 2006; Kaigler *et al*. 2006), as well as cell and gene delivery applications (Ramseier *et al*. 2006) (Fig. 21-6).

Guided tissue regeneration

Histologic findings from periodontal regeneration studies and Melcher's concepts of "compartmentalization" revealed that a new connective tissue attachment could be predicted if the cells from the PDL settle on the root surface during healing (Melcher 1976). Hence, the clinical applications of GTR in periodontics involve the placement of a physical barrier membrane to enable the previously periodontitis-affected tooth root surface to be repopulated with cells from the PDL, cells from the lamina propria of the gingival corium, cementum cells, and alveolar bone. GTR techniques utilize barrier membranes to facilitate the migration of bone cells and PDL cells to the defects by preventing soft tissue cells from infiltrating into the defect. This knowledge has been the key to developing standard clinical procedures for the placement of a fabricated membrane in GTR. GTR has recently

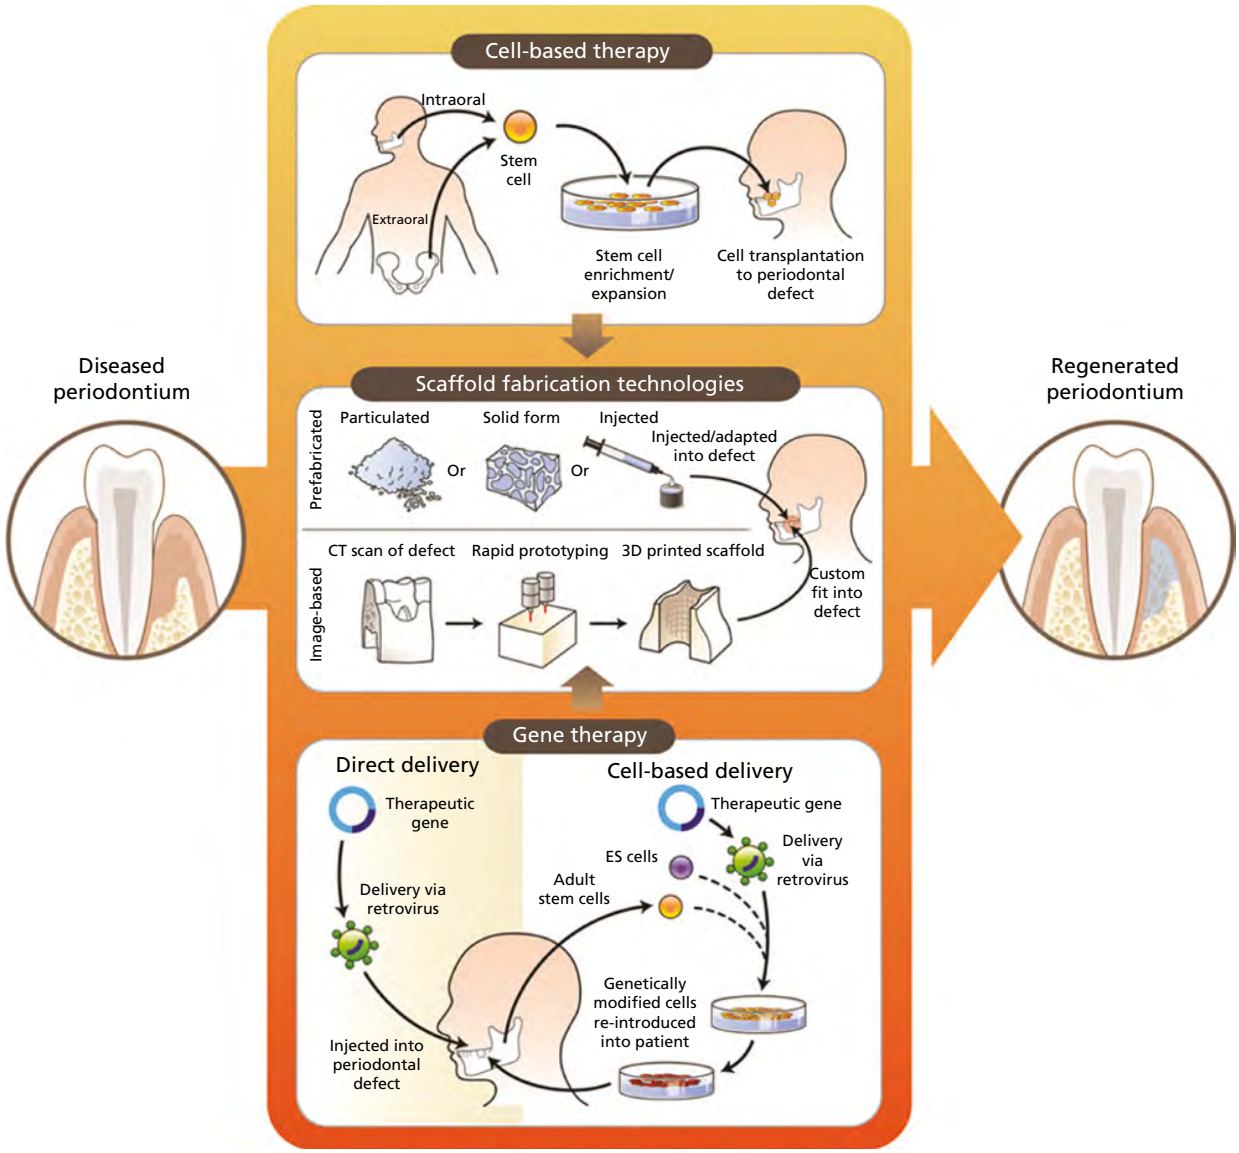

Fig. 21-6 Cell- and gene-based technologies using scaffolding matrices for periodontal tissue engineering. Extraoral and intraoral stem cells represent a viable and accessible alternative source to harvest and expand multipotent colonies. Adequate cell density could be reached *in vitro* in a controlled environment and made readily available for reimplantation into a periodontal defect site. The available direct and cell-based delivery of a therapeutic gene has been shown to increase the regenerative potential and enhance the availability of important factors. The gene of interest is either injected directly into the periodontal defect via a retrovirus or alternatively could be incorporated into a stem cell that is subsequently expanded and delivered into the area of interest. Prefabricated and image-based scaffolds are becoming an essential component in regenerative medicine. A defined supporting structure allows the localization and guidance of the appropriate cells, proteins and the establishment of a mechanically competent environment. Currently, scaffolds for periodontal regeneration are available in particulated, solid, and injectable forms. New developing technology has allowed the customization of scaffolds that would fit into the periodontal defect and include an external and internal architecture that enhances tissue orientation and regeneration. This figure highlights the potential of integrating the available tissue engineering strategies to enhance the outcome of periodontal regenerative therapy. ES cells, embryonic stem cells. (Source: Rios *et al*. 2011).

been combined with the delivery of different factors that are incorporated to augment the regenerative response.

Clinical applications of growth factors for use in periodontal regeneration

A number of studies have focused on the modification of the periodontitis-involved root surface in order to advance the formation of a new connective tissue attachment. However, despite histologic evidence of regeneration following root surface biomodification with citric acid, the outcome of controlled clinical trials have failed to show any improvements in clinical conditions compared with non–acid-treated controls (reviewed in Mariotti 2003). In recent years, biomodification of the root surface with enamel matrix proteins during periodontal surgery and following demineralization with ethylene–diamine–tetra-acetic acid (EDTA) has been introduced to promote periodontal regeneration. The application of enamel matrix proteins (amelogenins) has also been

evaluated as a promoter of periodontal regeneration because it initiates events that occur during the growth of periodontal tissues (Gestrelius *et al*. 2000). Enamel matrix derivative, a purified acid extract of porcine origin contains *enamel matrix derivate* (EMD), which has demonstrated the ability to advance periodontal regeneration (reviewed in Nibali *et al*. 2020). Thus far, EMD alone or in combination with grafts has demonstrated consistent potential to effectively treat intraosseous defects and the clinical results are generally stable over the long term (Trombelli & Farina 2008).

PDGF is a member of a multifunctional polypeptide family and exerts its biologic effects on cell proliferation, migration, ECM synthesis, and antiapoptosis (reviewed in Larsson *et al*. 2016 and Giannobile 1996). The clinical application of PDGF has been shown to successfully advance alveolar bone repair and CAL gain. Initial clinical trials reported the successful repair of class II furcations using demineralized freeze-dried bone allograft (DFDBA) saturated with rhPDGF-BB (Nevins *et al*. 2003). Subsequently, rhPDGF-BB mixed with a synthetic beta-tricalcium phosphate (β-TCP) matrix was shown to advance the repair of deep infrabony pockets as measured by radiographic bone fill in a large multicenter randomized controlled trial (Nevins *et al*. 2005, 2013). Both studies also demonstrated that the use of rhPDGF-BB was safe and effective in the treatment of periodontal osseous defects. In a recent systematic review on PDGF clinical applications, there is evidence on the use of this growth factor system to promote healing in extraction sockets, for sinus floor augmentation, intraoral soft tissue grafts, and ridge augmentation procedures (Tavelli *et al*. 2020).

BMPs are multifunctional polypeptides that have potent bone regenerative capacity. Fiorellini *et al*. (2005) reported that in a human buccal wall defect model, bone formation following tooth extraction was significant when the defect was treated with recombinant human BMP-2 (rhBMP-2) delivered by a bioabsorbable collagen sponge, compared with treatment with the collagen sponge alone. Furthermore, BMP-7, also known as osteogenic protein 1 (OP-1), stimulates bone regeneration around teeth, endosseous dental implants, and in maxillary sinus floor augmentation procedures (reviewed in Lin *et al*. 2016 and Avila-Ortiz *et al*. 2016).

In general, topical delivery of growth factors to periodontal wounds has shown promise, but as yet the impact is insufficient for the promotion of predictable periodontal tissue engineering (Kaigler *et al*. 2006). Growth factor proteins, once delivered to the target site, tend to suffer from instability and quick dilution, presumably due to proteolytic breakdown, receptor-mediated endocytosis, and solubility of the delivery vehicle. Because their half-lives are significantly reduced, the period of exposure may not be sufficient to act on osteoblasts, cementoblasts, or PDL cells. A clinical trial evaluated the regenerative effects of systemic delivery of teriparatide, a recombinant form of parathyroid hormone (PTH). The study demonstrated a periodontal anabolic effect favoring a regenerative outcome. Following periodontal surgery, teriparatide was systemically delivered for 6 weeks and results compared with a placebo control. Delivery of this recombinant molecule in this fashion was associated with improved clinical outcomes, including greater resolution of alveolar bone defects and accelerated osseous wound healing (Bashutski *et al*. 2010). More recently, a similar bone anabolic molecule used in the treatment of osteoporosis, the sclerostin monoclonal antibody (described in greater detail in Chapter 2) has shown strong potential to repair periodontal defects by increasing bone volume of alveolar bone (Taut *et al*. 2013; Yao *et al*. 2020).

Cell therapy for periodontal regeneration

Another emerging regenerative approach in the management of soft and hard tissue defects involves cell therapy (see Table 21.3). For regeneration of interdental papillae, early investigations of cell therapy using *ex vivo* cultivated autologous fibroblasts have shown success in the treatment of interdental papillary insufficiency (McGuire & Scheyer 2007). For larger soft tissue defects, a human oral mucosa equivalent, made of autogenous keratinocytes (EVPOME) placed on a cadaveric dermal carrier (Alloderm®), has shown efficacy in wound healing when compared with the dermal carrier alone (Izumi *et al*. 2003). EVPOME has also been successfully used to treat patients affected by squamous cell carcinoma of the tongue, leukoplakia of the tongue, gingiva, and buccal mucosa, or hypoplasia of the alveolar ridge (Hotta *et al*. 2007). In other soft tissue applications, allogenic foreskin fibroblasts have been utilized to promote keratinized tissue formation at mucogingival defects (McGuire & Nunn 2005). A tissue-engineered living cellular construct comprised of viable neonatal keratinocytes and fibroblasts has been evaluated for its ability to increase keratinized gingiva around teeth, and rendered similar clinical outcomes to conventional free gingival autografts (McGuire *et al*. 2011). Compared with the free gingival graft, this particular cell construct has also demonstrated increased potential to promote the expression of angiogenic factors during the early stages of wound healing and, therefore, constitutes a promising material for soft tissue grafting where free gingival grafts are typically indicated (Morelli *et al*. 2011).

The benefits of using somatic cells for the regeneration of soft and hard tissues in the craniofacial area have been illustrated in several preclinical and clinical studies. However, their lack of self-renewal capability and their commitment toward a single cellular phenotype limit their use in the treatment of more challenging craniofacial defects. Stem cells would provide benefit in these applications in that they can reproduce themselves (*self-renewal*) and

differentiate into a variety of specialized cell types (*multipotent*). *Bone marrow stromal cells* (BMSC) are multipotent because they have the ability to differentiate into osteoblasts, chondroblasts, adipocytes, myocytes, and fibroblasts when transplanted *in vivo* (Prockop 1997). *Mesenchymal stem cells* (MSCs) can be obtained from a variety of sources, but autologous MSC isolated from bone marrow of the iliac crest offer a predictable and a cost-effective therapy for the treatment of severely atrophic maxillary and mandibular ridges when compared with harvested autogenous bone (Soltan *et al*. 2007). Bone repair cells (ixmyelocel-T®; Aastrom Biosciences) consisting of *ex vivo* expanded, autologous bone marrow-derived, CD90+ MSCs have recently demonstrated the ability to accelerate bone regeneration and yield better quality bone in localized and large alveolar defects (Kaigler *et al*. 2013, 2015; Bajestan *et al*. 2017). Because these cells include MSCs, they not only serve to provide a source of stem and progenitor cells to a wound healing site, but also produce many growth factors actively involved in the establishment of a vasculature to support and sustain tissue regeneration.

Gene therapeutics for periodontal tissue repair

Although encouraging results for periodontal regeneration have been reported from various clinical investigations using recombinant tissue growth factors, topical protein delivery from existing vehicles has limitations such as transient biologic activity, protease inactivation, and poor bioavailability. Therefore, newer approaches seek to develop methodologies that optimize growth factor targeting to maximize the therapeutic outcome of periodontal regenerative procedures. Genetic approaches in periodontal tissue engineering show early progress in achieving delivery of growth factor genes such as *PDGF* or *BMP* to periodontal lesions (Taba *et al* 2005; Kaigler *et al*. 2006). Gene transfer methods may circumvent many of the limitations with protein delivery to soft tissue wounds (Giannobile 2002; Baum *et al*. 2003). It has been shown that growth factors (Jin *et al*. 2004; Plonka *et al*. 2017) or soluble forms of cytokine receptors (Cirelli *et al*. 2009) applied by gene transfer are more sustainable than proteins applied in a single application. Thus, gene therapy may achieve greater bioavailability of growth factors within periodontal wounds and thus provide greater regenerative potential.

Three-dimensional printed scaffolds for periodontal regeneration

Scaffolds are an integral aspect of tissue engineering approaches to periodontal regeneration, given that space maintenance and wound stability are critical considerations. The scaffold is expected to perform various functions, including the support of cell colonization, migration, growth, and differentiation. The design of the scaffolds also needs to consider biomechanical stability over time, complex 3-dimesional shape, and degradation kinetics (Vaquette *et al*. 2018; Yu *et al*. 2019). Multiphasic three-dimensional scaffolds, incorporating dedicated compartments for PDL, cementum, and bone formation, have the potential to enhance regenerative outcomes by controlling the complex temporal and spatial interactions during periodontal wound healing (Ivanovski *et al*. 2014). Three-dimensional (3D) printing, defined as an additive manufacturing technology for creating 3D objects from a numerical data file in a layer by layer fashion (Fig 21-7a), offers significant promise for the fabrication of multiphasic scaffolds for periodontal regeneration. This is because additive manufacturing is capable of exerting a high level of control over the microstructure and porosity of the multiphasic scaffolds, suitable for regeneration of different components of the periodontium (such as bone and PDL) (Fig 21-7b), and providing guidance for perpendicular periodontal fiber attachment to the root surface (Fig 21-7c, d) (Obregon *et al*. 2015; Staples *et al*. 2020). It also has the advantage of being able to produce custom scaffolds that can be fabricated to intimately fit individual periodontal defects, as recently described in a landmark human case report (Rasperini *et al*. 2015). Data from a computed tomography scan of the patient's defect was used to design and print a customized scaffold made from a biodegradable polymer (polycaprolactone [PCL]) (Fig 21-7e–j). The scaffold was initially well integrated into the host tissue (Fig 21-7k) and demonstrates the 'proof-of-concept' potential of 3D printed scaffolds for the treatment of a periodontal defect.

Conclusion

The periodontal healing process is governed by a complex multifactorial mechanism in which a number of local and systemic, micro- and macro-environmental variables interplay to define the final result. Only a profound understanding of biologic and clinical variables affecting the outcome of gingival and periodontal surgical procedures will allow clinicians to manipulate critical factors effectively in order to optimize the outcome and increase the predictability of periodontal regeneration (Figs. 21-8, 21-9, 21-10). This chapter has given a brief presentation of the healing mechanisms that are initiated in periodontal tissues following basic periodontal surgical procedures. The complexity of the cellular and molecular events that are activated during and after a periodontal intervention lead to some important conclusions:

- As clinicians, we must minimize any deviations from the strict surgical protocols in order to ensure the risk of any unfavorable healing events is minimized. It is important that the PASS principle of promotion of periodontal wound repair: *P*rimary wound stability, *A*ngiogenesis

to promote good wound perfusion, *S*pace creation for repopulation of the wound site by stem cells and those associated with regeneration and wound *S*tability. These principles will owe to a good clinical result (Wang & Boyapati 2006).

- As scientists, we should be able to translate the clinical signs and symptoms into the language of physiology and histology, and understand their nature so that interventions can be modified accordingly

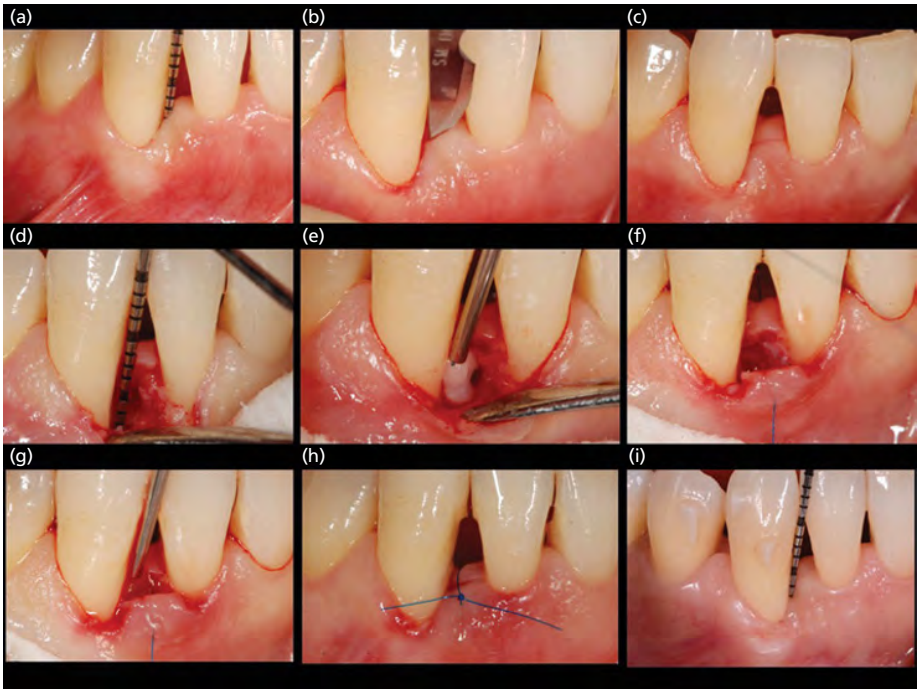

Fig. 21-8 (a) Severe probing pocket depth (PPD) (7 mm), mesial to tooth 43 at the re-evaluation after non-surgical periodontal treatment. (b), (c) A buccal incision of the papilla is performed to allow the elevation of a buccal flap. (d) In this case it was possible to elevate a minimum amount of buccal tissue to visualize the defect, without elevating the interdental papilla, according to the "single flap approach" (Trombelli *et al*. 2009) and modified MIST (Cortellini & Tonetti 2009). (Source: Case presentation courtesy of Giulio Rasperini) (e) After cleaning the root and debriding the defect, EDTA was applied onto the root surface for 2 minutes to remove the smear layer. (f) A simple interrupted monofilament suture is prepared and left loose. (g) After irrigation of the root with saline solution, EMD (Emdogain®, Straumann, Basel, Switzerland) was applied onto the clean root surface. (h) The suture can now be closed with a surgical knot. (i) One year later, the site probes 2 mm with a gain of 5 mm when compared with the baseline.

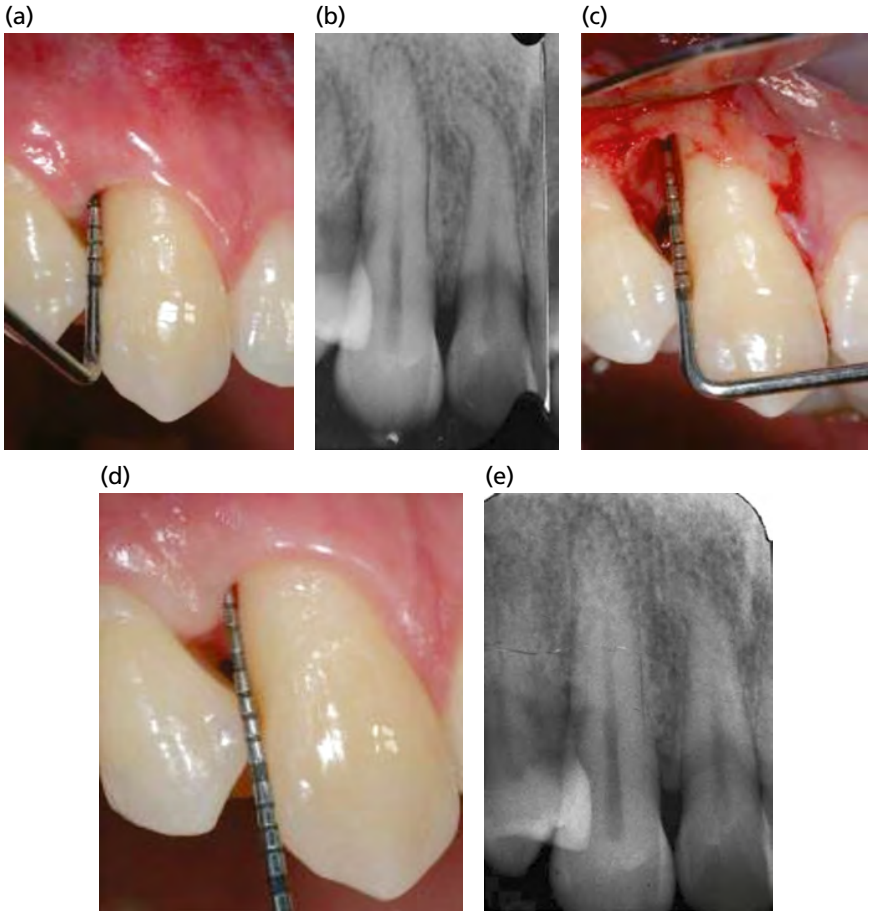

Fig. 21-9 (a) A 32-year-old male patient with severe periodontitis. Tooth 13 shows a probing pocket depth (PPD) of 10 mm distobuccal and a clinical attachment level (CAL) of 14 mm. (b) Periapical radiograph shows the infrabony defect distal to tooth 13. (c) After the buccal incision of the papilla, the interdental tissue is preserved attached to the palatal flap. After debridement of the granulation tissue and root planing, the infrabony defect is classified and measured: the predominant component is a 7-mm deep three-wall defect. One year after surgical intervention, the distal site of tooth 13 shows a PPD of 2 mm (gain of 8 mm from initial measurement) and a CAL of 7 mm (gain of 7 mm) (d) and the radiograph shows defect filling (e).

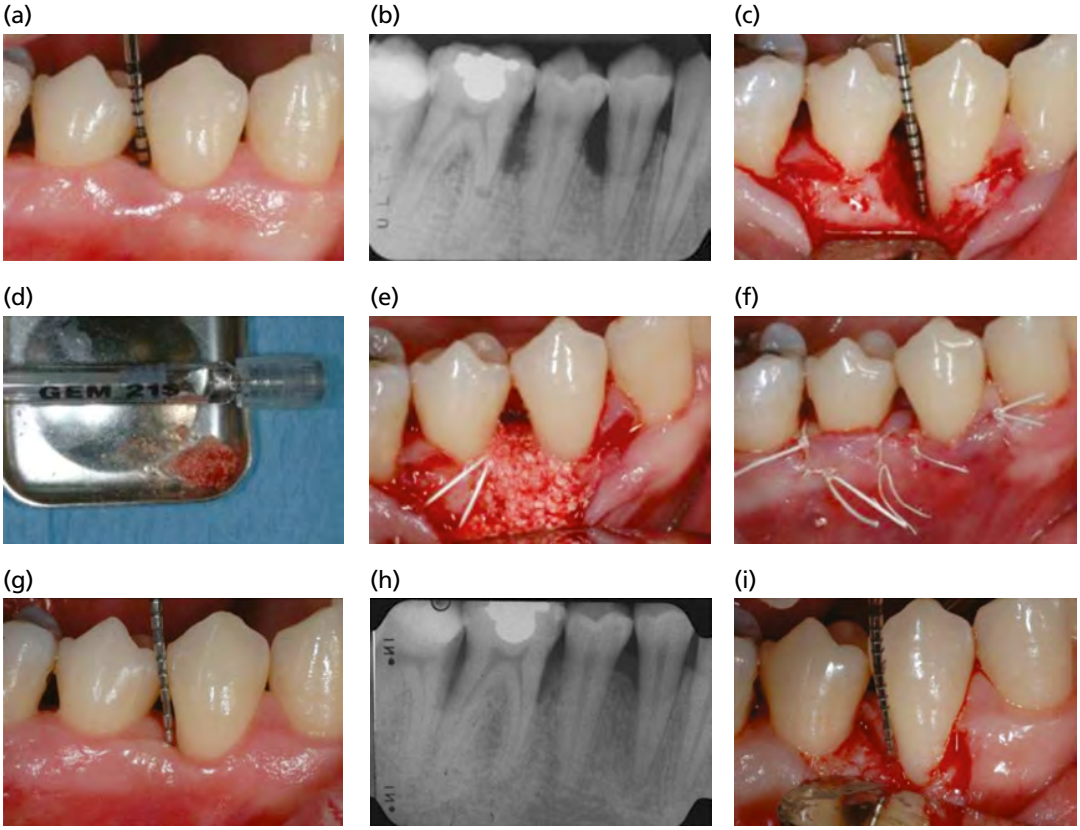

Fig. 21-10 (a) A 27-year-old patient at the re-evaluation visit after the initial phase showed three sites with a pocket probing depth (PPD) of <6 mm; the one distal to tooth 44 had a PPD of 7 mm and no gingival recession. (b) Periapical radiograph shows a one-wall defect distal to tooth 44 and a lesion between teeth 45 and 46. (c) Measurement of the pure one-wall defect shows an infrabony component of 6 mm. (d) Grafting material of the GEM 21S® is mixed with a few particles of autogenous bone chips, collected from the surgical area with a Rhodes instrument, and with the liquid component of the GEM 21S® (platelet-derived growth factor [PDGF]). (e) Liquid PDGF is placed in the defect together with the graft to rebuild the lost bone. (f) An off-set internal mattress suture is performed to keep and stabilize the flap coronal. A second internal mattress suture is performed with 7-0 Gor Tex® to allow optimal adaptation of the flap margins without interference from the epithelium. The two internal mattress sutures are tied but not knotted until there is a perfect tension-free closure of the wound. Two additional interrupted 7-0 sutures are placed to assure stable contact between the connective tissues of the edges of the flaps. The mesial and distal papilla are stabilized with additional interrupted sutures. Nine months after surgery the PPD is 2 mm (g), the periapical radiograph shows a good bone fill of the one-wall bony defect (h), and surgical re-entry shows formation of new bone (i).

Lindhe's Clinical Periodontology and Implant Dentistry

Lindhe's Clinical Periodontology and Implant Dentistry

Seventh Edition

Edited by

Tord Berglundh
Department of Periodontology, Institute of Odontology,
The Sahlgrenska Academy at University of Gothenburg,
Gothenburg, Sweden

William V. Giannobile
Harvard School of Dental Medicine, Boston, MA, USA

Niklaus P. Lang
Department of Periodontology, School of Dental Medicine,
University of Bern, Bern, Switzerland

Mariano Sanz
Faculty of Odontology, ETEP (Etiology and Therapy of Periodontal and Peri-Implant Diseases) Research Group, Complutense University of Madrid, Madrid, Spain and Department of Periodontology, Faculty of Dentistry, Institute of Clinical Dentistry,
University of Oslo, Oslo, Norway

WILEY Blackwell

Volume 2

Part 9: **Examination Protocols**

Chapter 22

Examination of Patients

Giovanni E. Salvi[1], Tord Berglundh[2], and Niklaus P. Lang[1]

[1]Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland
[2]Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Patient's history

As a basis for comprehensive treatment planning and understanding of the patient's needs, social and economic situations, as well as general medical conditions, the history of the patient is a revealing documentation. In order to expedite history taking, a health questionnaire may be filled out by the patient prior to the initial examination. Such a questionnaire should be structured in a way that the professional immediately realizes compromising or risk factors that may modify the treatment plan and hence, may have to be discussed in detail with the patient. The assessment of the patient's history requires an evaluation of the following six aspects: (1) chief complaint, (2) social and family history, (3) dental history, (4) oral hygiene habits, (5) tobacco consumption history and potential drug abuse, and (6) medical history and medications.

Chief complaint and expectations

It is essential to realize the patient's needs and desires for treatment. If a patient has been referred for specific treatment, the extent of the desired treatment has to be defined and the referring dentist should be informed of the intentions for treatment. However, patients reporting by themselves usually have specific desires and expectations regarding treatment outcomes. These may not be congruent with the true assessment of a professional with respect to the clinical situation. Satisfactory individually optimal treatment results may only be achieved if the patient's demands are in balance with the objective evaluation of the disease and the projected treatment outcomes. Therefore, the patient's expectations have to be taken seriously and must be incorporated in the evaluation in harmony with the clinical situation.

Social and family history

Before assessing the clinical conditions in detail, it is advantageous to elucidate the patient's social environment and to feel for his/her priorities in life including the attitude towards periodontal therapy and potential rehabilitation with dental implants. Likewise, a family history may be important especially with respect to forms of periodontitis with a rapidly progressing pattern.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Dental history

These aspects include an assessment of previous dental care and maintenance visits if not stated by a referring dentist. In this context, information regarding signs and symptoms of periodontitis noted by the patient such as migration and increasing mobility of teeth, bleeding gums, food impaction, and difficulties in chewing have to be explored. Chewing comfort and the possible need for tooth replacement with removable or fixed dental prostheses is determined.

Oral hygiene habits

In addition to the exploration of the patient's routine dental care including an assessment of frequency and duration of daily tooth brushing habits, the knowledge about interdental cleansing devices and additional supportive antiseptics and regular use of fluorides should be assessed. The patient's manual dexterity and his/her cleansing patterns with either manual or power-driven toothbrushes should be evaluated.

History of tobacco use

Since tobacco use has been documented to be the second most important risk factor after inadequate plaque control (Kinane *et al*. 2006; Bassetti *et al*. 2017) in the etiology and pathogenesis of periodontal diseases, the importance of tobacco use counseling cannot be overestimated. Moreover, based on the fact that cigarette smokers display an increased risk for peri-implant diseases and implant loss compared with non-smokers (Strietzel *et al*. 2007; Heitz-Mayfield & Huynh-Ba 2009; Meyle *et al*. 2019), the assessment of the tobacco use history represents an important step in the initial patient evaluation.

Hence, the determination of the tobacco use history including detailed information about exposure time and quantity have to be collected. Further aspects of tobacco cessation counselling are presented in Chapter 27.

Medical history and medications

General medical aspects may be extracted from the health questionnaire constructed to highlight the medical risk factors encountered for routine periodontal and/or implant therapy. The four major complexes of complications encountered in patients may be prevented by checking the medical history with respect to: (1) cardiovascular and circulatory risks, (2) bleeding disorders, (3) infective risks, and (4) allergic reactions. Further aspects are presented in Chapter 24.

In light of the increasing consumption of medications in the aging population, an accurate assessment of the patient's prescribed medications and their potential interactions and effects on therapeutic procedures have to be collected. With respect to treatment planning with dental implants, it may be indicated to contact the patient's physician for detailed information relevant to systemic risks (Bornstein *et al*. 2009; Chappuis *et al*. 2018).

Genetic testing before periodontal and implant therapy

Cytokine gene polymorphisms may modulate the host response to the bacterial challenge and influence susceptibility to periodontal and peri-implant diseases. Based on current evidence, however, it may be considered premature to recommend a systematic genetic screening of patients with periodontal diseases and candidates for implant therapy (Huynh-Ba *et al*. 2007, 2008).

Signs and symptoms of periodontal diseases and their assessment

Periodontal diseases are characterized by color and texture alterations of the gingiva, for example redness and swelling, as well as an increased tendency to bleeding on probing (BoP) in the gingival sulcus/pocket area (Fig. 22.1). In addition, the periodontal tissues may exhibit a reduced resistance to probing perceived as increased probing depth and/or tissue recession. Advanced stages of periodontitis may also be associated with increased tooth mobility as well as drifting or flaring of teeth (Fig. 22-2).

On radiographs, periodontitis may be recognized by moderate to advanced loss of alveolar bone (Fig. 22-3). Bone loss is defined either as "horizontal" or "angular". If bone loss has progressed at similar rates in the dentition, the crestal contour of the remaining bone in the radiograph is even and defined as being "horizontal". In contrast, angular bony defects are the result of bone loss that has occurred at different rates around teeth/tooth surfaces and hence, is defined as "vertical" or "angular" bone loss.

In a histological section, periodontitis characterized by the presence of an inflammatory cell infiltrate within a 1–2 mm wide zone of the gingival connective tissue adjacent to the subgingival biofilm on the tooth (Fig. 22-4). Within the infiltrated area there is a pronounced loss of collagen. In more advanced forms of periodontitis, marked loss of connective tissue attachment to the root and apical downgrowth of the dentogingival epithelium along the root are important characteristics.

Outcomes from experimental and clinical research indicated that periodontal diseases:

- Affect individuals with various susceptibility at different rates (Löe *et al*. 1986; Ramseier *et al*. 2017)
- Affect different parts of the dentition to a varying degree (Papapanou *et al*. 1988)
- Are site specific in nature for a given area (Socransky *et al*. 1984)

Fig. 22-1 (a–g) Buccal/labial and palatal/lingual views of a 59-year-old male patient diagnosed with severe generalized periodontitis with furcation involvement.

- Are sometimes progressive in character and, if left untreated, may result in tooth loss (Löe *et al*. 1986; Ramseier *et al*. 2017)
- Can be successfully treated and maintained long-term (Hirschfeld & Wasserman 1978; Rosling *et al*. 2001; Axelsson *et al*. 2004).

For effective treatment planning, the location, topography and extent of periodontal lesions should be recognized in all parts of the dentition. It is, therefore, mandatory to examine all sites of all teeth for the presence or absence of periodontal lesions. This, in turn, means that single-rooted teeth should be

examined at least at four sites (e.g. mesial, buccal, distal, and oral) and multirooted teeth at least at six sites (e.g. mesiobuccal, buccal, distobuccal, distooral, oral, and mesio-oral) with special attention to the furcation areas.

Because periodontitis includes inflammatory alterations of the gingiva and a progressive loss of periodontal attachment and alveolar bone, the comprehensive examination must include assessments describing such pathologic alterations.

Figure 22-1 illustrates the clinical status of a 59-year-old patient diagnosed with severe periodontitis.

Fig. 22-2 Buccal migration of tooth 13 as a sign of severe periodontitis.

The examination procedures used to assess the location and extension of periodontal disease will be demonstrated by using this case as an example.

Gingiva

Clinical signs of gingivitis include changes in color and texture of the soft marginal gingival tissue and BoP.

Various index systems have been developed to describe gingivitis in epidemiologic and clinical research. They are discussed in Chapter 6. Even though the composition of the inflammatory infiltrate can only be identified on histologic sections, inflamed gingival tissue can be correctly diagnosed on the basis of the tendency to bleed on probing. The symptom BoP to the bottom of the gingival sulcus/pocket is associated with the presence of an inflammatory cell infiltrate. The occurrence of such bleeding, especially in repeated examinations, is indicative of disease progression (Lang *et al*. 1986), although the predictive value of this single parameter remains rather low (i.e. 30%). On the other hand, the absence of BoP yields a high negative predictive value (i.e. 98.5%) and hence, is an important indicator of periodontal stability (Lang *et al*. 1990; Joss *et al*. 1994). Since trauma to the tissues provoked by probing should be avoided if the true vascular permeability changes

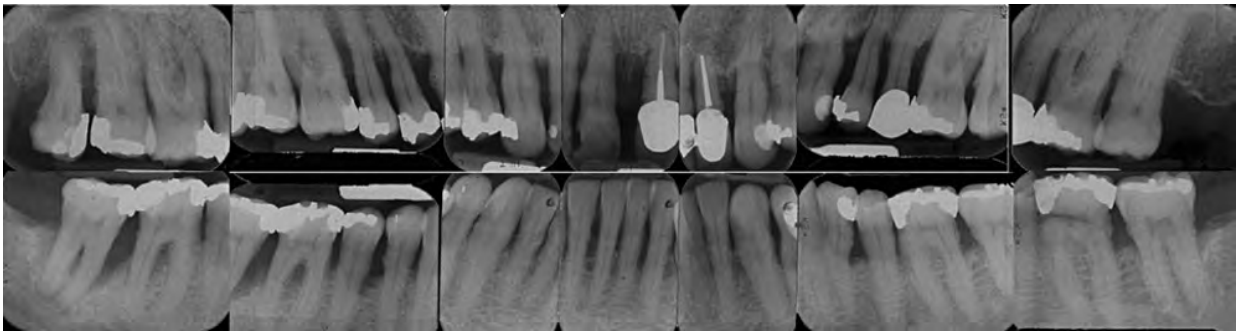

Fig. 22-3 Periapical radiographs of the patient presented in Fig. 22-1.

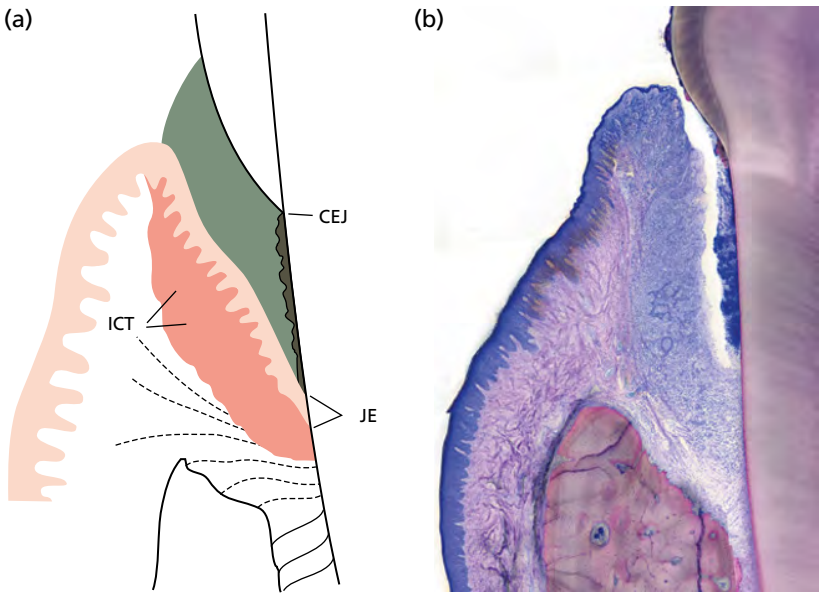

Fig. 22-4 Schematic drawing (a) and histologic section (b) illustrating the characteristics of periodontal disease. Note the zone of infiltrated connective tissue (ICT) lateral to the junctional epithelium (JE). CEJ, cementoenamel junction; JE, junctional epithelium. (Source: Part b courtesy of Professor D. Bosshardt, University of Bern, Switzerland.)

associated with inflammation are to be assessed, a probing pressure of 0.25 N should be applied when assessing BoP (Lang *et al*. 1991; Karayiannis *et al*. 1992). The identification of the apical extent of the gingival lesion is made in conjunction with *pocket probing depth* (PPD) measurements. In sites where "shallow" pockets are present, inflammatory lesions residing in the marginal portion of the gingiva are distinguished by probing in the superficial tissue. When the infiltrate resides in sites with attachment loss, the inflammatory lesion in the apical part of the pocket must be identified by probing to the bottom of the deepened pocket.

Bleeding on probing

A periodontal probe is inserted to the "bottom" of the gingival/periodontal pocket by applying light force and is moved gently along the tooth (root) surface (Fig. 22-5). If bleeding is provoked upon retrieval of the probe, the site examined is considered BoP-positive and hence, inflamed.

Figure 22-6 shows the chart used to identify BoP-positive sites in a dichotomous way at the initial examination. Each tooth in the chart is represented and each tooth surface is indicated by a triangle. The inner segments represent the palatal/lingual gingival units, the outer segments the buccal/labial units, and the remaining fields the two approximal gingival units. The fields of the chart corresponding to the inflamed gingival units are marked in red. The mean BoP score (i.e. gingivitis) is given as a percentage. In the example shown in Fig. 22-6, 104 out of a total number of 116 gingival units bled on probing, amounting to a BoP percentage of 89%. This method of charting not only serves as a means of documenting areas of health and disease in the dentition, but charting during the course of therapy or maintenance will disclose sites which turn healthy or remain inflamed. The topographical pattern will also identify sites with consistent or repeated BoP at various observation periods.

Fig. 22-5 Pocket probing depth in conjunction with bleeding on probing. A graduated periodontal probe is inserted to the "bottom" of the gingival/periodontal pocket applying light force and is moved gently along the tooth (root) surface.

At *implant sites*, BoP is assessed in a similar matter as for all teeth. It has to be realized that BoP-positive peri-implant mucosal sites represent a status of peri-implant mucositis. As for teeth, it has been demonstrated that such peri-implant mucositis sites, like for gingivitis sites, are reversible simply by the removal of biofilm in a systematic way (Salvi *et al*. 2012; Meyer *et al*. 2017). Peri-implant mucositis represents in most cases a precursor stage for the development of peri-implantitis.

Keratinized mucosa at implant recipient sites

In order to maintain health and tissue stability around dental implants, the presence of a minimum width of keratinized mucosa has been postulated. A width of keratinized mucosa <2 mm has been debated in the literature as a contributing factor for impaired plaque control with consequent increase in inflammation around dental implants (Bouri *et al*. 2008; Schrott *et al*. 2009; Crespi *et al*. 2010). The findings of a systematic review, however, indicated that the evidence in support of the need for keratinized mucosa around dental implants in order to maintain health and stability is limited (Wennström & Derks 2012). Nevertheless, the dimensions of the keratinized mucosa in edentulous areas should be evaluated in candidates for implant therapy (Roccuzzo *et al*. 2016).

Periodontal ligament and the root cementum

In order to evaluate the amount of tissue lost in periodontitis and also to identify the apical extension of the inflammatory lesion, the following parameters should be recorded:

- Pocket probing depth (PPD)
- Probing attachment level (PAL)
- Furcation involvement (FI)
- Tooth mobility (TM)

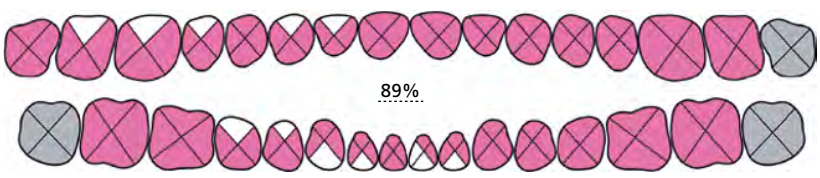

Fig. 22-6 Chart used to identify bleeding on probing-positive sites in a dichotomous way at the initial examination and during maintenance care.

Assessment of pocket probing depth

The probing depth (i.e. the distance from the gingival margin to the bottom of the gingival sulcus/pocket) is measured to the nearest millimeter by means of a graduated periodontal probe with a standardized tip diameter of approximately 0.4–0.5 mm (Fig. 22-7).

Fig. 22-7 Examples of graduated periodontal probes with a standardized tip diameter of approximately 0.4–0.5 mm.

The pocket depth should be assessed at each surface of all teeth as well as existing implants in the oral cavity. In the periodontal chart (Fig. 22-8), PPD <4 mm are indicated in black figures, while deeper PPD (i.e. ≥4 mm) are marked in red. This allows an immediate evaluation of diseased sites (i.e. red figures) both from an extent and severity point of view. The chart may be used for case presentations and discussions with the patient. For convenience, the therapist may download free of charge a template of the periodontal chart used in the Department of Periodontology at the University of Bern, Switzerland (www.periodontalchart-online.com).

Clinical probing of implant sites represent a sensitive diagnostic procedure for the detection of peri-implant diseases. Clinical probing will leave a

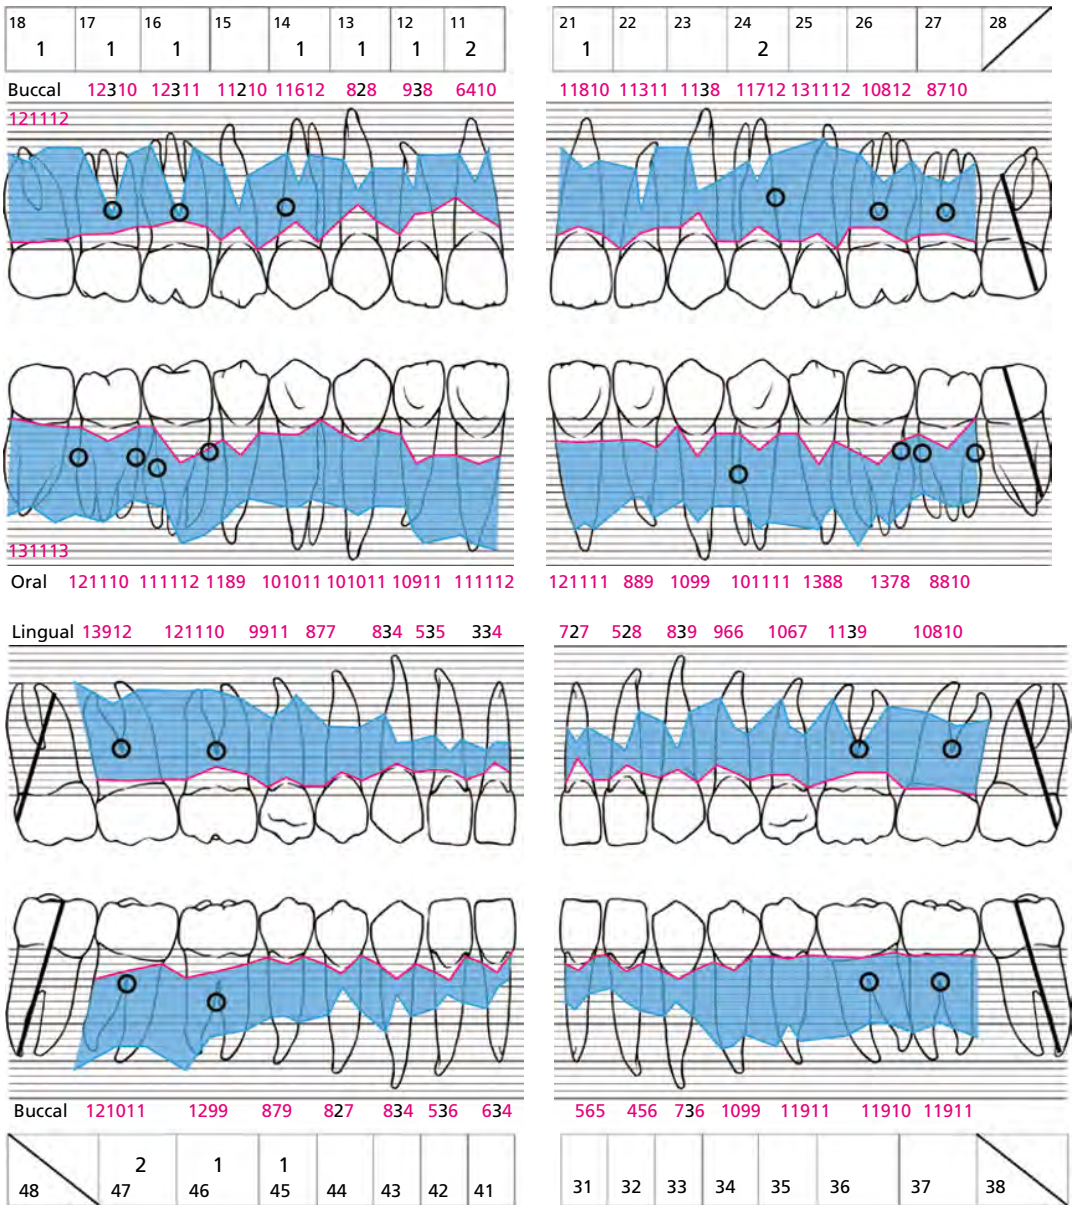

Fig. 22-8 Periodontal chart indicating pocket probing depth (PPD) <4 mm in black figures and PPD ≥4 mm in red figures. This allows an immediate evaluation of diseased sites (i.e. red figures) both from an extent and severity point of view.

short-term trauma to the peri-implant tissue that will repair completely during the course of 5–7 days with a junctional epithelium (Etter *et al*. 2002). Hence, the clinician does not have to worry about damaging the peri-implant soft tissue adhesion mechanism.

Results from PPD measurements will only in rare situations (i.e. when the gingival margin coincides with the cementoenamel junction [CEJ]) give proper information regarding the extent of loss of probing attachment. For example, an inflammatory edema may cause a swelling of the free gingiva resulting in a coronal displacement of the gingival margin without a concomitant migration of the dentogingival epithelium to a level apical to the CEJ. In such a situation, a pocket depth exceeding 3–4 mm represents a "pseudopocket". In other situations, an obvious loss of periodontal attachment may have occurred without a concomitant increase of PPD. A situation of this kind is shown in Fig. 22-9 where multiple recessions of the gingiva can be seen. Hence, the assessment of the PPD in relation to the CEJ is an indispensable parameter for the evaluation of the periodontal condition (i.e. PAL).

Assessment of probing attachment level

PAL may be assessed to the nearest millimeter by means of a graduated probe and expressed as the distance in millimeters from the CEJ to the bottom of the

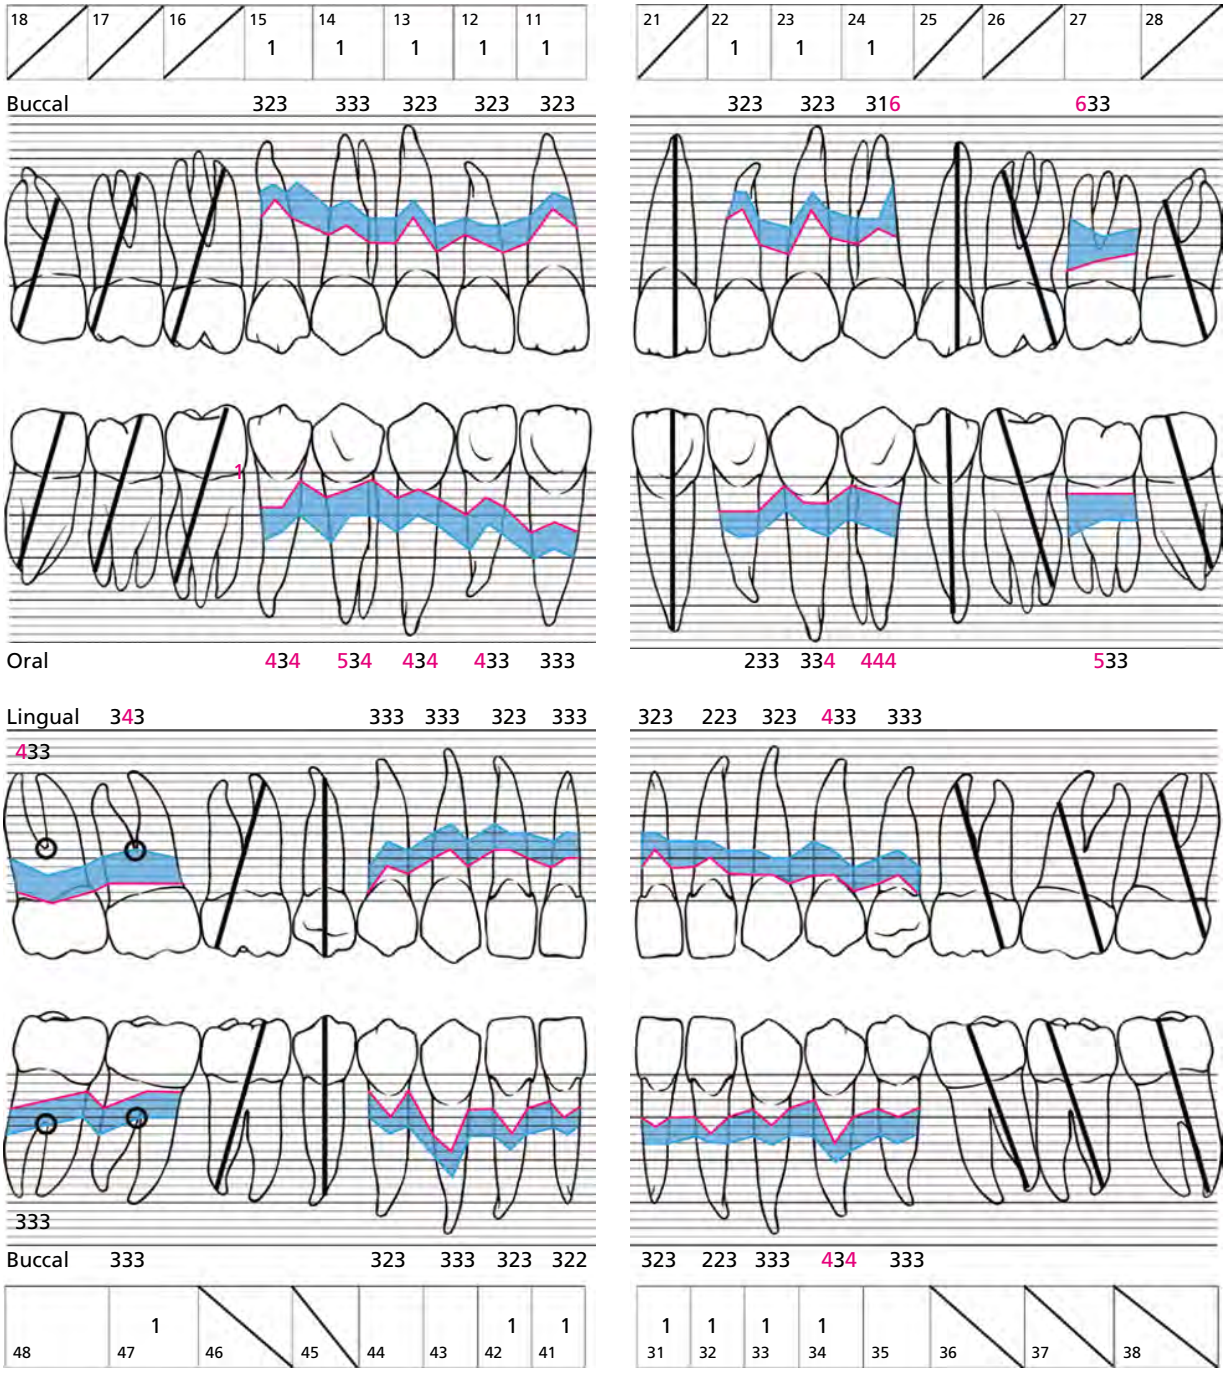

Fig. 22-9 Periodontal chart indicating periodontal attachment loss has occurred without a concomitant increase of probing pocket depth. Multiple buccal/labial as well as palatal/lingual gingival recessions can be seen.

probeable gingival/periodontal pocket. The clinical assessment requires the measurement of the distance from the free gingival margin (FGM) to the CEJ for each tooth surface. After recording this, PAL may be calculated from the periodontal chart (i.e. PPD - distance CEJ–FGM). In cases with gingival recessions, the distance CEJ–FGM turns negative and hence, will be added to the PPD to determine PAL.

Errors inherent in periodontal probing

The distances recorded in the periodontal examination using a periodontal probe have generally been assumed to represent a fairly accurate estimate of the PPD or PAL at a given site. In other words, the tip of the periodontal probe has been assumed to identify the level of the most apical cells of the dentogingival (junctional epithelium) epithelium. Results from research, however, indicated that this is seldom the case (Saglie *et al*. 1975; Listgarten *et al*. 1976; Armitage *et al*. 1977; Spray *et al*. 1978; Robinson & Vitek 1979; van der Velden 1979; Magnusson & Listgarten 1980; Polson *et al*. 1980). A variety of factors influencing measurements made with periodontal probes include: (1) thickness of the probe used, (2) angulation and positioning of the probe because of anatomic features such as the contour of the tooth surface, (3) graduation scale of the periodontal probe, (4) pressure applied on the instrument during probing, and (5) degree of inflammatory cell infiltration in the soft tissue and accompanying loss of collagen. Therefore, a distinction should be made between the histological and the clinical PPD to differentiate between the depth of the actual anatomic defect and the measurement recorded by the probe (Listgarten 1980).

Measurement errors depending on factors such as the thickness of the probe, the contour of the tooth surface, incorrect angulation, and the graduation scale of the probe can be reduced or avoided by the selection of a standardized instrument and careful management of the examination procedure. More difficult to avoid, however, are errors resulting from variations in probing force and the extent of inflammatory alterations of the periodontal tissues. As a rule, the greater the probing pressure applied, the deeper the penetration of the probe into the tissue. In this context, it should be realized that in investigations designed to disclose the pressure (force) used by different clinicians, the probing pressure was found to range from 0.03 to 1.3 N (Gabathuler & Hassell 1971; Hassell *et al*. 1973), and also, to differ by as much as 2:1 for the same dentist from one examination to another. In order to exclude measurement errors related to the effect of variations in probing pressure, so-called pressure sensitive probes have been developed. Such probes enable the examiner to probe with a predetermined pressure (van der Velden & de Vries 1978; Vitek *et al*. 1979; Polson *et al*. 1980). However, over and underestimation of the "true" PPD or PAL may also occur when this type of probing device is employed (Armitage *et al*. 1977; Robinson & Vitek 1979; Polson *et al*. 1980). Thus, when the connective tissue subjacent to the pocket epithelium is infiltrated by inflammatory cells (Fig. 22-10), the periodontal probe will penetrate beyond the apical termination of the dentogingival epithelium, resulting in an overestimation of the "true" depth of the pocket. Conversely, when the inflammatory infiltrate decreases in size following successful periodontal treatment and a concomitant deposition of new collagen occurs within the previously inflamed tissue area, the dentogingival tissue will become more resistant to penetration by the probe. The probe may then fail to reach the apical termination of the epithelium

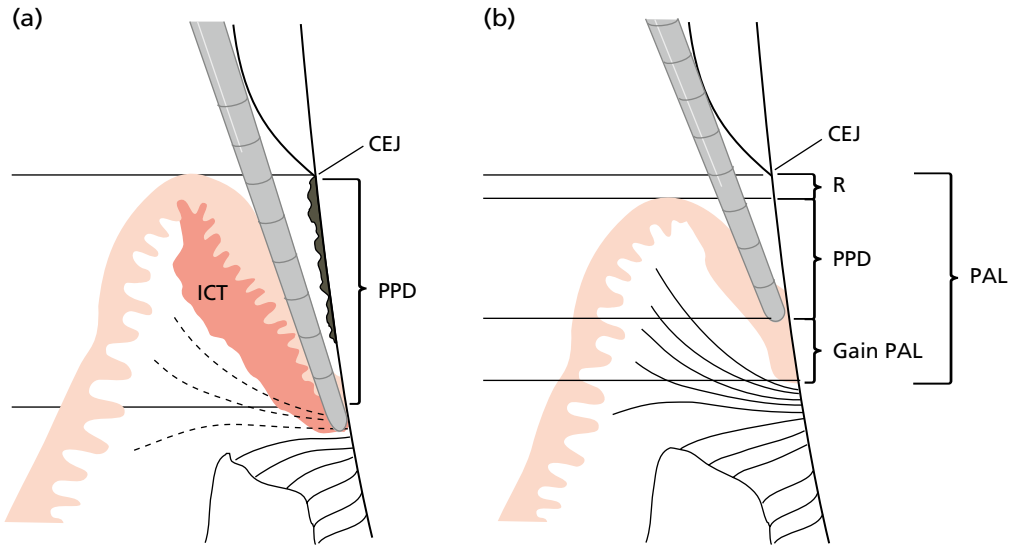

Fig. 22-10 (a) In the presence of an inflammatory cell infiltrate (ICT) in the connective tissue of the gingiva, the periodontal probe penetrates apically to the bottom of the histologic pocket; (b) following successful periodontal therapy, the swelling is reduced and the connective tissue cell infiltrate is replaced by collagen. The periodontal probe fails to reach the apical part of the dentogingival epithelium. CEJ, cementoenamel junction; Gain PAL, recorded false gain of attachment ("clinical attachment"); PAL, probing attachment level; PPD, probing pocket depth; R, recession

using the same probing pressure. This, in turn, results in an underestimation of the "true" PPD or PAL. The magnitude of the difference between the probing measurement and the histologic "true" pocket depth (Fig. 22-10) may range from fractions of a millimeter to a couple of millimeters (Listgarten 1980).

From this discussion it should be understood that reductions in PPD following periodontal treatment and/or gain of PAL, assessed by periodontal probing do not necessarily indicate the formation of a new connective tissue attachment at the bottom of the treated lesion. Rather, such a change may merely represent a resolution of the inflammatory process and may thus occur without an accompanying histologic gain of attachment (Figs. 22-10). In this context it should be realized that the terms "probing pocket depth" (PPD) and "probing attachment level" (PAL) have replaced the previously used terms "pocket depth" and "gain and loss of attachment". Likewise, the term PAL is used in conjunction with "gain" and/or "loss" to indicate that changes in PAL have been assessed by clinical probing.

Current knowledge of the histopathology of periodontal lesions and healing thereof has thus resulted in an altered concept regarding the validity of periodontal probing. However, despite difficulties in interpreting the significance of PPD and PAL measurements, such determinations still give the clinician a useful estimate of the extent of disease involvement, particularly when the information obtained is related to other findings of the examination procedure such as BoP and changes in alveolar bone height.

In recent years, periodontal probing procedures have been standardized to the extent that automated probing systems (e.g. Florida Probe™) have been developed yielding periodontal charts with PPD, PAL, BoP, FI, and TM at one glance (Gibbs *et al*. 1988).

Despite of all the sources of errors discussed, periodontal probing represents a very sensitive method to assess the extent and severity of periodontal lesions. This sensitivity is because periodontal probing has only – if any – false negative values.

Assessment of furcation involvement

The progression of periodontitis around multirooted teeth may involve the destruction of the supporting structures of the furcation area (Fig. 22-11). In order to plan the treatment of such involvement, a detailed and precise identification of the presence and extent of periodontal tissue breakdown within the furcation area is of importance.

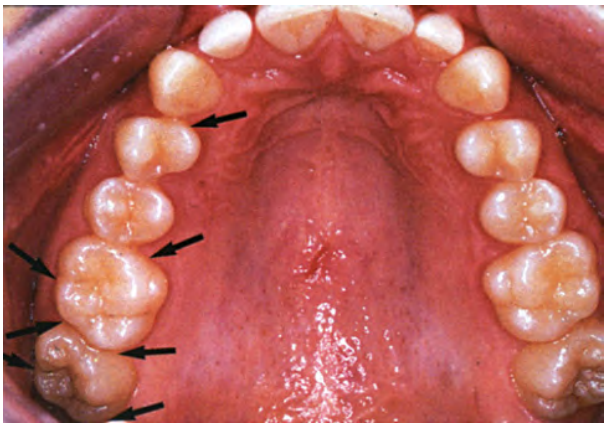
FI is assessed from all the entrances of possible periodontal lesions of multirooted teeth, i.e. buccal and/or lingual entrances of the mandibular molars. Maxillary molars and premolars are examined from the buccal, distopalatal and mesiopalatal entrances. Owing to the position of the first maxillary molars within the alveolar process, the furcation between the mesiobuccal and the palatal roots is best explored from the palatal aspect (Fig. 22-12).

FI is explored using a curved periodontal probe with graduations at 3 mm and 5 mm (Nabers furcation probe, Fig. 22-13a). Depending on the penetration depth, the FI is classified as "superficial" or "deep":

- *Class I*: horizontal probing depth ≤3 mm from one or two entrances (Fig. 22-13b).

Fig. 22-11 Superficial (tooth 46) and deep (tooth 16) periodontal tissue destruction in the buccal furcation areas.

(a)



(b)

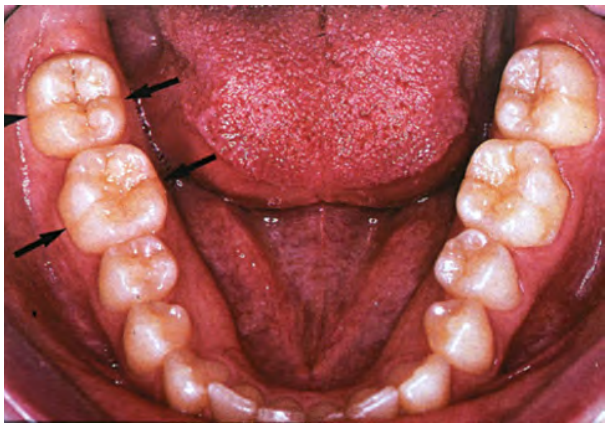


Fig. 22-12 (a, b) Anatomic locations for the assessment of furcation involvement in the maxilla and in the mandible.

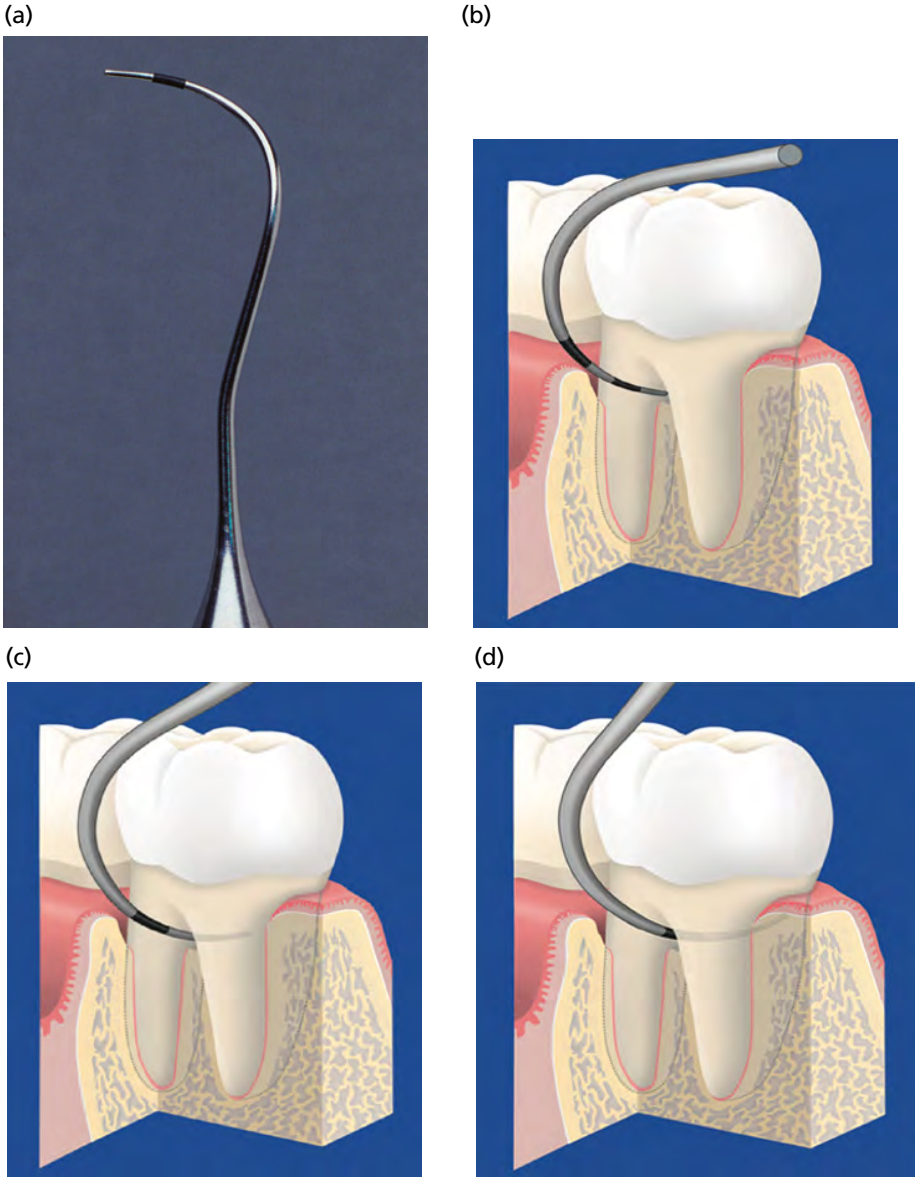

Fig. 22-13 (a) Furcation involvement is explored using a curved periodontal probe with graduations at 3 mm and 5 mm (Nabers furcation probe). (b) Class I: horizontal probing depth ≤3 mm from one or two entrances. (c) Class II: horizontal probing depth >3 mm in at the most one entrance and/or in combination with a FI class I. (d) Class III: horizontal probing depth >3 mm in two or more entrances usually represents a "through-and-through" destruction of the supporting tissues in the furcation.

- *Class II*: horizontal probing depth >3 mm in at the most one entrance and/or in combination with a FI class I (Fig. 22-13c).
- *Class III*: horizontal probing depth >3 mm in two or more entrances usually represents a "through-and-through" destruction of the supporting tissues in the furcation (Fig. 22-13d).

The FI degree is presented on the periodontal chart (Fig. 22-14) together with a description of which tooth surface the involvement has been identified on. The effects of various therapeutic approaches to the management of multirooted teeth with FI has been systematically appraised (Huynh-Ba *et al*. 2009; Salvi *et al*. 2014). A detailed description with respect to the management of furcation-involved teeth is presented in Chapter 33.

Assessment of tooth mobility

The continuous loss of the supporting tissues may result in increased TM. However, trauma from occlusion may also lead to increased TM. Therefore, the reason for increased TM as being the result of a widened periodontal ligament or a reduced height of the supporting tissues or a combination thereof should be elaborated. Increased TM may be classified according to Miller (1950):

- *Degree 0*: "physiologic" mobility measured at the crown level. The tooth shows mobility of 0.1–0.2 mm in the horizontal direction within the alveolus.
- *Degree 1*: increased mobility of the crown of the tooth of at the most 1 mm in the horizontal direction.

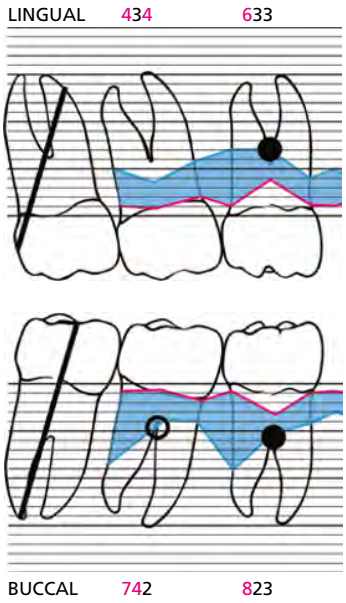

Fig. 22-14 The furcation involvement (FI) shown on the periodontal chart. Open circles represent a superficial FI (i.e horizontal probe penetration ≤3 mm) whereas filled black circles represent a deep FI (i.e. horizontal probe penetration >3 mm).

- *Degree 2*: visually increased mobility of the crown of the tooth exceeding 1 mm in the horizontal direction.
- *Degree 3*: severe mobility of the crown of the tooth in both horizontal and vertical directions and impinging on the function of the tooth.

It must be understood that plaque-associated periodontal disease is not the only cause of increased TM. For instance, trauma may result in tooth hypermobility. Increased TM can frequently also be observed in conjunction with periapical lesions or immediately following periodontal surgery. From a therapeutic point of view it is important, therefore, to assess not only the degree of increased TM, but also the cause of the observed hypermobility (see Chapter 13).

All data collected from measurements of PPD and PAL as well as assessments of FI and TM are included in the periodontal chart (see Fig. 22-8). The various teeth in this chart are denoted according to the two-digit system adopted by the World Dental Federation (FDI) in 1970.

Alveolar bone

Radiographic analysis

Radiographs provide information on the height and configuration of the interproximal alveolar bone (see Fig. 22-3). Obscuring structures such as roots often make it difficult to identify the outline of the buccal and lingual alveolar bony crest. The analysis of the radiographs must, therefore, be combined with a detailed evaluation of the periodontal chart in order to estimate correctly concerning "horizontal" and "angular" bony defects.

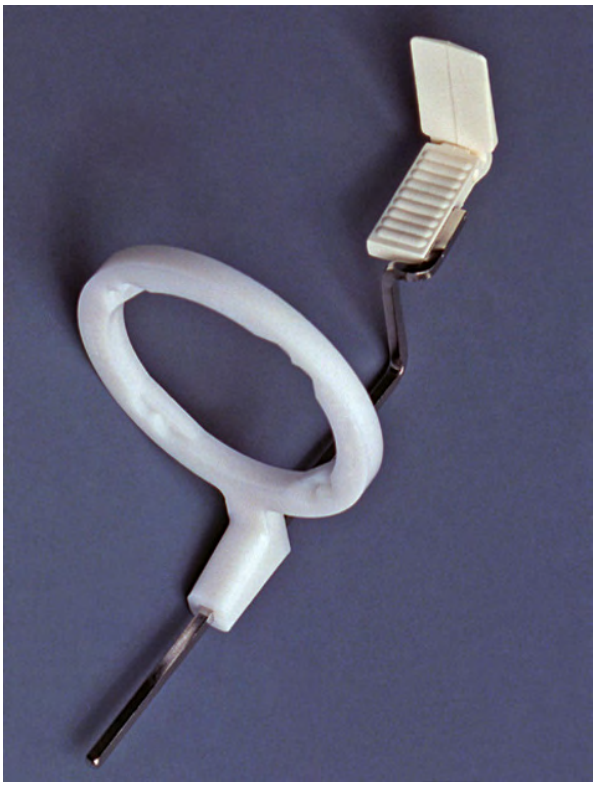

Fig. 22-15 The use of a Rinn filmholder and a long-cone paralleling technique yield reproducible radiographs.

Unlike the periodontal chart, which represents a sensitive diagnostic estimate of the lesions, the radiographic analysis is a specific diagnostic method yielding few false positive results and hence, being confirmatory to the periodontal chart (Lang & Hill 1977).

To enable meaningful comparative analysis, a reproducible radiographic technique should be used. A long-cone paralleling technique (Updegrave 1951) is recommended (Fig. 22-15).

Radiographic evaluation of implant recipient sites

In order to evaluate vertical bone height at potential implant recipients sites, panoramic radiography may be used as a reliable diagnostic tool to determine the preoperative implant length in premolar and molar mandibular areas (Vazquez *et al*. 2013). Furthermore, to determine accurately the bone volume and morphology at future implant recipient sites, cone beam computed tomography (CBCT) may offer valuable information in selected indications such as implant placement in conjunction with sinus floor elevation (Harris *et al*. 2012).

Diagnosis and classification of periodontitis

Based on the information regarding the condition of the various periodontal structures (i.e. the gingiva, the periodontal ligament, and the alveolar bone)

obtained through the comprehensive examination presented above, a classification of the patient regarding his/her periodontal conditions may be given. Four different tooth-based diagnoses may be used to determine the staging and grading of periodontitis.

Gingivitis

This diagnosis is applied to teeth displaying BoP-positive sites. The sulcus depth usually remains at levels of 1–3 mm irrespective of the level of clinical attachment. "Pseudopockets" may be present in cases of slightly increased probing depth without concomitant attachment and alveolar bone loss and presence/absence of BoP. The diagnosis of gingivitis usually characterizes lesions confined to the gingival margin.

Periodontitis

As proposed by the World Workshop on the Classification of Periodontal and Peri-Implant Diseases of 2017 (Tonetti *et al*. 2018), periodontitis is now classified in 1 out of 4 stages and its progression pattern is determined by grading (i.e. Grade A, Grade B, and Grade C). Extent, severity, and complexity will determine the stage of periodontitis affecting the patient (Table 22-1).

Periodontitis Stage I (former mild to moderate periodontitis)

Gingivitis in combination with attachment loss is termed "periodontitis". If the PPD does not exceed 4 mm and the bone loss yields a predominantly horizontal pattern, the classification corresponds to a stage I. Interdental PAL at the site of greatest loss does not exceed 2 mm.

Periodontitis Stage II

In Stage I and II, no teeth have been lost because of periodontitis. For Stage II, the maximum PPD is 5 mm with mostly horizontal bone loss. Interdental PAL at sites of greatest loss may be 3–4 mm.

Periodontitis Stage III (former advanced periodontitis)

In periodontitis Stage III, up to four teeth have been lost because of periodontitis. Interdental PAL at sites of greatest loss is at least 5 mm. In addition to periodontitis Stage II, complexity factors are noted: PPD is up to 6 mm, vertical bone loss is up to 3 mm, FI Class 2 or 3 may be present. Moderate alveolar ridge defects may be observed.

Periodontitis Stage IV

In periodontitis Stage IV, multiple tooth loss because of periodontitis (i.e. ≥5 teeth) jeopardizing the functionality of the dentition is observed. Interdental PAL at the sites of greatest loss is at least 5 mm. The complexity factors noted in addition to periodontitis Stage III, may be: a need for complex rehabilitation because of masticatory dysfunction, secondary occlusal trauma with at least a TM of Degree 3, severe

Table 22-1 Periodontitis stages I–IV according to Tonetti *et al*. (2018).

Periodontitis stage		Stage I	Stage II	Stage III	Stage IV
Severity	**Interdental CAL at site of greatest loss**	1–2 mm	3–4 mm	≥5 mm	≥5 mm
	Radiographic bone loss	Coronal third (<15%)	Coronal third (15–33%)	Extending to mid-third of root and beyond	Extending to mid-third of root and beyond
	Tooth loss	No tooth loss because of periodontitis		Tooth loss because of periodontitis of ≤4 teeth	Tooth loss because of periodontitis of ≥5 teeth
				In addition to stage II complexity:	In addition to stage III complexity:
Complexity	**Local**	Maximum probing depth ≤4 mm	Maximum probing depth ≤ mm	Probing depth ≥6 mm	Need for complex rehabilitation because of:
		Mostly horizontal bone loss	Mostly horizontal bone loss	Vertical bone loss ≥3 mm	Masticatory dysfunction
					Secondary occlusal trauma (tooth mobility degree ≥2)
				Furcation involvement Class II or III	Severe ridge defect
				Moderate ridge defect	Bite collapse, drifting, flaring
					Less than 20 remaining teeth (10 opposing pairs)
Extent and distribution	**Add to stage as descriptor**	For each stage, describe extent as localized (<30% of teeth involved), generalized, or molar/incisor pattern			

CAL, clinical attachment loss. (Source: Tonetti *et al*. 2018. Reproduced with permission from John Wiley & Sons.)

Table 22-2 Periodontitis grades A to C according to Tonetti *et al*. (2018).

Periodontitis grade			Grade A: slow rate of progression	Grade B: moderate rate of progression	Grade C: rapid rate of progression
Primary criteria	Direct evidence of progression	Longitudinal data (radiographic bone loss or CAL)	Evidence of no loss over 5 years	<2 mm over 5 years	>2 mm over 5 years
	Indirect evidence of progression	% bone loss/age	<0.25	0.25–1.0	>1.0
		Case phenotype	Heavy biofilm deposits with low levels of destruction	Destruction commensurate with biofilm deposits	Destruction exceeds expectation given biofilm deposits; specific clinical patterns suggestive of periods of rapid progression and/or early onset disease (e.g. molar/incisor pattern; lack of expected response to standard bacterial control therapies)
Grade modifiers	Risk factors	Smoking	Non-smoker	Smoker <10 cigarettes/day	Smoker ≥10 cigarettes/day
		Diabetes	Normoglycemic/no diagnosis of diabetes	HbAlc <7.0% in patients with diabetes	HbAlc ≥7.0% in patients with diabetes
Risk of systemic impact of periodontitis[a]	Inflammatory burden	High sensitivity CRP (hsCRP)	<1 mg/L	1–3 mg/L	>3 mg/L
Biomarkers	Indicators of CAL/bone loss	Saliva, gingival crevicular fluid, serum	?	?	?

[a] Refers to increased risk that periodontitis may be an inflammatory co-morbidity for the specific patient. CAL, clinical attachment loss; HbA1c, glycated hemoglobin. (Source: Tonetti *et al*. 2018. Reproduced with permission from John Wiley & Sons.)

alveolar ridge defects, bite collapse, drifting and flaring of teeth, less than 20 remaining teeth (i.e. 10 antagonistic pairs).

Grading of the progression pattern of periodontitis

Grading is used as an indicator of the rate of progression of periodontitis and is subdivided in Grade A, Grade B, and Grade C. The primary criteria are either direct or indirect evidence of progression (Table 22-2).

Grade A

This grade marks a slow rate of progression of periodontitis. There is no evidence of PAL loss over 5 years. The progression of radiographic bone loss or PAL is less than 0.25%, divided by the age of the patient. The patient is generally a non-smoker and normoglycemic. The inflammatory burden is less than 1 mg/L of C-reactive protein (CRP).

Grade B

The default Grade B marks a moderate rate of progression with fewer than 2 mm of PAL loss over 5 years. This corresponds to 0.25–1.0% alveolar bone loss divided by the age of the patient. If the patient is a smoker, he/she generally smokes fewer than 10 cigarettes/day. The HbA_{1c} is less than 7.0% in patients diagnosed with diabetes mellitus. The inflammatory burden corresponds to 1–3 mg/L of CRP.

Grade C

Grade C represents a rapid rate of disease progression with at least 2 mm PAL loss over 5 years. The percentage of bone loss divided by age is greater than 1.0. There is a disproportion between periodontal destruction and biofilms deposits. There are specific clinical patterns of destruction suggestive of periods of rapid progression and/or early onset diseases.

Risk factors may include smoking at least 10 cigarettes/day and HbA_{1c} levels of at least 7.0% in patients with diabetes mellitus. The inflammatory burden is greater than 3.0 mg/L of CRP.

Clinicians should initially assume a default value of Grade B and seek specific evidence to shift towards a Grade A or a Grade C.

Moreover, based on pathophysiology, two additional forms of periodontitis are recognized:

1. Necrotizing periodontitis
2. Periodontitis as a direct manifestation of systemic diseases.

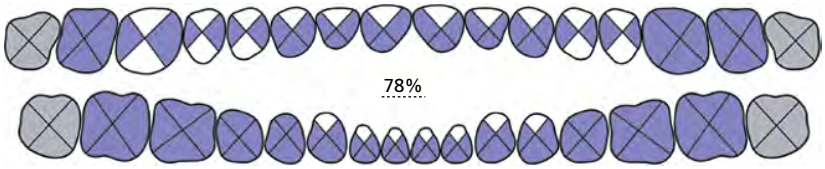

Fig. 22-16 The presence of bacterial biofilms is marked in the appropriate fields in the chart.

Oral hygiene status

In conjunction with examination of the periodontal tissues, the patient's oral hygiene practices must also be evaluated. Absence or presence of bacterial biofilms on each tooth surface in the dentition is recorded in a dichotomous manner (O'Leary *et al*. 1972). The bacterial deposits may be stained with a disclosing solution to facilitate their detection. The presence of biofilms is marked in appropriate fields in the chart shown in Fig. 22-16. The mean biofilm score for the dentition is given as a percentage in correspondence with the system used for BoP (see Fig. 22-6).

Alterations with respect to the presence of biofilm and gingival inflammation are monitored in a simple way by the repeated use of the combined BoP (see Fig. 22-6) and biofilm (Fig. 22-16) charts during the course of treatment. Repeated biofilm recordings alone (Fig. 22-16) are predominantly indicated during the initial phase of periodontal therapy (i.e. infection control) and are used for improving self-performed biofilm control. Repeated BoP charts alone (see Fig. 22-6), on the other hand, are predominantly recommended during supportive periodontal therapy (SPT).

Additional dental examinations

In addition to the assessment of biofilm deposits, retentive factors, such as supra- and subgingival calculus and defective margins of dental restorations, should be identified. Furthermore, the assessment of tooth sensitivity is essential for comprehensive treatment planning. Sensitivity to percussion may indicate acute changes in pulp vitality and lead to emergency treatment prior to systematic periodontal therapy. It is obvious that a complete examination and assessment of the patient will need to include the search for carious lesions both clinically and by means of bitewing radiographs.

A screening for functional disturbances may be performed using a short (i.e. 1–2 minute) test according to Shore (1963). In this test, harmonious function of the jaws with simultaneous palpation of the temporomandibular joints during opening, closing, and excursive movements is verified. Maximal mouth opening is assessed and finally, the lodge of the lateral pterygoid muscles is palpated for muscle tenderness. Further morphologic characteristics of the dentition as well as occlusal and articulating contacts may be identified.

Conclusion

The methods described in this chapter for the examination of patients with periodontal diseases and candidates for implant therapy provide a thorough analysis of the presence, extent, and severity of the disease in the dentition. The periodontal classification of the patient and the correct diagnosis for each individual tooth should form the basis for a pretherapeutic prognosis and the treatment planning of the individual patient (Chapter 25).

Introduction

Diagnostic imaging is an essential component in dental medicine, which supplements findings from clinical examination, facilitates the planning of non-surgical and surgical procedures, and assists in monitoring of treatment outcomes. Dental practitioners should be familiar with advantages and disadvantages of imaging modalities used in dental medicine prior to performing or also referring a patient for imaging procedures. The selection of an appropriate imaging modality should be based on the underlying condition of each patient including considerations of a potential benefit to a patient, which should comprise the risks of biological effects due to added radiation due to the radiographs taken. This chapter describes basic principles of diagnostic imaging in dental medicine with special emphasis on imaging modalities used for periodontal health/disease assessment and implant treatment planning as well as follow-up.

Basic principles of diagnostic imaging in dental medicine

Modalities

The physical principle of image formation varies among different diagnostic imaging modalities. They can be generally classified into two main categories according to whether the imaging modality is associated with ionizing radiation or not. In dental medicine, diagnostic imaging is primarily used for the evaluation of the health and pathology of hard tissues including teeth and jaws. Therefore, X-ray-based (e.g. ionizing) imaging modalities are predominant in clinical practice. These X-ray-based modalities include periapical radiographs, bitewings, occlusal

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

views, panoramic images, cephalometric views, cone beam computed tomography (CBCT) imaging, and multidetector computed tomography (MDCT) for selected cases. Ultrasound imaging and magnetic resonance imaging (MRI) are non-ionizing techniques, and are frequently used for the observation of biological/pathological changes of soft tissues in clinical medicine, but their use is still relatively uncommon in dental medicine. The non-ionizing nature of these modalities and the favorable soft tissue contrast motivate scientists and clinicians to introduce and adapt ultrasound imaging and MRI for evaluations of dentoalveolar pathologies, especially for periodontal/peri-implant diseases. The following sections provide a brief overview of the basic principles of ionizing and non-ionizing imaging modalities as currently used in dental medicine.

Ionizing modalities

Diagnostic imaging modalities used in dental medicine are mostly associated with ionizing radiation that is produced by the respective X-ray machines used. X-rays emitted from these machines are high energy photons of electromagnetic waves. When penetrating the human body, X-rays ionize electrons from atoms or molecules present in the scanned region and cause an exposure on a photographic film or digital receptor to generate an image (Rout & Brown 2012). According to the location of the X-ray film or digital receptor in relation to the patient's mouth, imaging modalities used in dental medicine can be categorized into intraoral and extraoral techniques.

Intraoral techniques

Periapical radiography

Periapical images are taken using a small size (ranging from 22 × 35 mm to 30.5 × 40.5 mm) X-ray film or digital receptor to capture a two-dimensional (2D) image with a restricted field of view (FOV) depicting two or three adjacent teeth and surrounding bone. The film or digital receptor is ideally positioned deep into the lingual vestibule or palatal vault, parallel to the long axis of the teeth or close to the lingual surface of the teeth, and stabilized by a receptor holding instrument. The central X-ray beam is directed through the external localizing ring of the holding instrument. Ideally, the entire length and periapical region of the observed teeth can be captured in one radiograph. Due to high spatial resolution and low radiation dose, periapical radiography is considered to be the first-line diagnostic imaging modality for the detection of early dentoalveolar pathologies, such as dental caries, periapical lesions, and marginal alveolar bone loss (Mupparapu & Nadeau 2016). Moreover, periapical images are commonly used to observe the morphology of roots, pulpal cavity, impacted teeth, determine the length for endodontic instrumentation, bone levels around teeth, or assess implant osseointegration and monitor peri-implant bone loss (Fig. 23-1).

Bitewing radiography

Bitewing images are taken using an X-ray film or digital receptor with a size similar to that of periapical images. The film or receptor is positioned in the lingual vestibule close to the lingual surface of the maxillary and mandibular posterior teeth. The receptor bite plate is gently fixed by the patient's teeth and the central X-ray beam is aimed through the mandibular premolar contacts or external localizing ring of the holding instrument. Bitewing radiography is able to capture 2D images that depict the coronal portions of the maxillary and mandibular posterior teeth on one side including the level and bone density of interdental alveolar crest. For a sufficient image of the crestal bone the normal size of periapical radiographs might be beneficial compared with narrow sized and long formats. As a result, bitewing radiography is mainly used for early diagnosis of caries and periodontal lesions, for example to detect interproximal/secondary caries and periodontitis (Fig. 23-2).

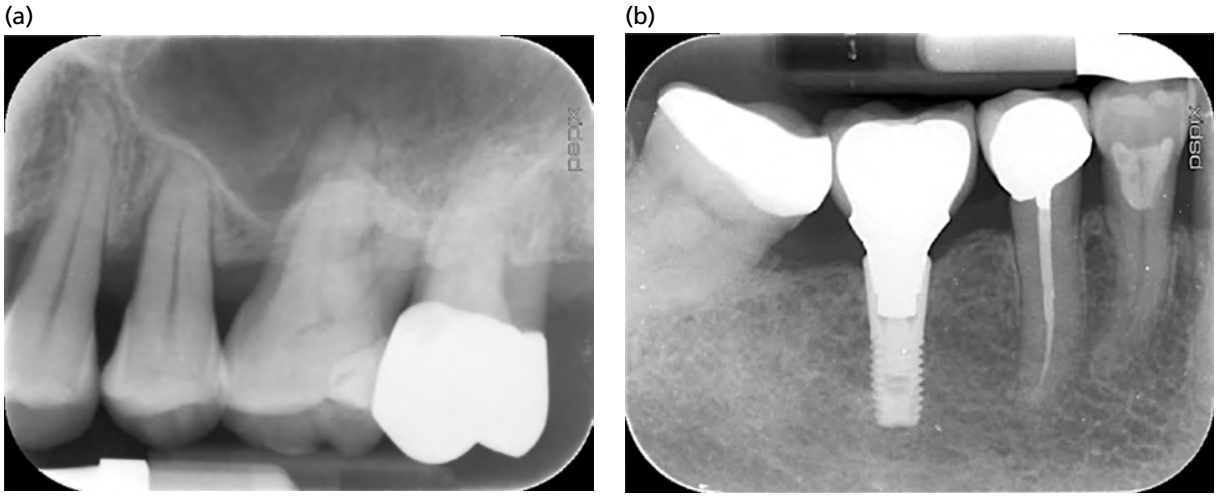

Fig. 23-1 Representative periapical images of the upper and lower jaws. (a) The periapical image of the posterior left maxilla shows mostly horizontal bone loss for the premolars, but also suspected furcation involvement for the molars. (b) The periapical image shows an osseointegrated implant at the site of tooth 46, and an endodontically treated second premolar.

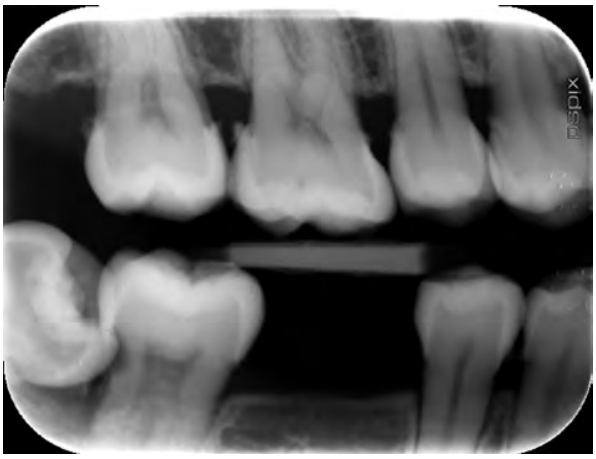

Fig. 23-2 This bitewing radiograph shows an impacted third molar with resorption on the distal surface of tooth 47 (undermining root resorption) and a missing first molar in the posterior right mandible. Furthermore, several calculus deposits on the mesial and distal surfaces of the upper posterior teeth can be observed.

Occlusal radiography

Occlusal images are taken using a large size (58 × 77 mm) X-ray film or digital receptor placed between the upper and lower teeth to capture a 2D image depicting the maxillary/mandibular teeth and arches, and palate/floor of the mouth. Occlusal radiography is less frequently used, but useful to locate supernumerary, unerupted, and impacted teeth, radiolucent/radiopaque lesions (e.g. cysts or sialoliths) in the region of jaws, palate, and floor of the mouth, and assess potential fractures in the anterior maxilla and mandible (Fig. 23-3). Small size X-ray film or digital receptor can be used in children with deciduous teeth to get a comfortable overview of the anterior teeth of the maxilla. Occlusal images can measure the width of the mandible, which was previously considered to be useful for the planning of implant treatment. However, due to the nature of 2D images, they can only display the width of the mandibular base and not of the alveolar process. Therefore, occlusal radiography is seldom recommended for implant patients nowadays with the wide availability of three-dimensional (3D) imaging techniques such as CBCT (Mallya & Lam 2019).

Fig. 23-3 The width of the mandibular base can be estimated on an occlusal image, but the alveolar process cannot be distinguished (vertical dimension).

Extraoral techniques

Extraoral techniques differ from intraoral techniques in that the films and receptors used are positioned outside the mouth/body of the patients. Extraoral techniques are able to capture images with a large FOV, depicting entire jaws or parts of the skull, which is useful to assess the general dental status of patients, and for the overall treatment planning process as well as imaging adjacent vital/endangered anatomical structures.

Panoramic radiography

Panoramic radiography is one of the most common extraoral imaging techniques used in dental medicine. Panoramic images are taken by using a rotation of the X-ray source and image receptor around the patient's head, which generates a curved image layer depicting the teeth, maxilla, mandible, and temporomandibular joints (TMJs). It can provide an overall view of the dentoalveolar structures in 2D for diagnostic and treatment purposes on one single image. The panoramic view is widely used as a routine and initial radiographic examination to evaluate the deciduous or permanent dentition, the position of impacted teeth and especially mandibular third molars in relation to the mandibular canal, bone levels, intraosseous lesions (such as cysts and tumors), and TMJs (Fig. 23-4). For patients where intraoral X-rays are not possible due to discomfort or difficulty in mouth opening, panoramic radiography is an alternative to acquire a useful diagnostic image. The limitations of panoramic views include low spatial resolution, image magnification and distortion, and the superimposition of the structures, such as cervical spine, soft tissues, and air spaces (Fig. 23-5). These ultimately limit the diagnostic accuracy of panoramic radiography. New techniques of panoramic radiography provide different "sharp layers" and are able to generate images with beneficial views with reduced superimposition concerning special indications.

Cephalometric radiography

Cephalometric radiography is mainly used in the field of orthodontics and orthognathic surgery. This technique is able to capture an image with a large FOV depicting the craniofacial region of patients. It can be taken by using a lateral or posteroanterior cephalometric projection to identify dental, skeletal, and soft tissue anatomic landmarks for the planning of orthodontic treatment and orthognathic surgery (Fig. 23-6). Cephalometric radiography is relatively seldom used in the field of periodontology and oral implantology.

Fig. 23-4 This panoramic view shows an overview of the dental and maxillofacial structures including the remaining teeth in the upper and lower jaws, the bone condition at the edentulous sites, the maxillary sinuses including lower aspects of the orbit and the temporomandibular joints.

Fig. 23-5 This panoramic view exhibits image distortion and superimposition artifacts of the cervical spine and air spaces that limit the diagnostic validity to evaluate the condition of the implants in the anterior maxilla and mandible.

Fig. 23-6 (a) Lateral and (b) posteroanterior cephalometric projections can show jaw dimensions, the relative position of the maxilla and mandible towards each other, and the facial profile. For completely edentulous patients, such information has been proposed to be helpful for treatment planning purposes of, for example, a full-arch implant rehabilitation.

Multidetector computed tomography

MDCT is one of the most common 3D imaging techniques used in medicine. MDCT units use fan-beam X-rays to capture multiple axial slices by continuously scanning from the top to bottom of the region of interest during image acquisition. The series of axial slices captured can be reconstructed into 3D images, which allows for the visualization and assessment of anatomic structures at different planes (Fig. 23-7). However, mainly due to the higher radiation dose, costs, and impaired availability and access in private practice, MDCT imaging is not a commonly used 3D imaging modality in dental medicine. Nevertheless, compared with CBCT, MDCT imaging has relatively superior soft tissue contrast resolution that can show density differences between certain types of soft tissues, which may be helpful for the evaluation of different soft tissue masses in the dental and maxillofacial region (Mallya & Lam 2019).

Cone beam computed tomography

Since the initial description of CBCT in 1998 in the field of dentistry, it has become an established 3D imaging technique, and continues to gain popularity in dental medicine (De Vos *et al*. 2009; MacDonald 2017). Because CBCT imaging uses a cone beam instead of a fan beam to capture images in one single rotation around the patient's head, the radiation dose of one CBCT scan is usually lower than an MDCT scan (Pauwels *et al*. 2015). The high spatial resolution of CBCT images is beneficial to visualize anatomical structures accurately and identify pathological changes in the dental and maxillofacial region (Fig. 23-8). Although the spatial resolution of CBCT images is still inferior to 2D images, it is reported that the spatial resolution of CBCT is twice to eight times higher than that of MDCT (Mallya & Lam 2019). Thus, the CBCT imaging modality is more frequently used in dental medicine compared with MDCT. However, the radiation dose of one CBCT scan is still considerably higher than that of conventional 2D imaging modalities. CBCT examination is only recommended for patients when clinical examination and conventional 2D images do not contribute sufficient diagnostic information (ICRP 2007; Carter *et al*. 2008; Horner *et al*. 2012). The clinical applications for CBCT include all fields in dental medicine but are mainly for the evaluation of the hard tissue including teeth and jaws. However, CBCT imaging has its limitations with respect to metallic artifacts and low contrast resolution (Koong 2015) as well as with movement artifacts (Spin-Neto *et al*. 2018). Low contrast resolution limits the visibility of soft tissue and lower density osseous structures on CBCT images. On the other hand, metal artifacts from dental restorations may influence the visibility of adjacent anatomic structures (Fig. 23-9).

Non-ionizing modalities

Imaging techniques used in dental medicine are mostly based on X-rays resulting in ionizing radiation exposure to patients. Although the biological effects of ionizing radiation stemming from dental X-ray devices have been considered almost negligible, repeated radiation exposures may be related to an increased risk of developing salivary gland tumors (Preston-Martin & White 1990), thyroid cancer (Memon *et al*. 2010), and meningioma (Longstreth *et al*. 2004). Therefore, there is increasing interest in the application of imaging modalities that do not employ ionizing radiation in order to prevent unnecessary radiation exposure to patients and to provide alternative imaging modalities for diagnostic purposes in the dentomaxillofacial region (Boeddinghaus & Whyte 2018).

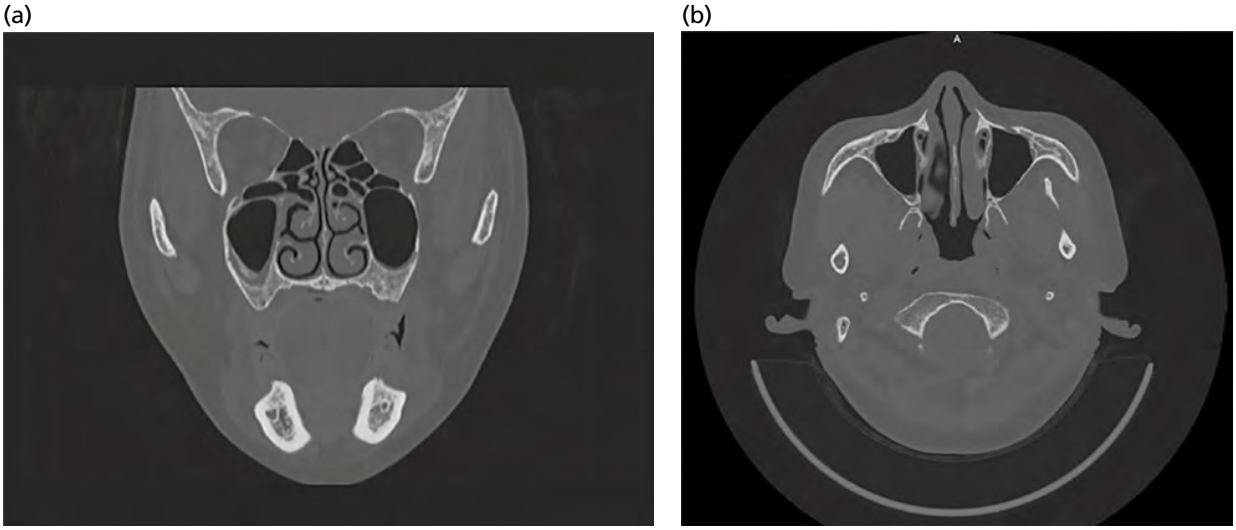

Fig. 23-7 The superior soft tissue contrast resolution of MDCT scans enables the visualization and differentiation of facial muscles with the surrounding soft tissues. (a) Coronal slice. (b) Axial slice.

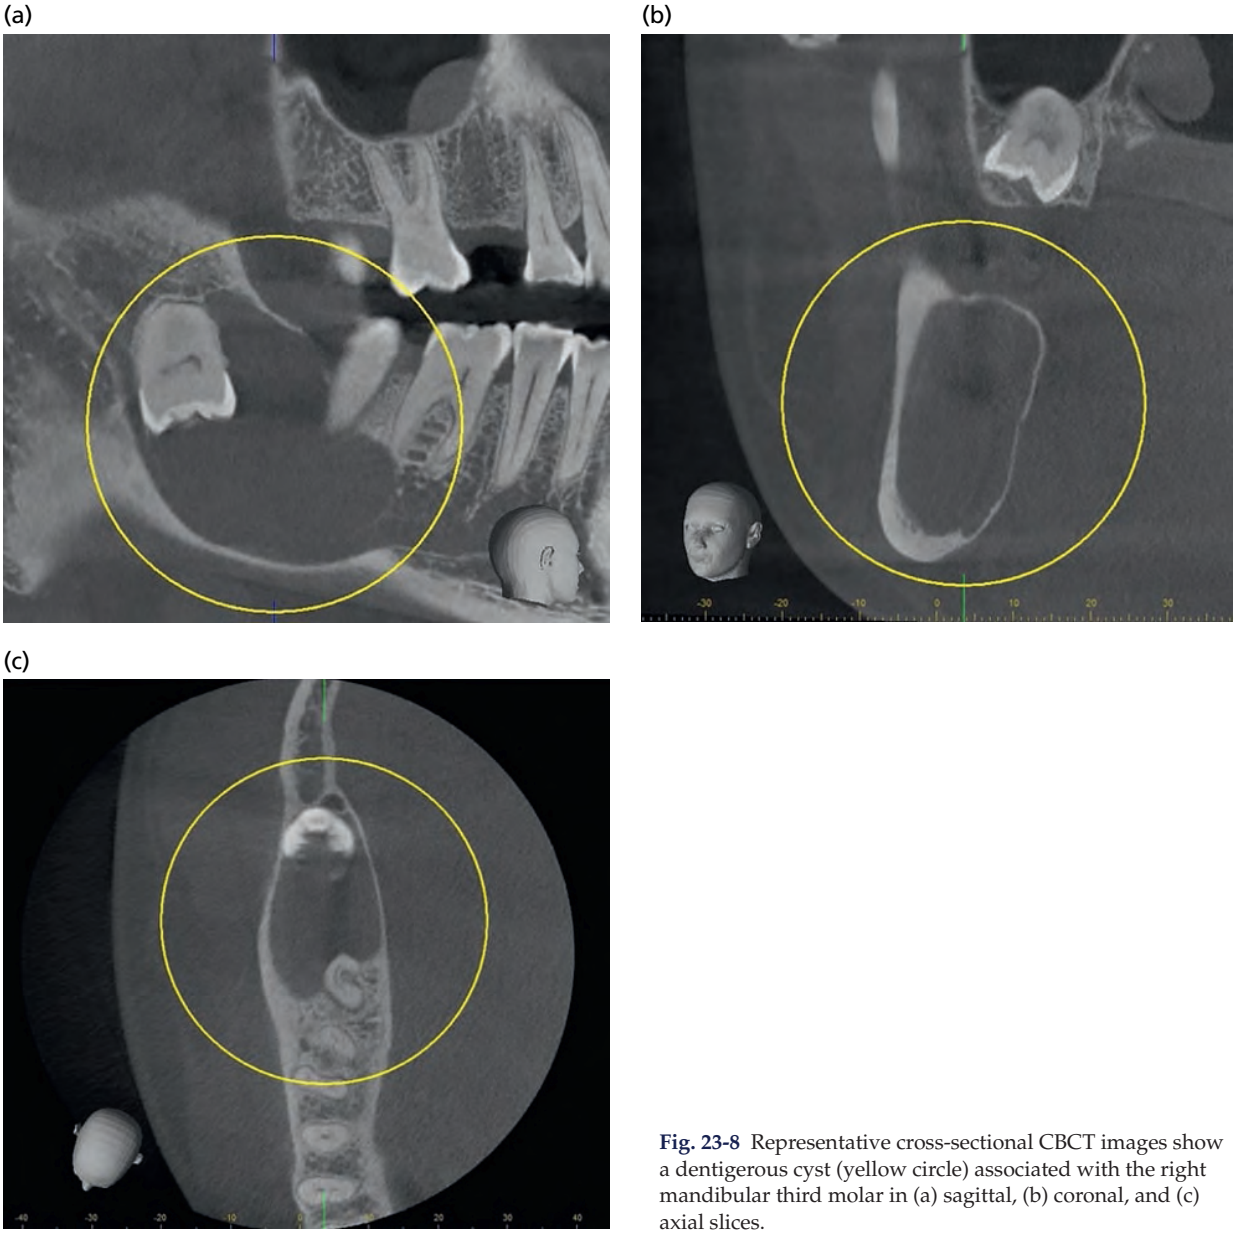

Fig. 23-8 Representative cross-sectional CBCT images show a dentigerous cyst (yellow circle) associated with the right mandibular third molar in (a) sagittal, (b) coronal, and (c) axial slices.

Ultrasound

Ultrasound imaging is a non-ionizing diagnostic modality that is based on the application of ultrasound and is frequently used in clinical medicine. A transducer emits sound waves of vibratory frequencies in the range of 1–20 MHz that pass through or interact with tissues of different acoustic impedance. Subsequently, the reflected sound waves are detected by the transducer, and eventually display a real-time cross-sectional 2D image (Shriki 2014). Although ultrasound imaging has been widely used for diagnosis of disease and image-guided surgery in clinical medicine, because of the size of the ultrasound transducer its application in dental medicine has been mostly limited to examining major salivary glands, superficial mass lesions, cervical lymph nodes, masticatory and neck muscles, maxillofacial fractures, and the TMJ (Mupparapu & Nadeau 2016). With the introduction of smaller intraoral transducers, ultrasound imaging may be a promising imaging modality to visualize the gingiva and the surface contour of the alveolar bone (Fig. 23-10) (Caglayan & Bayrakdar 2018). In addition, ultrasound images are not affected by metal artifacts, which may be very helpful for the evaluation of peri-implant bone resorption.

Magnetic resonance imaging

MRI is a revolutionary imaging technique that has been used in medicine since the 1980s; it does not employ ionizing radiation. This technique directs a radiofrequency pulse into the patient, who is placed in static magnetic fields generated by the MRI unit. This results in the hydrogen nuclei of the atoms in

the body of the patient to absorb resonance energy. As the radiofrequency pulse is turned off, the energy stored in the hydrogen nuclei is released. The scanner of the MRI unit detects the released energy and converts the energy to an electrical signal that is used for image reconstruction (Mallya & Lam 2019). In the dental and maxillofacial region, MRI can be used to evaluate the morphology and function of the TMJ, specifically for the diagnosis of disk pathologies including displacement or joint effusion (Koong 2015; Mupparapu & Nadeau 2016). Other potential applications of MRI include the evaluation of the floor of the mouth, salivary glands, tongue, and paranasal sinuses (Fig. 23-11). Although MRI has no known biological effects and is particularly useful in the evaluation of soft tissue, it is rarely used in general dental practice. This is because MRI units are relatively expensive and not widely accessible to dental practitioners. Patients with cardiac pacemakers, insulin pumps, and claustrophobia are not eligible for an MRI examination. Furthermore, MRI-generated images are severely affected by metal artifacts (Fig. 23-12), which limits its application for the evaluation of dentoalveolar pathology (Gunzinger *et al*. 2014). Imaging with MRI in dentistry using special coils has been attempted to acquire high-resolution images for various dental indications in a more reasonable acquisition time (Flugge *et al*. 2016).

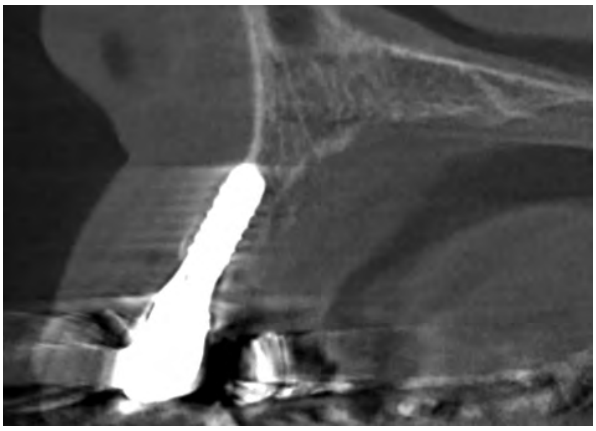

Fig. 23-9 Metal artifacts from a titanium dental implant and corresponding restoration may influence the visibility of buccal and oral bone on CBCT scans. Thus, the diagnostic validity for assessment of peri-implant bone conditions in CBCTs might be limited.

Radiation hazards and radiation dose protection

Diagnostic imaging modalities used in dental medicine are mainly based on X-rays. Ionizing radiation from X-rays may induce biological damage at a cellular level. Damage to the chromosome structures is of particular importance as there is a chance that irreparable chromosome damage may cause radiation-induced cell death, heritable mutations, and carcinogenesis (Omar *et al*. 2015). Thus, dental practitioners should have a clear understanding of the principle of radiation hazards and radiation dose protection measures.

Biological risks of radiation

The biological risks of radiation include deterministic and stochastic effects (Firetto *et al*. 2019). Deterministic effects are adverse effects that occur only when patients are exposed to ionizing radiation with a dose exceeding specific threshold values. Below this threshold dose, deterministic effects will not occur. However, if the threshold is exceeded, the severity of the deterministic effects increases with an increase of radiation dose. Relevant deterministic effects (the corresponding threshold values

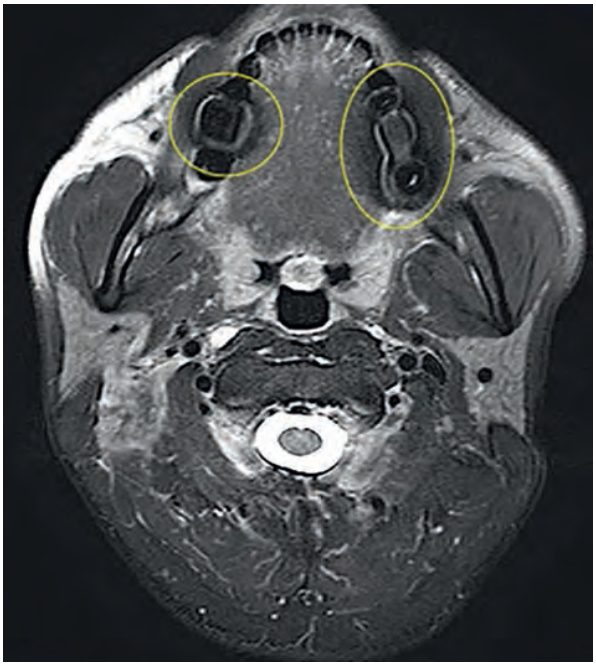

Fig. 23-12 Axial magnetic resonance image shows multiple hyperintense rings in the signal void (yellow circles) due to metallic artifacts around dental restorations, which influence the visibility of the adjacent anatomical structures.

in grays) include fetal abnormality (0.1–0.5 Gy), sterility (2–3 Gy), skin erythema (2–5 Gy), hair loss (2–5 Gy), and irreversible skin damage (20–40 Gy) (Dendy & Heaton 1999). Theoretically, the threshold values are significantly higher than the diagnostic radiation doses used in medical and dental examination.

On the other hand, when X-ray ionized electrons hit the chromosome structure, it may result in sublethal DNA damage. Damaged DNA may subsequently cause DNA mutation, and then develop to specific cancers, such as leukemia, thyroid cancer, salivary gland tumors, breast cancer, and brain or nervous system neoplasias. Occurrences of radiation-induced cancers are considered as stochastic effects. They can often occur years after radiation exposure. Compared with deterministic effects, the occurrence of stochastic effects is not linked to a specific dose threshold as a DNA mutation may be caused by a single X-ray exposure with the smallest radiation dose. Besides, it is generally accepted that there is a positive correlation between the risk of stochastic effects and radiation dose (Ludlow *et al*. 2008; Mallya & Lam 2019). The higher the radiation dose, the higher the risk of stochastic effects. As a result, stochastic effects are more related to radiation exposure in diagnostic imaging.

Principles of radiation dose protection

In the general population, radiation exposure is primarily attributed to natural background radiation and artificial radiation sources including medical exposure and consumer products. Medical exposure is reported as the largest artificial radiation source and represents approximately 14% of the total annual dose of ionizing radiation for individuals (Bornstein *et al*. 2019). MDCT has been reported to comprise 47% of the total annual medical imaging exposure in the USA (ICRP 2007). In dental medicine, CBCT imaging is more frequently used than MDCT. The radiation dose from CBCT imaging is reported to be up to 15 times less than MDCT, although it is still higher than that of conventional 2D dental radiographic imaging procedures (ICRP 2007; Ludlow & Ivanovic 2008; Loubele 2009). Epidemiological studies suggest that radiation exposure from dental procedures (2D or 3D) may be related to an increased risk of developing salivary gland tumors (Preston-Martin & White 1990), thyroid cancer (Memon *et al*. 2010), and

meningioma (Longstreth *et al*. 2004). Therefore, radiation risk should be minimized by adopting radiation dose protection principles including justification of patient exposures, optimization of patient dose, and dose limitation during radiological procedures.

Justification

The most effective way to protect patients from unnecessary ionizing radiation is to avoid unnecessary exposures. The principle of justification is that an imaging examination should be performed only when the benefit to a patient exceeds the risk of radiation exposure (Federal Guidance Report No. 9 1976; ICRP 2007). This means that clinicians should firstly obtain a patient's medical history and the results of the clinical examination prior to referring a patient for imaging. An imaging examination should be considered only when clinical examination cannot provide sufficient diagnostic information. Also of importance is an effective communication of any specific request for the imaging examination between the clinician and the operator who takes responsibility for the imaging examination to avoid any re-exposure. Generally, the determination of the type of diagnostic imaging modality should be considered based on the reason for referral, location, size, and characteristics of the anatomic structure/pathological changes, and the radiation dose to the patient. For periodontal evaluation, conventional intraoral radiography is the first choice to assess marginal bone loss of the teeth in question. Due to higher radiation doses, CBCT imaging should only be suggested in selected cases, such as furcation lesions. Although panoramic radiography allows dental practitioners to have an overview of the condition of remaining teeth and their supporting bone, a relatively low spatial resolution and potential image superimposition limit its application for diagnostic purposes in periodontology. For implant treatment planning purposes, CBCT has seen increased use and popularity as an adjuvant and even a primary imaging modality (Horner *et al*. 2012; Al-Ekrish 2018). The 3D information of CBCT compensates for the low spatial resolution of this technique. Intraoral or panoramic views are considered to be more appropriate imaging modalities for the assessment and monitoring of osseointegration following implant insertion and during follow-up.

Optimization

Once referral for an imaging examination has been justified, the next step is to ensure the examination is effectively performed in accordance with the principle of optimization that is also known as the As Low As Reasonably Achievable (ALARA) or As Low As Diagnostically Acceptable (ALADA) concept (ICRP 2007; Jaju & Jaju 2015). ALARA was established in 1977 to designate the optimization of X-ray doses in order to minimize radiation dose exposure. Almost a decade ago, the ALADA concept has been introduced with an emphasis on using as low a dose as possible to obtain diagnostically acceptable images instead of just "beautiful" images (Schulze 2012; Jaju & Jaju 2015). The implementation of the ALADA concept in dental practice includes determining a suitable diagnostic imaging modality to suit the patient's specific needs, using radiation detectors with maximum sensitivity, selecting appropriate exposure parameters, using shielding devices, and selecting a radiographic projection in which radiosensitive organs receive the minimum dose. As the radiation dose of MDCT/CBCT imaging is higher than conventional 2D imaging, much attention is now being paid to reducing radiation exposure from MDCT/CBCT. Reducing the FOV size can reduce the exposed area of the patient's body, which is the most straightforward measure to reduce radiation dose (Davies *et al*. 2012). In addition, reducing the FOV size improves image quality by reducing image noise and artifacts. Therefore, the FOV size should be selected carefully ideally to cover only the region of interest. For example, patients who need implant treatment for one missing tooth in a site with sufficient bone volume should not be referred for a CBCT scan with full coverage of the craniofacial region. In addition, novel low-dose scanning protocols are also considered as an option to reduce radiation exposure without an unacceptable loss of image quality for diagnostic and treatment purposes (Yeung *et al*. 2019a). This concept has already found recognition in various dental disciplines, specifically in pediatric dentistry (such as evaluation of orofacial clefts and impacted teeth), orthodontics (such as cephalometric analysis), endodontics (such as detection of periapical bone loss), oral implantology (such as implant planning), and oral and maxillofacial surgery (such as assessment of mandibular third molars and TMJs). Low-dose scanning protocols are available in some CBCT units, which provide pre-set dose reduction settings to reduce radiation exposure. Alternatively, manually adjusting imaging parameters including reducing the tube current (mA), exposure time(s), resolution (i.e. increasing voxel size), the number of projections, and/or adopting a partial rotation mode (e.g. 180° instead of 360° rotation) can also be applied for dose reduction.

Dose limitation

Radiation dose limitation is a constant safety issue in radiology, especially for occupationally exposed individuals. Unlike patients who can get direct benefit from medical exposures for diagnostic and treatment purposes, clinical staff who take responsibility for operating radiographic imaging equipment are at high risk of excessive exposure to ionizing radiation. In order to protect any member of clinical staff or individuals staying in dental settings from unnecessary occupational and public exposure, the principle of dose limitation should be strictly followed. According to the statement of the International Commission on Radiological Protection, the annual

dose for occupationally exposed individuals should not exceed 20 mSv of whole-body radiation exposure (ICRP 2007). Personnel protection including reduction of the chance of potential exposure from the primary X-ray beam and scattered radiation, and monitoring of the accumulated exposure level among occupationally exposed staff should be strictly implemented. Dental clinics equipped with an X-ray-based imaging device should meet the radiation shielding requirements based on local national regulations. The dose limitation of medical exposure is not applicable to patients who are referred for the imaging examination as these exposures are intentionally performed for diagnostic and treatment purposes. However, the use of shielding devices, such as protective lead aprons and thyroid collars, can effectively protect the thyroid gland and the trunk of the patient's body from primary and scattered radiation.

In addition, multiple institutions including the NCRP (National Council on Radiation Protection and Measurements) and EURATOM (European Atomic Energy Community) have recommended the use of so-called dose reference levels (DRLs) to standardize dose values for medical and dental diagnostic imaging. DRLs are acceptable upper limits of dose exposure values that should not be exceeded for standard diagnostic imaging procedures on patients as defined by the use of standard dimensions/phantoms (Schafer *et al*. 2014). Generally, a DRL is set based on the third quartile (75% percentile) of field measurements performed in a large number of establishments. For example, the NCRP recommends a national DRL of 1.6 mGy entrance skin dose for periapical and bitewing radiography (Mallya & Lam 2019). The use of DRLs provides a good framework regarding dose exposures for specific indications for the operator who takes responsibility for the imaging examination, and will very likely be a field with more focus in the future due to the growing availability of CBCT in dental medicine. Based on a national survey from Switzerland initiated by the Federal Office of Public Health (FOPH/ BAG), five DRLs for CBCT use for the most common indications for dental and ENT practice have been proposed (Deleu *et al*. 2020).

Diagnostic imaging in periodontology

Diagnosis of periodontal diseases should be based on data gathered from both clinical and imaging examinations. Patients with clinical symptoms and/or signs of periodontal diseases should be referred for an imaging examination to evaluate the supporting bony structures of the affected teeth. Diagnostic imaging is mainly used to identify the presence of bone destruction and also to assess bone defect morphology. Pathological changes confined to the soft tissue alone including dental plaque-induced gingivitis and non-plaque-induced gingival lesions or acute inflammatory lesions, such as acute periodontal abscess, are usually not seen on X-ray-based diagnostic images due to the absence of bone destruction. This section describes general recommendations on various diagnostic imaging modalities used for the evaluation of periodontal defects.

General recommendations

Two-dimensional modalities

Intraoral 2D images are currently deemed as the standard imaging modality to complement clinical findings for periodontal evaluation (Tonetti & Sanz 2019). Bitewing and periapical radiography are the two main 2D imaging modalities used for evaluation of the condition of the supporting bone. Bitewing radiography is usually more accurate in the evaluation of periodontal bone loss because the X-ray projection is more perpendicular to the long axis of the teeth. This leads to less distortion and superimposition of the image. However, bitewing radiography can only depict the most coronal portion of the alveolar bone due to its limited FOV (Fig. 23-13). The application of normal sized periapical radiographs as bitewing formats should be preferred instead of long and narrow sized radiographs. The advantage of this format is the visualization of slightly more bone and a more perpendicular projection for the whole format. Nevertheless, this limits the use of bitewing radiography in patients with moderate to severe periodontal bone defects exceeding the middle third of the root involved. In contrast, periapical radiography has the advantage of depicting the full length of the tooth, which is more suitable for the evaluation of the extent of periodontal bone destruction. A full-mouth intraoral X-ray examination is recommended for patients with clinical symptoms and/or signs of general periodontitis or periodontitis-susceptible patients (Fig. 23-14) (Tonetti & Sanz 2019). Panoramic radiography can also offer an overview of teeth and

Fig. 23-13 This bitewing radiograph exhibits a radiolucency in the region of the furcation of tooth 47. Unfortunately, this finding is not be entirely visible due to the limited field of view of the radiograph.

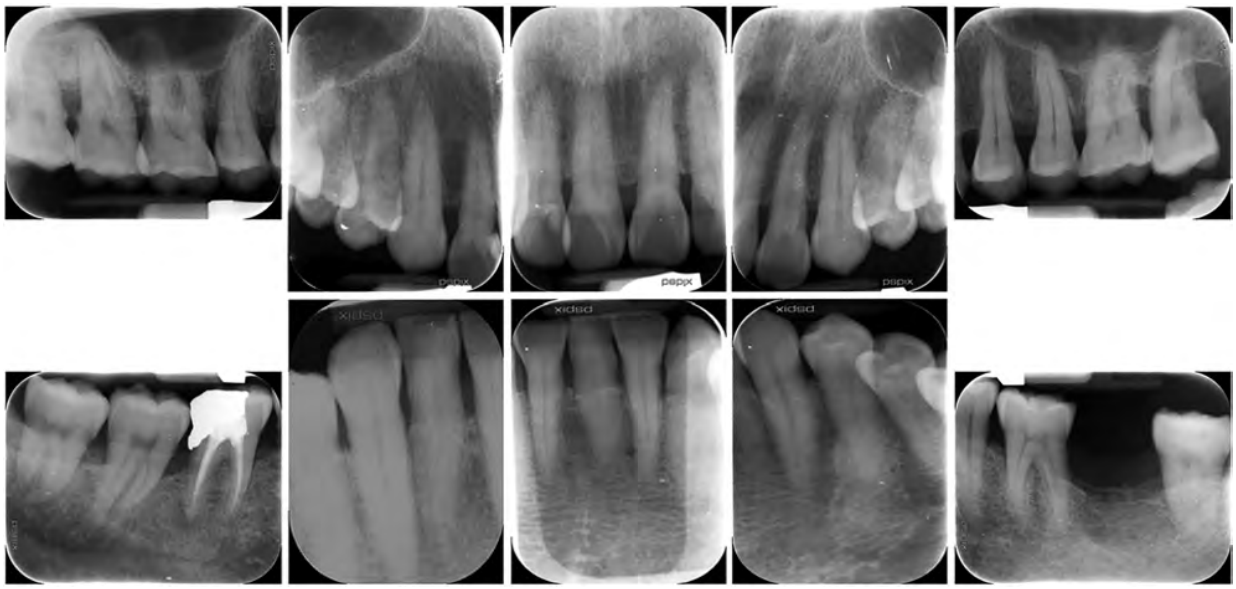

Fig. 23-14 An example of a full-mouth intraoral X-ray examination for periodontal diagnostics that consists of 10 periapical images, in this case demonstrating all teeth and their supporting bony structures. Overlap of teeth and difficulty in correctly placing the film or sensor might limit the visibility of interradicular bone in some areas. As an incidental finding, an apical lesion is visible here on the distal root of the first right mandibular molar (tooth 46).

the supporting bone in one single image. The lower spatial resolution, the vertical magnification of teeth, and superimposition of the image may lead to an incorrect estimation of the periodontal bone destruction. New technology for panoramic radiographs is available and offers different "sharp layers" so that the best possible image can be chosen or is automatically focused. For the ALARA principle, existing panoramic radiographs should be used. Therefore, the application of additional periapical radiographs depends on the clinical examination and the visualization of all regions on the panoramic radiograph.

Plaque-induced inflammatory periodontal bone loss originates at the alveolar crest. In the initial phase, a reduced density of the cortical bone of the interradicular alveolar crest and an erosion of the crest with a diffuse border may be observed in 2D images. As periodontitis progresses, the loss of supporting bone with/without a widened periodontal ligament space may occur and aggravate. The presence of bone loss is identified based on the level of the interradicular alveolar crest in relation to the cementoenamel junction (CEJ). In healthy subjects, the level of the interradicular alveolar crest should be located at 0.5–2.0 mm apically to the CEJ level of adjacent teeth, whereas the distance between the two levels in patients with periodontitis at the involved site is greater than 2.0 mm. Radiologically, the development of periodontitis can be classified, based on the degree of bone loss, into four stages (Mallya & Lam 2019) (Fig. 23-15):

- *Stage I:* The bone loss is less than 15% of the tooth root length
- *Stage II:* The bone loss is between 15% and 33% of the tooth root length
- *Stage III:* The bone loss extends to the middle-third of the tooth root
- *Stage IV:* The bone loss extends beyond the middle-third of the tooth root.

Bone defects can be categorized as horizontal or vertical bone loss. Horizontal bone loss usually involves multiple adjacent teeth, presenting the level of the interradicular alveolar crest parallel with an imaginary line passing through the CEJ levels of the involved teeth (Fig. 23-16). Vertical bone loss is often centered on one tooth more than the adjacent tooth, presenting an uneven and oblique bone destruction morphology. In some cases, an increased distance between the CEJ level and the interradicular alveolar crest may not be attributed to periodontal bone loss. For example, this distance on supraerupted or passively erupted teeth is greater than on healthy teeth, which results from the coronal movement of the teeth and not from the loss of supporting bone.

Two-dimensional imaging examination may be able to identify an intrabony defect. According to the condition of the buccal and oral cortical plates around an intrabony defect, these bone defects can be classified into three-walled, two-walled, and one-walled. A three-walled defect is defined as an intrabony defect enclosed by the buccal and oral cortical plates and interradicular alveolar bone. A two-walled bony defect is defined as an intrabony defect surrounded by either buccal or oral cortical plate and interradicular alveolar bone, and a one-walled bony defect is characterized by the absence of both buccal and oral cortical plates. For three-walled and two-walled bony defects, a reduced density of the alveolar bone with/without a slightly reduced level of the alveolar crest may be observed at the root

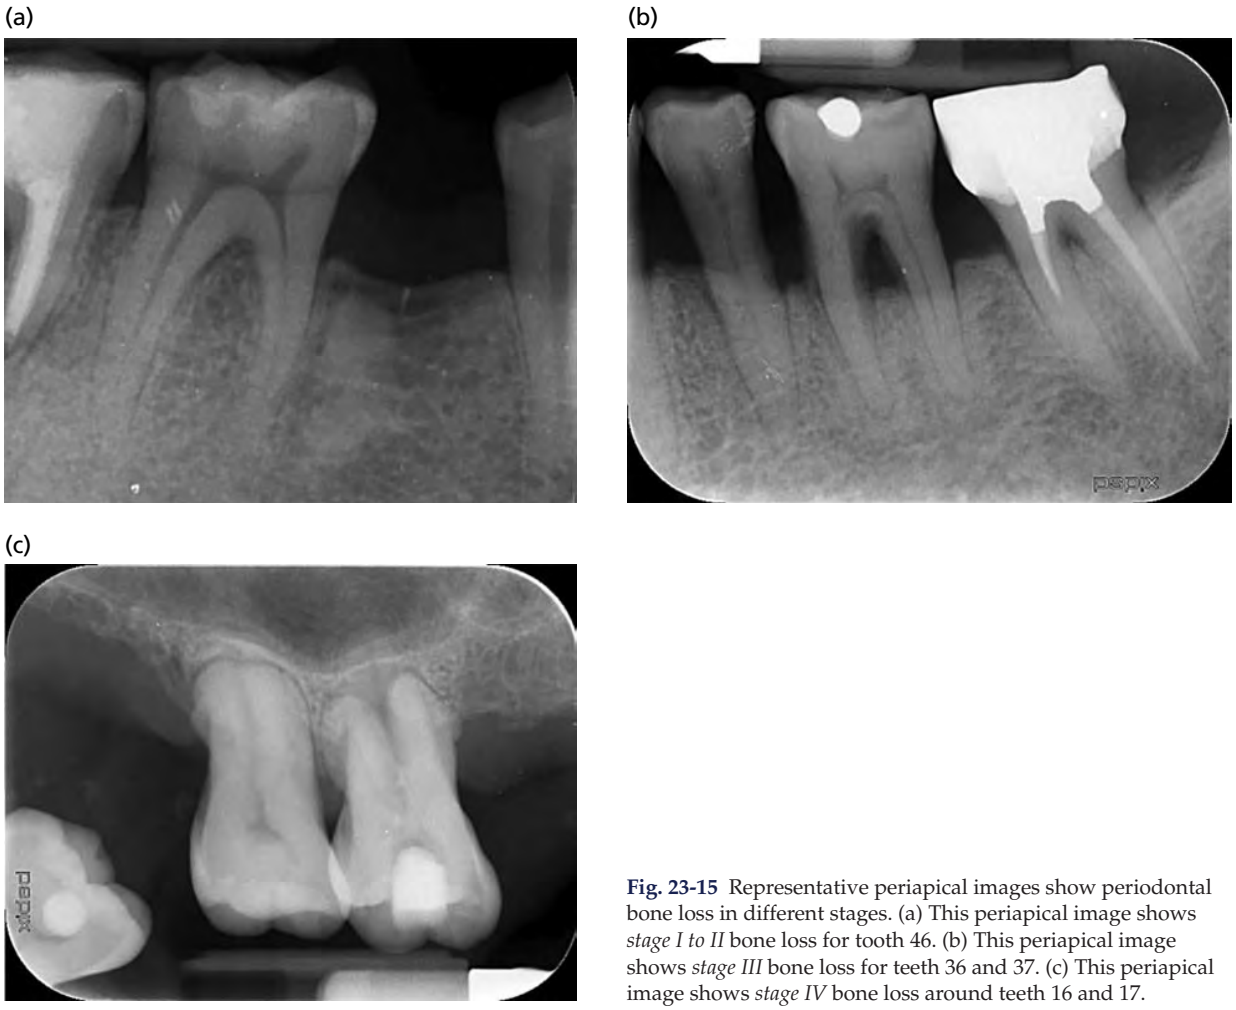

Fig. 23-15 Representative periapical images show periodontal bone loss in different stages. (a) This periapical image shows *stage I to II* bone loss for tooth 46. (b) This periapical image shows *stage III* bone loss for teeth 36 and 37. (c) This periapical image shows *stage IV* bone loss around teeth 16 and 17.

Fig. 23-16 The periapical image shows a reduced interradicular alveolar crest level affecting multiple adjacent teeth in the left posterior maxilla including the canine, premolars, and also first molar (e.g. horizontal bone loss).

surface on 2D images (Fig. 23-17). The exact contour of the bone destruction may not be clearly exhibited on 2D images as the intrabony defect is superimposed by either the buccal or oral cortical plate. Therefore, 3D diagnostic imaging is considered as a more appropriate option for the evaluation of three- and two-walled intrabony defects. However, due to the loss of both buccal and oral cortical plates, a one-walled intrabony defect can be clearly observed on 2D images (Fig. 23-17). Alternatively, a three- or two-walled bony defect may be identified on 2D images through inserting a gutta-percha tip into the periodontal pocket prior to X-ray exposure. The image of the inserted gutta-percha can point out the bottom level of the bone destruction. The interdental crater is a specific two-walled bony defect between adjacent teeth. The morphology of the interdental crater is a trough-like depression enclosed by the buccal and oral cortex and the root surface of the adjacent teeth. The imaging feature of an interdental crater on 2D images may present as a reduced density of the alveolar bone apically to the alveolar crest in connection with an increased density of alveolar bone apically to the bottom of the crater. This may not be clearly exhibited on 2D images as the defect is superimposed by the buccal and oral cortex, and thus a 3D imaging examination

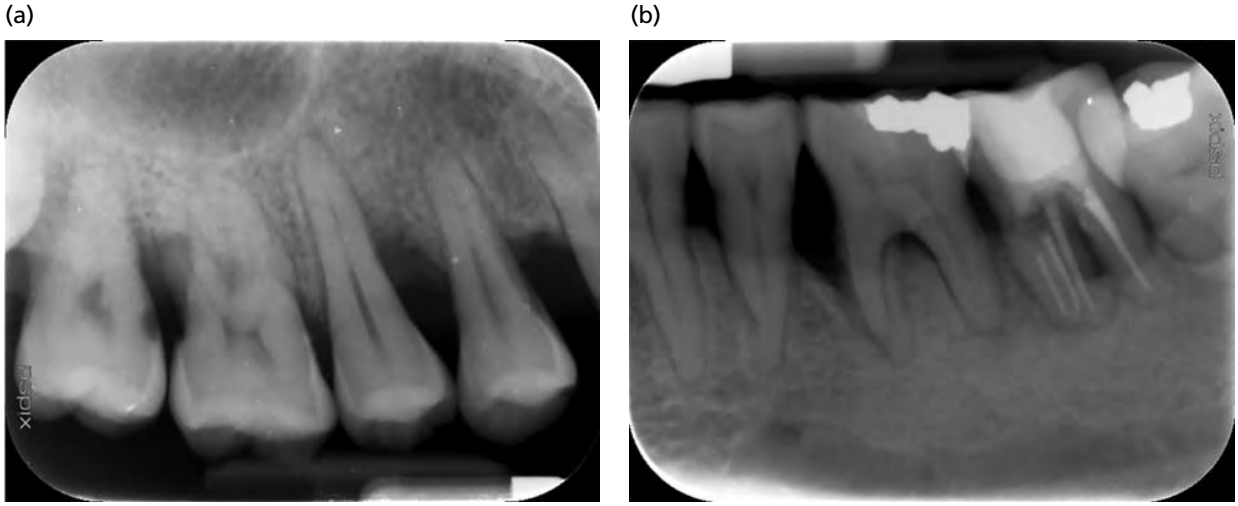

Fig. 23-17 Representative examples of bony defects around teeth as depicted in intraoral radiographs. (a) This periapical image exhibits a two-walled defect enclosed by the mesial surface of tooth 15, interradicular alveolar bone, and oral cortical plate. (b) This periapical image exhibits a one-walled defect enclosed by the mesial surface of tooth 36 and interradicular alveolar bone.

can be needed for the diagnosis of interdental craters (Vandenberghe *et al*. 2008).

Furcation defects are a relatively complex form of periodontal disease occurring in multirooted teeth. Due to the anatomic characteristics of multirooted teeth, the furcation region easily accumulates periodontal pathogenic bacteria, but on the other hand it is difficult to gain access for treatment. This leads to furcation defects being considered as the most common reason for the loss of molars (Nibali *et al*. 2016). Therefore, early diagnosis of furcation defects is crucial for the treatment outcome and in consequence also for the survival of the treated teeth. When periodontal pathogenic bacteria invade the furcation of multirooted teeth, a slight widening of the periodontal ligament space in the furcation region may be observed on 2D images. As the progression of periodontitis destroys more supporting bone, an increase of the radiolucent area in the furcation region may be detected (Fig. 23-18). In maxillary molars, the widening of the periodontal ligament space and the bone destruction in the furcation area may be superimposed by the palatal root. In this case, periapical radiography using an angulated technique is recommended to reveal such "hidden" furcation defects. Besides, the occurrence of an inverted "J" shaped radiolucency is a typical imaging feature for furcation defects between adjacent maxillary multirooted teeth. The hook of the "J" shaped radiolucency is caused by the bone destruction extending into the furcation region of a maxillary multirooted tooth (Fig. 23-19). On 2D images, however, relatively well-defined furcation defects are usually only seen when the buccal and oral cortical plates are destroyed. If one of these cortical plates is preserved, the furcation defect may only present as an area with decreased bone density. Therefore, CBCT is considered as a more accurate imaging examination to assess the extent and morphology of furcation defects (Walter *et al*. 2016).

For endo-perio lesions, 2D images can exhibit radiolucent defects extending from the alveolar crest to the apex of a tooth root, which reflects contiguity of periodontal and periapical inflammatory lesions (Fig. 23-20). Although it is considered that the larger radiolucent area is more likely to be the origin of perio-endo lesions, it cannot be evaluated by the imaging examination alone. Thus, the evaluation of the origin of perio-endo defects should be based on the morphology of the defect as well as clinical findings (Shenoy & Shenoy 2010).

In brief, due to the high spatial resolution and low radiation dose, intraoral 2D imaging examination is the first choice for the assessment of periodontal diseases. Besides, the 2D images are commonly used as a baseline record of the periodontal condition including the level of the alveolar crest, width of the periodontal ligament space, and density of the alveolar bone for comparison with follow-up images. However, 2D imaging modalities have several limitations. The bone deconstruction located at the buccal and oral side of the involved teeth cannot be clearly exhibited on 2D images. Additionally, dense buccal and/or oral cortical plates may affect the evaluation of the interproximal bone defects. This may cause misdiagnosis of the supporting bone condition and thus lead to a lower detection rate of periodontal bone defects (Vandenberghe *et al*. 2008). Furthermore, non-standardized follow-up radiographs could mimic bone healing or bone loss due to the deviation in X-ray projection angulation. This may result in a faulty assessment of the supporting bone conditions.

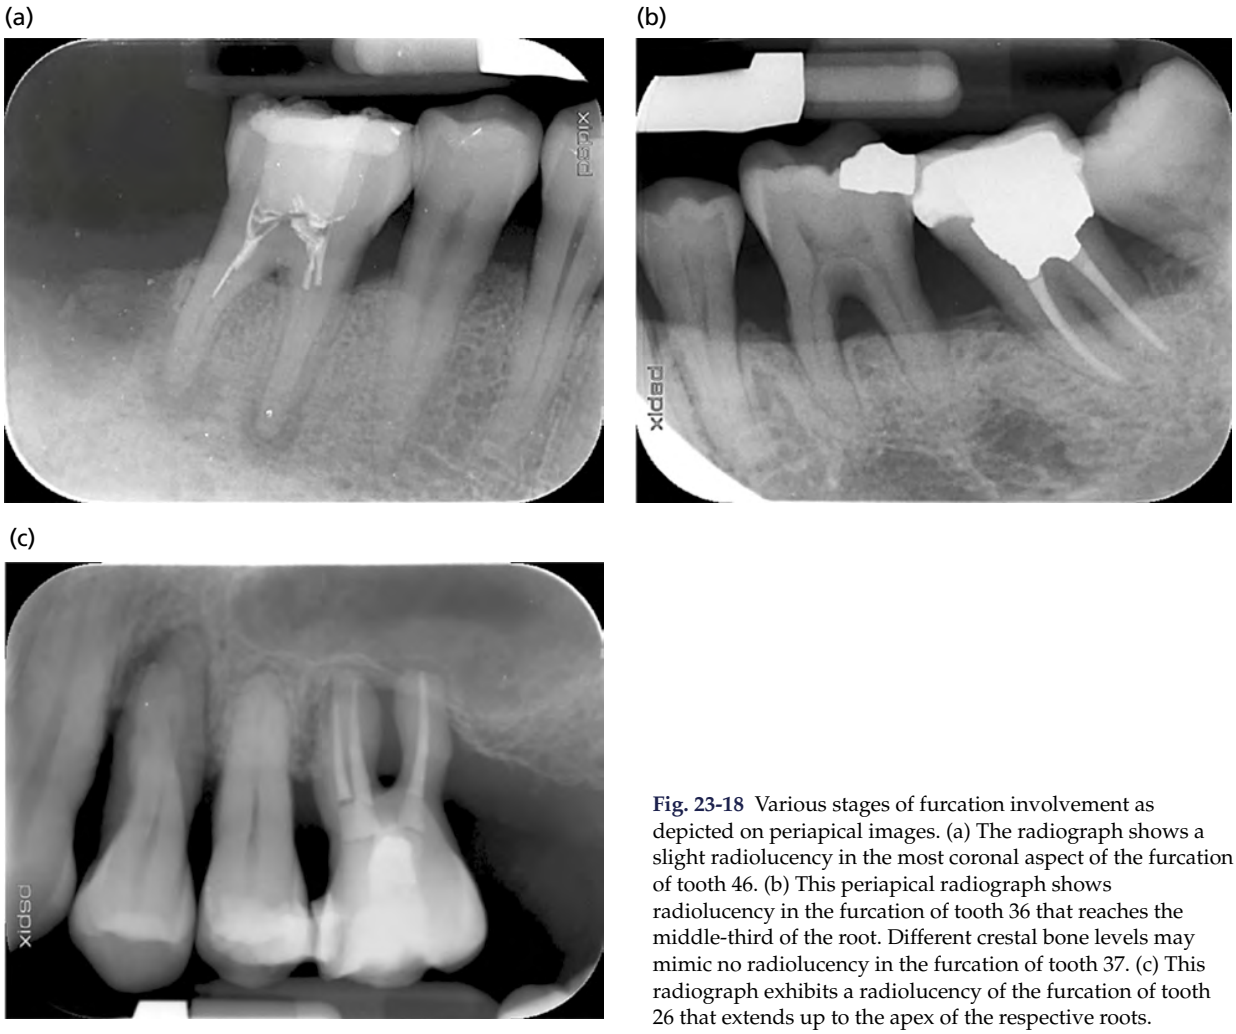

Fig. 23-18 Various stages of furcation involvement as depicted on periapical images. (a) The radiograph shows a slight radiolucency in the most coronal aspect of the furcation of tooth 46. (b) This periapical radiograph shows radiolucency in the furcation of tooth 36 that reaches the middle-third of the root. Different crestal bone levels may mimic no radiolucency in the furcation of tooth 37. (c) This radiograph exhibits a radiolucency of the furcation of tooth 26 that extends up to the apex of the respective roots.

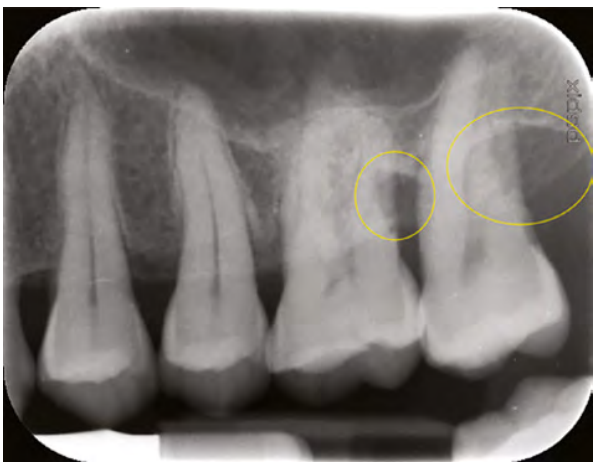

Fig. 23-19 A periapical image demonstrating a radiolucent triangle superimposed over the distal roots of tooth 26 and demonstrating the hooks of the "J" shaped radiolucency on the distal root of tooth 27, both of which indicate bone destruction extending into the furcation of the respective regions (yellow circles).

Fig. 23-20 This periapical image shows an extended radiolucency from the alveolar crest to the periapical region of tooth 46. This points towards the presence of periodontal and periapical inflammatory pathologies (perio-endo lesion).

Three-dimensional modalities

MDCT and CBCT as 3D imaging modalities allow cross-sectional views that display the architecture of all types of bone defects. This increases the accuracy in the evaluation of the presence, severity, and morphology of periodontal bone destruction (Misch *et al*. 2006; Mol & Balasundaram 2008,; Choi *et al*. 2018). A clear understanding of the 3D morphology of periodontal bone destruction and the involved roots is of great importance for treatment planning and will also influence the treatment outcome. As a result, 3D imaging modalities are recommended for the assessment of complex bone defects, especially for the intrabony and furcation defects in maxillary molars (Walter *et al*. 2009, 2010) (Fig. 23-21). Nevertheless, according to the principles of radiation dose protection, MDCT and CBCT are not recommended for routine preoperative imaging procedures in periodontology (ICRP 2007). Patients that present with clinical symptoms and signs of periodontal disease should initially be referred for 2D imaging. MDCT/CBCT is recommended only when 2D images cannot provide sufficient diagnostic information in the evaluation process of periodontal defects. Although it is reported that radiation doses for MDCT using low-dose protocols may be in the range of doses for CBCT imaging (Almashraqi *et al*. 2017), CBCT is still currently the most widely used 3D imaging modality for dental medicine and specifically for periodontal evaluations. The scanning protocol and the FOV of a CBCT examination should be determined based on the clinical and previous (2D) imaging findings on an individual case basis. Although CBCT imaging has several advantages for the evaluation of periodontal bone defects, it cannot be used to assess the condition of the gingiva. Moreover, a CBCT examination is not recommended for follow-up and monitoring of periodontal patients. In general, a follow-up

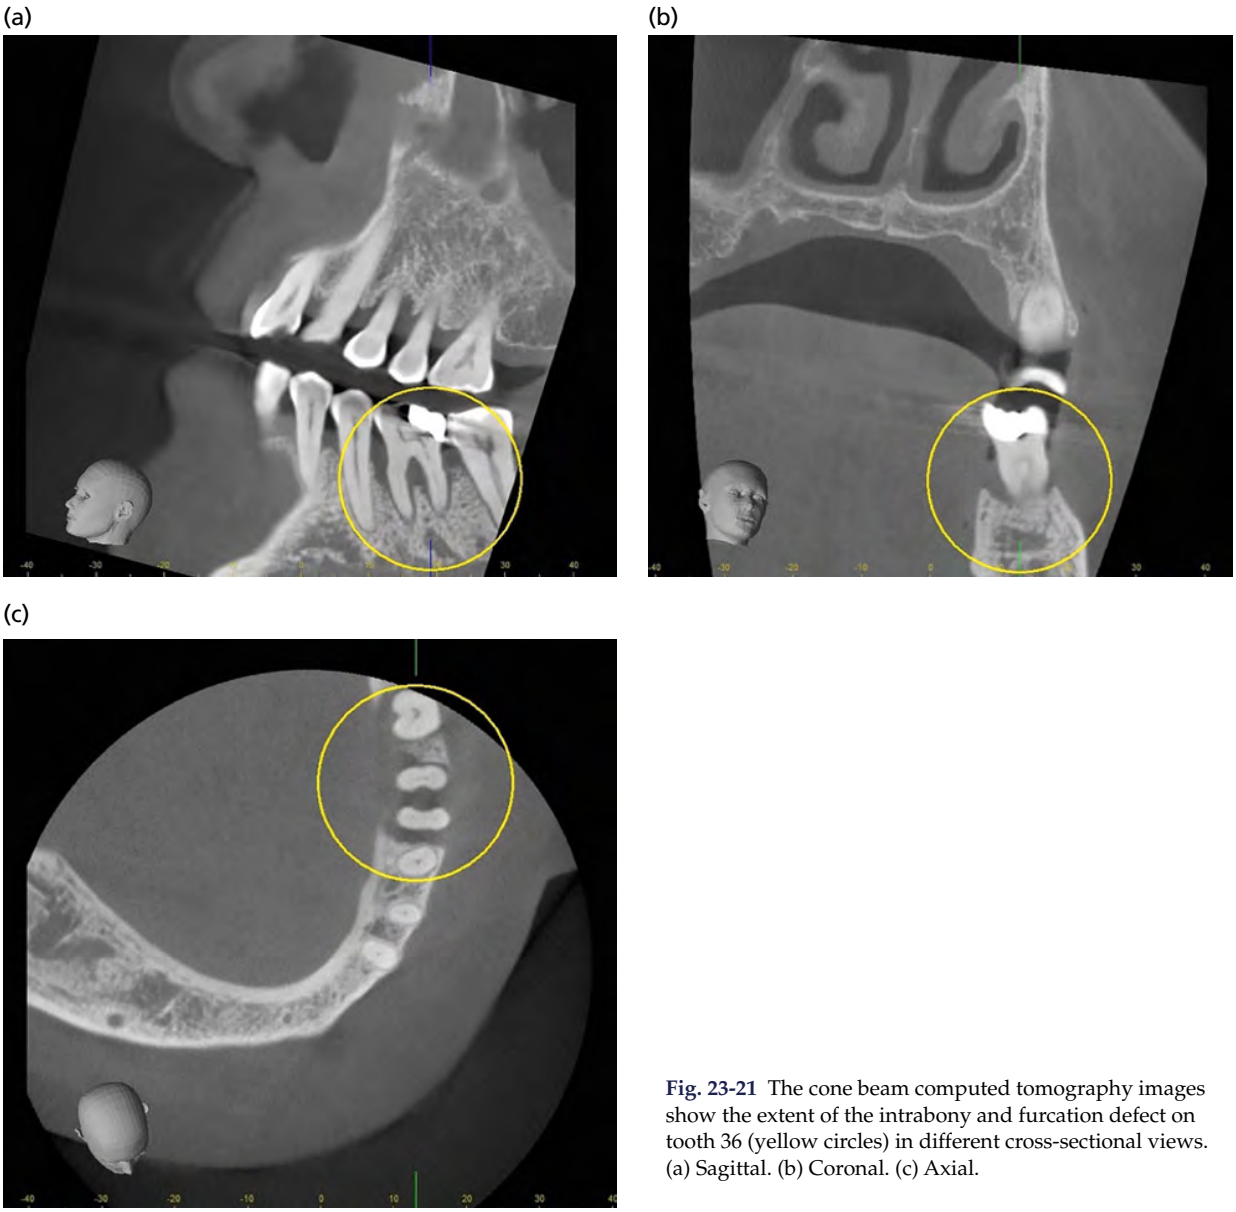

Fig. 23-21 The cone beam computed tomography images show the extent of the intrabony and furcation defect on tooth 36 (yellow circles) in different cross-sectional views. (a) Sagittal. (b) Coronal. (c) Axial.

examination should be done using 2D images to reduce the accumulated dose of radiation exposure. It is worth noting that the presence of periodontal bone loss detected in both 2D and 3D images only exhibits bone destruction and cannot indicate disease activity (Koong 2015). The bone loss may result from previous disease (history of periodontal disease) that has been controlled by appropriate treatment. As a result, the decision for any imaging modality must be based on current clinical findings.

Future trends and developments

Ultrasound

Patients with a high risk for periodontal diseases or those that have experienced periodontal treatment may need regular imaging during follow-up. Doing so will inevitably increase the accumulated dose of radiation exposure to the patient. Ultrasound imaging is a promising modality that does not employ ionizing radiation, with potential for real-time diagnostic workup and follow-up evaluations in patients with periodontal diseases. Before the advent of intraoral ultrasound transducers, ultrasound imaging was only feasible for assessing major salivary glands and superficial masses in the head and neck region, but not for periodontal diseases. Currently, small-footprint and high frequency (40-MHz) transducers designed especially for periodontal evaluation are under development, which will allow for non-ionizing, real-time, and chair-side imaging of the periodontal soft tissue, underlying alveolar bone surfaces, and buccal or oral bone defects (Chifor *et al*. 2015, 2019). Ultrasound can display the gingival thickness, gingival sulcus depth, and several relevant landmarks including the levels of alveolar bone crest, CEJ, and free gingival margin. These are of diagnostic value to assess the periodontal condition, especially to screen for and detect early forms of periodontitis. Furthermore, ultrasound is not affected by metallic materials commonly used for dental restorations or orthodontic purposes. This may increase diagnostic accuracy in the evaluation of buccal and oral bone loss at the most coronal position in close proximity to metal restorations or around orthodontic bone screws. During maintenance phases, ultrasound imaging is also useful to evaluate the stability of periodontal soft and bone tissues.

However, ultrasound imaging also has several limitations. Firstly, ultrasound can only exhibit the morphology of the gingiva and surface contour of the supporting bone and tooth portion not covered by bone. It is unable to depict periodontal bone defects covered by buccal or oral bone plates, such as three-walled intrabony and furcation defects, as ultrasonic waves cannot traverse bone tissue. Moreover, the interpretation of ultrasound images is subjective and dental practitioners may find interpretation difficult. Therefore, ultrasound images should be interpreted by appropriately trained clinical staff. These limitations may discourage the clinical use of ultrasound imaging in periodontology.

Magnetic resonance imaging

During periodontal evaluation, the health or disease of the gingiva is generally assessed through clinical examination because conventional X-ray-based imaging modalities are incapable of adequately depicting soft tissue. In contrast to ultrasound imaging, MRI can provide 3D observations of the periodontal soft tissue (Fig. 23-22). In addition, signal intensity changes in the investigated soft tissue using MRI reflect an increased water content, which can help to distinguish inflamed from healthy tissue, and assists in assessing the extent of inflammation (Mallya & Lam 2019). With different MRI sequences, one may also distinguish between infectious- and tumor-induced inflammation in soft and bone tissues (Schara *et al*. 2009). Although there is currently limited evidence for the application of MRI in the evaluation of periodontal disease (Gaudino *et al*. 2011; Ruetters *et al*. 2019), it is reported that MRI may provide sufficient spatial resolution and contrast to characterize inflamed gingiva and periodontal ligament for early diagnosis of gingivitis to an extent that cannot be matched by other imaging modalities used in dental medicine (Mallya & Lam 2019). Moreover, MRI may be helpful in evaluating the healing process (e.g. the degree of inflammation) in the gingiva and periodontal ligament after periodontal treatment. However, there are some limitations when considering MRI for periodontal evaluation (Mendes *et al*. 2020). Firstly, patients with cardiac pacemakers, insulin pumps, and claustrophobia are not suitable

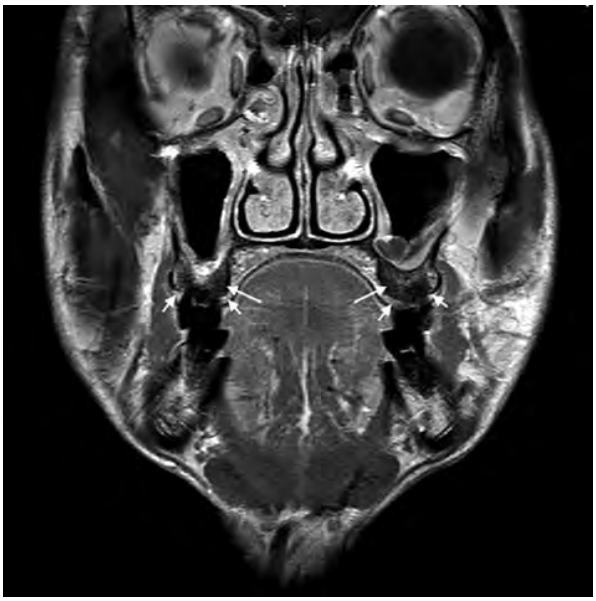

Fig. 23-22 The coronal cut of a magnetic resonance image shows the outline of the alveolar crest (long arrows). Based on this, the thickness of the gingival tissue (short arrows) can be estimated.

candidates for MRI scans. Secondly, several metallic materials used for dental restorations or orthodontic treatment may cause metal artifacts that affect the visibility and detectability of periodontal lesions. Furthermore, MRI units are relatively expensive and not as easily accessible to dental practitioners compared with conventional 2D and 3D X-ray-based imaging units. In addition, the operation of an MRI unit is much more sophisticated so that the scanning should be performed by qualified operators only. In spite of these limitations, MRI should be considered as a promising imaging modality because of its non-ionizing nature and superior soft tissue contrast. A specific user-friendly MRI unit designed for use in dental medicine may become a helpful diagnostic imaging tool to visualize pathology in the gingiva and supporting bone tissue.

Diagnostic imaging and artificial intelligence in periodontology

Digitally coded images generated in medicine that contain diagnostically important patient information are easily converted into computer language, and are thus considered as ideal to bridge the gap between medicine and artificial intelligence (AI) (Hung *et al*. 2020a; Leite *et al*. 2020). Following the processes of determination of the region of interest, identification of lesions, and classification of lesions, pathological changes on images may be automatically diagnosed using AI diagnostic algorithms and modeling. In periodontology, changes in bone density and continuity of the surface contour of the supporting bone could both contribute to the development of AI models for evaluation of periodontal bone defects. Currently, some research groups have proposed test models to automatically or semiautomatically identify and/or measure the degree of periodontal bone destruction (Lin *et al*. 2015, 2017). Moreover, an AI model has been reported to be able to predict the outcome of periodontal treatment (i.e. classifying periodontally compromised teeth into hopeful or hopeless teeth) (Lee *et al*. 2018). Interestingly, most of the proposed AI models were computed based on 2D intraoral images, mainly periapicals. These models can only identify interdental bone defects with evident bone loss because of a lack of 3D information for the entire supporting bone. Future trends for AI models built for periodontal diagnosis and treatment planning should exploit 3D images from CBCT, MDCT, and MRI to realize and implement automated classification of periodontal bone defects, calculation of the volume of bone loss, or propose treatment recommendations.

Diagnostic imaging in oral implantology

In oral implantology, diagnostic imaging is widely used for treatment planning, prosthetic evaluation, and follow-up examinations. The following section describes general recommendations on various diagnostic imaging modalities used in the pre-, intra-, and postoperative phases, and for special considerations including image-guided implant surgery, block grafting procedures, and zygoma implants.

General recommendations for implant treatment planning purposes

Using preoperative imaging examinations, implant surgeons expect to obtain diagnostic information about the condition of the bone at a future implant site, which cannot be evaluated by clinical examination only. A selection of appropriate diagnostic imaging modalities for each individual case is critical to achieve an optimal treatment outcome and minimize intra-/postoperative complications. The presence/absence of dentoalveolar pathology at the proposed implant site should be evaluated using preoperative imaging. Patients with periapical lesions of adjacent teeth, cystic lesions, or bone necrosis are suggested to receive corresponding treatment prior to implant placement. If a patient is considered as a suitable candidate for implant treatment, surgeons can proceed to assess the quantity of available bone at the edentulous site and to evaluate adjacent critical anatomic structures to determine the adequate surgical technique including position(s) and dimension(s) of the proposed implant(s).

Two-dimensional modalities

Before 3D imaging modalities were introduced into and available in dental medicine, the combination of various 2D diagnostic images including periapical, occlusal, and panoramic radiographs was recommended for the evaluation of the vertical, bucco-oral, and mesiodistal dimensions of the alveolar ridge for implant treatment purposes. These imaging techniques were also used to visualize neighboring vital anatomical landmarks such as the mandibular canal or maxillary sinus. However, occlusal images were subsequently considered inappropriate to evaluate the bucco-oral dimension as they can only depict the bucco-oral dimension of the mandibular body, but not that of the alveolar ridge, which is actually more relevant for dental implant insertion. Currently, periapical radiographs and panoramic views are still considered as the main 2D imaging modalities for implant treatment planning purposes (Al-Ekrish 2018).

Periapical radiography

Due to a restricted FOV, periapical radiography is mainly used to assess the alveolar bone condition of a single or two adjacent edentulous sites prior to dental implant treatment, but seldom used for patients with multiple missing teeth. Periapical radiography can provide an initial assessment regarding the healing of extraction sockets, the presence of retained roots, remaining pathologies, and also the presence of

Fig. 23-23 This periapical image shows a reduced bone level at the edentulous site of the former tooth 11, and an apical radiolucency at the root-filled tooth 21.

Fig. 23-24 This periapical image shows a wide fracture line on the root of tooth 11.

periapical lesions of adjacent teeth (Fig. 23-23). Based on its high spatial resolution, periapical radiography is an excellent tool for the assessment of bone structure, clearly displaying trabecular bone at the edentulous sites. Moreover, periapical radiography can provide a useful initial view to evaluate the condition of traumatized anterior teeth when evaluating the prognosis of anterior maxillary teeth (Fig. 23-24). However, periapical radiography cannot provide cross-sectional views to display bucco-oral dimensions of the alveolar ridge at a proposed implant site. Furthermore, the distortion and magnification of a periapical image limits accurate linear distance measurements between the adjacent teeth and distances between the alveolar crest and boundaries of critical anatomic structures, such as the floor of the nasal cavity and maxillary sinus, lingual undercuts of the mandible, or the upper limit of the inferior mandibular canal. Therefore, periapical images should be interpreted with caution and always in combination with clinical findings, especially for cases with limited bone volume at the edentulous sites.

Panoramic views

For patients with multiple missing teeth or a completely edentulous maxilla/mandible, panoramic images are considered as the first-line imaging modality to provide an estimate of the condition of the remaining teeth and/or bone volume (Mallya & Lam 2019). Moreover, the broad FOV depicted by panoramic images is able to visualize the entire floor of the nasal cavity and maxillary sinus, inferior mandibular canal, and mental foramen, which is helpful for the assessment of the vertical bone dimensions at all edentulous sites (Fig. 23-25). This is valuable information for the planning process of multiple implants in one single image. Similar to periapical images, panoramic views cannot provide accurate linear measurements, information about bucco-oral dimension of the alveolar ridge, and 3D evaluation and special visualization of critical anatomical structures. Using a standardized metallic ball – for example with a diameter of 5 mm – during panoramic image taking can help clinicians to assess bone dimensions by helping to calculate the magnification factor of panoramic images. Furthermore, the presence of superimposition artifacts of the spinal cord in panoramic images can affect the assessment of the anterior edentulous site in the maxilla and mandible.

Three-dimensional modalities

Three-dimensional diagnostic imaging modalities including MDCT and CBCT allow for an accurate visualization of anatomical structures or pathological changes in the maxillofacial region, and therefore are recommended when periapical and panoramic radiographs are both unable to provide sufficient diagnostic information for implant treatment planning. Considering the similar measurement accuracy between MDCT and CBCT as well as their cost-effectiveness, radiation dose, and availability, CBCT is more frequently used in implant dentistry (Bornstein *et al*. 2017).

Fig. 23-25 The panoramic view enables an overview of all edentulous regions including an initial assessment of the available vertical bone dimensions. Furthermore, peri-implant bone conditions of already inserted implants and vital anatomical structures, including the mandibular canal or maxillary sinuses, can be evaluated.

Fig. 23-26 The sagittal cone beam computed tomography plane shows the residual bone height in the anterior maxilla in a patient with an edentulous maxilla. A severely resorbed alveolar crest with a so-called knife-edged morphology can be seen.

In the anterior maxilla, the residual bone height (RBH) is considered as the vertical distance between the alveolar crest and the floor of nasal cavity, which is usually measured on sagittal or coronal CBCT planes (Fig. 23-26). The RBH in the anterior maxilla is usually sufficient in patients for the placement of conventional dental implants. Insufficient RBH in the anterior maxilla is mainly seen in patients with severe periodontitis or maxillary hypoplasia, or patients having experienced trauma or surgery. The residual bone width (RBW) in the anterior maxilla is the bucco-oral dimension of the alveolar ridge, which is also usually measured on sagittal CBCT planes. Compared with the RBH, the RBW in the anterior maxilla is frequently insufficient for implant placement without any simultaneous or staged bone augmentation procedures due to natural buccal ridge concavity or buccal bone resorption after tooth extraction. A knife-edged alveolar ridge is not infrequently observed in this region and presents as a narrow alveolar crest along with a relatively wide alveolar base (Fig. 23-26). In order to achieve an ideal aesthetic gingival contour around an implant placed in the anterior maxilla, the level of the alveolar crest at the edentulous site in relation to the level of the proposed implant shoulder and also the neighboring teeth should be carefully assessed during preoperative CBCT examinations. Furthermore, the nasopalatine canal is also a critical anatomic structure in proximity to the maxillary central incisors (Fig. 23-27). The morphology and dimensions of the nasopalatine canal vary considerably, but generally males present with higher values than females. A large nasopalatine canal may occupy the space needed for a planned implant at the site of the maxillary central incisor necessitating complex grafting procedures (Urban *et al*. 2015).

In the posterior maxilla, the maxillary sinus is the main anatomic structure that may affect the planning of implant treatment. The RBH in the posterior maxilla is the distance between the alveolar crest and the floor of the maxillary sinus, which is usually measured on coronal CBCT planes (Fig. 23-28). The RBW in the posterior maxilla is the bucco-oral dimension of the alveolar ridge, which is also measured on coronal CBCT planes. Due to resorption of the alveolar crest following loss of the posterior teeth, the RBH in the posterior maxilla is frequently insufficient for the placement of dental

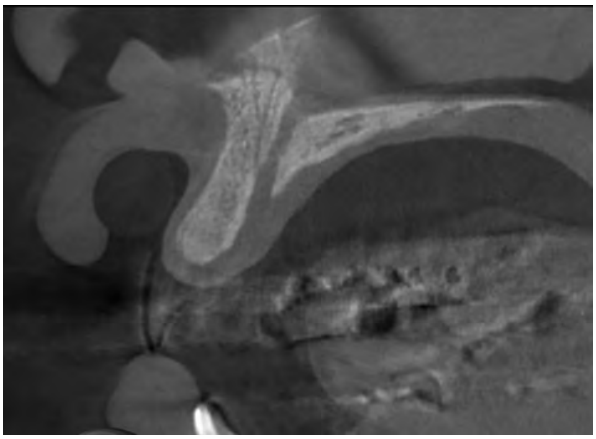

Fig. 23-27 The sagittal cone beam computed tomography view taken between teeth 11 and 21 exhibits the nasopalatine canal and its relation to the alveolar ridge.

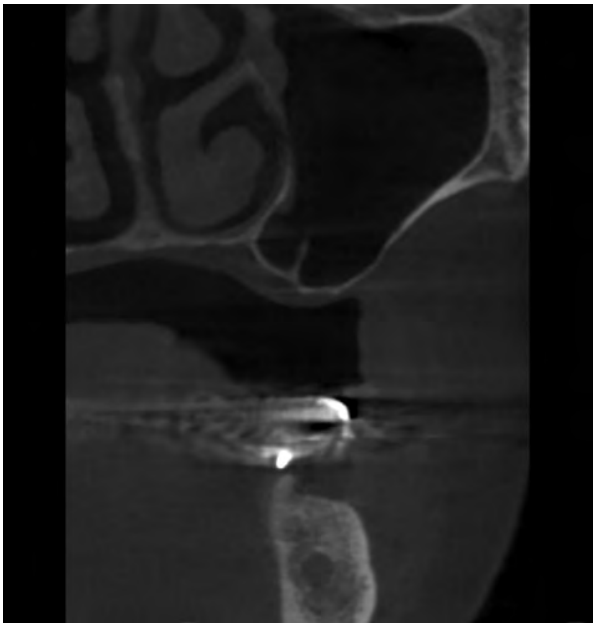

Fig. 23-28 The coronal cone beam computed tomography view shows a severely atrophic posterior maxilla, nicely pneumatized conditions of the maxillary sinus, and a septum located on the floor of the sinus. Furthermore, the outline of the mandibular canal can clearly be seen in the lower jaw.

implants with regular lengths (e.g. 8–10 mm). For those cases, sinus floor elevation (SFE) procedures including the lateral window and transcrestal osteotome approaches are recommended prior to or simultaneously with implant placement (Danesh-Sani *et.al* 2016). Before performing SFE procedures, the condition of the maxillary sinus needs to be assessed. Furthermore, the RBH at the edentulous site, morphology of the maxillary sinus floor (e.g. a flat floor or presence of maxillary sinus septum), and the presence/absence of sinus pathologies should be evaluated and diagnosed on CBCT images (Vogiatzi *et al*. 2014; Bornstein *et al*. 2016). Sinus pathologies such as a mucosal thickening, mucous retention cysts, accessory maxillary ostia, and obstruction of the primary maxillary ostium can be clearly detected on CBCT images (Fig. 23-29). These sinus pathologies were reported to have an association with maxillary sinusitis that may eventually result in postoperative infection and early implant loss following SFE procedures (Yeung *et al*. 2019b; Hung *et al*. 2020b). The thickness of the lateral wall of the maxillary sinus and the presence including location of the superior alveolar artery should be specifically assessed prior to any lateral window approach. The superior alveolar artery may course through the outer/inner surface of the sinus wall or be present inside the bone itself (Fig. 23-30). The course of the artery may complicate the preparation of the bony window, and even result in severe intra- or postoperative hemorrhages (Danesh-Sani *et al*. 2017). It has been reported that cutting a superior alveolar artery of a diameter greater than 2 mm may very likely cause severe bleeding (Guncu *et al*. 2011). Therefore, the presence and exact location of the superior alveolar artery in relation to the lateral sinus wall should be thoroughly assessed on CBCT scans prior to SFE surgery. The preoperative FOV of the posterior maxilla should contain the alveolar bone of all potential implant sites, the adjacent alveolar bone, and the lower third of the maxillary sinus without mandatory inclusion of the primary ostium.

The anterior mandible has been considered as a relatively safe zone for implant placement due to a lack of critical anatomical structures. However, penetrating the lingual cortex of the alveolar ridge in the anterior mandible with a surgical bur may damage the sublingual and submental arteries. This damage may result in immediate or delayed life-threatening hemorrhaging as the tongue will be pushed back towards the throat, with a risk of suffocation (Tomljenovic *et al*. 2016). Therefore, the morphology of the alveolar ridge and mandibular base of the patient should be carefully evaluated on CBCT images to prevent penetration of the lingual cortex during the drilling procedure (Fig. 23-31). The preoperative FOV of the anterior mandible should contain at least the region of both mental foramina including the whole vertical height of the mandible.

In the posterior mandible, the mandibular canal and mental foramen are the main anatomical landmarks that affect implant placement. The RBH in the posterior mandible is calculated as the distance between the alveolar crest and upper boundary of the mandibular canal, which is usually measured on coronal CBCT planes (see Fig. 23-28). The morphology of the mandibular canal and mental foramen can be clearly observed on CBCT images. The location of the mental foramen of patients with a severely atrophic mandible is often located close to the crest of the alveolar ridge (Fig. 23-32). In these cases, an incision on the alveolar ridge or detachment of the mucosa may injure the mental nerve, resulting in postoperative paresthesia. Furthermore, the location of the sublingual fossa should also be carefully assessed to prevent penetration of the lingual cortex during the drilling procedure, which will result in similar consequences to those observed in the anterior mandible (Fig. 23-33).

Although MDCT imaging is not frequently used for implant treatment planning today, it is considered as a useful tool specifically to evaluate the density

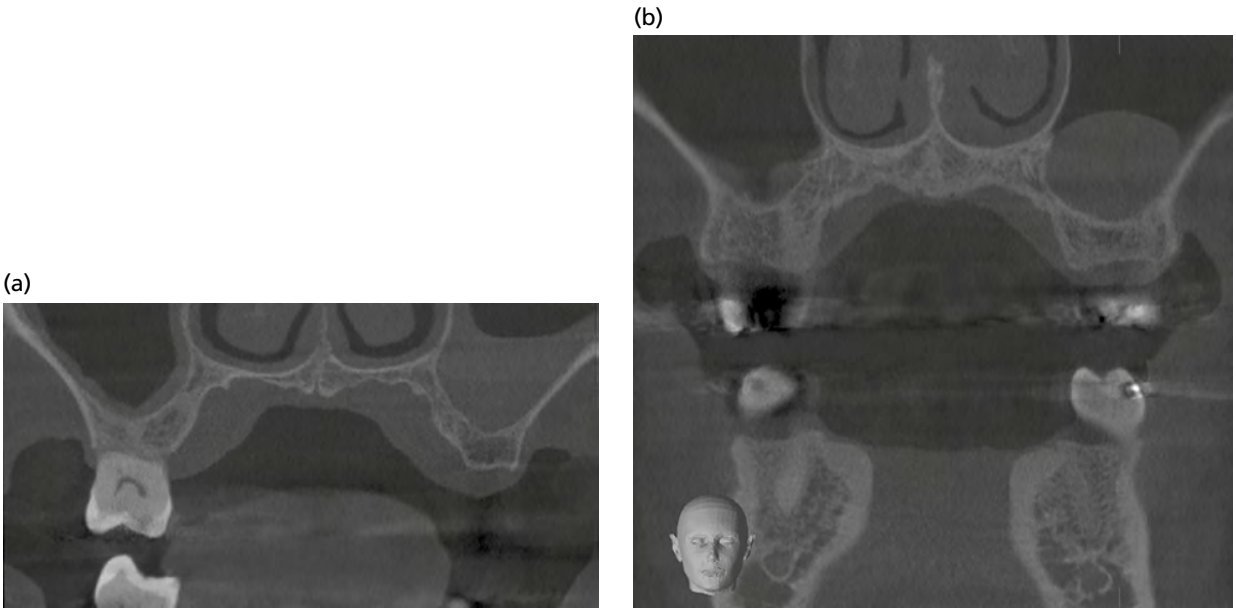

Fig. 23-29 (a) Slight and severe mucosal thickening can be respectively seen in the right and left maxillary sinuses. (b) A dome-shaped mucosa configuration on the floor of the left maxillary sinus can be seen, which is typical for a mucosal retention cyst. In the right maxillary sinus, the mucosal thickening seems to be confined to the floor.

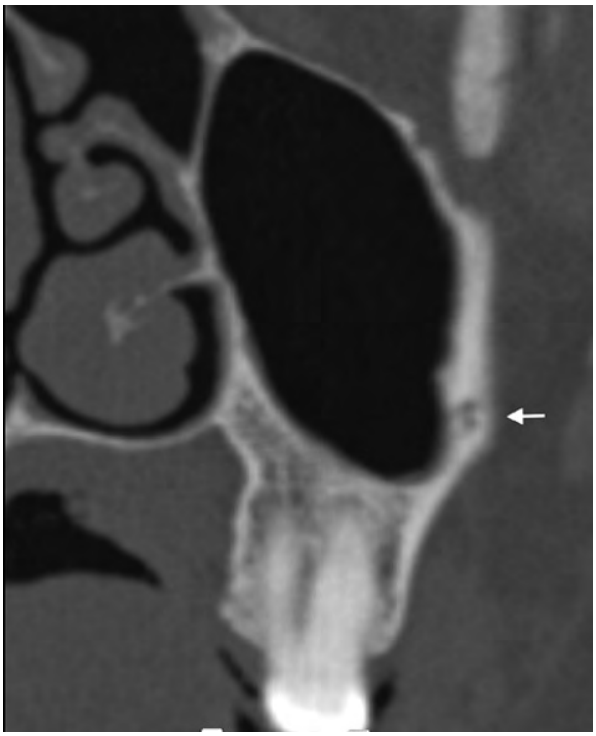

Fig. 23-30 The bony canal for the superior alveolar artery (arrow) can be seen in the lateral wall of the maxillary sinus.

of alveolar bone at a proposed implant site. The Hounsfield Unit (HU) is a standardized index with values proportional to the degree of X-ray attenuation by the body tissue. HUs are routinely used in MDCT for evaluating the degree of bone calcification or tissue densities (Razi *et al*. 2019). For CBCTs grey level values are used rather than HUs, which correspond to the X-ray intensity at that location during a particular exposure of the sensor. However, the applicability of grey levels in CBCT for bone density evaluation is hampered owing to excessive scattered radiation, artifacts, and noise resulting from the use of a cone-shaped beam in CBCTs (Pauwels *et al*. 2015). Thus, the quantitative evaluation of bone density on CBCT images is not recommended, especially to compare the differences in the grey level values in different CBCT units (Corpas Ldos *et al*. 2011; Razi *et al*. 2019). If there is a need to assess bone density, MDCT imaging should be recommended.

Preoperative FOV of the posterior mandible should contain the region of the potential implant sites including the adjacent teeth or bone and the whole vertical height of the mandible. If necessary or discussed for implant treatment planning, the donor site of autogenous block grafts should be also visualized.

For implant treatment planning with merged intraoral scans the complete crowns of the adjacent teeth should be visualized as the respective tooth cusps are frequently used as landmarks for matching of CBCT/MDCT and intraoral scans. See the section "Guided implant surgery" for more details and recommendations regarding diagnostic imaging for guided implant surgery.

Recommendations during and after implant placement (follow-up)

Diagnostic images taken during implant surgery are mainly used to evaluate drill position or dealing with intraoperative complications. Postoperative radiographic examinations are usually performed for prosthetic purposes (e.g. to check abutment/crown fit), and to evaluate the status of the placed dental implants during follow-up and maintenance (e.g. assess peri-implant bone conditions). Postoperative radiographs should be taken with the modality of follow-up, which is mostly 2D radiographs (see later).

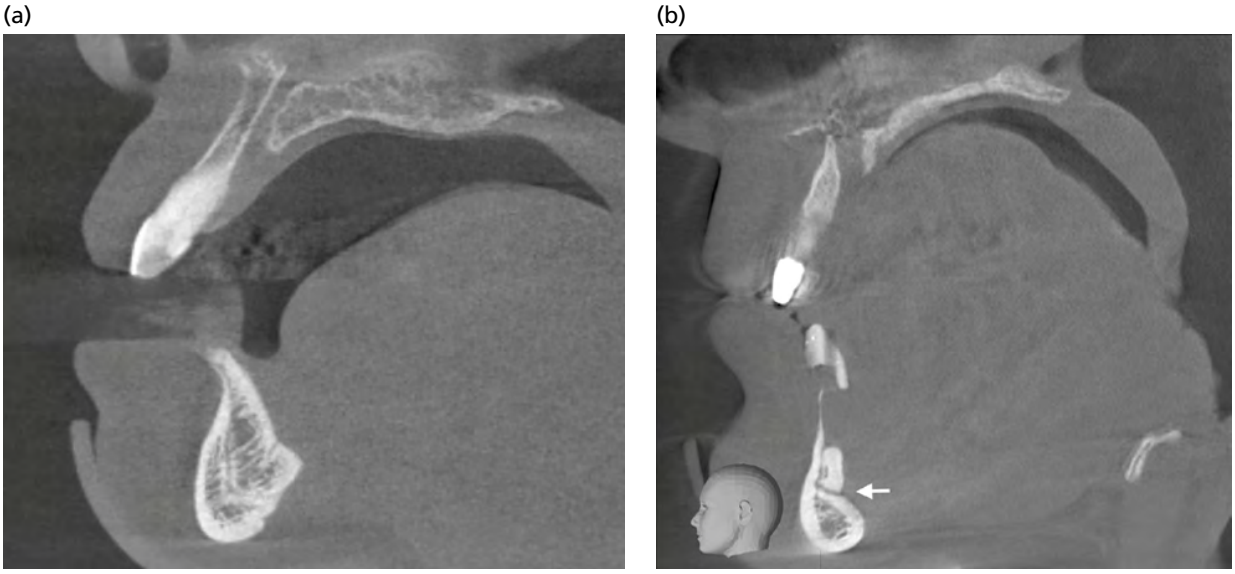

Fig. 23-31 Different morphologies and anatomical landmarks of the mandibular alveolar ridge as seen in cone beam computed tomography (CBCT) scans. (a) The sagittal CBCT image shows a narrow ridge and a wider alveolar base (pyramidal shape). (b) The CBCT image shows a thin, razor-edged remaining alveolar crest and a lingual canal in the symphyseal region (white arrow).

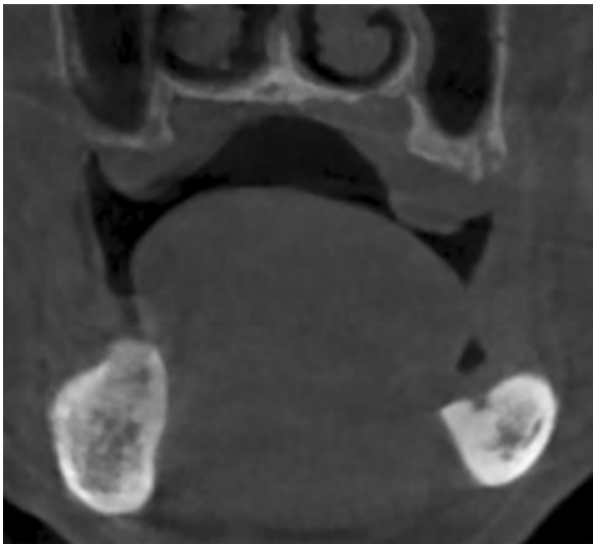

Fig. 23-32 The cone beam computed tomography scan (coronal view) exhibits a severely atrophic posterior mandible especially on the left resulting in the mental foramen to be located at the cranial aspect of the residual alveolar ridge.

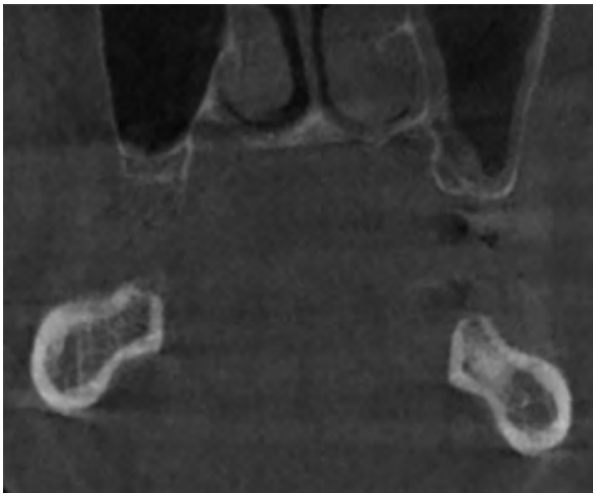

Fig. 23-33 This cone beam computed tomography scan (coronal view) shows extensive sublingual fossae on the lingual surface of the mandibular base on both sides. This morphology of the mandible might be a limiting factor for prosthetically driven implant placement.

Two-dimensional modalities

Often, postoperative diagnostic images are taken immediately after surgery to serve as a baseline record of the placed implants. Nevertheless, it has to be mentioned that there is no evidence available showing any benefit to the patient to justify routine 2D or 3D imaging after intervention, when there is no sign or symptom of any potential complication. Due to the high spatial resolution, periapical radiography is recommended as the optimal imaging modality used to record the level of the alveolar crest around the placed implants and the interface between the implant and bone tissue. Panoramic radiography is also commonly used for documentation, especially for patients who have received multiple implants. If there are more than five intraoral radiographs one should consider choosing a panoramic radiograph for radiation protection purposes (Dula *et al*. 2001). However, the level of the alveolar crest and bone density may not be accurately assessed in panoramic images owing to the lower spatial resolution and the distortion, magnification, and overlapping phenomena.

For a novice implant surgeon, intraoperative periapical and even segmented panoramic images might be helpful to evaluate the correct position of the pilot drill (Fig. 23-34). These images allow the surgeon to correct an inappropriate drill position before the remaining osteotomy steps. Occasionally, it is possible for patients to accidentally swallow or aspirate

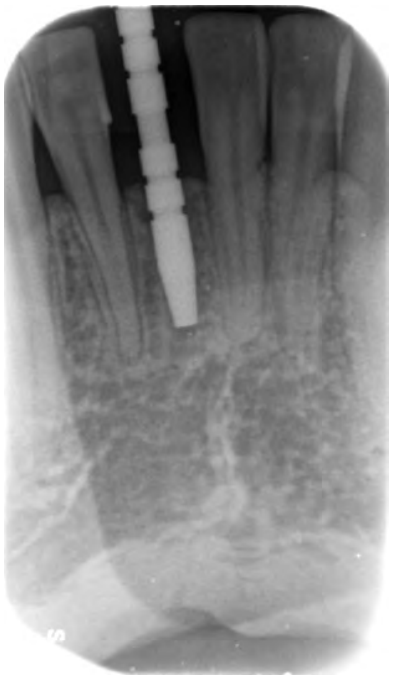

Fig. 23-34 The periapical image shows insertion depth and also the position of the prospective implant with the help of a paralleling guide pin.

Fig. 23-35 This periapical image highlights an incomplete seating of the healing abutment on the inserted implant presenting as a radiolucent gap between the implant and the abutment.

tiny instruments (such as a screwdriver or a cover abutment) used in implant surgery. If this occurs, the patient should be referred for a chest X-ray to determine whether the instrument was aspirated into the lung.

During the prosthetic phase, periapical and bitewing images are regularly used to assess correct osseointegration of the placed implant and the seating of a prosthetic abutment, frame, or prosthesis (Figs. 23-35, 23-36, 23-37, 23-38). After placement of a prosthesis, a periapical image is recommended to serve as a record for comparison with follow-up images.

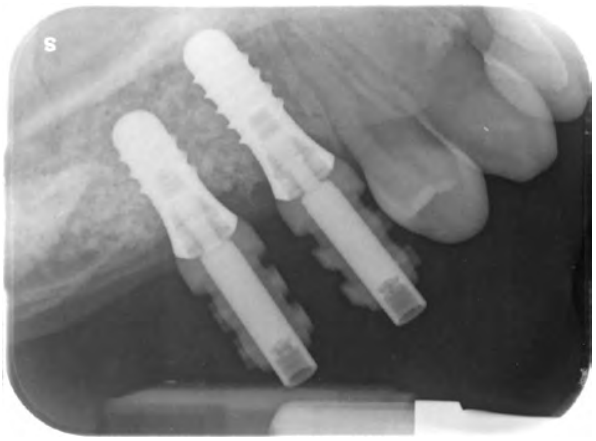

Fig. 23-36 This periapical image shows the seating of the impression posts on the implants presenting as close marginal contact between the implant and the posts.

Fig. 23-37 The periapical image shows complete seating of the final abutment on the implant presenting as close marginal contact between the implant and the abutment.

Fig. 23-38 The bitewing radiograph shows complete seating of the prosthesis (splinted crowns) on the implants presenting as a close marginal contact between the implants and the prosthesis.

In the maintenance phase, annual imaging examination of the marginal bone loss is recommended for implant patients. This recommendation is of particular relevance for patients with present risk factors such as tobacco smoking, inefficient oral hygiene use, or a history of periodontitis. Periapical radiographs are considered as the optimal imaging modality for follow-up. Justification for follow-up has to be based on clinical parameters like probing depth and inflammatory scores.

Three-dimensional modalities

MDCT/CBCT imaging is not recommended for routine follow-up examinations due to the high radiation dose, costs, and also implant-related artifacts. The severity of implant-related artifacts increases as the distance between two implants decreases, and thus the bone area between adjacent implants is difficult to assess. The reason for referrals for a MDCT/CBCT examination during and after implant surgery commonly results from the occurrence of intraoperative/postoperative complications, such as the displacement of an implant (for example into the maxillary sinus or damage of the mandibular canal), implant fracture, ailing/failing implants, and special cases of peri-implantitis (Fig. 23-39). For cases when 3D imaging seems appropriate, CBCT scans are usually recommended.

Peri-implant disease

Peri-implant disease includes peri-implant mucositis and peri-implantitis. Peri-implant mucositis is described as the presence of inflammation in the mucosa around dental implants without supporting bone loss. Peri-implantitis is defined as the phase following peri-implant mucositis, characterized by inflammation in the peri-implant mucosa and subsequent progressive loss of supporting bone tissue. Once the presence of peri-implantitis is identified, surgeons may consider resective and regenerative peri-implant treatment, or explantation and replacement of the implant. Periapical radiography and CBCT are the most common diagnostic imaging modalities to evaluate peri-implant bone defects. It is reported that periapical radiography and CBCT imaging exhibit comparable diagnostic accuracy in the assessment of peri-implant bone defects. Both modalities present a clinically acceptable diagnostic accuracy with sensitivity and specificity rates ranging from 59% to 67% for the detection of peri-implant bone defects (Bohner *et al*. 2017). Size and type of peri-implant bone defect are considered as influencing factors associated with diagnostic accuracy. Due to a higher spatial resolution, periapical radiography is considered more useful to detect small defects (Dave *et al*. 2013), but it may only be used to detect such bone defects at the mesial and/or distal sites of implants. In contrast, CBCT imaging can evaluate all types of peri-implant bone defects due to its 3D nature (Fig. 23-40). Although decreasing the voxel size of CBCT images can increase image quality that may be helpful to detect a small bone defect, it will also increase the dose of radiation exposure to the patient. However, metal artifacts seen on CBCT images that present as bright streaks radiating from the metallic restoration and implant and darkening of certain areas may hamper the evaluation of the status of implant osseointegration and bone defects around implants. Therefore, there is a general consensus that the status and condition of peri-implant

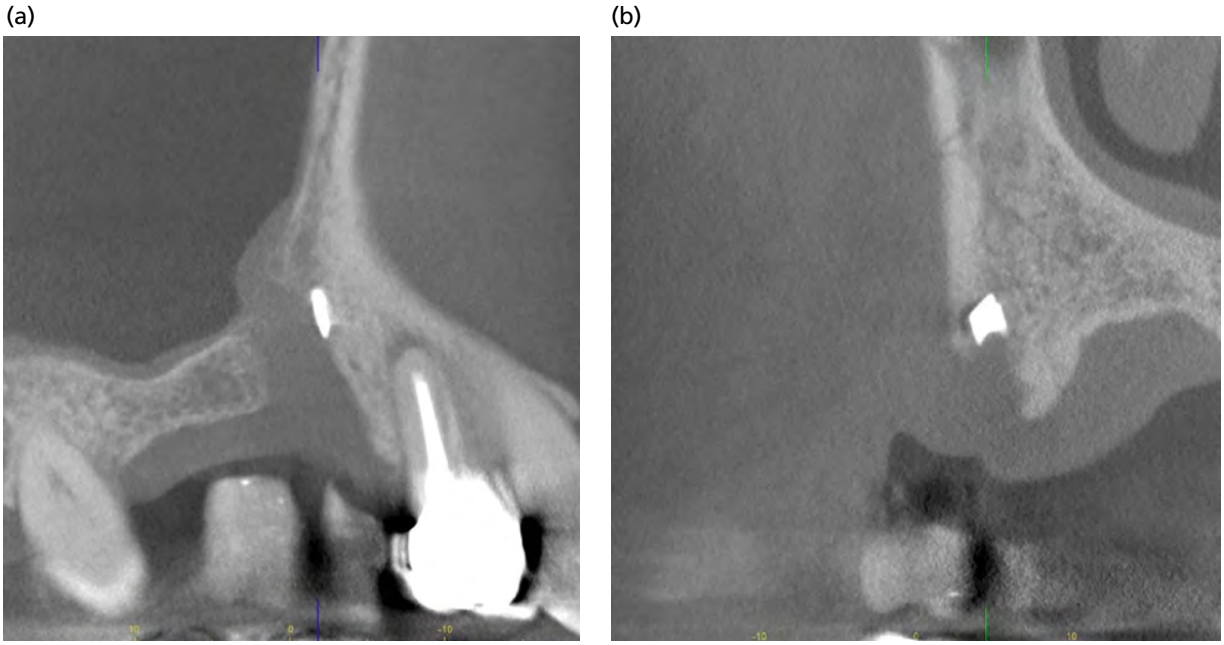

Fig. 23-39 The cone beam computed tomography images show a fragment of the implant remaining in the extraction socket in different cross-sectional views. (a) Sagittal. (b) Coronal.

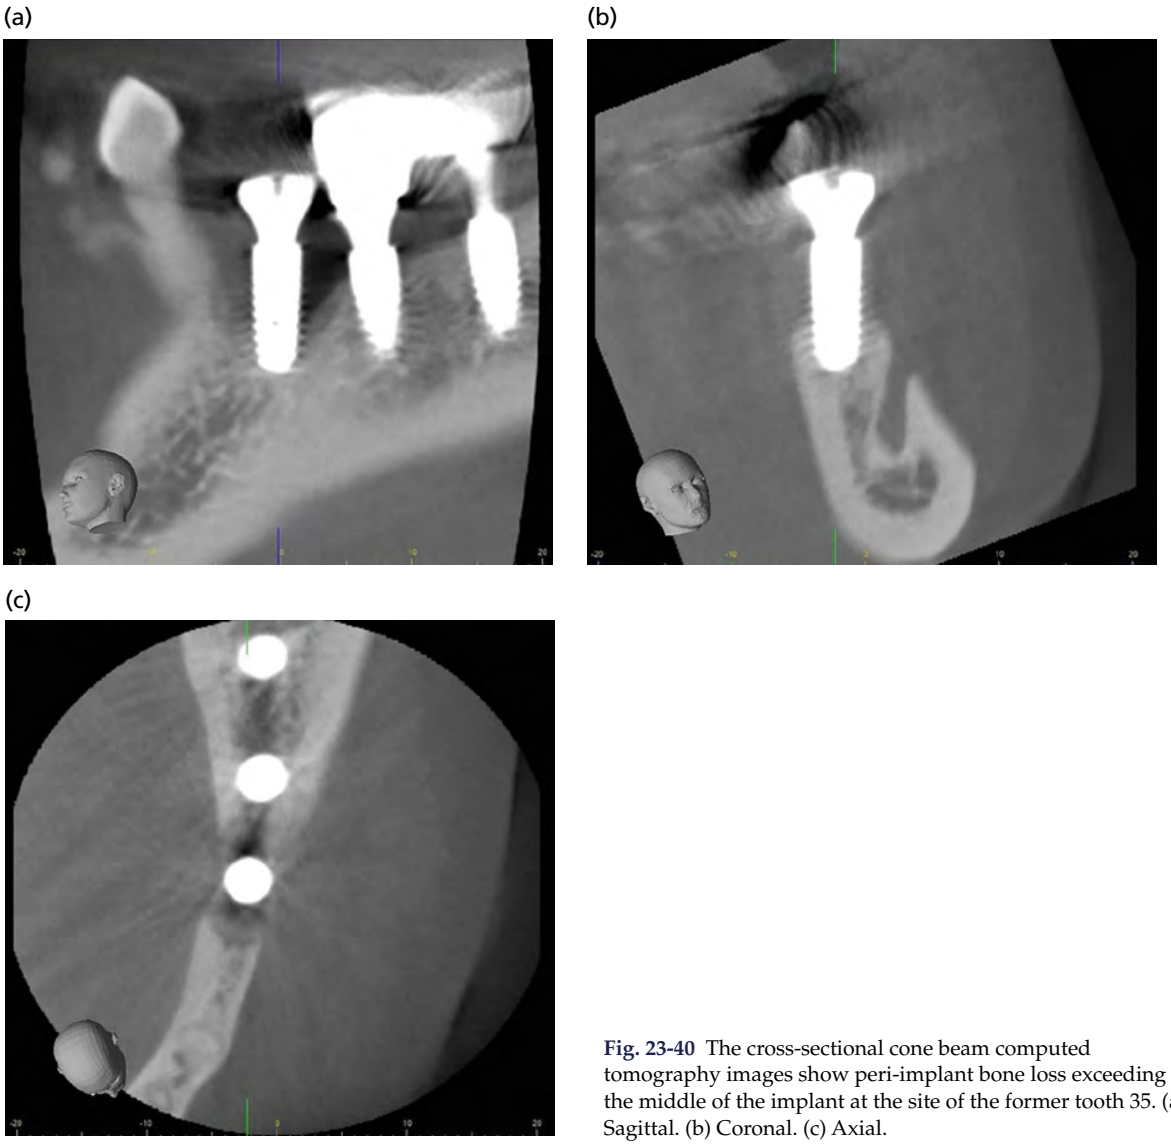

Fig. 23-40 The cross-sectional cone beam computed tomography images show peri-implant bone loss exceeding the middle of the implant at the site of the former tooth 35. (a) Sagittal. (b) Coronal. (c) Axial.

bone should be evaluated ideally by using periapical images (Fig. 23-41). A uniform radiolucent lining may be clearly observed around an ailing/failing implant (Fig. 23-42). A CBCT examination is recommended when 2D imaging does not suffice in patients with clinical signs and symptoms of peri-implant disease, and where the added imaging information might be influential for treatment planning. Therefore, the use of CBCT scans for the evaluation of peri-implant disease should be carefully assessed based on the ALARA/ALADA principle to protect patients from unnecessary exposure to ionizing radiation.

Recommendations for special indications and techniques

Guided implant surgery

Preoperative implant planning is essential to achieve an optimal treatment outcome. The accurate placement of dental implants in the planned position is one of the biggest concerns for surgeons. In the past several years, the conventional plaster-based surgical stent was frequently used to guide surgical implant placement. However, plaster-based surgical templates are mainly recommended for marking the entry point at the planned implant and also to control its angulation. Recent developments in the digital workflow, CAD/CAM technologies, and also real-time surgical navigation techniques have greatly increased the use and also acceptance of guided implant surgery, and it is widely considered as a reliable and accurate method to place implants as much in line with the planned position as possible (Nickenig *et al*. 2010; Wang *et al*. 2018; Zhou *et al*. 2018; Pellegrino *et al*. 2019). Diagnostic images are the basis of modern guided implant surgery as they provide essential imaging information. Guided implant surgery can be categorized into static and dynamic techniques. The static guided surgery technique is defined as the use of a computer-aided design and manufacturing (CAD-CAM) surgical

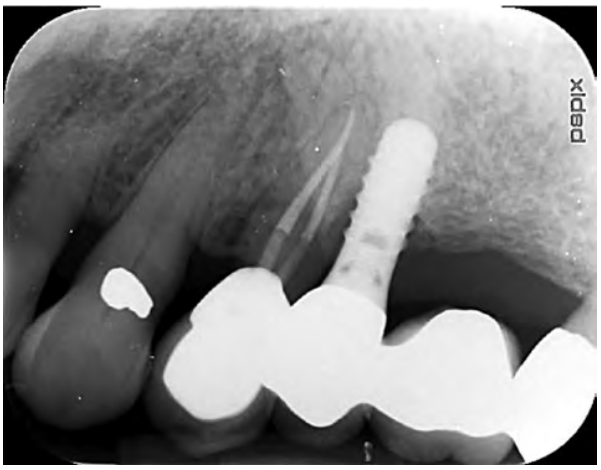

Fig. 23-41 The periapical radiograph exhibits bone loss at the mesial and distal aspects of the implant.

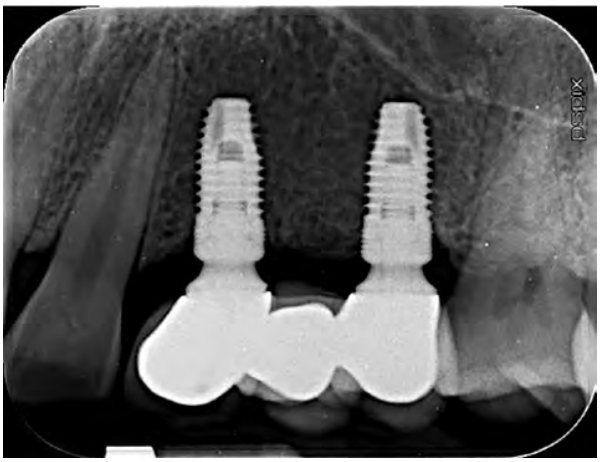

Fig. 23-42 The periapical radiograph shows a uniform radiolucent lining around both implants. Also noteworthy is the incomplete seating of the bridge work on the implants.

template to guide implant placement. The CAD-CAM surgical template is first designed virtually in the respective implant planning software using 3D image datasets including preoperative CBCT images, intraoral scan images, and/or images of the patient's stone model. A fusion of these images in the implant planning software can provide information about the contour of the soft tissue and bony structures to plan the exact future implant position. Moreover, the operator can manually set up the missing teeth or dentition in the software. This information allows implant surgeons to virtually design the position of the proposed implants taking into consideration the bone and soft tissue condition and the position of the prosthesis, thus perfectly adhering to the concept of prosthetic-driven implant planning. For completely edentulous patients, a specific double CBCT scan technique is commonly used to acquire sufficient information. This technique requires one scan of the patient wearing a complete denture embedded with several radiopaque makers, and another scan of the complete denture. Merging of the two CBCT images allows 3D evaluation of the position of the artificial teeth on the denture, bony structures, and the soft tissue contour in between.

To ensure maximum accuracy of the CAD-CAM surgical template, most of the commercially available implant planning software require that the slice thickness of the images should be less than 1 mm. Some software programs do not allow the loading of 3D image datasets with slice thicknesses that are too large. The slice thickness of CBCT images generally is between 0.1 mm and 0.4 mm, which meets the requirements of all available software. On the other hand, the slice thickness of MDCT ranges from 0.625 mm to 2.5 mm. Reducing the slice thickness of MDCT will significantly increase radiation dose. As a result, CBCT is recommended as the main imaging modality used for producing CAD-CAM surgical templates.

Dynamic guided implant surgery is a novel and emerging technique that allows for a complete 3D visualization of trajectories for implant placement through real-time analysis of the position of the surgical bur in relation to the planned trajectories exhibited on CT/CBCT images (Hung *et al*. 2016, 2017a). The application of this technique only needs one preoperative CT/CBCT scan of the patient who is wearing several invasive/non-invasive registration markers in the maxillofacial region. Subsequently, the CT/CBCT scan is used for planning of the implant placement trajectory. During surgery, the infrared camera of the navigation system keeps tracking the location of the patient and surgical instruments through the reflective registration markers in the reference array. The reference array functions to register the patient and surgical instruments to the CT/CBCT data, which enables real-time guided drilling procedures by exhibiting the trajectory, surgical instruments, and adjacent anatomic structures on the CT/CBCT images (Fig. 23-43) (Mandelaris *et al*. 2018; Wu *et al*. 2019).

Block grafting procedures

Autogenous block grafting is considered as a gold standard procedure to reconstruct severely deficient alveolar ridges in both the bucco-oral and vertical dimensions (Sakkas *et al*. 2017). Intraorally, the most common donor sites include the maxillary tuberosity, mandibular symphysis, retromolar area, and mandibular ramus. Before the surgery, the size of the deficiency should be carefully assessed to help harvest a similarly sized bone block from the donor site. Furthermore, critical anatomical structures in the proximity of the donor and recipient sites should also be carefully assessed to avoid intraoperative and postoperative complications, such as severe bleeding or paresthesia. Potential 3D diagnostic imaging of the donor and recipient sites for such cases comprises MDCT and CBCT. A second MDCT/CBCT scan around 6 months after the block grafting surgery is often also recommended to evaluate bone graft integration prior to implant placement.

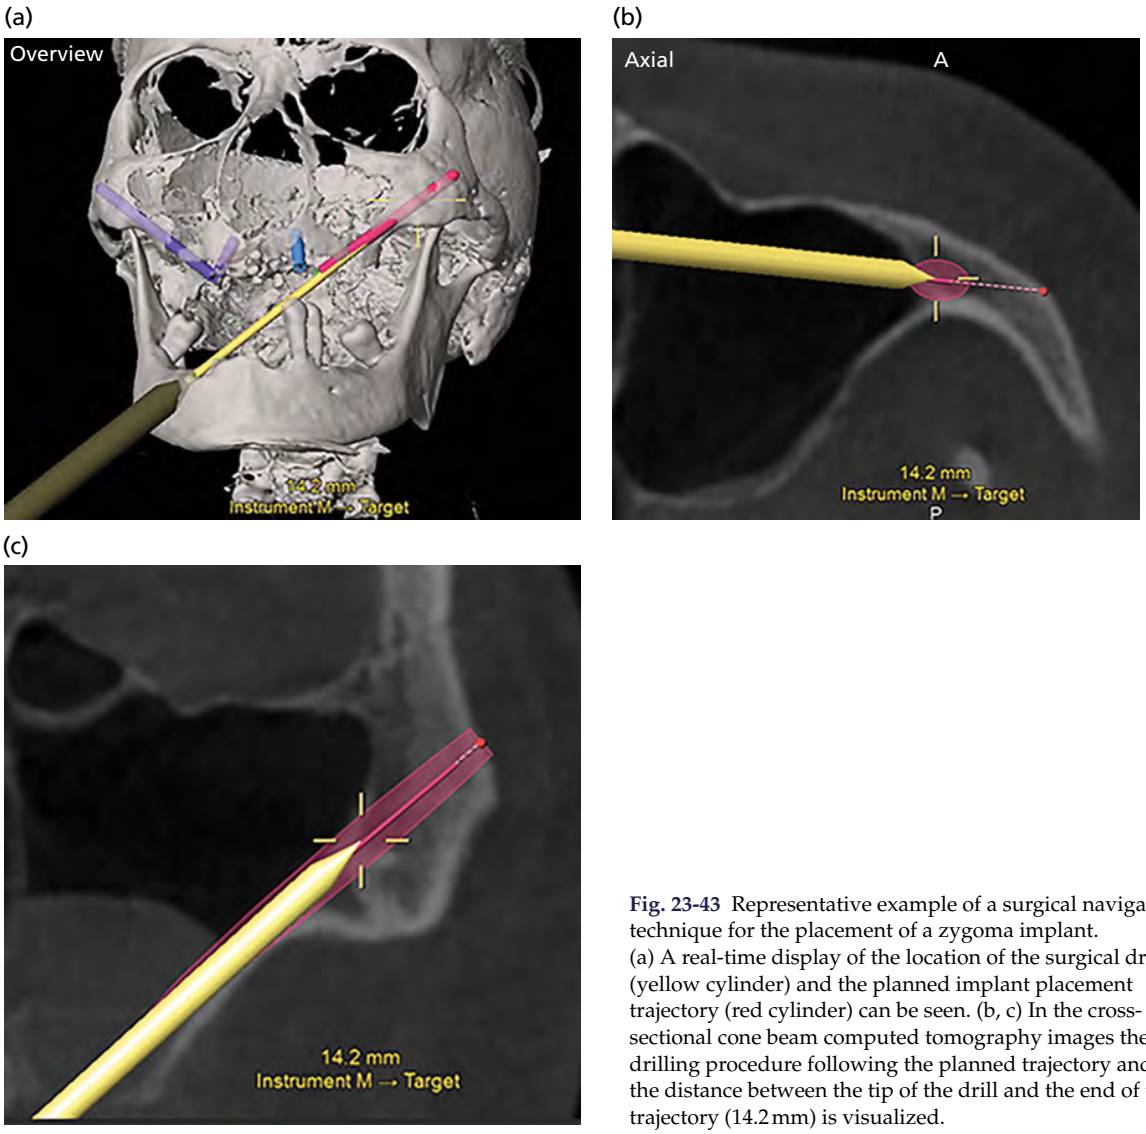

Fig. 23-43 Representative example of a surgical navigation technique for the placement of a zygoma implant. (a) A real-time display of the location of the surgical drill (yellow cylinder) and the planned implant placement trajectory (red cylinder) can be seen. (b, c) In the cross-sectional cone beam computed tomography images the drilling procedure following the planned trajectory and the distance between the tip of the drill and the end of the trajectory (14.2 mm) is visualized.

Zygoma implants

Zygoma implants are an alternative option for completely edentulous patients with severely atrophic maxilla where the placement of the conventional implants without major additional bone augmentation procedures is not feasible or possible. The planning for the zygoma implant trajectory should be made by the use of an implant planning software and MDCT/CBCT image datasets. The implant trajectory generally passes through the alveolar ridge, maxillary sinus, and zygomatic bone. An imaging evaluation only on coronal, sagittal, and axial planes of MDCT/CBCT scans cannot clearly display the complex trajectory, which may increase the risk of intraoperative complications, such as penetrating into the infratemporal fossa or lateral wall of the orbit. Thus, by using implant planning software a 360-degree observation along the axis of the planned implant is possible. This can also exhibit the portion of the implant inserted into the zygoma to optimize the bone–implant contact area and overall stability, which may be associated with the survival of the implant (Hung *et al*. 2017b). Furthermore, the presence of zygomatic nerves inside the zygoma should also be preoperatively observed on MDCT/CBCT images to avoid postoperative paresthesia. For patients with severely reduced width of the alveolar ridge, the coronal portion of a zygoma implant is very likely to lack buccal bone coverage. In this case, a flattening of the alveolar ridge, an additional horizontal bone augmentation procedure, or a more palatal placement of the implant should be considered. The relationship of the middle portion of the implant towards the lateral wall of the maxillary sinus can be classified as an intrasinus, through-sinus, or extrasinus situation (Fig. 23-44). For intrasinus and through-sinus situations, assessment of health or pathology of the maxillary sinus is mandatory prior to surgery.

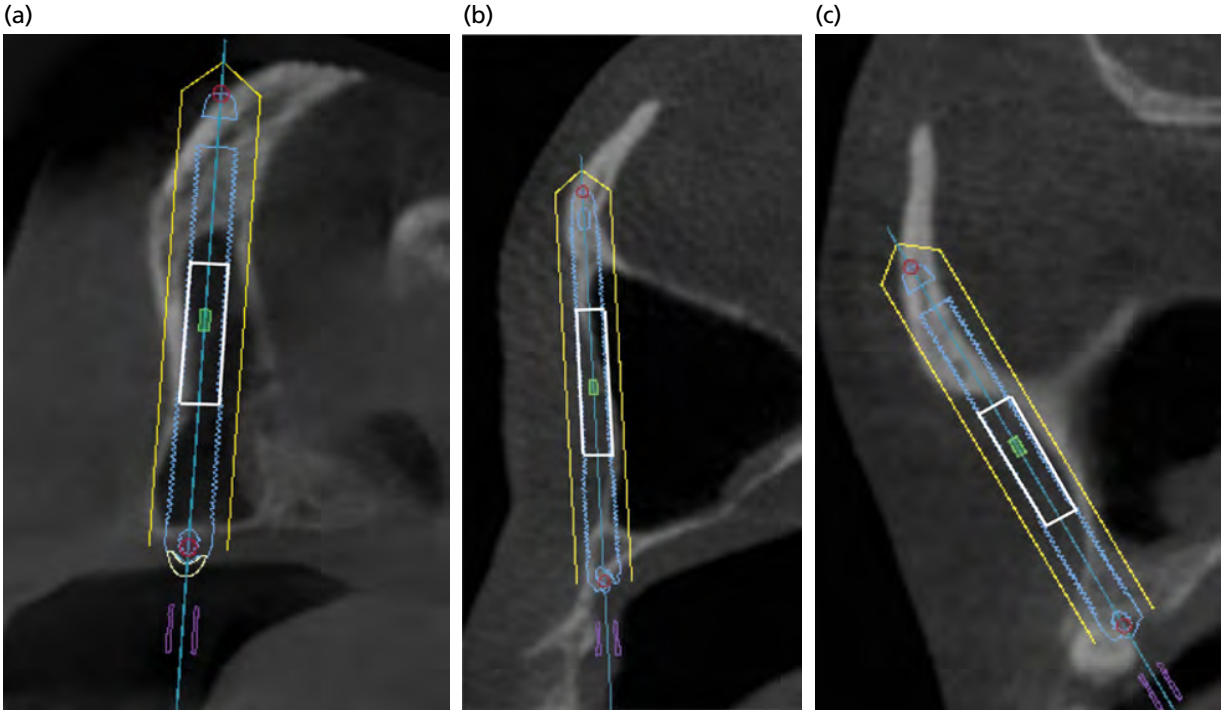

Fig. 23-44 Cross-sectional cone beam computed tomography images demonstrating the relationship of the middle portion (white rectangle) of the zygoma implant towards the lateral wall of the maxillary sinus: (a) intrasinus, (b) through-sinus, and (c) extrasinus situation.

Future trends and developments

Ultrasound

With the advent of intraoral transducers for ultrasound, research and potential applications in various fields of dental medicine have been boosted (Bhaskar *et al*. 2018). For the preoperative phase in oral implantology, ultrasound imaging is emerging as a promising tool to evaluate the phenotype of soft tissue (e.g. gingivae). In addition, ultrasound imaging has been suggested as a chairside screening device for an initial assessment of the surface morphology and buccooral dimension of the alveolar ridges at edentulous sites. In the intraoperative phase, ultrasound imaging may be used to identify the location and morphology of critical structures located on the surface of jaws, such as the greater palatine foramen, the mental foramen in edentulous patients with severely atrophied mandibles, or lingual foramina. During maintenance, ultrasound imaging may be useful to monitor marginal bone loss to identify potential peri-implantitis at an early stage without the use of conventional X-rays. All these are promising clinical applications of ultrasound imaging in oral implantology, but there is still a clear need for more research and device modifications to withstand the test of implementation in daily practice in the near future.

Magnetic resonance imaging

In the past decade, the application of MRI in implantology treatment has been mainly reported for the detection and evaluation of the mandibular canal and the neurovascular bundle from the adjacent trabecular bone, when it cannot be clearly identified on panoramic views, MDCT, or CBCT scans (Gray *et al*. 2003). However, the long imaging time of up to 30 minutes, inadequate spatial resolution with a slice thickness of 2–4 mm, the footprint of the devices, the technical expertise needed to run and maintain MRI devices, their high general cost, and also severe metal artifacts due to oral restorations, limit the application in dental medicine and more specifically for implant treatment purposes. More recently, novel MRI protocols developed for planning of implant treatment have been proposed. These protocols have shown to be able to reduce the imaging time to less than 10 minutes and also to increase the spatial resolution. These improvements put MRI on the map as a possible alternative imaging modality to evaluate the quality and quantity of bone and soft tissues at edentulous sites including anatomical landmarks of neighboring teeth such as the CEJ (Flugge *et al*. 2016; Ludwig *et al*. 2016). In addition, an MRI dataset has been reported to be promising for the production of a CAD-CAM surgical template with a comparable accuracy to a CBCT-based template (Mercado *et al*. 2019). Moreover, it is reported that the diagnostic accuracy of MRI in the evaluation of peri-implant bone defects is comparable with CBCT (Hilgenfeld *et al* 2018). Based on the non-ionizing nature of MRI, these novel possibilities in the field of implantology treatment are promising and certainly warrant further research.

Diagnostic imaging and artificial intelligence in implantology

Currently, potential applications of AI techniques in the field of implant treatment are still at an early developmental phase. AI models proposed for automated identification of changes in bone density may have potential for the diagnosis of jawbone lesions prior to implant placement or be helpful when planning for immediate loading procedures. In addition, AI models proposed for automated tooth detection and numbering on dental X-rays may be helpful to identify edentulous sites for potential future implant insertion (Tuzoff *et al*. 2019). Furthermore, AI may assist or perform automated measurements of residual alveolar ridge dimensions at edentulous sites, and also proceed with the placement of virtual implants on 3D images. This could simplify manual procedures, such as the marking of critical anatomical structures and the placement of implants on the respective images in conventional digital treatment planning workflows. After importing 3D image datasets of the patient, including intraoral scans and 3D radiographic scans such as CBCTs to an AI planning program, it could autogenerate several planning options, and the implant surgeon may then choose the best, adjusting the position of the planned implant(s) to confirm the final plan prior to production of a CAD-CAM surgical template.

On the other hand, automated identification of bone destruction around dental implants during the maintenance phase may be helpful for the (early) diagnosis of peri-implantitis. Deep learning techniques may be capable of analyzing information stored in each pixel of 2D or 3D images to help detect lesions that cannot be seen by the human eye.

Conclusions and future outlook

Unlike other dental treatment, such as tooth extraction and caries removal, periodontology and implantology treatment require a relatively long treatment and follow-up period. During this period, several imaging examinations may be required for diagnosis, treatment planning, postoperative evaluation, and follow-up assessments. A lifetime follow-up including respective radiographs to assess the periodontal/peri-implant bone condition may be necessary for patients who are susceptible to periodontal disease. Therefore, dental practitioners should always follow ALARA/ALADA principles to reduce radiation dose exposure for each imaging examination to minimize the accumulated dose to the patient. Although MDCT and CBCT allow for the visualization and assessment of anatomic structures or pathological changes in 3D with high diagnostic accuracy and precision, 2D imaging examinations are still considered as the baseline and standard of care. Thus, 3D imaging modalities should only be chosen if conventional imaging techniques do not provide sufficient information for diagnosis and treatment planning purposes in individual cases. The application of non-ionizing imaging modalities, including ultrasound and MRI, could eventually eliminate radiation dose exposures to the patient for periodontal and implant-related purposes. However, for the time being, such techniques are still limited mostly due to cost, availability, and lack of evidence.

Chapter 24

Patient-Specific Risk Assessment for Implant Therapy

Giovanni E. Salvi and Niklaus P. Lang

Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland

Introduction

From a patient's perspective the successful implant is esthetically acceptable, comfortable, low-cost, and functional. Practitioners usually discuss implant success in terms of level of marginal bone and absence of deep probing depths and mucosal inflammation. Although the two sets of criteria are not in conflict, they emphasize different points of view. During the consultation visit, before any care is delivered, the practitioner should discuss, based on patient-centered outcomes, what can be expected from placement of implants.

A final comprehensive treatment plan should be presented to the patient that includes all recommended dental therapy and alternative treatment options. The patient should also be informed about the sequence of the clinical procedures, risks and costs involved, and the anticipated total treatment time. This discussion between practitioner and patient is critically important in lowering the overall risk of treatment problems. Patients who understand what will be done, and why, are more likely to cooperate with the recommended treatment.

Systemic factors

Patient-based risk assessment begins with taking comprehensive medical and dental histories as well as conducting a complete examination of the candidate for implant therapy (see Chapter 22). A comprehensive medical history should include past and present medications and any substance used or abused. A standard medical history form filled out and signed by the patient is an efficient way to collect basic information (Fig. 24-1). This should always be followed by an interview to explore in more detail any potential medical risks of implant therapy. If any uncertainties remain regarding the patient's health after the interview, a written medical consultation should be obtained from the patient's physician.

Medical conditions

Osteoporosis

Osteoporosis is a complex group of systemic skeletal conditions characterized by low bone mass and microarchitectural deterioration of bone tissue.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Osteoporotic bone is fragile and has an increased susceptibility to fracture. Primary osteoporosis is a common condition and is diagnosed when other disorders known to cause osteoporosis are absent. Secondary osteoporosis is diagnosed when the condition is related to, or occurs as a consequence of, osteoporosis-inducing circumstances. These might include diet (e.g. starvation, calcium deficiency), congenital conditions (e.g. hypophosphatasia, osteogenesis imperfecta), drugs (e.g. alcohol abuse, glucocorticoids), endocrine disorders (e.g. Cushing's syndrome), and certain systemic diseases (e.g. diabetes mellitus, rheumatoid arthritis). Osteoporosis is assessed using bone densitometry in which a patient's bone mass or bone mineral density (BMD) is determined. BMD refers to grams of bone mineral per square centimeter of bone cross-section and is expressed in units of g/cm^2.

Scientific evidence indicates that there are no convincing findings that dental implant placement is contraindicated in the osteoporotic patient (Otomo-Corgel 2012). Implants placed in individuals with osteoporosis appear to successfully osseointegrate and can be retained for years (von Wowern & Gotfredsen 2001). However, in cases of secondary osteoporosis there are often accompanying illnesses or conditions that increase the risk of implant failure (e.g. poorly controlled diabetes

Please answer the following questions. All answers will be held in strict confidence.

1. Did you recently receive medical treatment or were hospitalized? ☐ yes ☐ no
   When yes, for which reason? _____
2. Are you currently taking medication? ☐ yes ☐ no
   When yes, which medication? _____
3. Do you suffer from any of the following diseases or disorders?
   ☐ Heart or cardiovascular disease ☐ High blood pressure ☐ Stroke
   ☐ Respiratory diseases ☐ Glaucoma ☐ Kidney disease
   ☐ Rheumatic fever ☐ Diabetes ☐ Epilepsy
   ☐ Osteoporosis ☐ Other _____
4. Have you ever had a severe infection? ☐ yes ☐ no
   ☐ Hepatitis ☐ Tuberculosis ☐ HIV
5. Do you have allergies? ☐ yes ☐ no
   When yes, which one(s) _____
6. Do you experience prolonged bleeding after tooth removal or a cut wound? ☐ yes ☐ no
7. Do you take blood thinners? ☐ yes ☐ no
8. Do you carry a medical alert card? ☐ yes ☐ no
9. Do you have a joint replacement? ☐ yes ☐ no
10. Have you suffered or are you suffering from a disease, which is not listed above? ☐ yes ☐ no
    When yes, which one(s) _____
11. Have you ever had a medical emergency during a dental appointment? ☐ yes ☐ no

mellitus, corticosteroid medications). Therefore, in the patient-specific risk assessment the presence of osteoporosis should alert the clinician to the possible presence of osteoporosis-associated circumstances that are known to increase the risk of implant failures.

Diabetes mellitus

Although there is a slight tendency for increased implant loss in a patient with diabetes compared with a patient without diabetes, the increased risk is not substantial in patients who are under good metabolic control (Shernoff *et al*. 1994; Kapur *et al*. 1998; Balshi & Wolfinger 1999; Fiorellini *et al*. 2000; Morris *et al*. 2000; Olson *et al*. 2000).

Patients with diabetes under suboptimal metabolic control often experience wound-healing difficulties and have an increased susceptibility to infections due to a variety of problems associated with immune dysfunctions. Solid clinical evidence, however, for the association of glycemic control with implant loss is lacking (Oates *et al*. 2013). In the risk evaluation of patients with diabetes it is important to establish the level of metabolic control of the disease. A useful test to determine the level of control over the last 90 days is a blood test for glycosylated hemoglobin (HbA_{1c}). This is a test for the percentage of hemoglobin to which glucose is bound. Normal values for a healthy individual or a patient with diabetes under good metabolic control are HbA_{1c} <6–6.5% and fasting blood

glucose <6.1 mmol/L (110 mg/dL). Patients with diabetes with HbA_{1c} values >8% are considered poorly controlled and have an elevated risk of encountering wound healing problems and infections.

Immunosuppression

In the early years of the AIDS epidemic, placement of dental implants was ill advised since affected patients developed major life-threatening oral infections. With the advent of effective HAART (i.e. highly active anti-retroviral therapy) regimens, most HIV-positive patients who take their medications live for many years without developing severe opportunistic infections. There have been no controlled studies dealing with the risk of dental implant failures in HIV-positive individuals. However, several publications suggest that placement of dental implants in HIV-positive patients is not associated with elevated failure rates (Rajnay & Hochstetter 1998; Baron et al. 2004; Shetty & Achong 2005; Achong *et al*. 2006; Oliveira *et al*. 2011). Low T-helper (CD4) cell counts (i.e. <200/μL) do not appear to predict increased susceptibility to intraoral wound infections or elevated failure rates of dental implants (Achong *et al*. 2006). Although more studies are needed, it appears that it is safe to place dental implants if the patient's HIV disease is under medical control.

History of radiation therapy to the jaws

Patients who have received radiation (i.e. absorbed dose of ≥60 Gy) to the head and neck as part of the treatment for malignancies are at an increased risk of developing osteoradionecrosis (ORN). Most cases of this complication of cancer treatment are triggered by the extraction of teeth or other oral surgery procedures such as insertion of implants. Implant failure rates of up to 40% have been reported in patients who have had a history of radiation therapy (Granström *et al*. 1993, 1999; Beumer *et al*. 1995; Lindquist *et al*. 1988). At one time it was believed that ORN was due to vascular derangement and hypoxia of bone cells caused by the tissue-damaging effects of radiation (Teng & Futran 2005). Based on this hypothesis, it has been recommended that oral surgical procedures in patients at risk of ORN be performed in conjunction with hyperbaric oxygen (HBO) therapy. Indeed, Granström *et al*. (1999) reported that use of HBO therapy improved implant survival rates. However, the value of HBO therapy for the management of ORN has been called into question partly based on a placebo-controlled, randomized clinical trial (Annane *et al*. 2004) and other reports indicating no advantage to HBO interventions (Maier *et al*. 2000; Gal *et al*. 2003). In addition, a systematic review by Coulthard *et al*. (2008) indicated that there is no evidence that HBO therapy improves implant survival in irradiated patients.

It is now believed that the pathogenesis of ORN is much more complex than a simple hypoxia-related phenomenon related to poor vascularity of irradiated tissues. Current evidence supports the view that ORN is a fibroatrophic process (Teng & Futran 2005). From the perspective of risk-assessment procedures for implant placement, patients who have a history of irradiation to the jaws should be considered at high risk for implant loss and HBO interventions will probably not lower that risk.

Hematologic and lymphoreticular disorders

A number of hematologic and lymphoreticular disorders carry an increased susceptibility to periodontitis and other infections (Kinane 1999). Among these disorders are: agranulocytosis, acquired neutropenia, cyclic neutropenia, leukocyte adherence deficiency, and aplastic anemia (e.g. Fanconi's syndrome). Since patients with these diseases frequently lose teeth early in life they often have extensive prosthetic needs that can be met by the placement of dental implants. In the risk-assessment process prior to implant placement the major concern to be considered is the increased susceptibility to infections that could occur around any implants that might be placed. There are no well-controlled studies of the success rates of implants placed in patients with these disorders. However, implants can be placed if the patient's disease is under control or in remission and a rigorous supportive therapy program must be an integral part of the overall treatment plan.

Medications

Bisphosphonates

Bisphosphonates are a widely prescribed class of drugs used for the treatment of osteoporosis and to reduce the bone-lytic effects of malignancies such as multiple myeloma and metastatic breast cancer (Woo *et al*. 2006). These pyrophosphate drugs are potent inhibitors of osteoclast activity that also have antiangiogenic effects by inhibiting the production of vascular endothelial growth factor (VEGF). The drugs have a high affinity for hydroxyapatite, are rapidly incorporated into all parts of the skeleton and have a very long half-life (i.e. decades). Relative potencies of the agents depend on their formulation. A complication associated with the use of bisphosphonates is the increased risk of developing osteonecrosis of the jaws (i.e. bisphopsphonates-related osteonecrosis of the jaws, BRONJ) (Ruggiero *et al*. 2004; Marx *et al*. 2005; Braun & Iacono 2006). The vast majority of cases of BRONJ occur in cancer patients who have received high-potency aminobisphosphonates (e.g. zoledronate, pamidronate) delivered intravenously to decrease the osteolytic effects of multiple myeloma or malignancies that have metastasized to bone (e.g. breast or prostate cancer).

Of major concern to the prospective implant patient who has been taking an oral bisphosphonate for osteoporosis is the possible risk of developing BRONJ after implant placement. Oral bisphosphonates have been reported to be associated with implant failure (Starck & Epker 1995; Chappuis *et al*. 2018) and BRONJ (Ruggiero *et al*. 2004; Marx *et al*. 2005; Kwon *et al*. 2012). Since bisphosphonates tightly bind to hydroxyapatite and have a very long half-life, it is likely that the length of time a patient has been taking oral bisphosphonates is important in determining the level of risk. Since oral bisphosphonates slowly accumulate in bone with time, an osteoporosis patient who has been taking the drug for 1 year is at a lower risk of developing BRONJ or implant failure than someone who has been on the drug for many years. It should be kept in mind that bone-remodeling processes are inhibited in patients who have been chronically taking oral bisphosphonates for osteoporosis. Collectively, the duration, the route (i.e. oral or intravenous), the type of bisphosphonate, and the dosage of the medication play an important role in the development of BRONJ (Bornstein *et al*. 2009; Madrid & Sanz 2009a; Otomo-Corgel 2012).

Anticoagulants

Patients who have blood-coagulation disorders or are taking anticoagulants are at an elevated risk of experiencing postoperative bleeding problems after implant surgery. Some patients with coagulation disorders may be at an elevated risk of implant loss (van Steenberghe *et al*. 2003), whereas other patients who chronically take oral anticoagulants can safely receive dental implants (Weischer *et al*. 2005). Patients who are on continuous oral anticoagulant therapy (e.g. coumarin derivatives, rivaroxaban) to reduce the risk of thromboembolic events and require dental implants for optimal restorative care should be evaluated on a case-by-case basis. Most of these patients can safely continue their anticoagulant therapy when they receive standard implant surgery (Madrid & Sanz 2009b). In such patients, local bleeding after the placement of dental implants can usually be well controlled by conventional hemostatic methods. The risk of developing life-threatening bleeding or bleeding that cannot be controlled using local measures following placement of dental implants is so low that there is no need to stop oral anticoagulant therapy (Beirne 2005). In addition, the risk of discontinuing anticoagulant medication prior to implant surgery thereby increasing the probability of thromboembolic events must be accounted for (Madrid & Sanz 2009b).

Therapeutic levels of an anticoagulant drug are measured by the international normalized ratio (INR) which is the patient's prothrombin time (PT) divided by the mean normal PT for the laboratory (i.e. PTR). The PTR is then adjusted for the reagents used to arrive at a standardized INR value that will be comparable anywhere in the world. A higher INR reflects a higher level of anticoagulation with an expected increased risk of hemorrhage (Herman *et al*. 1997). Although there are insufficient data to draw any evidence-based conclusions, placement of single implants is regarded as safe when the INR target values are 2.0–2.4 (Herman *et al*. 1997).

Cancer chemotherapy

Oral cancer patients are frequently candidates for the placement of dental implants since prostheses designed to replace missing portions of the jaws need to be anchored to implants. Since antimitotic drugs used as chemotherapy for cancer might affect wound healing and suppress components of the immune system, it is important to know if these drugs interfere with osseointegration and success of dental implants. In a retrospective study, implant success was compared in 16 oral cancer patients who had no chemotherapy with that in 20 patients who received postsurgical adjuvant chemotherapy with either cis- or carboplatin and 5-fluorouracil (Kovács 2001). It was found that these drugs did not have any detrimental effects on the survival and success of implants placed in the mandible. It has also been reported that some cancer patients who received cytotoxic antineoplastic drugs experienced infections around existing dental implants (Karr *et al*. 1992). Therefore, it is important to recognize that many anticancer drugs suppress or kill cells necessary for optimal innate and adaptive immunity. Patients who are receiving cancer chemotherapy should have thorough periodontal and supportive therapy in order to minimize the development of biologic complications.

Immunosuppressive agents

Any medication that interferes with wound healing or suppresses components of innate and adaptive immunity (e.g. corticosteroids) can theoretically increase the risk of implant loss. These drugs are potent anti-inflammatory agents that are commonly used for the management of a wide variety of medical conditions such as after liver transplants (Gu & Yu 2011). They can interfere with wound healing by blocking key inflammatory events needed for satisfactory repair. In addition, through their immunosuppressive effects on lymphocytes, they can increase the rate of postoperative infections. In general, these undesirable effects are greatest in patients who take high doses of the drugs for long periods of time.

Other medications

Recently, outcomes of a systematic review (Chappuis *et al*. 2018) indicated that proton pump inhibitors and serotonin reuptake inhibitors are significantly associated with implant loss. Hence, clinicians should consider the increased risk for implant loss in candidates for implant therapy and under the medication of such drugs.

Age

In adult patients, age is usually not considered a risk factor for implant loss. Indeed, most longitudinal studies of survival rates of implants include some patients who are well over 75 years of age (Dao *et al*. 1993; Hutton *et al*. 1995; Nevins & Langer 1995; Davarpanah *et al*. 2002; Becktor *et al*. 2004; Fugazzotto *et al*. 2004; Karoussis *et al*. 2004; Fransson *et al*. 2005; Herrmann *et al*. 2005; Quirynen *et al*. 2005; Mundt *et al*. 2006; Wagenberg & Froum 2006). An upper age limit is usually not listed as an exclusion criterion in such studies. Several reports indicate that there is not a statistically significant relationship between age of the patient and implant loss (Dao *et al*. 1993; Hutton *et al*. 1995; Bryant & Zarb 1998; Fransson *et al*. 2005; Herrmann *et al*. 2005; Mundt *et al*. 2006; Wagenberg & Froum 2006). It cannot be excluded that there may have been some selection bias in the above studies since older patients might have been excluded for medical reasons. On the other hand, older individuals included in the above studies may be atypical in that they were healthy enough to be good candidates for implant placement.

Outcomes of a longitudinal retrospective study indicated that patients aged 65 and older presented a similarly low rate of early implant loss compared with patients aged 35 to <55 years, while patients aged 80 years and older displayed a slight tendency for a higher rate of early implant loss suggesting that ageing does not seem to substantially compromise early wound healing of dental implants (Bertl *et al*. 2019).

Growth considerations

At the other end of the spectrum, a potential problem associated with the placement of dental implants in still-growing children and adolescents is the possibility of interfering with growth patterns of the jaws (Op Heij *et al*. 2003). Osseointegrated implants in growing jaws behave like ankylosed teeth in that they do not erupt and the surrounding alveolar housing remains underdeveloped. Dental implants may be of great help to young people who have lost teeth due to trauma or have congenitally missing permanent teeth. However, because of the potential deleterious effects of implants on growing jaws it is highly recommended that implants are not placed until craniofacial growth has ceased or is almost complete (Thilander *et al*. 2001). As a rule of thumb, implants should not be placed in young adults of less than 20 years of age.

Untreated periodontitis and oral hygiene habits

The association between self-performed oral hygiene levels and peri-implantitis has been shown to be dose-dependent (Ferreira *et al*. 2006). Partially edentulous patients with very poor and poor oral hygiene are at statistically significantly higher risks of developing peri-implant mucositis and peri-implantitis compared with patients with proper biofilm control (Ferreira *et al*. 2006). A direct cause–effect relationship between a 3-week period of abolished oral hygiene practices with experimental biofilm accumulation and the development of experimental peri-implant mucositis has been shown in humans (Pontoriero *et al*. 1994; Zitzmann *et al*. 2001; Salvi *et al*. 2012). A period of 3 weeks of resumed oral hygiene practices followed the experimental biofilm accumulation period (Salvi *et al*. 2012). Despite resumed optimal biofilm control, however, 3 weeks of wound healing were insufficient to re-establish pre-experimental levels of peri-implant mucosal health (Salvi *et al*. 2012). Furthermore, it has been shown that partially edentulous patients with high biofilm scores before implant placement experience more implant losses than those with lower biofilm levels (van Steenberghe *et al*. 1993).

Based on this evidence, it may be postulated that, if left untreated, peri-implant mucositis may lead to progressive destruction of peri-implant marginal bone (i.e. peri-implantitis) and, eventually, implant loss.

Moreover, high percentages of implants diagnosed with peri-implantitis are associated with the presence of iatrogenic factors such as cement remnants (Wilson 2009; Linkevicius *et al*. 2013; Kordbacheh Changi *et al*. 2019) and with an inadequate access for self-performed oral hygiene (Serino & Ström 2009). These findings indicate that, in addition to insufficient oral hygiene habits, retentive factors are related to the presence of peri-implantitis

Based on this evidence any patient-specific risk assessment should include an evaluation of the patient's ability to maintain high levels of self-performed biofilm control (Salvi & Lang 2004).

History of treated periodontitis

Periodontitis-susceptible patients treated for their periodontal conditions may experience more biologic complications and implant losses compared with non-periodontitis patients (Hardt *et al*. 2002; Karoussis *et al*. 2003; Ong *et al*. 2008; De Boever *et al*. 2009; Matarasso *et al*. 2010; Aglietta *et al*. 2011; Kordbacheh Changi *et al*. 2019). This observation is of special interest in patients treated for Stage III–IV periodontitis and rehabilitated with dental implants (De Boever *et al*. 2009; Swierkot *et al*. 2012; Sgolastra *et al*. 2015). One implication of these findings is that patients who have lost their teeth because of periodontitis might also be more susceptible to peri-implant infections.

Outcomes from long-term clinical studies of patients with treated periodontal conditions indicated that residual pocket probing depths (PPD) ≥6 mm, full-mouth bleeding on probing (BoP^+) ≥30% and heavy smoking (i.e. ≥20 cigarettes/day) represented risk factors for periodontal disease progression and tooth

loss over a mean period of 11 years of SPT (Matuliene *et al*. 2008). Moreover, findings from two clinical studies indicated that residual PPD ≥5 mm and BoP+ after completion of periodontal therapy represented risk factors for the survival and success rates of implants placed in periodontally compromised patients (Lee *et al*. 2012; Pjetursson *et al*. 2012). In a retrospective case-control study, the effects of periodontal conditions on the outcomes of implant therapy were evaluated in periodontally compromised patients stratified according to the presence of ≥1 residual PPD ≥6 mm after a mean follow-up period of 8.2 years (Lee *et al*. 2012). Patients with ≥1 residual PPD ≥6 mm displayed a significantly greater mean peri-implant PPD and radiographic bone loss compared with both periodontally healthy and periodontally compromised patients without residual PPD, respectively (Lee *et al*. 2012). Moreover, patients with ≥1 residual PPD ≥6 mm had significantly more implants with PPD ≥5 mm with BoP+ and radiographic bone loss compared with either of the other two groups of patients (Lee *et al*. 2012). Residual PPD ≥5 mm at the end of active periodontal therapy represented a significant risk for the onset of peri-implantitis and implant loss over a mean follow-up period of 7.9 years (Pjetursson *et al*. 2012). In addition, patients enrolled in regular SPT and developing periodontal re-infections were at greater risk for peri-implantitis and implant loss compared with periodontally stable patients (Pjetursson *et al*. 2012).

From a microbiological point of view, a similar composition of the subgingival microbiota was found in pockets around teeth and implants with similar probing depths (Papaioannou *et al*. 1996; Sbordone *et al*. 1999; Hultin *et al*. 2000; Agerbaek *et al*. 2006). Moreover, evidence exists that periodontal pockets might serve as reservoirs of bacterial pathogens (Apse *et al*. 1989; Quirynen & Listgarten 1990; Mombelli *et al*. 1995; Papaioannou *et al*. 1996; van Winkelhoff et al. 2000; Fürst *et al*. 2007; Salvi *et al*. 2008) that may be transmitted from teeth to implants (Quirynen *et al*. 1996; Sumida *et al*. 2002). Therefore, the risk assessment of patients with a history of treated periodontitis should emphasize the increased risk of developing peri-implantitis and should highlight the importance of successful periodontal therapy and regular maintenance care.

Compliance with supportive therapy

Based on the fact that biological implant complications are characterized by similar etiologic factors as those involved in the development of periodontal diseases (Heitz-Mayfield & Lang 2010), it may be assumed that long-term survival and success rates of dental implants can be achieved by applying the same principles used during supportive therapy (ST) of teeth. Outcomes from long-term clinical studies indicated that compliance with ST is an essential component for the prevention of disease recurrence (e.g. caries and periodontitis) and tooth loss (Lindhe & Nyman 1984; Ramfjord 1987; Kaldahl *et al*. 1996; Rosling *et al*. 2001; Axelsson *et al*. 2004). Patients treated for stage III–IV periodontitis and subsequently enrolled in a regular ST program experienced a mean incidence of tooth loss ranging between 2% and 5% over an observation period of 10 years (Lindhe & Nyman 1984; Yi *et al*. 1995; Rosling *et al*. 2001; König *et al*. 2002; Karoussis *et al*. 2004). On the other hand, lack of compliance with ST was associated with disease progression and higher rates of tooth loss (Axelsson *et al*. 2004; Ng *et al*. 2011; Costa *et al*. 2012a). In the majority of patients complying with ST, periodontal disease progression and tooth loss occurred rarely (Ng *et al*. 2011). In non-compliant patients, however, a seven-fold increase in tooth loss due to periodontitis was reported compared with compliant patients (Ng *et al*. 2011). Despite the evident benefits of ST, however, only a minority of patients complied with the recommended recall intervals (Mendoza *et al*. 1991; Checchi *et al*. 1994; Demetriou *et al*. 1995).

Peri-implant mucositis represents a common finding among patients not enrolled in a regular ST program including anti-infective preventive measures (Roos-Jansåker *et al*. 2006). Lack of adherence of partially edentulous patients with dental implants to a regular ST program was associated with a higher incidence of peri-implantitis and implant loss compared with those of compliant patients (Costa *et al*. 2012b; Roccuzzo *et al*. 2010, 2012; Monje *et al*. 2017). In partially edentulous patients, pre-existing peri-implant mucositis in conjunction with lack of ST was associated with a higher incidence of peri-implantitis over a 5-year follow-up period (Costa *et al*. 2012b). The outcomes of that study (Costa *et al*. 2012b) yielded a 5-year incidence of peri-implantitis of 18.0% in the group of patients with ST and of 43.9% in the group without ST, respectively. The logistic regression analysis revealed that lack of ST within the overall patient sample was significantly associated with peri-implantitis with an odds ratio (OR) of 5.92. Moreover, a diagnosis of periodontitis was significantly associated with the occurrence of peri-implantitis in the overall patient sample (OR = 9.20) and particularly in patients without ST (OR = 11.43) (Costa *et al*. 2012b). Patients with a history of stage III periodontitis and erratic compliance with ST yielded a significantly higher incidence of implant losses and peri-implant bone loss ≥3 mm compared with compliant patients after a follow-up period of 10 years (Roccuzzo *et al*. 2010, 2012). On the other hand, low incidences of peri-implant bone loss and high implant survival rates were reported in patients treated for periodontal disease and enrolled in regular ST (Wennström *et al*. 2004; Rodrigo *et al*. 2012). Patients attending a ST program two to three times a year over the 5 years after implant placement experienced a high implant survival rate (i.e. 97.3%), low amounts of bone level changes during the final 4 years (i.e. 0.02 mm/year), and a low percentage (i.e. 11%) of implants with >2 mm bone loss (Wennström *et al*. 2004).

Outcomes of a prospective cohort study with a 5-year follow-up indicated that implants placed in patients with treated periodontal conditions and enrolled in ST yielded a 20% prevalence of mucositis (Rodrigo *et al*. 2012). In that study (Rodrigo *et al*. 2012), upon diagnosis of mucositis or peri-implantitis, all implants with the exception of one were successfully treated according to a cumulative interceptive anti-infective protocol (Lang *et al*. 1997). In addition, data indicated that patients susceptible to periodontitis who received dental implants as part of their oral rehabilitation displayed a higher rate of compliance with scheduled ST appointments compared with patients who underwent periodontal surgery without receiving dental implants (Cardaropoli & Gaveglio 2012). Hence, in order to achieve high long-term survival and success rates of dental implants, enrolment in regular ST including anti-infective preventive measures should be implemented (Salvi & Zitzmann 2014). Therapy of peri-implant mucositis should be considered as a preventive measure for the onset of peri-implantitis.

Tobacco use history

Tobacco use is generally accepted as an important modifiable risk factor for the development and progression of periodontitis (Johnson & Hill 2004) and peri-implantitis (Javed *et al*. 2019). The reasons that smokers are more susceptible to both periodontitis and peri-implantitis are complex, but usually involve impairment in innate and adaptive immune responses (Kinane & Chestnutt 2000; Johnson & Hill 2004) and interference with wound healing (Johnson & Hill 2004; Labriola *et al*. 2005). Based on data from several longitudinal studies on implant survival, cigarette smoking has been identified as a statistically significant risk factor for implant loss (Bain & Moy 1993; Strietzel *et al*. 2007). In addition, smoking has been associated with increased risk for peri-implant marginal bone loss (Lindquist *et al*. 1997; Galindo-Moreno *et al*. 2005; Nitzan *et al*. 2005; Aglietta *et al*. 2011) and postoperative complications after sinus floor elevation and placement of onlay bone grafts (Levin *et al*. 2004). Tobacco consumption is such a strong risk factor for implant failure that smoking-cessation protocols are implemented as part of the treatment plan for implant patients (Bain 1996; Johnson & Hill 2004).

Although cigarette smoking does not represent an absolute contraindication for implant placement, smokers should be informed that they are at increased risk of implant loss and development of peri-implantitis with odds ratios ranging from 3.6 to 4.6 (Heitz-Mayfield & Huynh-Ba 2009).

Genetic susceptibility traits

Genetic polymorphisms are small variations in base-pair components of DNA that occur with a frequency of approximately 1–2% in the general population (Kornman & Newman 2000). These small variations in genes are biologically normal and do not cause major disease. However, gene polymorphisms can affect in subtle ways how different people respond to environmental challenges. Within the context of risk assessment for implant therapy, they affect how people respond to a microbial challenge and how efficiently their wounds heal.

Polymorphisms in the interleukin-1 (*IL-1*) gene cluster on chromosome 2q13 have been associated with a hyper-responsive inflammatory reaction to a microbial challenge. A specific composite genotype of *IL-1A* and *IL-1B* polymorphisms, consisting of allele 2 of both *IL-1A* –889 (or the concordant +4845) and *IL-1B* +3954 was associated with an increased risk of severe periodontitis in non-smokers (Kornman *et al*. 1997). Several investigators have attempted to determine whether this composite IL-1 genotype can serve as a risk marker for biologic complications such as marginal bone loss or even implant loss (Wilson & Nunn 1999; Rogers *et al*. 2002; Feloutzis *et al*. 2003; Gruica *et al*. 2004; Jansson *et al*. 2005). All of these reports found that being positive for the composite *IL-1* genotype was not associated with an increased risk of marginal bone loss or other implant-related problems. Hence, based on available evidence, it may be considered irrational to recommend a systematic genetic screening of patients who are candidates for implant therapy (Huynh-Ba *et al*. 2008; Dereka *et al*. 2012).

Conclusion

Patient-based risk-assessment represents a process in which an attempt is made to identify factors or indicators increasing the risk of complications that eventually lead to implant loss. Risk assessment of the implant patient is a critically important preamble to treatment planning and if properly done can minimize the complications associated with dental implants. In many cases, early identification of these factors or indicators makes it possible to avoid or eliminate them, thereby increasing the chances of long-term implant survival and success. Most of the systemic risk factors for implant complications are those that increase the patient's susceptibility to infections or those that interfere with wound healing. Important risk factors that can interfere with wound healing around dental implants are long-term use of bisphosphonates, history of radiation therapy of the jaws, and poor metabolic control of diabetes mellitus. Additional factors such as parafunctional habits (e.g. bruxism) and relationships of the jaws (e.g. vertical and sagittal dimensions) should be included in a comprehensive patient-based risk assessment.

Based on the fact that untreated oral infections can lead to implant complications, it is highly recommended that any endodontic, periodontal, or other oral infections be treated prior to implant placement.

Part 10: Treatment Planning Protocols

Chapter 25

Treatment Planning of Patients with Periodontal Diseases

Giovanni E. Salvi[1], Niklaus P. Lang[1], and Pierpaolo Cortellini[2,3]

Introduction

Caries, periodontal disease, and peri-implant disease represent opportunistic infections caused by biofilm development on the surfaces of teeth and implants. Factors such as bacterial specificity and pathogenicity as well as the susceptibility of the individual for disease, for example local and general resistance, may influence the onset, the rate of progression, and clinical characteristics of the biofilm-associated oral disorders. Findings from animal experiments and longitudinal studies in humans, however, have demonstrated that treatment, including the elimination or the control of the biofilm infection and the introduction of careful biofilm control measures, in most, if not all, cases results in dental, periodontal, and peri-implant health. Even if health cannot always be achieved and maintained, the arrest of disease progression following treatment must be the goal of modern dental care.

The treatment of patients affected by caries, periodontal disease, and peri-implant disease, including symptoms of associated pathologic conditions such as pulpitis, periapical periodontitis, marginal abscesses, tooth migration, etc., may be divided into four different phases:

1. Systemic phase of therapy including smoking counseling
2. Initial (or hygienic) phase of periodontal therapy, that is, cause-related therapy
3. Corrective phase of therapy, that is, additional measures such as periodontal surgery, and/or endodontic therapy, implant surgery, restorative, orthodontic and/or prosthetic treatment
4. Maintenance phase (care), that is, supportive periodontal therapy (SPT).

Treatment goals

In every patient diagnosed with periodontitis, a treatment strategy including the elimination of the opportunistic infection must be defined and

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

followed. This treatment strategy must also define the clinical outcome parameters to be reached through therapy. Such clinical parameters include:

- Reduction or resolution of gingivitis (bleeding on probing [BoP]): a full-mouth mean BoP ≤20% should be reached
- Reduction in pocket probing depth (PPD): no residual pockets with PPD >5 mm should be present
- Elimination of open furcations in multirooted teeth: beginning furcation involvement should not exceed 2–3 mm in horizontal direction
- Absence of pain
- Individually satisfactory esthetics and function.

It must be emphasized that risk factors for periodontal and peri-implant diseases that can be controlled must also be addressed. The three main risk factors for periodontal and peri-implant diseases are: (1) improper biofilm control, (2) tobacco consumption, and (3) uncontrolled diabetes mellitus (Kinane *et al*. 2006; Monje *et al*. 2017).

Systemic phase (including smoking counseling)

The goal of this phase is to eliminate or decrease the influence of systemic conditions on the outcomes of therapy and to protect the patient and the dental care providers against infectious hazards.

Consultation with a physician or specialist should enable appropriate preventive measures to be taken, if necessary. Efforts must be made to stimulate a smoker to enroll in a tobacco cessation program. Additional aspects are discussed in Chapter 27.

Initial phase (hygienic phase, infection control)

This phase represents the major cause-related therapy. Hence, the objective of this phase is the achievement of clean and infection-free conditions in the oral cavity through complete removal of all soft and hard deposits and their retentive factors. Furthermore, this phase should aim at motivating the patient to perform optimal biofilm control. Moreover, the initial phase of periodontal therapy may include caries excavation and provisional root canal medication. This phase is concluded by a re-evaluation and a planning of both additional and supportive therapies.

Corrective phase (additional therapeutic measures)

This phase addresses the sequelae of the opportunistic infections and includes therapeutic measures such as periodontal and implant surgery, root canal filling, and restorative and/or prosthetic treatment. The volume of corrective therapy required and the selection of means for the restorative and prosthetic therapy can be determined only when the level of success of the cause-related therapy can be properly evaluated. The patient's willingness and ability to cooperate in the overall therapy must determine the content of the corrective treatment. If this cooperation is unsatisfactory, it may not be worth initiating treatment procedures and there will no permanent improvement in oral health, function, and esthetics. The validity of this statement can be exemplified by the results of studies aimed at assessing the relative value of different types of surgical methods in the treatment of periodontal disease. Thus, a number of clinical trials (Lindhe & Nyman 1975; Nyman *et al*. 1975, 1977; Rosling *et al*. 1976a, b; Nyman & Lindhe 1979) have demonstrated that gingivectomy and flap procedures performed in patients with proper biofilm control levels often result in gain of alveolar bone and clinical attachment, while surgery in biofilm-contaminated dentitions may cause additional destruction of the periodontium.

Maintenance phase (supportive periodontal and peri-implant therapy)

The aim of this treatment is the prevention of reinfection and disease recurrence. For each individual patient a recall system must be designed that includes: (1) assessment of deepened sites with bleeding on probing, (2) instrumentation of such sites and (3) fluoride application for the prevention of dental caries (see Chapter 48). In addition, this treatment involves the regular control of prosthetic restorations incorporated during the corrective phase of therapy. Tooth sensitivity testing is applied to abutment teeth owing to the fact that loss of vitality represents a frequently encountered complication (Bergenholtz & Nyman 1984; Lang *et al*. 2004; Lulic *et al*. 2007). Based on the individual caries activity, bitewing radiographs should be incorporated in SPT at regular intervals.

Screening for periodontal disease

A patient seeking dental care is usually screened for the presence of carious lesions by means of clinical and radiographic examination. Likewise, it is imperative that such a patient is screened for the presence of periodontitis as well using a procedure termed the *basic periodontal examination* (BPE) or periodontal screening record (PSR).

Basic periodontal examination

The goal of the BPE is to screen the periodontal conditions of a new patient and to facilitate treatment planning. BPE scoring will allow the therapist to identify:

- Healthy or marginally inflamed (i.e. gingivitis) periodontal conditions in need of long-term preventive measures
- Periodontitis in need of periodontal therapy.

In the BPE the screening of each tooth or implant is evaluated. For this purpose, the use of a thin

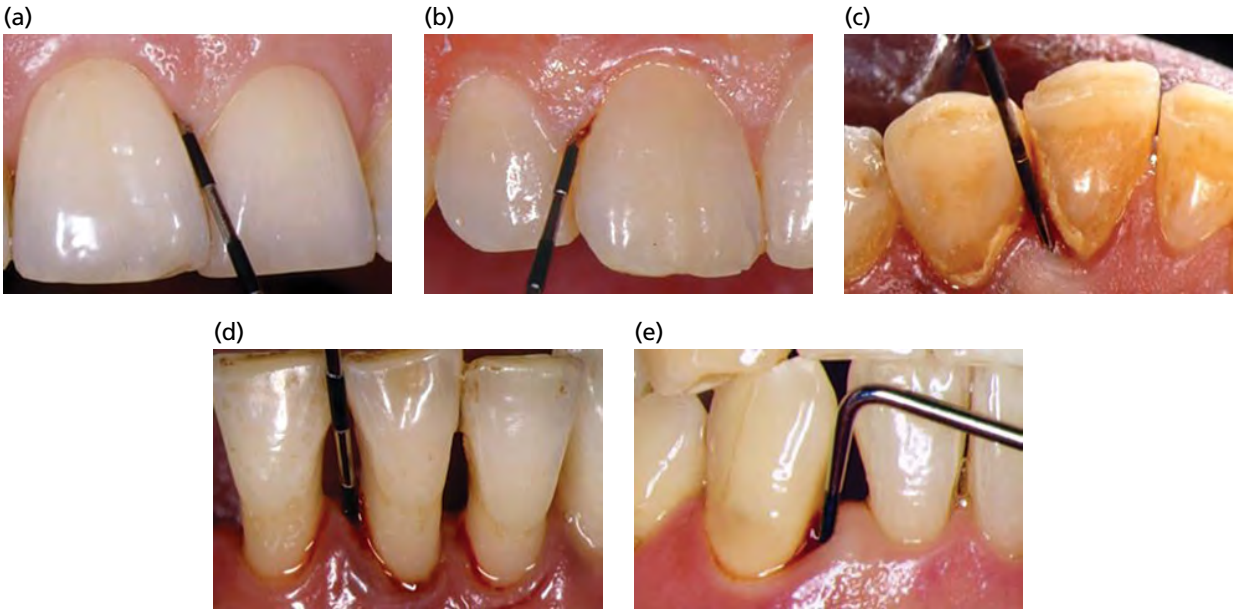

Fig. 25-1 Basic periodontal examination system code. (a) Code 0. (b) Code 1. (c) Code 2. (d) Code3. (e) Code 4. See text for details.

graduated periodontal probe is recommended. At least two sites per tooth/implant (i.e. mesiobuccal and distobuccal) should be probed using a light force (i.e 0.2 N). Each dentate sextant within the dentition is given a BPE code or score, whereby the *highest* individual site score is used.

BPE system code

- *Code 0*: PPD ≤3 mm, BoP negative, no calculus or overhanging fillings (Fig. 25-1a).
- *Code 1*: PPD ≤3 mm, BoP positive, no calculus or overhanging fillings (Fig. 25-1b).
- *Code 2*: PPD ≤3 mm, BoP positive, presence of supra- and/or subgingival calculus and/or overhanging fillings (Fig. 25-1c).
- *Code 3*: PPD >3 mm but ≤5 mm, BoP positive (Fig. 25-1d).
- *Code 4*: PPD >5 mm (Fig. 25-1e).

If an examiner identifies one single site with PPD >5 mm within a sextant, the sextant will receive a code of 4, and no further assessments are needed in this particular sextant. Patients with sextants given codes of 0, 1, or 2 belong to the relatively periodontally healthy category. A patient exhibiting a sextant with codes of 3 or 4 must undergo a more comprehensive periodontal examination (for details see Chapter 22).

The aim of the following text is to explain the overall objectives of the treatment planning of patients with BPE codes of 3 and 4 undergoing a comprehensive diagnostic process.

Diagnosis

The basis for the treatment planning described in this chapter is established by the clinical data collected from the patient's examination (see Chapter 22). As an example, a 27-year-old systemically healthy and non-smoking female patient (S.B.) was examined with respect to her periodontal conditions: gingival sites displaying signs of *BoP* were identified, *PPD* were measured, the *periodontal attachment level* was calculated, *furcation involvements* were graded, *tooth mobility* was assessed, and the radiographs were analyzed to determine the *height* and *outline* of the *alveolar bone crest*.

The clinical characteristics of the dentition of this patient are shown in Fig. 25-2. The periodontal chart and the radiographs are presented in Fig. 25-3 and Fig. 25-4, respectively. Based on these findings, each tooth in the dentition was given a diagnosis of either gingivitis or periodontitis and a pretherapeutic prognosis (Fig. 25-5). In addition to the examination of the periodontal conditions, detailed assessments of primary and recurrent caries were made for all tooth surfaces in the dentition. Furthermore, the patient was examined with respect to endodontic and occlusal problems as well as temporomandibular joint dysfunctions.

Treatment planning

Initial treatment plan

Provided that the patient's examination has been completed (see Chapter 22) and a diagnosis of all pathologic conditions has been made, an initial treatment plan can be established. At this early stage in the management of a patient, it is, in most instances, impossible to make definite decisions regarding all aspects of the treatment sequence, because:

1. *The degree of success of initial therapy is unknown.* The re-evaluation after initial, cause-related therapy forms the basis for the selection of the type of additional therapy. The degree of disease elimina-

Fig. 25-2 (a–d) Clinical extra- and intraoral photographs of a 27-year-old female patient (S.B.) diagnosed with periodontitis stage III grade C with furcation involvement.

tion that can be reached depends on the outcome of subgingival instrumentation, but also on the patient's ability and willingness to exercise proper biofilm control and to adopt adequate dietary habits.

2. *The patient's "subjective" need for additional (periodontal and/or restorative) therapy is unknown*. When the dentist has completed the examination of the patient and an inventory has been made regarding periodontal and/or peri-implant diseases, caries, pulpal disease, and temporomandibular joint disorders, the observations are presented to the patient (i.e. "the case presentation"). During the session of case presentation it is important to find out if the patient's subjective need for dental therapy coincides with the dentist's professional appreciation of the kind and volume of therapy that is required. It is important that the dentist understands that the main objective of dental therapy, besides *elimination of pain, is to satisfy the patient's claims regarding chewing function (comfort) and esthetics*, demands that certainly vary considerably from one individual to another.
3. *The result of some treatment steps cannot be predicted*. In patients exhibiting advanced forms of caries and periodontal or peri-implant diseases it is often impossible to anticipate whether or not all teeth that are present at the initial examination can be successfully treated, or to predict the result of certain parts of the intended therapy. In other words, critical and difficult parts of the treatment must be performed first, and the outcome of this treatment must be evaluated before all aspects of the definitive corrective phase can be properly anticipated and described.

Pretherapeutic single tooth prognosis (Fig. 25-5)

Based on the results of the comprehensive examination including assessments of periodontitis, peri-implantitis, caries, tooth sensitivity, and the resulting diagnosis, as well as considering the patient's needs regarding esthetics and function, a pre-therapeutic prognosis for each individual tooth (root) is made.

Three major questions are addressed:

1. Which tooth/root has a "*good" (secure)* prognosis?
2. Which tooth/root is "*irrational-to-treat*"?
3. Which tooth/root has a *"doubtful"(insecure)* prognosis?

Teeth with a *good* prognosis will require relatively simple therapy and may be regarded as secure abutments for function.

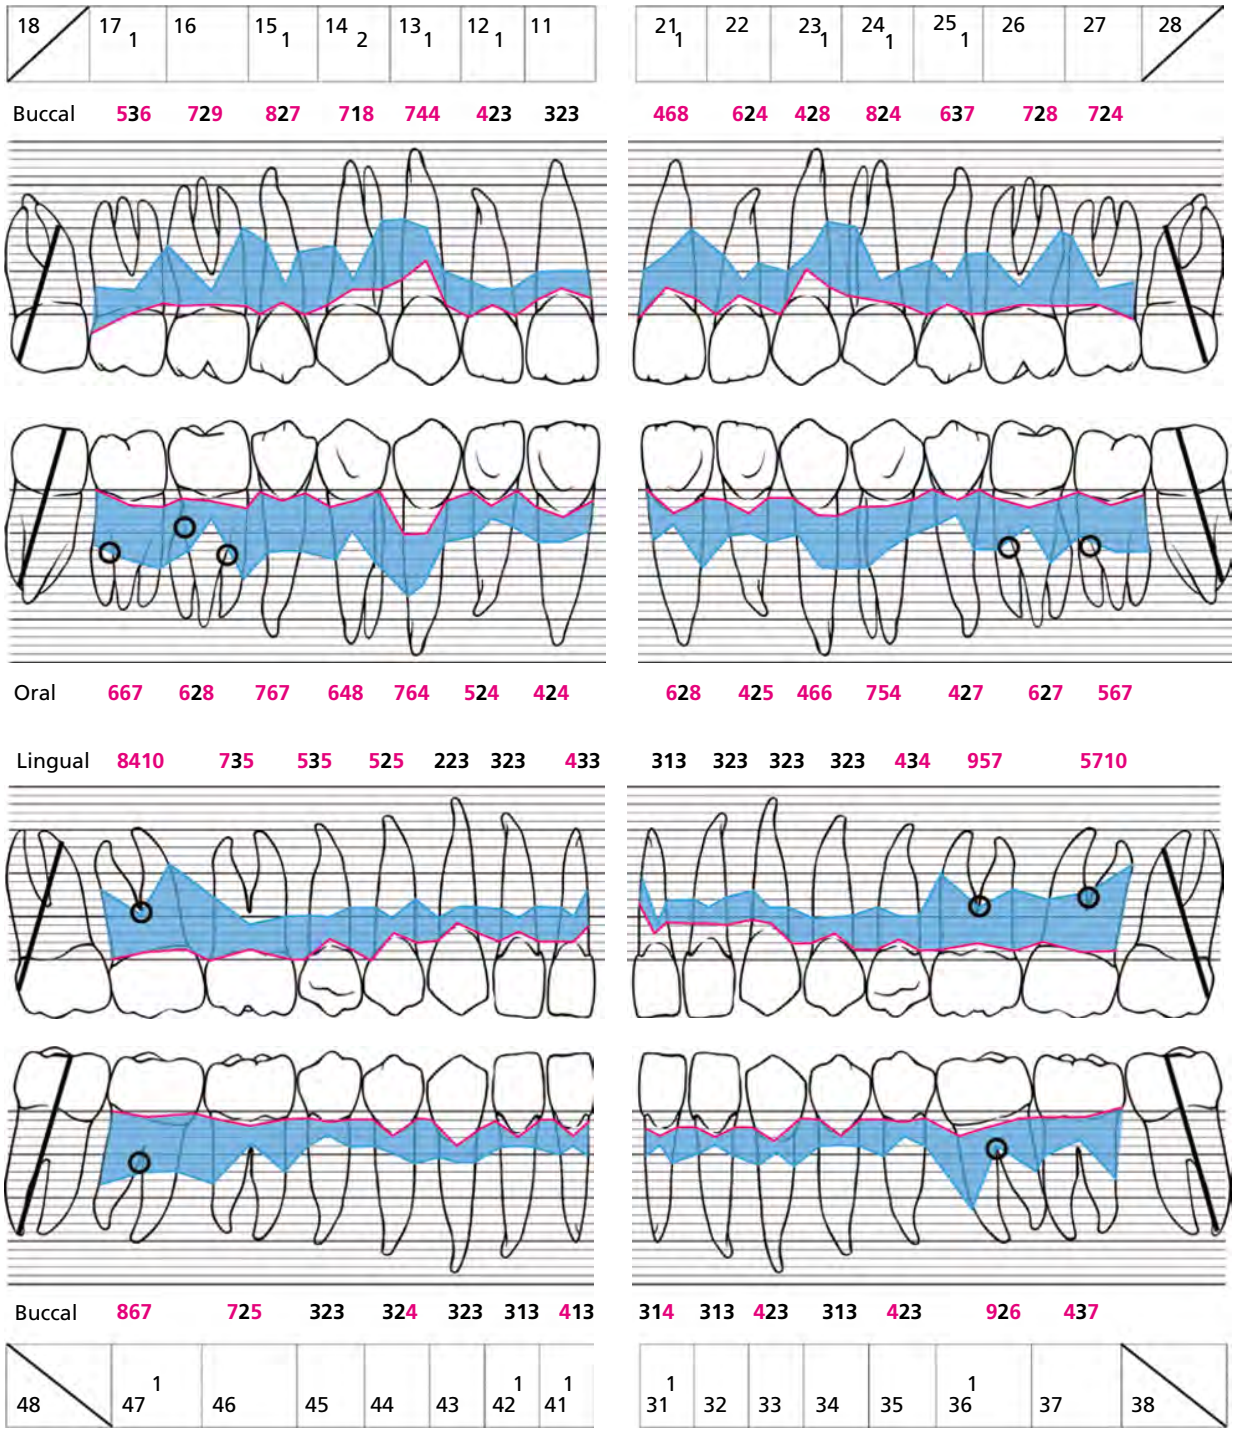

Fig. 25-3 Periodontal chart of the patient presented in Fig. 25-2.

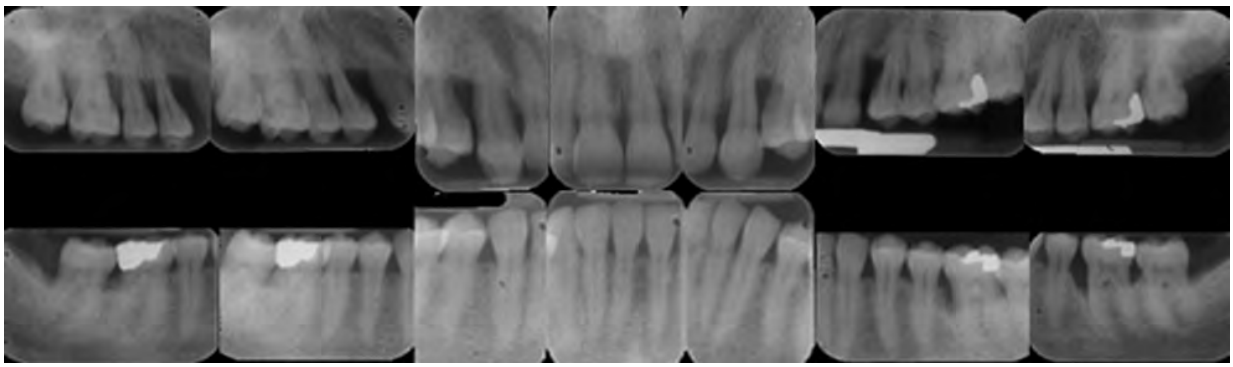

Fig. 25-4 Radiographs of the patient presented in Fig. 25-2.

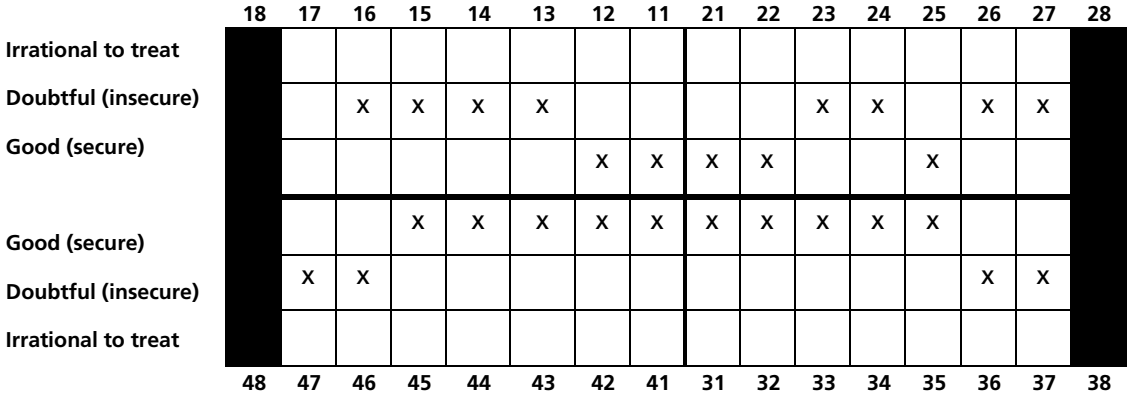

Fig. 25-5 Pretherapeutic single tooth prognosis of the patient presented in Fig. 25-2.

Teeth that are considered "irrational-to-treat" should be extracted during initial, cause-related therapy. Such teeth may be identified on the basis of the following criteria:

- *Periodontal:*
  - Recurrent periodontal abscesses
  - Combined periodontal-endodontic lesions
  - Attachment loss to the apical region.
- *Endodontic:*
  - Root perforation in the apical half of the root
  - Extensive periapical lesions (i.e. diameter >6 mm).
- *Dental:*
  - Vertical fracture of the root (hairline fracture)
  - Oblique fracture in the middle third of the root
  - Caries lesions extending into the root canal.
- *Functional:*
  - Third molars without antagonists and with periodontitis/caries.

Teeth with a *doubtful (insecure)* prognosis are usually in need of comprehensive therapy and must be brought into the category of teeth with a *good (secure)* prognosis by means of additional therapy. Such teeth may be identified on the basis of the following criteria:

- *Periodontal:*
  - Furcation involvement (class II or III)
  - Angular (i.e. vertical) bony defects
  - "Horizontal" bone loss involving more than two-thirds of the root
- *Endodontic:*
  - Incomplete root canal therapy
  - Periapical pathology
  - Presence of voluminous posts/screws.
- *Dental:*
  - Extensive root caries.

Case presentations

Case presentation 1

The "case presentation" is an essential component of the initial treatment plan and must include a description for the patient of different therapeutic goals and the modalities by which these may be reached. At the case presentation for patient S.B. the following treatment plan was described:

- The teeth in the dentition from 12 to 22 and from 45 to 35 will probably not confront the dentist with any major therapeutic challenges. For the remaining teeth in the dentition, however, the treatment plan may involve several additional measures.

Expected benefits inherent to a certain treatment plan versus obvious disadvantages should always be explained to and discussed with the patient. His/her attitude to the alternatives presented must guide the dentist in the design of the overall treatment plan.

Based on the pretherapeutic single tooth prognosis (Fig. 25-5), the following detailed treatment plan was presented to the patient.

Systemic phase

Owing to the fact that the patient was systemically healthy and a non-smoker, no medical examination and tobacco cessation counseling were required.

Initial phase (cause-related therapy, infection control)

The treatment was initiated and included the following measures to eliminate or control the bacterial infection:

1. *Motivation* of the patient and *instruction* in oral hygiene practices with subsequent check-ups and reinstruction.
2. *Scaling and root planing* under local anesthesia in combination with removal of biofilm retentive factors and teeth irrational to treat, if any.
3. *Excavation and restoration* of carious lesions of teeth 16 and 26.
4. *Endodontic treatment* of tooth 46.

Re-evaluation after initial phase

The initial phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination or degree of control of

Fig. 25-6 (a–c) Intraoral photographs of the patient presented in Fig. 25-2 at re-evaluation after initial non-surgical periodontal therapy.

the oral infections. This implies that a re-evaluation of the patient's periodontal conditions and caries activity must be performed. The results of this re-evaluation (Figs. 25-6, 25-7) form the basis for the selection, if necessary, of additional corrective measures to be performed in the phase of definitive treatment (i.e. corrective phase). In order to provide time for the tissues to heal, the re-evaluation should be performed not earlier than 6–12 weeks following the last session of subgingival mechanical instrumentation.

Planning of the corrective phase (i.e. additional therapy)

If the results of the re-evaluation, performed 6–12 weeks after completion of the initial treatment phase, show that periodontal disease and caries have been brought under control and the treatment goals (see previously) have either been reached completely or have been approached substantially, the additional treatment may be carried out. The main goal of this phase is to correct the sequelae caused by oral infections (i.e. periodontal and peri-implant diseases and caries). The following procedures may be performed:

- *Additional endodontic treatment with/without post-and-core build-ups*.
- *Periodontal surgery*: type (i.e. open flap debridement, regenerative or resective surgery) and extent of surgical treatment should be based on PPD measurements, degree of furcation involvement and BoP scores assessed at re-evaluation. Periodontal surgery is often confined to those areas of the dentition where the inflammatory lesions were not resolved by root instrumentation alone, in areas with angular bony defects or in furcation-involved multirooted teeth.
- *Installation of oral implants*: in regions of the dentition where tooth abutments are missing, implant therapy for esthetic and functional reasons may be considered. *It is essential to realize that implant therapy must be initiated when all dental infections are under control, i.e. after successful periodontal therapy.*
- *Definitive restorative and prosthetic treatment* including fixed or removable dental prostheses.

Corrective phase (additional therapy)

Patient S.B. exhibited, after initial therapy, low plaque and gingivitis scores (i.e. 5–10%) and no active carious lesions. The corrective phase, therefore, included the following components:

1. *Periodontal surgery (i.e. open flap debridement)* in the maxillary left and right quadrants as well as in the mandibular molar regions (Fig. 25-8)

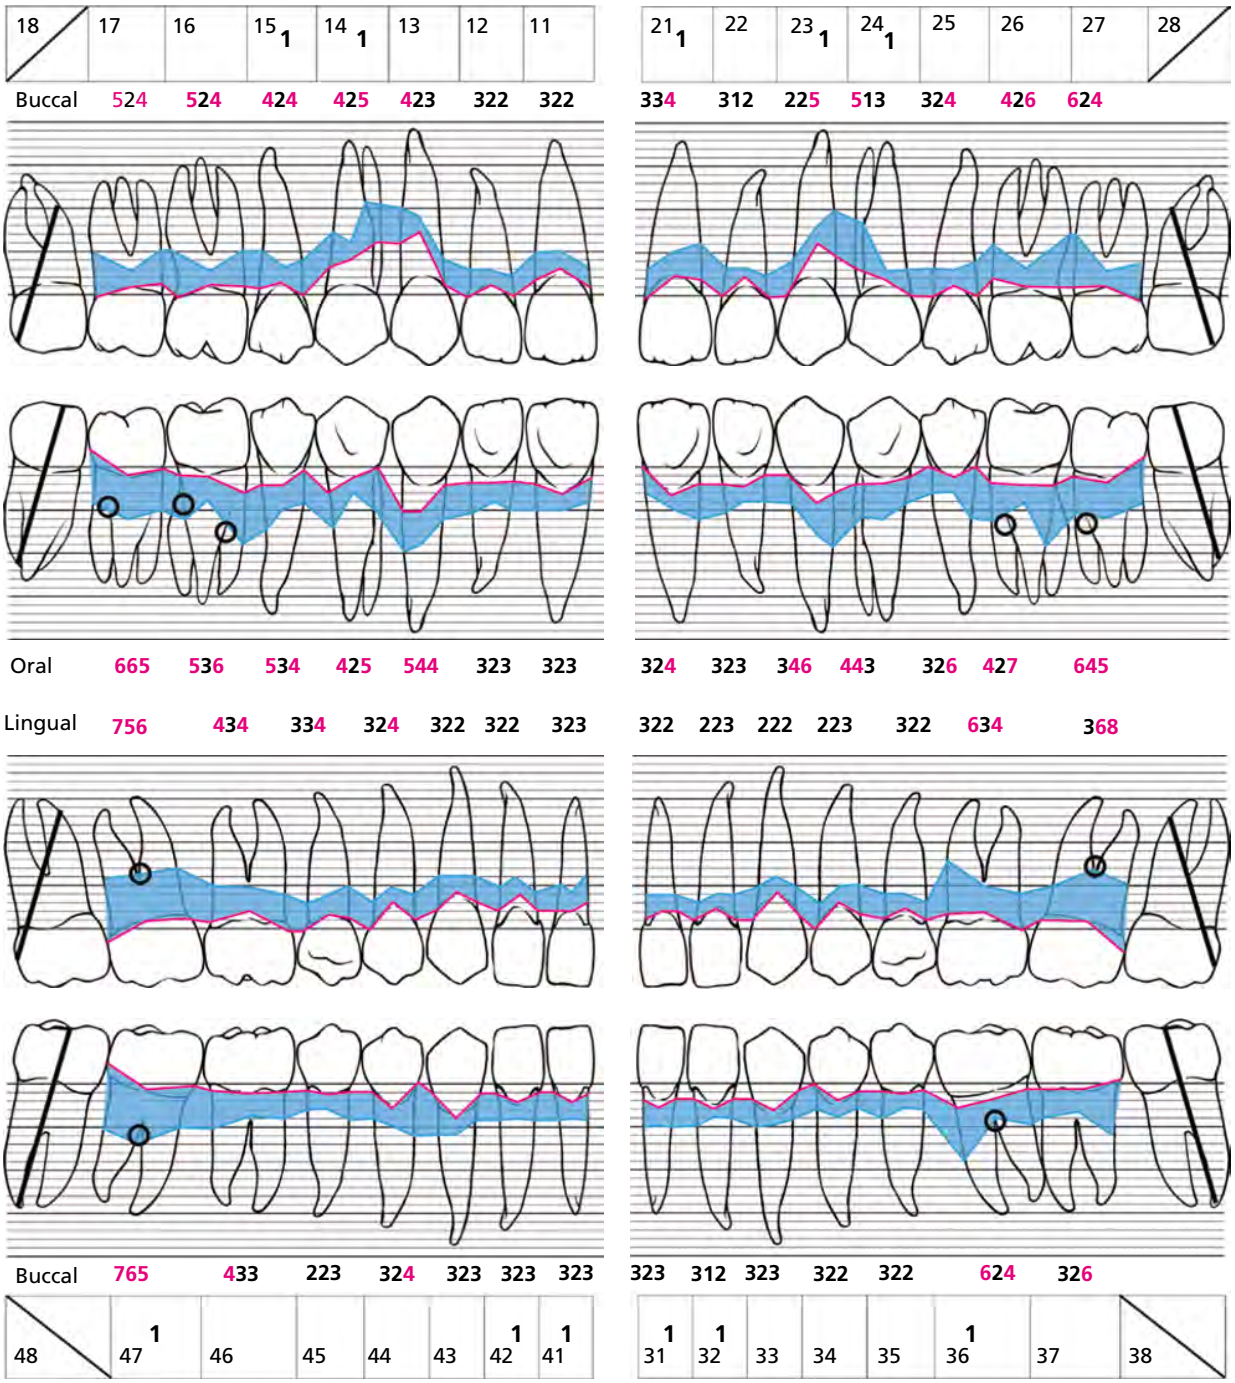

Fig. 25-7 Periodontal chart of the patient presented in Fig. 25-2 at re-evaluation after initial non-surgical periodontal therapy.

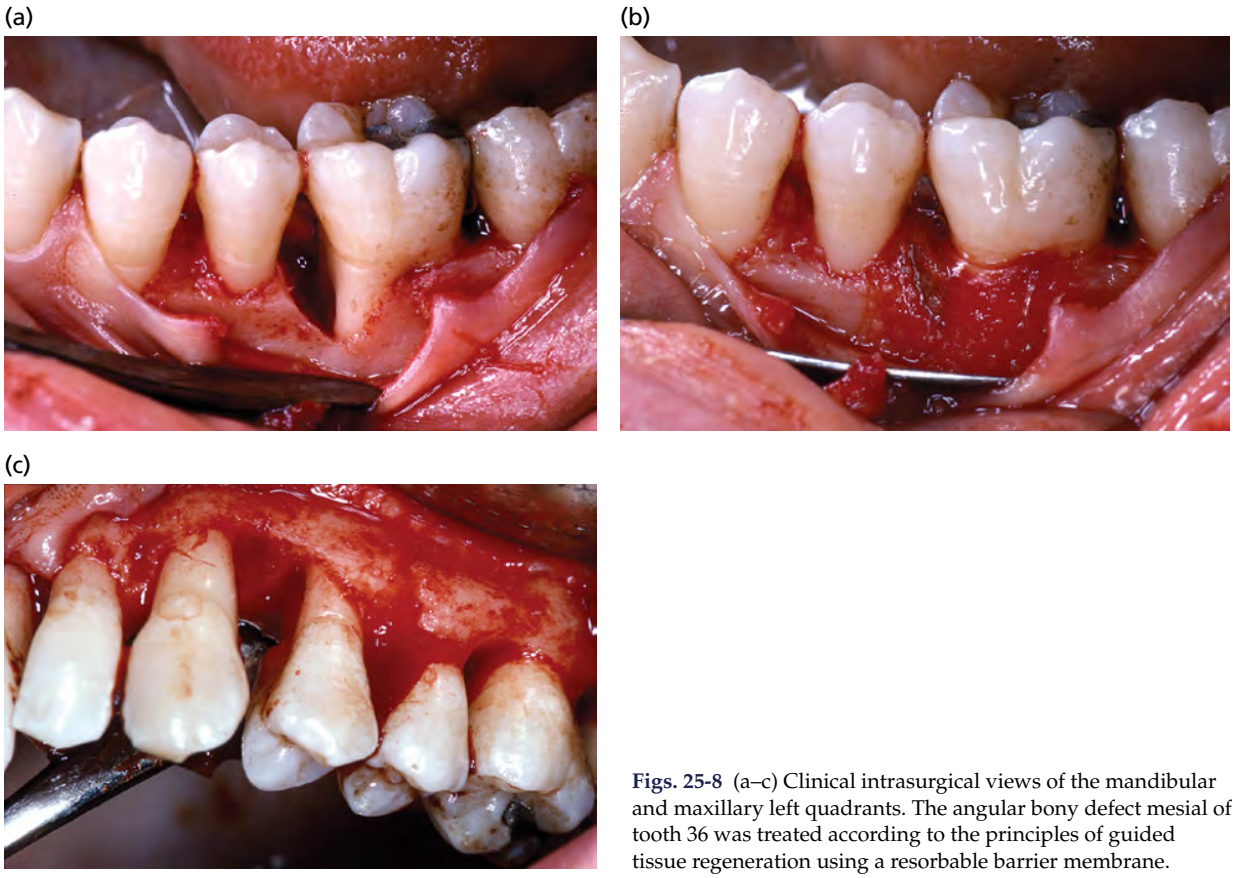
2. *Guided tissue regeneration (GTR)* for tooth 36 (Cortellini *et al*. 1995, 1999)
3. *Re-evaluation* after periodontal surgery (Figs. 25-9, 25-10)
4. *Orthodontic therapy* in the maxillary front area (Fig. 25-11)
5. *Restorative therapy* in the maxillary front area for esthetic reasons (Fig. 25-12).

Re-evaluation after corrective phase

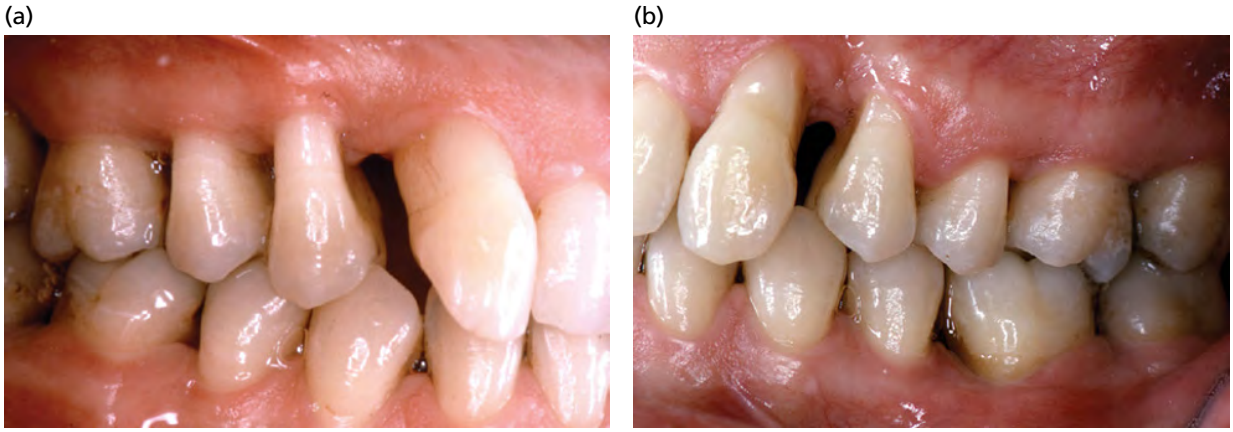
The corrective phase of therapy is completed with a thorough analysis of the results obtained with respect to the elimination of the sequelae of periodontal tissue destruction (Figs. 25-13, 25-14, 25-15). This implies that a re-evaluation of the patient's periodontal and peri-implant conditions must be performed. The results of this re-evaluation form the basis for the assessment of the residual periodontal risk. The outcomes of the periodontal risk assessment (PRA) (Lang & Tonetti 2003), in turn, will determine the recall frequency of the patient during the maintenance phase.

Maintenance phase (supportive periodontal and peri-implant therapy)

Following completion of cause-related therapy, the patient must be enrolled in a recall system aiming at preventing the recurrence of oral infections



Figs. 25-8 (a–c) Clinical intrasurgical views of the mandibular and maxillary left quadrants. The angular bony defect mesial of tooth 36 was treated according to the principles of guided tissue regeneration using a resorbable barrier membrane.



Figs. 25-9 (a, b) Clinical lateral views of the patient presented in Fig. 25-2 at re-evaluation after periodontal surgery.

(i.e. periodontitis, caries, and peri-implantitis). *SPT* should be scheduled at the re-evaluation after initial therapy and independently of the need for additional therapy. The time interval between the recall appointments should be based on a PRA (see Chapter 48) established at the re-evaluation after the corrective phase. It has been well established that self-performed biofilm control combined with regular attendance of maintenance care visits following active periodontal treatment represented effective means of controlling gingivitis and periodontitis and limiting tooth mortality over a 30-year period (Axelsson *et al*. 2004). It is important to emphasize, however, that the recall program must be designed to meet the individual needs of the patient. According to a PRA performed after completion of active therapy, some patients should be recalled every 3 months, while others may have to be checked once or twice a year (Lang & Tonetti 2003).

At the recall visits the following procedures should be carried out:

1. Update of the medical and tobacco use history
2. Soft tissue examination as a cancer screening
3. Recording of the full-mouth PPD ≥5 mm with concomitant BoP

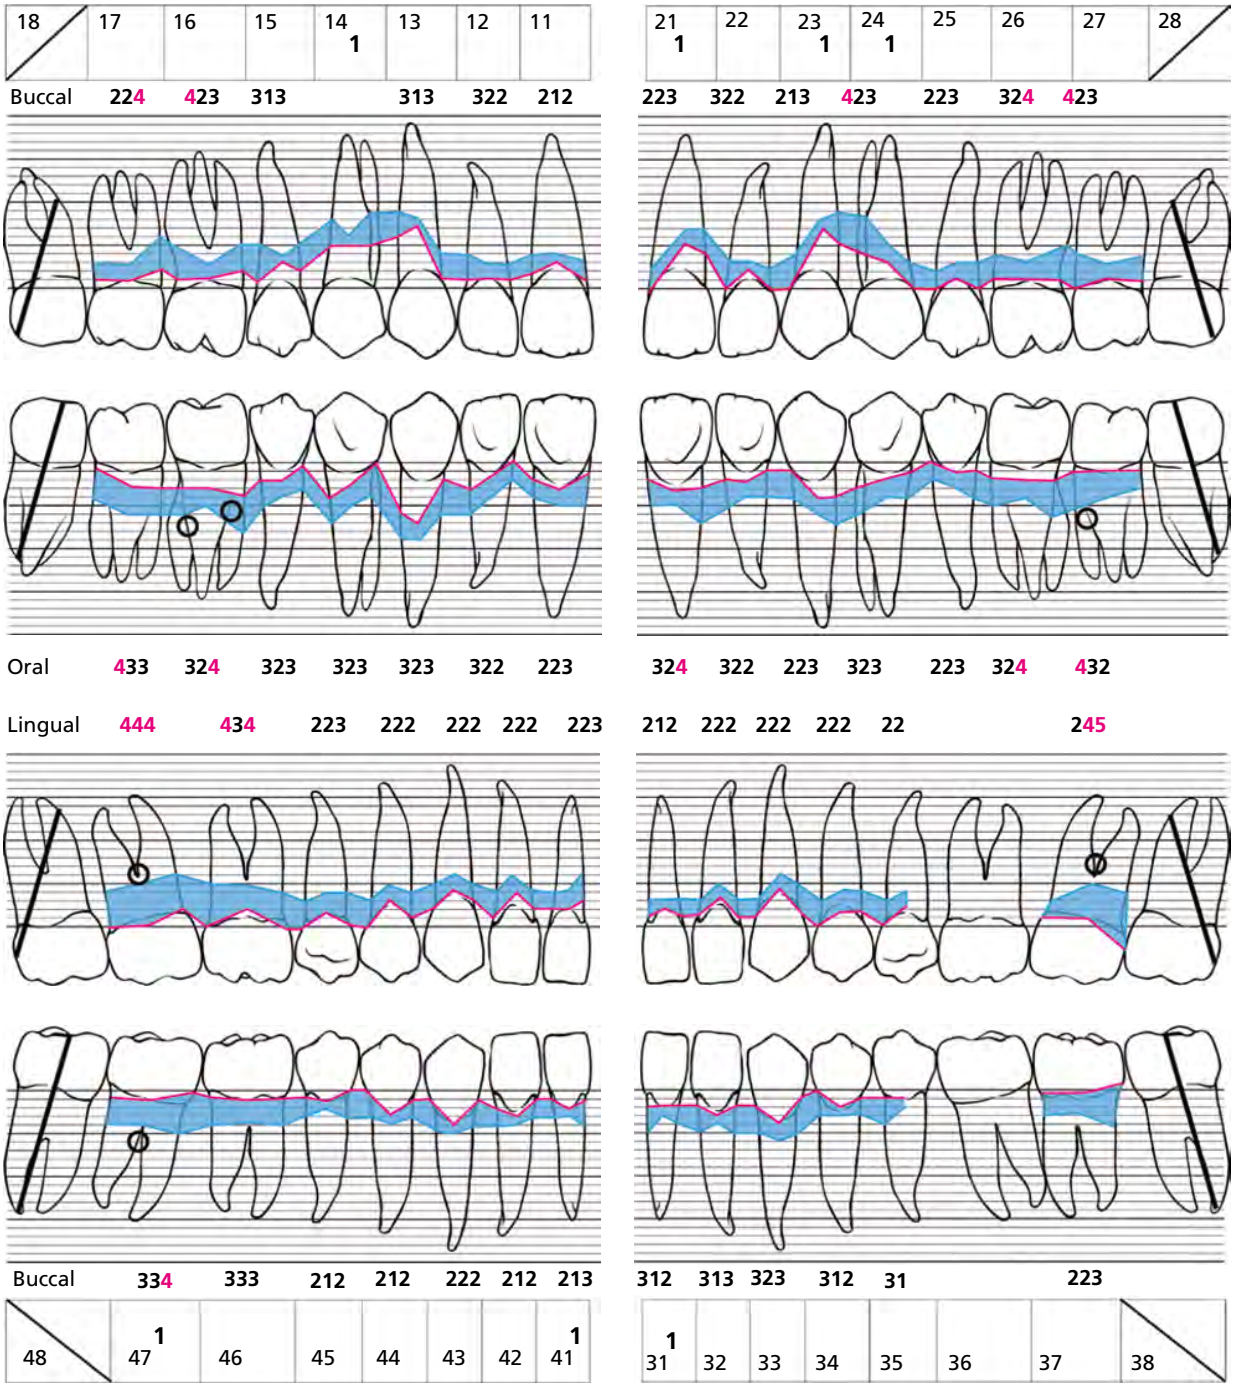


Fig. 25-10 Periodontal chart of the patient presented in Fig. 25-2 at re-evaluation after periodontal surgery. Tooth 36 has not been charted due to a 6-month healing period following guided tissue regeneration.

4. Re-instrumentation of bleeding sites with PPD ≥5 mm
5. Polishing and fluoridation for the prevention of dental caries.

Patient S.B., who is presented to describe the guiding principles of treatment planning was, during the first 6 months following active therapy, recalled twice (i.e. every 3 months) and subsequently once every 6 months based on the individual PRA.

Re-evaluation 20 years following active periodontal therapy

The SPT rendered according to the individual PRA has been successful in maintaining the dentition of this initially challenging case for at least 20 years (Figs. 25-16, 25-17, 25-18).

Case presentation 2

The treatment plan and treatment procedures of a 48-year-old male patient (M.A.) are presented. Patient M.A. was referred by his family dentist after spontaneous loss of tooth 17.

Dental history

The patient reported abscesses, especially in the posterior area and more frequently in the upper left molar area. In addition, he complained about gingival

bleeding while brushing and even spontaneous bleeding, bad breath and bad taste, increased tooth mobility, and impaired mastication on the left side. He had received a dental examination 2 years before, when he also received professional oral hygiene treatment. Home care was based on tooth brushing once per day with a manual toothbrush in the evening, without the use of any interdental cleansing devices.

The patient was concerned about the spontaneous loss of tooth 17 and reported that his father had lost many teeth in the same way. He also felt an increasing negative impact of his oral conditions on the

quality of his daily life especially in terms of chewing comfort and social relationships. The patient's main requests were to save as many teeth as possible and regain oral health and chewing comfort.

Medical history

At time of intake, patient M.A. was systemically healthy and reported a normal body weight and absence of stress. He was a non-smoker and in good physical shape, regularly partaking in physical activity. He was a full-time employee of the Italian state train company and married with two children.

Extra- and intraoral examinations

The extraoral examination, including the functional analysis of the temporomandibular joints, were within normal limits.

The intraoral examination revealed large amounts of bacterial biofilm and calculus in every sextant with the concomitant presence of severe gingival inflammation. In some sites, the gingiva was bleeding upon air blow. Tooth 17 was missing. In the upper left area, severe swelling was evident and purulence could be observed upon light finger pressure. The upper left molars were highly mobile and increased tooth mobility could be detected on several additional teeth. Multiple carious lesions were also detected. The BPE yielded a score of 4 in all sextants indicating the presence of severe periodontitis and thereby requiring a more comprehensive oral and periodontal examination.

Diagnosis

An appointment for a more comprehensive oral examination was scheduled during which intraoral photographs, full periapical radiographs, and a periodontal chart were taken (Fig. 25-19). Pulp sensitivity revealed that tooth 16 was vital whereas tooth 27 displayed questionable vitality and tooth 28 was non-vital. Primary and recurrent caries were diagnosed on teeth 14, 15, 16, 24, 26, 27, 28, 46, 45, 35, and 36.

The periodontal chart (Fig. 25-19) revealed a full-mouth plaque score (FMPS) of 78%, a full-mouth bleeding score (FMBS) of 85%, deep PPDs around most teeth in association with severe attachment loss, deep furcation involvement (FI) on tooth 16 and 26 and increased tooth mobility (TM) particularly in the upper left molar area.

Based on these findings, the patient was given a diagnosis of generalized periodontitis type III and grade B. In addition to caries, a diagnosis of endodontic-periodontal lesions was given to teeth 27 and 28.

Single tooth pretherapeutic prognosis

The single tooth pretherapeutic prognosis is shown in Fig. 25-20. Teeth 28, 48, and 38 were considered irrational to treat. Keeping in mind the expectation of the patient to save as many teeth as possible, teeth 18 and 27 were placed into the "doubtful" category. The rationale about keeping tooth 27 was to observe its potential for improvement after cause-related therapy, while tooth 18 did not present severe treats to justify its immediate extraction.

Systemic phase

Based on the fact that the patient was systemically healthy and a non-smoker, no medical or behavioral interventions were indicated.

Cause-related therapy

Non-surgical therapy consisted of motivation and instructions in oral hygiene practices followed by supragingival scaling and root planing under local anaesthesia. All bacterial biofilms, supra- and subgingival calculus deposits as well as their retentive factors were carefully eliminated. Controls of self-performed oral hygiene and re-instructions were scheduled during this phase. Moreover, teeth irrational to treat (i.e. 28, 38, 48) were extracted. The carious lesions were eliminated and teeth 46, 45, 14, 25, 35, 36, 21, 22, 23, 24, and 26 were restored with composite fillings.

Re-evaluation after cause-related therapy

The periodontal conditions were re-evaluated 3 months following completion of non-surgical therapy (Fig. 25-21). The periodontal chart shows the high-quality performance of the patient in terms of plaque control (FMPS: 5%) and very low levels of residual inflammation (FMBS: 8%). Most of the deep PPDs present at intake were resolved with an obvious increase in gingival recessions. Residual PPDs were still present at teeth 18, 16, 15, and 14 and FI degree 2 was diagnosed on the distal aspect of tooth 16. Furthermore, residual PPDs up to 13 mm were still present on the distal aspect of tooth 27 also revealing an open FI of this tooth. A residual PPD of 6 mm associated with an intrabony defect was detected on tooth 36 distally while on teeth 46 and 47 residual PPDs up to 8 mm were associated with osseous craters.

Most of the symptoms described by the patient at intake were resolved although an increase in root sensitivity was reported and treated with proper dietary instructions and topical fluoride application. The patient was enrolled into SPT with a 3-month recall frequency.

Corrective phase

At this time, tooth 27 was considered hopeless and extracted while periodontal surgery was planned in areas with residual PPDs.

In the first sextant, resective surgery was planned and performed on teeth 18, 16, 15, and 14 including

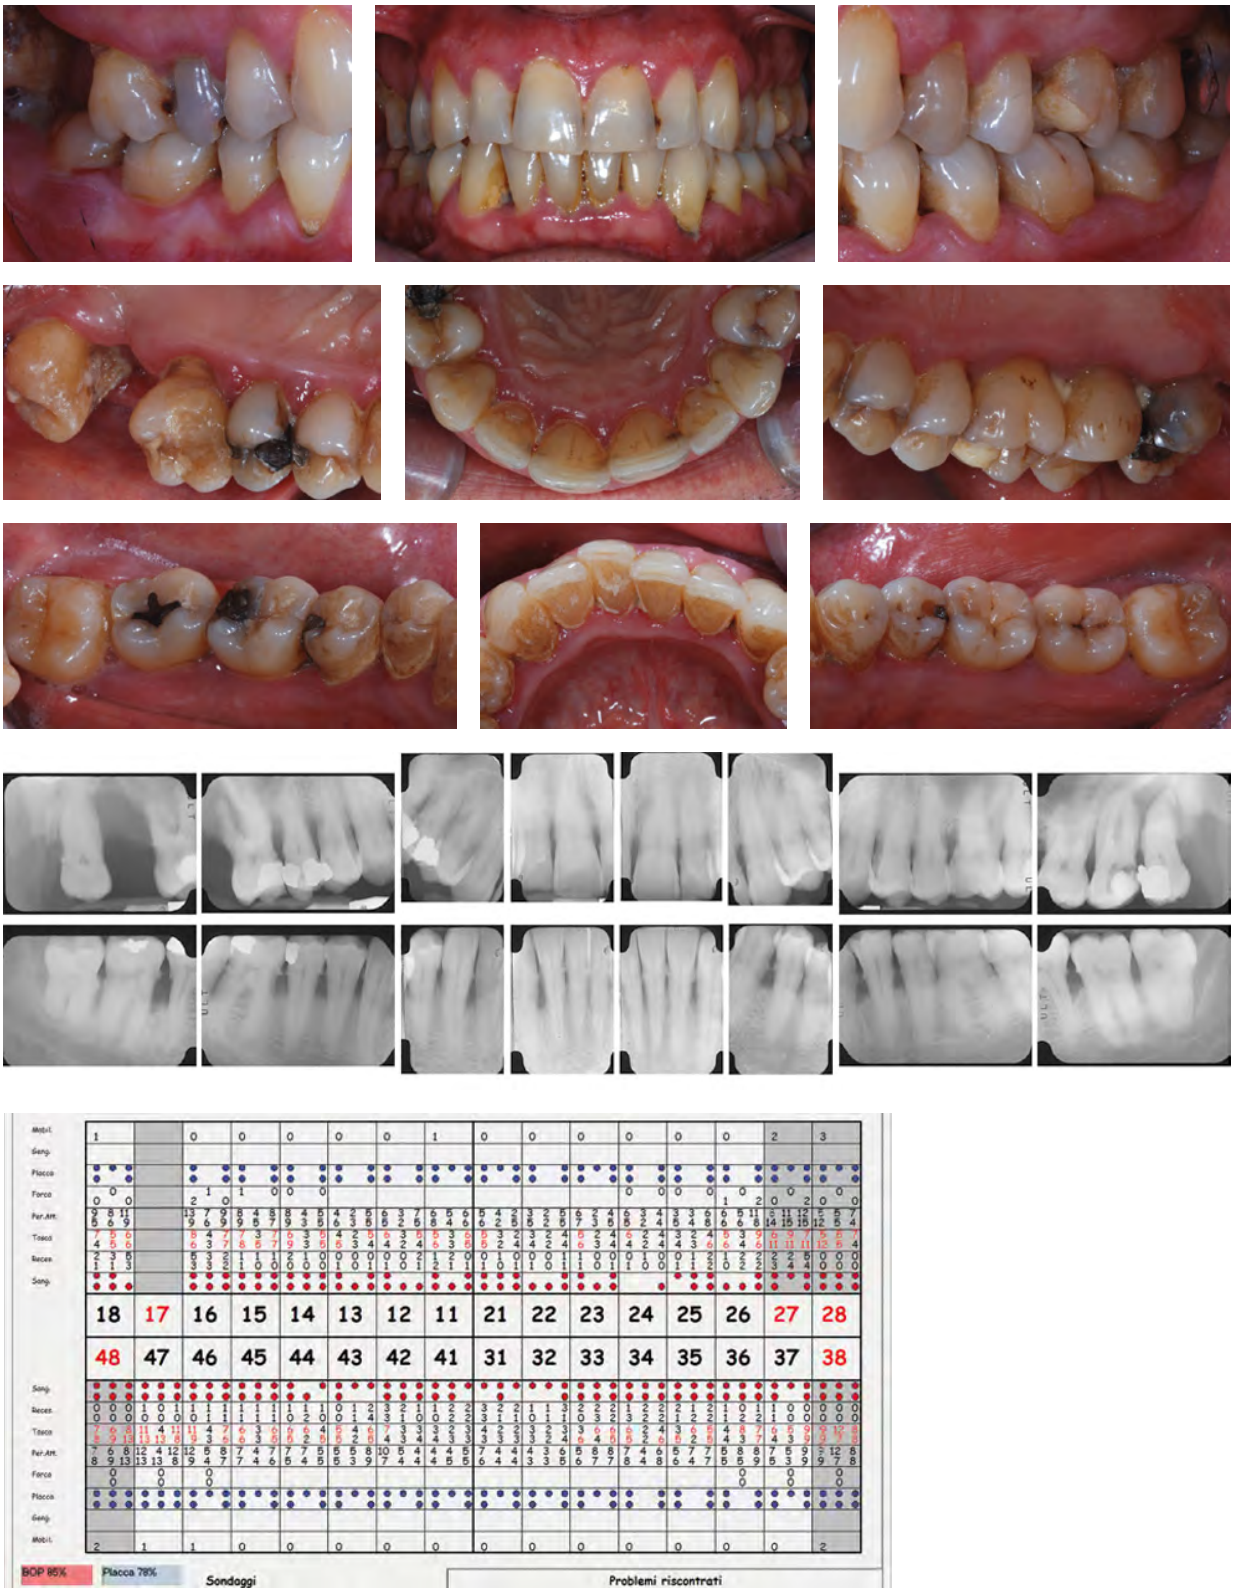

Fig. 25-19 Intraoral photographs, periapical radiographs, and periodontal chart of patient M.A. at intake.

root separation and extraction of the distobuccal root of 16 (Fig. 25-22a–f). Before surgery tooth 15 was treated with a temporary composite build-up and tooth 16 endodontically treated and restored with composite. Four months after surgery, tooth 16 was restored with a single-unit crown and tooth 15 with an onlay (Fig. 25-22g–l). Resective surgery was performed on teeth 47 and 46 (Fig. 25-23) and regenerative surgery was applied on tooth 36 (Fig. 25-24).

Patient M.A. was maintained in SPT with a 3-month recall frequency during the entire corrective phase.

Fig. 25-24 (a–j) Clinical and radiographic views of periodontal regeneration at the distal aspect of tooth 36 by means of minimally invasive surgery in combination with enamel matrix derivative. Tooth 38 was extracted during cause-related therapy.

Re-evaluation after corrective phase

After completion of the corrective phase including periodontal surgery and restorative therapy, a re-evaluation was performed 18 months after intake of the patient. Photographs and periapical radiographs were taken, and a periodontal chart made at this timepoint (Fig. 25-25). A FMPS of 14% and a FMBS of 4% were assessed with absence of residual PPDs >4 mm. No increased TM was detected. Except for minimal root sensitivity, the patient reported full chewing comfort and resolution of the symptoms described at intake.

The PRA indicated a residual low risk profile (Lang & Tonetti 2003) (Fig. 25-26). Despite this low residual risk, it was decided, with the agreement of the patient, to maintain a stringent SPT based on a 3-month recall frequency.

Re-evaluation 10 years following active periodontal therapy

Fig. 25-27 illustrates the photographs, periapical radiographs, and periodontal chart of patient M.A. 10 years after completion of active therapy. A FMPS of 11% combined with a FMBS of 14%, absence of residual PPDs >4 mm, stable radiographic marginal bone levels, and absence of recurrent caries indicated that patient's compliance and SPT were successful in maintaining long-term oral health following active periodontal therapy.

Conclusion

The overall treatment plan and the sequence of the different treatment procedures used in both case presentations were selected in order to illustrate the

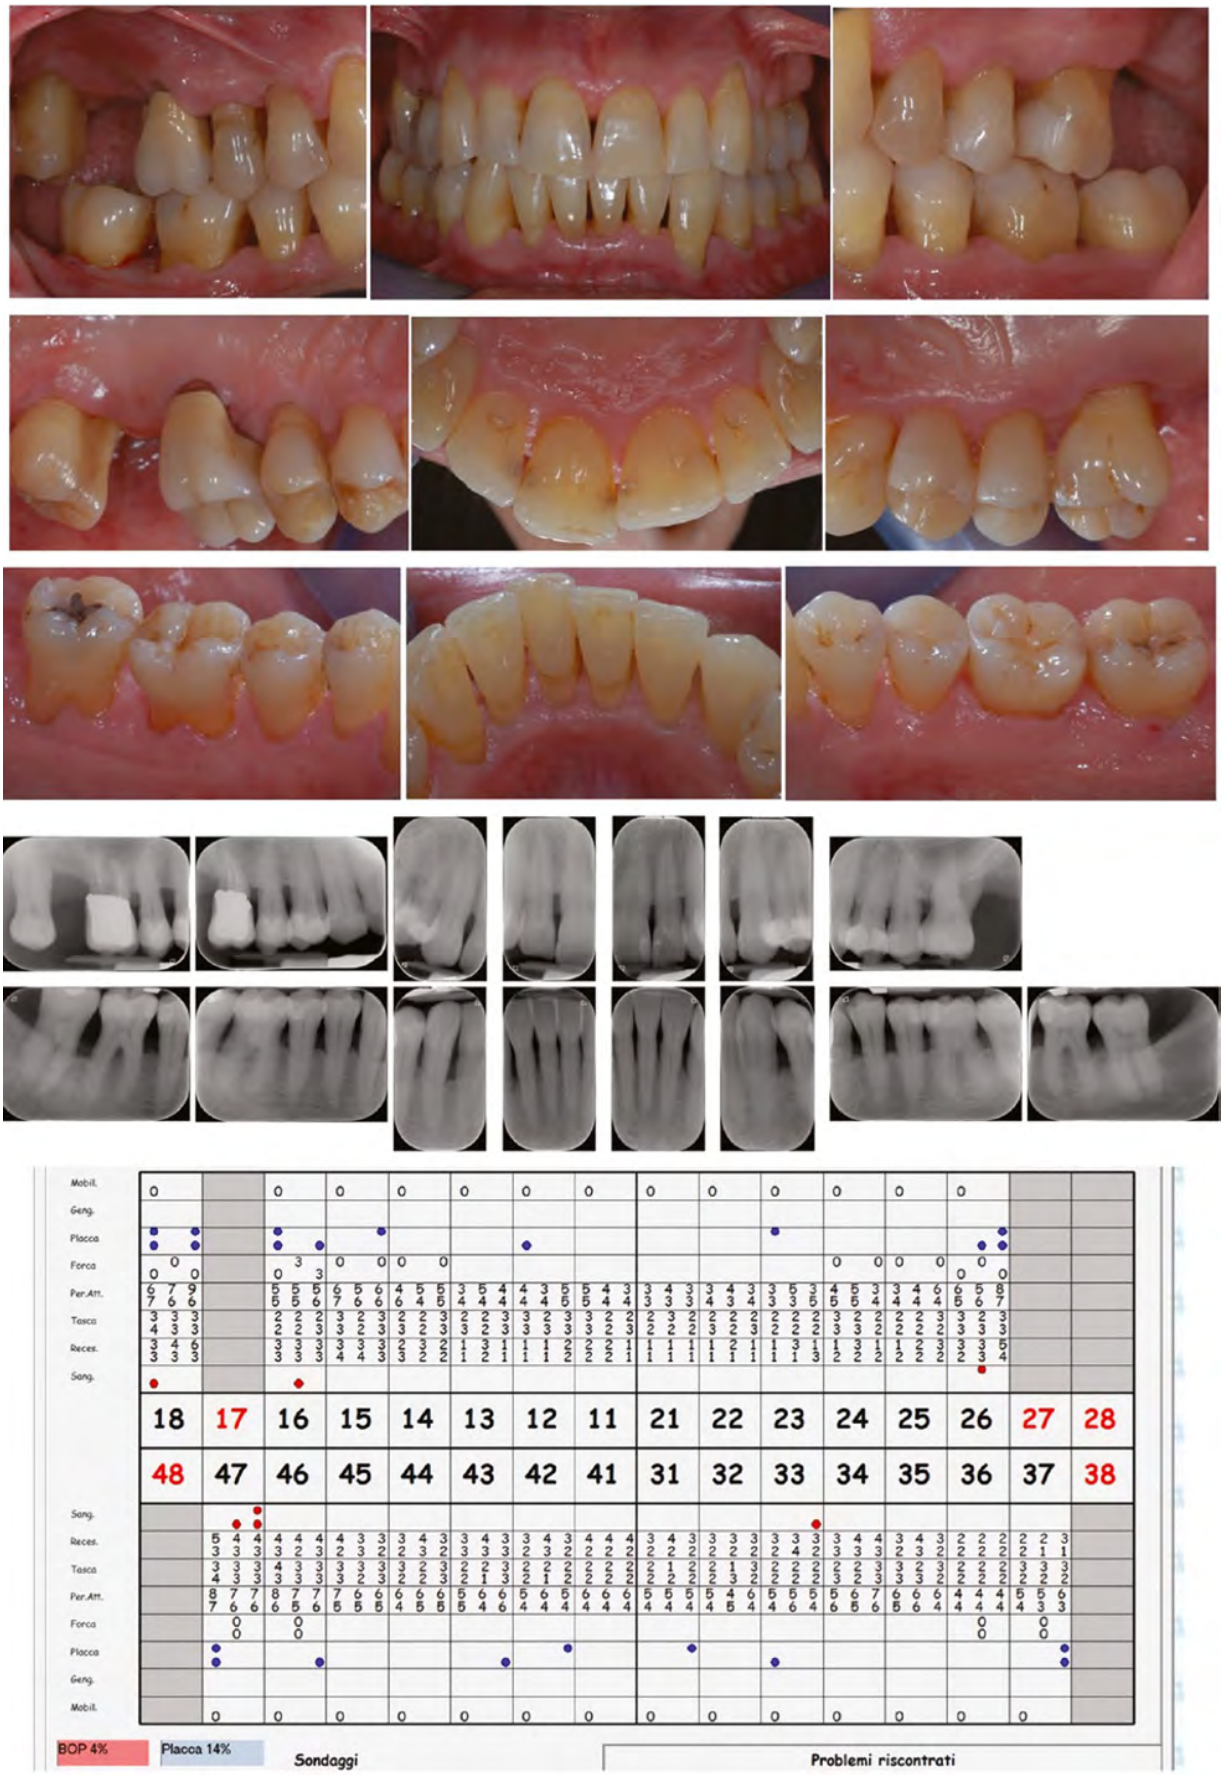

Fig. 25-25 Intraoral photographs, periapical radiographs, and periodontal chart of patient M.A. at completion of active therapy 18 months following intake.

following principle: *in patients exhibiting a generalized advanced breakdown of the periodontal tissues, considerable efforts should be made to maintain a functional dentition*. Extraction of one single tooth in such a dentition will frequently call for the extraction of several additional teeth for "prosthetic reasons". The end result of such an approach thus includes a prosthetic rehabilitation that, if the treatment planning had been properly done, could have been avoided.

The large variety of treatment problems that different patients present may obviously require deviations from the sequence of treatment phases (i.e. systemic phase, initial cause-related therapy, corrective phase, and supportive care) discussed in this chapter. Such deviations may be accepted as long as the fundamental principles characterizing the treatment phases are understood.

Chapter 26

Systemic Phase of Therapy

Niklaus P. Lang[1], Iain Chapple[2], Christoph A. Ramseier[1], and Hans-Rudolf Baur[3]

[1]Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland
[2]Periodontal Research Group, School of Dentistry, University of Birmingham, Birmingham, UK
[3]Department of Cardiology, Medical School, University of Bern, Bern, Switzerland

Introduction

The systemic phase of periodontal therapy should be concerned with general health implications of periodontal diseases and periodontal treatment. While the former aspects are described in Chapters 11, 12, and 14, the latter aspects are presented in this chapter.

The systemic phase of periodontal therapy is designed to protect the patient against unforeseen systemic reactions, to prevent complications affecting the general health of the patient and to protect the health care providers from (predominantly infectious) hazards in conjunction with the treatment of patients at risk.

In order to plan the systemic phase adequately, results from a health questionnaire filled in by the patient in the waiting area, the family and social history, the general medical and, in particular, the tobacco use history have to be evaluated. Also, any extra- and intraoral findings pertinent to the patient's systemic health have to be considered.

The systemic phase of periodontal therapy encompasses:

- Precautions for protecting the general health of the dental team and other patients against infectious and contagious diseases
- Protection against potentially harmful systemic effects of routine therapy
- Making allowances for systemic diseases or disorders that may influence the etiology, the healing potential, and the systemic response to therapy
- Controlling anxiety and low pain threshold
- Risk assessment and considerations of systematic supportive periodontal and peri-implant therapy
- Smoking counseling and instituting tobacco use cessation programs.

Protection of the dental team and their patients against infectious diseases

As a general principle, routine periodontal therapy should be postponed in a patient with an active contagious state of a disease until he/she has received adequate medical treatment. Given the fact that patients may not always be aware of such a state or

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

that all manifestations of disease may have abated, but the patient may still be a carrier of infectious agents, routine dental treatment should be carried out using specific precautions against transmission of the most serious diseases being transmitted orally. These include hepatitis A, B, and C (Levin *et al*. 1974), human immunodeficiency virus (HIV) infection, and venereal diseases (Chue 1975). Hygiene in the dental office, therefore, has to address the most contagious level of infective agents, the hepatitis viruses, and cope with the prevention of the transmission of these infections. As a minimal precaution, the wearing of rubber gloves and a fluid-resistant surgical mouth mask (Type IIR) is highly recommended for all dental therapy in all patients. Also, protective glasses for both the therapist and the patient should be worn during procedures generating aerosols, and FFP3 masks, visors, gowns, and head covers may be required for patients with SARS-COV-2.

Herpes simplex virus (Nahmias & Roizman 1973) and tuberculosis are further infectious diseases with a high transmission potential. Special precautions should be observed in patients with a recent history (2–3 years) of hepatitis, although the dental team may be vaccinated against hepatitis. If the medical history and the oral examination reveal that the patient may have overt or hidden systemic disease, he/she should be referred for medical examination prior to enrolling the patient into comprehensive periodontal care.

Protection of the patient's health

A number of systemic conditions may affect treatment planning, although they may have no direct relevance upon the pathogenesis and healing potential of periodontal lesions. Because over 50% of patients over 40 years of age may have systemic conditions or take medications affecting periodontal therapy, these aspects have to be carefully appraised prior to instituting further therapeutic measures.

For patients with life-threatening systemic conditions, such as coronary insufficiency or hypertensive heart disease, their physician should be consulted about appropriate patient management and whether treatment should be performed in a hospital or specialist clinic rather than a private practice setting. If the dental office is considered to be an adequate environment for treating these patients, shorter appointments should be scheduled. The treatment should be performed with complete pain control using local anesthesia with appropriate vasoconstrictors.

Prevention of complications

The complications most commonly encountered in the dental office are:

- Infective endocarditis
- Bleeding
- Cardiovascular incidents
- Allergic reactions and drug interactions
- Specific medications: bisphosphonates.

These may be prevented if appropriate precautions are taken. Hence, gaining awareness of possible complications from a medical history is an important step in treatment planning and comprehensive patient care.

Infective endocarditis and its prevention

Infective endocarditis (IE) is an uncommon, but life-threatening endocardial infection that arises due to bacteremia in patients who have congenital or acquired cardiac abnormalities. The incidence of IE is 1 per 100 000 individuals per year (DeSimone 2015). It causes significant morbidity, such as the need for remedial cardiac surgery (Murdoch *et al*. 2009), and the estimated absolute risk of mortality arising following dental interventions is illustrated in Table 26-1.

Invasive dental procedures are traditionally regarded as the most common risk factor for IE and consequently antibiotic prophylaxis (ABP) prior to such interventions has been the standard of care for over 50 years in most parts of the world (Wilson *et al*. 2007; Habib *et al*. 2015).

Interestingly, the risk of fatal anaphylaxis due to penicillin is estimated as 1 in 100 000 when administered orally and higher when administered parenterally (Kaufman 2003). Such adverse event statistics have historically created a dilemma when deciding on the balance of mortality risk for using ABP in IE prevention versus mortality risk when not using ABP in specific groups at risk of IE (Table 26-1). Moreover,

Table 26-1 Absolute risk following dental interventions. (Source: Adapted from Lalani *et al*. 2013.).

Condition	Mortality (per procedure)	Increasing risk of IE
Mitral valve prolapse	1 per 1 100 000 procedures	
Congenital heart disease	1 per 475 000	
Rheumatic heart disease	1 per 142 000	
Prosthetic heart valve	1 per 114 000	
History of previous IE	1 per 95 000	

IE, infective endocarditis.

there is a longstanding lack of evidence from randomized controlled trials (RCT) for any efficacy of ABP in preventing IE, due to ethical concerns over conducting such studies. In 2008, this led to a landmark decision in the UK by the National Institute for Health and Care Excellence (NICE) to conclude that ABP prior to invasive dental procedures was not cost-effective and should stop (NICE 2008). In contrast, the 2007 American Heart Association (AHA) guidelines (Wilson *et al*. 2007) retained the recommendation for ABP in high-risk patients only, as did the 2009 guidelines from the European Society of Cardiology (ESC) (Habib *et al*. 2009). However, the ESC amended their guidance in 2015 by expert consensus, in order to provide "clear and simple recommendations" (Habib *et al*. 2015). The latter include the use of a single oral dose of amoxicillin (2 g) administered 1 hour prior to high-risk procedures, and a single dose of oral clindamycin 600 mg 1 hour preoperatively in penicillin-allergic patients. The ESC update was published just prior to new data demonstrating a higher risk of fatal adverse reactions to clindamycin than to amoxicillin (Thornhill *et al*. 2015), further complicating the clinical decision-making algorithms.

This section, therefore, aims to discuss the background and controversy of the last 10–15 years surrounding the use, or non-use, of ABP for IE prevention in dental surgery and to document the current consensus guidance, derived from the AHA, ESC, and NICE recommendations, recently summarized in a pragmatic and balanced implementation document produced by the Scottish Dental Clinical Effectiveness Program (SDCEP 2018).

Pathogenesis of infective endocarditis

IE develops as an outcome of a complex series of interactions between the blood coagulation system (platelets and fibrin), matrix molecules, and blood-borne bacteria entering the vasculature at distant sites, such as the periodontium or tooth socket. Thus, the term "infective" is used and the manifestations of the endocarditis emanate from the hosts' immune-inflammatory response. There are four stages to the process.

Stage 1: development of non-infectious thrombotic endocarditis

The endothelium becomes traumatized by long-standing turbulent blood flow across a congenitally deformed cardiac structure (e.g. valve), normally through a narrow orifice or where blood travels from a high pressure to a low-pressure system (e.g. septal defect). The turbulence activates platelets and causes fibrin formation, resulting in endocardial deposits.

Stage 2a: a transient bacteremia

Bacteremia arising due to organisms passing through an exposed wound during periodontal therapy or tooth extraction can introduce *Streptococcal* species such as *S. viridans*, *Staphylococci* or *Enterococci* capable of adhering to the damaged endocardium. For example, FimA proteins from streptococci or adhesins from staphylococci can bind the fibrin-platelet complex and form small vegetations (Burnette-Curley *et al*. 1995).

Periodontal probing, ultrasonic scaling, and toothbrushing all produce bacteremia, but there is a lack of evidence from adequately powered studies that this is larger the more severe the periodontitis (Kinane *et al*. 2005).

Stage 2b: chronic low-grade bacteremia

Alternatively to Stage 2a, vascular entry of oral bacteria during normal daily function, such as chewing, tooth brushing, and interdental cleaning has been demonstrated to create an exposure equivalent to 5730 minutes per month of bacteremia (Guntheroth *et al*. 1984). Indeed, it has been proposed that twice daily tooth brushing creates a 154 000 times greater risk of bacteremia than a single tooth extraction, and that the sum of all routine daily activities over a year may create a 5.6 million times greater cumulative exposure to bacteremia than a tooth extraction (Roberts 1999). A systematic review and meta- analysis of the impact of oral daily activities and bacteremia reported that plaque accumulation and gingival inflammation significantly increased the prevalence of bacteremia following tooth brushing (Tomás *et al*. 2012).

Stage 3: bacterial adherence

Various aforementioned mediators of bacterial adhesion (e.g. FimA or adhesins) facilitate bacterial colonization of the platelet/fibrin/endothelium complex and an infected vegetation forms.

Stage 4: vegetation formation due to bacterial proliferation

The initial colonizers provide a substrate for adhesion of additional bacteria and vegetation density can reach 108–1011 bacteria per gram of vegetation, particularly on the left side of the heart (Wilson *et al*. 2007).

Signs, symptoms, and clinical investigations for IE

Symptoms of IE can develop in an "acute" manner over just a few days, or more insidiously over several weeks (Thornhill *et al*. 2016). Early identification is critically important to survival statistics, and at-risk patients should be educated in their identification. They include:

- Night sweats
- Dyspnea on exertion (shortness of breath)
- Spiking temperatures of 38°C or higher (90% of cases)
- Fatigue

- Joint pains
- Muscle pains
- Weight loss (unexplained)
- Skin rash (petechial-like red spots)
- New or worsening heart murmur (85% of cases)
- Red and sore lesions under skin of toes and fingers called Osler's nodes
- Confusion
- Stroke.

Diagnosis of IE is challenging. C-reactive protein (CRP) levels are elevated but are a non-specific finding, and blood cultures are essential in order to try and isolate causative organisms by polymerase chain reaction (PCR) or traditional selective culture (Habib *et al*. 2015). Imaging techniques such as echocardiography and transesophageal echocardiography are extremely important investigations. In addition, MRI (magnetic resonance imaging), PET (positron emission tomography) or CT (computerized tomography) scans may also be necessary.

Evidence for efficacy of antibacterial prophylaxis and risks

Remarkably, there is no evidence to support the effectiveness of ABP in the prevention of IE (Lockhart *et al*. 2007), due to a lack of RCTs (Durack 1995). Therefore, the decision by NICE in 2008 to cease recommending ABP in the UK provided an opportunity to explore the impact of dramatically reduced rates of prescribing ABP upon changes to the prevalence of IE and associated mortality in the UK. Thornhill and coworkers (2016) employed "change point analysis" to analyze a large dataset on ABP prescribing between January 2004 and March 2013 from the English Health Service Business Services Authority against IE incidence data and associated mortality between January 2000 and March 2013, obtained from UK hospital episode statistics (Thornhill *et al*. 2016). They employed a segmented regression analysis of an interrupted time series, with the interruption point set at 2008, and also analyzed secondary codes to identify patients at high risk of IE and also the causative bacteria. They reported that the reduction in ABP prescribing post-2008 was strongly and significantly associated with an increase in IE incidence in England in that period (Dayer *et al*. 2015), accounting for a further 35 cases per month. However, there was an overall gradual trend towards increased IE incidence pre-withdrawal of ABP prescribing, and the increase was in both high risk and lower risk individuals. There was a trend towards an associated "in-hospital mortality" increase, but this did not reach statistical significance. This study, although controversial, provides some new evidence for the use of ABP in high-risk groups, due to the demonstration of a temporal relationship between new IE cases in England following dramatic attenuation in ABP prescribing. It does not, however, establish a causal relationship and randomized trials are needed to achieve this, although they would be ethically challenging.

A further important advance in knowledge was new data demonstrating the adverse event rates from using ABP for IE were lower than previously thought. The American Heart Association (AHA) report on the need for ABP in IE prevention did not identify any proven cases of mortality arising from anaphylaxis associated with ABP in the preceding 50 years (Wilson *et al*. 2007). Indeed, there was only one fatal case reported for the use of 2 g oral amoxicillin, the mainstay of ABP provision in almost 50 years (Lee & Shanson 2007). Thornhill and co-workers (2016) examined ABP prescribing data between January 2004 and March 2014 in England, and data reported routinely in England using a long-established adverse event reporting system. The UK recommended dose for oral amoxicillin is 3 g and in penicillin-allergic patients, clindamycin is used at a single 600 mg oral dose, 1-hour presurgically. They found no reported fatalities from over 3 million prescriptions of amoxicillin and 22.6 non-fatal reactions per million prescriptions (Thornhill *et al*. 2015). For clindamycin there were 13 fatal and 149 non-fatal reactions per 1 million prescriptions. The authors concluded that amoxicillin used for ABP against IE was relatively safe but raised the small number of fatal and non-fatal reactions to clindamycin as worthy of note. The 2015 ESC guidelines recommend 600 mg oral clindamycin in penicillin-allergic patients for ABP, which was questioned by Thornhill and colleagues (2016). However, it is important to recognize that, by definition, clindamycin is employed only in patients with a history of atopy (to penicillin), and therefore the comparison between the relative safety of the two regimes needs careful interpretation.

High risk groups for IE and high-risk dental procedures

There is substantial consensus between the AHA, ESC, and NICE guidelines regarding high-risk groups for IE, albeit based largely on expert opinion (Table 26-2). In addition, the AHA and ESC guidelines identify three sub-groups (in italic in Table 26-2) that require special consideration due to their elevated risk of life-threatening complications and dental practitioners should consult with a cardiologist for such cases.

The use of ABP in high-risk cases should be limited to high-risk (invasive) procedures and is not necessary for routine care (Table 26-3).

The ESC, AHA, NICE, and SDCEP guidelines all highlight the critical importance of attaining and maintaining good oral health and hygiene as a primary preventive strategy for IE. This advice includes hygiene around oral piercings and recognizes the

chronic entry of oral bacteria during normal daily function as being a far greater risk than isolated invasive dental procedures (Tomás *et al*. 2012).

Table 26-2 Consensus of The American Heart Association, the European Society of Cardiology, and the National Institute for Health and Care Excellence guidelines regarding high-risk groups for infective endocarditis (IE). Italic typeface cases require "special consideration".

High risk for IE	Moderate risk for IE
Previous episode of IE	History of rheumatic fever
Structural congenital heart disease, including surgically corrected or palliated structural conditions (NOT isolated ASD, fully repaired VSD, or fully repaired DA, and closure devices that have fully endothelialized)	Unrepaired congenital anomalies of heart valves
Prosthetic cardiac valve replacement or repair with prosthetic material	Native valve disease not classified as high risk, e.g. bicuspid aortic valve, mitral valve prolapse, calcification within aortic stenosis
Acquired valvular heart disease with stenosis or regurgitation, or shunts	
Any type of cyanotic heart disease	

ASD, atrial-septal defect; DA, ductus arteriosus; VSD, ventricular-septal defect.

Consensus regime for ABP in IE

The recommended regimes for ABP in situations where it is deemed wise and requested by the patient are largely consistent in recommending oral amoxicillin 2 g (3 g in the UK) and oral clindamycin, 600 mg in penicillin-allergic patients, 1 hour presurgically. Parenteral administration is associated with a higher risk of adverse events and should ideally be limited to procedures performed under general anesthesia. Here, patients are starved presurgically and *Staphylococcal* bacteremia of nasal origin following nasal intubation is believed to pose a particular risk. The SDCEP guidance advocates the use of azithromycin oral suspension (200 mg/5 mL) in penicillin-allergic patients who cannot swallow clindamycin capsules and provides recommended protocols for intravenous administration and for children/adolescents.

Consent – who makes the decision?

"Informed consent" is the core, underpinning principal for any medical treatment and essentially involves a patient agreeing to do something or to allow something to happen only after all relevant facts have been disclosed. Patients must be mentally and linguistically competent to understand all the material risks and consequences of the proposed procedure, as well as alternatives, and should have been allowed time

Table 26-3 The use of antibacterial prophylaxis in high-risk cases should be limited to high-risk procedures. (Source: Adapted from SDCEP guidance.)

High-risk (invasive) procedures	Low-risk procedures
Root surface debridement/subgingival scaling	Basic periodontal examination/community periodontal index of treatment needs (CPITN) screening
Full periodontal examination (pocket charting in inflamed tissues)	Supragingival scaling
Surgical procedures with mucoperiosteal elevation	Supragingival prophylaxis
Periodontal plastic surgery procedures	Suture removal
Incision and drainage of abscesses	Administration of block or infiltration anesthetic in non-infected tissues
Placement of dental implants and uncovering of implants (second stage surgery)	Radiographs
Subgingival restorations including fixed prosthodontics	Placement or adjustment of orthodontic or removable prostheses
Treatment of peri-implantitis using submucosal access	Supragingival orthodontic band placement
Tooth extractions	
Endodontic treatment before apical stop has been established	
Placement of matrix bands	
Placement of subgingival rubber dam clamps	
Placement of preformed metal crowns	

to ask questions and clarify any concerns. Ultimately, the treatment decision, based on presentation of risks and benefits by the clinician, is made by the patient.

Summary

There is a European and North American consensus on the provision of ABP for the prevention of IE following dental procedures. Recent new evidence has informed the debate on this controversial area, and whilst the evidence base for efficacy of ABP is poor, recent UK data has demonstrated that ABP should be considered for high-risk patients undergoing invasive (high-risk) procedures. The decision lies with the patient, but clinicians should provide data on the risks and benefits, as well as alternatives, in a manner understood by the patient, thus enabling the patient to decide on their preferred course of action.

Bleeding

Due consideration must be given to patient on anticoagulant medication or patients on preventive anticoagulant drugs. For the first group of patients, a consultation with the patient's physician is indispensable. Especially prior to periodontal or implant surgical procedures, temporary adjustment of the intake of anticoagulant medication should be undertaken in cooperation with the physician. Careful planning and timing of these procedures is mandatory.

Salicylate therapy does not generally create issues for routine dental therapy, including surgical procedures, although consultation with the patient's physician is still advisable.

Individuals with known liver cirrhosis, or even patients with high alcohol consumption over many years without diagnosed cirrhosis, are at a potential risk for bleeding complications during periodontal and/or implant surgery, as their clotting mechanisms may be affected (Nichols *et al*. 1974). Again, medical consultation is recommended prior to periodontal treatment of such patients.

Extra precautions against bleeding should be taken when treating patients with any kind of blood dyscrasia or hemophilia. Following mandatory consultation with the patient's physician, it is recommended to render treatment in small segments (only a few teeth being instrumented at each visit) and to apply periodontal dressings over the treated area, even if the treatment only consisted of root instrumentation. With systematic periodontal treatment and institution of efficacious oral hygiene measures, the challenging symptom of oral bleeding can often be controlled irrespective of the patient's bleeding disorder.

Cardiovascular incidents

Cardiac patients are often treated with anticoagulants and, hence, may develop bleeding problems (as indicated previously), especially if their prescribed drugs (e.g. aspirin, indomethacin, sulfonamide, tetracycline) interact with coagulation. Other cardiovascular drugs (e.g. antihypertensive, anti-arrhythmic, diuretic) are often used in these patients and may increase the danger of hypotensive episodes during dental treatment.

Stress associated with dental procedures may precipitate anginal pain or congestive heart failure in patients with cardiovascular disease. Therefore, every effort should be taken in this patient population to keep dental appointments brief and to control anxiety and pain.

Allergic reactions and drug interactions

Full awareness of the patient's known allergies and the medications he/she is taking is essential before any drug is prescribed, administered, or used during treatment. The most common allergic reactions encountered in the dental office are those to some local anesthetics (Novocain®), penicillins, sulfonamide derivatives, and disinfectants, such as iodine. In case of known allergies, such drugs must be avoided. A consultation with the patient's physician is advisable to discuss the possible administration of replacement drugs.

Many patients – over 90% of those over the age of 60 years – regularly take medications for various systemic conditions. Special attention has to be devoted to possible drug interactions, especially in the elderly. Drugs prescribed as part of periodontal therapy or used during treatment may interfere with the effectiveness of drugs the patient is already taking, possibly creating a hazardous interaction. Hence, no new drugs should be prescribed without fully understanding their possible interaction with drugs already in use. Dentists should never change an existing drug therapy without prior discussion and preferably written consent from the physician.

Many patients regularly take tranquilizers and antidepressant drugs that have the potential for summation and synergistic effects with drugs that may be used during periodontal therapy. Moreover, the interaction and potentiation of these drugs with alcohol should be discussed with the patient.

Systemic diseases, disorders, or conditions influencing pathogenesis and healing potential

All possible attempts should be made to alleviate the effects of systemic diseases, such as blood disorders and diabetes mellitus, before any periodontal treatment is initiated. However, cause-related therapy may easily be carried out and generally results in remarkable success even during active stages of these systemic conditions. How far the treatment plan should progress with respect to pocket reduction and/or regenerative surgical procedures depends on

the seriousness of the patient's systemic involvement and likewise, to a great extent, on the potential threat to the patient's health from incomplete periodontal therapy.

Diabetes control, as an example, may be facilitated by successful control of the periodontal infection (Grossi *et al*. 1997; Genco *et al*. 2005). Thus, periodontal treatment may have a beneficial effect on the systemic health of the patient. Palliative treatment of advanced periodontitis with furcation involvement and residual deep pockets that cannot be reduced should not be undertaken for such patients. Rather, the involved teeth with repeated abscesses and pus formation should be extracted if necessary to accomplish infection control.

Clinical experience indicates that the healing response of the periodontal tissues is as good in patients with diabetes as in healthy individuals provided that the diabetes is well controlled. However, patients with juvenile diabetes may have angiopathic changes associated with a lowered resistance to infection that may require the use of antibiotics following periodontal or implant surgery. With controlled diabetes, premedication with antibiotics is not indicated. Hypoglycemia may be aggravated by the stress of periodontal surgery and, hence, precautions have to be taken to avoid hypoglycemic reactions in such patients.

Therapeutic doses of cortisone over a long period of time may cause considerable metabolic effects with systemic manifestations of a reduced rate of fibroblastic activity and hence, a lowered resistance to infection during wound healing. Nevertheless, such patients can be treated successfully by regular cause-related therapy with no significant delay in healing. The use of antibiotics is not recommended for these patients, unless there is a serious infectious condition in the mouth associated with the development of fever or swelling that is compromising the airway.

Specific medications: bisphosphonates as a threat to implant therapy

More than 10 years ago it was discovered that nitrogen-containing bisphosphonates inhibit an enzyme that controls osteoclastic function. The inhibition of this enzyme also inhibits the migration of the cells responsible for osseous healing. Hence, it is most likely that osteonecrosis may result from the inhibition of cell migration in cases of surgically exposed bone such as in implant installation. Bisphosphonate-related osteonecrosis of the jaws (BRONJ), therefore, represents a risk that should not be underestimated even in patients who are taking *oral* bisphosphonates. It should be a warning to all implant dentists that as early as 1 year after *oral administration* of biphosphonates, BRONJ has been reported (Sedghizadeh *et al*. 2009). Following the discovery of these results, a new pharmacokinetic model was developed to assess drug accumulation at 1 year. In this model the accumulated concentration of bisphosphonates in bone appears to predict toxic levels that lead to poor healing, when the jaw bone is exposed as a result of surgical therapy. This new mechanism for BRONJ was discovered by Landsberg *et al*. (2008). In this model the relevant toxicity level does not necessarily affect osteoclasts as hitherto believed, but it affects keratinocytes, endothelial cells, fibroblasts, macrophages, osteoblasts, osteoclast precursor bone marrow cells, and T-cells. All these cells are heavily involved in the healing of surgically denuded bone. Hence, it is most likely that by impaired osseous wound healing nitrogen-containing bisphosphonates may lead to BRONJ. Non-nitrogen bisphosphonates do not cause BRONJ.

The *in vitro* threshold for inhibition of keratinocyte migration (0.1 µM) was used as the toxic bisphosphonate level for wound healing inhibition in cases of surgically denuded bone. By administering an equivalent of 70 mg Fosamax® weekly, the number of doses resulting in toxic threshold levels could be calculated for various bone masses. The size of the individual's skeleton may therefore be the determining factor for the risk of BRONJ. Since the total quantity of bone mineral into which nitrogen containing bisphosphonates are stored affects the toxic threshold of a patient, it is obvious that the skeleton of smaller patients will reach toxic levels sooner than in larger patients. Once the toxic threshold for nitrogen-containing bisphosphonates in bone is surpassed, osteoclastic resorption will release enough drug to inhibit the ingrowth of the cell's indispensable for healing of denuded bone.

In patients on bisphosphonate medication, it is of utmost importance to evaluate carefully the history of the medication and relate it to the habitus of the patient before making decisions on possible implant or other surgical therapy. Consulting with the patient's physician is highly recommended.

Control of anxiety and pain

Many patients interested in maintaining a healthy dentition do not regularly seek dental care because of anxiety and apprehension related to such treatment. A recent study conducted in Australia revealed a prevalence of dental fear in adults ranging from 7.8% to 18.8% and of dental phobia ranging from 0.9% to 5.4%, respectively (Armfield 2010). Modern dentistry offers a variety of effective means for controlling pain and apprehension. This, in turn, means that dental treatments should no longer be feared by these patients. During history taking and the oral examination, the patient's profile regarding anxiety and pain thresholds should be considered.

Prior to therapy, an apprehensive patient may be premedicated using diazepam (benzodiazepine, Valium®, 2–5 mg) taken the night before, in the morning, and half an hour before an extensive

and/or surgical procedure. Painless dental care can be achieved by carefully and slowly applying local anesthetics.

Postoperative analgesic medication, such as non-steroidal anti-inflammatory drugs (NSAIDs) with analgesic and antipyretic properties are recommended. Diclofenac potassium, the active ingredient of Voltaren® (Voltarol) Rapid, inhibits prostaglandin synthesis by interfering with the action of prostaglandin synthetase. Following any kind of periodontal and implant surgery, 50 mg twice daily of Voltaren® Rapid is administered for 3 days (note: patients with gastric ulcers should not receive Voltaren® Rapid and care should be taken in patients with asthma). In addition, further adjunctive pain killers (mefenaminic acid, e.g. Ponstan® or Mephadolor® 500 mg not more than every 6–8 hours) may be prescribed depending on the individual patient's need and pain threshold.

Favorable personality interactions between the patient, the therapist, and the entire office staff may contribute to the overall control of anxiety but may require more time and consideration than that allocated to the routine patient.

Tobacco use cessation counseling

Second to poor oral hygiene habits, cigarette smoking constitutes the most important modifiable risk factor in the etiology and pathogenesis of periodontal diseases (Ramseier 2005; Ramseier *et al*. 2020). A careful assessment of the patient's smoking history has therefore become indispensable for comprehensive periodontal care.

In order to support periodontal patients to quit tobacco use, it is helpful for the clinician to have a proper understanding of the genesis of tobacco dependence. The term *tobacco dependence* refers to the condition of tobacco users suffering from both psychological tobacco use dependence and physical addiction to nicotine. Therefore, in order to predictably help people who smoke to quit, any approach to support tobacco use cessation should include both behavioural support to address the psychological component of the dependence and pharmacotherapy to treat the physical symptoms of withdrawal.

Today, professional evidence-based methods for tobacco use cessation predominantly consist of professional behavioural change counselling applying the so called "5A Method" (Ask, Advise, Assess, Assist and Arrange) in combination with pharmacotherapy. It has been shown that the success rates achieved by smoking cessation counselling are generally dependent on (1) the amount of time spent counseling, and (2) the prescribed drug. The success rates achieved by counseling lasting for 1–3 minutes, 4–30 minutes, 31–90 minutes, and >90 minutes are 14.0 %, 18.8 %, 26.5% and 28.4%, respectively (Fiore *et al*. 2008).

For practical reasons, periodontal care of people who smoke includes tobacco use brief interventions lasting 3–5 minutes at each appointment while focusing on the "AAR Method" (Ask, Advise, Refer) (Ramseier *et al*. 2010, Tonetti *et al*. 2015):

1. *Ask*: It is well recognized that the general medical history form plays a critical role in asking all patients about their tobacco use history. Asking all patients on a regular basis, allows a non-threatening introduction to the ensuing conversation between oral health professional and patient.
2. *Advise*: When advised and further asked about their readiness to quit, tobacco users often reply that they want to quit smoking "sometime" but that the time is not yet right. There are certain things they need to do first, which are seen as more important than giving up smoking. Even if the patient feels that they are ready to quit smoking, there may still be some uncertainty about the next steps. They may experience a lack of confidence to achieve this goal and feel under prepared to make a quit attempt. Behind this attitude is often the fear of failure, potential change to social habits, or worry about unwanted weight gain.
3. *Refer*: Making the arrangements for on-going support either via the dental office or other health agencies may provide the patients with valuable resources as they undertake a quit attempt. When available, referring to professional tobacco use cessation counseling services, whether in-house (including suitably trained dental personnel) or external (e.g. www.quitline.com) should be pursued.

Tobacco use brief intervention

A brief intervention for tobacco use cessation using motivational interviewing is presented in a clinical case example dialogue between a periodontist (Dr) and a patient (P) at the beginning of periodontal therapy (for more detailed information on motivational interviewing see Chapter 27).

Dr	"According to your tobacco use history, you are currently smoking cigarettes. May I ask you a few questions about your smoking?"	*Raising the topic Asking permission*
P	"Yes."	
Dr	"Could you tell me how you feel about your smoking?"	*Asking open questions (eliciting what the patient already knows)*
P	"Well I know I should quit. I know it's not good for my health. But I don't want to quit right now."	
Dr.	"So you don't feel that you want to quit right now, but you do have some concern about the health effects."	*Rolling with resistance*

P	"Yes."	
Dr	"Well, tell me more about what concerns you?"	
P	"Well, mainly that I would get lung cancer or something."	
Dr	"So you worry a bit about getting cancer because of smoking. Is there anything else that you don't like about smoking?"	
P	"Well if I quit my clothes would stop smelling."	
Dr	"So the smell of tobacco smoke is something you would like to be rid of?"	
P	"Yes, but I've smoked for many years, you know, and I tried to quit once before."	
Dr	"So even though you would like to be a non-smoker for health and other reasons you haven't had much success quitting."	*Reflecting on ambivalence*
P	"Yes, and right now I'm enjoying smoking so there's not much motivation to do try."	
Dr	"Well it sounds like even though you have some important reasons to quit, you're not very confident you could succeed and you don't feel ready to take on this challenge right now. I wonder if it would be OK for us to talk about this again next time to see where you are with it and whether I could help?"	*Summarizing*
P	"Yes that sounds fine."	

Conclusion

The goals of the systemic phase of periodontal therapy are to appraise those aspects that both the dental team and the systemic health of the patient may need to be protected against. Infection control in the dental office plays a central role. Protecting the patient against presumptive complications, such as infection, especially bacterial endocarditis, bleeding, cardiovascular episodes, and allergies, requires in-depth knowledge of the patient's medical history and oral examination.

Infective endocarditis prophylaxis is nowadays reserved for those patients with a history of a previous infective endocarditis, prosthetic heart valves, or surgically constructed conduits, and the use of antibiotics before dental treatment is unnecessary for patients with other cardiac abnormalities. Patients with systemic diseases such as diabetes mellitus or cardiovascular diseases are usually treated with a number of medications that may interact with drugs prescribed during periodontal therapy. Precautions should be taken, and consultation with the patient's physician prior to systematic periodontal therapy is recommended.

It has to be realized that periodontal treatment may also have a beneficial effect on the systemic health of the patient. Glycemic control may be facilitated in patients with diabetes if proper periodontal therapy is rendered.

Finally, tobacco use cessation counseling is part of modern periodontal treatment owing to the fact that, after inadequate oral hygiene standards, cigarette smoking constitutes the second most important risk factor for periodontitis.

Health behavior change counseling in periodontal care

Periodontal health is supported by healthy behaviors such as regular self-performed plaque control, avoidance of tobacco, and glycemic control in type 2 diabetes mellitus. Inadequate oral hygiene, tobacco use, and uncontrolled glucose levels, on the other hand, are shown to have a destructive impact on periodontal tissues. The dental community involved with oral health care should strive to enhance their understanding of the beneficial effects of healthy behaviors to target prevention and disease control successfully. With increasing evidence to support the potential benefits of health behavior change interventions, services aimed at the improvement of prevention on the individual level oriented toward encouragement of beneficial lifestyle behaviors have become a professional responsibility for all oral health care providers.

Data from epidemiological studies consistently reveal the prevalence of periodontal diseases in 20–50% of the adult population (Eke *et al*. 2012; Ide & Papapanou 2013). Gingivitis and periodontitis are initiated by oral pathogens that colonize to form a plaque biofilm (referred to as a polymicrobial community), then further modulated by local or systemic host factors (Hajishengallis & Lamont 2014). Based upon current models of periodontal pathogenesis, it is well accepted that disease occurs as a result of the interplay between the commensal microbiota, host, and environmental factors (Lang & Bartold 2018). Therefore, removal of the plaque biofilm remains as one of the key factors in attaining and maintaining periodontal health and therefore a prime focus for clinicians in facilitating adequate patient self-care.

In addition to the causal relationship of dental biofilms, a positive association between periodontal disease and tobacco use has been documented (Bergström 1989; Haber *et al*. 1993; Tomar & Asma 2000). Tobacco use contributes to the global burden of public health with almost one-third of the adult population using various forms of tobacco and an increasing number of annual deaths from tobacco-related diseases. Moreover, dietary factors have been shown

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

to significantly impact chronic diseases including obesity, cardiovascular diseases, type 2 diabetes, cancer, osteoporosis, and oral diseases (Petersen 2003; Suvan *et al*. 2018).

In summary, there is sufficient evidence to suggest that the patient's individual lifestyle behaviors are seen to be critical for the success of periodontal therapy with the benefits of therapy diminished in patients lacking in appropriate behaviors. In recent systematic reviews, it has been shown that in addition to self-performed plaque control, smoking cessation and the promotion of healthy lifestyles were the most important measures for the management of periodontitis (Carra *et al*. 2020; Ramseier *et al*. 2020). Therefore, it appears to be reasonable in clinical concepts for periodontal care to:

1. Incorporate behavior change techniques or tools to enhance patient motivation and capability toward oral hygiene self-care
2. Include holistic assessments of patient behaviors
3. Provide effective risk factor control interventions and behavior change counseling methods (where applicable).

The challenge

Since the 1960s, following the confirmation of plaque as an etiologic agent in gingival and periodontal inflammation by Löe and co-workers, periodontal care has traditionally included the instruction of effective oral hygiene procedures (Löe *et al*. 1965). In practice, as an example, a demonstration of a suitable toothbrushing method would be given to the patient, followed by recommendations of both the frequency and length of time per brushing. Earlier studies on the effectiveness of oral hygiene instructions consistently revealed that patient adherence to a proper daily oral hygiene regime fluctuates or generally remains poor (Johansson *et al*. 1984; Schüz *et al*. 2006). The reinforcement of oral hygiene habits through additional recall appointments may sometimes compensate for the ineffectiveness of one-time or repeated oral hygiene instructions. However, due to inconsistent patient adherence to clinician recommendations, supportive periodontal care visits are often cancelled resulting in a lack of professional maintenance care, in addition to wavering self-care, thus resulting in the further potential for recurrence of periodontal inflammation (Wilson *et al*. 1984; Demetriou *et al*. 1995; Schüz *et al*. 2006).

Unfortunately, many health education approaches seem to be inefficient in accomplishing long-term behavior change, potentially leading to frustration for both the patient and the clinician. The following hypothetical dialogue between a clinician (C) and a patient (P) illustrates how using a directive advice-oriented method for behavior change counseling may lead to an unproductive conversation and little likelihood of change by the patient:

C "Are you using the interdental brushes regularly?"
P "Yes, but not as often as I should."
C "I would strongly recommend that you try to use them daily. As you probably know there may be serious consequences if you don't clean between the teeth frequently enough."
P "I know I should use them more often, but…"
C "It's not something that is optional but rather very important!"
P "I know … …but I don't have the time!"

Since the clinician fails to offer the patient a chance to discuss the reasons to clean interdentally on a regular basis or the patient's perceived barriers to using interdental cleaning aids, the conversation reaches an impasse and behavior change becomes unlikely. In certain cases, the patient may even be blamed for poor compliance and further oral health education may be seen as pointless.

In order to reliably achieve beneficial outcomes in periodontal care, effective oral hygiene self-care (and risk factor control) is critical, and therefore it may be necessary to apply different tools or techniques as part of behavior change interventions for each individual and behavior. This can appear complicated and discouraging for clinicians. However, a focus on approaches based upon health behavior change principles common across a multitude of psychological theories can serve to simplify learning and application of health behavior change methods for clinicians. Motivational interviewing is an example of an approach that encompasses aspects fundamental to facilitating choice of healthy lifestyle habits and health behavior evidenced in the field of behavioral sciences. The preferred aim is to apply approaches to clinical practice that are shown to be effective in both primary and secondary prevention of oral diseases and are:

- based on the best available evidence
- applicable to oral hygiene behavior, tobacco use prevention and cessation, and dietary counseling, and
- suitable for implementation by the dental practice team in a cost-effective way.

Clinician–patient communication

At the center point of achieving meaningful clinician–patient interactions, regardless of the topic, lies the importance of effective communication. There are several different communication styles used, largely unconsciously, when interacting with people in everyday life. In providing patient care, evidence from psychological models suggest it is preferable to adapt to each patient's individual behavioral needs and to their own perceived interests or concerns using styles of communication as an advantage. As a framework for communication, Rollnick and colleagues have

proposed a three-style model for health care clinicians to communicate with their patients in daily practice, consisting of a directing, guiding, or following style (Rollnick *et al*. 2008):

- A *directing* style includes the delivery of expert advice and support. This has traditionally been a standard approach within dental care settings. Directing is appropriately used where there is a good rapport between the clinician and the patient. The advice should be well-timed, personally relevant, and delivered in such a way as to engage the patient. A directing style can be used after the patient poses a question or expresses interest in a topic. For example, "What can I do to stop the need for scaling every time I come back here?".
- A *following* style relies upon attentive listening skills and occurs in situations where understanding or sensitivity is required (such as when a patient has a particular concern or is perhaps upset). The goal of a clinician using a following style is not to immediately solve the patient's problem, but to provide support and encouragement. The *following* style is a valuable tool in enhancing rapport as it is a tangible demonstration of respect for the patient and their concern. As an example, the following style can be used after the patient has said something like: "There's so much going on in my life and now I am discouraged about my teeth too."
- In *guiding*, the clinician is collaborating with the patients to help them identify the patient's own goals, and how they might best achieve them. This style is most appropriate in clinician–patient discussions about health behavior changes, especially with individuals who may be ambivalent about changing a habit. An example of a statement of ambivalence might be: "I know that smoking isn't good for me, but it's the only pleasure I have in life". A *guiding* style would explore both sides of the statement further to allow the patient to identify for themself how to move from this ambivalent position.

During health behavior change conversations, some patients may benefit from *direction*, particularly those who have expressed interest in further information or advice. Others may have more pressing concerns and therefore need to be *followed*. However, those patients who appear to know what they need to do, but have not managed to do it yet, will be most receptive to a *guiding* (Rollnick *et al*. 2008).

During patient communication, it is important to be sensitive to the patient's response to the various styles of communication and to flow seamlessly between the styles as appropriate. If the rapport between the clinician and the patient seems to be interrupted this may be an alert that the style is too directive and not sufficiently engaging for the patient. The primary aim is for the interaction to be shared collaborative communication. Throughout all communication interactions with the patient, it is valuable to remember that asking questions should only occur when the patient is able to respond comfortably (i.e. without being interrupted by the clinician). Without this consideration, communication success will be challenged as the patient may feel a loss of control. A guiding interaction with the optimal opportunity to facilitate behavior change is based upon rapport and respect. It is focused on enhancing patient perception of autonomy, self-control or self-efficacy.

To keep a good balance of both rapport and progress being made toward establishing healthy habits during patient communication, four primary communication techniques may be considered and are summarized with the acronym OARS: *O*pen-ended questions, *A*ffirm the patient, *R*eflect, and *S*ummarize:

- *Ask open-ended questions*: Approaching the patient with multiple closed-ended questions (question that will be answered with "yes" or "no" or one-word responses) sets the patient's role to be passive rather than active. Open-ended questions invite thought, collaboration, and effort on the part of the patient. Example: "How do you feel about your oral hygiene regime?"
- *Affirm the patient*: It is human nature to presume a negative attitude, particularly when one's own behavior is coming under scrutiny. Acknowledging the patient's strengths and appreciation of his or her honesty will decrease defensiveness, increase openness, and the likelihood of change. Example: "You're clearly telling me just why you're not very concerned about your toothbrushing and I appreciate that honesty".
- *Reflect on what the patient is communicating*: Reflection is the primary way to demonstrate empathy (ability to understand another person's perspective). Appropriate reflection includes the genuine effort to understand the patient's perspective. It (1) captures the underlying meaning of the patient's words, (2) is concise, (3) is spoken as an observation or a comment, and (4) conveys understanding rather than judgment. Example: "You really seem to have lost hope that you will ever manage to clean between your teeth on a daily basis."
- *Summarize*: Summarizing the patient's statements demonstrates interest, organizes the conversation, and can be utilized to redirect a conversation that may have diverged, if necessary. It involves the compilation of the patient's thoughts on making a change in habit or behavior mentioned during the interactions. For example, "So there's a big part of you that doesn't feel ready to change right now. You really enjoy smoking, but you have been a little worried by the way some people react when they find out that you smoke. Is that about right?"

Evidence for health behavior change counseling

Evidence in general health care

Evidence for the positive impact of health behavior change interventions has generally grown over the past few years. Today, several internationally accepted clinical practice guidelines are available for various health behavior change interventions such as smoking cessation (Fiore *et al*. 2008), diabetes control (WHO 2006; Powers *et al*. 2017; VA/DoD 2017), physical exercise (WHO 2010; Rütten & Pfeifer 2016; Azar 2018), change of diet (WHO 2004; FANTA 2016) including carbohydrate reduction (WHO 2015), and weight loss (NIH 1998; Yumuk *et al*. 2015; Fitzpatrick *et al*. 2016). Most suggested methods include initial brief interventions followed by more extended counseling mostly adopting the basic principles of motivational interviewing (MI). A common recurring theme, across both behavioral scientists and clinicians, is the proposition that a patient's intrinsic motivation is related to patient values, experiences, understanding of risk, feelings of confidence, and self-esteem (Deci & Ryan 2012).

MI was initially developed for the treatment of addictive behaviors, particularly alcohol addiction. Therefore, the bulk of empirical studies pertaining to MI has been conducted in this area. Nevertheless, the explosion in the application of MI to other areas of behavior change has been sufficient to provide evidence for numerous published meta-analyses (Burke *et al*. 2003, 2004; Hettema *et al*. 2005; Rubak *et al*. 2005; Lundahl *et al*. 2010; Magill *et al*. 2018), the more recent of which include nearly 100 clinical trials and more than 3000 participants. The overall majority of meta-analyses indicate that MI-based interventions are at least equivalent to other active treatments and superior to no-treatment or placebo controls for addressing lifestyle choices involving addictive behaviors (drugs, alcohol, smoking, and gambling), health behaviors such as diet and exercise, risk behaviors, and treatment regime engagement, retention, and adherence. Effect sizes, on average in the medium range, are mostly dependent on counseling skills (Hettema *et al*. 2005; Lundahl *et al*. 2010; Magill *et al*. 2018). Of particular relevance to dental settings where only brief counseling is feasible, is that MI-based interventions are similarly efficacious as alternative active interventions despite involving significantly less contact time, suggesting that MI may be a particularly efficient method of counseling (Burke *et al*. 2004; Lundahl *et al*. 2010). Rubak *et al*. (2005) reported that in brief encounters of 15 minutes, 64% of studies showed a beneficial effect. In addition, when the intervention was delivered by physicians, an effect was observed in approximately 80% of studies suggesting that it is feasible for professionals who are not counseling experts to effectively deliver MI in brief encounters (Rubak *et al*. 2005).

Another particularly relevant target behavior for oral health is dietary habits. As indicated, meta-analyses have found significant effects of MI for changing dietary habits. Specifically, these studies have documented changes due to MI in overall dietary intake (Mhurchu 1998), fat intake (Mhurchu 1998; Bowen *et al*. 2002), carbohydrate consumption (Mhurchu 1998), cholesterol intake (Mhurchu 1998), body mass index (BMI) (Mhurchu 1998), weight (Woollard *et al*. 1995), salt intake (Woollard *et al*. 1995), alcohol consumption (Woollard *et al*. 1995), and consumption of fruits and vegetables (Resnicow *et al*. 2001; Richards *et al*. 2006). Particularly noteworthy when considering evidence of MI to facilitate health behavior change interventions in general health care settings are the similarities in effects across disciplines and lifestyle behaviors, suggesting the wide applicability of the methods.

Evidence in periodontal care

Within oral health care, an early study investigating the impact of MI in oral care examined the effect of its use compared with traditional health education for motivating 240 mothers of young children with high risk for developing dental caries to use dietary and non-dietary behaviors for caries prevention (Weinstein *et al*. 2004, 2006). In this study, an MI session and six follow-up phone calls over a year, in addition to an educational pamphlet and a video, was more effective than the pamphlet and video alone in preventing new dental caries among the children after two years. This result has been consistent with the results of the meta-analyses that have found MI to be efficacious on oral health for dietary change (Burke *et al*. 2003; Hettema *et al*. 2005; Lundahl *et al*. 2010).

Related to oral hygiene motivation, both short and long-term studies over the past decade have demonstrated a positive impact on (1) oral hygiene as measured by plaque indices, and (2) gingival inflammation as assessed by gingival indices. Almomani *et al*. (2009) were able to demonstrate a significant positive impact on oral hygiene in a 2-month trial. Subsequently, Jönsson *et al*. (2009a) conducted a case series pilot study with two patients over 2 years to follow the impact of an individually tailored oral hygiene program on the periodontal indices mentioned (Fig. 27-1). Following MI sessions using the techniques described in the present chapter as well as oral hygiene instructions on an individual basis as described in Chapter 28, both patients succeeded to improve their oral hygiene and their gingival health over an observation period of 2 years (Jönsson *et al*. 2009b). The same authors subsequently demonstrated the positive impact of MI in a larger study with 113 patients over a period of 12 months (Jönsson *et al*. 2009a, 2010).

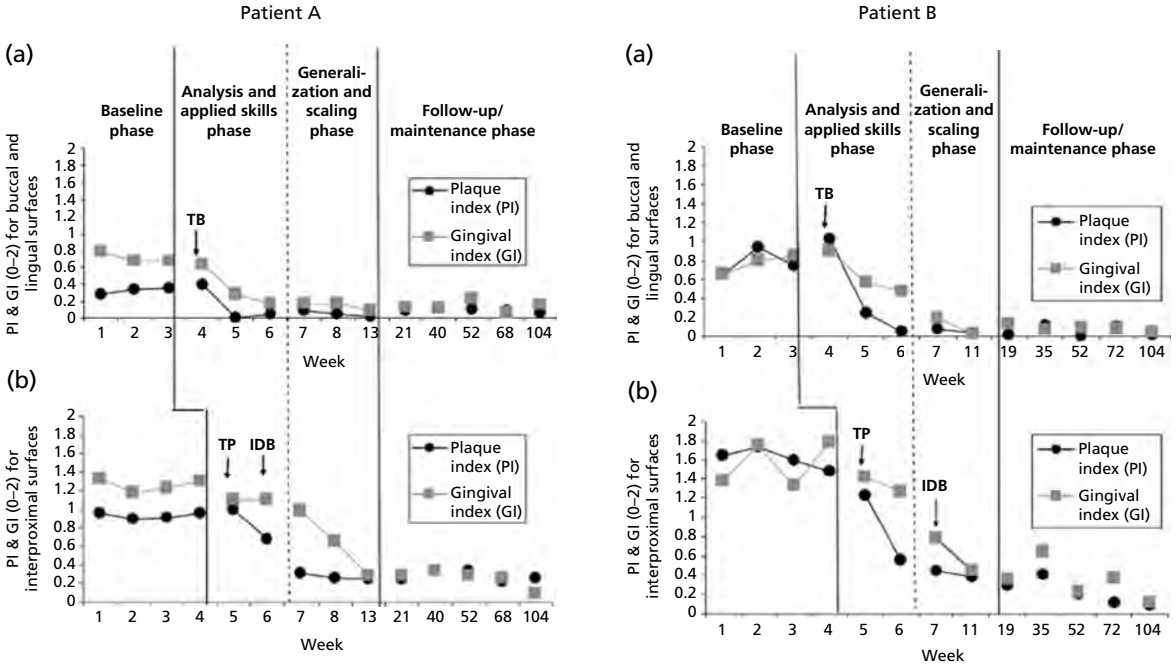

Fig. 27-1 Following an individually tailored treatment program for improved oral hygiene, both full mouth and interproximal plaque index and bleeding index from patient A and patient B dropped significantly over an observation period of 104 weeks. IDB, interdental brush; TB, toothbrush: TP, toothpick. (Source: From Jönsson *et al*. 2010. Reproduced with permission from John Wiley & Sons.)

In summary, evidence-based support for MI as an effective method of counseling for oral hygiene motivation is increasing. Two recent systematic reviews demonstrated improved effectiveness of MI when being implemented in periodontal care (Kopp *et al*. 2017; Carra *et al*. 2020). Moreover, two clinical trials demonstrated their positive impact of MI on communication with patients undergoing periodontal therapy (Woelber *et al*. 2015; Kitzmann *et al*. 2019).

Although second to plaque control, smoking cessation was found to be the next most important measure for the management of periodontitis (Ramseier 2005). Additional evidence suggests that dietary counseling using the principles of MI has an additional positive impact on clinical outcomes following periodontal therapy (Woelber *et al*. 2017, 2019).

Understanding health behavior change counseling

As discussed, focused health *education* efforts provided by clinicians are frequently ineffective in stimulating lasting changes in patient behavior. Considerable behavioral research suggests that the root of this common problem can be traced back to a false assumption inherent in the health education approach. Specifically, that behavior change is simply a function of a patient having the requisite knowledge or understanding, and that the role of the clinician is to provide the relevant information. MI, in contrast, is based on a different assumption of human behavior change. It assumes that the knowledge is insufficient to bring about behavior change and that, instead, sustained behavior change is much more likely when change is connected to something the individual values. In other words, motivation is elicited "from within the patient" rather than externally imposed upon the patient by a clinician. In MI, the assumption is that individuals have "within them" their own reasons for changing and that the role of the clinician is to elicit and reinforce these reasons. Similarly, patients are also the best person to identify attainable goals and the possible steps to reach when guided by a collaborative clinician.

As previously mentioned, MI originated in the field of addictive behavior but has increasingly been applied to a wide variety of other behavior change problems including health behaviors such as tobacco use, and diet and exercise (Burke *et al*. 2004; Hettema *et al*. 2005). The method was originally developed by William Richard Miller in response to his observations of the confrontational approach that was standard treatment for patients with alcohol problems in the 1970s. In contrast, he observed that the research literature suggested that positive outcomes were mostly related to a strong bond or "therapeutic alliance" between the counsellor and the patient. Miller developed an empathy-centered treatment which used the *therapeutic alliance* and *empathy* to engender the client's inherent motivation to change (Miller 1983). Subsequently, Miller met Stephen Rollnick, the co-founder of the MI method, who had been concentrating on *ambivalence*, or the extent to which the client envisioned the pros and cons of changing. Miller and Rollnick together began to explore the use of

language during MI, concentrating on the elicitation of client "change talk" to promote behavior change. In 1991 Miller and Rollnick published the first textbook edition of *Motivational Interviewing: Preparing People to Change Addictive Behaviors* in which they provided a detailed description of the approach. Since then, there has been increasing interest in the research and application of MI, with many researchers addressing the applicability of the method to addressing health behavior change (Resnicow *et al*. 2002). Subsequently, various approaches for the implementation of MI in the dental setting have been published in the textbook *Health Behavior Change in the Dental Practice* by Ramseier and Suvan (2010).

MI was originally defined as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence" (Miller & Rollnick 2002). The client-centered element refers to the emphasis that is placed on understanding and working from the perspective of the patient and their view of what it means to make a behavior change. For example, rather than a clinician simply telling a patient about the benefits of quitting smoking (from the clinician perspective), the clinician invites the patient to describe *his or her own view* of the advantages of quitting and disadvantages of continuing to smoke. Although the patient's perspective is central, because MI is also directive, the clinician takes deliberate steps to facilitate a particular behavioral outcome. For example, in patients undergoing periodontal therapy and without ignoring their concerns about changing, the clinician selectively reinforces and encourages elaboration of any patient statements (i.e. "change talk"), that are oriented toward the possibility or benefits of making a change (e.g. taking more time for oral hygiene self-care) (Kitzmann *et al*. 2019). By eliciting and elaborating upon the patient's own reasons for change the motivation for change that is fostered is intrinsic or internal, rather than externally imposed. This approach rests on the assumption that individuals are almost always ambivalent about changing their behavior (i.e. it is almost always the case that individuals can identify both pros and cons of changing). In applying behavior change approaches, clinicians therefore attempt to enhance intrinsic reasons for change by facilitating an exploration and resolution of the patient's underlying ambivalence.

General principles

Although MI methods and techniques provide a wealth of guidance of what to do and what not to do when counseling patients, Miller and Rollnick (2002) have emphasized that to successfully provoke behavior change, it is more important to embody the underlying philosophy than to be able to apply the collection of techniques. They have identified four general principles that capture the underlying philosophy of the method:

- First, a clinician should *express empathy* for the patient's behavior change dilemma. In other words, the clinician should communicate acceptance of the patient's perspective, providing and *expressing* full acknowledgement of the patient's feelings and concerns.
- The second principle is to *develop discrepancy* between the patient's current behavior and how they would ideally like to behave to be consistent with their broader goals and values. For example, the goal of being strong or responsible, or a good spouse or parent, can often be linked to being healthy and suggest the need for improved health behaviors.
- The third principle is to *roll with resistance*. When patients argue against change there is a strong tendency to fall into the trap of providing counter arguments. As a result, the patient expends all of their energy arguing against change which is precisely the opposite of what is desired, perhaps making them even less likely to change. MI clinicians therefore avoid arguing and instead use MI methods to "roll with resistance".
- The fourth principle is to *support self-efficacy* or the patient's confidence in their ability to make a change. Patients are unlikely to succeed in making a change even if they are motivated when they do not know how or do not believe they can. In periodontal care, clinicians therefore can make efforts to enhance their patients' confidence through such means as expressing their belief in the patient's ability to change or pointing out past successes or steps in the right direction (Woelber *et al*. 2015).

Giving advice

Although we have highlighted the distinction between advice-oriented health education and MI in this chapter, it is important to recognize that at times it is appropriate to provide information to address patients' questions, misapprehensions, or lack of knowledge. The MI skill code, which is used to assess clinician's adherence to principles of MI, distinguishes between giving advice *without* permission, which is prescribed, and giving advice *with* permission which is consistent with MI principles (Moyers *et al*. 2003). In essence, it is consistent with MI to provide information when the patient is willing and interested in receiving it. Clinicians commonly err by providing advice too soon in an encounter with a patient, resulting in patients perceiving the clinician as having an agenda that they are trying to "push". In contrast, it is common in MI practice to find that the process of eliciting the patient's perspective reveals gaps in knowledge, questions and concerns, and misapprehensions for which the patient would appreciate receiving more information. The clinician can then provide particularly relevant information that is much more likely to be well received. Rollnick *et al*. (1999) have outlined a three-step process that serves

as a useful framework for providing advice in an MI consistent style:

- Step 1: *Elicit* the patient's readiness and interest in hearing the information. For example, a clinician might say to a patient "I have some information related to [topic] that you may be interested in. Would you be interested in hearing more about that?"
- Step 2: *Provide* the information in as neutral a fashion as possible. For example, a clinician might say "Research indicates that…" or "Many of my patients tell me that…" This allows oral health-related information to be presented in a manner that supports the patient's autonomy.
- Step 3: *Elicit* the patient's reaction to the information presented. Following up will often facilitate the patient to integrate the new information in a way that brings about a new perspective and increases motivation to change. Alternatively, following up may reveal further gaps in knowledge or misunderstandings that can be addressed. If a patient "rejects" the information, it is important not to get into a debate. It is generally better to simply acknowledge the patient's perspective with statements such as "I can appreciate this information doesn't fit with your experience" or "I understand this information doesn't seem relevant to your situation" and then move on to a more productive area of conversation.

It may take several dental appointments for a patient to make significant and sustained health behavior change. Only relatively small steps towards change are likely to be accomplished following one brief encounter. Dental clinicians, who understand how to limit their expectations for each appointment, may ultimately feel less inclined to push the patient. By taking a long-term perspective (as appropriate for any behavior change process) they may be more aware of what they can accomplish in a relatively short amount of time, and therefore feel less frustration with resistant or highly ambivalent patients.

Agenda setting

Within clinical consultations, it is often the case that there is more than one health behavior affecting the patient's oral health. Achieving small changes can make a patient feel more able and confident to make other changes (Bandura 1995). In these situations, it is important to start where the patient feels most comfortable and encourage them to suggest the aspect they would like to talk about, rather than simply selecting what the dental clinician feels is the most pressing issue. One clinical tool that can help with this task is an 'agenda setting chart' (Rollnick *et al*. 1999). Using this tool, both the clinician and patient are enabled to target and discuss one behavior change goal at a time or at one dental visit, respectively. Moreover, the patient selects the issue that he or she would like to talk about first. Allowing the patient to choose reinforces respect and a sense of equal control.

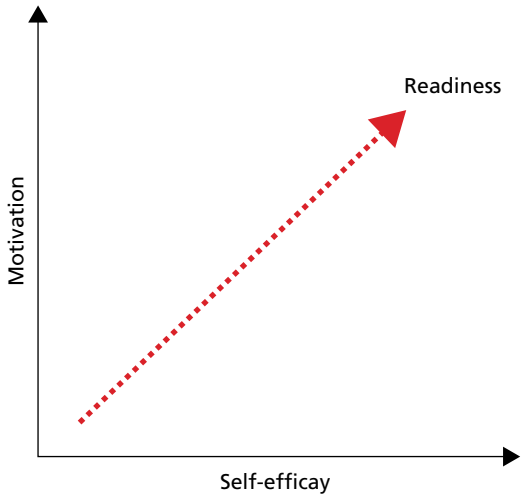

Fig. 27-2 Readiness to change. (Source: Adapted from Rollnick *et al*. 1999. Reproduced with permission from Elsevier.)

Readiness ruler

Clinicians often expect their periodontal patients to be ready to change their oral hygiene habits simply because they would like to have good oral health (Miller & Rollnick 2002). Assessing the periodontal patient's readiness to change involves learning about both the patient's motivation and self-efficacy to change (Rollnick *et al*. 1999; Woelber *et al*. 2015). Using this series of questions about readiness, the clinician can form a rather complete picture of a patient's position regarding change within a short amount of time.

When assessing both motivation and self-efficacy, the clinician seeks to discover the patient's specific motivators and values, in order to link them to the desired behavior change (Fig. 27-2). As described by Koerber (2010), particularly with brief interventions in dental settings, the readiness scale is a useful tool. It consists of (1) the motivation scale, and (2) the self-efficacy scale as described by Rollnick *et al*. (1999).

First, the motivation (importance) scale (Fig. 27-3) consists of three questions. For example:

1. "On a scale of 1 to 10, where 10 is absolutely important and 1 is not at all important, how would you rate the importance of brushing your teeth regularly?"
2. "Why did you rate it as (X) instead of 1?"
3. "Why did you rate it as (X) instead of a 10?"

Note that question 2 reveals the patient's motives, and question 3 reveals the patient's ambivalence.

Second, the self-efficacy (confidence) scale (Fig. 27-3) consists of the following questions:

1. "If you were convinced that brushing your teeth regularly was very important, on a scale of 1 to 10, how confident are you that you could do it? One means not at all confident and 10 means completely confident."
2. "Why did you rate it as (X) instead of 1?"
3. "Why did you rate it as (X) instead of 10?"

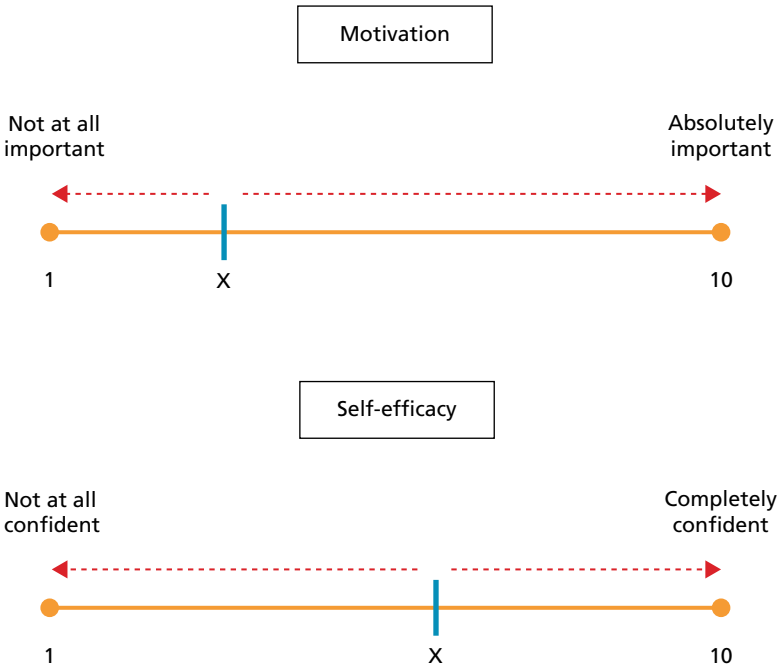

Fig. 27-3 Motivation (importance) and self-efficacy (readiness) scale.

It is to be noted that question 2 reveals a patient's strengths to make the change, and question 3 reveals the barriers.

Goal setting, planning, and self-monitoring

In alignment with the above-mentioned concepts and principles and to further assist the clinician's long-term efforts of patient counseling, a specific approach for oral hygiene motivation was first suggested at the 11th European Workshop of Periodontology in 2015 and summarized with the acronym GPS, for *G*oal setting, *P*lanning, and *S*elf-monitoring (Tonetti *et al*. 2015):

- *Goal setting*: While acknowledging the patient's autonomy and self-determination, the change to be made can be set as a (treatment) goal. In order to facilitate this step, the agenda setting chart can be used in order to address one particular behavior at a time. Alternatively, and often particularly suitable with people who smoke, oral hygiene behavior will be addressed first followed by dietary changes and followed by smoking cessation.
- *Planning*: This step consists of the close collaboration with the patient to decide when, where, and how he or she will undertake which step of (if not a complete) behavior change.
- *Self-monitoring*: Finally, the patients' ability to assess their own behavior in relation to the previously set goals will be encouraged. Clinicians often achieve this by increasing their patients' self-efficacy by giving positive feedback or praise.

Technology to facilitate behavior change

Most recently, technological advances in consumer devices have provided novel ways for clinicians to connect with patients and for patients to self-monitor behaviors ultimately encouraging self-efficacy. One example is the use of text messages to encourage patients in keeping steps toward a goal. In a recent systematic review of studies investigating the effect of mobile applications and text messages compared with standard oral hygiene instructions for improving oral hygiene regimes, 13 of 15 studies demonstrated a benefit associated with the groups that included adjunctive use of mobile applications to reinforce oral hygiene messages (Toniazzo *et al*. 2019). Authors suggest that it is unclear whether the observed benefits were due to increased patient engagement supporting self-efficacy, enhanced clinician patient relationship, increased understanding of their own personal oral health, or the possibility to intervene in breaking former habits. Perhaps the key is a synergy between these multiple aspects. This is a relatively new and emerging area of behavioral research but offers potentially new ways to facilitate healthy behaviors beyond the practice setting.

The patient activation fabric

Implementing motivational interviewing in a dental setting requires consideration of how to ensure the collaborative and empathic spirit of the method (Ramseier & Suvan 2010). A specific patient activation fabric was presented by Suvan *et al*. (2010). This model attempts to capture the interdependent

elements of the dental visit using the concept of interwoven threads (Suvan *et al*. 2010). Communication and information exchange blend together with clinical assessment and treatment (Fig. 27-4).

Band I: establish rapport

The goal of establishing rapport is to engage the patient quickly and establish an environment where both conventional dental treatment and health behavior change counseling can occur. Accomplishing this depends on much more than simply the amount of time taken. A warm, courteous greeting is a critical start in creating an environment of mutual trust and respect. Furthermore, such basic matters as how the patient and clinician are seated can contribute to the patient feeling like they are truly being invited to engage in a dialogue as a partner (Fig. 27-5), rather than feeling they are simply to be the recipient of expert advice (Fig. 27-6). These simple actions create the perception of the patient and clinician having equal control of the situation rather than one being dominant. Beginning with an open question that seeks the patient's chief complaint or reason for attending the visit is another simple and valuable step. These opening moments set the scene for the remainder of the visit and can save valuable time later in the session.

Before proceeding with the clinical assessment, it is important to list briefly the elements of the procedure to the patients then ask them if they would be happy to proceed with it at that time. Asking permission is a simple way to engage the patient while simultaneously encouraging a sense of autonomy. It may be helpful to explain to the patient the relevance of the information that they may hear you give to your assistant. These small actions help to keep your patient engaged in the consultation, rather than allowing them to shift to a passive role of lying helplessly on the dental chair throughout the assessment procedure.

Band II: information exchange

This second stage of the interaction would most often take place following initial clinical assessment of the patient's oral health status. This exchange of information allows both clinician and patient to understand the other's perspective and create a more accurate picture of the clinical problem and approaches to effective management. This discussion can take many different forms.

An alternative approach to providing information is one in which the clinician maintains a focus

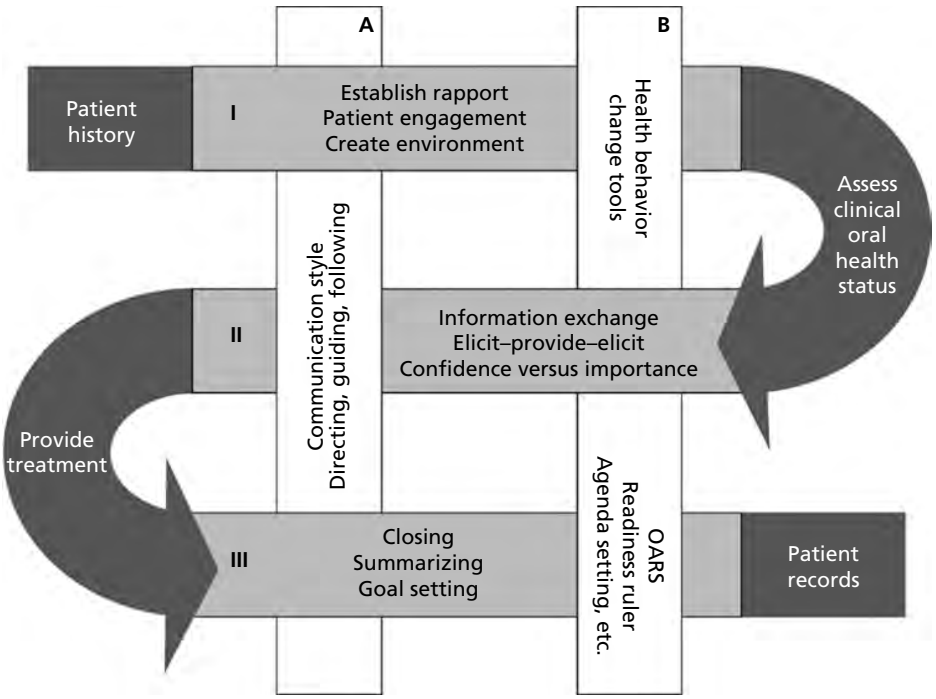

Fig. 27-4 Patient Activation Fabric for the Dental Visit (Implementation Model) from Suvan *et al*. (2010). The patient history and patient records positioned at the start and end depict the critical elements of documentation that serve to weave one dental visit into the next. The horizontal bands depict the three core strands of conversations constituting the visit. These bands labelled as "Establish Rapport", "Information Exchange", and "Closing" transition directly into the curves, representing the clinical assessment or treatment that takes place between the conversations as part of the flow of the appointment. The bands are woven together through the vertical ribbons (A, B) that signify the specific elements of the communication and interaction characterizing the approach. These vertical ribbons represent communication style and health behavior change tools and are consistent, yet flexible, recurring throughout the appointment ready to provide stability. OARS, *O*pen-ended questions, *A*ffirm the patient, *R*eflect, and *S*ummarize. (Source: Suvan *et al*. 2010. Reproduced with permission from John Wiley & Sons.)

Fig. 27-5 Appropriate position for a conversation: the clinician is facing the patient on the same seating level.

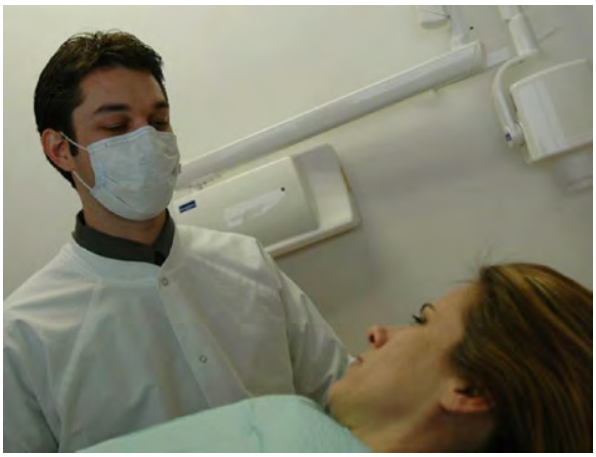

Fig. 27-6 Inappropriate position for a conversation: the clinician is wearing the face mask and is at a higher level to the supine patient.

on patient engagement using the elicit-provide-elicit method described above. Starting with what the patient already knows (elicit) immediately encourages patients to think, reflect, and acknowledge their own expertise. From that starting point the clinician can then, with permission, tailor the information offered to each patient (provide). Perhaps the most important step is the question that follows exploring what sense the patient makes of information provided (elicit). This question can open the door to dialogue rich with opportunity for discussions about possible change.

Leading into and moving on from this middle phase of the visit the clinician may be performing a number of clinical tasks including assessment and treatment. Conversations about behavior change are most valuable when the clinician and the patient are able to speak freely. Be mindful not to have these conversations when the patient is unable to be an equal participant, such as when the patient is physically incapable of speaking, or may be feeling pain or discomfort during or after clinical procedures.

Band III: closing

The third band takes place and functions as a closing to the visit. It may involve a brief summary of the clinical treatment that has been provided together with any expected side effects or post-treatment discomfort. Equally as important is that it serves to briefly summarize behavior change discussions. It provides the clinician with the opportunity to review the agreed goals or plan of action suggested by the patient in Band II. To ensure this is collaborative, the clinician should ask the patient if there is anything they would like to add to the plan and confirm with them that the most important points have been covered. Further treatment options may also be discussed if the patient is not too tired. However, this is not typically the best time for most patients to discuss important facts as they are usually focused on leaving the dental chair as soon as the appointment has concluded.

Ribbon A: communication style

Earlier in this chapter, styles of communication were presented highlighting that a spectrum exists with directing and following at opposite extremes and guiding in the middle as an intermediary style engaging both parties equally. A skilful movement between the three styles constitutes the well-managed interaction with the patient. In the model, communication style is labelled as a vertical ribbon interwoven through the entire visit. This portrays that at certain times during the visit, a particular style will tend to be more advantageous than the others. Maximum patient engagement without compromising the clinician's responsibility and ability to provide important information will be facilitated through use of a guiding style. Fundamental communication techniques such as asking open questions can encourage the two-way communication that characterizes a guiding style. However, this does not infer that it is the only style of communication used during the visit.

Ribbon B: health behavior change tools

The second vertical ribbon represents the many behavior change tools presented in this chapter to facilitate patient activation or interaction throughout the visit. Like Ribbon A, clinicians may choose the tool they feel will be most beneficial at certain points in the visit or conversation. The choice is driven by the goal to provide a relaxed atmosphere where conversations can be spontaneous and individualized to each patient.

Case examples

Oral hygiene motivation I

Using the following case example, MI is demonstrated in a dialogue for oral hygiene motivation between a clinician (C) and a patient (P) diagnosed with periodontitis at the beginning of periodontal therapy.

C	"Would you mind if we talk about methods to improve your oral hygiene during and after your gum treatment?"	*Raising the topic* *Asking permission*
P	"No, I don't mind."	
C	"Good. Could you let me know a little bit about how you usually clean your teeth?"	*Asking open questions (eliciting what the patient already does)*
P	"I usually brush once or twice a day."	
C	"So you brush your teeth regularly. What are you using when you clean your teeth?"	
P	"I use a toothbrush and toothpaste."	
C	"Very good. Could you let me know how you use your toothbrush?"	
P	"I brush all upper and lower teeth on the outside and the inside as I was shown a long time ago."	
C	"And how do you feel about brushing your teeth that way?"	
P	"I generally feel quite good about it. But since I have been told I have gum disease, I'm wondering if I haven't been brushing enough?"	
C	"So you have been making efforts to keeping your teeth clean but you're worried that maybe you haven't been brushing enough. It can be difficult to get to all the areas of your teeth and gums to remove the plaque that causes gum disease. I have some information related to prevention of gum disease that you might be interested in. Would you like to hear about it?"	*Reflective listening* *Showing empathy* *Asking permission*
P	"Yes."	
C	"The gum or periodontal disease you are diagnosed with was caused by bacterial plaque attached to your teeth over time. Plaque has to be entirely removed from all the tooth surfaces on a daily basis in order to prevent and control this disease. How confident are you that you were cleaning all the surfaces on a regular basis?"	*Providing information* *Assessing confidence*
P	"Not so much, although I thought that I was doing enough."	
C	"Well actually, research indicates that using a toothbrush alone is not sufficient to clean between the teeth. In order to clean these areas, an interdental device is needed such as a dental floss, a toothpick, or an interdental brush. Are you using any one of these devices?"	*Providing information*
P	"Yes, I've tried using dental floss."	
C	"How did you find the use of dental floss?"	*Asking open questions*
P	"I had some trouble getting to some of the spaces between my teeth. In other areas, the floss used to rip up too, so I quit using it."	
C	"I am sorry to hear that you had trouble using the dental floss. The floss can rip up at the edges of dental fillings or crowns. In spaces with extensive tartar built-up, the gap between your teeth may even be blocked out with tartar. Are you using anything else for cleaning?"	*Showing empathy*
P	"Yes, I use a toothpick whenever I have something stuck between my teeth."	*Asking open questions*
C	"So in addition to your regular brushing with toothpaste you are also using a toothpick from time to time to clean your teeth?"	*Reflective listening*
P	"That's right."	
C	"Good. During gum treatment, fillings and crowns with rough edges will be smoothed over and tartar can be removed which should make it easier to use things like dental floss or a toothpick between your teeth. Thinking of a 10-point scale where 0 is not at all important and 10 is extremely important, how important is it to you to floss or use a toothpick every day to clean the gaps between your teeth?	*Providing information* *Using readiness ruler on importance*
P	"Probably a 7."	
C	"That sounds quite important. What makes this so important to you?"	
P	"I want to do everything needed to keep my teeth. However, I am not quite sure if I will be able to keep doing it over time."	
C	"So you are quite motivated now because you want to look after your teeth, but you are worried about the long term. If you were to use the same 10-point scale to rate how confident you are that you can do it over the long term, where would rate yourself?"	*Using readiness ruler on self-efficacy*
P	"I would be at a 6."	

(*Continued*)

C	"That sounds fairly confident. What gives you that level of confidence?"	
P	"Well, taking care of my teeth and gums is part of my routine already so this would just need to be added to it. But it does take extra effort, so it's a matter of realizing that it's really that important for my gums."	
C	"So the fact that it can be part of your existing routine will help. But perhaps I can help you remain motivated in the long run by showing you at your follow-up visits the benefits you are achieving with your treatment by doing it regularly. How do you think that might help you to stick with it over time?"	*Supporting self-efficacy*
P	"Well, yes I think that would probably help a lot to see or learn from you that it really is making a difference to the success of my treatment."	
C	"Great! So, let me summarize what we have discussed. You plan to keep brushing on a regular basis with toothbrush and toothpaste and you will start to use a device for cleaning the gaps between your teeth after the issues with the rough filling and crown margins have been resolved. Then, each time you visit we will see how you are progressing with your cleaning at home and see if we need to find any other ways to help. Does that sound like it would work for you?"	*Summarizing*
P	"Yes, that sounds like it would work."	

Oral hygiene motivation II

In this second case example dialogue, MI is used in a conversation about oral hygiene at a visit for supportive periodontal therapy (SPT).

C	"From looking at your plaque-index, I noticed today that compared with your last visit 3 months ago there is more plaque around the areas between your teeth. I was wondering if you could tell me a little bit about how you find the cleaning between your teeth."	*Raising the topic* *Asking permission*
P	"Oh… I guess that I do not do it as often as I should. I barely have time now to do it every day, you know."	
C	"I understand. It takes time to clean all the areas between your teeth, you are right. May I ask you a few questions about your current oral hygiene habits so I could understand your situation better?"	*Showing empathy*
P	"Sure you can."	*Asking permission*
C	"Good. So, what do you use to clean your teeth currently?"	*Asking open questions (eliciting what the patient already does)*
P	"I am using an electric toothbrush and the interdental brushes you showed me."	
C	"Ok. How often do you use these?"	
P	"I use the electric toothbrush every day and I use the interdental brushes from time to time."	
C	"So you are using the toothbrush on a regular basis, but only occasionally using the interdental brushes. What is prompting you when you do decide to use the interdental brushes?"	
P	"Well, sometimes I just feel guilty that I haven't been using them and sometimes I can see the tartar on my teeth and am reminded to use them again."	
C	"So you sometimes worry that you are not using them enough and sometimes you can see on your teeth that you are not using them enough."	*Reflecting on ambivalence*
P	"Right, I suppose I should be doing better."	
C	"Well, let me ask you this. If you had to rate how important it is for you to use the interdental brushes every day on a scale from 0 to 10, 0 being not important at all and 10 being very important, where would you place yourself?"	*Using readiness ruler on importance*
P	"I guess the use of these brushes is pretty important. I'd say an 8."	
C	"Well that sounds very motivated. What makes it that important for you?"	
P	"Well I don't want to have a lot of problems with my teeth – I hate having fillings and of course I don't want to lose any teeth in the long run."	
C	"So avoiding pain and discomfort and keeping your teeth is important to you. So how confident are you that you can use the brushes on a daily basis? Where would you rate yourself on that 0 to 10 scale?"	*Using readiness ruler on self-efficacy*
P	"As I said, I know that I should use them more often, but finding the time is hard and I even just forget sometimes. I'd give it a 3."	
C	"Using them daily seems quite hard for you. Out of curiosity, though, it seems you do have little bit of confidence in doing this – may I ask you why a 3 instead of a 0 or a 1?"	
P	"Well, I just think that I would use them more often if they would become a part of my routine tooth cleaning, you know? I used to have toothpicks on my dinner table too and so I used them whenever I saw them sitting there. I could think about putting my interdental brushes on my sink next to my toothbrush. So, I would be reminded to use them after brushing my teeth with the electric toothbrush."	

C	"That sounds like a really good plan. Can you see any problems with doing that?"	*Supporting self-efficacy*
P	"No, not really. Once I have that reminder in place it's just a matter of staying committed to doing it."	
C	"Very good. So if I can summarize, it sounds like you feel quite motivated to use the interdental brushes every day, and that you think that if you put your interdental brushes on your sink next to your electric toothbrush that would help you remember to actually do it."	*Summarizing*
P	"Yes, that's right."	
C	"Well does that sound like something you want to do?"	
P	"Yes, I'll do that tonight."	

Conclusion

Sustained unhealthy behaviors not only affect general and oral health for individuals but also impact the burden of these diseases on a community level. Hence, services aiming at the improvement of prevention on an individual level oriented towards the change of inappropriate behavior have become a professional responsibility for all oral health care providers. Moving beyond oral hygiene instruction, health behavior change approaches specifically targeted at self-performed oral hygiene have become useful methods that can be incorporated into every day periodontal practice during both active and supportive periodontal therapy to encourage the modification of all common risk factors for periodontal diseases such as insufficient oral hygiene, tobacco use, unhealthy dietary habits, and alcohol abuse.

Chapter 28

Mechanical Supragingival Plaque Control

Fridus van der Weijden and Dagmar Else Slot

Department of Periodontology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam and Vrije Universiteit Amsterdam, Amsterdam, The Netherlands

Importance of supragingival plaque removal

People clean their teeth for a number of reasons: oral well-being, to feel fresh and confident, to have a nice smile, and the perception of fresh breath. A healthy smile is more than cosmetic. Oral cleanliness is the cornerstone for the preservation of oral health because it removes microbial plaque, preventing it from accumulating on the teeth and gingiva (Löe *et al*. 1965). Dental plaque is a bacterial biofilm that is not easily removed from the surface of the teeth. Biofilms consist of complex communities of bacterial species that reside on tooth surfaces or soft tissues. It has been estimated that between 400 and 1000 species can, at various times, colonize oral biofilms. In these microbial communities, there are observable associations between specific bacteria, due in part to synergistic or antagonistic relationships and in part to the nature of the available surfaces for colonization or nutrient availability (see Chapter 9). The products of biofilm bacteria are known to initiate a chain of reactions leading not only to host protection but also to tissue destruction (see Chapter 10). Plaque can be supragingival or subgingival and can be adherent or non-adherent to teeth or tissue. In addition, the microbial composition of plaque varies from person to person and from site to site within the same mouth (Thomas 2004). Plaque removal and/or control is fundamentally important in any attempt to prevent and control periodontal diseases (Chapple *et al*. 2015). In fact, without the continuous collaboration of patients, periodontal treatment has little success and results obtained do not last long.

Supragingival plaque is exposed to saliva and to the natural physiologic forces existing in the oral

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

cavity. Natural self-cleansing mechanisms include tongue movement, by which the tongue contacts the lingual aspects of the posterior teeth and, to a lesser extent, also cleans their facial surfaces. The cheek covers the buccal aspects of the posterior maxillary teeth and can thereby help to prevent the copious build-up of dental plaque on these surfaces. Saliva flow has some limited potential for cleaning debris from interproximal spaces and occlusal pits, but it is less effective in removing and/or washing out plaque. Friction through mastication might have a limiting effect on occlusal and incisal extensions of plaque although, for instance, chewing gum has no effect on plaque and gingivitis scores (Keukenmeester *et al*. 2013). These defenses can best be classified as superficial actions in controlling or mediating plaque build-up. Natural cleaning of the dentition is virtually non-existent. To be controlled, plaque must be removed frequently by active methods. Hence, the dental community continues to encourage proper oral hygiene and more effective use of mechanical cleaning devices (Cancro & Fischman 1995; Löe 2000).

Therefore, to maintain oral health, regular personal plaque removal measures must be undertaken. The most widespread means of actively removing plaque at home is toothbrushing. There is substantial evidence that demonstrates that toothbrushing and other mechanical cleansing procedures can reliably control plaque, provided that this cleaning is sufficiently thorough and is performed at appropriate intervals. Evidence stemming from large cohort studies has demonstrated that high standards of oral hygiene ensure the stability of periodontal tissue support (Hujoel *et al*. 1998; Axelsson *et al*. 2004). Based on a longitudinal study of the natural history of periodontitis in a dentally well-maintained male population (Schätzle *et al*. 2004), Lang *et al*. (2009) concluded that persistent gingivitis represents a risk factor for periodontal attachment loss and tooth loss.

Given the great importance that has been placed on plaque and personal oral hygiene in the periodontal therapy hierarchy, evidence is needed to support this leading role. In a review, Hujoel *et al*. (2005) systematically searched for evidence from randomized controlled trials regarding whether improved personal oral hygiene was associated with a decreased risk of periodontitis initiation or progression. These reviewers were unable to find randomized controlled trial evidence indicating that improved personal oral hygiene prevented or controlled chronic periodontitis. By itself, this finding is not surprising because, based on common sense, it would be unethical to provide periodontal treatment without oral hygiene instruction. Furthermore, almost 60 years of experimental research and clinical trials in different geographic and social settings have confirmed that effective removal of dental plaque is essential for dental and periodontal health (Löe 2000). The reduction of plaque mass through good oral hygiene will reduce the injurious load on these tissues.

As meaningful as oral hygiene measures are for disease prevention, they are relatively ineffective when used *alone* for the treatment of moderate and severe forms of periodontitis (Loos *et al*. 1988; Lindhe *et al*. 1989). Without an adequate level of oral hygiene in periodontitis-susceptible subjects, periodontal health tends to deteriorate once periodontitis is established, and further loss of attachment can occur (Lindhe & Nyman 1984).

Meticulous, self-performed plaque removal measures can modify both the quantity and composition of subgingival plaque (Dahlén *et al*. 1992). Oral hygiene acts as a non-specific reducer of plaque mass. This therapeutic approach is based on the rationale that any decrease in plaque mass benefits the inflamed tissues adjacent to bacterial deposits. The Socransky group (Haffajee *et al*. 2001) reported that a permanent optimal supragingival plaque control regimen could alter the composition of the pocket microbiota and lower the percentage of putative bacterial pathogens.

Currently, both primary prevention of gingivitis and primary and secondary prevention of periodontitis are based on the achievement of sufficient plaque removal. The concept of primary prevention of gingivitis is derived from the assumption that gingivitis and periodontitis are a continuum of the same inflammatory disease and that maintenance of healthy gingiva will prevent periodontitis. Consequently, preventing gingivitis could have a major impact on periodontal care expenditure (Baehni & Takeuchi 2003). Primary prevention of periodontal diseases includes educational interventions for periodontal diseases and related risk factors, and regular, self-performed plaque removal and professional, mechanical removal of plaque and calculus. Optimal oral hygiene requires appropriate motivation of the patient, adequate tools, and professional oral hygiene instruction.

Patient-administered mechanical plaque control is also considered the standard of care in the management of peri-implant disease (Salvi & Ramseier 2015). There is, however, a lack of evidence with regard to the most effective self-performed oral hygiene around dental implants. At present, home care recommendations can therefore only be based on the knowledge that is available with regard to home-based care of natural teeth (Louropoulou *et al*. 2014). However, there are various implant-supported prosthetic designs and the anatomic structure of the marginal gingival tissues is different from that around natural teeth. For instance, in case of exposed rough surfaces of the dental implant, the peri-implant conditions may even be jeopardized by the application of dental floss (Montevecchi *et al*. 2016; Van Velzen *et al*. 2016). The authors therefore strongly suggest further well-performed clinical trials in the near future to examine different aspects of oral hygiene around dental implants.

Self-performed plaque control

Maintenance of oral health has been an objective of humans since the dawn of civilization. Self-care has been defined by the World Health Organization as all of the activities that the individual undertakes to prevent, diagnose, and treat poor personal health though self-support activities or referral to health care professionals for diagnosis and care. Personal oral hygiene refers to the effort of the patient to remove supragingival plaque. The procedures used to remove supragingival plaque are as old as recorded history. The use of mechanical devices for the cleaning of teeth dates back to the ancient Egyptians 5000 years ago, who made brushes by fraying the ends of twigs. People often chewed on one end of a stick until the fibers of the wood formed a brush, which was then rubbed against the teeth to remove food. These chewing sticks were the ancestors of the *miswak*, which is still used today and is especially popular in Muslim communities. Salvadorine, an alkaloid content of the *miswak*, has proven antibacterial activity (Sofrata *et al*. 2008). A recent systematic review indicated that when used 3–5 times a day it can be as effective on plaque and gingivitis scores as a regular manual toothbrush (Adam *et al*. 2021). The Chinese are believed to have invented the first toothbrush in approximately 1600 BC. This primitive toothbrush was made of natural hog bristles from pigs' necks with the bristles attached to a bone or bamboo handle (Carranza & Shklar 2003). In his writings, Hippocrates (460–377 BC) included commentaries on the importance of removing deposits from the tooth surfaces. The observation that self-performed plaque removal is one of the foundations of periodontal health was clearly described in 1683 by the well-known Dutch scientist Antonie van Leeuwenhoek, who wrote, "Tis my wont of a morning to rub my teeth with salt and then swill my mouth out with water; and often, after eating, to clean my back teeth with a toothpick, as well as rubbing them hard with a cloth; wherefore my teeth, back and front, remain as clean and white as falleth to the lot of few men of my years, and my gums never start bleeding" (Carranza & Shklar 2003). Van Leeuwenhoek examined under the lens of an early microscope the scrapings from his own teeth. He observed tiny moving organisms floating and spinning through the soft mass. This centuries-old discovery seems primitive by today's standards, but this early description of the dental biofilm was the basis for modern-day microbiology.

Currently, toothbrushes of various kinds are important aids for mechanical plaque (dental biofilm) removal, and their use is almost universal. Furthermore, a fluoridated dentifrice is an integral component of daily home oral care. Over the past 60 years, oral hygiene has improved; in industrialized countries, 80–90% of the population brushes its teeth once or twice a day (Saxer & Yankel 1997). The use of interdental cleaning devices, mouth rinses, and other oral hygiene aids is less well documented, but the available evidence tends to suggest that only a small percentage of the population uses such additional measures on a regular basis (Bakdash 1995). The benefits of optimal home-use plaque-control measures include the opportunity to maintain a functional dentition throughout life; reduction of the risk of loss of periodontal attachment; optimization of esthetic values, such as appearance and breath freshness; and a reduced risk of complex, uncomfortable, and expensive dental care (Claydon 2008). There is increasing public awareness in the Western world of the value of good oral health practices. This fact has been demonstrated by the recorded increases in both public spending on oral hygiene products and industry spending on consumer-related advertising (Bakdash 1995). Dental care professionals must make daily decisions about the clinical care and the recommendations that they provide for their patients. The significant variety of oral hygiene products makes it difficult to choose the most appropriate oral hygiene devices. In this chapter various devices for mechanical supragingival plaque control will be discussed.

Brushing

Different cleaning devices have been used in different cultures over the centuries (toothbrushes, chewing sticks, chewing sponges, tree twigs, strips of linen, bird feathers, animal bones, porcupine quills, etc.). Toothbrushing is currently the most commonly implemented measure in oral hygiene practices. The toothbrush, when used properly, has no side effects, is easy to use, and is inexpensive. Used with toothpaste it removes tooth stain and is the vehicle to deliver therapeutic agents in toothpaste. According to the Lemelson-MIT Invention Index (2003), the toothbrush was selected as the number 1 invention that Americans could not live without; when they were asked to select from among five choices – toothbrush, automobile, personal computer, cell phone, and microwave – more than one-third of teens (34%) and almost half of adults (42%) cited the toothbrush. Toothbrushing alone, however, does not provide adequate interdental cleaning because a toothbrush can only reach the facial, oral, and occlusal tooth surfaces. It was suggested (Frandsen 1986) that the outcomes of toothbrushing are dependent on: (1) the design of the brush; (2) the skill of the individual using the brush; (3) the frequency of brushing; and (4) the duration of brushing. Also, the uniformity of the dentition and a person's attitude and commitment towards brushing play a role, and together mean that there is no single toothbrush suitable for all populations. Dental professionals must become familiar with the variety in shapes, sizes, textures, and other characteristics of available toothbrushes to provide their patients with proper advice. From the numerous products currently available on the market, only a few should be selected for any individual patient. It is important that the dental care provider understands the advantages and

disadvantages of the various toothbrushes (and other aids) to provide the patient with proper information during oral hygiene instruction sessions. It is quite possible that a given patient will obtain better results with one particular toothbrush than with another. Therefore, the provision of oral hygiene information should be tailored to the individual.

Motivation

Oral hygiene education is essential to the primary prevention of gingivitis. Improvement in a patient's oral hygiene is often accomplished through cooperative interaction between the patient and the dental professional. The role of the patient is to seek education regarding efficient self-performed plaque removal and to undergo regular check-ups to ensure a high level of oral hygiene. The patient must be involved in maintaining the health of the tissues, interested in a proposed treatment plan, and motivated to participate. Without compliance, which has been described as the degree to which a patient follows a regimen prescribed by a dental professional, a good treatment outcome will not be achieved. In this context, it should be realized that compliance with treatment recommendations is generally poor, particularly in patients with chronic diseases for which the risk of complications is not immediate or life threatening. Also, compliance with oral hygiene recommendations is generally poor (Thomas 2004).

Thus, however effective any toothbrushing method is, it will only be of any real value if the patient is prepared to use the technique on a regular basis (Warren & Chater 1996). The patient's positive attitude toward treatment can have positive long-term effects on her/his tooth cleaning efforts. Thus, well-motivated patients who are compliant with professional advice and instructions are likely to achieve and sustain ideal levels of plaque control. Good oral hygiene should form an integral part of overall health practices, along with regular exercise, stress management, diet and weight control, smoking cessation, and moderation in alcohol consumption. If the clinician can establish the link between oral health and general health for the patient, then the individual might be more willing to establish proper oral hygiene measures as part of her/his lifestyle. The issue of changing a patient's lifestyle is the more difficult part of motivational sessions (see Chapter 27). The principles of brushing and flossing are easy to learn. Integrating them into a person's daily routine is far more difficult. This difficulty can become a source of frustration for the clinician who has provided a patient with information about the necessity of personal oral hygiene measures.

Oral hygiene instruction

Oral hygiene education consists not only of knowledge transfer; it must also consider current habits and personal skills. Patients often present with non-specific brushing techniques and need sufficient support to establish methods that are appropriate for their respective needs. Ganss *et al*. (2009a) assessed toothbrushing habits in uninstructed adults and observed that when using a strict definition of appropriate brushing habits (defined as brushing at least twice daily for 120 seconds with a brushing force not exceeding 3 N and with circling or vertical sweeping movements), only 25.2% of the participants fulfilled all of the criteria.

Twice-daily brushing with fluoridated toothpaste is now an integral part of most people's daily hygiene routines in Western societies. However, it appears that most patients are unable to achieve total plaque control at each cleaning (Van der Weijden & Slot 2011). A systematic review was initiated to assess the effect of mechanical plaque control and was then refined to address the effect of manual toothbrushing on plaque and gingivitis parameters. It was concluded that in adults with gingivitis, the quality of self-performed mechanical plaque removal was not sufficiently effective and needed to be improved. Based on studies of 6 months or longer in duration, it appears that a single oral hygiene instruction session, during which the use of a mechanical toothbrush is described, in addition to a single professional session of "oral prophylaxis" at baseline, had a significant, albeit small, positive effect on the reduction of gingival inflammation in adults with gingivitis (Van der Weijden & Hioe 2005). A study evaluated the effects of yearly oral hygiene instructions during dental check-ups of 284 patients over a 5-year period (Furusawa *et al*. 2011). It was shown that these repeated instructions significantly contributed to improved plaque control compared with control in patients not receiving these instructions. An individually tailored oral health educational program, based on aspects of psychological interventions such as cognitive/behavioral models and motivational interviewing, are effective in achieving proper long-term oral hygiene behavior resulting in reduced plaque and gingivitis, specifically interproximally (Renz *et al*. 2007; Jönsson *et al*. 2009).

Oral mHealth

Mobile apps are software programs that run on smartphones and other mobile devices. There are thousands of mobile health apps available, and hundreds of them focus on dentistry. It is important to know that the majority is not reviewed by regulatory authorities. The US Food and Drug Administration (FDA) does not review or monitor health apps unless they are connected to or intended to be used as a medical device. An app that is intended for maintaining or encouraging a healthy lifestyle (and unrelated to the diagnosis, cure, prevention or treatment of a disease or condition), is not considered a medical device.

The National Health Service (NHS) in the UK has approved one app for dentistry. The app Brush DJ plays two minutes of music during which the teeth can be brushed. The app has short videos with instructions

for brushing and how to clean in between teeth. This app has been scientifically evaluated and 88% reported that the app motivated them to brush longer and 92% would recommend the app to their friends and family (Underwood *et al*. 2019). Also, text messages can be used to motivate and encourage positive oral hygiene behavior. It can even be used as a method to send messages regarding aligned topics such as dental visits, sugar, and fluoride. Self-performance monitoring systems are now available to track the areas being brushed and the pressure applied by use of video recognition and a motion sensor. Such feedback systems can lead to a prolonged learning effect resulting in improved oral hygiene (Graetz *et al*. 2013). Evidence suggests that teledentistry, particularly mHealth (messages and apps), is a promising clinical tool for preventing and promoting oral health, especially under the accelerated virtualization of dentistry (Fernández *et al*. 2021). Thus, a mobile app can be a promising tool to acquire oral health knowledge and improve oral hygiene (Toniazzo *et al*. 2019). Because most studies focus on children and orthodontic patients, further detailed evaluations are needed in order to recommend mHealth for daily use in particular among periodontitis patients.

Toothbrushing

Manual toothbrushes

The exact origins of mechanical devices for cleaning teeth in the Western world are unknown. The Chinese are given credit for developing the first handheld bristle toothbrush, as the earliest record of a toothbrush was found in Chinese writing from approximately 1000 AD. It was made from hairs from the neck of Siberian wild boar, which were fixed to a bamboo or bone handle. It was brought to Europe by traders. In 1698, Cornelis van Solingen, a doctor from The Hague, published a book in which he presented the first illustration of a toothbrush in Europe (Fig. 28-1). Over the past 350 or so years, toothbrushes have been crafted with bone, wood, or ivory handles that held the stiff bristles of hogs, boars, or other animals. The nobility used toothbrushes fashioned from silver.

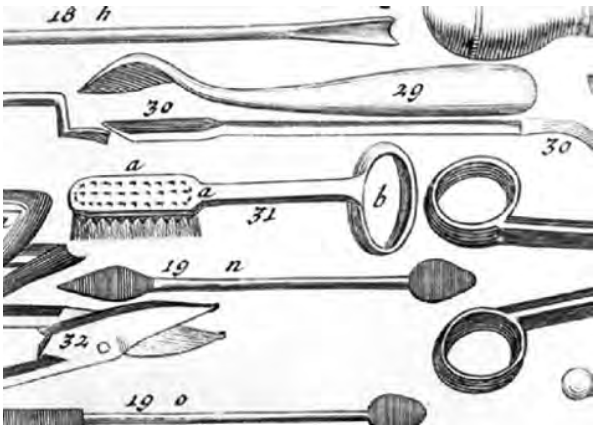

Fig. 28-1 Illustration of a toothbrush and tongue scraper from a book by Cornelis van Solingen. (Source: Courtesy of the University Museum of Dentistry in Utrecht, the Netherlands.)

The toothbrush was reinvented in the Western world in the late eighteenth century. The first mass-produced toothbrush was made by William Addis of Clerkenwald, England, circa 1780. The idea of the bristle bone toothbrush came to William Addis while in prison. In 1770, he had been sent to jail for causing a riot. Addis noticed that the prison floor was swept with a broom and reasoned that the current method to clean teeth with a cloth was highly ineffective and could thus be improved. Boredom and necessity drove Addis to take a small animal bone left behind from one of his meals and drilled holes into it. He then obtained some bristles from one of his guards. He tied the bristle filaments in tufts and passed them through the holes in the animal bone. Finally, he sealed the holes with glue. Upon his release from jail, he launched a business to manufacture toothbrushes. His business evolved into the company "Wisdom", which continues to manufacture toothbrushes today. The Addis version of the toothbrush had natural hog bristles. While acceptable at the time and no doubt efficacious in terms of plaque removal, natural products are inherently unhygienic, as the bristle fibers allow the accumulation and proliferation of orally derived bacteria. The first American to patent a toothbrush was H.N. Wadsworth (in 1857), and many American companies began to produce toothbrushes after 1885. In the early 1900s, celluloid began to replace the bone handle, a change that was hastened by World War I when bone and hog bristles were in short supply. Nylon filaments were introduced in 1938 by Du Pont de Nemours because World War II prevented the exportation of wild boar bristles from China. Nearly all current toothbrushes are made exclusively of synthetic materials. Their nylon filaments and plastic handles are easy to manufacture and are therefore more affordable. This ease of manufacture has made toothbrushing a common practice in most societies.

During toothbrushing, the removal of dental plaque is achieved primarily through direct contact between the filaments of the toothbrush and the surfaces of teeth and the soft tissues. At the European Workshop on Mechanical Plaque Control, it was agreed that the features of an ideal manual toothbrush are (Egelberg & Claffey 1998):

- Handle size appropriate to user's age and dexterity so that the brush can be easily and efficiently manipulated
- Head size appropriate to the size of the individual patient's requirements
- End-rounded nylon or polyester filaments not larger than 0.23 mm (0.009 inches) in diameter
- Soft filament configurations, as defined by the acceptable international industry standards (ISO)
- Filament patterns that enhance plaque removal in the appropriate spaces and along the gum line.

Additional characteristics could include an inexpensive price, durability, imperviousness to moisture, and easy to clean.

Modern toothbrushes have reached a certain stage of sophistication. Much imagination and inventiveness has been applied to toothbrush design and now numerous models are available. Combinations of different filaments and tuft arrangements are appealing for consumers but often not scientifically evaluated. To improve patient comfort, over time the shape of the brush head, the filaments, and the placement of filaments in the handles has changed (Voelker *et al*. 2013). Modern toothbrushes have filament patterns designed to enhance plaque removal from hard-to-reach areas of the dentition, particularly from proximal areas. A major shortcoming of the conventional flat-trim toothbrushes has been the "blocking effect" of tight bristle tufts, which prevents individual tufts from reaching interproximal areas. Filaments with crimped and tapered filaments are the most recent improvements. The designs are based on the premise that the majority of subjects in any population use a simple horizontal brushing action. Multiple tufts of filaments, sometimes angled in different directions, are also used (Jepsen 1998). These multilevel toothbrushes have alternating rows of taller and shorter bristle tufts acting independently, so they are not influenced by the adjacent bristles during brushing. Once independent motion is achieved, the longer bristles can effectively reach further between the teeth. Multilevel or angled toothbrush designs (Fig. 28-2) yield genuinely improved performance characteristics when compared with flat-headed brushes (Cugini & Warren 2006; Slot *et al*. 2012). Double- and triple-headed toothbrushes have been proposed to reach the lingual surfaces more easily, especially in molar areas, which are normally the tooth surfaces hardest to reach with regular toothbrushes. Although some studies have indicated that the use of such multiheaded toothbrushes might improve plaque control in lingual areas (Agerholm 1991; Yankell *et al*. 1996), their use is not widespread. The use of a triple-headed manual toothbrush was found to be favorable with respect to plaque removal in case a care-dependent individual is brushed by a caregiver (Kalf *et al*. 2018).

Fig. 28-2 Flat-trim, multilevel and angled manual toothbrush bristle tuft design.

Whereas handles used to be straight and flat, round and curved handles are more common today. The modern toothbrush has a handle size that is appropriate to the hand size of the prospective user, and greater emphasis has been placed on new ergonomic designs (Löe 2002). Several studies have investigated differences in plaque removal between brushes with different handle designs. In such studies, brushes with long and contoured handles appear to remove more plaque than brushes with traditional handles (Saxer & Yankell 1997).

Obviously, there can be no single "ideal" toothbrush for all populations. The choice of brush is usually a matter of individual preference, rather than governed by a demonstrated superiority of any one type. In the absence of clear evidence, the best toothbrush is the one that is (properly) used by the patient (Cancro & Fischman 1995; Jepsen 1998).

For a toothbrush company to qualify a toothbrush for the American Dental Association (ADA) Seal of Acceptance, it must be shown that:

- All of the toothbrush components are safe for use in the mouth
- Bristles are free of sharp or jagged edges and end points
- Handle material is manufacturer tested to show durability under normal use
- Bristles will not fall out with normal use
- Toothbrush can be used without supervision by the average adult to provide a significant decrease in mild gum disease and plaque
- Size and shape of the brush should fit in the mouth comfortably, allowing the user to reach all areas easily.

A company earns the ADA seal for its product by producing scientific evidence that the product is safe and effective, claims that are evaluated by an independent body of scientific experts – the ADA Council on Scientific Affairs – according to objective guidelines.

Efficacy

Toothbrush manufacturers have made great efforts to consider many different aspects when designing new models to meet the challenges of enhancing plaque biofilm removal through improved toothbrushing efficacy. Few toothbrush manufacturers have also attempted to evaluate toothbrush efficacy. The enthusiastic use of a toothbrush is not synonymous with a high standard of oral hygiene. Adults, despite their apparent efforts, do not appear to be as effective in their plaque removal as might be expected. The daily experience in dental practice is that patients exhibit plaque even though they reportedly engage in oral hygiene practices. De la Rosa *et al*. (1979) studied the patterns of plaque accumulation and removal with daily toothbrushing over a 28-day period following

dental prophylaxis. On average, approximately 60% of the plaque remained after self-performed brushing. Morris *et al*. (2001) reported on the 1998 UK Adult Dental Health Survey and observed that the mean proportions of teeth with plaque deposits were 30% in the 25–34-year-old age group and 44% in those aged 65 years and older.

Brushing exercise studies are commonly used for toothbrush evaluations. This study model provides useful indications of the plaque removal capacity of toothbrushes and facilitates the control of confounding variables, such as compliance. A systematic review was initiated by Slot *et al*. (2012) to assess the effect of a single brushing exercise using a manual toothbrush. In total, 212 brushing exercises as separate legs of experiments in 10 806 participants, were used to calculate a weighted mean overall percentage plaque reduction score. The sheer magnitude of the number of participants and the heterogeneity observed in the various study designs yielded results of particular value because they reflected what might be generally expected from a routine oral hygiene exercise as encountered among patients in everyday practice. Based on the baseline and end scores, a plaque reduction percentage was calculated for each of the eligible experiments taken from the selected studies. Using these data, a weighted mean difference was calculated as a 42% reduction in plaque index scores from baseline indices.

An interesting aspect of this analysis was that the estimated magnitude of the effect size of toothbrushing appeared to be dependent on the plaque index score used to assess the magnitude of the effect. Compared to the Quigley & Hein plaque index, the estimate with the Navy index resulted in a greater difference between pre- and post-brushing scores: 30% versus 53%, respectively.

The Navy plaque index (Elliott *et al*. 1972) and the Quigley & Hein plaque index (Quigley & Hein 1962) and their modifications are the two indices most commonly used for assessing plaque removal efficacy with toothbrushes. Although these indices score plaque in different ways, there appears to be a strong correlation between them (Cugini *et al*. 2006). The Quigley & Hein plaque index emphasizes the differences in plaque accumulation in the gingival third of the tooth, and it tends to overscore the incisal half of the crown at the expense of the gingival margin. The Navy plaque index gives greater weight to plaque in the immediate gingival area. The scores from both indices are descriptive. They do not represent strictly linear scales; rather, they ascend in severity. A score of 0 is given when no plaque is found. Higher scores are assigned in ascending order, corresponding roughly to increasing areas of tooth surfaces covered by plaque. Because plaque is colorless, it is usually visualized by staining prior to scoring. Plaque is then defined, in an operational sense, as "stainable material" (Fischman 1986). Such practices do not result in precise estimates of the dental biofilm because they fail to evaluate qualitative features.

Methods of toothbrushing

Although the toothbrush is the most used tool to remove dental plaque its proper use is not trivial and requires some skill. The ideal brushing technique is the one that allows for complete plaque removal in the least possible time, without causing any damage to tissues (Hansen & Gjermo 1971). There is no single oral hygiene method that is correct for every patient. The morphology of the dentition (crowding, spacing, gingival phenotype, etc.), the type and severity of periodontal tissue destruction, and the patient's own manual dexterity determine what kind of hygiene aids and cleaning techniques should be recommended. It should also be realized that during the course of periodontitis therapy, the techniques might have to be changed or adapted to the morphologic situation (longer teeth, open interdental spaces, exposed dentin).

Wainwright and Sheiham (2014) assessed methods of toothbrushing recommended for both adults and children by dental associations, toothpaste and toothbrush companies, and professional sources such as in dental textbooks and by experts. There appeared to be a wide diversity between recommendations on toothbrushing techniques, how often people should brush their teeth, and for how long. The most common method recommended was the (modified) Bass technique. The different toothbrushing methods that have been proposed over time can be proposed based on the position and motion of the brush.

Horizontal brushing is probably the most commonly used toothbrushing method. It is most frequently used by individuals who have never had instruction in oral hygiene techniques. Despite the efforts of the dental profession to instruct patients to adopt other, more efficient brushing techniques, most individuals use horizontal brushing because it is simple. The head of the brush is positioned perpendicular to the tooth surface, and then a horizontal back-and-forth scrubbing movement is applied (Löe 2000). The occlusal, lingual, and palatal surfaces of the teeth are brushed with an open mouth. To reduce the pressure of the cheek on the brush head, the vestibular surfaces are cleaned with the mouth closed.

Vertical brushing (Leonard [1939] technique) is similar to the horizontal brushing technique, but the movement is applied in the vertical direction, using up-and-down strokes.

Circular brushing (Fones [1934] method) is performed with the teeth closed, the brush placed inside the cheek, and a fast circular motion applied that extends from the maxillary gingiva to the mandibular gingiva, using light pressure. Back-and-forth strokes are used on the lingual and palatal tooth surfaces.

The *scrubbing method* includes a combination of horizontal, vertical, and circular strokes.

Sulcular brushing (Bass [1948] method) (see Box 28-1) emphasizes cleaning of the area directly

beneath the gingival margin. The head of the brush is positioned in an oblique direction toward the apex. The filament tips are directed into the sulcus at approximately 45° to the long axis of the tooth. The brush is moved in a back-and-forth direction using short strokes, without disengaging the tips of the filaments from the sulci. On the lingual surfaces in the anterior tooth regions, the brush head is kept in the vertical direction. The Bass method is widely accepted as an effective method for removing plaque, not only at the gingival margin but also subgingivally. A few studies have been conducted on teeth affected with periodontal disease and scheduled for extraction, in which the gingival margin was marked with a groove, and the depth of subgingival cleaning was measured. These studies showed that with the use of this brushing method, plaque removal could reach a depth of approximately 1 mm subgingivally (Waerhaug 1981a).

The *vibratory technique* (Stillman [1932] method), was designed for the massage and stimulation of the gingiva and for cleaning the cervical areas of the teeth. The head of the brush is positioned in an oblique direction toward the apex, with the filaments placed partly in the gingival margin and partly on the tooth surface. Light pressure, together with a vibratory (slight rotary) movement, is then applied to the handle, while the filament tips are maintained in position on the tooth surface.

The *vibratory technique* (Charters [1948] method) was originally developed to increase cleansing effectiveness and gingival stimulation in the interproximal areas. Compared with the Stillman technique, the position of the brush head is reversed. The head of the brush is positioned in an oblique direction, with the filament tips directed toward the occlusal or incisal surfaces. Light pressure is used to flex the filaments and gently force the tips into the interproximal embrasures. A vibratory (slight rotary) movement is then applied to the handle, while the filament tips are maintained in position on the tooth surface. This method is particularly effective in cases with receded interdental papillae because the filament tips can easily penetrate the interdental space and in orthodontic patients (Fig. 28-3).

With the *roll technique*, the head of the brush is positioned in an oblique direction toward the apex of the teeth, with the filaments placed partly in the gingival margin and partly on the tooth surface. The sides of the filaments are pressed lightly against the gingiva. Next, the head of the brush is rolled over the gingiva and teeth in an occlusal direction.

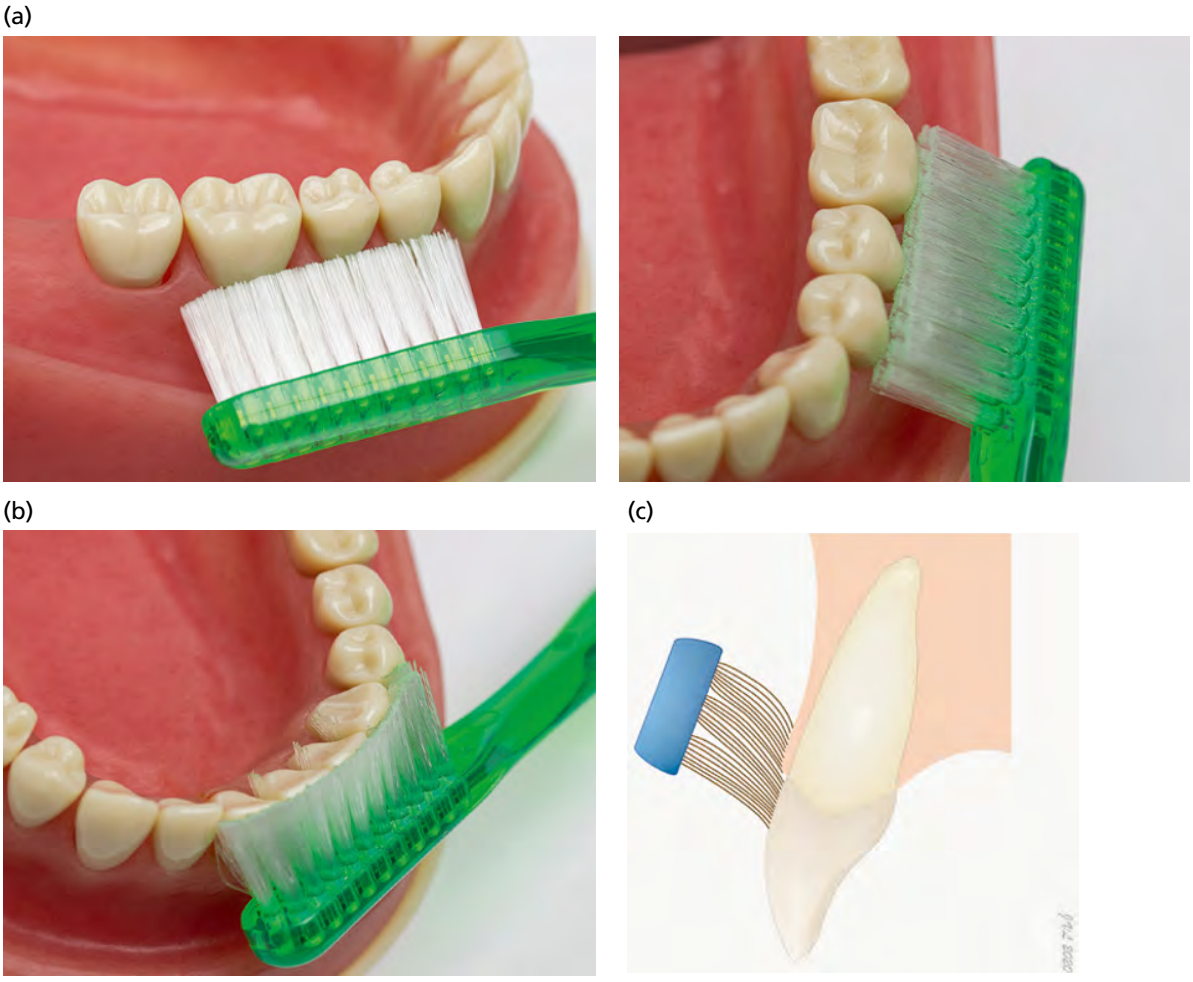

Fig. 28-3 Charters method of toothbrushing. (a) Note how the head of the toothbrush is placed in the right and left mandible. (b) The bristles are forced into the interproximal areas. (c) Note the angulation of the bristles against the buccal tooth surface. (Source: Schematic drawing courtesy of Joep Laverman. Printed with permission.)

Finally, the *modified Bass/Stillman technique* emerged because the Bass and Stillman methods were both designed to concentrate on the cervical portion of the teeth and the adjacent gingival tissues and could be modified to add a roll stroke. The brush is positioned similarly to in the Bass/Stillman technique. After activation of the brush head in a back-and-forth direction, the head of the brush is rolled over the gingiva and teeth in the occlusal direction, making it possible for some of the filaments to penetrate interdentally.

In the 1970s, several investigators compared various methods of brushing. Because of varying experimental conditions, the outcomes of these studies are difficult to compare. To date, no method of toothbrushing has been shown to be clearly superior to others. As early as 1986, Frandsen commented on this issue, stating, "Researchers have realized that improvement in oral hygiene is not as dependent upon the development of better brushing methods as upon improved performance by the persons using any one of the accepted methods." Therefore, because no particular toothbrushing method has been found to be clearly superior to the others, there is no reason to introduce a specific toothbrushing technique with each new periodontal patient. In most cases, small changes in the patient's own method of toothbrushing will suffice, always bearing in mind that more important than the selection of a certain method of toothbrushing is willingness and thoroughness on the part of the patient to clean his/her teeth effectively. Implementation of the toothbrushing methods described above must be made according to a patient's needs. For example, because the Bass method has been associated with gingival recession (O'Leary 1980), it is not be indicated in individuals with energetic toothbrushing habits who also have a thin gingival phenotype. Van der Sluijs *et al*. (2017, 2018 a, b) evaluated various recommendation related to toothbrushing methods. As the lingual surfaces in general demonstrate more plaque and bleeding on probing than other areas of the mouth it has been suggested that the toothbrush should therefore first be applied to these surfaces. This presumption, however, was not supported by the outcome of a split-mouth study (Van der Sluijs *et al*. 2018a). Rinsing before brushing has also been proposed in order to hydrate the biofilm, reduce adherence, and render plaque more readily detached by mechanical cleaning methods. This pre-rinsing with water does not contribute significantly to toothbrushing efficacy (Van der Sluijs *et al*. 2017).

Frequency of use

Although the ADA recommends that teeth should be brushed twice per day with a fluoride toothpaste and cleaned in between daily with floss or an interdental cleaner, there is no true consensus as to the optimal frequency of toothbrushing. How often teeth must be brushed and how much plaque must be removed to prevent dental disease from developing are not known. The majority of individuals, including periodontal patients, are usually unable to remove dental plaque completely with daily brushing. However, complete plaque removal does not seem to be necessary. Theoretically, the proper level of oral hygiene is the extent of plaque removal that prevents gingivitis/periodontal disease and tooth decay in the individual patient. The prevention of gingival inflammation is important because inflammatory conditions of soft tissues also favor plaque accumulation (Lang *et al*. 1973; Ramberg *et al*. 1994; Rowshani *et al*. 2004).

Results from cross-sectional studies have been equivocal when the self-reported frequency of tooth cleaning has been related to caries and periodontal disease. A survey, using a questionnaire to assess oral hygiene practices, observed no statistically significant differences in periodontal health measurements (gingival inflammation, probing pocket depth, attachment loss) between subjects performing acceptable (brushing at least once a day) and unacceptable self-reported brushing behavior (Lang *et al*. 1994). However, correlation coefficients have revealed a weakly positive, but significant, relationship between the frequency of tooth brushing and oral hygiene and gingival health (Addy *et al*. 1990). Disease appears to be related more to the quality of cleaning than to its frequency (Bjertness 1991). Kressin *et al*. (2003) evaluated the effect of oral hygiene practices on tooth retention in a longitudinal study with 26 years of follow-up. They observed that consistent brushing (at least once per day) resulted in a 49% reduction in the risk of tooth loss, compared with a lack of consistent oral hygiene habits.

If plaque is allowed to accumulate freely in the dentogingival region, subclinical signs of gingival inflammation (gingival fluid) appear within 4 days (Egelberg 1964). The minimum frequency of tooth cleaning needed to reverse experimentally induced gingivitis is once every day or every second day. Bosman and Powell (1977) induced experimental gingivitis in a group of students. Signs of gingival inflammation persisted in those students who removed plaque only every third or fifth day. In the groups who properly cleaned their teeth once per day or every second day, the gingiva healed within 7–10 days.

Based on the observation that the onset of gingivitis appears to be more closely related to the maturation and age of the plaque than to its amount, the minimum frequency of brushing needed to prevent the development of gingivitis was investigated in a prospective study. Dental students and young dental faculty members with healthy periodontal conditions were assigned to study groups with different cleaning frequencies over periods of 4–6 weeks. The results indicated that students who thoroughly removed plaque once daily or even every second day did not develop clinical signs of gingival inflammation over

a 6-week period. This tooth cleaning included the use of interproximal aids (dental floss and woodsticks) and toothbrushes (Lang *et al*. 1973). Caution should be exercised in extrapolating the results obtained from studies including dentally aware subjects to the average patient.

As a point of principle, it is reasonable to state that meticulous mechanical removal of plaque by toothbrushing, combined with the removal of interdental plaque once every 24 hours, is adequate to prevent the onset of gingivitis and interdental caries (Axelsson 1994; Kelner *et al*. 1974). From a practical standpoint, it is generally recommended that patients brush their teeth at least twice daily, not only to remove plaque but also to apply fluoride through the use of a dentifrice to prevent caries. This advice also considers feelings of oral freshness. For most patients, it might be desirable to perform all necessary procedures (e.g. brushing and interdental cleaning) at the same time and in the same manner each day. Unfortunately, for subjects who live busy, stressful lives, this level of dedication can be difficult to achieve (Thomas 2004). Despite most individuals claiming to brush their teeth at least twice per day, it is clear from both epidemiologic and clinical studies that mechanical oral hygiene procedures, as performed by most subjects, are insufficient to control supragingival plaque formation and to prevent gingivitis and more severe forms of periodontal disease (Sheiham & Netuveli 2002).

Duration of brushing

Patients usually believe that they spend more time on toothbrushing than they actually do. A cause of insufficient oral hygiene in the general population is therefore often too short brushing time (Saxer *et al*. 1998). The least amount of time spent on brushing was observed in a study performed on English school children; in the 13-year-old group, the children spent approximately 33 seconds on brushing (MacGregor & Rugg-Gunn 1985). Approximately one-third of the studies that were reviewed reported an average brushing time of <56 seconds, whereas two-thirds of the studies reported brushing times of between 56 and 70 seconds. Two investigations reported an average brushing time of ± 90 seconds (Ayer *et al*. 1965; Ganss *et al*. 2009a). MacGregor and Rugg-Gunn (1979) reported that of a mean 50-second brushing time, only 10% of that time was spent on the lingual surfaces.

The best estimates of actual manual brushing time range between 30 and 60 seconds (Van der Weijden *et al*. 1993; Beals *et al*. 2000). Some caution regarding these estimates should be exercised, as the act of measuring brushing time has been shown to affect brushing behavior (MacGregor & Rugg-Gunn 1986).

The toothbrushing in the study by Van der Weijden *et al*. (1993) was performed by a dental professional. This study compared the effect of brushing time on plaque removal using manual and electric toothbrushes, utilizing five different brushing times (30, 60, 120, 180, and 360 seconds). The results indicated that 2 minutes of electric toothbrushing was as effective as 6 minutes of manual toothbrushing. The authors furthermore observed that at 2 minutes, an optimum in plaque-removing efficacy was reached with both manual and electric toothbrushes. Two systematic reviews have evaluated in a subanalysis the effect of a single brushing exercise with a manual or an electric toothbrush relative to the toothbrushing time (Slot *et al*. 2012; Rosema *et al*. 2016) and found that brushing duration contributed to the observed range in results. For the manual toothbrush, based on the Quigley & Hein plaque index scores, the estimated weighted mean efficacy as represented in plaque score reduction was 27% after 1 minute and 41% after 2 minutes (Slot *et al*. 2012).

A number of studies in the literature address the question of whether, in adult patients, the duration of toothbrushing correlates with the efficacy of plaque removal. Some of these studies evaluated the use of electric toothbrushes (Van der Weijden *et al*. 1996a; McCracken *et al*. 2003, 2005) while others compared manual toothbrushes with electric toothbrushes (Preber *et al*. 1991) or evaluated only manual toothbrushes (Hawkins *et al*. 1986; Gallagher *et al*. 2009). The results from these studies indicated that the duration of brushing was consistently correlated with the amount of plaque that was removed.

Based on the above observations, the duration of toothbrushing is likely to be an important determinant of plaque removal in the general population; therefore, it should be stressed during toothbrushing instruction sessions. As plaque removal is strongly correlated with brushing time for any given toothbrush, brushing for 2 minutes or longer should be encouraged, regardless of the brush used. Brushing time is also likely the most easily controlled parameter of effective everyday brushing.

Toothbrush filaments

The characteristics of an effective toothbrush correspond to the primary functional properties of the filaments. Most modern toothbrushes have nylon filaments. The end of a toothbrush filament can be cut in either a blunt or a rounded manner (see Filament end-rounding later). Today, many manufacturers vary the length or diameter of the filaments mounted in the head. The degrees of hardness and stiffness of a toothbrush depend on the filament characteristics, such as material, diameter, and length. Toothbrushes with thinner filaments are softer, while thicker-diameter filaments are stiffer and less flexible. Curved filaments can be more flexible and less stiff than straight filaments of equal length and diameter. Also, the density of the filaments in a tuft influences its stiffness, as each filament provides support to adjacent filaments, and each tuft provides support to adjacent tufts.

Consequently, the number of filaments per tuft also determines the hardness of a toothbrush. Increased stiffness will prevent the filament ends from bending back during brushing, avoiding the potential risk of damaging the gums. However, the filament must be sufficiently stiff so that during brushing, sufficient pressure (shear force) is exerted to allow for proper plaque removal.

Concern about toothbrush filaments relates primarily to the potential for hard and soft tissue abrasion. Consider that a rod represents a filament of a toothbrush. While brushing, a vertical upward load is exerted, which, in turn, exerts an effect of the same order of magnitude on the oral mucosa. The force of the brush, acting on the individual filament, is thus always as great as the load exercised by the filament on the mucosa. If the load is increased, then the load increases to the same extent. Consequently, the risk of soft tissue damage increases as the filament's tip can penetrate into the mucosa. However, elastic rods demonstrate a peculiarity in their behavior. They suddenly fold back laterally when a certain load limit is exceeded. When folding back, the rod suddenly gives way elastically (without breaking), and the load on the oral mucosa diminishes abruptly. Thus, a load greater than this fold-back limit cannot be transferred to the mucosa by the rod via its tip.

As late as 1967, most people were buying hard brushes (Fanning & Henning 1967). The shift in preference to soft brushes of a specific design paralleled the change that occurred in oral health care when calculus was identified as the prime etiologic agent in periodontal disease (Mandel 1990). The concentration on plaque, especially in the crevicular area, and attention to intrasulcular brushing strongly influenced the change from hard to soft filaments, primarily because of the concern for trauma to the gingival tissues (Niemi *et al*. 1984). Soft filaments are universally recommended for sulcular brushing, such as with the Bass method. Patients can brush at the cervical areas without fear of discomfort or soft tissue laceration. However, various studies have shown that subjects cleaned significantly better with medium and hard brushes than with soft-bristled brushes (Robertson & Wade 1972; Versteeg *et al*. 2008a). Therefore, it appears that the filaments must have a degree of stiffness to create sufficient abrasion to dislodge plaque deposits. There is no point in using a brush with very thin filaments that merely stroke across the tooth and, as a result of the lack of load, no longer clean the tooth surface. However, to avoid damaging the gums when positioning the toothbrush, they must not be too hard: the harder the toothbrush filaments, the greater the risk of gingival abrasion (Khocht *et al*. 1993). People also tend to prefer medium-to-hard brushes because they feel that their teeth are cleaner after brushing with a stiffer brush. Versteeg *et al*. (2008a) showed that when there is no clinical indication for a soft toothbrush, the professional advice with regard to effectiveness should indeed be for a toothbrush of medium stiffness. Soft-filament brushes are particularly recommended for brushing shortly after periodontal surgery for patients with highly inflamed gingiva and for patients with naturally finely textured atrophic or sensitive mucosa. However, the topic of filament stiffness should not be addressed by itself; brush–toothpaste interaction should also be considered. The capacity of a toothbrush to hold and move polish/abrasive over the tooth surface affects the amount of hard tissue abrasion (see Toothbrush abrasion later).

Filament end-rounding

End-rounding has become increasingly common in the toothbrush-manufacturing process to reduce gingival abrasion (Fig. 28-4). The logic that smooth filament tips would cause less trauma than filament tips with sharp edges or jagged projections has been validated in both animal and clinical studies (Breitenmoser *et al*. 1979). Danser *et al*. (1998) evaluated two types of end-rounding and observed their effects on the incidence of abrasion. The form to which the ends were rounded had no effect on the level of plaque removal. Tapered filaments (Fig. 28-5) have endings in the shape of an extreme rotational ellipsoid instead of a hemisphere. This shape has been suggested to give the filaments very soft endings, combined with good stability of the filament corpus. As a result, more flexibility is introduced into the filaments, which are presumably less harmful. The efficacy of tapered toothbrush filaments has been tested in laboratory studies, and it has been found that they were able to reach into the interproximal areas of the teeth, under the gum line, and into the fissures. A recent systematic review, however, found no firm evidence in support of a tapered filament toothbrush over the use of an regular toothbrush with

Fig. 28-4 Filament end-rounding.

Fig. 28-5 Tapered toothbrush filaments.

end-rounded filaments (Hoogteijling *et al*. 2018). The outcomes of clinical studies comparing end-rounded filaments with flat-trimmed toothbrush head configurations have been equivocal (Dörfer *et al*. 2003; Versteeg *et al*. 2008b).

Wear and replacement

Common sense dictates that toothbrushes should be replaced because the filaments and tufts do not retain their shape forever. Completely worn brushes lose the capacity to remove plaque effectively. This result most likely occurs because of a loss of shear force, as the tips of the filaments can no longer disrupt the plaque adequately. The exact moment at which a toothbrush should be replaced is difficult to determine. In general, dental associations, professionals, and the oral care industry advocate toothbrush replacement every 3–4 months. While this advice would seem reasonable, there is little actual clinical proof that this recommendation is correct. Patients do not appear to heed this advice; the evidence indicates that the average age at which a toothbrush is replaced ranges from 2.5 to 6 months (Bergström 1973). On average, each person in the USA purchases three toothbrushes every 2 years.

Common sense would suggest that a worn toothbrush with splayed or frayed filaments loses its resilience and is less likely to be as effective in removing plaque as a new brush. Because of the variability in subjects' brushing techniques and the force applied to the teeth while brushing, the degree of wear varies significantly from subject to subject. It is also likely that different brushes, made from various materials, would exhibit differences in longevity.

Because many patients use their brushes for periods significantly longer than the recommended time of 3 months, it is important to know whether excessive wear is of clinical relevance. There is inconclusive evidence about the relationship between toothbrush wear and plaque removal. The age of the toothbrush by itself appears not to be the critical parameter that is crucial to plaque removal efficacy. Studies with laboratory-worn toothbrushes have reported that such toothbrushes had inferior plaque removal efficacy compared with new brushes (Kreifeldt *et al*. 1980; Warren *et al*. 2002). However, artificially worn toothbrushes might not properly mimic the characteristics of naturally worn brushes. The wear of laboratory-worn toothbrushes will inevitably be highly uniform and will not reflect the variations in wear seen in normal toothbrush use. Most studies in which naturally worn toothbrushes were studied reported no statistically significant decreases in the reduction of whole-mouth plaque scores after brushing compared with when using new toothbrushes (Daly *et al*. 1996; Sforza *et al*. 2000; Tan & Daly 2002; Conforti *et al*. 2003; Van Palenstein Helderman *et al*. 2006). Toothbrush wear per individual patient is fairly consistent (Van Leeuwen *et al*. 2019). Rosema *et al*. (2013) evaluated the plaque-removing efficacy of new and used manual toothbrushes and found that wear rate seemed to be the determining factor with regard to loss of efficacy. Similarly, Van Leeuwen *et al*. (2019) found toothbrushes with extreme wear to be less effective than those with no or light wear. They suggested that bristle splaying is a more appropriate measure of brush replacement time than the commonly used toothbrush age. Splaying of the outer tufts beyond the base of the toothbrush is a condition that indicates it is time to change the brush.

Kreifeldt *et al*. (1980) studied tapering of toothbrush filaments with regard to toothbrush wear and reported that new brushes were more efficient in removing dental plaque than old brushes. They also examined worn toothbrushes and observed that, as a result of wear, the filaments exhibited tapering that proceeded from the insertion to the free end. For example, filaments were seen that tapered from 0.28 mm at one end to 0.020–0.015 mm at the free end. They concluded that, among wear factors, tapering contributed the most to loss of effectiveness. Their explanation for this observation was that as tapering results in a reduction of filament diameter, the brush will become softer and remove less plaque. Based on this tapering phenomenon, some commercially available brushes have filaments that change color after a certain amount of use. These wear indicator filaments serve to remind patients that it is time to replace the brush.

Electric (powered) toothbrushes

In well-motivated and properly instructed individuals who are willing to invest the necessary time and effort, mechanical measures using traditional toothbrushes and adjunctive manual (interdental) devices are effective in removing plaque. Maintaining a

dentition that is close to plaque-free is not easy, however. The high prevalence of gingivitis indicates that toothbrushing is not as effective in practice as it is in supervised studies. The electric toothbrush represents an advance that has the potential to enhance both plaque removal and patient motivation (see Box 28-2). Electric toothbrushes have been around since the 1940s, starting with devices such as the Motodent (circular brush head) and the Toothmaster (straight brush head). An example of the latter can be found in the National Museum of Dentistry in Baltimore, Maryland, USA. The first successfully marketed electric toothbrushes were introduced more than 50 years ago. In 1954, the Swiss inventor Dr Philippe Guy E. Woog invented an oscillating, motorized electric toothbrush. This toothbrush was further developed by Bemann and Woog and first appeared in 1956 in Switzerland. In 1959, it was introduced in the USA as the Broxodent at the centennial celebration of the ADA by E.R. Squibb and Sons. This early electric brush was a plug-in device that featured bristles that moved from side to side. In 1961, a cordless, rechargeable model was introduced by General Electric, the so-called Automatic Toothbrush, which soon took the lead in what was turning out to be a very competitive market.

The first electric toothbrushes were basically mechanized versions of manual toothbrushes, with the bristles moving back and forth in an imitation of the way people brushed by hand. Studies of the use of these early electric toothbrushes showed that there was no difference in plaque removal when compared with manual toothbrushes, although they had mixed effects on gingivitis. In 1966, the consensus from the research reports on toothbrushing of the World Workshop in Periodontics stated, "in non-dentally oriented persons, in persons not highly motivated to oral health care, or in those who have difficulty in mastering suitable hand brushing technique, the use of an electric brush with its standard movements may result in more frequent and better cleansing of the teeth".

Since the 1980s, tremendous advances have been made in the technology of electrically powered toothbrushes. Various electric toothbrushes have been developed with unique motions to improve the efficiency of plaque removal, using increased filament velocity and brush stroke frequency, and various filament patterns and motions. Whereas older electric toothbrushes used a combination of horizontal and vertical movements, mimicking closely the back-and-forth motion of traditional brushing methods, the more recent designs have incorporated a variety of actions, such as vibrating at ultrasonic frequencies, and have heads that rotate, heads that move from side to side, or sets of bristles that move one way and then the other way. The electric toothbrush that in the 1980s successfully steered away from a conventional brushing mode and instead mimicked the small round rotating brush head of dental prophylaxis instruments was the Rotadent (Zila, Fort Collins, CO, USA) (Boyd *et al*. 1989). It was sold with three different brush heads in different shapes to facilitate access to all areas of the oral cavity. However, the consumer found it difficult to control. In the 1980s the Interplak was introduced (Conair, Stamford, CT, USA), with independent tufts of bristles that performed rotary and counter-rotary movements (Van der Weijden *et al*. 1993). Although being effective it lost popularity because of the complicated gearing system which could not cope with the abrasive nature of toothpaste.

The development of an oscillating–rotating round brush head by Braun (Kronberg, Germany) made control of the brush easier. Oscillating–rotating brushes are designed with round heads that move back and forth, with alternating one-third turns clockwise and counterclockwise. The original oscillating–rotating toothbrush, the Braun Oral-B Plaque Remover (D5), featured a small, round brush head that made rotating and oscillating movements at a speed of 2800 oscillating rotations/min. A further development of this brush, the Braun Oral-B Ultra Plaque Remover (D9), maintained the oscillating–rotating action but at an increased speed (3600 rotations/min). A clinical study with the D9 demonstrated equivalence in safety and a trend toward greater plaque removal (Van der Weijden *et al*. 1996b). Newer developments in oscillating–rotating brush technology are the addition of high-frequency vibrations in the direction of the bristles, creating three-dimensional movements during brushing. This modification was developed to enhance penetration and the removal of plaque from the proximal spaces of the dentition. Studies have shown that the three-dimensional movements performed by the brush are safe and more efficient regarding plaque removal (Danser *et al*. 1998).

Another advance in this technology has been the development of sonic toothbrushes, which have a high frequency of filament movement in excess of approximately 30 000 strokes/min. For example, the rechargeable Oral-B Sonic Complete® (Oral-B Laboratories, Boston, MA, USA) and the Philips Sonicare® Elite (Philips Oral Healthcare, Snoqualmie, WA, USA) both use a side-to-side motion operating at a frequency of 260 Hz, but are based on different technologies. Toothbrushes with bristle motion at a high frequency can generate a turbulent fluid flow in the oral cavity. This flow can cause hydrodynamic forces (wall shear forces) that act parallel to a surface. The vibration of toothbrush bristles could further enable energy transfer in the form of sound pressure waves. *In vitro* studies have indicated that non-contact biofilm reduction can be obtained by these hydrodynamic effects. However, *in vivo*, the additional beneficial effects of higher amounts of non-contact biofilm removal have not yet been shown clinically (Schmidt *et al*. 2013).

The electric toothbrush should not be considered a substitute for a specific interdental cleaning method,

such as flossing, but it can offer advantages in terms of an overall approach to improved oral hygiene. The use of an electric toothbrush was found to improve plaque removal from the surfaces of implant-supported fixed partial dentures, especially from the area of the prostheses touching the alveolar ridge (Maeda *et al*. 2019).

Electric brushes versus manual toothbrushes

To some extent, modern design features of electric brushes have overcome the limitations of manual dexterity and skill of the user (Fig. 28-6). These modern toothbrushes remove plaque in a shorter time than a standard manual brush. It takes 6 minutes to remove the same percentage of plaque using a manual toothbrush that is removed in 1 minute using a powered toothbrush in the hands of a professional operator (Van der Weijden *et al*. 1993, 1996a). The new generation of electric brushes has better plaque removal efficacy and gingival inflammation control on the proximal tooth surfaces (Egelberg & Claffey 1998). Of this latter aspect the superiority was clearly demonstrated in a study conducted on extracted teeth (Rapley & Killoy 1994).

A systematic review of single brushing exercises showed that the efficacy in plaque removal using an electric toothbrush provides a weighted mean plaque score reduction of 46% on average, with a range of 36–65%, dependent on the index scale to score plaque. Power supply (rechargeable or replaceable battery), mode of action, as well as brushing duration and type of instructions are factors which contribute to the variation in the observed efficacy (Rosema *et al*. 2016). The collective evidence also shows that electric toothbrushes have superior efficacy over manual toothbrushes in reducing plaque and gingivitis (Sicilia *et al*. 2002; Yaacob *et al*. 2014; De Jager *et al*. 2017; Elkerbout *et al*. 2020; Wang *et al*. 2020). The conclusion from a Cochrane Oral Health Group review was that in the long term, electric toothbrushes reduced plaque by 21% and gingivitis by 11%, when compared with manual brushes (Yaacob *et al*. 2014). Any reported side effects were localized and temporary. The greatest body of evidence was found for oscillating–rotating brushes the effect of which has recently been summarized in a systematic review of studies up to 3 months in duration. This provided evidence supporting recommendations for patients with various degrees of gingival bleeding to use oscillating–rotating electric toothbrushes (Grender *et al*. 2020). Collective evidence for high-frequency, high-amplitude sonic powered toothbrushes showed that these also decreased plaque and gingivitis significantly more effectively than manual toothbrushes in everyday use in studies lasting up to 3 months (De Jager *et al*. 2017).

Modern electric toothbrushes are known to enhance long-term compliance. In a study involving periodontitis patients with persistently poor compliance, Hellstadius *et al*. (1993) found that switching from a manual to an electric toothbrush reduced plaque levels and that the reduced levels were maintained over a period of between 12 and 36 months. The electric brush significantly improved compliance, and patients expressed a positive attitude toward the new brush. Another study reported 62% of people continuing to use their electric toothbrushes on a daily basis 36 months after purchase (Stålnacke *et al*. 1995). In a survey conducted in Germany, most dentists stated that the time their patients spent on toothbrushing was too short (Warren 1998). Approximately half of the dentists stated that they recommended that their patients use an electric toothbrush, and the vast majority of the dentists believed that changing to an electric toothbrush would improve the condition of their patients' teeth and gums. The findings from a US practice-based study, involving a large number of subjects who switched from manual toothbrushes to the Braun Oral-B Ultra Plaque Remover

Comparison of different electric toothbrushes

Today's marketplace is crowded with dozens of electric brushes. The choices range from inexpensive, disposable, battery-operated, rotating brushes to sophisticated, rechargeable electric brushes. To establish the superiority of electric brushing over any other mode, the most well-known review, from a decade ago, performed in collaboration with the Cochrane Oral Health Group, assessed the collective evidence on efficacy of electric brushes and their effects on oral health (Deacon *et al*. 2011). The selection criteria were studies that were randomized, involved at least 4 weeks of unsupervised brushing, enrolled participants who had no impairment of manual dexterity, and compared two or more electric brushes with different modes of action. Brushes with a rotation–oscillation action reduced plaque and gingivitis more than those with side-to-side action in the short-term. However, the difference was small and its clinical importance unclear. Due to the low numbers of trials using other types of electric brushes, no other definitive conclusions can be drawn regarding the superiority of one type of electric toothbrush over another. However, it must be emphasized that absence of evidence is not evidence of absence, and it might be that future trials show the superiority of specific toothbrush designs. The most recent review based on single brushing exercises evaluated dental plaque removal using an oscillating–rotating power toothbrush as compared with a high-frequency sonic power toothbrush. It was concluded that there is some evidence of a very small but significant beneficial effect of an oscillating–rotating power toothbrush (Van der Sluijs *et al*. 2021). In addition, the difference in efficacy of oscillating–rotating power toothbrushes compared with other powered toothbrushes was recently systematically reviewed and analyzed (Clark-Perry & Levin 2020; El-Chami *et al*. 2021; Van der Sluijs *et al*. 2021). Altogether this shows that there is some evidence to suggest that oscillating–rotating power toothbrushes might remove more plaque and reduce the number of bleeding sites better than other powered toothbrushes, including high-frequency, high-amplitude sonic-powered toothbrushes. Based on studies with at least a 4-week duration, little to no difference in plaque and gingivitis scores was found with oscillating–rotating power toothbrushes compared with side-to-side powered toothbrushes (El-Chami *et al*. 2021). Further research is required before evidence-based advice concerning the relative performances of different electric toothbrushes can be provided by health care professionals to the public.

Safety

The safety of electric toothbrushes has been a concern of dental care professionals. One fear was that they would be used excessively and compulsively. For example, enthusiastic electric brush users could apply too much force and compromise their gingival tissues, thereby promoting recession. In a systematic review of the effects of oscillating–rotating and manual brushes on hard and soft tissues, the authors determined the safety of this design of electric toothbrush as comprehensively as possible (Van der Weijden *et al*. 2011). They searched the existing literature, using a variety of electronic databases, for any study that compared the safety of oscillating–rotating brushes to that of manual brushes, including all but the weakest levels of evidence. Having extracted the relevant data from the 35 most appropriate original papers, the data were grouped by research design (randomized controlled trials with safety as the primary outcome, trials in which safety was a secondary outcome, studies that used a surrogate marker of safety, and laboratory-based studies). Within these groups, the designs of the original studies were usually so diverse that it was impossible to bring the results together into a single statistical analysis. Nevertheless, the original data consistently failed to indicate problems with the safety of rotation–oscillation brushes. However, the majority of the trials considered safety as a secondary outcome. Therefore, the evidence was usually anecdotal rather than quantitative. The review authors concluded, "This systematic review of a large body of published research in the preceding two decades consistently showed oscillating–rotating toothbrushes to be safe when compared with manual brushes, and collectively indicated that there is no evidence that they do pose a clinically relevant concern to either hard or soft tissues". The outcomes were consistent with the observations in the reviews of Yaacob *et al*. (2014), Deacon *et al*. (2011) and El-Chami *et al*. (2021) reporting only minor and transient side effects.

Electrically active (ionic) toothbrush

Several toothbrushes (ionic, electronic, and electrically active) have been marketed over the years that are designed to send a small, imperceptible electronic current through the brush head onto the tooth surfaces, presumably to disrupt the attachment of dental plaque and to damage the electrostatic bonding of plaque proteins to tooth surfaces. Thus, these currents could enhance the efficacy of brushes in plaque elimination. Electrons should eliminate H^+ ions from the organic acid in the plaque, which could result in decomposition of the bacterial plaque (Hoover *et al*. 1992). The first record of a charged toothbrush, "Dr. Scott's Electric Toothbrush", was found in the

February 1886 issue of *Harper's* weekly magazine. The handle of Dr Scott's toothbrush was purportedly "charged with an electromagnetic current which acts without any shock, immediately upon the nerves and tissues of the teeth and gums. . .arresting decay. . .and restoring the natural whiteness of the enamel".

Hotta and Aono (1992) studied an electrically active manual toothbrush that was designed with a piezoelectric element in the handle. This brush generated a voltage potential corresponding to the bending motion of the handle as the teeth were brushed. In this study, no difference in the amount of remaining plaque after brushing was observed between the placebo and the electrically active brush. Other toothbrushes that have claimed an "electrochemical" effect on dental plaque have had semiconductors of titanium oxide (TiO_2) incorporated into the brush handle. In the presence of light, saturated low-energy electrons in the wet semiconductor are transformed into high-energy electrons. An electron current of approximately 10 nA was measured to run from the semiconductor to the tooth (Weiger 1988). Some short-term clinical studies of the use of these kinds of brushes have documented beneficial effects in terms of plaque reduction and gingivitis resolution (Hoover *et al*. 1992; Galgut 1996; Weiger 1998; Deshmukh *et al*. 2006), while others have failed to do so (Pucher *et al*. 1999; Moreira *et al*. 2007). One 6-month study reported lower plaque scores and improvement of gingivitis with the ionic brush compared with the control, but these findings were not substantiated in subsequent 6- and 7-month studies (Van der Weijden *et al*. 1995, 2002b).

Interdental cleaning

There is confusion in the literature regarding the definitions of the proximal, interproximal, interdental, and proximal sites. Commonly used indices are not suitable for assessing interdental plaque (directly under the contact area), thereby limiting the interpretation of interdental plaque removal. In 1998, the European Workshop on Mechanical Plaque Control proposed the following definitions. *Proximal* areas are the visible spaces between teeth that are not under the contact area. These areas are small in healthy dentition, although they can increase after periodontal attachment loss. The terms *interproximal* and *interdental* can be used interchangeably and refer to the area under and related to the contact point.

Based on consensus, interproximal cleaning is essential to maintain interproximal gingival health, in particular for secondary prevention (Chapple *et al*. 2015). The rationale for considering interdental cleaning under a separate heading is related to toothbrushing alone being considered optimally capable of thoroughly cleaning the *flat* surfaces of the teeth, that is the buccal, lingual, and occlusal surfaces, with the exceptions of pits and fissures. Toothbrushes do not reach the proximal surfaces of teeth as efficiently, nor do they reach into the interproximal areas between adjacent teeth. Therefore, measures for interdental plaque control should be selected to complement plaque control by toothbrushing (Lang *et al*. 1977; Hugoson & Koch 1979). The interdental gingiva fills the embrasure between two teeth apical to their contact point. This is a "sheltered" area which is difficult to access when the teeth are in their normal position. In populations that use toothbrushes, the interproximal surfaces of the molars and premolars are the predominant sites of residual plaque. The removal of plaque from these surfaces remains a valid objective because in patients susceptible to periodontal diseases, gingivitis and periodontitis are usually more pronounced in these interdental areas than on the oral or facial aspects (Löe 1979). Dental caries also occur more frequently in the interdental region than on the oral or facial smooth surfaces. A fundamental principle of prevention is that the effect is greatest where the risk of disease is greatest. Therefore, interdental plaque removal, which cannot be achieved with a toothbrush alone, is of critical importance for most patients.

A number of interdental cleaning methods have been developed, ranging from flossing to the more recently introduced electrically powered cleaning aids. Flossing is the most universally applicable method. However, not all interdental cleaning devices suit all patients or all types of dentitions. Apart from the ease of use, the ability and motivation of the patient should be taken into consideration when recommending an interdental cleaning method. The most appropriate patient-specific interdental cleaning devices must be selected to enable each individual patient to achieve a safe and high standard of interdental cleaning (Amarasena *et al*. 2019).

The selection made from among the numerous commercially available devices is dependent for the most part on the contour of the papilla, size of the interdental space, morphology of the proximal tooth surfaces, and tooth alignment. In subjects with normal gingival contours and embrasures, dental floss or tape can be recommended. At sites where soft tissue recession has become pronounced, flossing becomes progressively less effective. Thus, an alternative method (either woodsticks, rubber/elastomeric interdental cleaning sticks, or interdental brushes) should be recommended. In addition, it should be borne in mind that the advice offered might need to change as the effectiveness of treatment and improved oral hygiene change the shapes of the interproximal regions.

A review of interdental cleaning methods (Warren & Chater 1996) concluded that all conventional devices are effective, but each method should be suited to a particular patient and to a particular situation in the mouth (Table 28-1). Furthermore, for maximum effectiveness, the level of oral

Table 28-1 Interdental cleaning methods recommended for particular situations in the mouth.

Situation	Interdental cleaning method
Intact interdental papillae; narrow interdental space	Dental floss or small woodstick/rubber/elastomeric interdental cleaning stick
Moderate papillary recession; slightly open interdental space	Dental floss, woodstick/rubber/elastomeric interdental cleaning stick or small interdental brush
Complete loss of papillae; wide open interdental space	Interdental brush
Wide embrasure space; diastema, extraction diastema, furcation or posterior surface of most distal molar, root concavities or grooves	Single-tufted/end-tufted brush or gauze strip

hygiene advice delivered to the patient must contain enough information to enable the patient to be able to identify each site in turn, to select a device, and to clean all interdental surfaces effectively (Claydon 2008). The starting point is an evaluation of existing products. An ideal interdental cleaning device should be user-friendly, remove plaque effectively, and have no deleterious soft tissue or hard tissue effects. Gingival bleeding during interdental cleaning can be the result of trauma, such as lacerations and gingival erosions, or it can be an indication of inflammation. Patients must be aware that bleeding *per se* is not a sign that interdental cleaning should be avoided but is more likely an indicator of inflammation that needs to be treated (Gillette & Van House 1980).

Dental floss and tape

Of all the methods used for removing interproximal plaque, dental flossing is the most frequently recommended. Levi Spear Parmly, a dentist based in New Orleans, USA is credited with being the inventor of modern dental floss. As early as 1815, Parmly recommended tooth flossing with a piece of silk thread. In 1882, the Codman and Shurtleft Company of Randolph, Massachusetts, USA, started to mass-produce unwaxed silk floss for commercial home use. In 1898, the Johnson & Johnson Company of New Brunswick, New Jersey, USA, was the first to patent dental floss. During the 1940s nylon floss, which was more resistant to shredding, replaced silk as the material for dental floss. Dr Charles C. Bass is considered to be for making teeth flossing an important part of dental hygiene.

Dental floss and tape (see Box 28-3) – the latter a broader type of dental floss – are most useful where the interdental papillae completely fill the embrasure space. When properly used, effective flossing removes up to 80% of proximal plaque. Even subgingival plaque can be removed because dental floss can be introduced 2–3.5 mm beyond the tip of the papilla (Waerhaug 1981b). Several types of floss (waxed, unwaxed) are available. Studies have shown no difference in the effectiveness of unwaxed versus waxed dental floss. Unwaxed dental floss is generally recommended for patients with normal tooth contacts because it slides through the contact area easily. It is the thinnest type of floss available, yet when it separates during use it covers a larger surface area of the teeth than waxed floss. Waxed floss is recommended for patients with tight proximal tooth contacts.

Ease of use is the most important factor that influences whether patients will use floss on a daily basis. Many people find using dental floss difficult to master because of the manual complexity of the technique which in turn has a negative effect on compliance (Graziani *et al*. 2018). Unlike toothbrushing, few people have learned how to use dental floss properly. However, like any other skill, flossing can be taught, and those patients who are given appropriate instruction will increase their flossing frequency (Stewart & Wolfe 1989). Patients benefit from step-by-step instructions (see Box 28-3) and frequent re-instruction and reinforcement in the use of floss are necessary. Because many people think that the purpose of flossing is to remove particles of food, they must be advised that the objective is to remove plaque that adheres to the tooth surface.

To facilitate flossing, a special floss holder can be used. These holders can be re-used and are normally made of a plastic that is durable, lightweight, and easy to clean. Research has revealed that reductions in bacterial plaque biofilm and gingivitis are equivalent with either hand flossing or the use of a floss holder. Powered flossing devices have been introduced. In comparison with manual flossing, no differences were found in terms of plaque removal or gingivitis reduction, although patients preferred flossing with the automated device (Gordon *et al*. 1996).

Flossing is also time-consuming. When a patient is unwilling to use dental floss, alternative interdental hygiene aids should be recommended, even if these aids are less efficient. If a patient finds a particular method or device more appealing to use, long-term compliance becomes an achievable goal. Although it is clear that flossing, when properly used, removes plaque in a very efficient manner, there is no evidence that flossing in adult patients with preserved interproximal periodontal tissues should be routinely indicated (Burt & Eklund 1999).

Three systematic reviews and one meta-review are available concerning the efficacy of dental floss. The first, by Berchier *et al*. (2008), evaluated the collective evidence to determine the effectiveness of dental floss, in combination with toothbrushing, on plaque and the clinical parameters of gingivitis in adults. The majority

of the included studies showed that there was no benefit from flossing. The meta-analysis of plaque and the gingival index scores also showed no significant differences between groups. Advocacy for flossing as an interdental cleaning method hinges, in large part, on common sense. However, common sense arguments are the lowest level of scientific evidence. A Cochrane review included a variety of floss-related products and, based on the combined evidence, concluded that there was some evidence that flossing, in addition to toothbrushing, reduced gingivitis compared with toothbrushing alone (Sambunjak *et al*. 2011). The most recent Cochrane review summarized the evidence for all interdental cleaning devices and included 15 trials evaluating floss plus toothbrushing versus toothbrushing alone. It was concluded that low-certainty evidence suggested that flossing, in addition to toothbrushing, may reduce gingivitis (Worthington *et al*. 2019). A meta-review based on evidence gathered from existing systematic reviews concluded that the majority of available studies fail to demonstrate that flossing is generally effective in plaque removal (Salzer *et al*. 2015). Thus, there is weak, very unreliable evidence that flossing plus toothbrushing could be associated with a small reduction in plaque. This is also confirmed in two Bayesian Network Meta-Analysis concerning the efficacy of interdental oral hygiene aids. It quantitatively provided a global ranking of efficacy where, with respect to the reduction of gingival bleeding, dental floss ranked last (Kotsakis *et al*. 2018; Liang *et al*. 2020).

That dental floss has no additional effects on toothbrushing is apparent from more than one review. Hujoel *et al*. (2006) found that flossing was only effective in reducing the risk of interproximal caries when applied professionally. High-quality professional flossing, performed in first-grade children on school days, reduced the risk of caries by 40%. In contrast, self-performed flossing failed to show a beneficial effect. The lack of an effect on caries and the absence of an effect on gingivitis in the systematic review by Berchier *et al*. (2008) were most likely the consequences of plaque not being removed efficiently.

That flossing does not appear to be effective in the hands of the general public does not preclude its use. For instance, in interdental situations that only allow for the penetration of a string of dental floss, floss is the best available tool. Although floss should not be the first tool recommended for cleaning open interdental spaces, if the patient does not like any other tool, flossing could still be part of oral hygiene instruction. Floss can also still be advised in interdental sites, where other interdental cleaning devices will not pass through the interproximal area without trauma (Chapple *et al*. 2015). The dental professional should realize that proper instruction, sufficient motivation of the patient, and a high level of dexterity are necessary to make the flossing effort worthwhile. Routine instruction in using floss is not supported by scientific evidence.

Woodsticks

While flossing is the most widely advocated interdental cleaning method, picking of teeth may well be one of humanity's oldest habits and the toothpick one of our earliest tools. The toothpick might date back to the days of cave people, who probably used sticks to pick food from between their teeth. A 1.2 million-year-old hominin jawbone was recently discovered at an excavation site in northern Spain. The jawbone had an interproximal groove with fragments of non-edible wood, which suggests that picking at teeth may be one of humanity's earliest interdental oral hygiene activities (Hardy *et al*. 2016). The ancient Romans made use of toothpicks fabricated from bone and metal. Saxon women carried ivory toothpicks. The evolution of the primitive toothpick took a second pathway in more acquisitive societies, becoming part of personal care kits, along with depilatory tweezers and earwax scoops (Mandel 1990). In 1872, Silas Noble and J. P. Cooley patented the first toothpick-manufacturing machine.

Originally, dental woodsticks were advocated by dental professionals as "gum massagers" used to massage inflamed gingival tissue in the interdental areas, to reduce inflammation, and to encourage keratinization of the gingival tissue (Galgut 1991).

The key difference between a toothpick and a woodstick (wooden stimulator/cleaner) relates to the triangular (wedge-like) design of the latter. Woodsticks should not be confused with toothpicks, which are simply intended to remove food debris after meals (Warren & Chater 1996). Woodsticks are inserted interdentally, with the base of the triangle resting on the gingival side (see Box 28-4). The tip should point occlusally or incisally, with the triangle against the adjacent tooth surfaces. Triangular, wedge-like woodsticks have been found to be superior in plaque removal compared with round or rectangular woodsticks, because they fit the interdental area more snugly (Bergenholtz *et al*. 1980; Mandel 1990). Woodsticks are usually made of soft wood to prevent injury to the gingiva. Their tapered form makes it possible for the patient to angle the woodstick interdentally and even clean the lingually localized interdental surfaces. Unlike floss, woodsticks can be used on the concave surfaces of the tooth roots. Some are handheld, while others are designed to be mounted in a handle, which facilitates access to the interdental areas in the posterior region of the mouth (Axelsson 2004). The wood can store fluoride crystals, both on the surface and in the porosities. These crystals readily dissolve when woodsticks are moistened with saliva (Axelsson 2004).

Woodsticks have the advantage that they are easy to use and can be used throughout the day, without the need for special facilities, such as a bathroom or a mirror. They are also environmentally friendly. A national dental survey showed that the Swedish population prefers using woodsticks to dental floss

for the removal of interdental plaque: approximately 46% of adults used woodsticks sporadically and 12% used woodsticks daily. In contrast, dental floss was used occasionally by 12% of adults and daily by only 2%. In other words, adults used woodsticks as oral hygiene aids four to six times more frequently than dental floss (Axelsson 1994). Woodsticks can be used in primary prevention, including in posterior areas, even in cases of poor manual dexterity. To use woodsticks, there must be sufficient interdental space available; in these cases, woodsticks are an excellent substitute to dental floss. Woodsticks can clearly be recommended for patients with open interdental spaces for secondary prevention of periodontal diseases.

Although woodsticks have good cleansing capacity in the central part of the interproximal surfaces of teeth in contact, their effect is reduced on the lingual side of these surfaces. Woodsticks are somewhat difficult to use in the far posterior regions of the jaws because of the lack of accessibility and because the triangular cross-section must pass into the embrasure space at a specific angle (Bassiouny & Grant 1981). When used in healthy dentition, woodsticks can depress the gingival margin. Long-term use can cause permanent loss of the papilla and opening of the embrasure, which can have important esthetic implications for the anterior dentition.

Hoenderdos *et al*. (2008) performed a systematic review to evaluate and summarize the available evidence on the effectiveness of using woodsticks in combination with toothbrushing, to reduce both plaque and clinical inflammatory symptoms of gingival inflammation. The evidence as collected only refers to triangular-shaped woodsticks. No data were gathered with respect to other shapes of woodsticks such as round or square toothpicks. The heterogeneity of the data precluded quantitative analysis and only allowed for a descriptive analysis. In seven studies, improvement in gingival health represented a significant incremental benefit realized by the use of triangular woodsticks. None of the studies that scored visible interdental plaque demonstrated any significant advantage of using woodsticks, as opposed to alternative methods (toothbrushing only, dental floss, or interdental brushes), in patients with gingivitis. The latest Cochrane review (Worthington *et al*. 2019), with only one included study on woodsticks, also concluded that this device reduced gingivitis but had no effect on plaque scores.

A series of histologic investigations in patients with periodontitis has shown that the papillary area with the greatest inflammation corresponds to the middle of the interdental tissue. It is difficult to assess the mid-interdental area clinically, as it is usually not available for direct visualization (Walsh & Heckman 1985). When used on healthy dentition, woodsticks depress the gingiva by up to 2–3 mm (Morch & Waerhaug 1956) and therefore clean part of the subgingival area. Thus, woodsticks can specifically remove subgingivally located interdental plaque that is not visible and therefore not evaluated by the plaque index. This physical action of woodsticks in the interdental area could produce a clear, beneficial effect on interdental gingival inflammation.

The studies included in the review by Hoenderdos *et al*. (2008) showed that changes in gingival inflammation were as apparent as changes in bleeding tendency as indicators of disease. Numerous studies have shown that sulcular bleeding is a very sensitive indicator of early gingival inflammation. Bleeding following the use of woodsticks can also be used to increase patient motivation and awareness of gingival health. The dental care professional can also demonstrate the gingival condition to the patient, using an interdental bleeding index (Eastman Interdental Bleeding Index; Caton *et al*. 1988). This method is a reliable and validated clinical indicator for detecting interdental inflammatory lesions (Barendregt *et al*. 2002). It can be used as a self-assessment tool for gingivitis patients because the presence of bleeding provides immediate feedback on the level of gingival health. This could encourage patients to include woodsticks as part of their oral hygiene regimens (Walsh *et al*. 1985).

Rubber/elastomeric interdental cleaning sticks

The most recent development for interdental cleaning is the rubber/elastomeric interdental cleaning stick (RICS) (see Box 28-5). The first product was Soft-pick®, marketed by the GUM® Company (Sunstar Europe S.A., Etoy, Switzerland). Its plastic core with soft elastomeric bristles is said to massage the gum and dislodge food. It is presented as an alternative to flossing and should improve patient compliance. A more recent development is a comparable product called EasyPick™ from the TePe® Company (Tepe Munhygienprodukter AB, Malmö, Sweden) where the core is firm covered by a flexible silicone coating and lamellae. Only a handful of clinical trials have evaluated this new device. In gingivitis patients, adjuvant use to toothbrushing of RICS as compared with dental floss, showed no difference of plaque and gingivitis scores (Yost et al. 2006; Abouassi *et al*. 2014; Graziani *et al*. 2017). In four studies with a follow-up design, no differences with respect to plaque score reduction was observed for the RICS compared with interdental brushes (Yost *et al*. 2006; Abouassi *et al*. 2014; Graziani *et al*. 2017; Hennequin-Hoenderdos *et al*. 2017). In addition, for overall bleeding scores no difference was found, but one study that analyzed the accessible sites in a separate analysis found RICS to be preferable to interdental brushes (Hennequin-Hoenderdos *et al*. 2017). In contrast, one study evaluating efficacy of RICS compared with interdental brushes according to the gingival index scores showed that the interdental brush achieved a significant greater reduction (Yost *et al*. 2006). Moreover, the RICS led to less abrasions of

the gingiva (Hennequin-Hoenderdos *et al*. 2017) and was preferred by the study participants (Abouassi *et al*. 2014; Hennequin-Hoenderdos *et al*. 2017). So far, no comparisons to woodsticks have been published. Overall, the evidence suggests that RICS may be recommended as an alternative interdental cleaning device for patients with gingivitis (Van der Weijden *et al*. 2021). The evidence supports user safety and participants' preference.

Interdental brushes

Interdental brushes (see Box 28-6) were introduced in the 1960s as an alternative to woodsticks. They are effective in the removal of plaque from the proximal tooth surfaces (Bergenholtz & Olsson 1984). Interdental brushes consist of soft nylon filaments twisted into a fine stainless steel wire. This "metal" wire can prove uncomfortable for patients with sensitive root surfaces. For such patients, the use of plastic-coated metal wires might be recommended. The support wire is continuous or inserted into a metal/plastic handle. The most common forms are cylindrical or conical/tapered (like a Christmas tree). In patients receiving supportive periodontal therapy the conical interdental brushes were found to be less effective than cylindrical ones with respect to lingual approximal plaque removal (Larsen *et al*. 2017). Less common are those with a waist-shape (like a diabolo). It is suggested that it may result in more contact at the lingual and buccal line angles because of the larger diameter at the base and tip section than in the middle (Chongcharoen *et al*. 2011). The waist-shaped interdental brush was found to more effective in plaque removal as compared with a cylindrical interdental brush among patients receiving supportive periodontal therapy (Schnabl *et al*. 2020). The development of triangular interdental brushes was generated by the inconsistency between the form of the interdental space and the shape of the interdental brush which creates insertion resistance. The triangular brushes were found to penetrate the interdental space more easily than conventional cylindrical interdental brushes (Wolff *et al*. 2006a).

Whereas bristle filament stiffness appears to have no statistically significant influence on the cleaning efficacy (Wolff *et al*. 2006b) the length of the filaments in cross-section should be tailored to the interdental space. Interdental brushes are available for the smallest to the largest interdental spaces (Fig. 28-7). Although unconfirmed in the scientific literature, it is believed that the most efficient cleaning is achieved if the brush selected is slightly larger than the embrasure space, as long as they can be inserted into the interdental space (Wolff *et al*. 2006a). Patients require interdental brushes of various sizes. Schmage *et al*. (1999) assessed the relationship between the interdental space and the position of the teeth. Most of the interproximal spaces in the anterior teeth were small and of an appropriate size for the use of floss. Premolars and molars have larger interproximal spaces and are accessible with interdental brushes. The brush can be inserted obliquely into the interdental space from the apical direction leaning towards the mesial and distal aspect of the interproximal space (Schnabl *et al*. 2020). As the posterior proximal spaces have wider lingual embrasures, conical-shaped interdental cleaners are not the first choice. Approaching then from the lingual side will result in more effective plaque removal, but this technique is not easy. Cleaning is performed with a back-and-forth motion. The interdental brush is the aid of choice when root surfaces with concavities or grooves have been exposed. Interdental brushes are also the most suitable cleaning devices for "through-and-through" furcation defects.

Fig. 28-7 With interdental brushes, the diameter of the metal wire core is a determining factor with regard to access. A close fit of the brushing filaments influences the cleaning capacity.

Like woodsticks, interdental brushes are easy to use. They come with different types of handles. This can be the metal wire core itself or handles/holders that are round or flat. The wire, or the handles that have a flexible neck can be bent to form the best insertion angle. Also angled handles are available which have been found to be less effective in plaque removal than straight interdental brushes (Jordan *et al*. 2014). When not used properly, interdental brushes can elicit dentin hypersensitivity. To minimize the risk of hard tissue abrasion, interdental brushes should be used without dentifrice except in special cases, and then only for the short term. Interdental brushes can also be used as carriers to apply fluoride or antimicrobial agents, for example chlorhexidine gel, into the interdental space to prevent caries or the recolonization of residual pockets. Brushes should be discarded when the filaments become loose or deformed.

Interdental brushes represent the ideal interdental cleaning tool, especially for periodontitis patients. Waerhaug (1976) showed that individuals who habitually used interdental brushes were able to maintain supragingival proximal surfaces free of plaque and

to remove some subgingival plaque below the gingival margin up to a depth of 2–2.5 mm below the gingival margin. In a study in patients with moderate-to-severe periodontitis, Christou *et al*. (1998) demonstrated that interdental brushes were more effective than dental floss in the removal of plaque and in promoting pocket reduction. Patients reported that the use of interdental brushes was easier than using dental floss. This finding is in agreement with those of previous studies (e.g. Wolffe 1976). Additionally, the perception of efficacy was better for interdental brushes. Significantly fewer patients reported problems with using interdental brushes. Even if the efficacy of interdental brushes were not better than that of floss, the long-term use of interdental brushes might be more easily implemented in patients' routines than floss. Patient acceptance is a major issue to be considered when it comes to the long-term use of interdental cleaning devices. Interdental brushes are considered to be less time-consuming and more efficacious than floss for interdental plaque removal.

Slot *et al*. (2008) systematically reviewed the literature to determine the effectiveness in patients with gingivitis or periodontitis of interdental brushes used as adjuncts to toothbrushes in terms of plaque and clinical parameters of periodontal inflammation. The majority of the studies showed a positive significant difference in plaque index when using interdental brushes compared with floss. No differences were identified for gingival or bleeding indices. Meta-analysis revealed a significant effect with the Silness and Löe plaque index in favor of the interdental brush group compared with the floss group. Most of the included studies did not discuss the different interdental brush sizes, nor did they indicate whether interdental brushes were used in all available proximal sites. Two of the included studies showed a significant effect on pocket depth reduction with the use of interdental brushes compared with the use of floss. That interdental cleaning with interdental brushes is the most effective method for interdental plaque removal is supported by a meta-review (Saelzer *et al*. 2015), the latest Cochrane review (Worthington *et al*. 2019), and a Bayesian Network Meta-Analysis (Kotsakis *et al*. 2018). A network meta-analysis of studies with participants in periodontal maintenance demonstrated that for plaque removal the adjuvant use of interdental brushes was significantly more effective than the manual toothbrush alone (Slot *et al*. 2020). The reduced pocket depth might have been related to the reduction in swelling with concomitant recession (Jackson *et al*. 2006). However, the effect on pocket depth cannot readily be explained by a reduction in the level of gingival inflammation (Slot *et al*. 2008). As an alternative explanation for the observed effect, which seems conceivable, Badersten *et al*. (1975) suggested that mechanical depression of the interdental papilla is induced by interdental brushes, which, in turn, causes recession of the marginal gingiva. This result, together with the good plaque removal, could have been the origin of the improved reduction in pocket depth.

Single-tufted/end-tufted brushes

Single-tufted brushes have smaller brush heads, which have a small group of tufts or a single tuft (see Box 28-7). The tuft can be 3–6 mm in diameter and can be flat or tapered. The handle can be straight or contra-angled. Angled handles permit easier access to lingual and palatal aspects. The filaments are directed into the area to be cleaned and are activated with a rotating motion. Single-tufted toothbrushes are designed to improve access to the distal surfaces of the posterior molars and to tipped, rotated or displaced teeth; to clean around and under fixed partial dentures and pontic, orthodontic appliances or precision attachments; and to clean teeth affected by gingival recession and irregular gingival margins or furcation involvement. Little research has been performed with this type of brush. A cross-over study compared the single tuft to a flat-trim toothbrush. The results indicated that the single-tuft brush was effective in removing plaque from relatively hard-to-reach sites. More plaque was removed on the buccal side of the maxillary molars and on the lingual interproximal side of the mandibular molars (Lee & Moon 2001).

Dental water jets/oral irrigators

The dental water jet was developed by a hydraulic engineer, John Mattingly, and a dentist, Gerald Moyer. It was introduced to the dental profession in 1962 and has been studied extensively for the past several decades. Prior to 1964, Mattingly built the units at home, and they were sold exclusively through Dr Moyer's practice. In 1964, a patient who loved the device raised thousands of dollars to help make the units available in stores. A few years later, Waterpik® devices could be found in drug stores and department stores. In 2001, the American Academy of Periodontology stated, "Among individuals who do not perform excellent oral hygiene, supragingival irrigation with or without medicaments is capable of reducing gingival inflammation beyond that normally achieved by toothbrushing alone. This effect is likely due to the flushing out of subgingival bacteria". The pulsating, hydrodynamic forces produced by irrigators can rinse away food debris from interdental spaces and plaque-retentive areas (see Box 28-8). An *ex vivo* scanning electron microscopy study demonstrated that the hydraulic forces of a dental water jet can remove the biofilm above and below the cementoenamel junction (Gorur *et al*. 2009). It has been reported that a pulsating stream of water is better than a continuous flow. Irrigation is not, however, a monotherapy but an adjunct designed to supplement or enhance other home oral care methods (brushing and flossing) intended for mechanical plaque removal (Hugoson 1978; Cutler *et al*. 2000) (Fig. 28-8).

Fig. 28-8 Dental water jet. Fluid flow can be either continuous or pulsated.

Husseini *et al*. (2008) performed a systematic review of the existing literature to evaluate the effectiveness of oral water irrigation as an adjunct to toothbrushing on plaque and clinical parameters of periodontal inflammation compared with toothbrushing alone or to regular oral hygiene. The heterogeneity of the data prevented quantitative analysis; therefore, a descriptive approach was undertaken. None of the included studies showed a significant difference between toothbrushing and the use of a dental water jet in combination with toothbrushing. When observing visual signs of gingival inflammation, three of the four studies reported a significant effect with the use of a dental water jet as an adjunct to regular oral hygiene. Two of the four studies showed a significant reduction in probing depth as a result of using a dental water jet as an adjunct to regular oral hygiene. The authors concluded that there is evidence that suggests a positive tendency toward improved gingival health when using a dental water jet as an adjunct to toothbrushing, as opposed to regular oral hygiene (i.e. self-performed oral hygiene without any specific instructions). A 4-week evaluation showed (within the limits of this short evaluation period) that when combined with manual toothbrushing, the daily use of an oral irrigator is significantly more effective in reducing gingival bleeding scores than the use of dental floss (Rosema *et al*. 2011). A 2-week evaluation found that the oral irrigator is more effective than interdental brushes for the reduction of gingival bleeding (Goyal *et al*. 2016). A Bayesian Network Meta-Analysis concerning the efficacy of interdental oral hygiene aids quantitatively provided a global ranking of efficacy where, with respect to the reduction of gingival bleeding, oral irrigators together with interdental brushes ranked highest (Kotsakis *et al*. 2018). The Waterpik® Water Flosser (Water Pik Inc, Fort Collins, Colorado, USA) received the ADA seal of acceptance in February 2017.

The selected papers for this systematic review reported no statistically significant reduction in plaque with use of a dental water jet (Husseini *et al*. 2008). Plaque reduction is a prerequisite for an oral hygiene device to be considered valuable. Despite the lack of an effect on the plaque index, these studies did find a significant effect on the bleeding index. The mechanisms underlying these clinical changes in the absence of a clear effect on plaque are not understood. Different hypotheses have been put forward by authors to explain the results. One hypothesis is that when patients with gingivitis perform supragingival irrigation on a daily basis, the populations of key pathogens (and their associated pathogenic effects) are altered, reducing gingival inflammation (Flemmig *et al*. 1990). There is also the possibility that water pulsations alter specific host–microbial interactions in the subgingival environment and that inflammation is reduced independent of plaque removal (Chaves *et al*. 1994). Another possibility is that the beneficial activity of a dental water jet is at least partly due to removal of food deposits and other debris, flushing away of loosely adherent plaque, removal of bacterial cells, interference with plaque maturation, and stimulation of immune responses (Frascella *et al*. 2000). Other explanations include mechanical stimulation of the gingiva or a combination of previously reported factors. Irrigation can reduce plaque thickness, which might not be easily detected using two-dimensional scoring systems. This fact could explain the absence of an effect on plaque but a positive effect on gingival inflammation.

Irrigation devices can increase the delivery of fluid beneath the gingival margin (Flemmig *et al*. 1990). Greater penetration of a solution into periodontal pockets was achieved by patient-applied supragingival irrigation compared with mouth rinsing (Flemmig *et al*. 1995). Studies evaluating the capacity of supragingival irrigation to project an aqueous solution subgingivally have determined that supragingival irrigation with a standard irrigation tip was capable of delivering water or a medicinal fluid 3 mm subgingivally or to approximately half the probing depth of a 6-mm pocket (Larner & Greenstein 1993). Irrigation devices can be used with water or with disinfectant solutions (Lang & Räber 1982). The use of chlorhexidine in suboptimal concentrations (e.g. 0.06%) has resulted in improved plaque inhibition and has had anti-inflammatory effects (Lang & Räber 1982; Flemmig *et al*. 1990).

Success with pulsating oral irrigators with regular tips is limited to the subgingival area and periodontal pockets (Wennström *et al*. 1987). With a specially designed tip (Pik Pocket® subgingival irrigation tip; Water Pik Inc.), the pulsating stream of fluid can penetrate more deeply into the pocket areas (Cobb *et al*. 1988). These blunt-ended cannulas can also be used to inject antimicrobial agents into shallow-to-moderate periodontal pockets.

Supragingival irrigation applies considerable force to the gingival tissues. Irrigation was shown to have the potential to induce bacteremia. However, given the collective evidence, it appears that irrigation is safe for healthy patients (Husseini *et al*. 2008).

Another oral irrigator device is the Sonicare AirFloss (Philips Oral Healthcare, Snoqualmie, WA, USA), which uses a spray of microbubbles and a small dose of fluid to generate the interdental cleaning action, through which it is claimed disrupts plaque biofilm structures. The nozzle tip is designed to act as a guide to the spaces between teeth. When the two commercially available oral irrigators are compared, the Water Flosser was found to be significantly more effective than the AirFloss for reducing gingivitis and plaque (Sharma *et al* 2012a, b; Goyal *et al*. 2015). There is clearly a need for more published clinical research studies regarding this device to establish its clinical value.

Tongue cleaners

Regular tongue cleaning has been performed since ancient times and is still carried out by the native populations of Africa, the Arab countries, India, and South America. Many ancient religions emphasized the cleanliness of the entire mouth, including the tongue. Indian people's daily ritual of oral hygiene was not confined to brushing of the teeth; the tongue was also scraped, and the mouth was rinsed with concoctions of betel leaves, cardamom, camphor, or other herbs.

The dorsum of the tongue, with its papillary structure, furrows and crypts, harbors a great number of microorganisms. It forms a unique ecologic oral site with a large surface area (Danser *et al*. 2003). The tongue is said to act as a reservoir, which permits the accumulation and stagnation of bacteria and food residues (Outhouse *et al*. 2006). Tongue bacteria can serve as a source of bacterial dissemination to other parts of the oral cavity, for example the tooth surfaces, and can contribute to dental plaque formation. These bacteria make the greatest contribution to the bacteria found in the saliva. Therefore, tongue brushing has been advocated as part of daily home oral hygiene, together with toothbrushing and flossing (Christen & Swanson 1978). Tongue brushing has also been advocated as a component of the so-called "full-mouth disinfection" approach in the treatment of periodontitis, with the aim of reducing possible reservoirs of pathogenic bacteria (Quirynen *et al*. 2000).

A large variety of tongue cleaners are commercially available. A modern tongue-scraping instrument can consist of a long strip of plastic ribbon. This strip is held in both hands and is bent so that the edge can be pulled down over the dorsal surface of the tongue. A study that evaluated preference and perception of effectiveness with respect to nine commercially available tongue scrapers found this to vary the tongue-cleaning device designs. No single feature stood out as being specifically related to perception of effectiveness although sharpness and comfort were negatively correlated (Beekmans *et al*. 2017). Tongue brushing also appears to be an easy method of cleaning the tongue surface, provided that the gag reflex can be controlled. However, in a systematic review, it was concluded that scrapers or cleaners are more effective than toothbrushes for tongue cleaning (Outhouse *et al*. 2006) and with them the gag reflex is reduced (Van der Sleen *et al*. 2010). Patients should be informed that it is most important to clean the posterior portion of the tongue dorsum, but in reality, it is likely that many patients do not reach far enough to contact the posterior dorsum during tongue cleaning because extended reaching causes the gag reflex.

Tongue cleaning is a simple and fast procedure that helps to remove microorganisms and debris from the tongue (see Box 28-9). When tongue cleaning is practiced on a daily basis, the process becomes easier. Eventually, the patient can indeed feel "unclean" when tongue debris is not removed on a regular basis. In a study by Gross *et al*. (1975), the test group was instructed to brush the tongue as an adjunct to normal oral hygiene measures. The control group was not instructed to clean the tongue. A reduction of 40% in the presence of tongue coating was noted in the test group compared with the control group. In a group of systemically healthy young adults self-reported tongue cleaning behavior was associated with slightly lower bleeding on probing scores (Van Gils *et al*. 2019).

Some studies have shown that tongue brushing, in combination with other methods of oral hygiene, is an effective method for reducing the formation of dental plaque. In contrast, Badersten *et al*. (1975) found no difference in *de novo* plaque accumulation between a 4-day period of tongue brushing and a 4-day period of no oral hygiene procedures. The authors suggested that the majority of the important plaque-forming bacteria might not originate from the tongue. Another reason for not finding an effect of tongue brushing on plaque formation might be that brushing the posterior part of the dorsum of the tongue is difficult due to inaccessibility and discomfort.

Yaegaki and Sanada (1992) observed six times more tongue coating in patients with periodontal problems than in those who were periodontally healthy. Consequently, individuals with periodontal diseases will likely present with microbial flora more favorable to exacerbating the formation of volatile sulfur compounds than healthy individuals. Over the years, oral malodor has become a topic of interest to both the scientific community and to people who suffer from it. Regular mechanical tongue cleaning can play a role in controlling bacterial numbers and removing tongue coating. Individuals with coated tongues showed significantly higher malodor scores than individuals with non-coated tongues (Quirynen *et al*. 2004). Van der Sleen *et al*. (2010) demonstrated in their systematic review that mechanical approaches, such as tongue brushing or tongue scraping to clean the dorsum of the tongue, have the potential to reduce tongue coating and oral malodor. This systematic review detected only one study that

included patients with chronic oral malodor, with an unknown evaluation period and a high potential risk of bias. This study stood in contrast to the other included studies, which evaluated the effect of tongue cleaning in cases of morning bad breath. Consequently, no firm statement can be made as to whether mechanical tongue cleaning contributed to a reduction in oral halitosis (Slot *et al*. 2015). More research is needed to assess the effect of mechanical tongue cleaning, particularly in true halitosis populations.

Foam brushes, swabs, or tooth towelettes

Tooth towelettes are being marketed as a method of plaque removal when toothbrushing is not possible. Their use is not meant to replace a daily toothbrushing regimen.

Finger brushes, such as the I-Brush®, are mounted on the index finger of the brushing hand and use the agility and sensitivity of the finger to clean the teeth. Consequently, the pressure with which they are applied can be well controlled because the finger can actually feel the tooth and gingival surfaces and help position the brush for more effective scrubbing. During a 3-week clinical trial (Graveland *et al*. 2004), no adverse effects were found with the I-Brush®. The results showed that the finger brush removed less plaque than a regular manual toothbrush. In particular, proximal plaque reduction was poor in comparison with manual toothbrushing. Based on these results, it was concluded that there were no beneficial effects of the finger brush in comparison with regular manual toothbrushes.

Foam brushes resemble a disposable soft sponge on a stick, and they have been dispensed to hospital patients for intraoral cleansing and refreshing since the 1970s. They are used in particular for oral care in medically compromised and immunocompromised patients to reduce the risk of oral and systemic infection (Pearson & Hutton 2002). Lefkoff *et al*. (1995) studied the effectiveness of such a disposable foam brush on plaque. In this study, regular manual toothbrushes were found to be significantly more effective in retarding the accumulation of plaque from a plaque-free baseline on both facial and lingual surfaces. However, the foam brush did show some plaque-preventive capabilities by maintaining plaque formation below 2 mm at the cervical margin of the tooth. Nevertheless, according to most authors, foam brushes should not be considered a substitute for regular toothbrushes. In a study by Ransier *et al*. (1995), foam brushes were saturated with a chlorhexidine solution. The authors found foam brushes that had been soaked in chlorhexidine to be as effective as regular toothbrushes in controlling plaque and gingivitis levels. Therefore, if hospitalized patients cannot use a toothbrush, an alternative could be the use of chlorhexidine applied with a foam brush.

Dentifrices

The use of a toothbrush is usually combined with that of a dentifrice, with the intention of facilitating plaque removal and applying agents to the tooth surfaces for therapeutic or preventive reasons, to produce fresh breath, and to make the toothbrushing procedure more pleasant. The term dentifrice is derived from the Latin words *dens* (tooth) and *fricare* (to rub). A simple, contemporary definition of a dentifrice is a mixture used on the tooth in conjunction with a toothbrush. Dentifrices are marketed as powders, pastes, and gels. Dentifrice was used as early as 500 BC in both China and India; modern toothpastes were developed in the 1800s. In 1824, a dentist named Peabody was the first person to add soap to toothpaste. John Harris first added chalk to toothpaste in the 1850s. Colgate mass-produced the first toothpaste in a jar. In 1892, Dr. Washington Sheffield of Connecticut, USA manufactured toothpaste in a collapsible tube (Dr. Sheffield's Creme Dentifrice). Advancements in synthetic detergents made after World War II have allowed the replacement of the soap used in toothpaste with emulsifying agents, such as sodium lauryl sulfate. Later, fluoride was added.

Traditionally, it was believed that dentifrices should contain an abrasive. The addition of abrasives supposedly facilitated plaque and stain removal without producing gingival recession/tooth abrasion or altering the remaining components of the dentifrice. For many decades, abrasive systems, such as calcium carbonate, alumina, and dicalcium phosphate, have been used. Today, most dentifrices contain silica. Although more expensive, silica can be combined with fluoride salts, and it is very versatile. It has also been shown to increase the abrasiveness of dentifrices, resulting in even more plaque removal (Johannsen *et al*. 1993).

Conflicting reports have been published concerning the added value of using dentifrice for plaque removal. Studies by de la Rosa *et al*. (1979) and by Stean and Forward (1980) validated the use of dentifrice because they found that there was a reduction in plaque growth after brushing with a dentifrice as opposed to brushing with water. Similarly, Eid and Talic (1991) reported overall reductions in plaque of 67% for manual toothbrushing with a dentifrice and 59% for toothbrushing with water. In contrast, in a study by Gallagher *et al*. (2009), the use of 1.5 g of dentifrice showed no additional effect after 1 minute of brushing compared with brushing without dentifrice. Paraskevas *et al*. (2006) also studied whether dentifrice had a beneficial effect on plaque removal and whether an abrasive additive was a contributor. Their results showed that among 40 subjects using three different hydrated, silica-based dentifrices in a crossover study, the difference in abrasiveness (RDA 80 and 200) did not play a role in plaque removal. Moreover, significantly more plaque (3%) was removed when the

brushing procedure was performed without dentifrice. In another study by Paraskevas *et al*. (2007), the group that used dentifrice removed a significant 6% less plaque compared with the group that did not use dentifrice. Furthermore, in a study by Jayakumar *et al*. (2010), a 9% difference in plaque removal, in favor of the non-dentifrice group, was observed. The results of a study by Rosema *et al*. (2013) showed a difference in plaque removal of 2% in favor of the non-dentifrice group. Although this difference in plaque score reduction did not reach the level of significance, it is noteworthy that the use of dentifrice did not seem to increase the amount of "instant" plaque removal (i.e. the immediate effect of brushing, as opposed to prolonged effects beyond the brushing exercise). These results are also supported by a report from the ADA Division of Science (American Dental Association 2001), which accepts that "plaque removal is associated minimally with abrasives." The effectiveness of plaque removal during toothbrushing with dentifrice appears to be essentially a function of the access of brush filaments, rather than dentifrice abrasives (Gallagher *et al*. 2009). Also, a recent systematic review demonstrated that there is moderate certainty evidence that toothbrushing with a dentifrice does not provide an added effect for the mechanical removal of dental plaque (Valkenburg *et al*. 2016). In 1998, the concept of "dry brushing" was introduced: brushing without dentifrice and a toothbrush not wetted with water (O'Hehir & Suvan 1998). The purpose of this was to avoid the smooth perception of tooth surfaces being the results of reduced surface tension, as provided by surfactants of a dentifrice. A recent study indicated that dry brushing did not contribute significantly to toothbrush efficacy. The participants did not perceive that pre-wetting a toothbrush influenced filament stiffness and cleaning capability. Moreover, they found brushing without dentifrice to be uncomfortable (Van der Sluijs *et al*. 2018b).

Another factor that might be involved in the process of plaque removal is the detergent (or surfactant) contained in the dentifrice formulation. Detergents are surface-active compounds that are added to the formulation because of their foaming properties. This foaming effect could be beneficial in clearing loosened plaque from the teeth and also in providing the pleasant feeling of cleanness. Today, dentifrice formulations also contain ingredients that could help improve oral health. Fluoride is almost omnipresent in commercially available toothpastes. Problems with dentifrice formulation have involved finding compatible constituents to combine with the active ingredients in dentifrice formulas. Over the years, many dentifrice formulations have been tested and become well established because of their antiplaque and/or antigingivitis properties (Valkenburg *et al*. 2019). Nowadays toothpastes also carry cosmetic functions such as the whitening of teeth (Soeteman *et al*. 2018). For additional information, see Chapter 29.

Some substances in dentifrices can induce local or systemic side effects. Chlorhexidine in dentifrices can foster tooth staining. Pyrophosphates, flavorings, and detergents, especially sodium lauryl sulfate which is present in most commercially available dentifrices, have been implicated as causative factors in certain oral hypersensitive reactions, such as aphthous ulcers, stomatitis, cheilitis, burning sensations, and oral mucosal desquamation. In such cases, the dental professional should identify these conditions and advise the patient to discontinue use of the suspected dentifrice.

Side effects

A toothbrush is one of the most familiar devices of everyday use and few people would ever think about its associated risks. However, in view of the universal availability and presence, and the frequency with which toothbrushes are used, adverse events can be expected. A systematic review of case reports found that the oral use of a toothbrush can be related to serious adverse events such as ingestion, impaction, instant trauma, gingival traumatic injury, and seizures. Given the incidence of reporting, important recommendations are that a toothbrush should not be used to induce vomiting, nor should people walk or run with this device in their mouths, especially children (Oliveira *et al*. 2014).

Brushing force

In a study evaluating toothbrushing habits in unstructed adults, the mean brushing force was 2.3 ± 0.7 N, with a maximum of 4.1 N (Ganss *et al*. 2009a). Brushing force with electric toothbrushes has consistently been shown to be lower than that with a manual toothbrush (by approximately 1.0 N) (Van der Weijden *et al*. 1996c). McCracken *et al*. (2003) observed, for a range of pressures from 0.75 to 3.0 N, that the improvement in plaque removal when forces in excess of 1.5 N with an electric toothbrush were used was negligible. In a feedback study, a professional brusher was asked to brush with a pressure of 1.0 N, 1.5 N, 2.0 N, 2.5 N, and 3.0 N, during which time the efficacy with regard to brushing force was determined. An increase in efficacy was observed when the brushing force was raised from 1.0 N to 3.0 N (Van der Weijden *et al*. 1996c). Hasegawa *et al*. (1992) evaluated the effects of different toothbrushing forces on plaque reduction by brushing at 100-*g* force intervals on a scale from 100 to 500 *g*. The results of their study corroborated the findings of earlier studies that with increasing force, more plaque is removed. In addition, they observed that 300 *g* seemed to be the most effective brushing force when using a manual toothbrush for both children and adults. Forces exceeding 300 *g* caused pain and gingival bleeding in the test patients. As shown in a manual brushing study in which efficacy was plotted against brushing force, the relationship between force and efficacy does not appear to be linear (Van der Weijden *et al*. 1998). Using a manual toothbrush, a positive correlation was

identified between efficacy and force (up to 4.0 N). The greater the force used, the more effective was the plaque removal. However, efficacy decreased when forces of >4.0 N were used. Indeed, there appeared to be a negative correlation. The hypothesis is that this negative correlation was due to the distortion of the brushing filaments. Beyond 4.0 N, brushing was no longer performed with the tip of the filament but, due to bending, with its side, indicating that brushing force is not the sole factor that determines efficacy. Other factors, such as the action of the brush, the size of the brush head, brushing time, and manual dexterity, could be of greater importance.

Excessive brushing force has been mentioned as a factor that is partly responsible for toothbrush trauma (gingival abrasion). For patients who use excessive force, manual and electric toothbrush manufacturers have introduced toothbrush designs that can limit the amount of force used and thus reduce the chance of damage to soft and hard tissues. There appears to be no linear correlation between brushing force and gingival abrasion. An *in vitro* experiment revealed that under severe erosive conditions, neither total mineral loss nor the spatial loss of mineralized dentin (measured using profilometry) significantly increased after brushing, regardless of the force applied. The demineralized organic dentin matrix was strikingly resistant to mechanical impact, although it was compressed with greater brushing forces (Ganss *et al*. 2009b).

Mierau and Spindler (1989) performed a quantitative assessment of patterns of toothbrushing habits in 28 subjects over nine sessions. The least variations among individuals were observed with regard to brushing force. Brushing force ranged from 1.0 to 7.4 N between individuals. The authors did not observe any (visual) lesions from brushing in those individuals using a brushing force of <2 N. If the brushing force was >2 N, co-factors such as brushing time, brushing method, and frequency of brushing appeared to be associated with acute brushing lesions. Burgett and Ash (1974) argued that the potentially detrimental effect of brushing is related to the force applied at a particular point, that is the pressure. It should be recognized that the head of a manual brush is larger than the head of an electric brush. Because the forces are given as a total of the force over the entire brush, it could be that the unit pressure is less for manual brushes than for electric brushes. Van der Weijden *et al*. (1996c) observed no difference in pressure between soft manual (11.32 g/mm^2) and electric toothbrushes (11.29 g/mm^2), demonstrating that the pressures for the electric and the manual brushes were similar.

Toothbrush abrasion

Because various mechanical products are used in personal control of supragingival plaque, the possibility exists that some deleterious effects can occur as a consequence of these oral hygiene practices (Echeverría 1998). The simple act of removing deposits from teeth requires that the toothbrush–dentifrice combination possess some level of abrasiveness. The filaments must have a sufficient degree of stiffness to create abrasion to dislodge plaque deposits. This stiffness must be balanced against potentially detrimental effects on dental hard and soft tissues. The wear on a tooth consists of a combination of attrition (tooth-to-tooth contact wear), erosion (acid-mediated surface softening), and abrasion (wear because of toothbrushing with toothpastes). Toothbrush abrasion is modified by toothbrush filament stiffness (Wiegand *et al*. 2008).

It has long been known that toothbrushing can have some unwanted effects on the gingiva and hard tooth tissues (Kitchin 1941). Trauma to hard tissues leads to cervical abrasion of the tooth surfaces (Fig. 28-9). These lesions have been associated with toothbrush stiffness, the method of brushing, and brushing frequency. Cervical tooth abrasions have a multifactorial etiology, but in most cases, they are the consequence of toothbrushing with excessive brush pressure and an excessive number of toothbrushing episodes/time. Both situations are likely linked to personality traits (*compulsive brushers*). Tooth wear has also been associated with toothbrush characteristics, especially with the finishing and hardness of the filaments (Fishman 1997). It has been stated that hard tissue damage is mainly caused by the abrasives in dentifrice (Axelsson *et al*. 1997; Meyers *et al*. 2000). The capacity of a toothbrush to hold and move polish/abrasive over the tooth surface particularly affects the amount of hard-tissue abrasion. The influence of the type of toothbrush was negligible when water was used as a substrate, but when toothpaste was added the abrasion values diverged by more than ten-fold depending on the toothbrush. A softer toothbrush might have caused similar or even more abrasions than a harder brush (Tellefsen *et al*. 2011).

In many instances, *tooth abrasion* is found in combination with *gingival recession*. Whereas gingival recession is associated with different etiologic/risk factors, for example periodontal inflammation, smoking, gingival phenotype, or repeated periodontal instrumentation, inadequate use of the toothbrush is likely the most significant cause (Björn *et al*. 1981). Clinical experience supports the idea that, with improper use, toothbrushing can cause superficial damage to the gingival tissues. Patients with good oral hygiene have been found to have more gingival recession and more dental abrasions than patients with poor oral hygiene. Unfortunately, there have been few studies in the dental literature concerning gingival lesions resulting from toothbrushing. Thus, the extent to which oral hygiene procedures can traumatize the gingival tissues is not clear. An experimental study investigated the healing time of a freshly induced abrasion lesion. An area away from the gingival margin at the palate was brushed with a manual toothbrush. Lesions caused by 30 seconds of brushing needed at least 24 hours to heal in 40% of cases (De Nutte *et al*. 2018).

Gingival abrasions as a result of brushing are often reversible, localized, superficial lesions. It is unlikely that gingival abrasion is induced by a single factor. One

Fig. 28-9 (a) Soft tissue damage as a result of extensive toothbrushing. Note the gingival recession on the buccal gingival surface of tooth 13. (b) Note the multiple ulcerations of the buccal gingival margin in the right maxilla. (c, d) Hard tissue damage (arrows) has resulted after extensive use of interdental brushes.

factor, which has already been mentioned as related to gingival abrasion, is brushing force. In the literature, other factors have been suggested, such as brushing method (e.g. the Bass method), abusive toothbrush use, toothbrushing duration, manual or powered toothbrushing, toothbrush grip, brush head shape, stiffness of the filaments, end-rounding of toothbrush filaments, and toothbrushing frequency (Van der Weijden & Danser 2000, Hennequin-Hoenderdos *et al*. 2018).

Toothbrushes with hard bristles remove plaque better but can also cause more soft-tissue trauma compared with brushes with softer bristles (Ranzan *et al*. 2019). Zimmer *et al*. (2011) investigated the effectiveness and potential harmfulness of manual toothbrushes of the same type but with different bristle stiffnesses. Based on their observations, they suggested that in general a toothbrush with medium stiffness can be advised. For subjects with poor oral hygiene, a toothbrush with hard bristles should be considered. If a patient already shows soft tissue damage, a soft toothbrush should be recommended (Versteeg *et al*. 2008a). Sharp-edged and unacceptably rounded filament tips represent a greater threat to dental tissues. Breitenmoser *et al*. (1979) evaluated the effects of filament end forms on the gingival surface. It was found that manual toothbrushes with cut filament ends resulted in significantly greater gingival lesions than rounded ends. Further research has shown in several studies that filaments with sharp edges can cause soft tissue injury. The depth of epithelial lesions caused by toothbrushing was influenced by the quality of filament end-rounding (Plagmann *et al*. 1978). End-rounded filaments showed significantly less abrasion to soft tissues compared with non-end-rounded filament tips (Alexander *et al*. 1977; Hennequin-Hoenderdos *et al*. 2017). Oral soft tissue injuries are similar for both tapered and end-rounded bristles (Ranzan *et al*. 2019).

The pattern of toothbrushing is that most right-handed people begin on the buccal surfaces of the anterior teeth on the left side. Accordingly, the most severe gingival recession and abrasion defects are localized to the buccal surfaces on the left side (MacGregor & Rugg-Gunn 1979).

Interestingly, there has been little debate regarding the role of dentifrice in the abrasion of soft tissues. This fact is somewhat surprising when abrasion of dental hard tissues is almost entirely a function of dentifrice. Detergents in dentifrice, agitated over a mucosal surface, can enhance the removal of the protective salivary glycoprotein layer and exert cytotoxic action on the overlying epithelial cells (Addy & Hunter 2003). No statistically significant differences in the incidence of gingival abrasions were identified between brushing with dentifrice or without dentifrice (Versteeg *et al*. 2005; Rosema *et al*. 2013). This finding was in agreement with those of Alexander *et al*. (1977), who

used hamster cheek pouch tissue that was brushed mechanically for various intervals. The results showed that the dentifrice/polishing agent applied to the tissue with a brush did not increase the abrasive effects of the brush (using protein removed during brushing as an index of tissue abrasion). Meyers *et al*. (2000) investigated the effects of three commercially available dentifrices on tooth and gingival surfaces by means of scanning electron microscopy quantification. The results indicated that none of the dentifrices tested was harmful to teeth or soft tissues.

Toothbrush contamination

Toothbrushes may be the cause of disease transmission and increase the risk of infection since they can serve as a reservoir for microorganisms in healthy, diseased, and medically ill adults (Agrawal *et al*. 2019). Commonly, after oral use, toothbrushes are rinsed with plain water and stored in the bathroom. There is a high chance of cross-infection by sharing or keeping them in close proximity. Review of the literature showed that toothbrushes of healthy and oral diseased adults become contaminated with pathogenic bacteria from the dental plaque, design, environment, or a combination of factors (Frazelle & Munro 2012). However, potential impact of this contamination on disease transmission was not researched (Van der Weijden & Slot 2015). Decontaminating a toothbrush by exposing it to (microwave or ultra-violet) radiation and disinfecting agents reduces bacterial load (Agrawal *et al*. 2019).

Importance of instruction and motivation in mechanical plaque control

A fundamental principle for all preventive action is that the effect is greatest when the risk of the development of disease is greatest. Needs-related instruction in oral hygiene should therefore aim to intensify mechanical plaque removal on those individual teeth and surfaces that are at risk. A prerequisite for establishing needs-related tooth-cleaning habits is a well-motivated, well-informed, and well-instructed patient (Axelsson 2004). Mechanical plaque control demands active participation of the individual subject; therefore, the establishment of proper home oral care habits is a process that greatly involves and depends on behavioral changes. As toothbrushing is a daily habit, it is not easily altered, even after professional instruction. When implementing behavioral changes, dental professionals should try to ensure that the patient recognizes his/her oral health status and the role of his/her personal oral hygiene procedures in the prevention of caries and periodontal diseases. The patient should be informed about the casual relationship that led to the disease process and should be encouraged to take responsibility for his/her own oral health. The dental team has numerous opportunities to demonstrate to the patient the soft tissue alterations elicited by inflammation and the responsible etiologic factors. Most commonly, as with sports coaching, a one-to-one professional–patient approach should be employed.

Many patients spend too little time brushing, or they brush haphazardly. The importance of thorough plaque removal should be stressed. Toothbrushing instruction for a patient involves teaching what, when, where, and how. A recommended toothbrushing regimen should take into account the characteristics of the toothbrush and dentifrice, and the individual's behavior with regards to brushing frequency, duration, pattern, force, and method. Toothbrushing habits are locally acquired at home and can be supplemented periodically with more formal instruction from the dental professional. Training of toothbrushing skills requires many repetitions of the same movements to incorporate them into an individuals' habitual motor program (Hayasaki *et al*. 2014). In addition, instruction should also involve a description of specific toothbrushing methods, the grasp of the brush, the sequence and amount of brushing, the areas of limited access, and supplementary brushing for occlusal surfaces and the tongue. The possible detrimental effects from improper toothbrushing and variations for special conditions can be described (Wilkins 1999). The design of toothbrushes or a specific toothbrushing method is of secondary importance to the skills of the individual in using the brush (Frandsen 1986). The simplest, least time-consuming procedures that will effectively remove bacterial plaque and maintain oral health should be recommended. If a patient prefers a specific oral hygiene strategy, the clinician can evaluate this and modify the technique to maximize effectiveness rather than changing it. Although it is necessary to give all patients honest feedback on their plaque removal efforts, it is also important to reward positive performance and not entertain unrealistic expectations, so that the patient will not dread each maintenance visit.

Oral hygiene instruction should also include components such as self-assessment, self-examination, self-monitoring, and self-instruction. With this purpose, several devices and chemical agents have been used to make dental plaque more evident to the patient. The interested patient can be informed and motivated, for example, through the use of disclosing agents to visualize plaque at the gingival margin or in the interdental spaces (Oliveira *et al*. 2021). Disclosing agents are chemical compounds, such as erythrosine, fuchsine or fluorescein-containing dye, that stain dental plaque and thus make it fully evident to the patient using either regular or ultraviolet light. Erythrosine has been used for many years as a means of motivating patients and evaluating the effectiveness of oral hygiene, and it has received Food and Drug Administration (FDA) approval (Arnim 1963) (Fig. 28-10). When applied immediately before toothbrushing, the patient can identify the amount of plaque formed since the last toothbrushing episode, thus receiving immediate feedback about his/her cleaning performance. This procedure is useful during the early phase of plaque control. Later, the disclosing agent should be applied after toothbrushing, which allows the patient to identify those areas

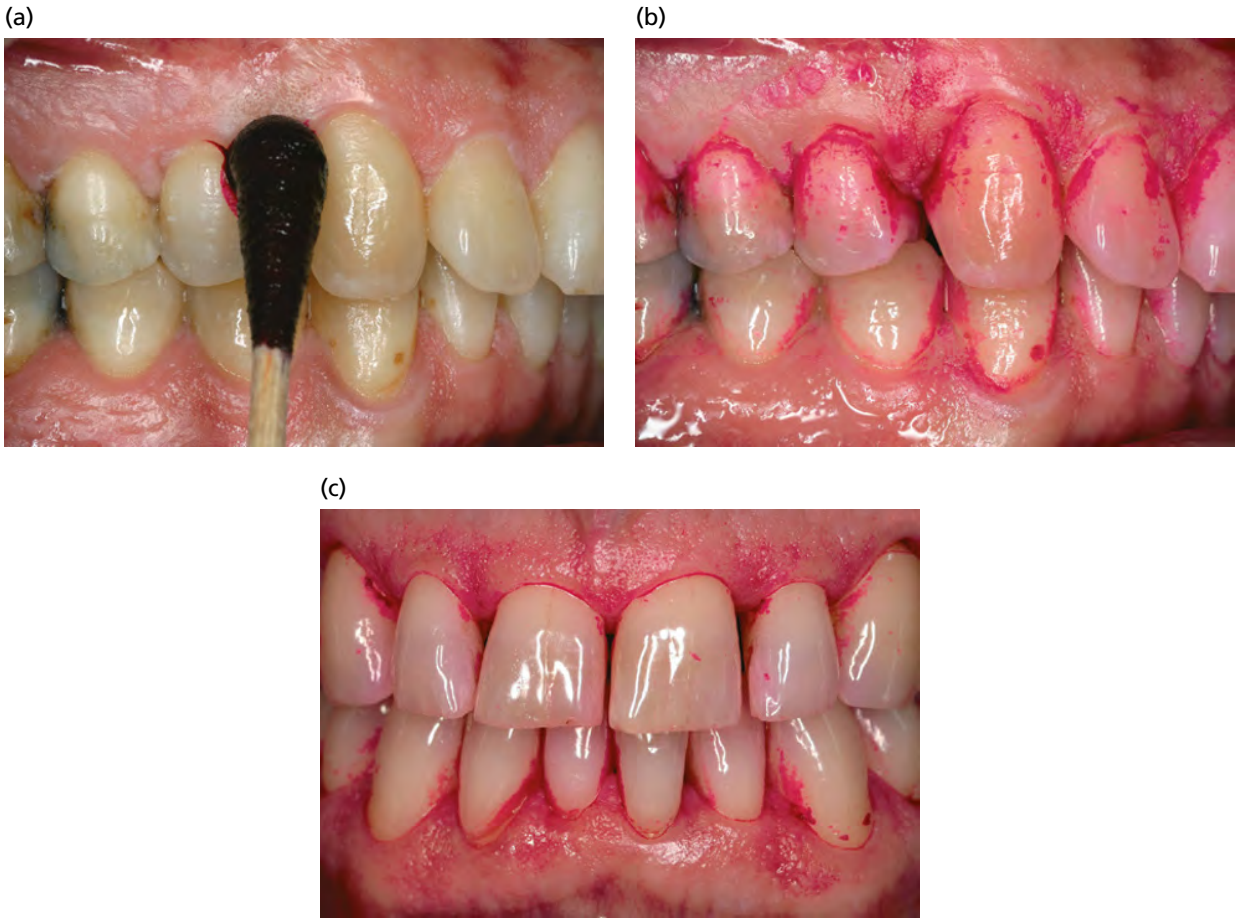

Fig. 28-10 (a) Disclosing solution is often used to identify plaque. (b) Note the remaining plaque on the buccal tooth surfaces after staining. (c) After self-performed tooth cleaning, remaining plaque can be identified by the patient following rinsing with a disclosing solution.

needing additional cleaning efforts. Disclosing solution is available in liquid and tablet forms. The liquid form might offer some advantages in that the operator can ensure that all surfaces are adequately covered. Red disclosing solution remains in the mouth for some time and can temporarily stain the lips and gingiva. This may create an esthetic problem for some patients but can be eliminated by protecting the lips with petroleum jelly. Two-tone agents (containing methylene blue and erythrosine) are also available that distinguish an old plaque accumulation from a more recent one.

Disclosing plaque in the patient's mouth is usually not sufficient to establish good oral hygiene habits. Other factors might influence the individual to modify or determine his/her behavior. These factors could be more or less beyond the control of the dental professional (such as social and personal factors, environmental settings, and past dental experiences), or they may lie within the control of the professional (such as the conditions of treatment and the instruction and education of the patient). All of these factors should be considered in the design of an individualized oral hygiene program.

A variety of methods can be used to deliver advice and instructions. The effects of various oral hygiene instruction programs, administered individually or in groups, have been evaluated in a number of clinical studies. These studies have evaluated whether instruction given during one visit only is similar to step-by-step instruction provided over several visits, and whether the use of pamphlets or videotapes is superior to self-instruction manuals and to personal instruction given by a dental professional. In a study by Renton-Harper *et al*. (1999), an instructional video for an oscillating–rotating electric toothbrush was evaluated. The subjects who followed the instructional video benefited significantly and considerably in terms of plaque removal compared with subjects who received only written instructions. Different types and amounts of feedback given to the patients using disclosed plaque scores and phase-contrast demonstrations have also been investigated. These studies have usually reported similar improvements in plaque and gingivitis scores, irrespective of the mode of instruction. However, these results should be interpreted with caution because the subjects participating in these studies were examined at regular intervals; therefore, it is difficult to separate the effects of repeated examinations from the effects of the instructions (Renvert & Glavind 1998).

If oral hygiene motivation, information, and instruction are combined with professional tooth cleaning, the effects in terms of reduction of plaque levels and levels of gingival inflammation can persist even after 6 months (Van der Weijden & Hioe 2005). Rylander and

Lindhe (1997) recommended that oral hygiene instruction be provided over a series of visits, allowing for the possibility of giving the patient immediate feedback and reinforcing the patient in his/her home oral care activities. The protocol below is based on the one used in several clinical trials by Lindhe and Nyman (1975), Rosling *et al*. (1976), and Lindhe *et al*. (1982) in which the role of plaque control in preventing and arresting periodontal diseases was clearly demonstrated.

First session

1. Apply a plaque-disclosing solution to the teeth and, with the aid of a hand mirror, demonstrate all sites with plaque to the patient (see Fig. 28-10b). The plaque score can be recorded using a plaque control record (Fig. 28-11).
2. Ask the patient to clean his/her teeth using his/her traditional technique. With the aid of a hand mirror, demonstrate the results of the toothbrushing to the patient, again identifying all sites with plaque (see Fig. 28-10c).
3. Without changing the technique, ask the patient to clean the surfaces with plaque.

Depending on the plaque remaining after this second toothbrushing, the dental professional should either improve the technique or introduce an alternative system of toothbrushing. So as not to overload the patient with too much information during the first session, the use of adjunctive devices for interproximal cleaning can be introduced or improved in the second session.

Second session

1. A few days after the first session, the disclosing solution is again applied. The results, in terms of plaque deposits, are identified in the mouth, recorded in the plaque control record, and discussed with the patient.
2. The patient is then invited to clean his/her teeth, according to the directions previously provided during the first session, until all staining is removed. In many cases, toothbrushing instructions will need to be reinforced. Positive recognition should be given to the patient at the same time.

If necessary, the use of interproximal cleaning aids can now be introduced or improved.

Third and subsequent sessions

1. One or 2 weeks later, the procedure used in the second session is repeated. However, the efficacy of self-performed plaque control should be evaluated and presented to the patient at each appointment. This repeated instruction, supervision, and evaluation aims to reinforce the necessary behavioral changes.

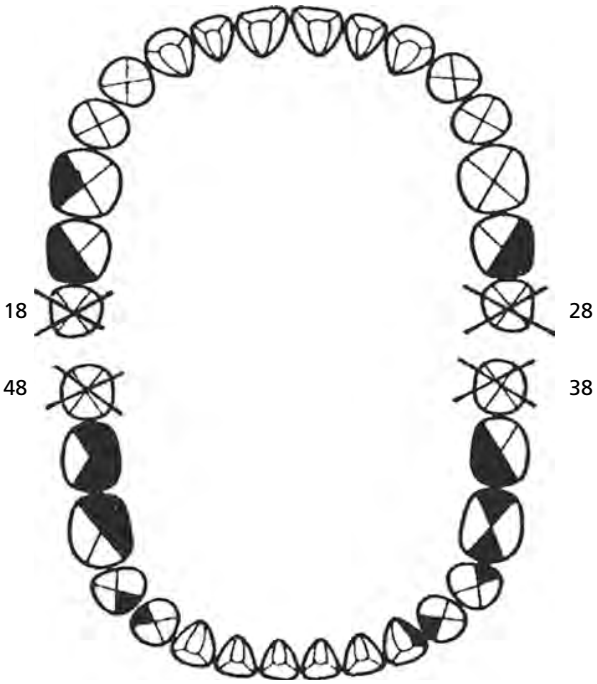

Fig. 28-11 Chart showing the teeth and tooth surfaces in the maxilla and mandible. The distribution of tooth surfaces with dental plaque (shadowed areas) is identified. In this case, the plaque score is 17%.

The long-term results of oral hygiene instruction are dependent on behavioral changes. Patients might fail to comply with given instructions for many reasons, ranging from unwillingness to perform oral self-care, poor understanding, lack of motivation, poor dental health beliefs, and unfavorable dental health values due to stressful life events or poor socioeconomic status. Although the use of behavior-modification techniques can offer an advantage over traditional instruction techniques, there is limited research in this area to clarify the relationship between health beliefs and compliance.

Conclusion

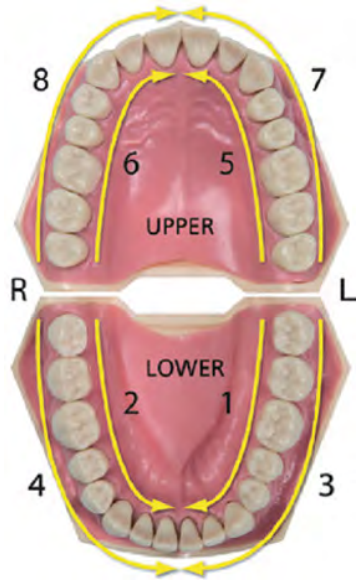
- Ultimately, the goal of a patient's self-care program is to prevent, arrest, and control periodontal disease and caries. The patient's ability to remove plaque from all areas, including interproximal areas, is an essential part of this.
- Oral hygiene instruction should be tailored to each individual patient on the basis of his/her personal needs and other factors.
- The patient should be involved in the instructional process.
- An individualized maintenance program should follow basic oral hygiene instruction.

Acknowledgments

All of the figures illustrating the procedures in Boxes 28-1 to 28-9 are used with permission from the Paro Praktijk Utrecht.

Box 28-1 Instructions for manual toothbrushing.

It is of the utmost importance, in addition to using the correct toothpaste and also brushing for at least 2 minutes, to brush the teeth in a set sequence. This technique prevents certain areas from being missed. Areas untouched by the brush will allow plaque to continue to grow. Try to choose a brush with medium or soft bristles and a small head.



Instructions

- Hold the brush firmly and place the bristles at an angle against the edge of your gums (use a 45° angle). Take care to ensure that the bristles are in contact with a small part of the gum margin.
- Place the brush against the molar or tooth at the back of the mouth and make short back-and-forth scrubbing movements. Brush from the back to the front of the mouth and try to overlap the strokes. Do not brush more than two teeth simultaneously. Always start at the back and work slowly forward.
- Always hold the brush head horizontally when cleaning the outside surfaces of the teeth. It is easier to hold the head vertically when brushing the inside surfaces of the top and bottom teeth.
- Avoid too much pressure and fast movements, and be aware of feeling contact with the gum margin. Also, avoid brushing too vigorously, thereby preventing damage to the gums.

When cleaning the teeth, keep using the same sequence of brushing. For example, brush the inside of the lower left jaw (15 seconds) and then the inside right (15 seconds). Then, brush the left on the outside (15 seconds), followed by the right on the outside (15 seconds). Repeat the same sequence in the upper jaw. Finally, brush the chewing surfaces with small scrubbing movements. Replace the brush when the bristles start to bend or splay.

Box 28-2 Instructions for electric (power) toothbrushes.

The importance of using a set sequence of brushing movements is applicable when using an electric toothbrush. The question of whether or not an electric brush is better than a manual one has been asked many times. Both brushes allow a high level of oral hygiene to be achieved. However, research has shown that electric toothbrushes are more efficient, and many people report that they are easier to use.

Instructions

- Place the brush firmly on the hand piece. Grip the brush in the palm so that the bristles of the head are somewhat angled toward the gums (at an angle of approximately 70°). Try to allow the longer bristles to penetrate between the teeth and take care that the bristles contact your gums.
- Switch on the brush, place the head on the last tooth in the mouth (check the angle), and move the head gradually (over approximately 2 seconds) from the back to the front of this tooth.
- Try to follow the contours of both the teeth and the gums. Place the brush head on the next tooth and repeat this process.
- Allow the electric toothbrush to do the work. It is not necessary to press hard or make brushing movements.
- Use a timer! Many brushes will provide some form of signal after 30 seconds (the apparatus stops for a moment). This is the point at which to move on to a new part of the mouth.

Remember to clean the brush and its head thoroughly when finished.

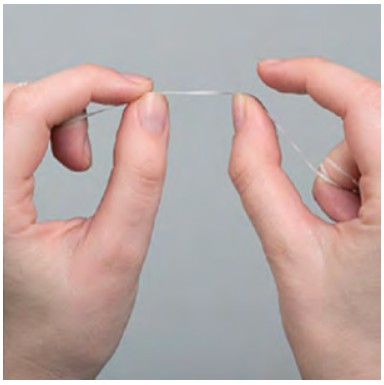
Box 28-3 Instructions for use of dental floss.

The use of dental floss has become part of oral care, in addition to correct, more frequent, and longer tooth brushing. Floss can be purchased in a variety of thicknesses and types and with or without a layer of wax. If there is sufficient space between the front and back teeth, it is advisable to use the somewhat thicker tape rather than the thinner floss.

Instructions

- Take approximately 40 cm of floss and wind the ends loosely around the middle fingers. Allow for 10 cm between the middle fingers. Then, hold the floss taut between the thumb and first finger so that roughly 3 cm remains between the thumbs. Alternatively, a loop or circle of dental floss can be created.
- Using a sawing movement, allow the tightly stretched piece of floss to pass between the contact of the front and back teeth. This action might be difficult where the teeth are so close together that the space between them is limited. Avoid allowing the floss to slip so quickly between the teeth because through this "snapping" the gums may be damaged.
- Stretch the floss in a "U" shape around one of the teeth, press firmly against the side of the tooth surface and carefully allow the floss to pass just under the gum, once again with a sawing movement.
- Draw the floss up to the contact point with a sawing movement, and then repeat the process on the other tooth bordering the space filled with gum tissue.
- Remove the floss from between the teeth, once again with a sawing movement, and repeat this process for all of the other spaces in the mouth.
- Use a clean piece of floss for each separate space by unwinding part of it from around one middle finger while winding it around the other middle finger.

Do not worry if at first your gums bleed slightly. This bleeding will stop after using the floss a number of times. Do not give up!



Box 28-4 Instructions for use of woodsticks.

Most adults have sufficient space available between the incisors and molars to allow woodsticks to be used. These sticks come in different thicknesses, they are made from wood, and they have a triangular cross-section, mimicking the shape of the space between the teeth. Woodsticks can only be used once and are ideal for use when you have a few spare moments – for example, when sitting in traffic!

Instructions

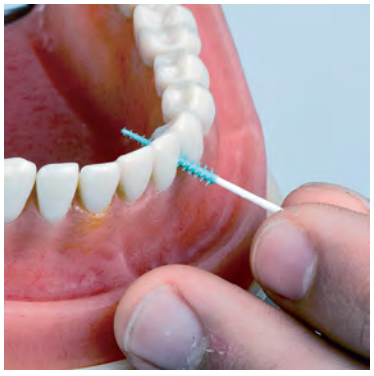
- Hold the woodstick firmly between the thumb and first finger, roughly halfway along its length. When possible, place the other fingers for support on the chin. Moisten the tip of the woodstick by sucking on the point of it, thus making it softer and more flexible.
- Place the flat side of the woodstick (i.e. not the sharp side) against the gum. In the upper jaw, the flat surface will face upward, and in the lower jaw, it will face downward.
- Push the woodstick firmly from the outer side of the space into the space until the stick just becomes wedged. Then, pull it back slightly, and push it back once again, using a light, sawing motion at right angles to the outer surfaces of the teeth. Light pressure can also be applied simultaneously to the gums. Repeat this action a few times, angling the woodstick to contact the surfaces of the teeth enclosing the space.
- When using a woodstick between the premolars and molars, close the mouth slightly to reduce tension in the cheeks, thus making the movements easier.

With this method, all of the spaces between the teeth throughout the mouth can be cleaned. Should the woodstick prick the surface of the gums with the point, angle it a little differently – in the upper jaw, the point will face downward, and in the lower jaw, it will face upward. During use, the soft wood can become splayed. As soon as the first signs of splaying are evident, the woodstick should be discarded.

Do not be concerned if your gums bleed a little at first – this bleeding will disappear after using the woodsticks repeatedly for a period of time. Do not give up!

Box 28-5 Instructions for use of rubber/elastomeric interdental cleaning sticks.

Most adults have sufficient interdental space to allow rubber/elastomeric interdental cleaning sticks to be used. The sticks have a firm but flexible conical plastic core that is either covered with a soft rubber/elastomeric coating and bristles or a flexible silicone coating and lamellae. Although they resemble an interdental brush the working effect is that of a toothpick. They come in different sizes and for the best result, it is important to choose the right size. They are intended for single-use and are ideal to bring along and use on-the-go.



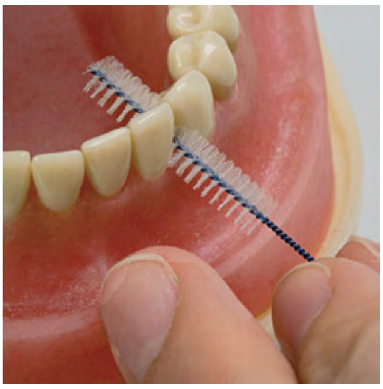
Instructions

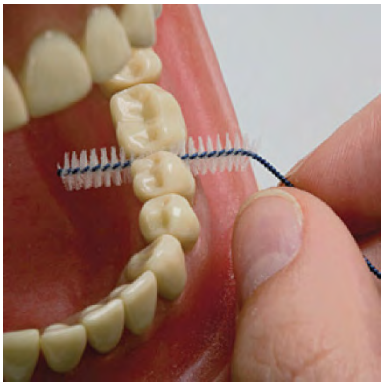
- Detach an interdental cleaning stick from the strip.
- Hold the stick between the thumb and first finger, at the grip. When possible, place the other fingers for support on the chin.
- Place the point of the stick in the interdental space.
- Push the stick into the space as far as possible and then pull it back slightly. Repeat this a few times moving it back and forth using a light, sawing motion.
- Use a straight insertion angle into the interdental space.
- Simultaneously, light pressure can also be applied against the gums.
- Do not force the stick into tight spaces between teeth
- When cleaning between the premolars and molars, close the mouth slightly to reduce tension in the cheeks, thus making the movements easier.
- Try to clean all interdental spaces with one stick but if it bends use a new one.
- After use, deposit the used interdental cleaner stick in the trash basket.

Do not be alarmed if your gums bleed a little at first – this bleeding does not mean that you have injured yourself but is a sign of inflammation of the gums. It will therefore disappear after regular use. So, do not give up!

Box 28-6 Instructions for use of interproximal brushes.

Interdental brushes can be purchased in a variety of sizes, ranging from small (1.9 mm) to very large (14 mm). It is important to choose the correct diameter of the bristle part of the brush. The size of the space between the teeth determines the size of the diameter of the bristles on the brush. Dental professionals can precisely identify which sizes you need and also demonstrate their proper use. A brush that is too small will not completely clean the interdental spaces, and a brush that is too large can injure the gums. The wire of an interdental brush must be thin and the bristles as fine and as long as possible. With such dimensions, the interdental brush will fill the entire space between the teeth quite softly and gently. Tooth spacing varies, so it is often necessary to use a different size of brush within one mouth for optimal cleansing. To remove dental plaque effectively, there should be a slight degree of resistance when the brush is moved back and forth between the teeth.





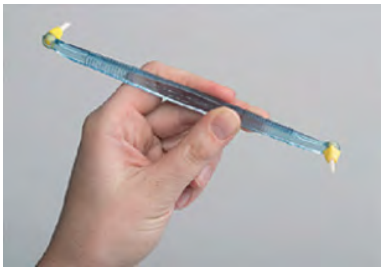
Instructions

- Always use the interdental brush *without* toothpaste.
- Hold the interdental brush just behind the bristles between the thumb and forefinger. Support can be achieved when necessary by placing your other fingers on your chin. From the outer side of the space, push the interdental brush carefully between the teeth, taking care that the brush remains at a right angle to the teeth.
- You may bend the interdental brush slightly to improve accessibility to the posterior interdental spaces.
- Avoid scraping the center (metal spiral part) of the brush against the teeth.
- Slide the brush in and out of the space using the full length of the bristle part of the brush. This action will remove the dental plaque.
- The area of contact between the brush and the teeth can be somewhat increased by using differing angles of insertion.
- Do not push interdental brushes between the teeth with force. Slight pressure of the brush against the gums should be used, as it will allow the bristles to penetrate slightly underneath the gum margin.
- By slightly closing the mouth, it will be easier to manipulate the brush as the tension in the cheeks is lessened. It might also be helpful to bend the brush slightly to ease insertion.
- Cleanse all areas between the teeth where an interdental brush will fit. Rinse interdental brushes thoroughly after use and allow them to dry out. It is often a good idea to combine the use of interdental brushes and woodsticks.

Do not be alarmed if the gums bleed initially. This bleeding does not mean that you have an injury but inflammation, which is caused by concealed, old plaque. This reaction is fairly normal during the first week. Using the interdental brush will soon cure this inflammation, and the bleeding will stop. As the inflammation subsides, the interdental spaces will become slightly larger, and you will most likely need a larger interdental brush. Ask your dental professional.

Box 28-7 Instructions for use of single-tufted/end-tufted brushes.

The single-tufted toothbrush is a small brush with a small, single tuft of short bristles attached to the end. The end-tufted brush has a number of small tufts attached in a similar manner. These brushes are an option for cleansing areas of the dentition that cannot be reached with other oral hygiene aids, for example, a lone-standing tooth, the back surface of the last molar or a tooth in the arches, wires and locks of orthodontic braces, grooves or the entrances to areas where the roots have split apart.



Instructions

- Hold the single-tufted brush as you would hold a pen. This method prevents too much force being applied to the gums.
- Place the single-tufted brush at an angle directed toward the gums (approximately 45°) – this angle allows the bristles to reach just under the gum margin.
- Use small, rotational pencil movements.
- The bristles of the brush will then rotate under and along the gum margin. The brush should then be slowly moved along the tooth surface to cover all areas.

Box 28-8 Instructions for use of oral irrigators.

There are various brands of oral irrigators. Before starting to use a product, it is advisable to read the manufacturer's instructions carefully and to be sure you understand how an oral irrigator works.

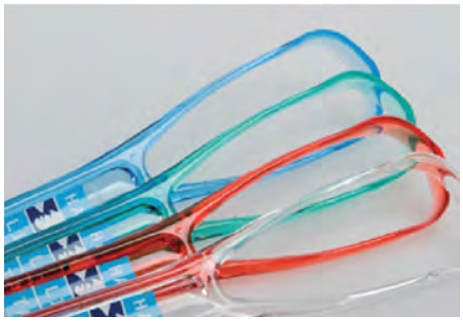
Instructions

- Fill the water reservoir with lukewarm water and plug the power cord into the wall outlet. You can use a cup to fill the reservoir. If the unit has removable tips, press the appropriate tip firmly into the irrigator handle. The tip should snap into place because it works under pressure and may shoot away otherwise.
- Test the oral irrigator before use.
- Breathe calmly through your nose. Lean over the sink, and close your lips enough to prevent splashing, while still allowing water to fall from the mouth into the sink.
- Aim the tip just above and toward the gum line at a 90° angle, and press the switch that allows the water to flow.
- *Do not* attempt to watch yourself in the mirror. You will make a mess!
- Starting with the back teeth (where your molars are located), follow the gum line. Take your time to get in between teeth. Continue to work slowly forward until all areas around and between teeth have been cleaned.
- Use the same sequence each time you use the irrigator so that you do not miss any teeth.
- At difficult to reach areas you can adjust the angle of the nozzle, for example while cleaning the brackets of an orthodontic appliance or at root furrows.
- Spit out excess water as needed.
- Empty any water remaining in the reservoir after use. Dry thoroughly to avoid bacterial growth. Make sure to unplug the unit before cleaning it.

Irrigating is a technique that relies on your sense of touch. At first, it might take a little longer until you develop a routine and become more comfortable with the oral irrigator. Depending on the power level, you might need to refill the water reservoir. Antiseptics can be added if that has been advised by your dental care professional. If so, a mouth rinse or another antiseptic is added to the water in the reservoir.

Box 28-9 Instructions for use of tongue cleaners.

Tongue cleaning is a useful addition to the daily oral hygiene routine. Many bacteria can be found within the grooves on the back of the tongue, which can cause bad breath. By brushing or scraping the tongue, this problem can be markedly helped or prevented entirely. One of the problems associated with tongue cleaning is that it can stimulate a gag reflex, especially when first applying this procedure. This reflex occurs more frequently with brushing than when using a scraper. Some people find it less of a problem if they clean their tongue in the evening.



Instructions

- There are various types of tongue cleaners: the most effective seems to one having the form of a loop.
- Extend the tongue as far as possible out of your mouth.
- Breathe calmly through your nose.
- Place the tongue cleaner as far back as possible on the tongue and press lightly with it so that the tongue becomes flattened.
- Ensure full contact of the tongue cleaner with the tongue.
- Pull the tongue cleaner slowly forward.
- Clean the middle part of the tongue, first using the raised edge on one side of the instrument.
- Use the smooth surface of the tongue cleaner on the sides of the tongue.
- Repeat these scraping movements a number of times.
- Rinse the mouth several times.

Remember to clean the tongue cleaner thoroughly after each use.

Chapter 29

Chemical Dental Biofilm Control

David Herrera and Jorge Serrano

ETEP (Etiology and Therapy of Periodontal and Peri-Implant Diseases) Research Group, Complutense University of Madrid, Madrid, Spain

Rationale for supragingival biofilm control

Bacteria present in oral biofilms are responsible for the most prevalent diseases of mankind: caries and periodontal diseases. Therefore, control of oral biofilms becomes essential for the prevention of these diseases.

In the prevention of periodontal diseases, three levels can be distinguished (Baehni & Takeuchi 2003):

- *Primary prevention*: to protect individuals from pathogens, by means of barriers between the pathogens and the host; trying to keep the population in health; avoiding the development of the disease.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

- *Secondary prevention*: to limit the progression of the disease, once the pathogen has contacted the host; trying to recover health, without damage to the host tissues.
- *Tertiary prevention*: to limit the progression of the disease; trying to restore the host tissues, but with some degree of functional damage.

Primary prevention for periodontal diseases is based on supragingival biofilm control, by means of mechanical and/or chemical oral hygiene products, that are able to limit gingivitis development (Baehni & Takeuchi 2003). Primary prevention of periodontitis assumes that healthy gums (without gingivitis) will not develop periodontitis. Programs for the general population should be implemented, to control dental plaque levels and prevent gingivitis, considering different factors (Sheiham & Netuveli 2002):

- Toothbrushing must be part of daily personal hygiene habits.
- Behavioural factors should be considered.
- Cleaning methods should be socially accepted.
- The proposed methods should be easy to comply with in daily life.
- The hygiene procedures should be simple to perform.
- Quality control methods should be part of the program to assure adequate quality.

Secondary and tertiary prevention of periodontal diseases, once disease progression is arrested after proper active periodontal therapy, are achieved by means of supportive periodontal are programs that include both individual biofilm control and periodic re-evaluation with professional plaque control (Hugoson *et al*. 1998; Saxer & Yankell 1997; Baehni & Takeuchi 2003).

Oral hygiene products

Thus, supragingival biofilm control becomes essential in primary, secondary, and tertiary prevention of periodontal diseases. In order to control biofilms in the oral cavity, different oral hygiene products have been developed and marketed. Oral hygiene products refer to "mechanical devices and chemical formulations designed to provide oral health and cosmetic benefits to the user" (Addy & Moran 1997). Thus, oral hygiene products include both mechanical devices, but also chemical formulations.

Mechanical biofilm control

Physical disruption and elimination of dental biofilms can be accomplished by means of manual toothbrushes, different devices for interdental cleaning, powered toothbrushes, etc. (van der Weijden & Slot 2011).

The manual toothbrush is the most widely used method of plaque control (Saxer and Yankell, 1997; Hugoson *et al*. 1998), and it has demonstrated efficacy in biofilm control and gingivitis prevention (Hancock 1996; van der Weijden & Hioe 2005). Some powered toothbrushes have also demonstrated efficacy (van der Weijden *et al*. 1998).

Devices for interdental cleaning have also demonstrated efficacy in reducing plaque and gingival indices (Kinane 1998). However, their use is not common, because of a lack of proper instruction in their use, difficulties in performance, limited time of use, and awareness of potential adverse effects. Among the available devices, flossing is most commonly used, but interdental brushes are better accepted.

Limitations of mechanical biofilm control

Mechanical devices have demonstrated their efficacy in biofilm and gingivitis control, but different studies (Rugg-Gunn & MacGregor 1978; Lavstedt *et al*. 1982; Addy 1986; Addy *et al*. 1986; Albandar and Buischi 1995; Hugoson *et al*. 1998; Hugoson & Jordan 2004) and systematic reviews (van der Weijden & Hioe 2005) have shown that mechanical control alone may not be enough in a wide proportion of the population for the prevention of the onset or the reactivation of periodontal diseases. Different explanations for this can be found:

- Limited time of usage: the normal mean brushing time does not exceed 37 seconds (Beals *et al*. 2000).
- Devices for interdental cleaning are used daily by <10% of the population (Ronis *et al*. 1994) and only 2–10% flossed daily (Lang *et al*. 1995; Stewart *et al*. 1997; MacGregor *et al*. 1998).
- Even patients instructed in oral hygiene habits tended, with time, to come back to baseline plaque levels (Stewart *et al*. 1997). In most of the studies on mechanical biofilm control, the Hawthorne effect will be present and it may be a relevant hypothesis to test if those patients, included in a study, will maintain their oral hygiene habits after the end of the study (Johansen *et al*. 1975; Emilson & Fornell 1976; Löe *et al*. 1976; Lindhe *et al*. 1993; Yates *et al*. 1993;Claydon *et al*. 1996; Rosling *et al*. 1997b).
- Lack of control of other oral biofilms, besides dental plaque, because of a lack of adequate instructions on cleaning (tongue dorsum, cheek mucosal surfaces) or to a lack of access (tonsils) (Greenstein 2002, 2004; Quirynen *et al*. 1995)

In addition, there are circumstances in which adequate mechanical plaque control is not possible: after oral or periodontal surgery, in patients with intermaxillary fixations, in acute mucosal or gingival infections where pain precludes mechanical hygiene, in mentally or physically handicapped patients, etc. (Storhaug 1977; Nash & Addy 1979; Shaw *et al*. 1984; Zambon *et al*. 1989; Hartnett & Shiloah 1991; Laspisa *et al*. 1994; Eley 1999).

Chemical biofilm control

Chemical dental plaque control may be necessary in those subjects who are unable to properly control supragingival biofilm with mechanical devices. The use of chemical products should be adjunctive to that of mechanical devices. Mechanical biofilm control will reduce the amount of biofilm and disrupt its structure, allowing the chemical formulations to be more effective (FDI Commission 2002b). Adjunctive use may be more relevant than sole use, because most chemical agents are only able to act against the most external parts of the biofilm. However, some agents have shown some capacity for penetration, such as chlorhexidine (CHX) (Netuschil *et al*. 1995) and essential oils (Pan *et al*. 1999;Pan *et al*. 2000; Fine *et al*. 2001).

The use of chemical formulations (especially antiseptics) to control plaque and gingivitis levels has been widely evaluated, and efficacy for some formulations has been observed in different systematic reviews (Hioe & van der Weijden 2005; Gunsolley 2006; Paraskevas & van der Weijden 2006; Addy *et al*. 2007; Stoeken *et al*. 2007; Gunsolley 2010; Sahrmann *et al*. 2010; Afennich *et al*. 2011; Hossainian *et al*. 2011; Escribano *et al*. 2016; Serrano *et al*. 2015; Figuero *et al*. 2019, 2020).

Mechanism of action

Chemical plaque control may be achieved by different mechanisms of action (Fig. 29-1), with a quantitative (reduction of the number of microorganisms) and/or qualitative (altering the vitality of the biofilm) effect (FDI Commission 2002b):

- By preventing bacterial adhesion
- By avoiding bacterial growth and/or co-aggregation
- By the elimination of an already established biofilm
- By altering the pathogenicity of the biofilm.

Categories of formulations

Formulations for chemical biofilm control can be classified according to their effects (Lang & Newman 1997):

- *Antimicrobial agents*: bacteriostatic or bactericidal effects *in vitro*.
- *Plaque-reducing/inhibitory agents*: quantitative or qualitative effect over the plaque that may or may not be enough to affect gingivitis and/or caries.
- *Antiplaque agents*: affect the plaque sufficient to show a benefit in terms of gingivitis and/or caries control.
- *Antigingivitis*: reduce gingival inflammation without, necessarily, affecting dental plaque, including anti-inflammatory drugs.

These definitions are widely accepted in Europe, but in North America the term "antiplaque" refers more often to agents capable of significantly reducing plaque levels and "antigingivitis" to agents capable of significantly reducing gingivitis levels.

Ideal features

The features of the ideal chemical agent for plaque control have been proposed by different authors (Loesche 1976; van der Ouderaa 1991; Baker 1993; Fischman 1994):

- *Specificity*. Agents and formulations for chemical plaque control should demonstrate a wide spectrum of action, including bacteria, viruses, and yeasts. More specific products, such as antibiotics, must not be used in the prevention of periodontal diseases, and their use should be limited for the prevention of bacteraemia, at-risk patients, and for the treatment of some periodontal conditions (Herrera *et al*. 2008).
- *Efficacy*. Antimicrobial capacity must be demonstrated against microorganisms implicated in gingivitis and periodontitis, both in *in vitro* and *in vivo* studies. Although bactericidal effects may be only achieved at high dosages, antimicrobial effect should also be present at lower dosages (FDI Commission 2002b).
- *Substantivity*. The effects of the chemical formulations do not depend only on the antimicrobial activity *in vitro*. Other factors will influence the *in vivo* activity, among which substantivity may be one of the most relevant. Substantivity has been defined as the duration of the antimicrobial action *in vivo* (FDI Commission 2002b) and as a measurement of the contact time between the agent and the substrate in a defined medium. This time may be longer than expected with simple mechanical deposition (von Abbé 1974) (Fig. 29-2). According to their substantivity, agents have been divided (Kornman 1986a) into three distinct generations: (1) first generation agents show very limited substantivity, with limited time of action, and include phenolic derivatives, plant extracts, fluorides, quaternary ammonium compounds and oxygenating agents; (2) second generation agents, demonstrated a good substantivity and CHX is the best example; (3) third generation agents include those which interfere or prevent bacterial or biofilm adhesion.
- *Safety*. This must be demonstrated in animal models, before its use in humans. Because of the chronicity of the conditions to be prevented and the foreseeable long-term use, the secondary effects must be minimal.
- *Stability*. Agents must be stable at room temperature for an extended period of time. Care should be taken when mixing different ingredients in a formulation to avoid interference between molecules.

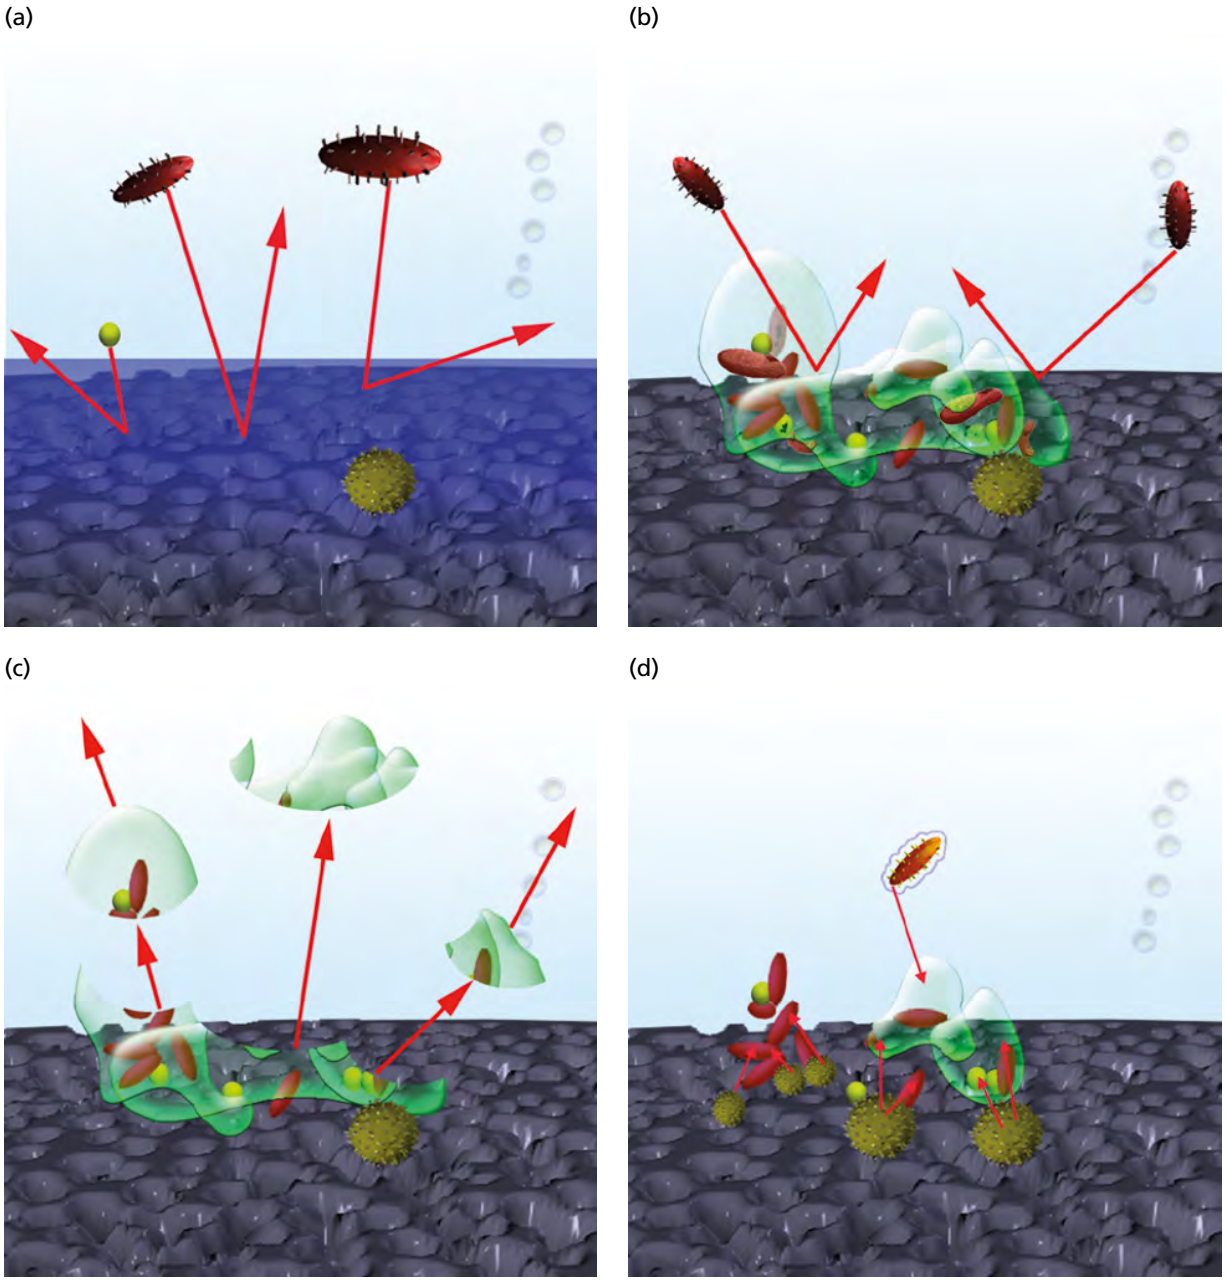

Fig. 29-1 Mechanisms of effect of antiplaque agents on bacterial biofilms (in green). (a) Prevention of bacterial adhesion to tooth surfaces: the active agent forms a pellicle (blue film) over the tooth surface, interfering with bacterial adhesion (red arrows), thus avoiding bacterial colonization. (b) Bactericidal or bacteriostatic effect, avoiding bacterial proliferation and co-aggregation: interference with bacterial division (damaged bacterial cells depicted in red) leads to interference in biofilm formation. In addition, biofilm maturation is also avoided, as co-aggregation of new species (red arrows) is impeded, due to the non-favorable environmental conditions. (c) Biofilm disruption from tooth surfaces: "chemical brushing". The agent induces a detachment and/or biofilm elimination from the tooth surface, by means of the chemical of the links between the surface and the biofilms, and in the biofilm structure disruption (red arrows). (d) Alteration of biofilm pathogenicity or enhancing host immune systems by different mechanisms: enhanced host defence systems, allowing for a more effective biofilm control by the host (short red arrows); or the presence of defined bacterial species that may influence biofilm development and maturation, by means of the release of different products, such as bacteriocins, or by competition for nutrients (long red arrow).

Evaluation of activity of agents for chemical biofilm control

In order to assess the plaque inhibitory and antiplaque activity of chemical compounds, different consecutive phases have been proposed, with the last stage being randomized clinical trials of home use with at least 6-months' duration (Addy & Moran 1997).

In vitro studies

Bacterial tests evaluate the antimicrobial activity of a product, by providing the minimum inhibitory concentration (MIC) and the minimum bactericidal concentration (MBC) against different bacterial species. The information provided is limited (antibacterial activity, spectrum of action), because many other

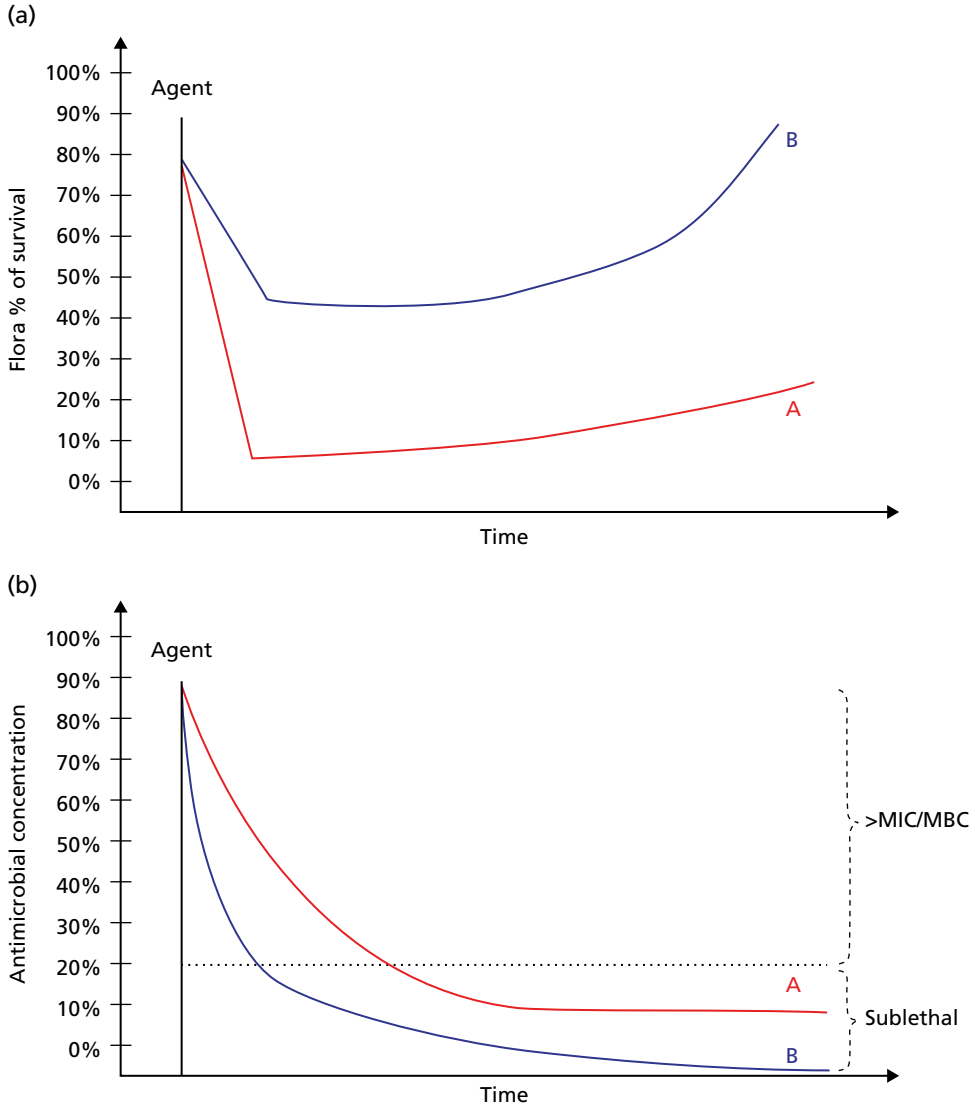

Fig. 29-2 Substantivity. (a, b) Two agents with different substantivity (measurement of the contact time between the agent and the substrate in a defined medium): with time, the concentration of the product decreases and the bacterial concentration increases. Product A has better substantivity than Product B. (a) Time after contact versus percentage of bacterial survival. (b) Time after contact versus concentration of the antibacterial agent. MIC, minimum inhibitory concentration: MBC, minimum bactericidal concentration.

factors will influence the effects *in vivo*, and the bacterial species are tested as planktonic cells, whereas in the mouth they are organized as sessile biofilm cells. However, antibacterial tests are useful for initial screening of products or for evaluation of the effects of the addition of new agents in a formulation.

Uptake studies are *in vitro* studies that assess the adsorption of products on different surfaces, such as hydroxyapatite, enamel, dentine, and acrylic.

Bioavailability and activity can be assessed by different chemical methodologies, such as spectrophotometry, or by indirect methods, such staining.

Biofilm models allowed formulations to be tested *in vitro* against sessile biofilm bacterial cells, which may better simulate real life conditions (Xu *et al*. 2000; Shapiro *et al*. 2002; Socransky & Haffajee 2002). However, a standardized and accepted model is already available, and conversely, several attempts of different *in vitro* biofilm models have been proposed (Sanchez *et al*. 2011). In addition to information on antimicrobial activity, other relevant information, such as the penetration of the agent in the biofilm, can be obtained. Both CHX and essential oils have demonstrated capacity to both penetrate and have a bactericidal action in the biofilm (Arweiler *et al*. 2001, 2003; Shapiro *et al*. 2002; Ouhayoun 2003; Corbin *et al*. 2011; Guggenheim & Meier 2011; Otten *et al*. 2011) (Fig. 29-3).

In vivo study models

Depot studies assess the retention of an agent in the mouth after a single use, by measuring the agent level in saliva or in dental plaque. These studies do not provide information on the activity of the product (Rolla *et al*. 1971; Bonesvoll *et al*. 1974a, b; Gjermo *et al*. 1974, 1975; Bonesvoll 1978; Bonesvoll & Gjermo 1978).

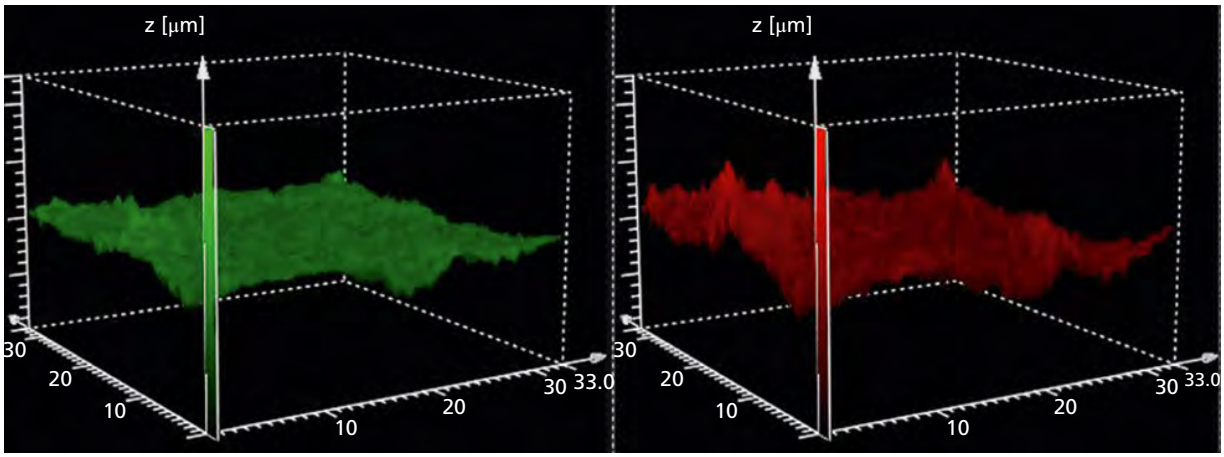

Fig. 29-3 Three-dimensional assessment of cell vitality in a biofilm, with a confocal microscope. Cells in green show vitality and cells with damaged cytoplasmatic membrane appear in red. This tool allows for the assessment of the capacity biofilm penetration by an antiseptic and its bactericidal activity.

In vivo biofilm study models assess the effects of different formulations on disks of enamel, dentine, or other materials, inserted into the mouth of patients (with different prosthetic devices) and retrieved for the evaluation of the biofilms formed under the presence of different products (cross-over designs) (Pan *et al*. 2000; Sreenivasan *et al*. 2004).

Antimicrobial tests *in vivo* are designed as cross-over studies (with a placebo and a positive control), with the amount of bacteria in saliva measured before and after (for several hours and at different times) a single use of a tested formulation (either as a mouth rinse, a dentifrice, or rinsing with a dentifrice in an aqueous slurry). This study design has been extensively used since its first use with CHX (Schiott *et al*. 1970) and provides information on antimicrobial capacity and duration of the effect.

Plaque regrowth models are also designed as cross-over studies (with a placebo and a positive control), in which plaque regrowth after professional prophylaxis is measured for a period of time (normally 3–4 days), and only use of the tested formulation is allowed for oral hygiene (no mechanical hygiene). Information on the plaque inhibitory capacity of the formulation is obtained (Harrap 1974; Addy *et al*. 1983; Moran *et al*. 1992; Arweiler *et al*. 2002; Pizzo *et al*. 2008).

Experimental gingivitis models follow the same design as plaque regrowth models but for longer periods of time (typically 12–28 days), allowing for the evaluation as an outcome variable of gingivitis indices (Löe 1965; Löe & Schiott 1970). No mechanical hygiene is permitted. Parallel studies can also be designed because of the longer duration of the study periods.

Home-use clinical trials

It is a general consensus that plaque inhibitory and antiplaque activities have to be shown in long-term (at least 6 months), home-use, randomized clinical trials, and concomitantly show safety, based on the lack of relevant side effects. In these studies, the use of the tested formulations is adjunctive to mechanical plaque control. The characteristics of these trials, in order for their conclusion to be valid, have been proposed (Council on Dental Therapeutics 1986):

- Double blind (patients and examiner).
- Controlled (negative and/or positive controls). It is not valid to compare the effects of the tested formulation against the baseline values, because of the Hawthorne effect (improvement of the oral hygiene habits of patients because of their awareness of their presence in the study) and to the performance of a professional prophylaxis at the beginning of these studies (Overholser 1988).
- Minimum of 6 months of duration. This period permits a number of advantages: 6 months is the typical period of time between two consecutive supportive periodontal therapy visits; it permits for an adequate evaluation of long-term adverse events, including microbiological effects; and it may compensate for part of the Hawthorne effect, because its effect will slowly disappear as the study progress (Overholser 1988).
- Microbiological evaluation to assess the overgrowth of pathogenic, opportunist, or resistant strains.
- Microbiological sampling and evaluation of plaque and gingival indices should be carried out at least at baseline, at the final evaluation, and at an intermediate point (e.g. 3 months).

In addition, other factors with regards to the quality of these studies should be considered, such as the selection of a representative population, with homogeneous study groups for different factors (age, smoking, gender, general, oral and periodontal health, etc.). Clinical trials must be clear, comparable, and with internal and external validity (Koch & Paquette 1997).

Based on the availability of at least two independent investigations with 6-month duration showing significant differences, as compared with the

negative control, in terms of plaque and gingivitis, different products have received a "seal of approval" for plaque inhibitory and/or antiplaque activity, by the American Dental Association (ADA) and the Food and Drug Administration (FDA).

In the following section, the scientific evidence supporting the use of the most common agents is reviewed, and special attention paid to 6-month, home-use, clinical trials and to systematic reviews with meta-analysis of 6-month studies.

Active agents

Antibiotics

- *Specific agents*. Penicillins, tetracyclines, metronidazole, vancomycin, kanamycin, and spiramycin.
- *Characteristics*. When systemically taken, their effects are stronger, because of the stable serum levels (also in the gingival crevicular fluid) maintained; when topically or locally applied, the effects are smaller, because of the limited time of action.
- *Evaluation*. Different groups of antibiotics have shown an effect on dental biofilms.
- *Limitations*. Use against dental plaque is not recommended because of the poor benefit-to-risk ratio, including adverse effects and an increase in bacterial resistance (Genco 1981; Kornman 1986; Slots & Rams 1990; Herrera *et al*. 2000; van Winkelhoff *et al*. 2000).
- *Usefulness, marketed*. Should not be used for chemical plaque control.

Enzymes: disruption of the biofilm

- *Specific agents*. Dextranase, mutanase, proteases, and lipases.
- *Characteristics*. Very limited substantivity and frequent side effects (Addy *et al*. 1986).
- *Evaluation*. Use *in vivo* is limited because of side effects. Other enzymes and combinations of enzymes have been evaluated, but only *in vitro* data are available (Johansen *et al*. 1997; Donlan & Costerton 2002).
- *Limitations*. Frequent side effects (Hull 1980; Addy *et al*. 1986).
- *Usefulness, marketed*. No.

Enzymes: enhancement of the host defences

- *Specific agents*. Glucose oxidase and amyloglucosidase.
- *Characteristics*. Mechanisms of action rely on the catalysation of thyocianate into hypothyocianate, through the salivary lactoperoxydase system.
- *Evaluation*. Evaluation of their *in vivo* effect on gingivitis has shown contradictory results, and no long-term studies are available (Addy *et al*. 1986; Moran *et al*. 1989; Kirstila *et al*. 1994; Hatti *et al*. 2007).
- *Limitations*. Limited scientific evidence available.
- *Usefulness, marketed*. Marketed as Zendium® by Opus Health Care AB (Malmö, Sweden) as a mouth rinse with amyloglucosidase, glucosidase and lactoperoxidase, sodium fluoride, xylitol and zinc, and no alcohol; and, also, in toothpaste. Another commercialized toothpaste is Bioxtra® (Bio-X Healthcare, Namur, Belgium), with lactoferrin, lysozyme, and lactoperoxidase.

Amine alcohols

- *Specific agents*. Delmopinol (Fig. 29-4) and octapinol.
- *Characteristics*. Mechanism of action is not fully understood, but they are not antimicrobials and the effect is achieved by the inhibition of the biofilm matrix formation or by the disruption of the biofilm matrix. Delmopinol also inhibits glucane synthesis by *Streptococcus mutans* (Rundegren *et al*. 1992; Elworthy *et al*. 1995) and reduces acid synthesis by bacteria (Simonsson *et al*. 1991).
- *Evaluation*. Delmopinol has been formulated and clinically evaluated as a mouth rinse at 0.1% and 0.2% (Collaert *et al*. 1992; Moran *et al*. 1992; Abbott *et al*. 1994; Claydon *et al*. 1996; Zee *et al*. 1997) and has demonstrated efficacy as an antiplaque agent as concluded in a systematic review (Addy *et al*. 2007). It was approved by FDA in 2005 as a medical device as a 0.2% mouth rinse indicated in the treatment of gingivitis (Imrey *et al*. 1994).
- *Limitations*. Most relevant side effects are dental staining, a temporary feeling of numbness in the mucosa (e.g. tongue), and burning sensation.
- *Usefulness, marketed*. Delmopinol has been marketed in several countries by Sinclair Pharma (Paris, France), under the name of Decapinol®, both as a 0.2% delmopinol mouth rinse with 1.5% of alcohol, and as a toothpaste with 0.2% delmopinol and 0.11% sodium fluoride.

Detergents

- *Specific agents*. The most important and frequently used detergent or surfactant (active-surface compounds) is sodium lauryl sulphate (SLS).
- *Characteristics*. SLS has demonstrated substantivity of 5–7 hours. The foaming properties of detergents may help in removing plaque, although there is not enough evidence to support this statement.
- *Evaluation*. SLS has a limited antimicrobial and plaque-inhibitory effect (Addy *et al*. 1983; Moran *et al*. 1988b).
- *Limitations*. SLS has been associated with oral hypersensitive reactions, including cheilitis, stomatitis or aphthous ulcers, burning sensation, and desquamation (Herlofson & Barkvoll 1996; Chahine *et al*. 1997; Plonait & Reichart 1999).
- *Usefulness, marketed*. SLS is present in many dentifrice and mouth rinse formulations, but it has not been formulated as a single active agent product.

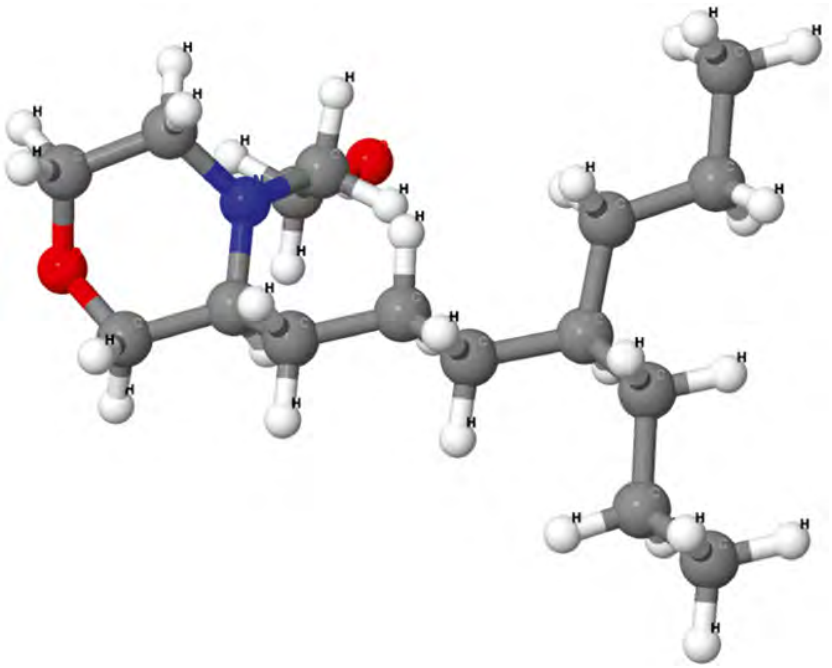

Fig. 29-4 Chemical structure of delmopinol (prepared with Jmol; www.jmol.org/)

Oxygenating agents

- *Specific agents*. Sodium peroxyborate and peroxycarbonate, and hydrogen peroxide.
- *Characteristics*. Exert antimicrobial effects through the release of oxygen.
- *Evaluation*. Peroxyborate and peroxycarbonate have demonstrated some antimicrobial and plaque inhibitory capacity (Moran *et al*. 1995). Hydrogen peroxide was evaluated in a systematic review (Hossainian *et al*. 2011) of 10 publications, three of which (one with a 6 month follow up) had a low risk of bias. No effect was observed in the short term, but the 6-month study showed significant benefits in the modified gingival index (Hasturk *et al*. 2004).
- *Limitations*. No long-term data are available for peroxyborate and peroxycarbonate, and only one study for hydrogen peroxide has been published. At low concentrations (i.e. <1.5% for hydrogen peroxide), adverse events are not common, but at higher concentrations a painful sensation in the mouth and ulcers may be frequent (Rees & Orth 1986).
- *Usefulness, marketed*. Peroxyborate (Bocasan®, Amosan®) and peroxycarbonate (Kavosan®) were marketed by Procter and Gamble (Cincinnati, OH, USA), but they are only available now in some countries; hydrogen peroxide is available in North America as Rembrant® (Dent-Mat Corp., Santa Maria, CA, USA).

Metal salts: zinc salts

- *Specific agents*. Zinc lactate, zinc citrate, zinc sulphate, and zinc chloride.
- *Characteristics*. At low concentrations, no adverse effects are present.
- *Evaluation*. As sole agents they have limited effects on plaque, but used in combination with other active agents there is an improvement in substantivity and action. More recently, 6-month, home-use studies, assessing dentifrices with zinc salts, have reported a therapeutic effect in patients with a diagnosis of gingivitis in whom statistically significant reductions in gingival and plaque indices were observed (Zhong *et al*. 2015; Delgado *et al*. 2018).
- *Limitations*. Limited data for individual agents are available.
- *Usefulness, marketed*. In combination with CHX, cetylpyridinium chloride, triclosan, hexetidine, etc. Combination products have been evaluated for plaque control (zinc lactate with CHX, zinc citrate with triclosan), but some combinations have also been evaluated for halitosis control (zinc lactate with CHX and cetylpyridinium chloride), tartar control (zinc chloride with essential oils), or ulcer healing (zinc sulphate with triclosan).

Metal salts: stannous fluoride

- *Specific agents*. Stannous fluoride has been included in dentifrices, mouth rinses, and gels since 1940. Several formulations have been tested, but the two most commonly evaluated are the combination of stannous fluoride with amine fluoride (addressed in the following section), and different formulations with 0.454% stannous fluoride dentifrice, combined with sodium hexametaphosphate (SHMP) in the most recent formulation.
- *Characteristics*. Combination of tin and fluoride (SnF_2); difficult to formulate in oral hygiene products because of limited stability for hydrolysis in the presence of water (Miller *et al*. 1969). Specifically, it is not frequently used in mouth rinse due to its limited stability in aqueous solutions.

- *Evaluation*. Several 6-month studies have been published, evaluating gel or dentifrice products, more frequently (six investigations) with the 0.454% stannous fluoride formulation (Beiswanger *et al*. 1995; Perlich *et al*. 1995; Mankodi *et al*. 1997; McClanahan *et al*. 1997; Williams *et al*. 1997), but also with stannous fluoride plus SHMP (Mankodi *et al*. 2005a; Mallatt *et al*. 2007; Boneta *et al*. 2010) and older formulations (Wolff *et al*. 1989; Boyd & Chun 1994). Less frequently, mouth rinse products were assessed (Leverett *et al*. 1984, 1986). In a systematic review, the 0.454% stannous fluoride formulation provided significant benefits in terms of gingivitis (weighted mean difference [WMD] 0.441, P <0.001, with significant heterogeneity $P = 0.010$) (Gunsolley 2006). In another systematic review (Paraskevas & van der Weijden 2006), the meta-analysis was limited because of the availability of data, and data pooling was performed at the final study visit, assuming that no differences were found at baseline. In addition, the results combined different stannous fluoride formulations, including the combination with amine fluoride. The results demonstrated significant differences at the final visit (and no differences at baseline) in terms of gingival index (WMD −0.15), modified gingival index (WMD −0.21). and plaque index (WMD −0.31), always with significant heterogeneity.
- *Limitations*. Main limiting factor is dental staining (Brecx *et al*. 1993; Paraskevas & van der Weijden 2006).
- *Usefulness, marketed*. Most recently marketed formulation is Crest Pro-Health® (Procter & Gamble, Mason, OH, USA), with 0.454% stannous fluoride with SHMP, zinc lactate, and SLS, approved by the ADA. The previous formulation with 0.454% stabilized stannous fluoride was marketed as Crest Gum Care or Crest Plus Gum Care (Procter & Gamble, Mason, OH, USA).

Metal salts: stannous fluoride with amine fluoride

- *Specific agents*. Amine fluoride was developed in the 1950s at the University of Zurich.
- *Characteristics*. Stannous fluoride and amine fluoride have demonstrated bactericidal activity against bacteria, and activity is increased if they are combined. Amine fluoride exerts its antimicrobial action by antiglycolytic activities. The activity of stannous/amine fluoride seems to be greater as dentifrice, with 8 hours of action after use (Weiland *et al*. 2008).
- *Evaluation*. Six-month studies are available, assessing stannous/amine fluoride as dentifrice (Sgan-Cohen *et al*. 1996; Shapira *et al*. 1999), mouth rinse (Zimmermann *et al*. 1993), or both (Mengel *et al*. 1996; Paraskevas *et al*. 2005), revealing no significant benefit of the dentifrice alone, whereas the mouth rinse achieved significant plaque and gingivitis reductions. If both products were used in combination, either no significant effects (Mengel *et al*. 1996) or significant effects on plaque, but not on gingivitis (Paraskevas *et al*. 2005), were reported.
- *Limitations*. Tooth staining is the most common adverse effect (Paraskevas *et al*. 2005).
- *Usefulness, marketed*. Both the dentifrice and the mouth rinse are marketed as Meridol® (GABA International AG, Therwil, Switzerland).

Other fluorides

- *Specific agents*. Sodium fluoride and sodium monofluorophosphate.
- *Characteristics*. Usefulness has been shown in reducing caries incidence (Petersson 1993).
- *Evaluation*. Fluoride ion has not demonstrated plaque-inhibitory nor antiplaque properties.
- *Limitations*. Not been evaluated as individual agents.
- *Usefulness, marketed*. Present in most dentifrices.

Natural products

- *Specific agents*. Sanguinarine extract and other herbal ingredients (camomile, echinacea, sage, myrrh, rhatany, peppermint oil).
- *Characteristics*. Sanguinarine is an alkaloid obtained from the plant *Sanguinaria canadensis*.
- *Evaluation*. Sanguinarine extract has demonstrated low bactericidal capacity in an *in vitro* biofilm model (Shapiro *et al*. 2002), whereas the clinical evaluation reported contradictory results (Moran *et al*. 1988a; Scherer *et al*. 1998; Quirynen *et al*. 1990). At least six home-use, 6-month oral hygiene trials were performed in the 1980s and early 1990s, assessing sanguinarine extract with zinc chloride, as dentifrice (Lobene *et al*. 1986; Mauriello & Bader, 1988), as mouth rinse (Grossman *et al*. 1989), or the combined use (Hannah *et al*. 1989; Harper *et al*. 1990; Kopczyk *et al*. 1991). Significant reductions in terms of plaque and gingivitis were reported with combined use.
- *Limitations*. Use of formulations with sanguinarine was associated to oral leukoplakia (Mascarenhas *et al*. 2002).
- *Usefulness, marketed*. Viadent® (Colgate, Piscataway, NJ, USA), with sanguinarine extract is no longer available. Paradontax® (GlaxoSmithKline, Middlesex, UK) contains other active components.

Essential oils

- *Specific agents*. Mouth rinse with eucalyptol (0.092%), menthol (0.042%), methyl salicylate (0.060%), and thymol (0.064%) with alcohol (26.9%, in the original formulation) (Fig. 29-5).
- *Characteristics*. Multiple mechanisms of action have been proposed, such as cell wall disruption, inhibition of bacterial enzymes, extraction of endotoxins derived from lipopolysaccharide (LPS) of Gram-negative bacteria (Fine *et al*. 1985), and anti-inflammatory action based on antioxidant activity (Firatli *et al*. 1994; Sekino & Ramberg 2005).

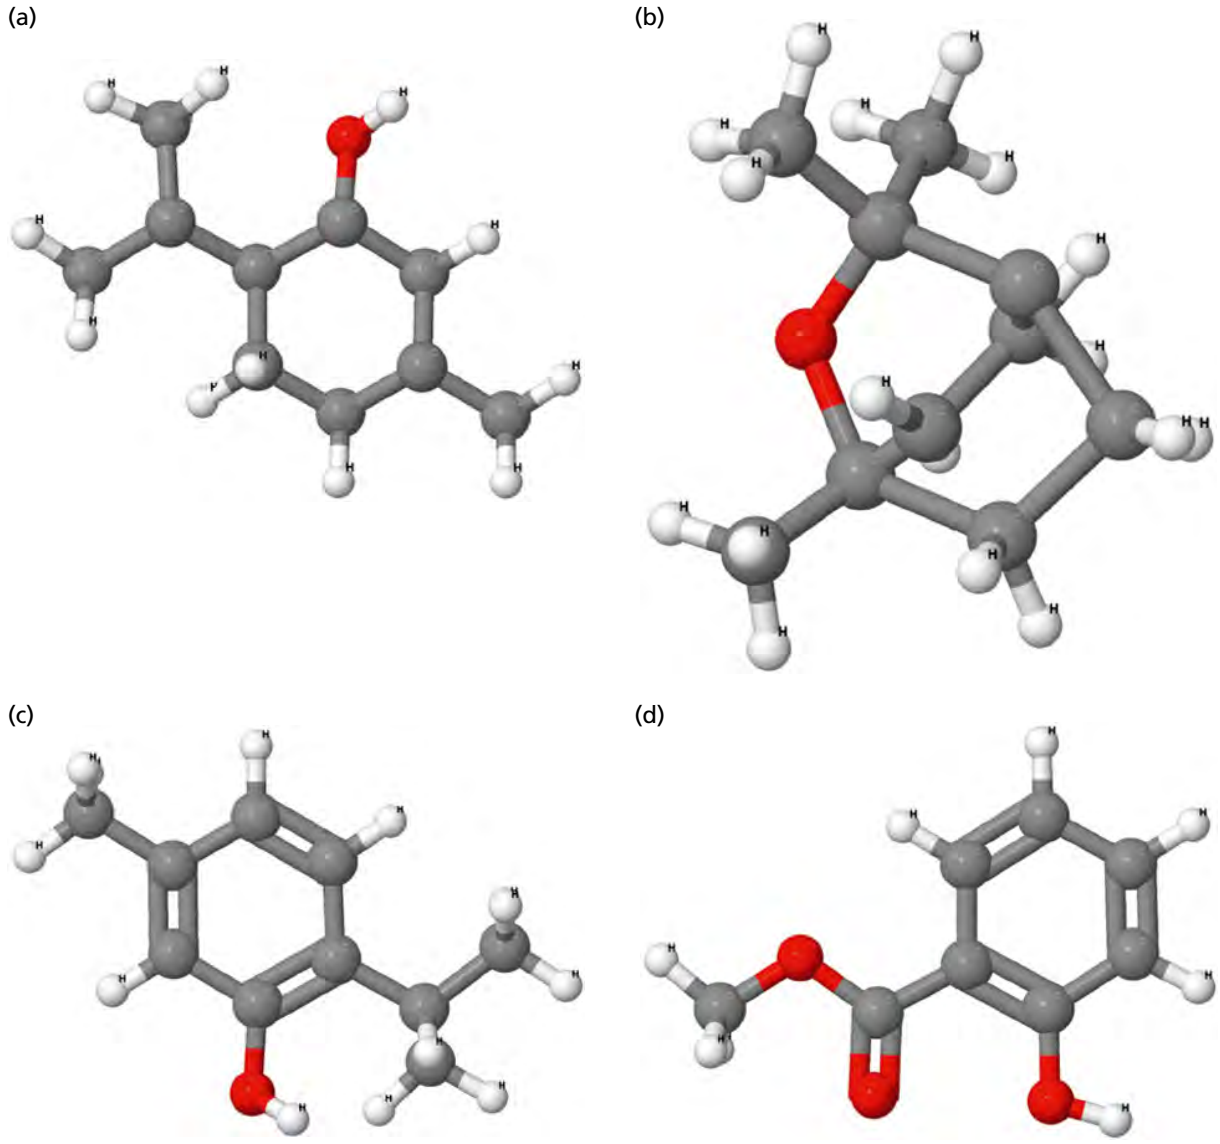

Fig. 29-5 Chemical structure of essential oils: (a) Menthol. (b) Eucalyptol. (c) Thymol. (d) Methyl salicylate (prepared with Jmol).

- *Evaluation*. A mouth rinse with essential oils has demonstrated antimicrobial activity in biofilm models *in vitro* (Fine *et al*. 2001; Shapiro *et al*. 2002), and plaque inhibitory and antiplaque effects in different home-use, 6-month oral hygiene studies (Lamster, 1983; Gordon *et al*. 1985; DePaola *et al*. 1989; Grossman *et al*. 1989; Overholser *et al*. 1990; Beiswanger *et al*. 1997; Charles *et al*. 2001, 2004; Sharma *et al*. 2002, 2004; Bauroth *et al*. 2003). In a systematic review (Stoeken *et al*. 2007), including investigations of 6 months or more, 11 papers were included and statistically significant differences in the meta-analysis were found for both plaque (WMD −0.83, P <0.00001; with significant heterogeneity, P <0.00001) and gingivitis index (WMD −0.32, P <0.00001; with significant heterogeneity P <0.00001).
- *Limitations*. Secondary effects include a burning sensation and tooth staining. There is some controversy concerning alcohol-containing mouth rinses (including Listerine®) and oral cancer (Blot *et al*. 1983). However, critical assessment of the literature does not support those statements (Claffey 2003; Ciancio 1993).
- *Usefulness, marketed*. There are different formulations of Listerine® antiseptic (Johnson & Johnson Healthcare Products, Skillman, NJ, USA).

Triclosan

- *Specific agents*. Triclosan [5-chloro-2-(2,4 dichlorophenoxy) phenol] is a non-ionic bisfenolic, broad spectrum antibacterial agent (Ciancio 2000) (Fig. 29-6).
- *Characteristics*. Formulated both in mouth rinses and in dentifrices. In mouth rinses, at 0.2%, there is a limited bactericidal activity (Shapiro *et al*. 2002; Arweiler *et al*. 2003) and a substantivity of approximately 5 hours (Jenkins *et al*. 1991a). As a dentifrice, it can be detected for up to 8 hours in dental plaque (Gilbert & Williams 1987) and it has been normally formulated in combination with

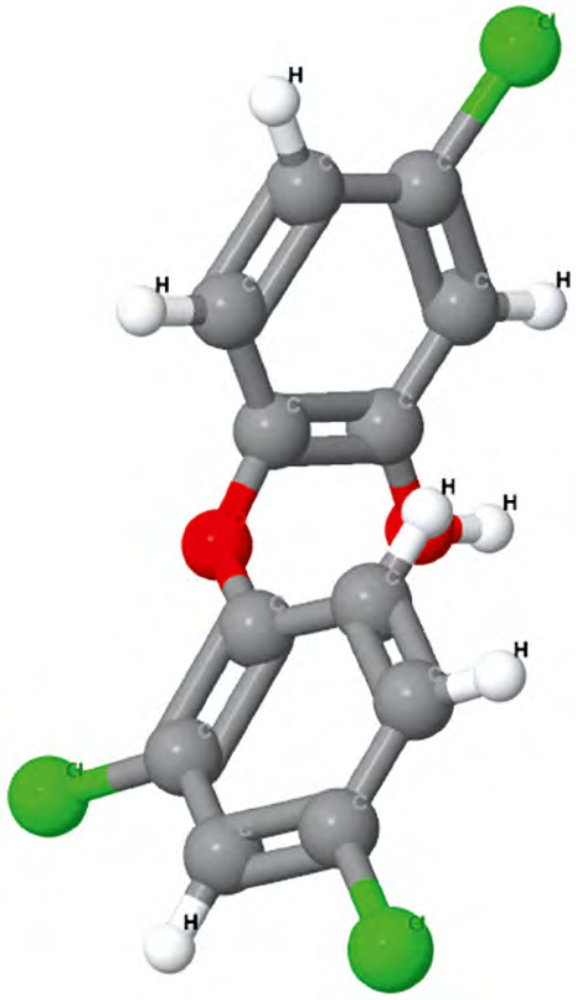

Fig. 29-6 Chemical structure of triclosan (prepared with Jmol).

polyvinyl-methyl ether maleic acid copolymer, zinc citrate or pyrophosphate, in order to improve the substantivity and/or the antimicrobial activity. Triclosan may also induce anti-inflammatory effects (Barkvoll & Rolla, 1994; Gaffar *et al*. 1995; Kjaerheim *et al*. 1996) through inhibition of the cyclooxygenase and lipoxygenase pathways which induces the reduction in the synthesis of prostaglandins and leukotrienes.

- *Evaluation*. Home-use, 6-month, oral hygiene studies are available for three distinct triclosan dentifrice formulations (triclosan with copolymer, triclosan with zinc citrate, triclosan with pyrophosphate), and a mouth rinse with triclosan and copolymer.
  - A *dentifrice with triclosan and zinc citrate* was extensively evaluated in the 1990s (Svatun *et al*. 1989, 1990, 1993a, b; Stephen *et al*. 1990; Palomo *et al*. 1994; Renvert & Birkhed 1995). Conflicting results were reported, and a limited meta-analysis conducted (performed with end of trial values, rather than with the changes), demonstrating a limited but significant effect on plaque (WMD –0.07, P <0.00001) and a more important effect on bleeding (WMD –10.81%, P <0.00001) (Hioe & van der Weijden 2005). Conversely, no significant differences were observed in another systematic review over baseline-final changes (Gunsolley 2006).
  - A *dentifrice with triclosan and copolymer* has also been extensively evaluated in 6-month studies (Garcia-Godoy *et al*. 1990; Cubells *et al*. 1991; Deasy *et al*. 1991; Bolden *et al*. 1992; Denepitiya *et al*. 1992; Mankodi *et al*. 1992; Lindhe *et al*. 1993; Svatun *et al*. 1993b; Palomo *et al*. 1994; Kanchanakamol *et al*. 1995; Triratana *et al*. 1995; Hu *et al*. 1997; McClanahan *et al*. 1997; Charles *et al*. 2001; Allen *et al*. 2002; Winston *et al*. 2002). In a limited meta-analysis over final visit values, a significant effect was observed for the Turesky modification of the plaque index (WMD –0.48, P <0.0001) and for the Talbott modification of the gingival index (WMD –0.24, P <0.0001), in both cases with significant heterogeneity (Hioe & van der Weijden 2005). In another meta-analysis, evaluating changes between baseline and final visit, a significant effect on plaque was observed (WMD 0.823), with significant differences in 14 out of the 18 included arms; and for gingivitis (WMD 0.858), in both cases with significant heterogeneity (Gunsolley 2006).
  - A *dentifrice with triclosan and pyrophosphate* has been evaluated less frequently (Palomo *et al*. 1994; Renvert & Birkhed 1995; Grossman *et al*. 2002; Winston *et al*. 2002), and the results showed significant heterogeneity and conflicting results (Gunsolley 2006).
  - A *mouth rinse with triclosan and copolymer* was evaluated in the 1990s in at least four 6-month trials (Worthington *et al*. 1993; Ayad *et al*. 1995; Triratana *et al*. 1995; Schaeken *et al*. 1996), demonstrating statistically significant differences both in plaque and gingival indices. The formulation of triclosan and copolymer in mouth rinse has also been tested as a prebrushing agent; a meta-analysis of two 6-month studies resulted in a WMD of 0.269 (P <0.0001) (Angelillo *et al*. 2002).
- *Limitations*. There are no relevant side effects, but a risk of formation of a carcinogenic product (chloroform) has been suggested in an *in vitro* study testing the combination of triclosan and free chlorine present in water (Rule *et al*. 2005). Also, environmental problems have been suggested: the presence of triclosan in the food chain (Park *et al*. 2017); triclosan accumulation in the bristles of dental toothbrushes, with delayed release (Han *et al*. 2017); possible action as an endocrine disruptor (Veldhoen *et al*. 2006).
- *Usefulness, marketed*. Triclosan (0.30%) with copolymer and sodium fluoride (0.24%) is marketed as Colgate Total® (Colgate-Palmolive Co.). This formulation is no longer available in some markets. The formulation of triclosan and co-polymer as mouth rinse has been marketed as Plax®, although different products under this name have been marketed, including formulations with sodium benzoate.

Bisbiguanides

- *Specific agents*. CHX digluconate, alexidine dihydrochloride, and octenidine dihydrochloride.
- *Characteristics*. Symmetric molecules, with two chlorophenolic rings and two biguanides groups connected by a central bridge of hexametilene (Fig. 29-7).
- *Evaluation*. Excellent plaque inhibitor and antiplaque agent. CHX is the reference, since the other bisbiguanides show similar or inferior activity (Shapiro *et al*. 2002).
- *Limitations*. Similar among all bisbiguanides, but there are more studies for CHX.
- *Usefulness, marketed*. Many CHX formulations are available on the market.

Chlorhexidine

CHX is the most widely evaluated and the most efficacious agent against oral biofilms. Its activity was first investigated more than 50 years ago (Schroeder 1969).

CHX is most often formulated in mouth rinses with a concentration 0.1–0.2% (Löe *et al*. 1976; Segreto *et al*. 1986; Grossman *et al*. 1989; Flemmig *et al*. 1990; Lang *et al*. 1998). These concentrations achieve the ideal CHX dosage of 18–20 mg/use. Clinical activity is observed with dosages of 5–6 mg twice per day. Higher dosages do not increase the effect (but do increase adverse effects) (Cancro *et al*. 1974). To obtain a 20-mg of dosage with a 0.2% formulation, rinsing with 1 mL should last for 30 seconds; with a 0.12% formulation, 15 mL should last for 60 seconds.

More recently, formulations with lower concentrations (e.g. 0.05%) have been marketed, aiming to decrease adverse effects. The resulting dosages are approximately 5 mg per use, which is at the lower limit of clinical activity; therefore, the complete formulation is crucial and combination with other active agents (triclosan, cetylpyridinium chloride, zinc salts) has been proposed (Joyston-Bechal & Hernaman 1993; Marsh & Bradshaw 1995; Claydon *et al*. 2001; Shapiro *et al*. 2002).

Characteristics

CHX is active against Gram-positive and Gram-negative bacteria, against yeast, and also against viruses, including human immunodeficiency virus and hepatitis B virus (Wade & Addy 1989).

- *Antimicrobial effect*. Depending on the concentration, CHX may show different antimicrobial effects. At low concentrations, it increases the permeability of the plasmatic membrane, leading to a bacteriostatic effect (Hugo & Longworth 1964, 1965). At higher concentrations, it induces precipitation of cytoplasm proteins and cell death, thus having a bactericidal effect (Hugo & Longworth 1966; Fine 1988). However, bacterial cells arranged in biofilms will show higher resistance against antimicrobials. Against biofilms, CHX has demonstrated the capacity to penetrate and to actively act inside the biofilm, both altering biofilm formation or having a bactericidal effect (Arweiler *et al*. 2001; Shapiro *et al*. 2002).
- *Plaque inhibitory effect*. In addition to the antimicrobial effect, CHX molecules adhere to the tooth surface and interact with bacterial cells that are also trying to adhere to the tooth surface; therefore, CHX interferes with bacterial adhesion (Rolla & Melsen 1975; Wolff 1985; Fine 1988; Jenkins *et al*. 1988, 1989). CHX also interacts with salivary glycoproteins, thus leading to the reduced salivary pellicle formation. In addition, it has been suggested that CHX affects the activity of bacterial enzymes involved in glucan production (glycosiltranferase C) (Vacca-Smith & Bowen 1996).

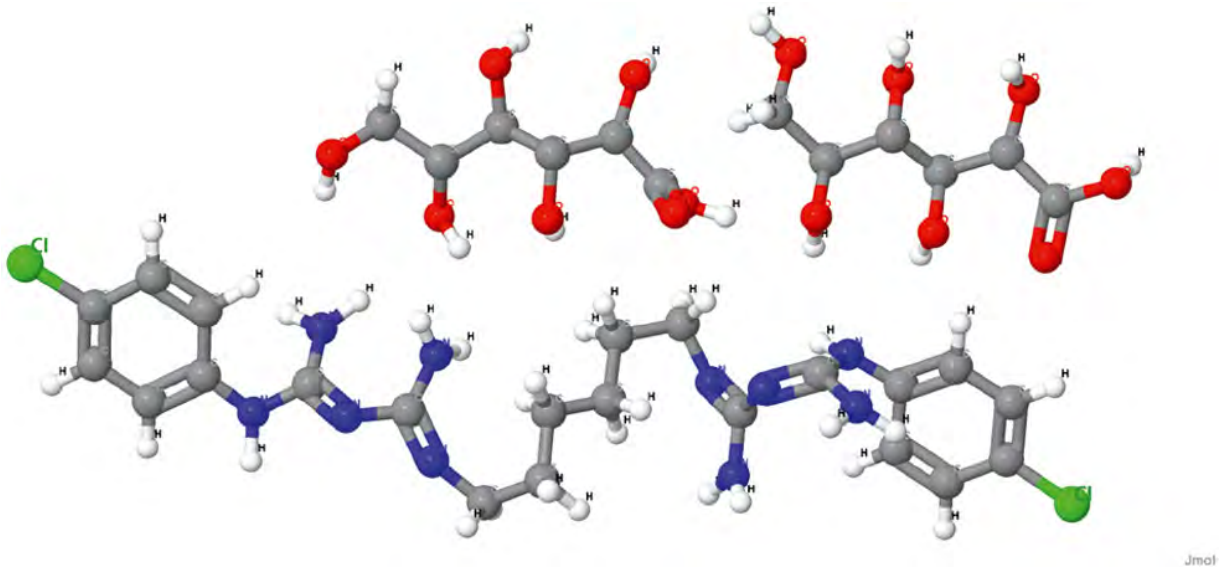

Fig. 29-7 Chemical structure of chlorhexidine digluconate (prepared with Jmol).

- *Substantivity*. CHX molecules bind reversibly to oral tissues, with a slow release (Bonesvoll *et al*. 1974a, b) that allows for sustained antimicrobial effects for up to 12 hours (Schiott *et al*. 1970).

Evaluation of chlorhexidine in clinical studies

Six-month studies are available both for mouth rinses and for dentifrices.

Two 6-month studies evaluating CHX containing *dentifrices* have been published. The difficulties in formulating CHX in dentifrices are well known because of the high risk of inactivation. However, a 1% CHX dentifrice (Yates *et al*. 1993) and a 0.4% CHX dentifrice with zinc (Sanz *et al*. 1994) both demonstrated significant benefits in terms of plaque and, for the 1% CHX dentifrice, also in gingival inflammation.

Different 0.12% and 0.2% *mouth rinse* formulations have been evaluated in 6-month studies (Grossman *et al*. 1986, 1989; Flemmig *et al*. 1990; Overholser *et al*. 1990; Sanz *et al*. 1994; Hase *et al*. 1998; Lang *et al*. 1998; Charles *et al*. 2004; Stookey 2004), and each independent study revealed statistically significant benefits in terms of both plaque and gingival indexes, with one exception. In a systematic review with 0.12% formulations (six studies, one unpublished), the WMD for plaque was 1.040 (P <0.001) and for the gingival index was 0.563 (P <0.001, significant heterogeneity P = 0.013) (Gunsolley 2006).

A systematic review comparing *0.12% and 0.2% formulations* (Berchier *et al*. 2010) included eight papers (with a study duration of 3–14 days, except for one paper reporting 3-month results). For the Quigley and Hein Plaque Index (Quigley & Hein 1962), meta-analyses of seven papers calculated a significant difference (WMD: 0.10; P = 0.008), although the difference was not considered to be clinically relevant and none of the individual studies showed significant differences. For gingival inflammation, no difference was observed in a meta-analysis of three papers.

CHX and essential oils mouth rinses have been compared. In a systematic review (van Leeuwen *et al*. 2011) of 19 papers, meta-analyses were carried out on studies with a follow up of 4 weeks or more. Significant differences (favoring the CHX groups) were found at the final visit for plaque (four studies, WMD 0.19; P = 0.0009), but no significant difference in gingival inflammation (three studies, WMD 0.03; P = 0.58). Significantly more staining was observed in the CHX groups (WMD: 0.42; P <0.000001). It must be highlighted that the meta-analyses considered final visit values, rather than the changes between the baseline and final visit. In addition, different CHX concentrations and formulations were pooled, as well as different follow-up times. Another meta-analysis only included 6-month studies (Gunsolley 2006) and pooled data from four studies (Grossman *et al*. 1989; Overholser *et al*. 1990; Segreto & Collins 1993; Charles *et al*. 2004). A significant difference (P = 0.02) in plaque was reported, favoring 0.12% CHX formulations, with two individual studies demonstrating significant differences. For the gingival index, one study reported significant differences, and the pooled results showed a tendency to significant differences (P = 0.068). The authors highlighted that the essential oils mouth rinse showed 60% of the effect of CHX mouth rinses for both parameters.

Limitations of chlorhexidine use, safety and adverse effect

CHX safety has been extensively studied. Only heating for long periods of time can induce the formation of 4-chloroanilinine, which has been shown to be cancerogenic and mutagenic. Despite the low risk of formation of 4-chloroanilinine, CHX formulations are marketed in dark bottles, and should be kept at room temperatures, out of direct sunlight. No adverse microbiological changes, including the overgrowth of opportunistic strains, are induced after long-term use (Schiott *et al*. 1970, 1976a, b).

Reported adverse events include the following:

- Hypersensitivity reaction (Beaudouin *et al*. 2004).
- Neurosensory deafness if the product is placed in the middle ear (Aursnes 1982).
- Taste alterations (Marinone & Savoldi 2000; Breslin & Tharp 2001), particularly affecting salty and bitter taste; they are reversible and disappear soon after discontinuation of product usage.
- Uni- or bi-lateral parotid tumefaction (Flotra *et al*. 1971; van der Weijden *et al*. 2010).
- Staining, either of teeth, mucosa, tongue dorsum or restorations (Flotra *et al*. 1971).
- Mucosal erosion (Almqvist & Luthman 1988).
- Healing process alterations. *In vitro* studies have suggested some inhibition of fibroblast proliferation in culture. However, *in vivo* studies, using CHX mouth rinses after periodontal surgery, have not found interference with the healing process; indeed, a better resolution of inflammation was observed (Sanz *et al*. 1989).
- Increase in calculus formation (Yates *et al*. 1993).

Tooth and tongue staining is the most common adverse effect (Fig. 29-8) and different mechanisms have been proposed to explain staining associated with CHX usage (Watts & Addy, 2001):

- Degradation of the CHX molecule to para-chloraniline
- Catalysis of Maillard reactions
- Protein denaturation, with formation of metal sulfide
- Precipitation of anionic dietary chromogens.

Among the suggested mechanisms, precipitation of anionic dietary chromogens onto adsorped cations has been considered as the most suitable (Addy & Moran 1995; Watts & Addy 2001). The intensity of staining seems correlate with the frequency of intake

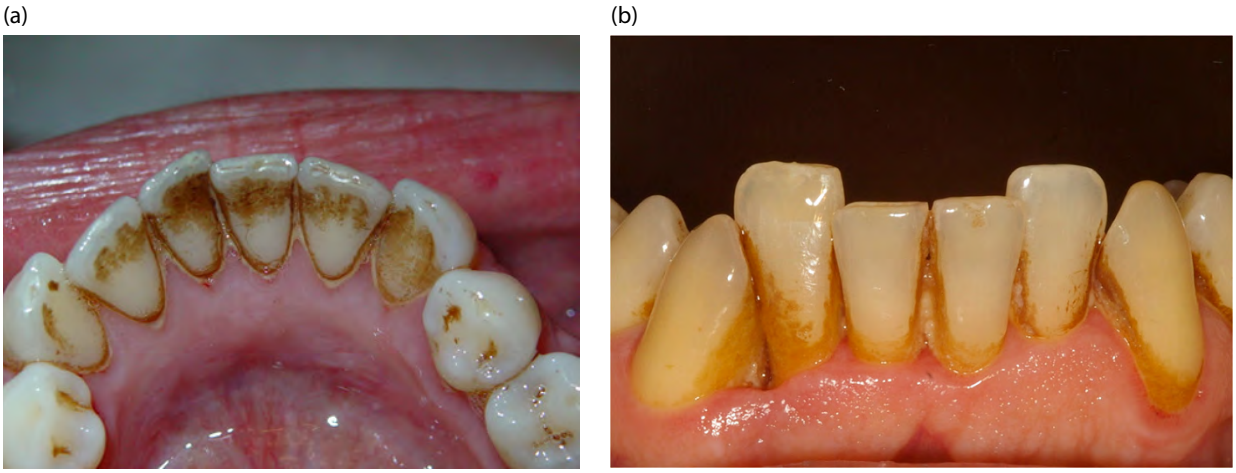

Fig. 29-8 Tooth staining after chlorhexidine use. (a) Lingual aspect. (b) Buccal aspect.

of chromogenic products, such as coffee, tea, wine, and tobacco; and also with the concentration of CHX in commercial formulations. In addition, a direct correlation has been observed between staining and antimicrobial effect (Addy *et al*. 1989; Claydon *et al*. 2001).

Usefulness and availability

The first CHX formulations in Europe were 0.2% mouth rinses in a hydroalcohol vehicle, and the first studies demonstrating antiseptic activity also evaluated 0.2% products (Löe *et al*. 1976). However, the CHX formulation that obtained the ADA seal was Peridex® (Zila Pharmaceuticals, Phoenix, AZ, USA), and was formulated at 0.12%. Since then, many CHX formulations have been marketed. However, it has been demonstrated that the mere presence of CHX in a product does not assure clinical activity (Harper *et al*. 1995; Herrera *et al*. 2003). Therefore, study models and/or clinical trials are needed to confirm that the activity of a new formulation is similar to that of the reference products already evaluated. In addition, concerns for adverse effects and the presence of alcohol in mouth rinses have led to new formulations without alcohol, with lower CHX concentration, and/or combined with other active agents.

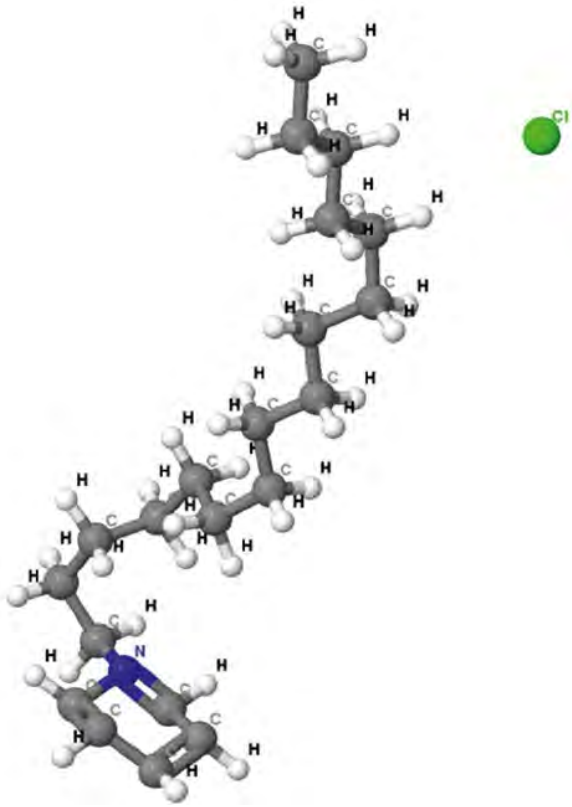

Fig. 29-9 Chemical structure of cetylpyridinium chloride (prepared with Jmol).

Quaternary ammonium compounds

- *Specific agents*. Benzylconium chloride and cetylpyridinium chloride (CPC) (Fig. 29-9).
- *Characteristics*. Monocationic agents that rapidly adsorb to oral surfaces (Bonesvoll & Gjermo 1978). Substantivity approaches 3–5 hours (Roberts & Addy 1981), due to rapid desorption, loss of activity, less retention or neutralization (Bonesvoll & Gjermo 1978). The mechanism of action relies on the hydrophilic part of the CPC molecule interacting with the cell membrane, leading to the loss of cell components, disruption of cell metabolism, inhibition of cell growth, and finally cell death (Merianos 1991; Smith *et al*. 1991). Because of the positive charge of this active hydrophilic part, other products in the formulation may easily inactivate the agent, making it crucial that a CPC formulation is evaluated for bioavailability.
- *Evaluation*. Three 6-month trials have been published, one for a 0.05% formulation (Allen *et al*. 1998) and two with 0.07% formulations (Mankodi *et al*. 2005b; Stookey *et al*. 2005). With the addition of four unpublished studies, a meta-analysis demonstrated significant benefits in terms of plaque (seven studies, three published; $P < 0.001$) and gingivitis (five studies, two published; $P = 0.003$), although high heterogeneity and variability were observed, including the evaluation of different formulations

(Gunsolley 2006). In another systematic review, the meta-analysis of the three 6-months studies revealed a WMD of 0.42 (P <0.00001; heterogeneity P = 0.06) for the Quigley and Hein plaque index at the final visit (Haps *et al*. 2008).

- *Limitations*. The safety of CPC formulations, marketed since 1940, have been demonstrated for concentrations 0.045–0.1% (Nelson & Lyster 1946; Margarone *et al*. 1984; Lin *et al*. 1991; Segreto 2004; Stookey 2004; Federal Register 2004). Adverse effects are less frequent than with CHX formulations, and include tooth and tongue staining, transient gingival irritation and aphthous ulcers in some individuals (Lobene *et al*. 1979). In addition, no significant changes in the oral microbiota or overgrowth of opportunistic species have been observed (Ciancio *et al*. 1975).
- *Usefulness, marketed*. with 0.05% CPC (Cepacol Combe, White Plains, NY, USA), with 0.045% CPC (Scope, Procter & Gamble, Cincinnati, OH, USA), and with 0.07% CPC (Crest ProHealth, Procter & Gamble, Cincinnati, OH, USA).

Hexetidine

- *Specific agents*. Hexetidine is a pyrimidine derivative.
- *Characteristics*. Shows antimicrobial properties against Gram-positive and Gram-negative bacteria and yeast (*Candida albicans*) (Menghini & Sapelli 1980; Jones *et al*. 1997). However, oral retention seems to be limited and antimicrobial activity may not last more than 90 minutes (McCoy *et al*. 2000).
- *Evaluation. In vitro* results suggest some bactericidal activity, even in biofilm models (Shapiro *et al*. 2002), but with a wide variability. In a systematic review (Afennich *et al*. 2011), six randomized controlled trials (RCTs) were identified, but the longest follow-up was 6 weeks; the results demonstrated heterogeneity and therefore, *in vivo* results have not demonstrated plaque inhibitory or antiplaque activity for hexetidine products.
- *Limitations*. Tooth staining, mucosal erosion, and parotid gland swelling, but with low frequency (Addy & Moran 1984; Yusof 1990; van der Weijden *et al*. 2010).
- *Usefulness, marketed*. Normally formulated at 0.1%, with many different brand names (Bactidol, Hexalen, Hexoral, Hextril, Oraldene, Oraldine, Oraseptic).

Povidone iodine

- *Specific agents*. Iodine is a recognized antibacterial agent, which is combined with a synthetic polymer, povidone.
- *Characteristics*. At 1% it has demonstrated substantivity of only 1 hour.
- *Evaluation*. Limited substantivity leads to a very limited plaque inhibitory action (Addy *et al*. 1977; Addy & Wright 1978). It has been evaluated combined with 1.5% of hydrogen peroxide (5% of povidone iodine), both short term (Maruniak *et al*. 1992) and for 6 months (Clark *et al*. 1989), combining rinsing and subgingival irrigation, with clear reductions of gingivitis (Greenstein 1999). Povidone iodine has also been used in the treatment of necrotizing gingivitis (Addy & Llewelyn 1978) and as an adjunct to scaling and root planing, which significantly decreased pocket depth but with only small clinical significance (Sahrmann *et al*. 2010).
- *Limitations*. No relevant side effects, but it may affect thyroid function.
- *Usefulness, marketed*. Betadine® (10% povidone iodine; still available), Perimed® (1.5% hydrogen peroxide with 5% of povidone iodine; no longer available).

Other evaluated products

- *Acidified sodium chlorite*. Suggested to have similar activity to CHX (Fernandes-Naglik *et al*. 2001), but with the potential to erode enamel (Pontefract *et al*. 2001).
- *Chlorine dioxide*. Frequently used against oral halitosis, its plaque-inhibitory and antiplaque effects have still to be assessed (Paraskevas *et al*. 2008; Shinada *et al*. 2010).
- *Salifluor*. 5n-octanoyl-3′-trifluormethylsalicylanilide was tested in the late 1990s with acceptable results (Furuichi *et al*. 1996; Nabi *et al*. 1996).
- *Polyhexamethylene biguanide hydrochloride*. Evaluated in study models in the early 2000s, at concentrations of 0.04–0.2%, demonstrating the capacity to inhibit plaque regrowth (Rosin *et al*. 2002; Welk *et al*. 2005).
- *Herbal products*. Herbal extracts of tea tree oil (*Melaleuca alternifolia*) have been evaluated, with conflicting results (Arweiler *et al*. 2000). Also, green tea extracts have been formulated in mouth rinse, but there is limited evidence available assessing their activity (Venkateswara *et al*. 2011).
- *Ethyl lauroyl arginate (LAE)*. LAE hydrochloride is a cationic surfactant, active against bacteria, algae, and fungi, by modifying the permeability of membranes. It is widely used in the food industry both as an antimicrobial agent and as a food preservative (E243) (Aznar *et al*. 2013). In humans, it is metabolized in lauric acid and arginine, and both are naturally present in food (Hawkins *et al*. 2009). In the oral cavity, LAE may create a barrier to prevent bacterial adhesion on tooth surfaces. Initial findings from short-term clinical studies have shown conflicting results: reductions in plaque levels and gingival inflammation after 4 weeks (Gallob *et al*. 2015); in periodontitis patients, after 3 months, similar reductions to those seen for the use of 0.12% CHX for bleeding and plaque (Pilloni *et al*. 2018); in experimental gingivitis, significant impact on plaque, but not enough to prevent the onset of gingival inflammation (Valor *et al*. 2018).

Future approaches

Future approaches for chemical biofilm control should be based on non-antimicrobial actions because of the problems associated with the excessive use of antimicrobials and the risk of an increase in the emergence of resistant strains.

- *Molecular signaling*. Because signaling molecules (such as acyl homoserine lactones) are involved in biofilm architecture and detachment, future treatment approaches may focus on quorum-sensing systems (Donlan & Costerton 2002). In addition, inhibitors of quorum-sensing processes may reduce the virulence of certain pathogens (Rasch *et al*. 2007; Harjai *et al*. 2010).
- *Inhibition of transcription genes*. If the genes that are activated or repressed during initial biofilm formation are identified and selectively targeted, this may inhibit biofilms formation (Donlan & Costerton 2002).
- *Probiotics and prebiotics*. The use of probiotic products (with putative beneficial bacterial species, such as *Streptococcus salivarius, Lactobacillus reuteri, Lactobacillus salivarius*), may have an effect on biofilm composition, either by competition or by release of bacteriocins. Some studies have reported a decrease in pathogenic species (Mayanagi *et al*. 2009) and some improvement in the levels of plaque and gingival inflammation (Krasse *et al*. 2006; Shimauchi *et al*. 2008; Harini & Anegundi 2010; Teughels *et al*. 2011; Iniesta *et al*. 2012; Montero *et al*. 2017). In addition, the use of prebiotic products, or the combination of prebiotic and probiotic formulations, may be relevant in influencing less pathogenic biofilms (Rosier *et al*. 2018).
- *Molecules interfering with bacterial adhesion*. LAE hydrochloride is an example of this mode of action.
- *Molecules interfering with the biofilm matrix*. Delmopinol is an example of this mode of action.

Delivery formats

Different formats are available to deliver agents for chemical plaque control: mouth rinses, gels, dentifrices, chewing gums, aerosols, varnishes, sustained release devices, lozenges, and irrigators (Addy & Renton-Harper 1996).

Mouth rinses

Mouth rinses are formulated with different ingredients, including colorings, flavorings, preservatives (sodium benzoate), stabilizers, and active agents.

Among the stabilizers, one of the most frequently used is alcohol. However, some controversy exists with regards to the inclusion of alcohol in mouth rinse formulations, because of the suggested association between alcohol and oropharyngeal cancer. However, critical assessment of the literature does not support this statement (Ciancio 1993; Claffey 2003), but mouth rinses containing alcohol should not be used by children, former alcoholics, and in patients with different conditions affecting the oral mucosae (e.g. lichen planus, leucoplakia). Other suggested problems associated with the presence of alcohol in mouth rinses are:

- Systemic toxicity in children: cases arising from swallowing alcohol-containing mouth rinses have been reported, but very infrequently (for review see Eley 1999).
- Intra-oral discomfort: probably concentration related (Bolanowski *et al*. 1995).
- Softening of composite hardness: this softening affect can be directly related to the percentage of alcohol in the mouth rinse (McKinney & Wu 1985; Penugonda *et al*. 1994).

Most agents for chemical plaque control have been formulated as mouth rinses, since this vehicle has a number of advantages:

- Favorable pharmacokinetics: easier to reach the effective dosage of the active agent.
- Can be used independently of the ability of the patient to perform tooth brushing.
- Allows access to difficult-to-reach areas, such as the tonsils, which can be reached by gargling.
- Easy to use and well accepted by patients.

Dentifrices

Dentifrices represent the ideal vehicle, especially from a preventive perspective, since they are used as an adjunct to the most frequently employed oral hygiene measure, which is toothbrushing. However, a number of disadvantages can be listed:

- Formulation of some active agents may be difficult.
- Pharmacokinetics are less predictable.
- Not possible to perform toothbrushing in some situations, thus limiting the use of a dentifrice: for example, patients with disabilities, after oral surgery, intermaxillary fixations, etc.
- Does not reach difficult-to-access areas, such as the tonsils or the dorsum of the tongue.

The ingredients in a dentifrice formulation are:

- *Abrasives*. These determine the consistency of the dentifrice and ease dental plaque and staining removal. However, higher dentifrice abrasivity does not seem to contribute to increased plaque removal with a manual toothbrush. It appears that the mechanical action provided by the use of a toothbrush is the main factor in the plaque-removing process (Paraskevas *et al*. 2006). The most common abrasives are calcium carbonate, alumina, dicalcium phosphate, and silica.

- *Detergent*. The most widely use is SLS, which provides some antimicrobial action (Jenkins *et al*. 1991a, b), although no evidence is available to support its effectiveness in plaque removal.
- *Thickeners*. These include silica and gums, and they influence the viscosity of the toothpaste.
- *Sweeteners*, such as sodium saccharin.
- *Humectants*. These prevent the toothpaste from drying up; glycerine and sorbitol are the most commonly used.
- *Flavorings*, such as mint, strawberry.
- *Coloring agents*.
- *Active agents*, including fluorides, triclosan, CHX (with some difficulties in the formulation, due to the interference with anionic detergents and with flavorings), CPC, and other active agents (anticalculus agents, whitening products, desensitizing agents).

Gels

Gels do not include abrasives or detergents. Active agents are formulated more easily in gels than in dentifrice, but disadvantages are similar: less predictable pharmacokinetics, impossible to use in some clinical situations, and lack of access to some difficult-to-reach areas.

CHX gels are available with different concentrations, including 0.1%, 0.12%, 0.2%, 0.5%, and 1%, to be used with toothbrushing or applied in trays. For tooth brushing, the amount of CHX delivered is not predictable (Saxen *et al*. 1976). When a gel is applied in a dental tray, a reduction in the levels of plaque and inflammation has been reported (Francis *et al*. 1987b; Pannuti *et al*. 2003; Slot *et al*. 2010), although the acceptance by patients with disabilities and therapy providers was not high (Francis *et al*. 1987a).

CHX gels may also be used for other purposes, such as the prevention of alveolitis after tooth extraction (Hita-Iglesias *et al*. 2008; Minguez-Serra *et al*. 2009). Its use has also been suggested as part of the protocol for full-mouth disinfection, including tongue brushing with a 1% CHX gel for 1 minute and subgingival irrigation of pockets with 1% CHX gel (Bollen *et al*. 1996, 1998). More recently, it has been evaluated in peri-implant mucositis therapy (Heitz-Mayfield *et al*. 2011), with limited effects.

Gels containing 0.4% stannous fluoride have also been evaluated, reporting reductions in gingival inflammation and in bleeding on probing (Tinanoff *et al*. 1989; Boyd & Chun 1994).

Chewing gums

CHX has been formulated in chewing gums for use as an adjunct to or even short-term replacement for mechanical plaque control. A reduction in the levels of plaque and gingival inflammation has been reported (Ainamo & Etemadzadeh 1987; Smith *et al*. 1996; Simons *et al*. 2001; Kolahi *et al*. 2008).

Varnishes

CHX varnishes have been used in the prevention of root caries (Clavero *et al*. 2006; Baca *et al*. 2009), although no solid evidence is available to support their use (Bader *et al*. 2001; Zhang *et al*. 2006).

Lozenges

Both CPC and CHX have been formulated as lozenges. For CPC lozenges, interactions with other ingredients of the formulation have been observed (Richards *et al*. 1996). Clinical use is associated with a reduction in levels of plaque and gingival inflammation, although smaller than those achieved with a CHX mouth rinse (Vandekerckhove *et al*. 1995). Reductions in plaque and gingivitis levels have also been reported for CHX lozenges. The mean plaque score was reduced by 62.8% (from 2.38 to 0.89; P <0.0001), after 1 week of usage (Kaufman *et al*. 1989).

Irrigators

The use of irrigators has been suggested to remove food debris from teeth and dental restorations. It may help to improve oral health in subjects not using interdental devices (Frascella *et al*. 2000). The use of irrigators is not associated with an improvement in plaque levels, but it may have some effect on gingival inflammation (Husseini *et al*. 2008). Different agents can be used with irrigators, and good results have been reported for CHX (Lang & Raber 1981).

Sprays

The advantage of aerosols is that the agent is used exactly where it is needed. However, the dosage is not predictable. Aerosols with 0.2% CHX have been used in patients with disabilities to prevent biofilm formation (Francis *et al*. 1987b; Kalaga *et al*. 1989b). Their use on all dental surfaces is associated with a reduction in plaque levels similar to that obtained with mouth rinsing, but the adverse effects are also the same (Francis *et al*. 1987b; Kalaga *et al*. 1989a). Recent evidence suggests that oral sprays are an acceptable delivery method for antiseptic agents (Zhang *et al*. 2019).

Sustained-release devices

CHX is also present in sustained release devices, designed with a therapeutic purpose, and includes chips, gels, and xanthan gels. A review of their effects can be found in Chapter 37.

Selection of delivery format

The most frequently used delivery formats for chemical biofilm control are dentifrices and mouth rinses, either alone or simultaneously. The obvious benefit

of dentifrice delivery is that no other delivery format is needed; a dentifrice is used by the majority of patients. However, mouth rinse delivery offers better distribution around the mouth (Serrano *et al*. 2015) and better pharmacokinetic properties (Cummins & Creeth 1992).

In clinical studies, mouth rinses normally show greater benefits in terms of plaque and gingival indices: in the systematic review by Serrano *et al*. (2015), the WMDs in the Turesky plaque index were 0.425 for dentifrices and 0.522 for mouth rinses, whereas for the modified gingival index (MGI) WMDs were 0.355 and 0.439, respectively. In the review by Figuero *et al*. (2020), the results in changes in plaque indices showed, again, a larger impact for mouth rinses ($n = 43$; standardized-WMD = −1.231; 95% CI [−1.490; −0.973]; $P < 0.001$) than for dentifrices ($n = 45$; standardized-WMD = −0.803; 95% CI [−1.054; −0.552]; $P < 0.001$), with the meta-regression showing a tendency towards statistically significant differences between dentifrices and mouth rinses (coefficient = 0.423; 95% CI [−0.169; 0.864]; $P = 0.059$). In addition, when plaque levels were assessed as percentage of sites with plaque, mouth rinses offered better results than dentifrices (27.70% versus 14.00%, respectively), with statistically significant differences in the meta-regression (coefficient = 13.80%; 95% CI [2.40%; 25.10%]; $P = 0.020$).

Therefore, some evidence suggests that the adjunctive use of mouth rinses may provide better outcomes than that of dentifrices (Figuero *et al*. 2020). However, the evidence is conflictive and statistically significant differences were only observed for secondary outcomes. In addition, direct comparisons between similar agents/formulations, delivered either as dentifrices or mouth rinses, are not available.

It has been suggested (Serrano *et al*. 2015), based on the reported findings, that mouth rinses may be the delivery format of choice for periodontitis patients, while dentifrices may be more suitable for less susceptible subjects, in which the added effect of chemical biofilm control is less relevant, and the lower cost of using only one product (namely, dentifrice) may be justified.

Clinical indications for chemical plaque control: selection of agents

As has been reviewed, different agents (alone or in combination) in different delivery formats and formulations are available for clinical use. In addition, many different indications have been proposed. Therefore, it may be challenging for the clinician to decide whether or not to prescribe a chemical oral hygiene product and, if the evaluation favors a prescription, which one should be prescribed, as well as which formulation, in which delivery format, at which dosage, and for how long. In this section, some recommendations are provided, based on the scientific evidence available. However, due to the limitations of the evidence, all suggestions should be viewed with caution and each clinical case considered individually.

Different clinical scenarios, depending on the duration of product usage and the main objective of the intervention, are considered: single use, short-term use (either with a preventive or a therapeutic aim), and long-term use (either for a preventive or a therapeutic aim).

Single use

Different objectives may be considered for a single use.

To decrease the bacterial load

CHX has been shown to reduce the presence of bacteria in aerosols generated during different oral interventions (e.g. instrumentation with sonic or ultrasonic devices), decreasing the risk of cross contamination in a dental setting (Stirrups, 1987; Worrall *et al*. 1987; Logothetis & Martinez-Welles 1995). Also, a single rinsing with essential oils has been shown to affect bacterial presence in aerosols (Fine *et al*. 1993).

To decrease the risk of bacteremia

Different studies have assessed the effect of CHX usage on the risk of bacteremia associated with dental interventions (scaling, tooth extraction), both by means of rinsing (Jokinen 1978; Rahn *et al*. 1995; Lockhart 1996; Brown *et al*. 1998; Tomas *et al*. 2007) or subgingival irrigation (MacFarlane *et al*. 1984). Other active agents have also been evaluated: essentials oils (Fine *et al*. 1993; DePaola *et al*. 1996; Fine *et al*. 2010) or povidone iodine, both as mouth rinse (Jokinen 1978) or subgingival irrigation (Rahn *et al*. 1995). However, after the evaluation of the available evidence, a recent consensus report concluded that CHX, used as an oral rinse, does not significantly reduce the level of bacteremia following dental procedures (Centre for Clinical Practice (NICE) 2008). In addition, the American Heart Association concluded: "topical antiseptic rinses do not penetrate beyond 3 mm into the periodontal pocket and, therefore, do not reach areas of ulcerated tissue where bacteria most often gain entrance to the circulation. On the basis of these data, it is unlikely that topical antiseptics are effective in significantly reducing the frequency, magnitude, and duration of bacteremia associated with a dental procedure" (Wilson *et al*. 2007).

To decrease the risk of infection of the surgical area

CHX has been evaluated as a preoperative measure before oral surgery, to decrease bacterial load and decrease the risk of postoperative infection (Worrall *et al*. 1987).

Summary: The general aim of single use is to reduce the bacterial load in the oral cavity before

an intervention. The highest bactericidal action is desirable and is demonstrated by CHX formulations both *in vitro* and *in vivo*. Because of the single use, side effects are not common and if present, they will rapidly disappear. In case of intolerance, other active agents may be considered, such as CPC (Pitten & Kramer 2001), essentials oils (Fine *et al*. 1993, 2010; DePaola *et al*. 1996), or povidone iodine (Jokinen 1978; Rahn *et al*. 1995).

Short-term use for the prevention of dental biofilm formation

In clinical situations in which mechanical control may be limited due to discomfort or postoperative instructions to avoid mechanical contact with a treated area, the use of chemical plaque control may have a preventive objective in a short-term basis. The most widely use agent for preventive indications (aiming to compensate for the limitations of mechanical biofilm control) is CHX, because side effects will be limited due to the short-term usage.

After subgingival instrumentation or periodontal surgery

When mechanical control may be limited due to discomfort or to postoperative instructions to avoid mechanical contact with the treated area (e.g. regenerative or mucogingival surgery), both CHX mouth rinses (Sanz *et al*. 1989; Christie *et al*. 1998; Eley 1999) and essential oils mouth rinses (Zambon *et al*. 1989; Laspisa *et al*. 1994) have demonstrated benefits. Use of antiseptic products should be maintained until mechanical biofilm control is again adequate.

The European Federation of Periodontology (EFP) S3 Level Clinical Practice Guideline (CPG), for the treatment of stage I–III periodontitis, included a recommendation of the adjunctive use (to subgingival instrumentation) of chlorhexidine mouth rinses in step 2 of periodontal therapy, which reads "adjunctive antiseptics may be considered, specifically chlorhexidine mouth rinses for a limited period of time, in periodontitis therapy, as adjuncts to mechanical debridement, in specific cases" (Sanz *et al*. 2020). The recommendation was based on a previously published systematic review (da Costa *et al*. 2017).

Prevention of postsurgical infection

When CHX rinses were used during postsurgical care, a lower infection rate (17 infections in 900 procedures, 1.89%) was observed, compared with procedures with no CHX as part of the postsurgical care (five infections in 153 procedures, 3.27%) (Powell *et al*. 2005). In addition, a lower incidence of post-extraction alveolitis has been reported with the use of a 0.2% CHX gel (Hita-Iglesias *et al*. 2008; Minguez-Serra *et al*. 2009) or with a 0.2% CHX rinse (Tjernberg 1979).

Patients with intermaxillary fixations

After bone fractures or after orthognathic or cosmetic maxillary surgeries, when no mechanical hygiene is possible, CHX mouth rinses have shown to be useful in biofilm formation prevention (Nash & Addy 1979).

Patients with mucosal or gingival acute infections

In these patients, pain precludes mechanical hygiene, and CHX mouth rinses may be useful in biofilm formation prevention (Eley 1999).

Short-term use for therapy

Other clinical situations may require the short-term use of antiseptic products with a therapeutic aim. The most widely used agent for therapeutic indications (aiming to control the pathogenic microorganisms) is CHX, since the risk of side effects of CHX usage will be limited due to the short-term usage. Side effects, if they appear, are easily reversible.

Gingivitis therapy

Chemical agents may have limited antimicrobial activity against an organized biofilm, because of the difficulties of penetration and action. Therefore, chemical agents should be used in conjunction with mechanical debridement. The recommended agent is a CHX mouth rinse (Hartnett & Shiloah 1991). Other agents have been evaluated in necrotizing gingivitis, such as oxygenating agents and iodine povidone (Wade *et al*. 1966; Addy & Llewelyn 1978).

Candidiasis therapy

CHX mouth rinses have been proposed as an alternative in candidiasis treatment (Ellepola & Samaranayake 2001; Torres *et al*. 2007). However, as sole therapy, complete resolution is not achieved, and it is more effective in combination with specific antifungal agents (e.g. itraconazole) (Simonetti *et al*. 1988). However, a possible interaction between CHX and nystatin has been proposed, due to the formation of a less soluble salt (Barkvoll & Attramadal 1989). Also, as part of candidiasis therapy, the immersion of the dental prosthesis in 0.2% CHX is effective in eliminating *Candida* spp. from the prosthesis (Olsen 1975; Uludamar *et al*. 2011). In cases of intolerance to CHX, CPC mouth rinses have been proposed as an alternative (Pitten & Kramer 2001).

Peri-implant mucositis therapy

Treatment strategies have been developed based on mechanical or chemical plaque control, alone or in combination, and some of them have been evaluated in RCTs. No additive effect (over mechanical

control) from the application of a CHX gel was observed (Thone-Muhling *et al*. 2010; Heitz-Mayfield *et al*. 2011), as was also true for irrigation of the sulcus (Porras *et al*. 2002). In one study, CHX irrigation provided better results that CHX rinsing (Felo *et al*. 1997). In home-use studies, an essential oil mouth rinse (Ciancio *et al*. 1995), a triclosan/copolymer dentifrice (Ramberg *et al*. 2009), and a 0.03% CHX and 0.05% CPC mouth rinse (Pulcini *et al*. 2019) have demonstrated better clinical results than the negative control.

Peri-implantitis therapy

Adjunctive CHX application in the treatment of peri-implantitis lesions has been shown to have only limited effects on clinical and microbiological parameters (Renvert *et al*. 2008).

In periodontitis therapy

The adjunctive use of antiseptics (especially CHX mouth rinses) has been evaluated, most frequently in the full-mouth disinfection approach (Quirynen *et al*. 1995, 2000; Greenstein 2002, 2004). The use of different CHX formulations (including mouth rinse, spray, irrigation, gel for the tongue dorsum) in addition to subgingival instrumentation within 24 hours showed additional benefits in some studies (Quirynen *et al*. 2000). However, systematic reviews have not confirmed these results, although modest benefits favoring full-mouth approaches were observed (Eberhard *et al*. 2008a, b; Lang *et al*. 2008). The use of CHX mouth rinse during the step 2 periodontal therapy may help in controlling the dental biofilm, resulting in additional benefits in terms of clinical and microbiological parameters (Faveri *et al*. 2006; Feres *et al*. 2009).

Long-term use for the prevention of dental biofilm formation

Patients carrying fixed or removable orthodontic appliances

The presence of these appliances makes mechanical control more difficult, facilitates plaque retention, and thus promotes gingivitis development (Ristic *et al*. 2007; Levin *et al*. 2008). Additionally, many orthodontic patients, especially children and adolescents, fail to floss because they find this procedure time-consuming and tedious in the presence of orthodontic arch wires (Alexander 1993). A common strategy to improve mechanical plaque removal in these patients is the addition, as part of the oral hygiene regimen, of a chemotherapeutic antimicrobial agent (Ainamo 1977). The efficacy of different active ingredients, such as CHX (Brightman *et al*. 1991; Anderson *et al*. 1997; Chin *et al*. 2006; Olympio *et al*. 2006), essential oils (Tufekci *et al*. 2008), amine/stannous fluoride (Ogaard *et al*. 2006), CPC (Herrera *et al*. 2018), or sanguinarine (Hannah *et al*. 1989) in the form of mouth rinses, toothpastes or gels, has been evaluated in clinical studies. Most of these clinical studies have reported significant benefits from the adjunctive use of these products, although the magnitude of the reported benefits might not have clear clinical relevance. In addition, the use of some of the formulations was associated with adverse effects (such as staining with the use of CHX).

Patients with disabilities

In patients with physical or mental disabilities, the use of CHX improves plaque and gingival health (Storhaug 1977). In these patients, a spray (0.2% CHX) is preferred (Francis *et al*. 1987a, b; Kalaga *et al*. 1989b; Clavero *et al*. 2003).

Patients with gingival overgrowth or enlargement

In these patients, mechanical control is more difficult and CHX mouth rinse may be helpful (O'Neil & Figures 1982; Saravia *et al*. 1990; Francetti *et al*. 1991).

Periodontitis patients

Together with an adequate professional supportive periodontal therapy program, chemical agents may be recommended to improve biofilm control and to decrease the risk of disease progression. A careful consideration of the risk-to-benefit ratio should be made, because these patients will be in supportive therapy for life. Lower dosage CHX mouth rinses have been evaluated and a formulation with 0.05% CHX and 0.05% CPC reported beneficial effects with limited adverse events (Soers *et al*. 2003; Santos *et al*. 2004; Quirynen *et al*. 2005; Escribano *et al*. 2010). Also, a dentifrice with triclosan and copolymer, evaluated for 2 years, demonstrated a significant reduction in the detection of deep pockets and sites with clinical attachment loss and bone loss (Rosling *et al*. 1997a, b; Bruhn *et al*. 2002).

In a systematic review (Figuero *et al*. 2020), the impact of chemical plaque control was compared between periodontitis patients with gingival inflammation and gingivitis patients. Changes in gingival indices tended to be greater in periodontitis patients ($n = 16$; standardized-WMD = −1.564; 95% CI [−2.197; −0.931]; $P < 0.001$) versus gingivitis patients (= 44; standardized-WMD = −1.289, 95% CI [−1.560; −1.018]; $P < 0.001$), but meta-regression did not find statistically significant differences between them (coefficient = −0.266; 95% CI [−1.027; 0.495]; $P = 0.487$).

The EFP S3 Level CPG, for the treatment of stage I–III periodontitis, included different recommendations on the adjunctive use (to mechanical supragingival biofilm control) of mouth rinses and dentifrices for gingival inflammation control, as part of the step

Supportive Periodontal Care. It was highlighted that "adjunctive measures, including antiseptic, may be considered in specific cases, as part of a personalized treatment approach" (Sanz *et al*. 2020). Among the recommended agents, CHX, essential oils, and cetylpyridinium chloride were listed for mouth rinse formulations, and CHX, triclosan-copolymer, and stannous fluoride-sodium hexametaphosphate, for dentifrice formulations.

Patients with dental implants

The use of different agents (CHX, triclosan, stannous fluoride, essentials oils) has been suggested to favor biofilm control and decrease the risk of peri-implant diseases (Ciancio *et al*. 1995; Di Carlo *et al*. 2008; Sreenivasan *et al*. 2011). In RCTs, triclosan/copolymer significantly improved clinical and microbiological variables, as compared with a fluoride dentifrice, after 6 months (Sreenivasan *et al*. 2011). A toothpaste containing 0.3% triclosan was more effective than a toothpaste without triclosan in maintaining a healthy peri-implant environment around treated implants and implants with no history of peri-implantitis during a 2-year maintenance program (Stewart *et al*. 2018); conversely, no influence in implant survival and clinical variables was observed for the use of 0.12% CHX mouth rinses in a 5-year study (Truhlar *et al*. 2000).

General population

The main aim is to allow for the presence of a biofilm in equilibrium with the host response to maintain periodontal health. Different agents have demonstrated an antiplaque effect in 6-month trials, including mouth rinses with CHX (Gunsolley 2006), with essentials oils (Stoeken *et al*. 2007), with delmopinol (Addy *et al*. 2007), with CPC (Gunsolley 2006), or with dentifrices with triclosan and copolymer (Hioe and van der Weijden 2005; Gunsolley 2006), and with stannous fluoride (Gunsolley 2006; Paraskevas & van der Weijden 2006).

The benefit of the daily usage of antiseptic products in a general population is a subject of controversy. However, the results of available studies reflect clinical benefits beyond those obtained with improvement in mechanical oral hygiene due to oral hygiene instructions. As suggested by the systematic review by Gunsolley (2006), reductions observed in the placebo groups in plaque (15.7, standard deviation SD = 18.7) and gingivitis (18.5, SD = 15.6) are associated with the Hawthorne effect and to oral hygiene instructions, and should mimic efficacy of oral hygiene instructions provided in clinical practice. The added benefit of the addition of CHX or essentials oils mouth rinses were evident and significant (for CHX 40.4, SD = 11.5 in plaque and 28.7, SD = 6.5 in gingivitis; for essentials oils, 27.0, SD = 11.0 and 18.2, SD = 9.0, respectively).

Another relevant question is which product for chemical biofilm control is the most efficacious. As discussed before, the answer should be different for dentifrices and for mouth rinses, and it is based on the results of two systematic reviews with conventional meta-analysis (Serrano *et al*. 2015; Figuero *et al*. 2020) and two with network meta-analyses (Escribano *et al*. 2016; Figuero *et al*. 2019).

For mouth rinses, in the systematic review by Figuero *et al*. (2020), 11 different mouth rinse formulations were included, with a large variability in the number of studies testing each formulation. The studies showing the largest impact on gingival inflammation indices, providing that more than one study was available, were essential oils (standardized-WMD = 2.248, $n = 10$), cetylpyridinium chloride (standardized-WMD = 1.499, $n = 5$), and CHX at high concentration (standardized-WMD = 1.144, $n = 5$). In network meta-analyses, CHX and essential oil mouth rinses were ranked as the most efficacious agents in terms of changes in plaque and gingival indices (Escribano *et al*. 2016; Figuero *et al*. 2019).

For dentifrices, in the systematic review by Figuero *et al*. (2020), 14 different dentifrice formulations were considered, also with a large variability in the number of available studies. The formulations showing the largest impact on gingival inflammation indices, providing that more than one study was available, were stannous fluoride with sodium hexametaphosphate (standardized-WMD = 1.503, $n = 2$), triclosan and copolymer (standardized-WMD = 1.313, n–18), and CHX (standardized-WMD = 1.278, $n = 2$). In network meta-analyses, CHX and triclosan and copolymer were the most effective agents for plaque reduction, but no clear differences were observed for gingival index control (Escribano *et al*. 2016; Figuero *et al*. 2019).

Long-term use for the prevention of other oral conditions

Predisposed patients, with high risk of suffering oral infections

In patients with blood dyscrasia who are immunesuppressed, the use of CHX mouth rinses may help to prevent oral or systemic complications, but they may not be useful once the infection appears (Eley 1999). In patients with mechanical ventilation, reduction of aerobic pathogens in the oropharyngeal tract was observed in patients using a CHX gel (Fourrier *et al*. 2005). Studies with CHX have demonstrated its capacity to prevent oral complications, such as the occurrence of chronic or opportunistic infections, including *Candida* spp. infections in high-risk patients (irradiated patients, patients in chemotherapy, or bone marrow transplant recipients) (for review, see Addy & Moran 1997).

Oral mucositis prevention (associated with radiation or chemotherapy in head and neck cancer patients)

CHX rinses have proposed as part of combined treatments to prevent or treat oral mucositis. CHX mouth rinses in the prevention of oral mucositis have been evaluated in numerous RCTs (Ferretti *et al*. 1990; Spijkervet *et al*. 1990; Epstein *et al*. 1992; Foote *et al*. 1994; Dodd *et al*. 1996; Pitten *et al*. 2003; Lanzos *et al*. 2010, 2011), but the outcomes were quite different. Seven studies were included in a meta-analysis (Stokman *et al*. 2006) that showed no effect of CHX in the prevention of mucositis in chemotherapy and radiotherapy patients (odds ratio 0.7; 95% CI 0.43–1.12).

Caries prevention

CHX use has been shown to reduce counts of *Streptococcus mutans* in at-risk patients (Ullsfoss *et al*. 1994; Quirynen *et al*. 2005). The best vehicle was varnish, followed by gel and mouth rinse (Emilson & Fornell 1976; Emilson 1994). Also, a reduction in caries incidence was reported in dentifrice with sodium fluoride (Dolles & Gjermo 1980; FDI Commission 2002a). Based on the previous findings, the use of CHX and fluoride together was suggested, but different studies reported poorer results for CHX formulations with sodium fluoride (Shapiro *et al*. 2002; Herrera *et al*. 2003). Essential oil mouth rinses have also been shown to reduce *S. mutans* levels (Fine *et al*. 2000; Agarwal & Nagesh 2011), but no studies on caries incidence are available. Dentifrices with triclosan and copolymer or a zinc salt, have demonstrated superior anticaries activity than fluoride dentifrices (Panagakos *et al*. 2005), even in long-term studies (Mann *et al*. 2001). In high-risk patients, amine and stannous fluoride may also be recommended, based on their proven remineralization and anticaries action (Tinanoff *et al*. 1980; Paraskevas *et al*. 2004).

Candidiasis prevention

CHX has been evaluated with regards to candidiasis prevention in patients with systemic diseases and in patients with a dental prosthesis (Ferretti *et al*. 1987, 1988; Toth *et al*. 1990; Barasch *et al*. 2004; Elad *et al*. 2006).

Prevention of recurrent aphthous ulcers

CHX use may reduce the incidence, duration, and severity of ulcers, including in patients with fixed orthodontic appliances (Shaw *et al*. 1984). Triclosan formulations may also decrease the incidence of oral ulcers (Skaare *et al*. 1996).

Halitosis therapy and secondary prevention

Different chemical agents and formulations have been evaluated, with two main aims: antibacterial and interference with volatilization of odoriferous compounds. Among the most evaluated agents, the following may be highlighted: essential oils mouth rinses (Pitts *et al*. 1983; Kozlovsky *et al*. 1996); triclosan with zinc or copolymer (van Steenberghe 1997; Sharma *et al*. 1999; Niles *et al*. 2003; Hu *et al*. 2005); or CHX, especially if combined with zinc salts and CPC (Roldan *et al*. 2003b; Winkel *et al*. 2003; Roldan *et al*. 2004). In order to be effective, these agents need to be used in conjunction with adequate oral hygiene and tongue scrapping or brushing (Roldan *et al*. 2003a). This topic is covered in detail in Chapter 28.

Conclusion

The main aim of supragingival biofilm control would be to allow for the presence of a biofilm in equilibrium with the host response, in order to maintain a health status. Due to the limitations of mechanical biofilm control, chemical control has been extensively evaluated and is widely used.

Although different vehicles are available to deliver the active agents, two of them can be highlighted: mouth rinses, due to the favorable pharmacokinetics and the ease of use, and dentifrices, due the concomitant use with tooth brushing, their pharmacokinetic profiles are less favorable and they are more difficult to formulate.

Most of the agents are antimicrobials, but other mechanisms of action have also been proposed and some marketed effective agents are not antimicrobials (e.g. delmopinol).

In the evaluation of the different agents and formulations, 6-month, home-use, RCTs provide the highest level of evidence, especially when their results are pooled in systematic reviews with meta-analyses. For mouth rinses, those showing the largest impact on gingival inflammation indices were essential oils, cetylpyridinium chloride, and CHX, at high concentrations; CHX and essential oil mouth rinses were the most efficacious agents in terms of changes in plaque and gingival indices (see Table 29-1). For dentifrices, stannous fluoride with sodium hexametaphosphate, triclosan, and copolymer, and CHX were the formulations that showed the largest impact on gingival inflammation indices; CHX and triclosan with copolymer were the most effective agents for plaque reduction, but no clear differences were observed for gingival index control (see Table 29-2).

However, CHX products are not free of adverse effect, especially tooth staining. Therefore, in a clinical situation in which the product is needed for a prolonged period of time, the risk-to-benefit ratio should be evaluated. In some clinical situations, the benefits will compensate for the adverse effects (staining), such as in patients with disabilities or with high systemic risk. In clinical scenarios in which the benefits do not compensate for the adverse effects, other alternatives with less effect but also with fewer adverse events should be considered.

Table 29-1 Summary of meta-analyses of 6-month, home-use, randomized clinical trials: plaque levels.

Active agent (delivery format)	Study	*n*	WMD/ SMD	*P* value	95% CI	Heterogeneity	
						P value, I^2	Method
Chlorhexidine (mouth rinse)	Gunsolley (2006)	6	1.040	*P* <0.001	NA	Low, I^2 <25%[a]	Fixed??
	Serrano *et al*. (2015)	3	0.640	*P* = 0.000	0.75–0.52	*P* = 0.149, I^2 = 47.4%	Fixed

Chapter 30

Non-Surgical Therapy

Jan L. Wennström and Cristiano Tomasi

Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

According to the clinical guidelines for the treatment of patients with periodontitis stages I–III by the European Federation of Periodontology (Sanz *et al*. 2020), treatment should be given according to a pre-established stepwise approach. Hence, whereas *the first step* in the treatment is directed towards motivation and behavioral changes to achieve adequate self-performed oral hygiene practices and the control of local and systemic modifiable risk factors, *the second step* is focused on professional interventions aimed at reducing/eliminating the subgingival biofilm and calculus.

The second step of treatment involves various non-surgical means to control the subgingival infection causing pathologic lesions in the tooth supporting tissues. Pocket/root instrumentation, combined with effective self-performed supragingival plaque control measures, serves this purpose by altering the subgingival ecology through disruption of the microbial biofilm, reduction of the amount of bacteria, and suppression of the inflammation. A variety of instruments and approaches to treatment may be utilized in non-surgical therapy.

This chapter outlines the various means and methods used in non-surgical periodontal therapy and their respective merits, shortcomings, and clinical efficacy. Considerations in relation to the selection of instruments and treatment approach are also addressed, as well as re-evaluation after the initial phase of non-surgical therapy.

Goal of non-surgical pocket/root instrumentation

Periodontitis is strongly associated with the presence of bacterial biofilms and dental calculus on root surfaces. Hence, the ultimate goal of non-surgical pocket/root instrumentation is to render the root free from microbial deposits and calculus. However, several *in vitro* (e.g. Breininger *et al*. 1987; Rateitschak-Pluss *et al*. 1992) and *in vivo* studies (e.g. Waerhaug 1978; Eaton *et al*. 1985; Caffesse *et al*. 1986; Sherman *et al*. 1990; Wylam *et al*. 1993) have shown that complete removal of hard and soft deposits is not a feasible objective of closed pocket/root instrumentation, even with the most meticulous scaling and root planing procedures (SRP). Nevertheless, non-surgically performed

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

SRP is an effective treatment modality for periodontal disease, as demonstrated by the marked reduction in clinical signs and symptoms of the disease following treatment (e.g. van der Weijden & Timmerman 2002; Suvan *et al*. 2020). Taken together, these observations indicate that there may exist an individual threshold level of remaining bacterial load following instrumentation below which the host can cope with the infection, and hence the goal of non-surgical pocket/root debridement is to reach below this threshold level for all pathologic tooth sites. Besides the quantity and quality of the remaining biofilm, host-related and modifiable environmental factors are to be recognized in this respect, for example diabetes, smoking, and stress. Although it is not feasible by probing the root surface to determine if adequate debridement has been achieved (Sherman *et al*. 1990), clinical signs of resolution of the inflammatory lesion (e.g. lack of bleeding on probing, increased tissue resistance to probing or "pocket closure") are indeed useful assessments to indicate sufficient removal of subgingival biofilms and calculus. Nonetheless, from a practical standpoint, if calculus is detected clinically, it should be removed.

Debridement, scaling, and root planing

Kieser (1994) proposed that, in preference to the traditionally practiced combination of scaling and root planing (SRP), pocket/root instrumentation should be performed as three separate stages of treatment – *debridement*, *scaling*, and *root planing* – with objectives pursued in an orderly sequence. According to the author, *debridement* is defined as instrumentation for disruption and removal of microbial biofilms, *scaling* instrumentation for removal of mineralized deposits (calculus), and *root planing* instrumentation to remove "contaminated" cementum and dentin in order to restore the biologic compatibility of periodontally diseased root surfaces. Furthermore, it was advocated that the healing obtained following pocket/root debridement should be clinically assessed before any repeated instrumentation efforts, or proceeding to the next stage of instrumentation. Although the intention of the various stages of instrumentation is different, overlap to some degree is of course inevitable.

Since periodontal diseases are infections caused by bacteria residing in subgingival biofilms, the need to lower the microbial load by disruption/removal of subgingival biofilms is indisputable. Calculus does not in itself induce inflammation, but has a deleterious effect because of its ability to provide an ideal surface for microbial colonization (Waerhaug 1952). In fact, it has been demonstrated that epithelial adherence to subgingival calculus can occur following its disinfection with chlorhexidine (CHX) (Listgarten & Ellegaard 1973). Thus, the rationale for the removal of calculus relates to eliminating, as far as possible, surface irregularities harboring pathogenic bacteria.

The rationale for performing root planing was originally based on the concept that bacterial endotoxins penetrate into the cementum (Hatfield & Baumhammers 1971; Aleo *et al*. 1974), and for this reason it was thought necessary to remove not only biofilms and calculus but also underlying cementum. However, evidence gained from experimental studies demonstrated that endotoxins were only loosely adherent to the surface and did not penetrate into the cementum (Hughes & Smales 1986; Moore *et al*. 1986; Hughes *et al*. 1988; Cadosch *et al*. 2003). Furthermore, animal and human studies revealed similar clinical and histologic healing following treatment of infected root surfaces, previously exposed to the periodontal pocket, in conjunction with flap surgery by polishing only with a low-abrasive paste as following extensive SRP, provided supragingival hygiene was meticulous (Nyman *et al*. 1986, 1988). Hence, aggressive tooth substance removal does not seem warranted and pocket/root instrumentation should preferably be carried out with instruments that cause minimal root substance removal, but are effective in disrupting the biofilm and removing calculus.

Instruments used for non-surgical pocket/root debridement

Non-surgical periodontal treatment may be carried out using various types of instruments, for example hand instruments, sonic and ultrasonic instruments, air polishing, and ablative laser devices.

Hand instruments

The use of traditional hand instruments of steel allows good tactile sensation, but tends to be more time consuming than other methods, and requires correct and frequent instrument sharpening. A hand instrument is composed of three parts: the working part (the blade), the shank, and the handle (Fig. 30-1). The cutting edges of the blade are centered over the long axis of the handle in order to give the instrument proper balance. The blade is made of carbon steel or stainless steel. Instruments with titanium, plastic, or carbon fiber blades are also available and used for bacterial

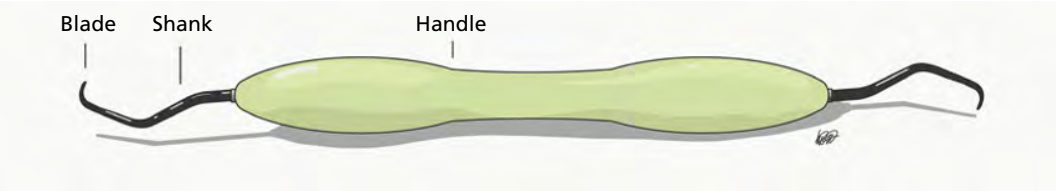

Fig. 30-1 Curette demonstrating the handle, shank, and blade.

biofilm and calculus removal on dental implant surfaces. Hand instruments are categorized based on the design of the blade. The most common categories of hand instruments are sickles and curettes.

A *sickle* has either a curved or a straight blade with a triangular cross-section and two cutting edges (Figs. 30-2, 30-3). The "facial" surface between the two cutting edges is flat in the lateral direction but may be curved in the direction of its long axis. The "facial" surface converges with the two lateral surfaces of the blade. Sickles are mainly used for debridement/scaling supragingivally but may be used also subgingivally at tooth sites with shallow pockets.

Fig. 30-2 Working end of a sickle, which has a triangular cross-section and two cutting edges.

Curettes are instruments used for debridement and scaling, both supra- and subgingivally (Fig. 30-3). The working part of the curette is the spoon-shaped blade that has two curved cutting edges, united by the rounded toe. The curettes are usually made "double-ended" with mirror-turned blades. The length and angulation of the shank as well as the dimensions of the blade differ between different brands of instruments (Fig. 30-4). Curettes with extended shanks and mini-blades have been designed to improve the efficacy of subgingival instrumentation in deep and narrow pockets. In addition, the availability of double-ended universal curettes with double cutting blades has markedly reduced the number of instruments needed. In fact, with only two types of such curettes (e.g. LM Dual Gracey™ curettes; Syntette™ and Syntette™ Anterior) the entire dentition may be properly reached for subgingival debridement. The tip of these instruments is designed with two elliptical cutting edges that allows for treatment of both mesial and distal tooth surfaces (Fig. 30-3).

Use of curettes for subgingival debridement/scaling

Subgingival instrumentation should preferably be performed under local anesthesia. The root surface of the diseased site is explored with a probe to identify (1) the probing depth, (2) the anatomy of the root surface (irregularities, root furrows, open furcations, etc.), and (3) the location of the calcified deposits.

The type of hand instrument most suitable for subgingival debridement is the curette. The angulation of the cutting edge of the curette to the tooth surface influences the efficiency of debridement. The optimal angle is approximately 80° (Fig. 30-5c). Too obtuse an

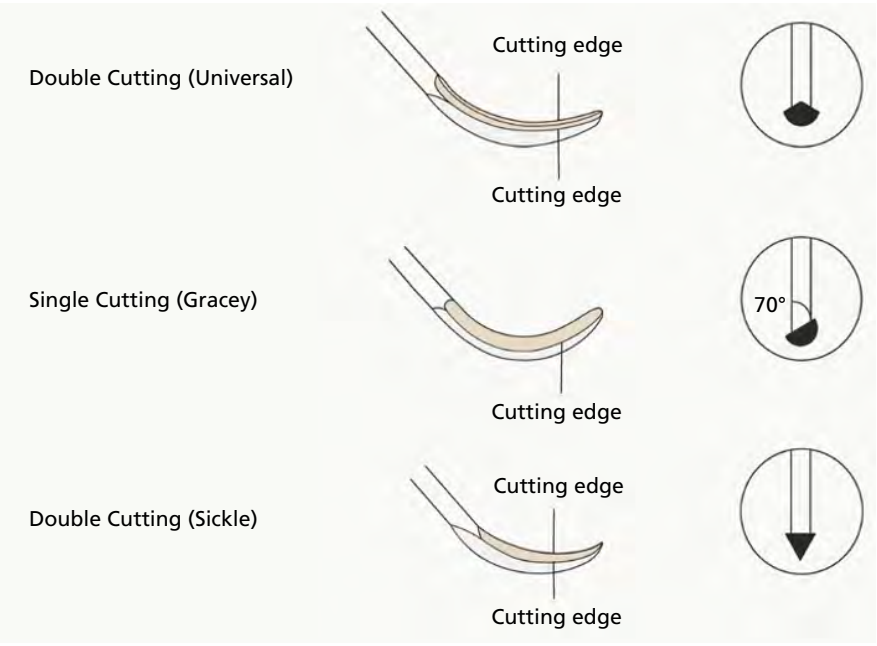

Fig. 30-3 Examples of the working end of instruments and their design with cutting edges.

Fig. 30-4 Selection of instruments with varying shank configurations to facilitate debridement of different areas of the dentition.

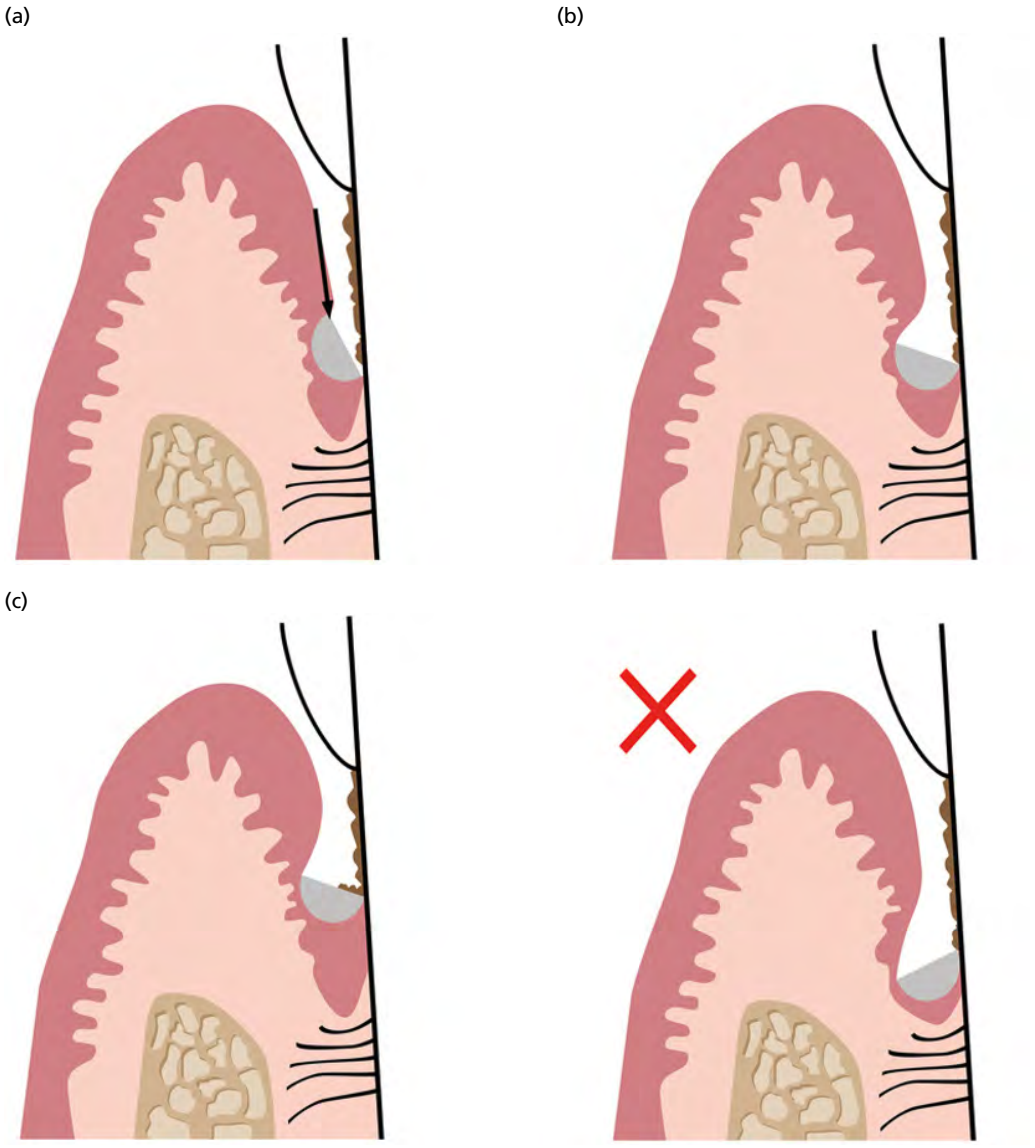

Fig. 30-5 (a) Curette is inserted into the periodontal pocket. Note the near 0° angulation of the face of the curette against the root surface to facilitate access of the pocket. (b) Bottom of the periodontal pocket is identified with the distal edge of the blade of the curette. (c) Curette is turned to a proper cutting position for scaling. Blade is moved along the root surface in a scaling stroke to remove calculus. (X) A too obtuse or acute angulation will result in ineffective calculus removal.

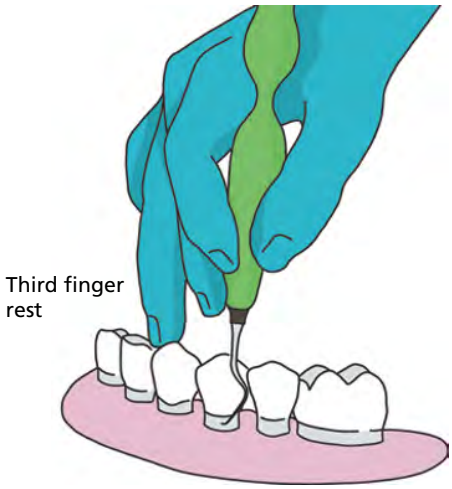

Fig. 30-6 A modified pen grasp and "third finger rest" in the premolar and molar region of the mandible.

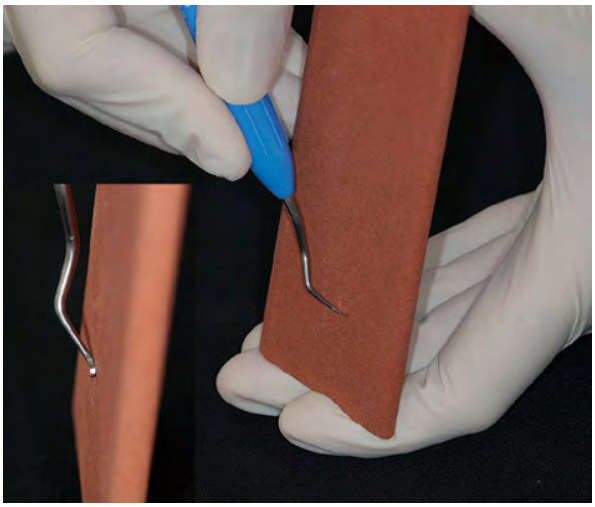

Fig. 30-7 Sharpening of a curette. The original geometry of the cutting edge must be maintained during the sharpening procedure.

angle, as shown in Fig. 30-5X, or too acute an angle will result in ineffective removal and burnishing of subgingival calculus deposits.

The instrument is held in a modified pen grasp and the blade inserted into the periodontal pocket with the face of the blade parallel to and in light contact with the root. It is important that all root surface instrumentation is performed with a proper finger rest. This implies that one finger – the third or the fourth – must act as a fulcrum for the movement of the blade of the instrument (Fig. 30-6). A proper finger rest serves to (1) provide a stable fulcrum, (2) permit optimal angulation of the blade, and (3) enable the use of wrist–forearm motion. The finger rest must be secured as close as possible to the site of instrumentation to facilitate controlled use of the instrument.

After the base of the periodontal pocket has been identified with the lower edge of the blade, the instrument is turned into a proper working position: that is, the shank is parallel to the long axis of the tooth (Fig. 30-5). The grasp of the instrument is tightened somewhat, the force between the cutting edge and the root surface is increased, and the blade is moved in a coronal direction. Strokes must be made in different directions to cover all aspects of the root surface (cross-wise, back and forth) but, as stated previously, strokes should always start from an apical position and be guided in a coronal direction. The probe is inserted into the pocket again and the surface of the root assessed anew for the presence of calculus.

Frequent sharpening of the cutting edge of the instrument is necessary to obtain efficient calculus removal. The angle between the face and the back of curettes must be maintained at approximately 70° during sharpening (Fig. 30-7). A greater angle will result in dulling of the cutting edge, whereas a more acute angle results in a fragile and easily worn cutting edge. A new generation of hand instruments that have sharpen-free blades are now available.

Sonic and ultrasonic instruments

A common alternative to hand instrumentation for non-surgical periodontal therapy is the use of sonic and ultrasonic instruments. Sonic devices use air pressure to create mechanical vibration that in turn causes the instrument tip to vibrate; the frequencies of vibration range from 2000 to 6000 Hz (Gankerseer & Walmsley 1987; Shah *et al*. 1994). Ultrasonic scalers convert electrical current into mechanical energy in the form of high-frequency vibrations at the instrument tip; the vibration frequencies range from 18 000 to 45 000 Hz with an amplitude range of 10–100 µm.

There are two types of ultrasonic scalers: magnetostrictive and piezoelectric. In *piezoelectric scalers* the alternating electrical current causes a dimensional change in the handpiece that is transmitted to the working tip as vibrations. The pattern of vibration at the tip is primarily linear. In *magnetostrictive scalers* the electrical current produces a magnetic field in the handpiece that causes the insert to expand and contract along its length and in turn causes the insert to vibrate. The pattern of vibration at the tip is elliptical. Modified sonic and ultrasonic scaler tips, for example the tiny, thin, periodontal probe type (Fig. 30-8), are available for use in deep pockets.

Wear of the ultrasonic tip will affect the working performance of the ultrasonic instrument and therefore the degree of loss of tip dimension should be checked regularly (Fig. 30-9). A 1 mm wear of the tip will reduce the amplitude of the tip movement by more than half (Lea et al. 2006). The same effect is obtained if too much pressure (50 g) is applied to the instrument. Water is typically used as coolant during instrumentation, but the use of antiseptic solutions such as CHX or povidone-iodine have also been proposed. A potential hazard for the operator with the use of these devices is the production of contaminated aerosol due to the high vibration frequency (Timmerman *et al*. 2004).

Fig. 30-8 Inserts of different length and curvature for piezoelectric (left) and magnetostrictive (right) ultrasonic devices.

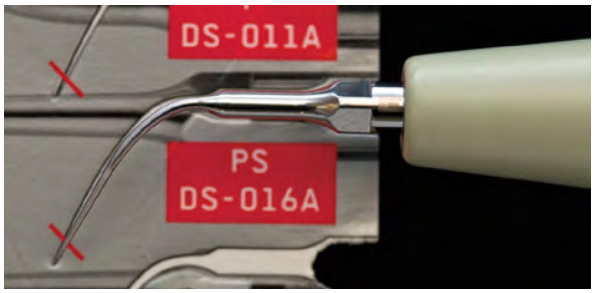

Fig. 30-9 Control of wear of the piezoelectric ultrasonic tip. The red line marks the level of wear when the tip should be discarded because of loss of instrument efficacy.

Another type of ultrasonic instrument is the Vector system (Sculean *et al*. 2004; Guentsch & Preshaw 2008) which uses a working frequency of 25 000 Hz and a coupling at the head of the handpiece to transfer energy indirectly to the working tip, providing an amplitude of movement of 30–35 µm. These instruments are cooled by a water-based medium containing polishing particles of various sizes dependent on the therapeutic indication. The amount of contaminated aerosol is said to be reduced compared to that produced by other ultrasonic or sonic devices.

Air-polishing devices

For removal of soft deposits (plaque and debris) from tooth surfaces, air-polishing devices may be used. These instruments are effective in the supragingival area to remove staining and plaque, with a reduced working time compared to other polishing procedures. The introduction of low-abrasive powders (i.e. glycine and erythritol) and the development of devices with a subgingival nozzle have opened the possibility of using air-polishing in subgingival instrumentation (Fig. 30-10). A specially designed subgingival nozzle delivers the glycine powder/air spray perpendicularly to the root surface, while water is sprayed in the apical direction. In addition, the effective working pressure is reduced compared with that of supragingivally applied air polishing. Bacterial biofilms on root surfaces are effectively removed by glycine powder/air polishing without causing damage to the root surface (Petersilka 2011; Bozbay *et al*. 2018). However, due the inability of glycine powder/air polishing to remove calculus, air-polishing should only be considered as a potentially adjunctive measure to hand or machine-driven instrumentation in the initial phase of periodontal therapy.

Ablative laser devices

A laser is a device that produces coherent electromagnetic radiation. Laser radiation is characterized by a low divergence of the radiation beam and, with few exceptions, a well-defined wavelength. The term laser is well known as the acronym for "light amplification by stimulated emission of radiation".

Ablative laser therapy has bacteriocidal and detoxification effects, is capable of removing bacterial biofilm and calculus with extremely low mechanical stress and no formation of a smear layer on root surfaces, and can remove the epithelium lining and inflamed tissue within the periodontal pocket (Ishikawa *et al*. 2009). However, with regard to the removal of inflamed tissue, studies have shown that curettage of the soft tissue walls has no added benefit over SRP (Lindhe & Nyman 1985).

ErbiumYAG (Er:YAG) lasers are capable of effectively removing calculus from the root surface. To reduce potential damage to the root surface, some Er:YAG laser devices are equipped with a feedback system based on a diode laser that activates the main laser irradiation only if calculus is detected. Er:YAG laser irradiation energy is absorbed by water and organic components of the biologic tissues, which raises the temperature and causes water vapor production, and thus an increase in internal pressure within the calculus deposits. The resulting expansion of the calculus deposits causes their separation from the root surface. Inadvertent irradiation and reflection from shiny metal surfaces may damage a patient's eyes, throat, and oral tissues other than the targeted area. Therefore, care must be taken when using these devices and both patient and operator

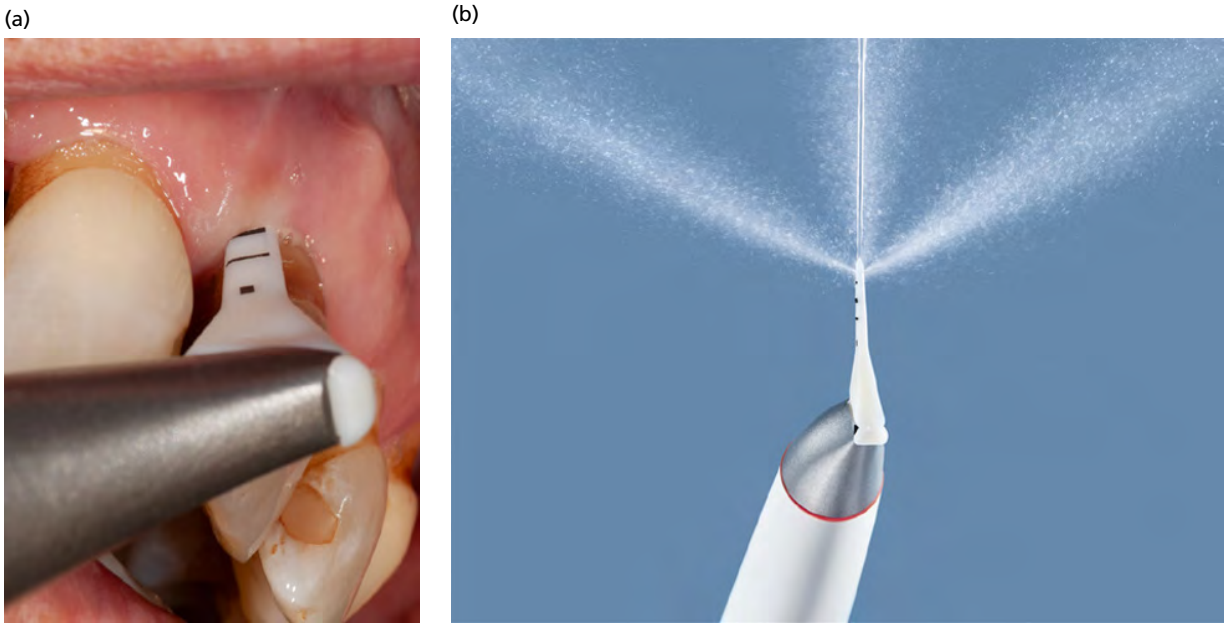

Fig. 30-10 (a) The specially designed subgingival nozzle applied for debridement of periodontal pockets by glycine powder/air spray polishing. (b) Lateral direction of powder/air jet while water jet is apically directed. (Source: Reproduced with permission from EMS, Nyon, Switzerland.)

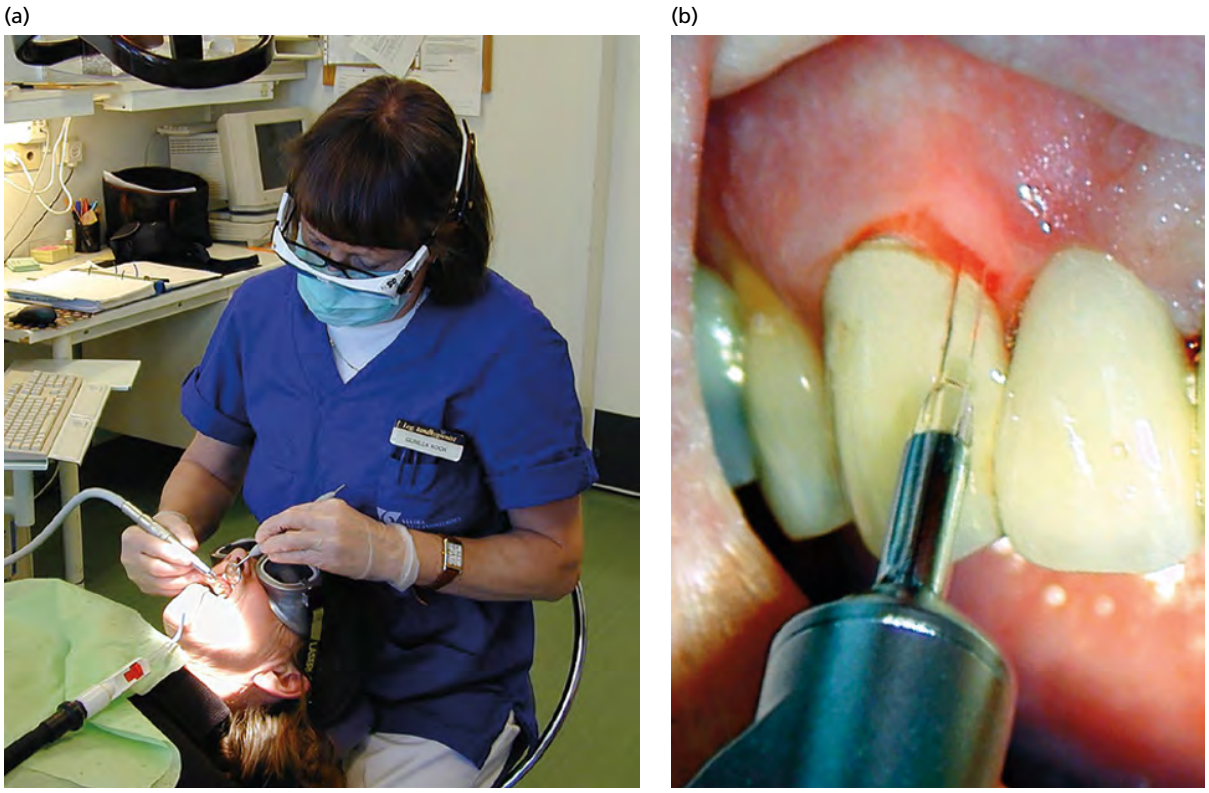

Fig. 30-11 (a) Using a laser in periodontal treatment: patient and operator must wear protective eyeglasses. (b) Er:YAG laser tip inserted into the pocket and activated.

must use protective eyeglasses (Fig. 30-11). There may also be a risk of excessive tissue destruction from direct ablation and thermal side effects.

Other types of lasers such as carbon dioxide lasers, diode lasers, and Nd:YAG lasers are not effective in removing calculus and hence, their use in periodontal therapy has been primarily as an adjunct therapy to SRP. Carbon dioxide lasers, when used with relatively low energy output in a pulsed and/or defocused mode, have root conditioning, detoxification, and bactericidal effects on contaminated root surfaces. Diode lasers of different wavelength have been introduced as an adjunctive measure to mechanical subgingival debridement to detoxify the root surface or

in photodynamic therapy to reduce bacterial load. In photodynamic therapy a photoactive compound such as toluidine blue is placed in the pocket and activated with a laser in order to produce free radical ions that have a bactericidal effect (Ishikawa *et al*. 2009). Another potential application for diode lasers is as low-level laser therapy (LLLT), which may stimulate cell proliferation and promote wound healing (Walsh 1997).

Approaches to subgingival debridement

The traditional modality of non-surgical therapy as an initial periodontal treatment phase is pocket/root instrumentation, including root planing, by jaw quadrant or sextant, depending on the extent and severity of the disease, at a series of appointments (Badersten *et al*. 1984). However, various other treatment protocols have also been proposed in the literature as alternatives to this conventional staged approach of SRP for periodontal infection control. In order to prevent re-infection of treated sites from remaining untreated periodontal pockets, Quirynen *et al*. (1995) advocated the benefit of carrying out the pocket/root instrumentation of the entire dentition within a time frame of 24 hours (*full-mouth SRP*). They also considered the risk of re-infection from other intraoral niches such as the tongue and tonsils and therefore also included tongue cleaning and an extensive antimicrobial regimen with CHX (*full-mouth disinfection protocol*). Other proposed treatment protocols that similarly challenge the traditional approach of non-surgical periodontal therapy restrict the number of and the interval between treatment sessions and the time allocated to instrumentation, and may or may not include the adjunctive use of various antimicrobials.

Full-mouth instrumentation protocols

The first full-mouth instrumentation protocol described by Quirynen *et al*. (1995) comprised two sessions of SRP within 24 hours, each covering half of the dentition. However, the total time used for subgingival instrumentation in this approach did not differ from that of the traditional quadrant-wise approach. As already mentioned, the benefit of this treatment protocol was suggested to be a reduced risk of re-infection of treated sites from the otherwise untreated sites, as well as a potential boost to the immunologic response by inoculation of periodontal bacteria into the local vasculature. From the patient's perspective, a tangible benefit of the full-mouth treatment protocol is that fewer appointments, but not necessarily less chair-time for treatment, are required. Apatzidou and Kinane (2004) described a modified protocol in which the SRP of the entire dentition was completed at two sessions on the same day. Another proposed approach consisted of four sessions of SRP on four consecutive days (Eren *et al*. 2002). In all these protocols the time allocated for SRP was 1 hour per jaw quadrant.

Adhering to the concept of differentiation between debridement, scaling, and root planing in non-surgical periodontal therapy (Kieser 1994), modified approaches to the full-mouth instrumentation protocol have been proposed that involve pocket/root debridement by the use of piezoelectric ultrasonic devices in a single-visit, full-mouth procedure, limited to 45–60 minutes to minimize removal of root substance (Wennström *et al*. 2005; Zanatta *et al*. 2006; Del Peloso Ribeiro *et al*. 2008) or without time limit (Koshy *et al*. 2005). Hence, common features of these modified protocols are that the initial subgingival treatment is reduced to one session only and that markedly less time is devoted to instrumentation than that to SRP in the previously described protocols for full-mouth instrumentation.

Full-mouth disinfection protocols

Several intraoral niches, such as the tongue, mucosa, saliva, and tonsils, may act as reservoirs for Gram-negative strains recognized as periodontal pathogens (Beikler *et al*. 2004), and translocation of these bacteria might result in rapid recolonization of a recently instrumented pocket. Hence, as already mentioned, in order to optimize the treatment outcome of the full-mouth SRP approach, Quirynen *et al*. (1995) proposed adjunctive therapy including tongue cleaning and an extensive antimicrobial regimen with CHX (*full-mouth disinfection protocol*). The CHX regimen in conjunction with each treatment session included (1) brushing the dorsum of the tongue for 1 minute with 1% CHX gel, (2) rinsing twice with 0.2% CHX solution for 1 minute, (3) spraying the tonsils four times with a 0.2% CHX solution, (4) three subgingival irrigations with 1% CHX gel (repeated after 8 days), and (5) instructing the patient to rinse twice daily with a 0.2% CHX solution for 2 weeks. The protocol was later modified by adding the instruction that patients should rinse the mouth and spray the tonsils twice daily with a 0.2% CHX solution for a period of 2 months after the SRP (Mongardini *et al*. 1999).

Other full-mouth instrumentation protocols including adjunctive antimicrobial therapy can be found in the literature, but none is as rigorous as the full-mouth disinfection protocol proposed by the Quirynen group. For example, Koshy *et al*. (2005) included the use of 1% povidone iodine solution as a coolant during the full-mouth ultrasonic debridement session, instruction of patients in careful oral hygiene and brushing of the tongue, as well as mouth rinsing with a 0.05% CHX solution twice daily for 1 month.

Clinical outcomes following various approaches to pocket/root instrumentation

A number of systematic reviews on the efficacy of mechanical non-surgical periodontal therapy have been published (e.g. van der Weijden &

Timmerman 2002; Hallmon & Rees 2003; Lang *et al*. 2008; Eberhard *et al*. 2015; Suvan *et al*. 2020). There is a consensus among these reviews that pocket/root instrumentation combined with proper supragingival plaque control measures is an effective treatment modality in reducing probing pocket depths (PPDs) and improving clinical attachment levels (CALs) (Figs. 30-12, 30-13), and that there is no major difference in the efficacy of pocket/root instrumentation using hand or power-driven instruments (sonic/ultrasonic). Furthermore, it was deliberated that the data available from published clinical studies are too limited to judge whether the adverse effects of the treatment may vary with the type of instrument used.

Both in the Cochrane review by Eberhard *et al*. (2015) and the most recent systematic meta-analyses (Suvan *et al*. 2020) comparing *full-mouth instrumentation* versus quadrant-wise SRP revealed no statistically significant differences with regard to mean PPD reduction or CAL change. Subgroup analyses of initially moderate (5–6 mm) and deep (>6 mm) pockets at single- and multirooted teeth disclosed no significant differences for either between the two treatment approaches.

The comparison between *full-mouth disinfection* and quadrant-wise SRP performed in the Cochrane review (Eberhard *et al*. 2015), based on data from six trials, failed to find a statistically significant difference

between the two treatment protocols overall regarding probing depth reduction, but found some differences in favor of *full-mouth disinfection* in specific subgroups, such as deep sites at 6 months follow-up for single and multirooted teeth. Corresponding analyses in a systematic review by Lang *et al*. (2008) showed outcomes of similar magnitude in favor of the full-mouth disinfection approach. However, none of the systematic reviews found any significant differences for the clinical outcome variables between full-mouth disinfection and full-mouth instrumentation, not supporting the extensive use of CHX adopted in these protocols.

Conclusion: All three non-surgical treatment approaches to periodontal infection control (conventional staged quadrant-wise SRP, full-mouth instrumentation and full-mouth disinfection) result in marked improvements in clinical conditions, and the decision to select one approach over another has to involve considerations other than just clinical outcomes.

Microbiologic outcomes following various approaches to pocket/root instrumentation

Removal of subgingival plaque and calculus deposits through subgingival debridement in combination with efficient self-performed supragingival infection control alters the ecology of the pockets through reduction in the quantity of microorganisms, resolution of the inflammation, and a decrease in pocket depth, and species that may have flourished in the subgingival environment of the diseased pocket may find the new habitat less hospitable. A decrease in the total bacterial count for sites of >3 mm depth, from 91×10^5 to 23×10^5, has been observed immediately following subgingival debridement (Teles *et al*. 2006). Furthermore, a decrease in the mean counts and number of sites colonized by *Porphyromonas gingivalis*, *Aggregatibacter actinomycetemcomitans*, *Prevotella intermedia* (Shiloah & Patters 1994), *Tannerella forsythia*, and *Treponema denticola* (Haffajee *et al*. 1997; Darby *et al*. 2005) and an increase in proportion of streptococci (e.g. *Streptococcus gordonni*, *Streptococcus mitis*, *Streptococcus oralis*, and *Streptococcus sanguinis*) and *Actinomyces* spp., *Eikenella corrodens*, and *Gemella morbillarum* were observed several weeks following subgingival debridement. An increase in the proportions of Gram-positive aerobic cocci and rods is associated with periodontal health (Cobb 2002). Interestingly, microorganisms do not exist in isolation in the subgingival environment, but rather as members of communities. Socransky *et al*. (1998) identified groups of organisms that were commonly found together and subdivided microorganisms into

complexes accordingly. Members of the "red" and "orange" complexes are most commonly identified at sites displaying signs of periodontitis. Hence, a re-emergence of species of the red and orange complexes 3–12 months post debridement may indicate lack of resolution of the periodontal lesion (Haffajee *et al*. 2006). It is also important to recognize that in the absence of appropriate home care, the re-establishment of the pretreatment microflora will occur in a matter of weeks (Magnusson *et al*. 1984; Loos *et al*. 1988; Sbordone *et al*. 1990).

In a study comparing the microbiologic outcome of *full-mouth instrumentation* and quadrant-wise SRP (Quirynen *et al*. 2000), it was demonstrated by phase-contrast microscopy and culturing techniques that both treatment approaches reduced the total number of facultative and strict anaerobic species, as well as the number of black-pigmented bacteria, spirochetes, and motile rods in subgingival samples, but also that the reductions were more pronounced following the full-mouth instrumentation. Other studies comparing the microbiologic outcomes following the two treatment approaches using polymerase chain reaction (PCR) techniques (Apatzidou *et al*. 2004; Koshy *et al*. 2005; Jervøe-Storm *et al*. 2007) also reported reductions in presumptive periodontal pathogens, but no detectable differences between the approaches. Hence, these studies failed to support the concept that a full-mouth debridement approach may prevent or delay recolonization of instrumented pockets. Besides the different microbiologic techniques employed in these studies compared with the study by Quirynen *et al*. (2000), the fact that the patients in the former studies showed a high standard of oral hygiene before the initiation of the subgingival instrumentation may explain the contradictory findings. It should be noted that the Quirynen study was primarily designed as a "proof of principle" study, and in order to increase the chance for cross-contamination, interproximal cleaning in the quadrant-wise SRP group was prohibited until the last quadrant had been instrumented.

Studies evaluating microbiologic alterations after *full-mouth ultrasonic instrumentation* with a restricted time protocol (45 minutes of ultrasonic debridement) (Zanatta *et al*. 2006; Del Peloso Ribeiro *et al*. 2008) also showed significant reductions in the frequency and amount of presumptive periodontal pathogens, as evaluated by the use of real-time PCR; reductions were similar to those after conventional quadrant-wise SRP.

More favorable microbiologic changes have been reported following *full-mouth disinfection* as compared with quadrant-wise SRP with respect to decreases in the total amount of motile organisms and spirochetes, total number of facultative or strict anaerobic bacteria, black-pigmented bacteria, as well as frequencies and levels of "red" and "orange" microbial complexes detected using differential phase-contrast microscopy, culturing, and DNA–DNA hybridization technique (Quirynen *et al*. 1999, 2000; De Soete *et al*. 2001). By contrast, Koshy *et al*. (2005) could not detect any added microbiologic benefits as recorded by PCR following their modified full-mouth disinfection approach compared with quadrant-wise instrumentation. The question of differences in microbiologic outcomes following full-mouth instrumentation, full-mouth disinfection, and conventional staged quadrant-wise SRP was addressed in a systematic review (Lang *et al*. 2008). Based on the analysis of seven studies, it was concluded that no superior reductions in either bacterial load or specific presumptive periodontal pathogens could be proven for any of the three treatment modalities.

The effect on the microbiome of non-surgical treatment has been confirmed in clinical trials that have adopted metagenomic techniques for analysis, which allow decoding of all the genetic material present in plaque samples (Takahashi 2015; Yang *et al*. 2016; Chen et al. 2018). Such analyses have also revealed that the oral microbiome is far more complex and heterogeneous than previously perceived (Huttenhower *et al*. 2012), and that methabolic pathways and microbial interactions in biofilms are significant factors to consider (Marsh & Zaura 2017).

Considerations in relation to selection of instruments and treatment approach

Selection of instruments

It has been demonstrated that hand, sonic, and ultrasonic instruments produce similar periodontal healing response with respect to PPD, bleeding on probing, and CAL (Badersten *et al*. 1981, 1984; Lindhe & Nyman 1985; Kalkwarf *et al*. 1989; Loos *et al*. 1987; Copulos *et al*. 1993; Obeid *et al*. 2004; Wennström *et al*. 2005; Christgau *et al*. 2006; Suvan *et al*. 2020). With respect to root surface loss, sonic and ultrasonic scalers have been shown to produce less loss than hand instruments (Ritz *et al*. 1991; Busslinger *et al*. 2001; Schmidlin *et al*. 2001; Kawashima *et al*. 2007; Bozbay *et al*. 2018).

In comparison to hand instrumentation, the use of sonic and ultrasonic instruments may provide better access to deep pockets and furcation areas (Kocher *et al*. 1998; Beuchat *et al*. 2001). In addition, the flushing action of water used as coolant during sonic and ultrasonic instrumentation removes, to a certain extent, debris and bacteria from the pocket area, but the use of antiseptic solutions, for example CHX, iodine, and Listerine®, as coolant has shown no greater effects compared with water irrigation (Koshy *et al*. 2005; Del Peloso Ribeiro *et al*. 2006, 2010; Feng *et al*. 2011; Krück *et al*. 2012; Van der Sluijs *et al*. 2016). However, tactile sensation is reduced, contaminated aerosols are produced (Barnes *et al*. 1998; Harrel *et al*. 1998; Rivera-Hidalgo *et al*. 1999; Timmerman *et al*. 2004), and some patients may find the vibration,

sound, and water spray uncomfortable. The use of the Vector ultrasonic system has been shown to result in clinical and microbiologic outcomes comparable to those achieved by manual instrumentation and conventional ultrasonic instruments; however, it may be less efficient in removing large accumulations of calculus (Sculean *et al*. 2004; Christgau *et al*. 2007; Kahl *et al*. 2007; Guentsch & Preshaw 2008).

The effect of air-polishing has been investigated in maintenance patients, and the results indicate that air polishing with glycine powder is a valid treatment approach to subgingival mechanical debridement during SPT in sites with moderate deep (5–6 mm) pockets (e.g. Moëne *et al*. 2010; Wennström *et al*. 2011; Flemmig *et al*. 2012; Zhang *et al*. 2019). However, in the presence of subgingival calculus and in the initial phase of periodontal therapy, hand/machine-driven instrumentation should be selected as the primary approach to root debridement. Whether subgingival air-polishing used as an adjunct to hand/ultrasonic instrumentation may have beneficial effects on the healing of periodontal lesions has not been addressed scientifically.

The use of Er:YAG lasers produces results comparable to those with hand or ultrasonic instrumentation (Schwarz *et al*. 2008; Sgolastra *et al*. 2012; Salvi *et al*. 2020). However, no adjunctive benefit of the use of Er:YAG lasers over mechanical debridement alone has been demonstrated (Schwarz *et al*. 2003; Lopes *et al*. 2010; Rotundo *et al*. 2010; Salvi *et al*. 2020). The use of other types of lasers has not shown treatment effects comparable to mechanical debridement or any adjunctive effect when used in combination with hand or ultrasonic instrumentation (Ambrosini *et al*. 2005; Schwarz *et al*. 2008; Slot *et al*. 2009; Salvi *et al*. 2020). Contradictory findings have been reported with regard to beneficial clinical and microbiologic effects of photodynamic diode laser therapy when used as an adjunct to mechanical debridement (Christodoulides *et al*. 2008; Chondros *et al*. 2009; Lulic *et al*. 2009; Salvi *et al*. 2020). There is no evidence of positive healing effects of LLLT when applied following mechanical pocket/root debridement (Lai *et al*. 2009; Makhlouf *et al*. 2012; Matarese *et al*. 2017). Hence, the European S3 Level Clinical Practice Guidelines in Periodontology, developed by the European Federation of Periodontology (Sanz *et al*. 2020), recommend that these various adjunctive therapies should not be used in clinical practice.

Selection of treatment approach

At the VI European Workshop on Periodontology the effects of full-mouth debridement with and without adjunctive use of antiseptics was addressed. Based on evaluation of the systematic reviews by Lang *et al*. (2008) and Eberhard *et al*. (2015), the consensus of the workshop was that *full-mouth debridement* and *full-mouth disinfection* do not provide clinically relevant advantages over the conventional staged quadrant-wise SRP in the treatment of patients with moderate-to-advanced periodontitis (Sanz & Teughels 2008). Furthermore, the clinical recommendations given were that (1) "all three modalities may be recommended for debridement" and (2) "clinicians should choose the modality of debridement according to the needs and preferences of the patient, their personal skills and experience, the logistic setting of the practice and the cost-effectiveness of the therapy rendered. It should be noted that the performance of optimal oral hygiene practices is an inseparable principle to be observed with any protocol of mechanical debridement". Similar recommendations are provided in the recently published clinical guideline for the treatment of patients with periodontitis stages I–III by the European Federation of Periodontology (Sanz *et al*. 2020).

Considering cost-to-benefit issues, it is of interest to note that piezoelectric ultrasonic debridement performed as a single-visit, full-mouth procedure restricted to 45–60 minutes of pocket/root instrumentation has been shown to result in comparable healing outcomes to those of SRP performed in a quadrant-wise manner at weekly intervals (Wennström *et al*. 2005; Zanatta *et al*. 2006; Del Peloso Ribeiro *et al*. 2008). This finding indicates that sufficient removal of subgingival deposits may be attainable using a shorter treatment time than that traditionally allocated to non-surgical pocket/root instrumentation. Calculating the efficiency of the treatment approaches, in this case the time used for instrumentation in relation to the number of pockets reaching the end point of treatment success (PPD ≤4 mm), it was shown that the full-mouth ultrasonic approach was three times more favorable than the quadrant-wise SRP approach (Wennström *et al*. 2005). Hence, tangible benefits of full-mouth ultrasonic debridement as an initial approach to subgingival infection control would be fewer appointments and less chair-time for treatment. Furthermore, available data regarding patients' experience of discomfort/pain related to the treatment do not indicate differences between full-mouth ultrasonic debridement and the quadrant-wise approach. It has to be recognized, however, that it is the quality of the instrumentation, not the time factor, that is the important issue in pocket/root debridement, and that the goal of the instrumentation is to reduce the bacterial load at all tooth sites below the threshold level at which the individual host can cope with the remaining infection. It is important to point out that the studies referred to should not be interpreted to justify a protocol of a defined time for instrumentation in non-surgical periodontal therapy, but merely illustrate that many, but not all, pockets may respond positively to less aggressive instrumentation, which in fact supports the concept proposed by Kieser (1994) that the clinical healing obtained following initial pocket/root debridement should be assessed before more extensive instrumentation efforts, including root planing, are performed.

Re-evaluation following initial non-surgical periodontal treatment

Although recent studies indicate that the conventional section-wise as well as the full-mouth debridement approach, combined with careful instruction in self-performed plaque control methods, are evidence-based and rational initial approaches to the treatment of patients with chronic periodontitis (Fig. 30-12), it is important to be aware that all lesions may not be resolved (Fig. 30-13). Hence, a critical component in the establishment of periodontal infection control is to follow up the initial non-surgical treatment and to perform a re-evaluation examination with regard to sites with remaining clinical signs of pathology.

An increased resistance of the periodontal tissues to probing and absence of bleeding are signs of resolution of the inflammatory lesion related to a sufficient removal of biofilm/calculus. Thus, clinical end points of treatment success may be defined as (1) no bleeding on pocket probing and (2) "pocket closure", that is a PPD of ≤4 mm. PPD change is a combined result of recession of the gingival margin and decreased probe penetration into the pocket due to resolution of the inflammatory lesion in the bordering soft tissues (Fig. 30-14).

Pocket reduction or "pocket closure" as an important outcome variable is validated by data showing that it demonstrates lower risk for disease progression and tooth loss (Westfelt *et al*. 1988; Badersten *et al*. 1990; Claffey & Egelberg 1995; Lang & Tonetti 2003; Matuliene *et al*. 2008). In a retrospective study including 172 subjects followed for a mean of 11 years after active periodontal therapy, Matuliene *et al*. (2008) reported that, compared with a PPD of ≤3 mm, a remaining PPD of 5 mm represented a risk factor for tooth loss with an odds ratio of 7.7. The corresponding odds ratios for a remaining PPD of 6 mm and ≥7 mm were 11.0 and 64.2, respectively. The long-term influence of the variable "bleeding on probing" on tooth loss was addressed in a 26-year longitudinal study of 565 Norwegian males (Schätzle *et al*. 2004), and revealed that teeth that at all examinations were positive for bleeding on probing had a 46 times higher risk of being lost compared with teeth not showing gingival inflammation. Hence, these data justify the use of "pocket closure" and absence of bleeding on probing as clinical end points of treatment success in the re-evaluation following periodontal treatment.

On average about 35% of initially pathologic pockets may not reach the end point of treatment success at re-evaluation following initial non-surgical periodontal therapy, and this percentage is independent of the type of instruments or approach used for subgingival debridement (Wennström *et al*. 2005; Jervøe-Storm *et al*. 2006; Suvan *et al*. 2020). Generally, clinical improvement is less pronounced at molars, particularly at furcation sites, than at single-rooted teeth (Lindhe *et al*. 1982; Loos *et al*. 1989). However, there are certainly many other factors related to the patient, the tooth, and the tooth site that might influence the treatment response. The use of multilevel statistical modeling allows the simultaneous investigation of factors at different levels. As an example, in Table 30-1 the probability of "pocket closure" (final PPD ≤4 mm) following initial non-surgical therapy could be estimated for pockets of various initial PPD, taking into consideration the factors smoking habit, single- or multirooted tooth, as well as presence/absence of supragingival plaque at the level of the tooth site (Tomasi *et al*. 2007). The marked difference in probability of pocket closure noted between smokers and non-smokers (e.g. 36% versus 63% for 7 mm deep pockets) places the focus on smoking as a significant factor influencing treatment outcome following non-surgical periodontal therapy. Smoking is proven to negatively affect the outcome of all modalities of

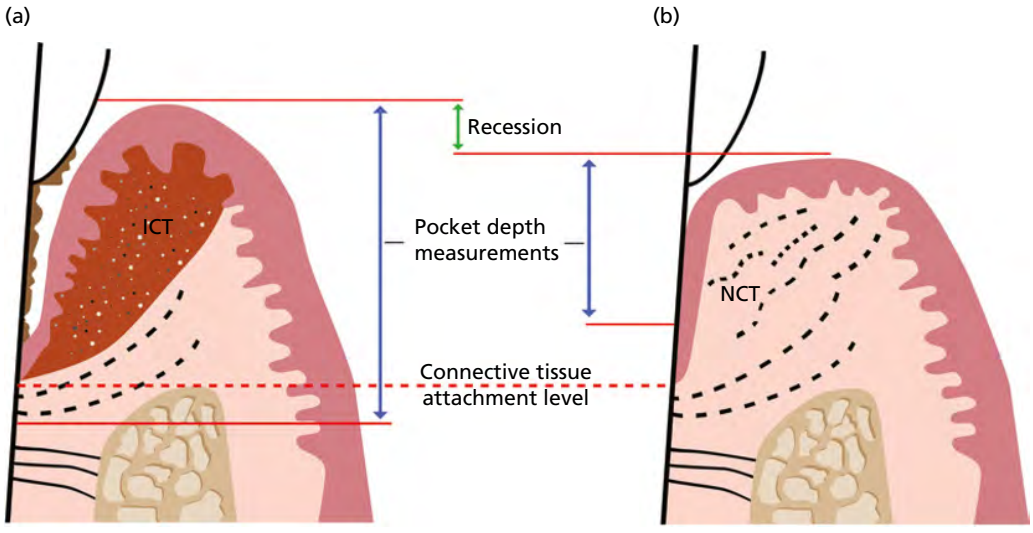

Fig. 30-14 A gingival unit (a) before and (b) after periodontal therapy. Probing depth measurements are shown by the blue lines. The dotted line indicates the "histologic" attachment level. The green line shows degree of recession of the gingival margin. ICT, infiltrated connective tissue; NCT, non-infiltrated connective tissue.

Table 30-1 Predicted probability of pocket closure (probing pocket depth ≤4 mm and no bleeding on probing) for sites with different initial depth.

	Oral hygiene	Tooth-type	Initial pocket depth		
			6 mm	7 mm	8 mm
Non-smoker	No plaque	Single-rooted	84%	63%	36%
	No plaque	Multirooted	70%	43%	19%
	Plaque	Single-rooted	76%	50%	24%
	Plaque	Multirooted	57%	30%	12%
Smoker	No plaque	Single-rooted	64%	36%	16%
	No plaque	Multirooted	43%	20%	7%
	Plaque	Singlerooted	51%	25%	10%
	Plaque	Multirooted	31%	12%	4%

periodontal therapy (Labriola *et al*. 2005; Heasman *et al*. 2006) and hence, if the patient is a smoker, inclusion of a smoking cessation program should be considered as an adjunctive measure.

Efficacy of repeated non-surgical pocket/root instrumentation

If the patient fails to maintain an adequate standard of oral hygiene, efforts have to be devoted to improving the patient's motivation. Persisting pathologic pockets, that is with a PPD of ≥5 mm and bleeding on probing, should be subjected to re-instrumentation efforts which now may also include root planing. The patient is then scheduled for a new re-evaluation and a decision regarding potential need for supplementary active treatment options. Whether it will be worthwhile to once again carry out repeated non-surgical instrumentation of a site/tooth that shows poor response to the performed subgingival debridement, or if other treatment modalities (e.g. adjunctive antimicrobial therapy, open-flap debridement, surgical pocket reduction) to achieve the goal of periodontal infection control should be selected, is a delicate decision in which both subject- and site-specific factors, as well as clinical skills and experience, have to be considered. Largely clinical improvements following pocket retreatment by non-surgical SRP are rather limited compared with those following the initial phase of subgingival instrumentation (Badersten *et al*. 1984; Wennström *et al*. 2005). It has been shown that of all sites that respond poorly to initial mechanical debridement, only 11–16% might be brought to a successful treatment end point following mechanical re-instrumentation, and about 50% of the pockets with an initial PPD of ≥7 mm will remain as non-successful sites (Wennström *et al*. 2005). Another study evaluating the outcome of re-instrumentation of periodontal sites showed that the overall probability of achieving "pocket closure" 3 months after retreatment was about 45%, whereas for sites with a PPD of >6 mm, the probability was only 12% (Tomasi *et al*. 2008). The fact that pockets associated with molars, furcation sites, and angular bone defects have been shown to respond less favorably to repeated non-surgical instrumentation (e.g. Axtelius *et al*. 1999; D'Aiuto *et al*. 2005; Tomasi *et al*. 2007) should be considered in the decision-making process regarding selection of retreatment procedure and the potential benefit of repeated non-surgical instrumentation.

Chapter 31

Treatment of Acute Periodontal and Endo-Periodontal Lesions

David Herrera[1] and Magda Feres[2]

[1] ETEP (Etiology and Therapy of Periodontal and Peri-Implant Diseases) Research Group, Complutense University of Madrid, Madrid, Spain

[2] Department of Periodontology, Dental Research Division, Guarulhos University, Guarulhos, São Paulo, Brazil and The Forsyth Institute, Cambridge, MA, USA

Introduction

Acute lesions affecting the periodontal tissues (see Chapter 19) often require immediate action, with the patient seeking emergency care because of acute pain, which is uncommon in periodontal practice. Moreover, and also in contrast with most chronic periodontal diseases and conditions, rapid onset and destruction of periodontal tissues may occur as a result of acute lesions, making early and swift diagnosis and treatment imperative (Papapanou *et al*. 2018). This chapter focuses on two acute conditions (abscesses in the periodontium and necrotizing periodontal diseases [NPDs]) and on endo-periodontal lesions (EPLs), which can occur in acute or chronic forms.

Treatment of periodontal abscesses

For the management of a periodontal abscess, the first crucial step is a quick and accurate diagnosis (see Chapter 19). Once it has been diagnosed, the type of periodontal abscess that has developed must be clarified (e.g. whether it is in a pre-existing pocket, and the associated etiological factors). The treatment should include two distinct phases: the initial control of the acute condition, in order to arrest tissue destruction and to control the symptoms (e.g. pain), and the management of the pre-existing and/or residual lesion, especially when the patient with a periodontal abscess has periodontitis.

Control of the acute condition

Four therapeutic alternatives have been proposed for periodontal abscesses: (1) tooth extraction, (2) drainage and debridement of the abscess, (3) systemic or local antimicrobials alone or in combination, and (4) surgery.

Tooth extraction

If the periodontal support of the tooth is severely damaged, and its prognosis is hopeless after the additional destruction caused by the abscess, the preferred treatment should be tooth extraction (Smith & Davies 1986). The rapid destruction of periodontal tissues caused by a periodontal abscess may negatively affect the prognosis of the affected tooth, and

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

this has been considered the main cause of tooth extraction during periodontal maintenance (Smith & Davies 1986; Chace & Low 1993; McLeod *et al*. 1997; Silva *et al*. 2008). In addition, in periodontal abscesses in non-periodontitis patients with alteration of the root surface, in the category of severe root damage (fissure or fracture, cracked tooth syndrome) tooth extraction may also be the treatment of choice (for details, see the last section of this chapter).

Drainage and abscess debridement

The best treatment for a periodontal abscess, as for other abscesses in the body, should include drainage (through the pocket or through an external incision), compression and debridement of the soft tissue wall, and the application of topical antiseptics after drainage. However, no specific study has directly evaluated this treatment approach. If the abscess is associated with a foreign body impaction, the object must be eliminated through careful debridement (Abrams & Kopczyk 1983), although the foreign body is normally no longer present.

Antimicrobials

Systemic antimicrobials can be used as sole treatment, as initial treatment, or as an adjunctive treatment to drainage. Sole or initial treatment may only be recommended if pre-medication is required, or when the infection cannot be conclusively located and adequate drainage cannot be ascertained (Lewis *et al*. 1986). As an adjunctive treatment to drainage and debridement, systemic antimicrobials may be considered if there is clear systemic involvement (Ahl *et al*. 1986; Lewis *et al*. 1986). The duration and type of antibiotic therapy is also a matter for discussion, including the recommendation of shorter courses of drugs (Lewis *et al*. 1986; Martin *et al*. 1997). The available scientific evidence on the efficacy of these therapies, however, is very limited, with only two prospective case series and one randomized clinical trial (RCT) available. Smith and Davies (1986) evaluated drainage of the abscess, together with adjunctive systemic metronidazole (200 mg, three times a day [t.i.d.], 5 days), followed by delayed periodontal therapy. They followed 22 abscesses for up to 3 years, and most studied teeth (14) were finally extracted. Hafström *et al*. (1994) proposed drainage through the periodontal pocket, irrigation with sterile saline, supragingival scaling, and tetracycline for 2 weeks (1 g per day). Twenty abscesses were included in this study, with 13 of them followed for 180 days, with significant reductions in suppuration, bleeding, and probing depth that lasted, in the latter case, for 6 months. The authors highlighted the importance of drainage and an increased potential for regeneration if deep scaling is not performed at the initial phase of abscess treatment. Herrera *et al*. (2000) compared azithromycin (500 mg, once a day [q.d.], 3 days) versus amoxicillin plus clavulanate (500 plus 125 mg, t.i.d., 8 days), with delayed scaling (after 12 days), in 29 patients with an abscess, followed for 1 month. Both protocols were similarly effective in controlling signs and symptoms of the acute processes, including significant reductions in probing depth (1.6–1.8 mm) or in pain or swelling.

Local antimicrobials have only been tested in a RCT (Eguchi *et al*. 2008) which compared irrigation with sterile physiological saline and 2% minocycline hydrochloride ointment (Periocline®, Sunstar Inc., Osaka, Japan) with irrigation with sterile physiological saline without the local antibiotic in 91 patients for 7 days. At 7 days, microbiological outcomes (frequency of detection of different pathogens) and periodontal pocket depth reduction (test, 0.56 mm versus control, 0.18 mm) were considered better in the test group.

Periodontal surgery

Surgical procedures have also been proposed, mainly for abscesses associated with deep vertical defects (Kareha *et al*. 1981), or in cases after subgingival periodontal instrumentation in which calculus is left after treatment (Dello Russo 1985). A case series evaluating a combination of an access flap with deep scaling and irrigation with doxycycline is also available, reporting "good results", but no clear data were presented in the manuscript (Taani 1996).

Treatment protocol

In summary, the first line of treatment for a periodontal abscess is drainage and debridement, as for all abscesses in the human body. Alternative approaches may be considered in specific clinical scenarios:

- If tooth prognosis is deemed hopeless, tooth extraction should be the treatment of choice.
- If drainage and debridement is not possible because of a lack of access or the abscess is not well-localized, or there is a need to premedicate the patient, a systemic antimicrobial should be prescribed as initial therapy and, when possible, drainage and debridement should be scheduled.
- If the infection is associated with severe systemic involvement and/or the immune system of the patient is affected, an adjunctive systemic antimicrobial should be considered.
- If there is solid evidence that the abscess is caused by a foreign body impaction which is still in place, periodontal surgery may be the only approach to eliminate the foreign body.

When selecting a systemic antimicrobial, there is a choice of drugs and dosages which may be effective. However, metronidazole, 200–250 mg, t.i.d., for the duration of the active lesion (2–3 days) may be the best option, considering the similarity of the microbiological profile of these lesions with that of periodontitis (for details see Chapter 19).

Subgingival mechanical instrumentation must be avoided at this first stage of treatment because it may

cause irreversible damage to healthy periodontal tissues adjacent to the lesion, particularly when the swelling is diffuse or is associated with marked tissue tension. In addition, acute lesions have some potential for regeneration during healing. Therefore, subgingival mechanical instrumentation should only be performed once the acute lesion has been controlled.

Re-evaluation of treatment outcomes

After drainage and debridement, the patient should be recalled 24–48 hours later to evaluate the resolution of the abscess (Fig. 31-1) and, if needed, the duration of the antimicrobial intake. Once the acute phase has resolved, the patient should be scheduled for management of the pre-existing and/or residual lesion.

Management of the pre-existing and/or residual lesion

Periodontal abscesses in periodontitis patients should be treated appropriately depending on the clinical scenario. Periodontal therapy should be recommended for acute exacerbation in untreated patients; for patients in periodontal maintenance or refractory cases, and different treatment options should be considered after evaluation of the possible reasons for active disease onset. In patients already receiving active periodontal therapy, adequate subgingival instrumentation should be performed in those who have already been treated with scaling and root planing or with systemic antimicrobials with no adjunctive instrumentation; in abscesses detected after a periodontal surgery, careful removal of possible foreign bodies may be needed.

No additional treatments are needed for periodontal abscesses in non-periodontitis patients. For cases of impaction, advice should be given to the patient on oral hygiene. For cases associated with orthodontic factors, consultation with the orthodontist may be crucial. For cases of gingival overgrowth, periodontal surgery may be considered. For patients with root damage, the severity and magnitude of the damage will influence both the prognosis and management, once the periodontal abscess has been controlled.

Treatment of necrotizing periodontal diseases

Due to the specific features of NPDs (rapid tissue destruction, acute course/onset, and pain), the diagnosis (see Chapter 19) and treatment of these conditions must be provided as quickly as possible. Conventional periodontal therapies may need adjunctive measures (Johnson & Engel 1986; AAP 2001). Treatment should be organized in successive stages,

Fig. 31-1 Treatment of a periodontal abscess with systemic antibiotics (azithromycin, 500 mg, q.d., 3 days), without drainage, debridement or instrumentation (a) Baseline situation; (b) 5 days after antibiotic therapy; (c) 12 days after antibiotic therapy, just before the subgingival instrumentation.

including the control of the acute condition and a subsequent treatment phase that should include treatment of the pre-existing condition, corrective treatment of the disease sequelae, and a supportive or maintenance phase. However, different approaches can be applied, depending on the level of compromise in a patient's immune system: moderately and/or short-term immunocompromised patients or continuously and severely immunocompromised patients.

Treatment of necrotizing periodontal diseases in moderately and/or short-term immunocompromised patients

Control of the acute condition

There are two main objectives for treatment in patients who are moderately and/or short-term systemically immunocompromised: to arrest the NPD process and tissue destruction, and to control the patient´s general feeling of discomfort and pain, which may be interfering with nutrition and oral hygiene practices (Holmstrup & Westergaard 2008). The first task should be a careful superficial debridement to remove soft and mineralized deposits. Power-driven devices (e.g. ultrasonic devices) are usually recommended at this stage, exerting minimum pressure over the ulcerated soft tissues, without anesthesia. The debridement should be performed daily, becoming deeper as the tolerance of the patient improves, for as long as the acute phase lasts (normally 2–4 days). To avoid pain, mechanical oral hygiene measures should be limited; in addition, brushing directly on the wounds may impair healing. During this period the patient is advised to use antiseptic agents; chlorhexidine-based mouth rinses (at 0.12–0.2%, twice daily) are recommended. Other products have also been suggested, such as 3% hydrogen peroxide diluted 1:1 in warm water, and other oxygen-releasing agents, which not only contribute to the mechanical cleaning of the lesions, but also provide the antibacterial effect of oxygen against anaerobes (Wennstrom & Lindhe 1979). Other oxygen-based therapies have also been evaluated, such as a local oxygen therapy, which may help to reduce or even eradicate microorganisms, resulting in faster clinical healing with less periodontal destruction (Gaggl *et al*. 2006).

In severe cases with clear systemic involvement (e.g. fever or malaise), or in those patients who show an unsatisfactory response to debridement, the use of systemic antimicrobials may be considered. Metronidazole, at a dose of 250 mg every 8 hours, may represent the first line of treatment, due to its effectiveness against strict anaerobes (Loesche *et al*. 1982). Other systemic drugs have also been proposed, including penicillin, tetracyclines, clindamycin, amoxicillin, or amoxicillin plus clavulanate. Conversely, locally delivered antimicrobials are not recommended because they cannot reach adequate concentrations to be able to treat bacteria present within the tissues.

Re-evaluation of treatment outcomes

Patients must be followed-up very closely, daily if possible, and as symptoms and signs improve, strict mechanical hygiene measures should be enforced. In addition, complete debridement of the lesions should be performed (i.e. complete elimination of calculus and biofilm deposits; see Fig. 31-2).

Management of the pre-existing condition

NPDs normally develop over a pre-existing gingivitis (necrotizing gingivitis) or periodontitis (necrotizing periodontitis). Once the acute phase has been controlled, the treatment of the pre-existing chronic condition should be implemented, including professional mechanical plaque removal (in gingivitis) and/or scaling and root planing (in periodontitis). Oral hygiene instructions and motivation should be enforced. Existing predisposing local factors, such as overhanging restorations, interdental open spaces, and tooth malposition should be carefully evaluated and treated (Horning & Cohen 1995). At this stage, and also during the acute phase of therapy, attention should be paid to the control of the systemic predisposing factors, including smoking, inadequate sleep, psychological stress, or relevant systemic conditions.

Management of the residual lesions/sequalae

The correction of the altered gingival topography caused by the disease should be considered (Fig. 31-3)

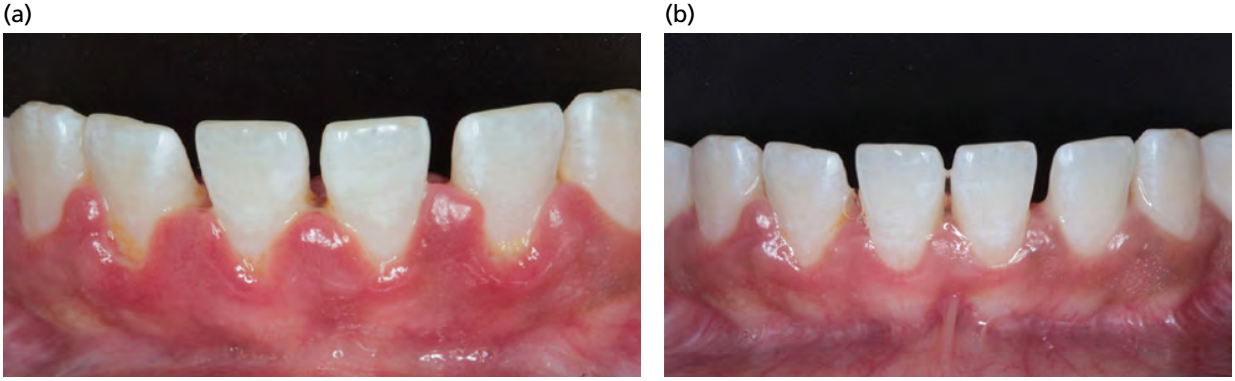

Fig. 31-2 Healing of necrotizing gingivitis lesions, after treatment, in the lower anterior sextant. (a) Lesions with necrosis in the interdental papillae. (b) Complete resolution after 60 days. (Source: Courtesy of Dr. Nidia Castro dos Santos and Mauro Santamaria.)

Fig. 31-3 Sequelae, namely absence of interdental papillae and gingival crater formation. (Source: Courtesy of Dr. Marcio Grisi.)

because gingival craters may favor plaque accumulation and disease recurrence. Gingivectomy and/or gingivoplasty procedures may be helpful to treat superficial craters; for deep craters, periodontal flap surgery or even regenerative surgery represent more suitable options (Holmstrup & Westergaard 2008).

Supportive periodontal care

During this phase, the main goals are compliance with oral hygiene practices and the control of the predisposing factors as previously explained.

Treatment of necrotizing periodontal diseases in continuously and severely immunocompromised patients

HIV-positive patients

HIV-positive patients may not be aware of their serologic status. Occurrence of NPDs in systemically healthy individuals is suggestive of HIV infection, and therefore the affected individuals should be screened for HIV (Hodge *et al*. 1994; Horning & Cohen 1995; Holmstrup & Westergaard 2008). Although no sound scientific evidence is available to support a specific therapeutic protocol for NPDs in HIV-positive patients (Winkler *et al*. 1989; Ryder 2000; Yin *et al*. 2007), a commonly used treatment includes debridement of bacterial deposits, alone or combined with the irrigation of the site with iodine povidone, based on its hypothetic anesthetic and bleeding control effects (Yin *et al*. 2007), or with chlorhexidine. Careful consideration should be made regarding the use of systemic antimicrobials, because of the risk of overinfection with *Candida* spp. Metronidazole has been recommended because of its relatively narrow spectrum and limited effects on Gram-positive bacteria, which may prevent *Candida* spp. overgrowth (Winkler *et al*. 1989; Ryder 2002; Yin *et al*. 2007). Other authors have suggested that HIV-positive patients may not need antibiotic prophylaxis for the treatment of NPDs (Lucartorto *et al*. 1992), and there are no clear data to support the two protocols. In non-responding cases, the use of antifungals may be beneficial, including clotrimazole lozenges, nystatin vaginal tablets, systemic fluconazole, or itraconazole, mainly in cases of severe immune suppression (Ryder 2002; Yin *et al*. 2007). The decision on which treatment protocol should be selected, together with ultrasonic debridement (i.e. alone or with irrigation with povidone iodine or chlorhexidine; with or without adjunctive systemic metronidazole; with or without antifungals) may depend on the systemic status of the patient and the severity of the lesion. Therefore, in HIV-positive patients, systemic status should be closely monitored, including viral load and hematologic and immune status, leading to a customized periodontal treatment plan (Robinson 2002; Ryder 2002; Yin *et al*. 2007).

Children with severe malnourishment, extreme living conditions, and/or severe (viral) infections

NPDs in children in certain regions of Africa (including noma) is associated with a severely compromised immune response caused by severe malnourishment, extreme living conditions, and severe (viral) infections. Very limited information is available on the management of this condition. Recommendations for the prevention of noma include: encouraging good nutritional practices, promotion of breast-feeding during the first 3–6 months of life, immunization against endemic communicable diseases, proper oral hygiene practices, segregation of livestock from human living areas, and education about the etiology and consequences of noma (Enwonwu 2006). Yet it is clear that the elimination of the primary causes would require improvement in living conditions through the eradication of poverty.

If the condition has already developed, and it is in an acute phase, management should include the following (Enwonwu 2006): correction of dehydration and electrolyte imbalance, treatment of associated diseases (e.g. malaria and measles), testing for HIV infection, the administration of antibiotics (e.g. penicillin and metronidazole), local wound care with antiseptics, and removal of tissue sloughs and sequestra. Surgery should only be performed once the acute phase has been controlled.

Treatment of endo-periodontal lesions

Treatment of EPLs has always been a challenge for clinicians, because they are normally associated with a poor tooth prognosis. However, it is important to bear in mind that not all EPLs should lead to tooth extraction; many cases are treatable and may have a favorable prognosis over time (Rotstein & Simon 2004; Sunitha *et al*. 2008) (see Fig. 31-4). Understanding the biological factors that influence the prognosis of a tooth with an EPL is crucial for effective treatment planning (see Chapter 19). In brief, EPLs may occur in acute or chronic forms. For example, acute lesions associated with a recent traumatic or iatrogenic event (e.g. root fracture or perforation) are normally accompanied by an abscess and pain, whereas in subjects with periodontitis or in periodontal maintenance,

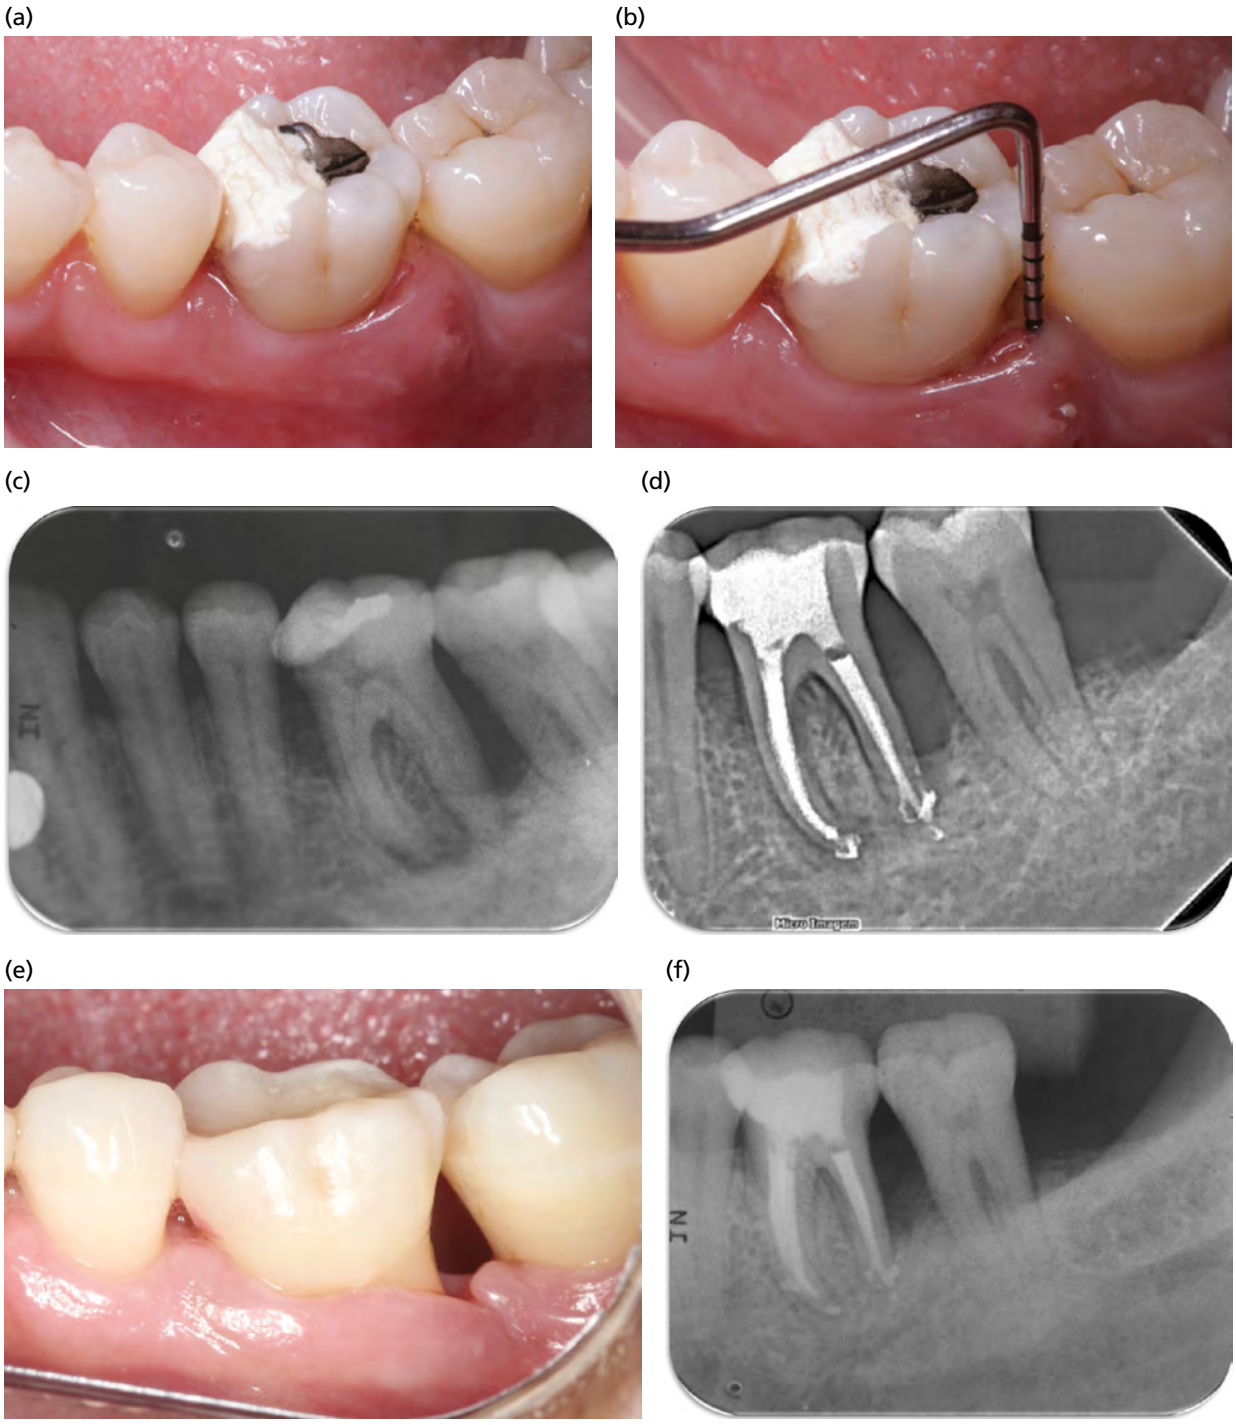

Fig. 31-4 Endo-periodontal lesion without root damage (grade 3) in a non-periodontitis patient, with acute presentation (tooth 36). (a, b) Clinical examination showed presence of periodontal pocket of 10 mm, sinus tract and absence of vitality, and (c) radiographic examination showed evidence of severe bone loss. Treatment included: *session 1* – first phase of endodontic treatment, with access and cleaning of the root canal, medication with calcium hydroxide; *session 2* (30 days after the first session) – scaling and root planning, systemic clarithromycin (500 mg, two times a day [b.i.d.], 3 days), calcium hydroxide was changed; *session 3* (30 days after the second session) – root canal filling (d). At 6 months post-treatment, there were no clinical signs of inflammation (e) and radiographic bone stability was observed (f). (Source: Courtesy of Dr. Mauro Santamaria.)

EPLs normally present slow and chronic progression without evident symptoms. A classification system for these lesions has been recently proposed and is presented in Chapter 19 (Herrera *et al*. 2018). This is relevant, since the precise classification of a condition is the first step towards defining effective treatment protocols.

Prognosis of teeth with endo-periodontal lesions

Determining the prognosis of a tooth affected by an EPL is one of the most difficult steps in managing these lesions, and it should be based on the following criteria: (1) presence/absence of root damage;

(2) presence of periodontitis; (3) anatomic problems (e.g. grooves); (4) severity and extent of the periodontal defect on the affected tooth (including furcation involvement) (Rotstein & Simon, 2004; Schmidt *et al*. 2014, Rotstein 2017; Herrera *et al*. 2018).

One of the main reasons for the proposal of the new classification scheme for EPLs in 2018 (Herrera *et al*. 2018; Chapter 19) was the inability of the previous classification systems to establish clinical criteria able to define the prognosis of a tooth affected by these lesions. According to the classification system proposed in 2018, the three main prognoses for a tooth with an EPL are: (1) hopeless, (2) poor, and (3) favorable. These prognoses vary according to the different categories proposed in the new classification, especially with EPLs associated or not with root damage.

EPLs with root damage are associated with root fracture, perforation of the pulp chamber/root canal, or root resorption. The teeth affected by such lesions usually have a hopeless prognosis, and usually extraction is the only option. The exceptions to these cases will be discussed later in this chapter and include partial fractures, small perforations, or minor root resorptions (see *Steps in the management of an endo-periodontal lesion*). The prognosis of EPLs without root damage mainly depend on the presence of periodontitis and the degree of periodontal destruction around the affected tooth. In periodontitis patients, the dysbiosis present in the oral cavity is so profound that changing this ecology back to symbiosis becomes a real challenge (Socransky & Haffajee 2002; Haffajee *et al*. 2006; Teles *et al*. 2006, 2013) and this may influence the treatment of the EPLs in patients with periodontitis. Similarly, the more severe is the periodontal destruction around the tooth affected by an EPL, the poorer is the prognosis.

Should endo-periodontal lesions with hopeless or poor prognosis be treated?

The decision of whether or not to treat a tooth with EPLs with a hopeless or poor prognosis has been a topic of debate, mainly due to the multiple biological implications and therapeutic outcomes associated with such cases. Interpreting the literature in this area is not easy, because most of the published clinical studies dealing with EPLs are case reports or case series. In addition to the fact that these studies do not provide robust data for evidence-based practice, they normally present only cases that have shown a favorable prognosis after one or more therapeutic modalities. This makes it difficult to establish the percentage of treatment success for EPLs associated with a poor prognosis, or even the actual survival rate of such cases. Some authors have made the therapeutic decision to extract the teeth affected by EPLs with poor prognosis (Pecora *et al*. 1996; Casap *et al*. 2007; Blanchard *et al*. 2010; Keceli *et al*. 2014), while others have successfully treated such cases with a single therapy or a combination of protocols (Table 31-1).

A few unconventional therapeutic options have been proposed for the treatment of teeth with EPLs and hopeless prognosis, including intentional replantation of teeth after performing disinfecting procedures (Oishi 2017; Zakershahrak *et al*. 2017; Yan *et al*. 2019). In theory, a tooth with an EPL of poor prognosis could be treated and remain in the mouth until the clinician is able to evaluate the post-treatment improvement in the long term. However, the function of that tooth in the patient's mouth needs to be considered on the decision of maintaining or extracting the tooth. General questions are important to determine the real viability of leaving this tooth in the mouth, such as if that tooth will be a prothesis abutment, or it needs an indirect rehabilitation (e.g. fixed prosthesis). It is important to remember that multirooted teeth with poor prognosis (e.g. affected by deep periodontal pockets, tooth mobility, or furcation defects), should not be left in the mouth of patients who need complex oral rehabilitation treatment, because these teeth are highly likely to be lost over time (Ekuni *et al*. 2009; Nibali *et al*. 2016).

Steps in the management of an endo-periodontal lesion

The treatment of EPLs have some peculiarities due to the great variability on the prognosis of the tooth affected by such lesions. The clinical characteristics of EPLs and the full mouth periodontal condition greatly influence treatment decision. Thus, before treatment two critical tasks should be accomplished: (1) to determine differential diagnosis between EPL with or without root damage, and (2) to decide whether to extract or to maintain the tooth (e.g. EPLs with tooth damage normally leads to tooth extraction). If the decision is to maintain the tooth, proceed to next steps of evaluation: (3) full-mouth periodontal assessment, and (4) decide whether to extract or to maintain the tooth (e.g. EPLs without tooth damage but with severe periodontal destruction that will be involved in an oral rehabilitation treatment normally should not be maintained). If the decision is to keep the tooth, proceed to the treatment phase, (5) endodontic and periodontal treatments (Fig. 31-5).

Differential diagnosis between endo-periodontal lesions with or without root damage

Because EPLs with root damage normally lead to tooth extraction, the first step of its management should be the precise differential diagnosis between a lesion with or without root damage. As described in Chapter 19, the main risk factors for the occurrence of an EPL with root damage are trauma and iatrogenic events (Herrera *et al*. 2018). Detailed dental history, and clinical and radiographic examination are normally able to determine the presence of cracks, fractures, perforations, and external root resorption (i.e. root damage). The signs/symptoms may be evident, facilitating the diagnosis, as in the case of a patient reporting a recent episode of trauma in the

Table 31-1 Treatment protocols for endo-periodontal lesions reported in publications including ≥10 lesions and their main characteristics.

Reference	Country	Study design	Number of volunteers	Mean age (or range) (years)	Number of teeth	EPL diagnostic	Full-mouth periodontal diagnosis	Treatment	Maximum follow-up	Prognosis
Ustaoglu *et al.* (2020)	Turkey	RCT	45	40	45 (intrabody defects)	Primary periodontal lesion with secondary endodontic involvement or true combined EPLs in single-rooted teeth	ND	Root canal treatment, OHI, supragingival scaling and SRP, OFD, T-PRF, and GTR	9 months	Favorable
Oh *et al.* (2019)	Korea	Retrospective study	41	ND	52	EPL	ND	Root canal treatment, OHI, supragingival scaling, and SRP, OFD + Bio-Oss© with or without bioresorbable collagen membranes	5 years	Favorable
Saida *et al.* (2018)	Japan	Case series	17	55.5	17	Primary endodontic lesions with secondary periodontal involvement, periodontal lesions, and "true" combined lesion	ND	Tooth extraction, cleaning of alveolus and dental root, resection of 2–3 mm of apical roots, sealing of the apical foramen, Emdogain© on the root surfaces, tooth insertion in the alveolus	2 years	Favorable
Tewari *et al.* (2018)	India	RCT	35	42.1	35	Periodontitis patient with at least one non vital tooth with concurrent EPL with apical radiolucency along with communication through periodontal pocket	Chronic periodontitis	SRP, root canal treatment, OFD after 21 days or 3 months of SRP/root canal	6 months	Favorable
Song *et al.* (2018)	South Korea	Retrospective study	83	43.12	83	EPL: Class D, Class E, Class F (Kim & Kratchman 2006)	ND	Endodontic microsurgery	12 months	Favorable
Raheja *et al.* (2014)	India	Clinical study	31	45.48	31	Combined EPL	ND	*Test*: Root canal (with CHX intracanal) + SRP + OFD *Control*: Root canal (without CHX intracanal) + SRP + OFD	6 months	Favorable (Test better than Control)
Song *et al.* (2012)	South Korea	Clinical study	172	11–71	172	EPL with endodontic or combined endo-periodontal origins	ND	OFD	10 years	Favorable

Kim *et al.* (2008)	South Korea	Clinical study	227	ND	263	Lesions of endodontic origin and combined endodontic-periodontal origin	ND	AMX 250 mg (t.i.d., 7 days) and ibuprofen 400 mg (1 hour before and after surgery), OFD, endodontic microsurgery	5 years	Favorable
Casap *et al.* (2007)	Israel	Case series	20	44.8	30	Subacute periodontal infection due to EPL, root fracture and/or periapical lesion	ND	Tooth extraction and implant placement	72 months	Hopeless
Pecora *et al.* (1996)	USA	Case series	9	41	32	Vertical root fractures (13), horizontal root fractures (8), root perforations (4), combined endodontic-periodontal involvement (7)	ND	Tooth extraction and implant placement	6 months	Hopeless

AMX, amoxicillin; CHX, chlorhexidine; EPL, endo-periodontal lesion; GTR, guided tissue regeneration; ND, not described; OFD, open flap debridement; OHI, oral hygiene instructions; RCT, randomized clinical trial; SRP, scaling and root planing; T-PRF, titanium-prepared platelet rich fibrin; t.i.d., three times a day.

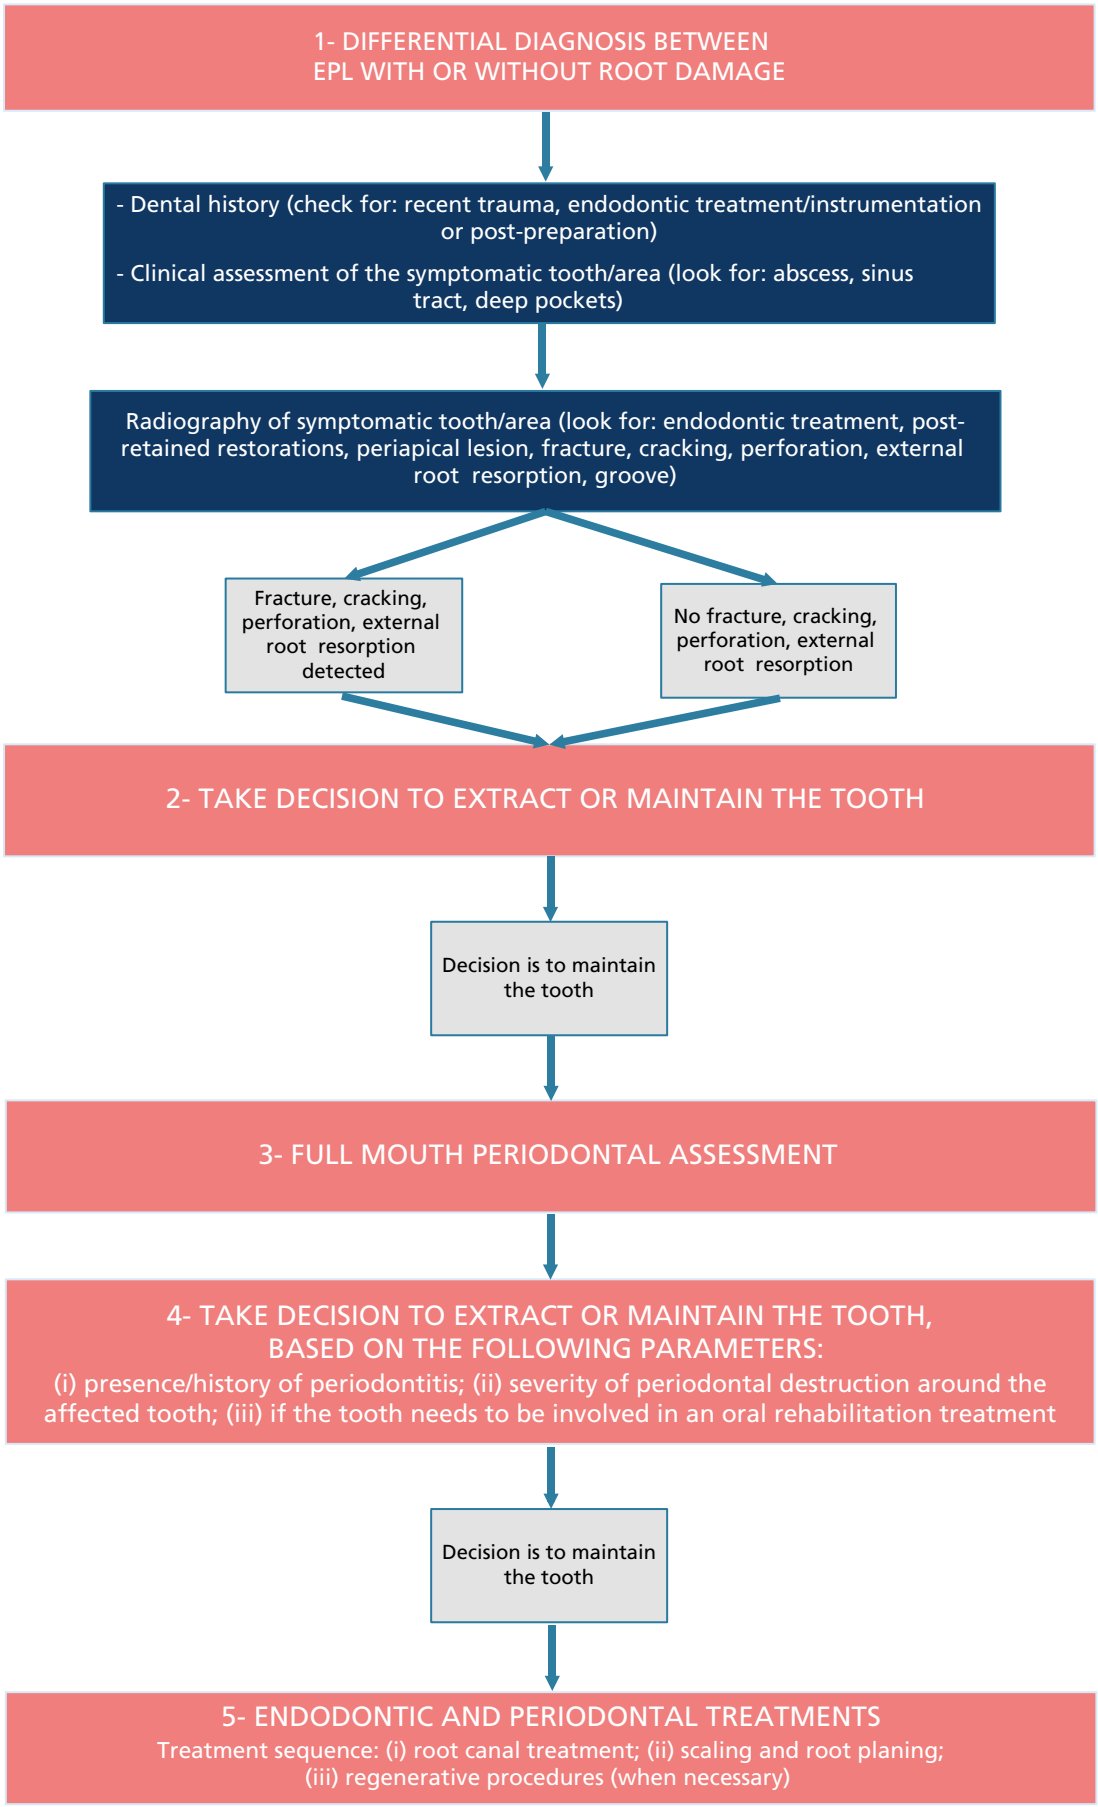

Fig. 31-5 Steps in the management of an endo-periodontal lesion (EPL).

trauma in the same region of a tooth presenting symptomatology or an abscess. Similarly, a patient with recent history of endodontic treatment and/or post preparation may indicate a diagnosis of perforation. Usually, radiography together with the presence of a deep pocket (or furcation involvement) would detect a fracture, crack, or perforation in such cases. However, caution should be taken in order to avoid misdiagnosis. For example, sometimes tomography is needed in order to confirm the diagnosis: a radicular groove might mimic a vertical root fracture on a radiograph (Attam *et al*. 2010) or a perforation may be overlooked in normal radiography (Fig. 31-6). Careful radiographic/tomographic evaluation and clinical examination of the root anatomy is of great importance at this stage to assess the integrity of the root and to help with differential diagnosis (Herrera *et al*. 2018). Nevertheless, if the clinical information does not allow the clinician to reach a definitive diagnosis, the clinician may decide to perform periodontal access surgery in order to examine the root surface. However, such surgeries can only be performed in the absence of clinical signs of an acute periodontal process (Sooratgar *et al*. 2016; Dhoum *et al*. 2018; Tewari *et al*. 2018). If there are difficulties in identifying any fracture lines or root damage during surgical procedures, the use of methylene blue and microscopic inspection have been suggested (Floratos & Kratchman 2012; Taschieri *et al*. 2016).

Decision to extract or to maintain the tooth (with root damage)

EPLs with root damage normally have very poor prognosis, but some cases associated with partial root damage may be treatable. Thus, if the EPL is associated with root damage, the extent of the damage should be carefully evaluated. Complete vertical root fractures would lead to tooth extraction, but some authors have obtained good clinical results when treating teeth with incomplete root fractures, by means of periodontal surgery and apicoectomy (Taschieri *et al*. 2016) or regenerative procedures (Floratos & Kratchman 2012). Intentional extraction, retrograde root canal treatment, and intentional replantation has also been suggested as a treatment option for incomplete fractures (Oishi 2017). Furthermore, teeth with external root resorption have also been successfully treated by means of open flap debridement and regenerative techniques (White & Bryant 2002). Also, *in vitro* and animal studies have suggested that chamber/root canal perforations may be treatable and treatment success depends on the size, location, time of diagnosis and treatment, severity of periodontal destruction, and biocompatibility of the repair material used (Jew *et al*. 1982; Himel *et al*. 1985; Beavers *et al*. 1986; Dazey & Senia 1990; Lee *et al*. 1993; Fuss & Trope 1996; Lomcali *et al*. 1996; Rotstein 2017). Overall, the best outcomes of treatment were observed for small perforations which were immediately sealed. Trioxide aggregate seems to be the most commonly used material to seal root perforations (Rotstein 2017).

Full-mouth periodontal assessment

If the decision based on the presence/absence of root damage is to maintain the tooth, a full-mouth periodontal assessment should be conducted in order to detect if the patient has periodontitis. Unfortunately, it is not common to find complete full-mouth periodontal information in the available scientific literature. Most interventional studies only report on the clinical characteristics of the "tooth" affected by an EPL (Table 31-1). In addition to the full-mouth periodontal evaluation, it is important to carefully determine the extent of the periodontal destruction around the tooth affected by the EPL. Several parameters should be assessed at the tooth level: probing depth, attachment level, presence of cavities, bleeding on probing, suppuration and mobility, as well as tooth vitality/sensibility and percussion tests (Herrera *et al*. 2018).

Decision to extract or to maintain the tooth (without root damage)

Based on the periodontal clinical parameters, the clinician should again take the decision to maintain or extract the tooth. At this stage, this decision should take into account the following: (1) presence/history of periodontitis, (2) severity of periodontal destruction around the affected tooth (grade of the lesion, Chapter 19), (3) if the tooth needs to be involved in oral rehabilitation treatment. If the tooth is to be maintained, anti-infective treatment of endodontic and periodontal tissues should begin.

Endodontic and periodontal anti-infective treatments

At this stage, all EPLs would require endodontic and periodontal treatment, but the concomitant resolution of these combined infectious processes is a challenge for clinicians. A wide spectrum of different anti-infective therapeutic options has been proposed. Table 31-1 presents a summary of the characteristics of the studies reporting on the treatment of at least 10 cases of EPLs (Kim *et al*. 2008; Song *et al*. 2012; Raheja *et al*. 2014; Saida *et al*. 2018; Song *et al*. 2018; Tewari *et al*. 2018; Oh *et al*. 2019; Ustaoglu *et al*. 2020). Overall, these studies have used the following treatment options (not in sequence order): non-surgical endodontic therapy, non-surgical periodontal therapy, or a combination of non-surgical endodontic therapy and non-surgical and/or surgical periodontal therapy. Periodontal surgeries normally consisted of an open flap debridement alone or in combination with regenerative (e.g. enamel matrix derivatives) or resective procedures, with or without local or systemic antimicrobials. In addition, over the years, the use of regenerative therapies has become more common in the treatment of EPLs (Fig. 31-7).

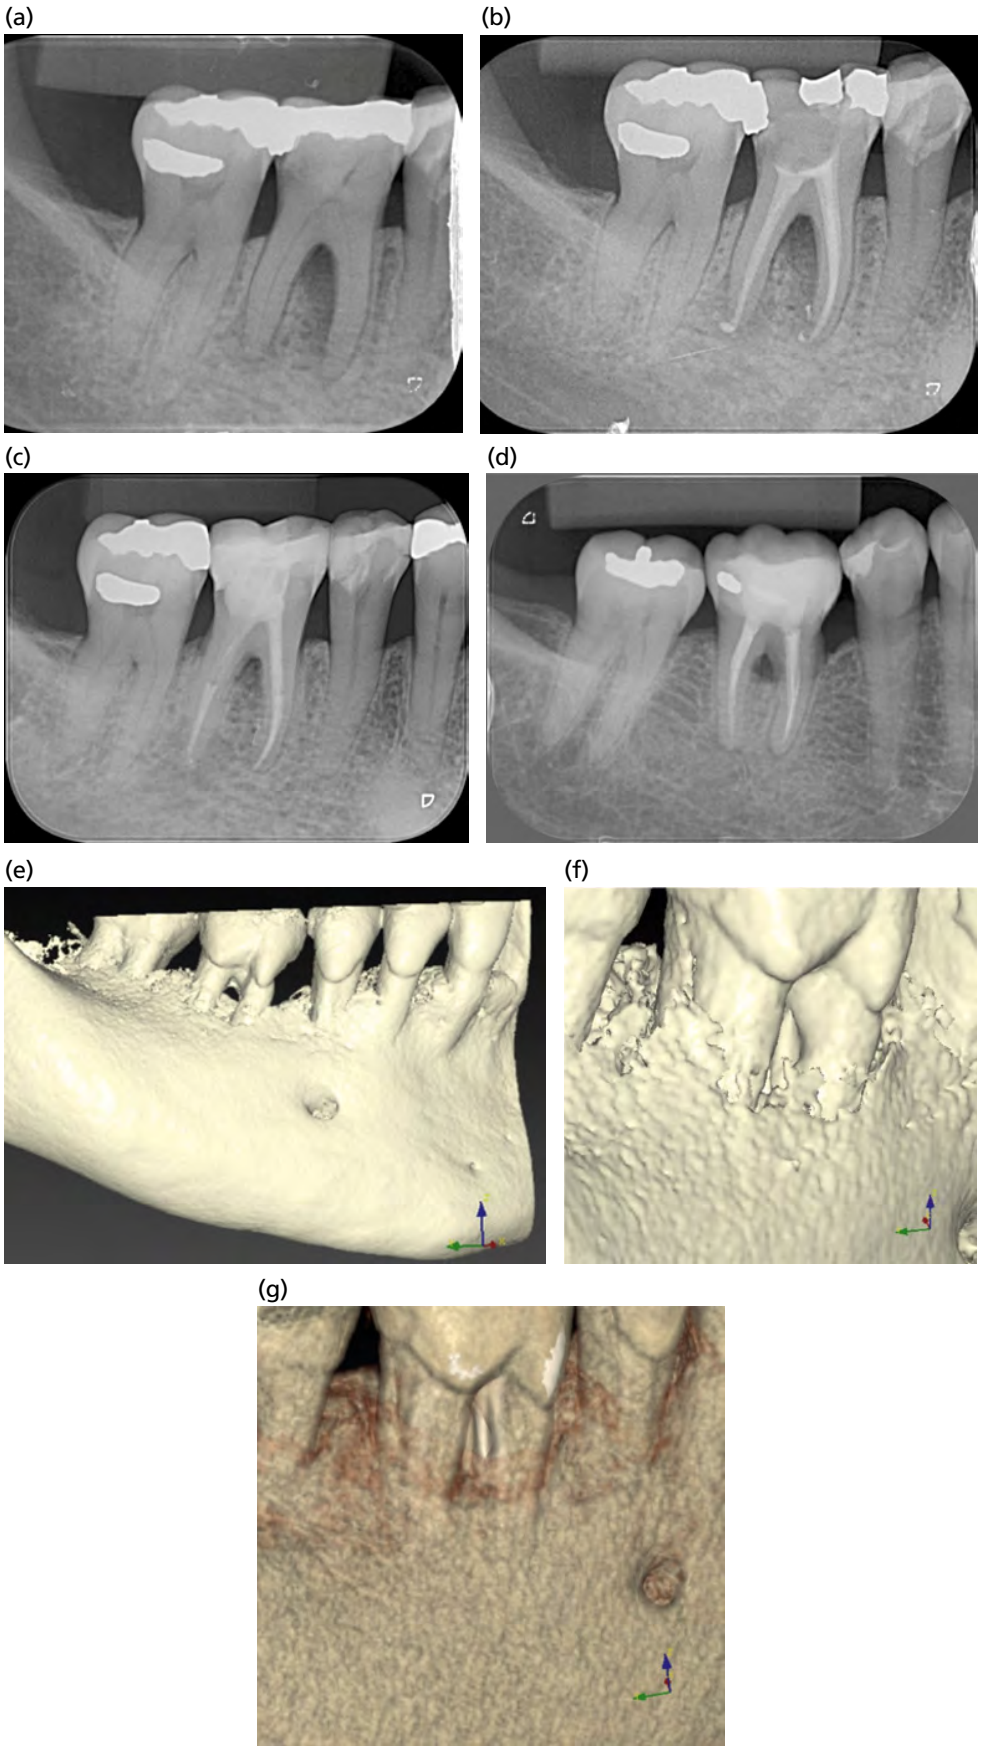

Fig. 31-6 Endo-periodontal lesion without root damage (grade 2) in a patient with periodontitis (tooth 46). (a) The tooth presented with class II furcation, bleeding on probing, and absence of vitality. (b) Treatment involved scaling and root planing and root canal treatment. (c) 6 months post-treatment, radiographic bone gain was observed. (d) During the supportive periodontal therapy session, 30 months post-treatment, bone resorption in the furcation region was detected, and (e–g) the 3D image of the tomography showed a perforation in the mesial root, with a new diagnosis of endo-periodontal lesion with root damage. Tooth extraction was recommended. (Source: Courtesy of Dr. Marcio Grisi.)

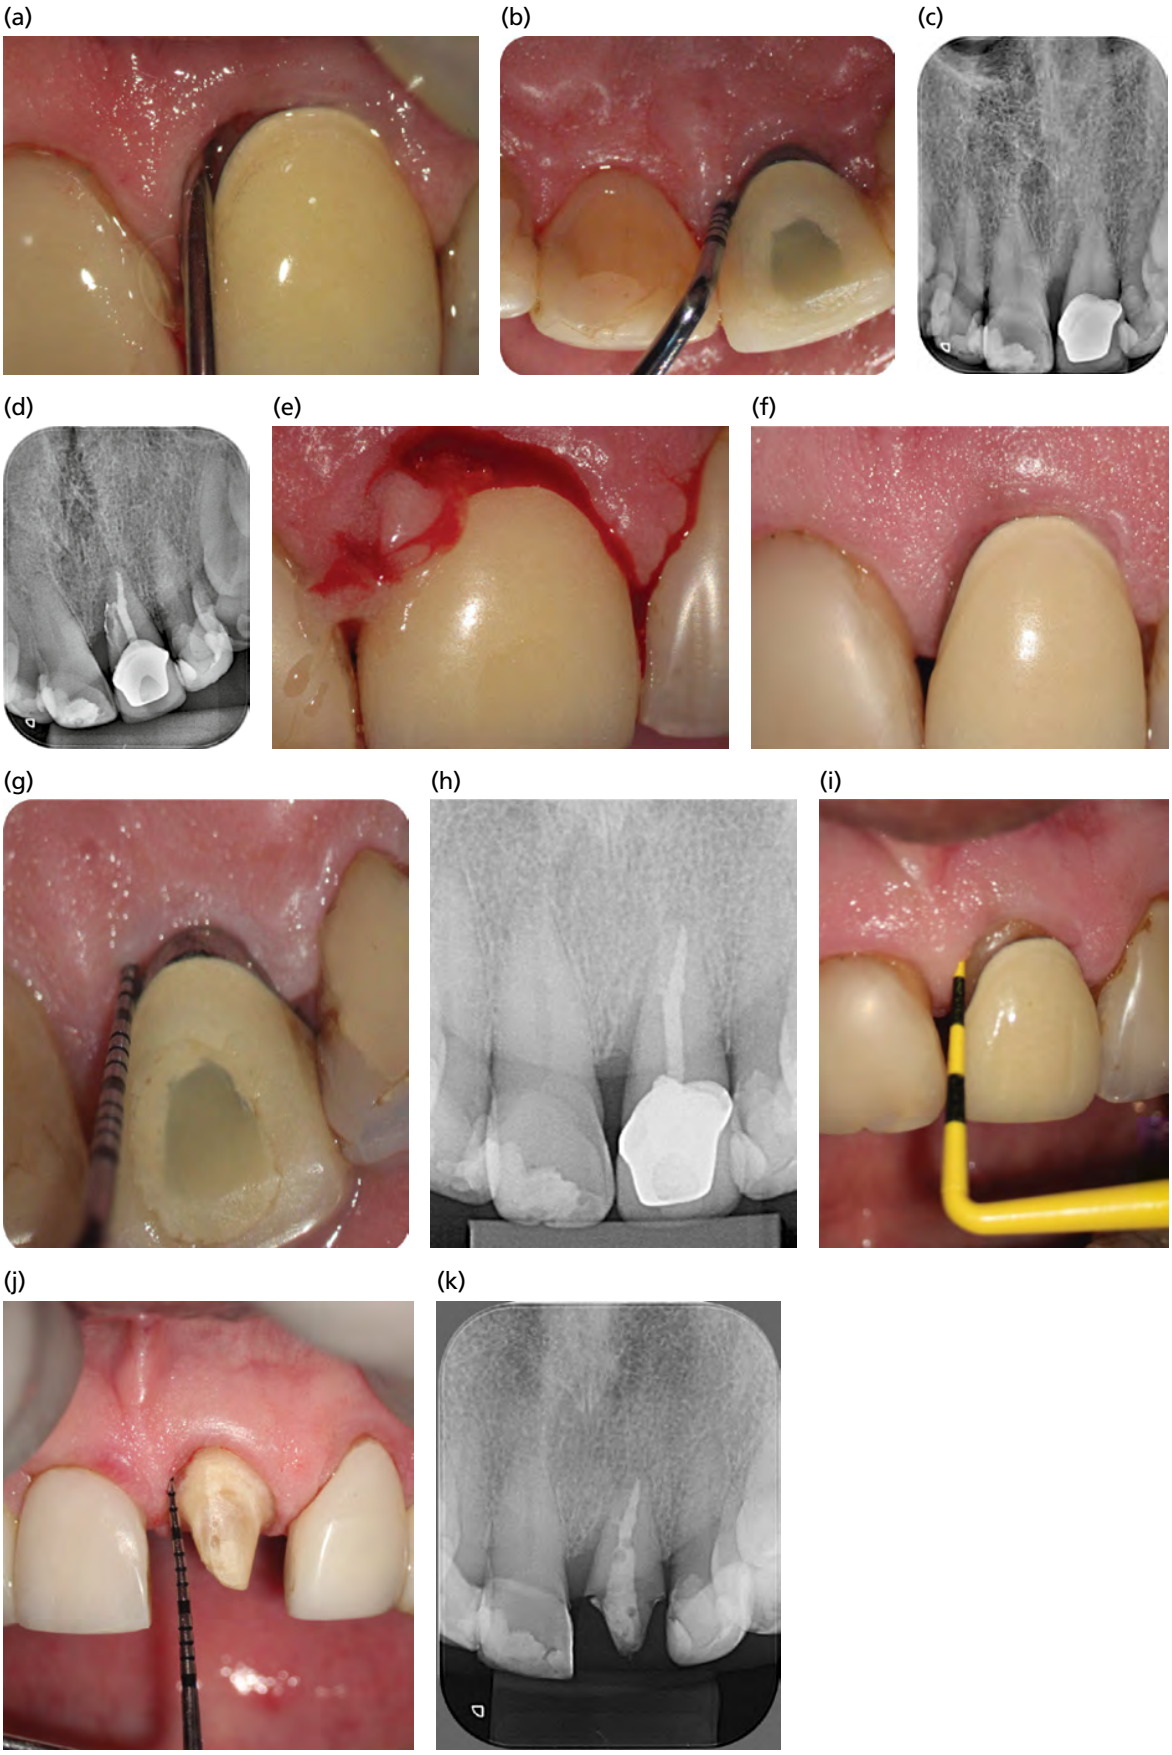

Fig. 31-7 Endo-periodontal lesion without root damage (grade 3) in non-periodontitis patient. Clinical examination showed deep periodontal pockets in the (a) buccal and (b) palatal surfaces, (c) radiographic bone loss and absence of vitality. The treatment included: root canal treatment (d) immediately followed by scaling and root planing with the application of enamel protein derivatives (Emdogain®), without surgical access (e). At 6 months post-treatment, clinical findings compatible with health were observed in the (f) buccal, and (g) palatal surfaces, and (h) bone gain was detected. At 24 months post-treatment, periodontal health was maintained (i) and the tooth was prepared for the next phases of the rehabilitation treatment (j, k). (Source: Courtesy of Dr. Marcio Grisi.)

The sequence order of the anti-infective treatment of EPLs has been a topic of debate. A systematic review published in 2014 (Schmidt *et al*. 2014), including 23 studies and 111 teeth with EPLs, and using tooth loss and probing pocket depth reduction as outcomes variables, concluded that there is some evidence to support the notion that root canal treatment should be the first therapeutic procedure for EPLs. However, this conclusion should be interpreted with caution as a marked heterogeneity was observed among the included studies, regarding the treatment protocols used. Thus, it is not yet fully established in the literature that endodontic treatment should always precede periodontal treatment in the management of EPLs.

The time lapse between endodontic and periodontal treatment in the management of EPLs have also been assessed and discussed. Most authors have stated that a time lapse of 1–3 months between endodontic and periodontal treatment should be respected, in order to facilitate adequate periapical and periodontal healing (Solomon *et al*. 1995; Chapple & Lumley 1999; Zehnder *et al*. 2002; Vakalis *et al*. 2005; Abbott & Salgado 2009; Oh *et al*. 2009; Raheja *et al*. 2014). However, an observation period of at least 6–12 months before re-evaluation of the first treatment stage of EPLs was advocated by Zehnder (2001), while Gupta *et al*. (2015) suggested that non-surgical periodontal treatment may be performed simultaneously with endodontic treatment. More robust studies in this area are necessary in order to determine the long-term clinical results of teeth affected by EPLs and treated by different treatment modalities and sequence orders.

Introduction

Periodontal surgery must be considered as an adjunctive to cause-related therapy and, therefore, the various surgical methods described in this chapter should be evaluated on the basis of their potential to facilitate removal of subgingival deposits and self-performed infection control, with the ultimate goal being to enhance the long-term maintenance of periodontal health.

The recently published EFP S3 level clinical guideline for the treatment of periodontitis stages I–III (Sanz *et al*. 2020) recommends that patients, once diagnosed, should be treated according to a pre-established stepwise approach to therapy that, depending on the disease stage, should be incremental, each including different interventions. *The first and second steps of periodontal therapy* are commonly referred to as cause-related therapy and include, in the first step, all needed behavioural change and motivation to undertake successful removal of supragingival dental biofilm by the patient and all measures headed toward risk factor control (smoking, glycaemic control, etc.). The second step includes all professional interventions aimed at reducing/eliminating the subgingival biofilm and calculus (subgingival instrumentation), with or without the use of adjunctive therapies (antimicrobials, anti-inflammatory, etc.).

These first and second steps of therapy should be used for all patients with periodontitis, irrespective of their disease stage, only in teeth with loss of periodontal support and/or periodontal pocket formation. The response to these two steps should be assessed once the periodontal tissues have healed (periodontal re-evaluation), usually between 6 and 12 weeks after the completion of the second step of therapy. Only when the endpoints of therapy (no periodontal pockets >4 mm with bleeding on probing (BoP) or no deep periodontal pockets [≥6 mm]) have not been achieved, then the third step of therapy should be considered.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

When the treatment is successful in achieving stable periodontitis, defined by gingival health on a reduced periodontium (BoP in <10% of the sites; shallow probing depths of 4 mm or less and no 4 mm sites with BoP), these patients should be placed in a supportive periodontal care (SPC) program. If these criteria are met but BoP is present at >10% of sites, then the patient is diagnosed as a patient with stable periodontitis. with gingival inflammation. Therefore, adequate measures for inflammation control should be implemented to prevent recurrent periodontitis, since periodontitis patients will always remain at increased risk of recurrent periodontitis in the presence of gingival inflammation.

The *third step of therapy* is aimed at treating those areas of the dentition not responding adequately to the second step (presence of pockets >4 mm with BoP or presence of deep periodontal pockets [≥6 mm]). The main purpose of this step of therapy is to gain further access to subgingival instrumentation, or in those lesions that add complexity in the management of periodontitis (intrabony and furcation lesions) to either regenerate or resect them. It may include the following interventions:

- Repeated subgingival instrumentation with or without adjunctive therapies
- Access flap periodontal surgery
- Resective flap periodontal surgery
- Regenerative periodontal surgery.

This chapter focuses on periodontal surgical techniques (access and resective flap periodontal surgeries) that specifically aim to gain further access to subgingival instrumentation and reduce pocket depths or other anatomical areas not suitable for subgingival instrumentation. Regenerative periodontal surgery and surgical treatment of furcation lesions are discussed in Chapters 38 and 33, respectively

The individual response to the third step of therapy should be re-evaluated to assess whether the previously defined endpoints of therapy have been achieved. In this case, patients should be placed in supportive periodontal care. However, in patients with severe stage III periodontitis these endpoints of therapy may not be achievable in all teeth and these sites will need close monitoring with frequent subgingival instrumentation.

Techniques in periodontal surgery (historical perspective)

Over the years, different surgical techniques have been introduced and used in periodontal therapy. Firstly, procedures were aimed to excise "*diseased gingiva*" (gingivectomy procedures), then tissue elimination included not only inflamed soft tissue but also "*infected and necrotic bone*" that required exposure of the alveolar bone (flap procedures). Other concepts, such as the importance of maintaining the mucogingival complex (i.e. a wide zone of gingiva) and the possibility for regenerating the periodontal tissues, were subsequently introduced and gave way to specific "tailor-made" techniques.

This section will describe the surgical procedures which represented important steps in the development of the surgical concepts of modern periodontal surgery.

Gingivectomy procedures

This surgical approach had already been described in the latter part of the nineteenth century, when Robicsek (1884) introduced the so-called *gingivectomy* procedure aimed at "pocket elimination" and usually combined with recontouring of the gingiva to restore its normal architecture. Robicsek (1884) and later Zentler (1918) described the procedure, indicating the incision line where the gum should first be excised. This incision was initially straight (Robicsek) (Fig. 32-1) and then scalloped (Zentler) (Fig. 32-2),

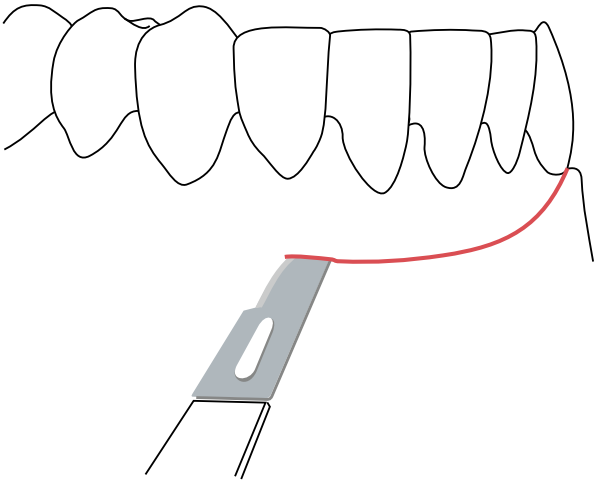

Fig. 32-1 Gingivectomy. Straight incision technique. (Source: Robicsek, 1884, reviewed in 1965 by the American Academy of Periodontology.Reproduced with permission from John Wiley & Sons.)

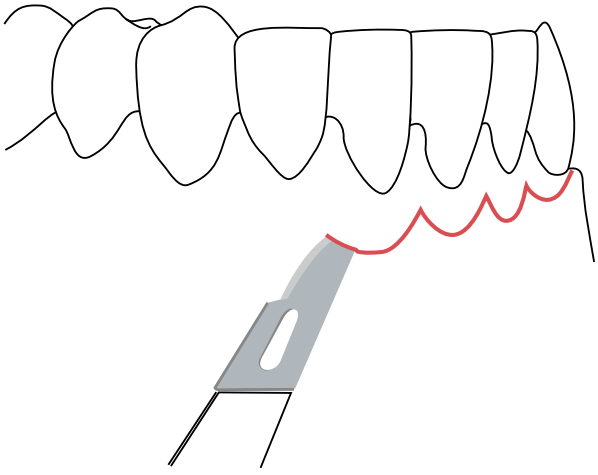

Fig. 32-2 Gingivectomy. Scalloped incision technique. (Source: Zentler 1918. Reproduced with permission from John Wiley & Sons.)

on both the labial and lingual aspects of each tooth. Subsequently, the diseased tissue was eliminated with a hook-shaped instrument and the exposed alveolar bone was scraped. The area was then covered with an antibacterial gauze or painted with disinfecting solutions. The deepened periodontal pocket was therefore eradicated, and the established dentition could be kept clean more easily.

In the second half of the twentieth century, the gingivectomy procedure was frequently employed in the treatment of periodontitis (Goldman 1951). It was defined by Grant *et al*. (1979) as being "the excision of the soft tissue wall of a pathologic periodontal pocket" and required precise steps to follow:

- Once the area was anesthetized, the bottom of each pocket was identified (Fig. 32-3a) and bleeding points were produced on the outer surface of the soft tissue (Fig. 32-3b). These bleeding points describing the depth of the pockets in the area were used as the guideline for the incision.
- The primary incision (Fig. 32-4), with either a scalpel or an angulated gingivectomy knife joined all the bleeding points with a beveled incision (external bevel) directed towards the base of the pocket, providing a thin and properly festooned margin of the remaining gingiva.
- Once the primary incision was completed on the buccal and lingual aspects of the teeth, the interproximal soft tissue was separated from the interdental periodontium by a secondary incision (Fig. 32-5). The incised tissues were carefully removed with a curette or a scaler (Fig. 32-6) and the exposed root surfaces were carefully debrided (Fig. 32-7). The gingival contours were then checked and, if necessary, corrected with the use of knives or rotating diamond burs.
- To protect the incised area during the period of healing, the wound surface was covered by a periodontal dressing (Fig. 32-8) that remained in position for 10–14 days.

Flap procedures

Original Widman flap

In 1918, Leonard Widman published one of the first detailed descriptions of the use of a flap procedure for pocket elimination. In his article "*The operative treatment of pyorrhea alveolaris*", Widman described a mucoperiosteal flap design that aimed to remove

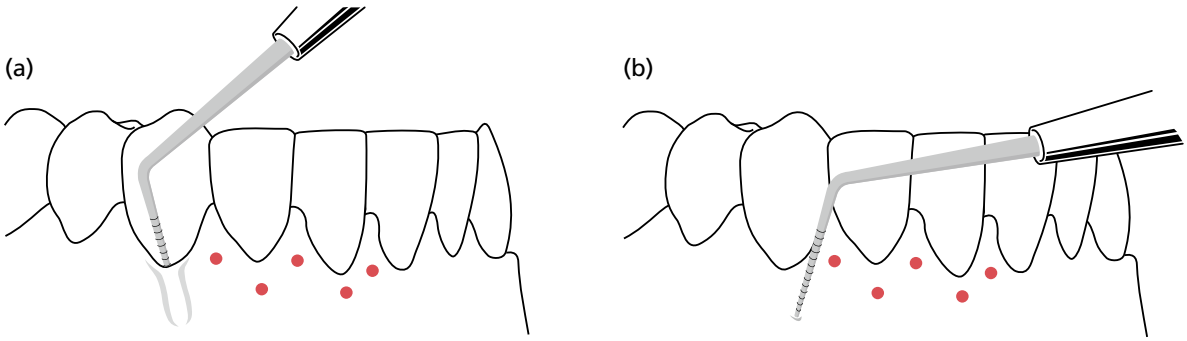

Fig. 32-3 Gingivectomy. Pocket marking. (a) An ordinary periodontal probe is used to identify the bottom of the deepened pocket. (b) When the depth of the pocket has been assessed, an equivalent distance is delineated on the outer aspect of the gingiva. The tip of the probe is then turned horizontally and used to produce a bleeding point at the level of the bottom of the probeable pocket.

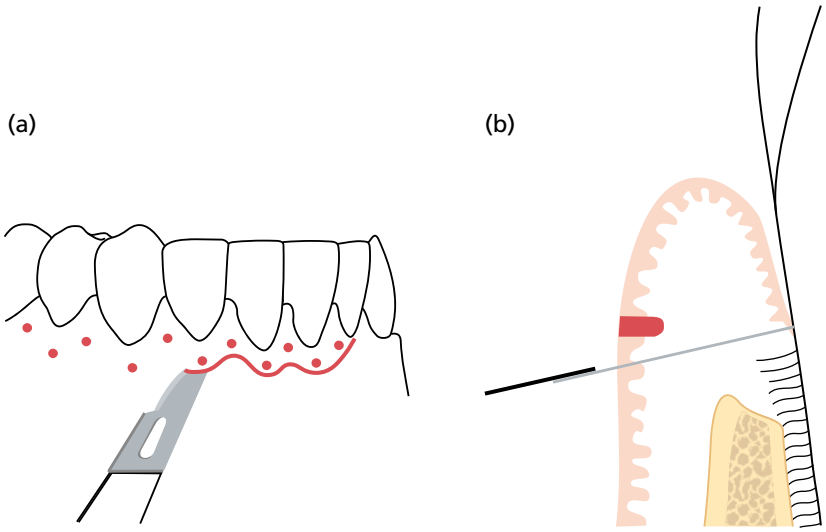

Fig. 32-4 Gingivectomy. (a) Primary incision. (b) The incision is terminated at a level apical to the "bottom" of the pocket and is angulated to give the cut surface a distinct bevel.

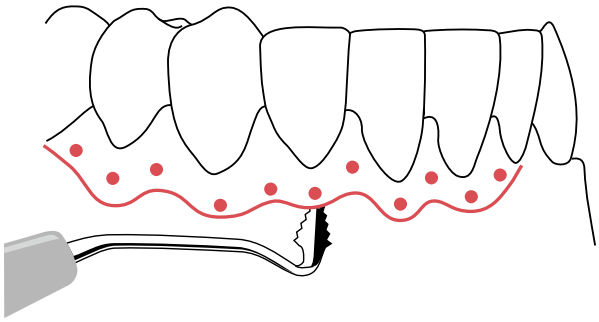

Fig. 32-5 Gingivectomy. The secondary incision through the interdental area is performed with a Waerhaug knife.

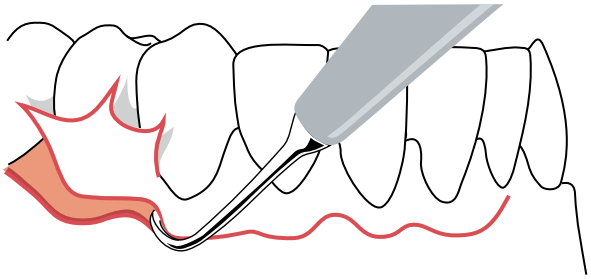

Fig. 32-6 Gingivectomy. The detached gingiva is removed with a scaler.

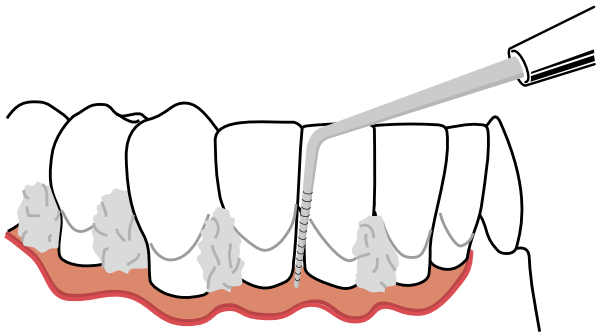

Fig. 32-7 Gingivectomy. Probing for residual pockets. Gauze packs have been placed in the interdental spaces to control bleeding.

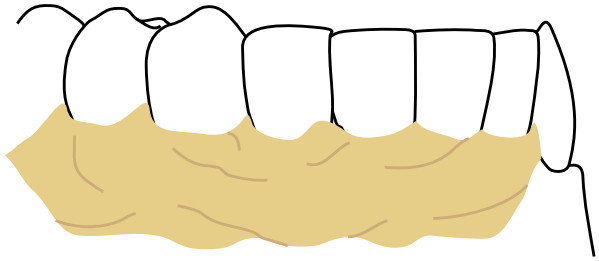

Fig. 32-8 Gingivectomy. The periodontal dressing has been applied and properly secured.

the pocket epithelium and the inflamed connective tissue, thereby facilitating optimal cleaning of the root surfaces. The technique consisted of two releasing incisions connected by a gingival incision that demarcated the area scheduled for surgery (Fig. 32-9). Buccal and lingual incisions using an internal bevel followed the outline of the gingival margin aiming

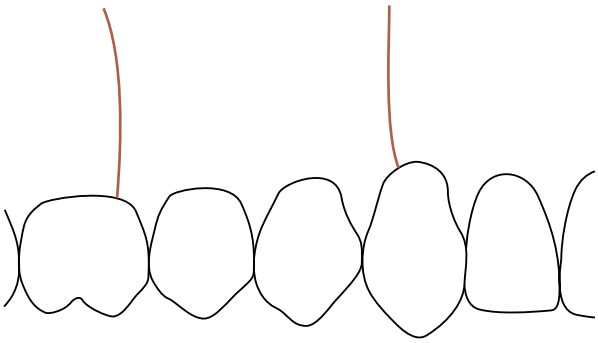

Fig. 32-9 Original Widman flap. Two releasing incisions demarcate the area scheduled for surgical therapy. A scalloped reverse bevel incision is made in the gingival margin to connect the two releasing incisions.

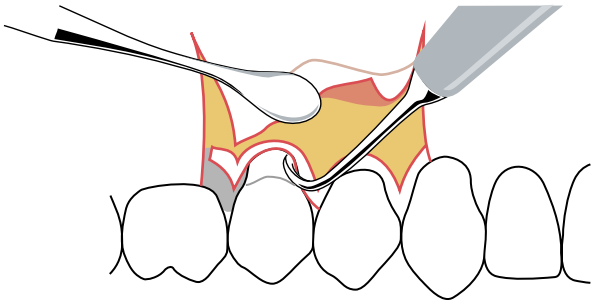

Fig. 32-10 Original Widman flap. The collar of inflamed gingival tissue is removed following the elevation of a mucoperiosteal flap.

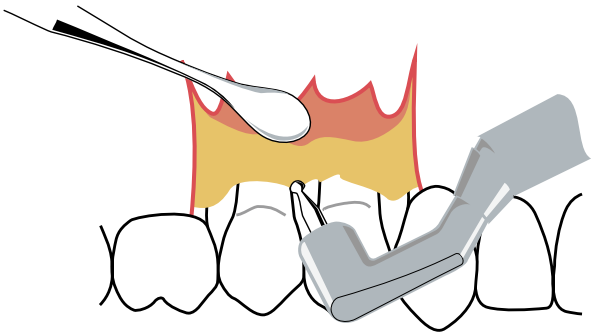

Fig. 32-11 Original Widman flap. By bone recontouring, a "physiologic" contour of the alveolar bone may be re-established.

to separate the pocket epithelium and the inflamed connective tissue from the non-inflamed gingiva. Then a mucoperiosteal flap was elevated exposing at least 2–3 mm of the marginal alveolar bone and after removing the collar of inflamed tissue around the neck of the teeth, the exposed root surfaces were carefully instrumented (Fig. 32-10). Bone recontouring was recommended to achieve an ideal anatomic form of the underlying alveolar bone (Fig. 32-11). Then buccal and lingual flaps were laid back over the alveolar bone and secured in this position with interproximal sutures (Fig. 32-12) often leaving the interproximal areas without soft tissue coverage of the crestal bone.

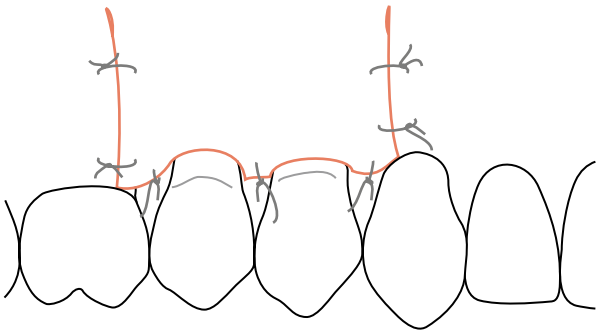

Fig. 32-12 Original Widman flap. The coronal ends of the buccal and lingual flaps are placed at the alveolar bone crest and secured in this position by interdentally placed sutures.

Neumann flap

Only a few years later, Neumann (1920) suggested the use of another flap design, which differed from the one described by Widman in that an *intracrevicular incision* is made through the base of the gingival pockets. Following flap elevation, the inside of the flap was curetted to remove the pocket epithelium and the granulation tissue, the root surfaces were subsequently debrided, and any irregularities of the alveolar bone crest were corrected. The flaps were then trimmed to allow both an optimal adaptation to the teeth and a proper coverage of the alveolar bone on both the buccal/lingual (palatal) and the interproximal sites. Neumann pointed out the importance of removing the soft tissue pockets, that is replacing the flap at the crest of the alveolar bone

Modified flap operation

In a publication from 1931, Kirkland described a surgical procedure called the *modified flap operation*, which involved intracrevicular incisions through the pockets on both the labial and the lingual aspects (Fig. 32-13), thus allowing the retraction of buccal and lingual full thickness flaps to permit proper root debridement, but without eliminating any soft or hard tissue, just the pocket epithelium and granulation tissue from the inner side of the flaps (Figs. 32-14, 32-15). The flaps were then replaced in their original position and secured with interproximal sutures (Fig. 32-16).

The *modified flap operation*, in contrast to the *original Widman flap* and the *Neumann flap*, did not include removal of non-inflamed tissues and apical displacement of the gingival margin, thus causing a minimal amount of trauma to the remaining periodontal tissues and a minimum of discomfort to the patient.

Apically repositioned flap

In the mid-1950s the focus of periodontal surgery shifted towards the aim of preserving *an adequate zone of attached gingiva* after surgery once the periodontal pockets had been eliminated. One of the first authors to describe a technique aimed at the preservation of

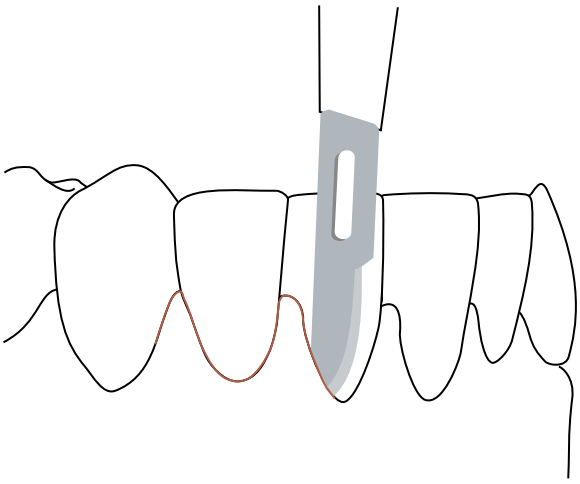

Fig. 32-13 Modified flap operation (the Kirkland flap). Intracrevicular incision.

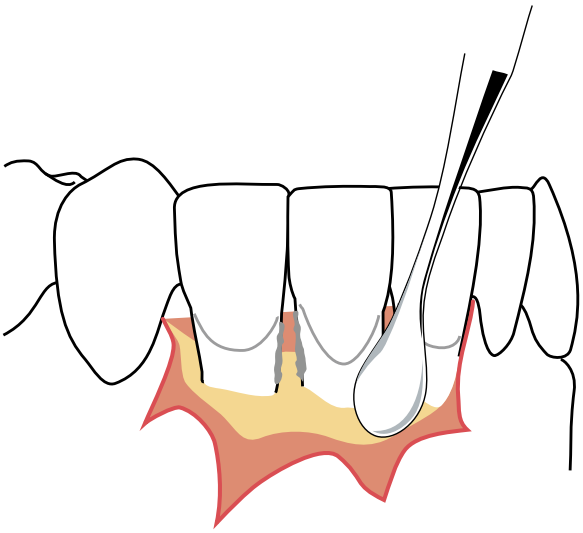

Fig. 32-14 Modified flap operation (the Kirkland flap). The gingiva is retracted to expose the "diseased" root surface.

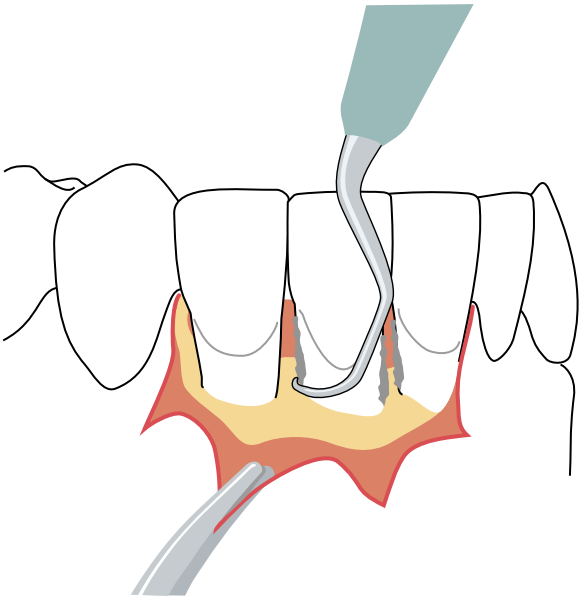

Fig. 32-15 Modified flap operation (the Kirkland flap). The exposed root surfaces are subjected to mechanical debridement.

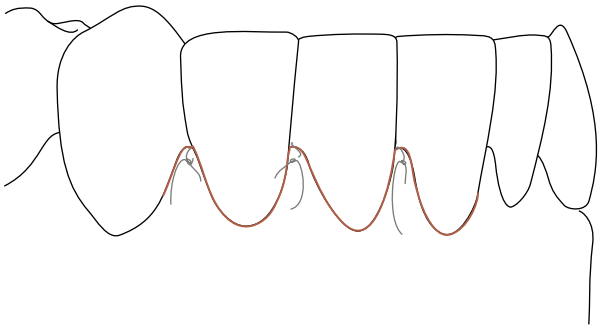

Fig. 32-16 Modified flap operation (the Kirkland flap). The flaps are repositioned at their original position and sutured.

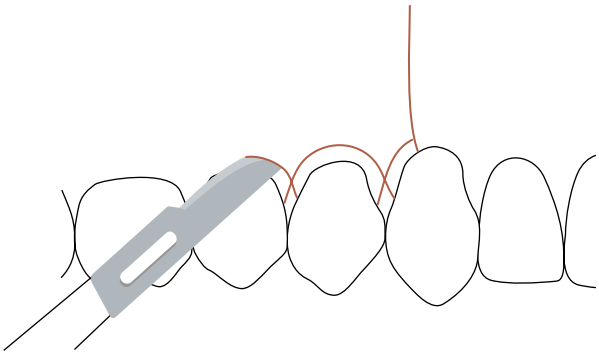

Fig. 32-17 Apically repositioned flap. Following a vertical releasing incision, the reverse bevel incision is made through the gingiva and the periosteum to separate the inflamed tissue adjacent to the tooth from the flap.

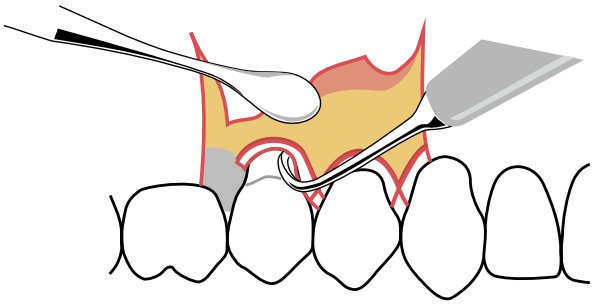

Fig. 32-18 Apically repositioned flap. A mucoperiosteal flap is raised and the tissue collar remaining around the teeth, including the pocket epithelium and the inflamed connective tissue, is removed with a curette.

gingiva was Nabers (1954) with the surgical technique for "repositioning of attached gingiva", which was later modified by Ariaudo and Tyrrell (1957). In 1962, Friedman described more precisely this surgical technique and proposed the term *apically repositioned flap*, because at the end of the surgical procedure, the entire complex of the soft tissues (gingiva and alveolar mucosa), rather than the gingiva alone, was displaced in the apical direction. Hence, instead of removing the excessive gingiva after the osseous surgery (if performed), the whole mucogingival complex was maintained and repositioned apically. This surgical technique was used on buccal surfaces in both upper and lower jaws and on lingual surfaces in the lower jaw, while a bevel flap technique (see later) had to be used on the palatal aspect of maxillary teeth where the lack of alveolar mucosa made it impossible to reposition the flap in an apical direction.

This apically repositioned flap technique (Friedman 1962) involved the following phases:

- A reverse bevel incision dependent on the pocket depth as well as the thickness and the width of the gingiva (Fig. 32-17). This beveling incision followed a scalloped outline ensuring maximal interproximal coverage of the alveolar bone when repositioning the flap. Vertical releasing incisions extending into the alveolar mucosa) were made at each of the end points of the reverse incision, making apical repositioning of the flap possible. When the gingiva was thin and only a narrow zone of keratinized tissue was present, the incisions were made close to the tooth.
- A full thickness mucoperiosteal flap including buccal/lingual gingiva and alveolar mucosa was raised beyond the mucogingival line in order to be able later to reposition the soft tissue apically. The marginal collar of tissue, including pocket epithelium and granulation tissue, was removed with curettes (Fig. 32-18), and the exposed root surfaces were carefully scaled and planed.
- The alveolar bone crest was then recontoured with the objective of recapturing the normal form of the alveolar crest, but at a more apical level (Fig. 32-19).
- Following careful adjustment, the buccal/lingual flaps were repositioned to the level of the newly recontoured alveolar bone crest and secured in this position (Figs. 32-20, 32-21).

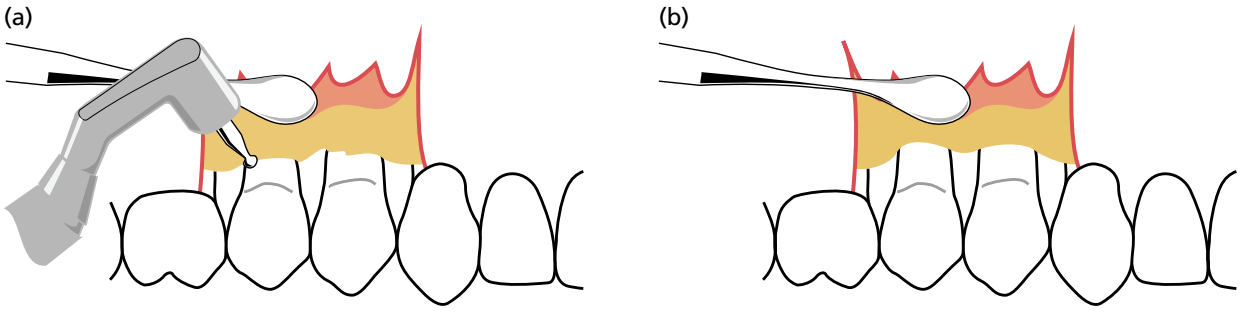

Fig. 32-19 Apically repositioned flap. Osseous surgery is performed with the use of a rotating bur (a) to recapture the physiologic contour of the alveolar bone (b).

- To handle periodontal pockets on the palatal aspect of the maxillary teeth, Friedman described a modification of the "apically repositioned flap", which he termed the *beveled flap* (Fig. 32-22), since this palatal flap was secondarily scalloped and thinned with a beveled incision once the tooth surfaces were debrided and osseous recontouring was performed (Fig. 32-23) so the gingival margins were adjusted to the alveolar bone crest (Fig. 32-24).
- Flaps were then secured in the apical position with interdental sutures (Fig. 32-25).

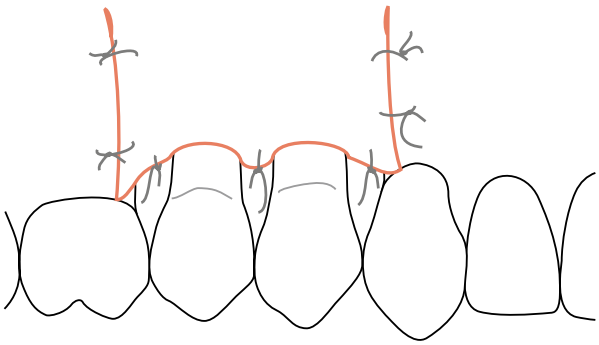

Fig. 32-20 Apically repositioned flap. The flaps are repositioned in an apical direction to the level of the recontoured alveolar bone crest and retained in this position by sutures.

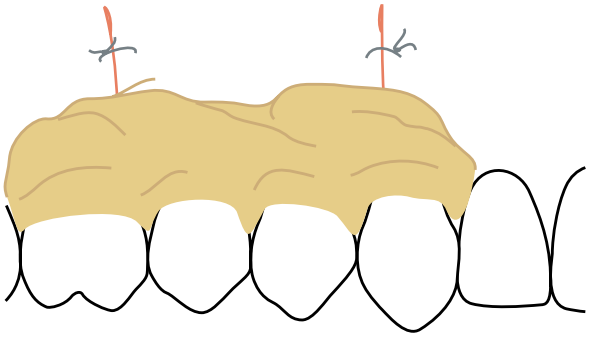

Fig. 32-21 Apically repositioned flap. A periodontal dressing is placed over the surgical area to ensure that the flaps remain in the correct position during healing.

Modified Widman flap

Ramfjord and Nissle (1974) described the *modified Widman flap* technique, which was also termed the *open flap curettage* technique. It should be noted that, while the *original Widman flap* technique included both apical displacement of the flap(s) and osseous recontouring (elimination of bony defects) to obtain

Fig. 32-23 Beveled flap. Scaling, root planing, and osseous recontouring are performed in the surgical area.

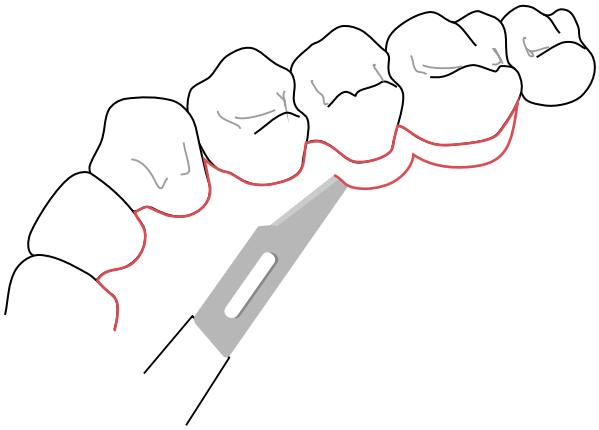

Fig. 32-24 Beveled flap. The palatal flap is replaced, and a secondary, scalloped, reverse bevel incision is made to adjust the length of the flap to the height of the remaining alveolar bone.

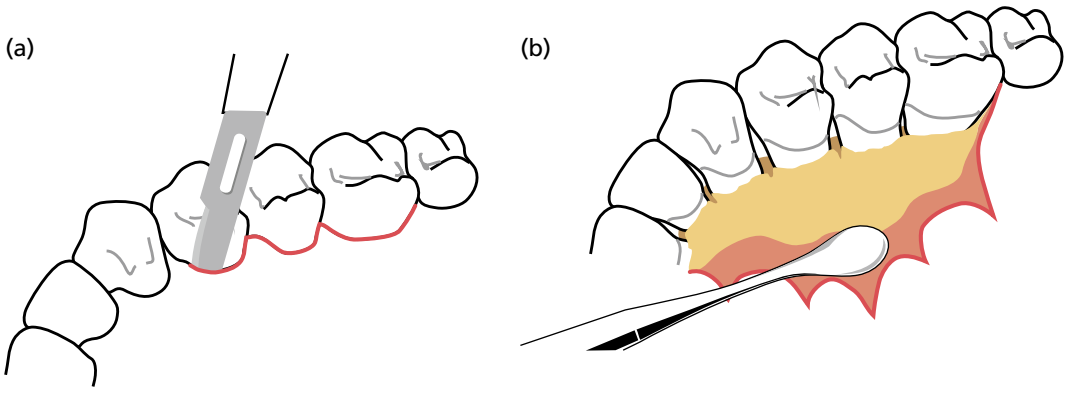

Fig. 32-22 Beveled flap. A primary incision is made intracrevicularly through the bottom of the periodontal pocket (a) and a conventional mucoperiosteal flap is elevated (b).

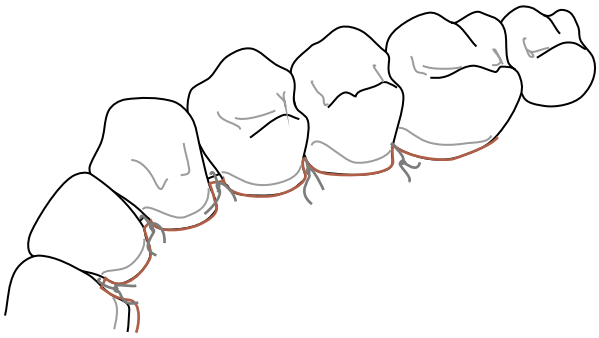

Fig. 32-25 Beveled flap. The shortened and thinned flap is replaced over the alveolar bone and in close contact with the root surfaces.

proper pocket elimination, the *modified Widman flap* technique is not intended to meet these objectives. The main advantages of the *modified Widman flap* technique in comparison to the procedures previously described were, according to Ramfjord and Nissle (1974): (1) the possibility of obtaining a close adaptation of the soft tissues to the root surfaces; (2) minimum of trauma to which the alveolar bone and the soft connective tissues are exposed; and (3) less exposure of the root surfaces, which from an esthetic point of view is an advantage in the treatment of anterior segments of the dentition.

This surgical design included an initial horizontal scalloped incision (Fig. 32-26) placed approximately 1 mm from the buccal gingival margin in order to separate properly the pocket epithelium from the flap. If the pockets on the buccal aspects of the teeth were <2 mm deep or if aesthetic considerations were important, an intracrevicular incision was recommended. A similar incision technique was used on the palatal aspect and these incisions extended as far as possible in between the teeth to allow enough interdental gingiva for proper coverage of the interproximal bone when the flap was repositioned and sutured. Vertical releasing incisions were not usually required. Then an intracrevicular incision was made around the teeth (*second incision*) to the alveolar crest (Fig. 32-27) thus facilitating the gentle separation of the collar of pocket epithelium and granulation tissue from the root surfaces. A *third incision* (Fig. 32-28) made in a horizontal direction close to the surface of the alveolar bone crest that separated the soft tissue collar of the root surfaces from the bone facilitated the raise of buccal and palatal full-thickness flaps exposing only a few millimeters of the alveolar bone crest (Ramfjord *et al*. 1977).

The pocket epithelium and the granulation tissues were then removed by means of curettes. The exposed roots were carefully scaled and planed, except for a narrow area close to the alveolar bone crest in which remnants of attachment fibers may be preserved. Angular bony defects are carefully curetted. The flaps were then trimmed and adjusted to the alveolar bone to obtain complete coverage of the interproximal bone (Fig. 32-29). If this adaptation cannot be achieved by soft tissue recontouring, some bone could be removed from the outer aspects of the alveolar process in order to facilitate proper flap adaptation. The flaps were sutured together with individual interdental sutures.

Distal wedge procedures

In many cases the treatment of periodontal pockets on the distal surface of distal molars is complicated by the presence of bulbous tissues over the tuberosity or by a prominent retromolar pad. This area frequently presents limited amounts of keratinized gingiva or the presence of distal angular bony defects which makes the removal of this tissue by gingivectomy contraindicated (Fig. 32-30). These tissues should then be reduced in size rather than

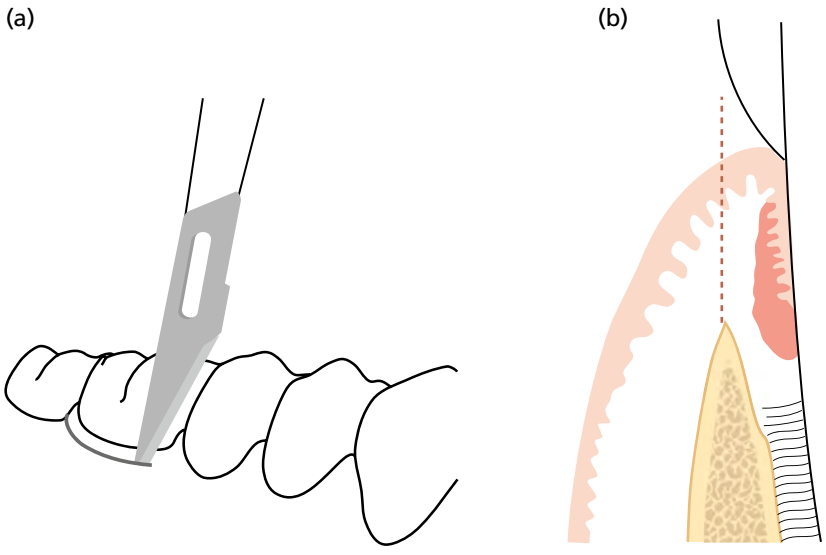

Fig. 32-26 Modified Widman flap. The initial incision is placed 0.5–1 mm from the gingival margin (a) and parallel to the long axis of the tooth (b).

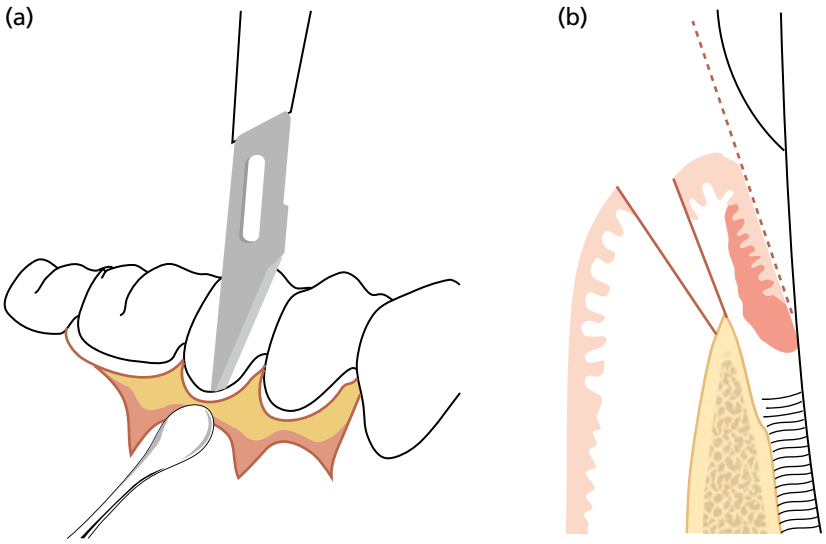

Fig. 32-27 Modified Widman flap. Following careful elevation of the flaps, a second intracrevicular incision (a) is made to the alveolar bone crest (b) to separate the tissue collar from the root surface.

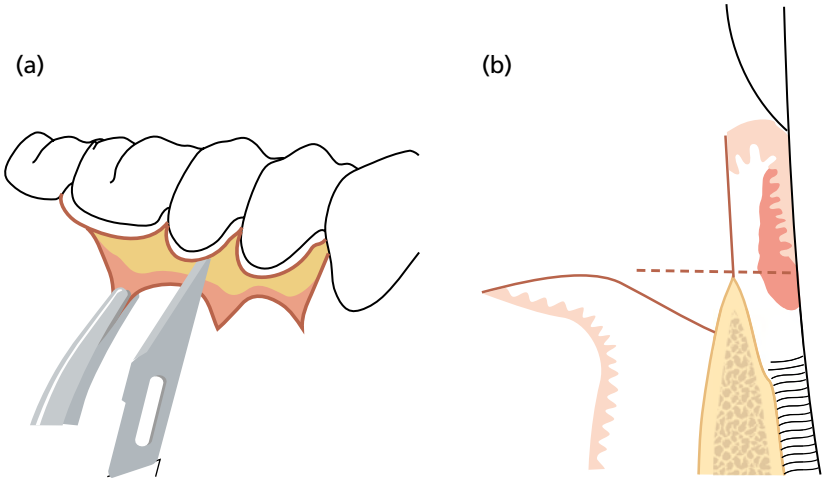

Fig. 32-28 Modified Widman flap. A third incision is made perpendicular to the root surface (a) and as close as possible to the bone crest (b), thereby separating the tissue collar from the alveolar bone.

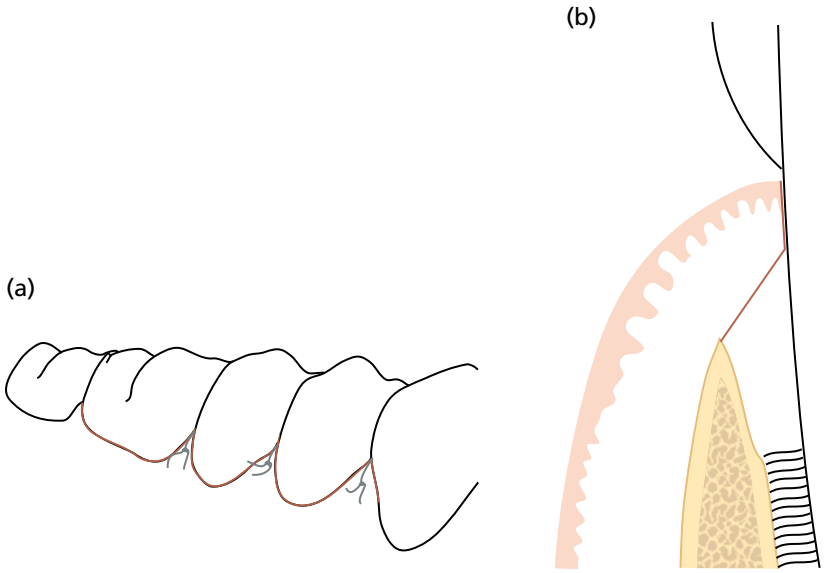

Fig. 32-29 Modified Widman flap. (a) Following proper debridement and curettage of angular bone defects, the flaps are carefully adjusted to cover the alveolar bone and sutured. (b) Complete coverage of the interdental bone as well as close adaptation of the flaps to the tooth surfaces should be accomplished.

removed *in toto*, which is accomplished by the distal wedge procedure (Robinson 1966). This technique involves incision of the buccal and lingual/palatal flaps, with vertical incisions through the tuberosity or retromolar pad, forming a triangular wedge (Fig. 32-31a). The facial and lingual walls of the tuberosity or retromolar pad are then deflected and the incised wedge of tissue is dissected and separated from the bone (Fig. 32-31b). The walls of the facial and lingual flaps are then reduced in thickness by undermining incisions (Fig. 32-31c). Loose tags of tissue are removed, and the root surfaces are debrided. If necessary, the bone is recontoured. This surgical design facilitates access to the osseous defect and makes it possible to preserve sufficient amounts of gingiva and mucosa to achieve soft tissue coverage.

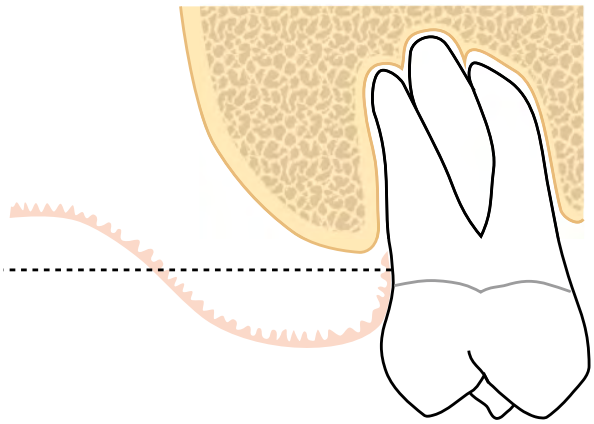

Fig. 32-30 Distal wedge procedure. Simple gingivectomy incision (dashed line) can be used to eliminate a soft tissue pocket and adjacent fibrous tissue pad behind a maxillary molar.

The buccal and lingual flaps are then replaced over the exposed alveolar bone, and the edges trimmed to avoid overlapping wound margins. The flaps are secured in this position with interrupted sutures (Fig. 32-31d). The sutures are removed after approximately 1 week. Depending on the anatomy of the tuberosity or retromolar area, different surgical designs have been described with the purpose of eliminating the excessive tissue and at the same time preserving keratinized tissue (Fig. 32-32). One such design is the modified distal wedge procedure that includes two parallel reverse bevel incisions, one buccal and one palatal, made from the distal surface of the molar to the posterior part of the tuberosity, where they are connected with a buccolingual incision (Figs. 32-33. 32-34, 32-35).

Osseous surgery

The principles of osseous surgery in periodontal therapy were outlined by Schluger (1949) and Goldman (1950). They pointed out that alveolar bone loss caused by inflammatory periodontal disease often

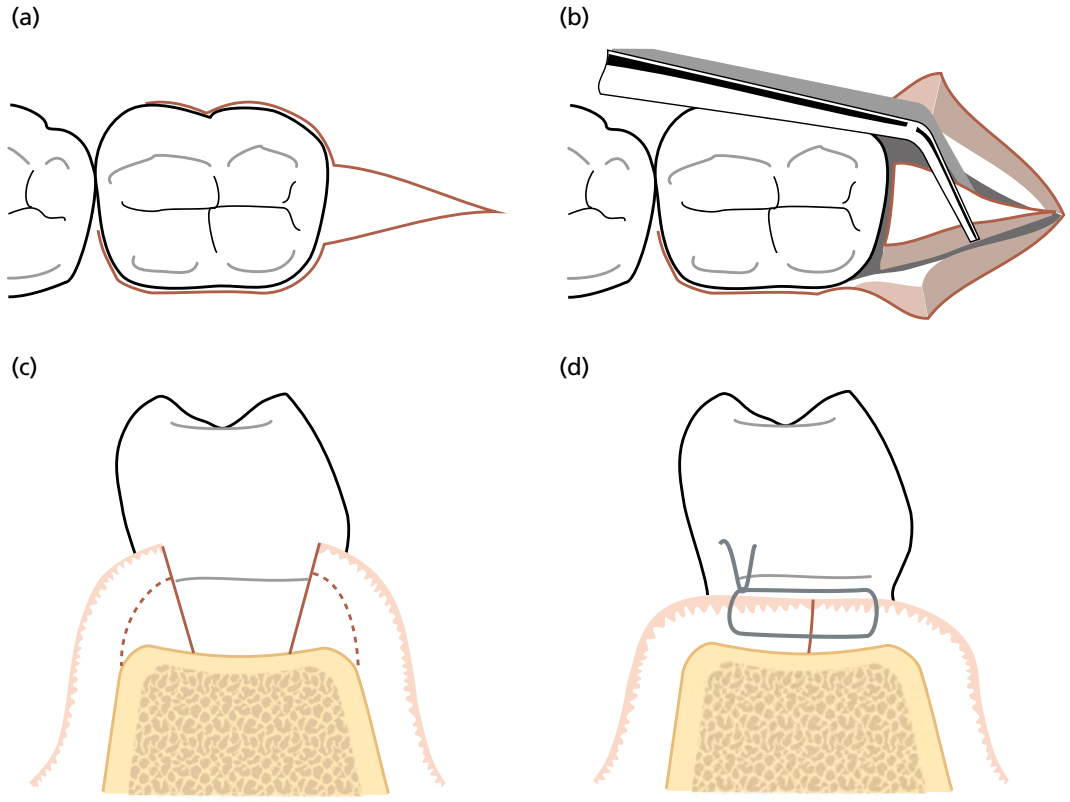

Fig. 32-31 Distal wedge procedure. (a) Buccal and lingual vertical incisions are made through the retromolar pad to form a triangle behind a mandibular molar. (b) A triangular-shaped wedge of tissue is dissected from the underlying bone and removed. (c) Walls of the buccal and lingual flaps are reduced in thickness by undermining incisions (dashed lines). (d) The flaps, which have been trimmed and shortened to avoid overlapping wound margins, are sutured.

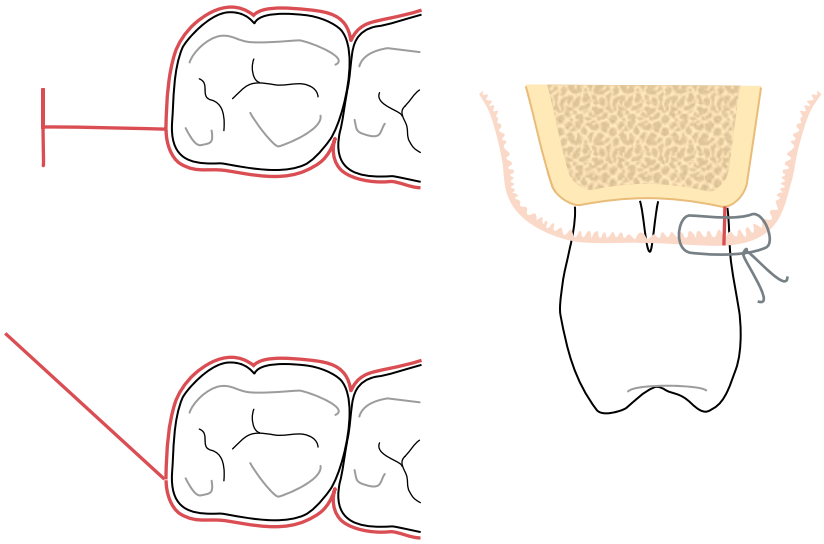

Fig. 32-32 Modified incision techniques in distal wedge procedures. To ensure optimal flap adaptation at the furcation site, the incision technique may be modified. The amount of attached keratinized tissue present as well as the accessibility to the retromolar area has to be considered when placing the incision.

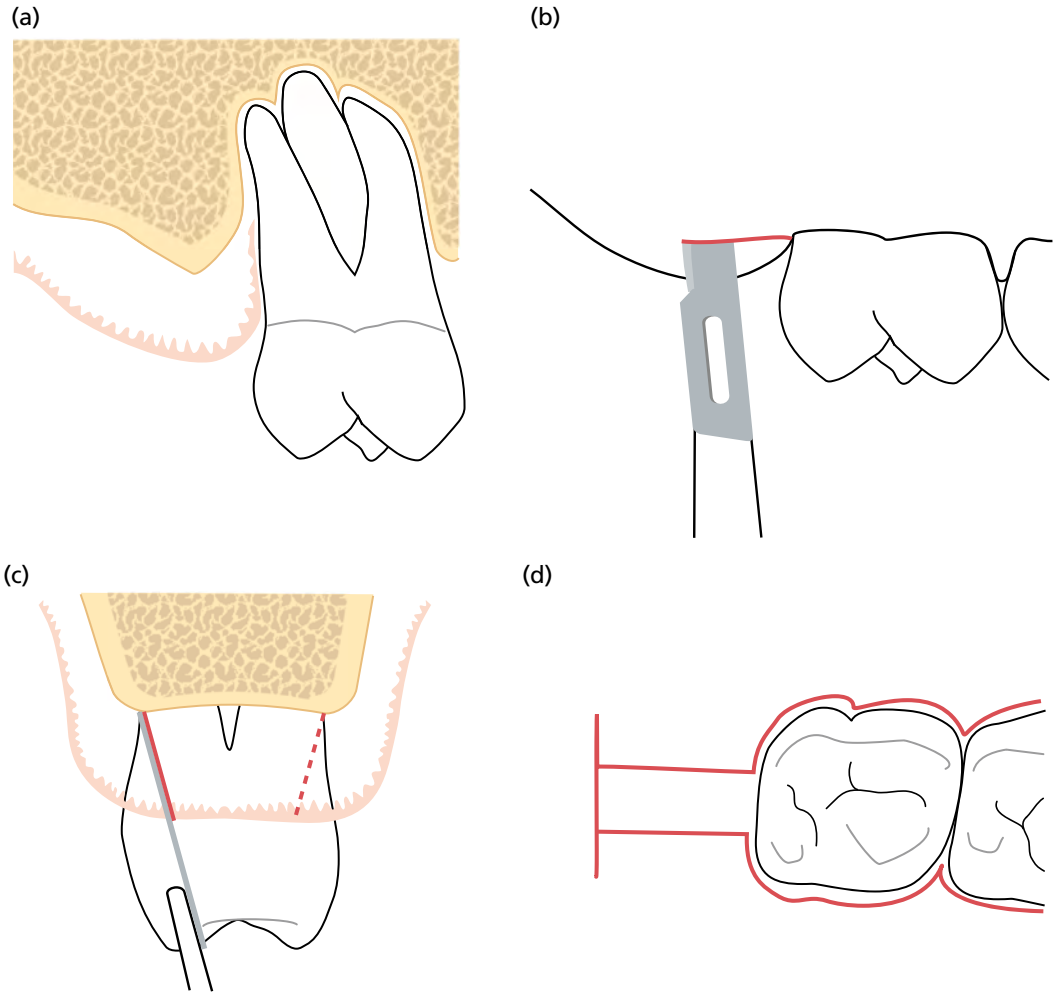

Fig. 32-33 Modified distal wedge procedure. (a) A deep periodontal pocket combined with an angular bone defect at the distal aspect of a maxillary molar. (b–d) Two parallel reverse bevel incisions, one buccal and one palatal, are made from the distal surface of the molar to the posterior part of the tuberosity, where they are connected with a buccolingual incision (d). The buccal and palatal incisions are extended in a mesial direction along the buccal and palatal surfaces of the molar to facilitate flap elevation.

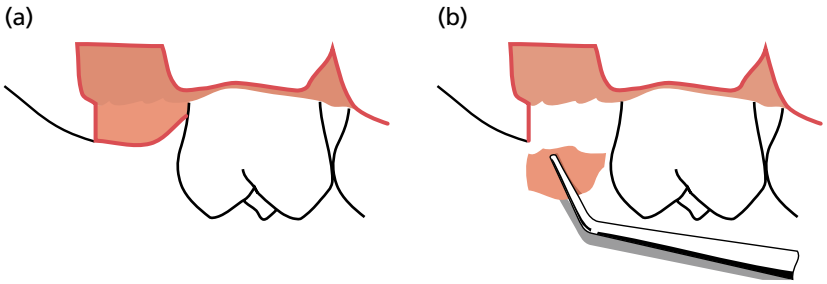

Fig. 32-34 Modified distal wedge procedure. (a) Buccal and palatal flaps are elevated and (b) the rectangular wedge is released from the tooth and underlying bone by sharp dissection and then removed.

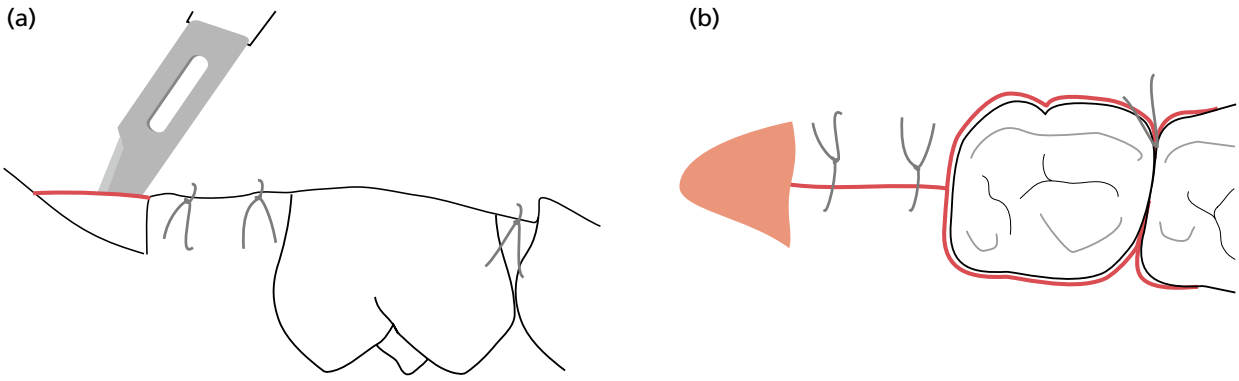

Fig. 32-35 Modified distal wedge procedure. (a, b) Following bone recontouring and root debridement, the flaps are trimmed and shortened to avoid overlapping wound margins and sutured. A close soft tissue adaptation should be accomplished to the distal surface of the molar. The remaining fibrous tissue pad distal to the buccolingual incision line is "levelled" by the use of a gingivectomy incision.

resulted in an uneven outline of the bone crest and because they thought that these gingival contours were closely dependent on the contour of the underlying bone as well as the proximity and anatomy of adjacent tooth surfaces, the elimination of soft tissue pockets often had to be combined with osseous reshaping and the elimination of osseous craters and angular bony defects to establish and maintain shallow pockets and optimal gingival contour after surgery.

Osteoplasty

The term *osteoplasty* was introduced by Friedman in 1955. The purpose of osteoplasty was to reshape the alveolar bone *without* removing any "supporting" bone. Examples of osteoplasty are the thinning of thick osseous ledges and the establishment of a scalloped contour of the buccal (lingual and palatal) bone crest (Fig. 32-36). In flap surgery without bone recontouring, interdental morphology may sometimes preclude optimal mucosal coverage of the bone postsurgically, even if pronounced scalloping of soft tissue flaps is performed. In such a situation, removal of non-supporting bone by vertical grooving to reduce the buccolingual dimension of the bone in the interdental areas may facilitate flap adaptation, thereby reducing the risk of bone exposure during healing as well of ischemic necrosis of unsupported mucosal flaps due to flap margin deficiencies.

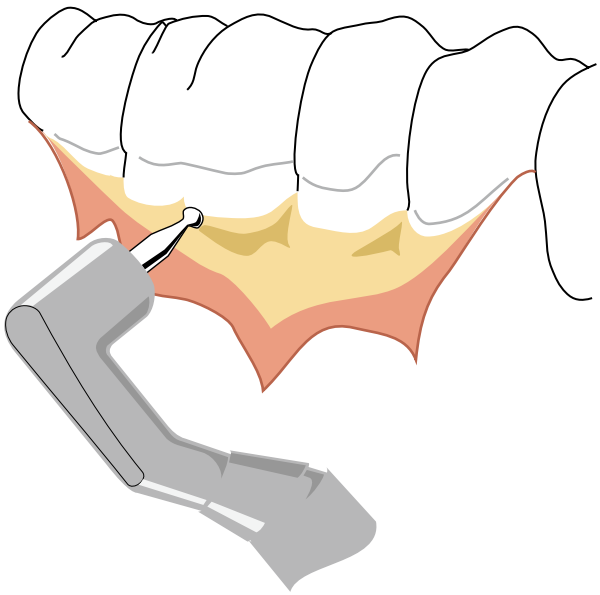

Fig. 32-36 Osteoplasty. Thick osseous ledges in a mandibular molar region area are eliminated with the use of a round bur to facilitate optimal flap adaptation.

Removal of non-supporting bone may sometimes also be required to gain access for intrabony root surface debridement. The levelling of interproximal craters and the elimination (or reduction) of bony walls of circumferential osseous defects are often referred to as "osteoplasty" since usually no resection of supporting bone is required (Fig. 39-37).

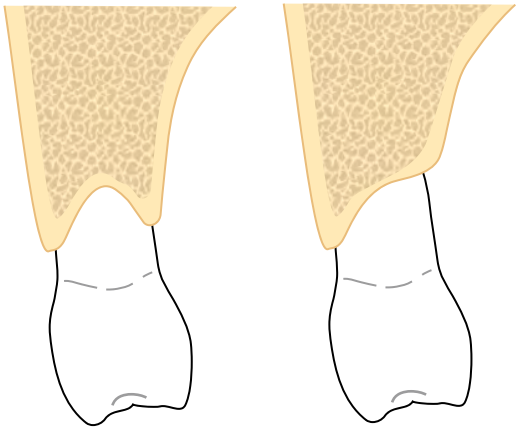

Fig. 32-37 Osteoplasty. Levelling of an interproximal bone crater through the removal of the palatal bone wall. For aesthetic reasons, the buccal bone wall is maintained to support the height of the soft tissue.

Ostectomy

Ostectomy involves the elimination of *supporting bone* that is directly involved in the attachment of the tooth. The objective of ostectomy was to establish a "*physiologic*" anatomy of the alveolar bone (positive architecture), but at a more apical level. However, the need for this positive architecture of the alveolar bone has never been demonstrated and extensive bone removal of supporting bone in molar areas may cause the opening of a furcation defect or cause extensive gingival recession. Therefore, as a general rule, supporting bone should not be removed. Currently, ostectomy is only indicated in the presence of craters where its access for instrumentation or for improved flap adaptation requires reduction of the buccal and/or lingual crater walls to the base of the osseous defect (Fig. 32-38a). When bone resection has been carried out in the interdental area, the buccal and lingual/palatal bone margins may subsequently be recontoured to compensate for discrepancies in bone height resulting from the interdental bone resection. However, this reduction should never compromise the opening of a furcation or the tooth periodontal support (Oschenbein 1986) (Fig. 32-38b).

Techniques in periodontal surgery (current perspective)

Objectives of surgical treatment

Traditionally, *pocket elimination/closure* has been a main objective of surgical periodontal therapy. The removal of the pocket by surgical means served two purposes: (1) the elimination of the pocket, which maintained an environment conducive to progression of periodontitis and (2) the root surface was made accessible for professional debridement and for self-performed tooth cleaning after healing.

From these two objectives, the necessity for pocket elimination has been challenged, since a zero-pocket dentition after periodontal therapy seems to be unrealistic. However, long-term cohort studies evaluating the incidence of progression of periodontitis after successful periodontal therapy have demonstrated that presence of residual pockets (probing pocket depth [PPD] ≥6 mm) and persistent BoP (open pockets) in sites with deep probing depths (PPD >4 mm + BoP) are significantly associated with disease progression (Claffey & Egelberg 1995; Matuliene *et al*. 2008). Therefore, the current end point of periodontal therapy is to achieve a dentition with no sites with deep pockets. This new information has thus formed the basis of the role played by periodontal surgery in the preservation of teeth, because presence of residual disease after the second step of periodontal therapy requires further treatment as part of the third step of periodontal therapy. However, *increased pocket depth* should not be the only indication for periodontal surgery, since the *probeable depth*, that is the distance from the gingival margin to the point where tissue

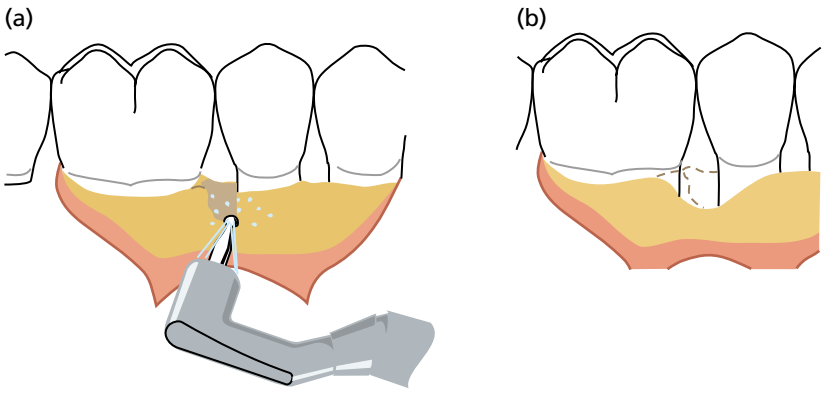

Fig. 32-38 Ostectomy. (a) Combined one- and two-wall osseous defect on the distal aspect of a mandibular bicuspid has been exposed following reflection of mucoperiosteal flaps. Since aesthetics is not a critical factor to consider in the posterior tooth region of the mandible, the bone walls are reduced to a level close to the base of the defect using rotating round burs under continuous saline irrigation. (b) Osseous recontouring completed. Note that some supporting bone has to be removed from the buccal and lingual aspect of both the second bicuspid and the first molar in order to provide a hard tissue topography which allows a close adaptation of the covering soft tissue flap.

resistance stops further periodontal probe penetration, may not correspond to the "true" depth of the pocket, mainly in the presence of gingival inflammation (see Chapter 22). Furthermore, there is no established correlation between *probeable* pocket depth and the presence or absence of active disease. This means that signs other than increased probing depth should be present to justify surgical therapy. These include clinical signs of inflammation, especially exudation and BoP (to the bottom of the pockets), as well as aberrations of gingival morphology.

In conclusion, the main objective of periodontal surgery is to contribute to the long-term preservation of the periodontium by facilitating plaque removal and infection control, and periodontal surgery can serve this purpose by:

- Creating accessibility for proper professional scaling and root planing
- Establishing a dentition without deep pockets and open pockets
- Establishing a gingival morphology which facilitates self-performed infection control.

In addition, periodontal surgery may aim to regenerate the periodontal attachment lost due to destructive disease (regenerative procedures in periodontal therapy are discussed in Chapter 38) or to change the anatomy of furcation lesions to improve accessibility for infection control (treatment of furcation lesions are discussed in Chapter 33)

Indications for surgical treatment

Impaired access for scaling and root planing

The difficulties in accomplishing proper root debridement with a non-surgical approach increase with (1) increasing depth of the periodontal pockets, (2) increasing width of the tooth surfaces, and (3) the presence of root fissures, root concavities, furcations, and defective margins of dental restorations in the subgingival area.

Provided a correct technique and suitable instruments are used, it is usually possible properly debride pockets that are up to 5 mm deep (Waerhaug 1978; Caffesse *et al*. 1986). However, this 5 mm limit cannot be used as a universal rule of thumb. Reduced accessibility and the presence of one or several of the above-mentioned impeding conditions may prevent proper debridement of shallow pockets, whereas at sites with good accessibility and favorable root morphology, proper debridement can be accomplished even in deeper pockets (Badersten *et al*. 1981; Lindhe *et al*. 1982b).

It is often difficult to ascertain by clinical means whether subgingival instrumentation has been properly performed. Following scaling, the root surface should be smooth – roughness will often indicate the presence of remaining subgingival calculus. It is also important to monitor carefully the gingival reaction to subgingival debridement. If inflammation persists and if bleeding is elicited by gentle probing in the subgingival area, the presence of subgingival deposits should be suspected (Fig. 32-39).

Fig. 32-39 Evaluation following non-surgical instrumentation reveals persistent signs of inflammation, bleeding following pocket probing, and a probing depth of ≥6 mm. Flap elevation to expose the root surface for proper cleaning should be considered.

If such symptoms are not resolved by repeated subgingival instrumentation, surgical treatment should be performed to expose the root surfaces for proper cleaning.

Impaired access for self-performed plaque control

The level of infection control that can be maintained by the patient is determined not only by his/her interest and dexterity, but also, to some extent, by the morphology of the dentogingival area. The patient's responsibilities in an infection-control program must include the cleansing of the supragingival tooth surfaces and the marginal part of the gingival sulcus.

Pronounced gingival hyperplasia and presence of gingival craters (Fig. 32-40) are examples of morphologic aberrations that may impede proper home care. Likewise, the presence of restorations with defective marginal fit or adverse contour and surface characteristics at the gingival margin may seriously compromise plaque removal.

In the treatment of periodontitis, the dentist should prepare the dentition in such a way that home care can be effectively managed. At the completion of treatment, the following objectives should have been met:

- No sub- or supragingival dental deposits
- No open pockets (no BoP to the bottom of the pockets >4 mm)
- No deep pockets (pockets ≥ 6 mm)
- No plaque-retaining aberrations of gingival morphology
- No plaque-retaining parts of restorations in relation to the gingival margin.

These requirements lead to the following indications for periodontal surgery:

- Accessibility for proper root debridement
- Pocket depth reduction
- Establishment of a morphology of the dentogingival area conducive to infection control
- Correction of gross gingival aberrations
- Shift of the gingival margin to a position apical to plaque-retaining restorations

Contraindications for periodontal surgery

Patient cooperation

Because optimal postoperative infection control is decisive for the success of periodontal treatment (Rosling *et al*. 1976; Nyman *et al*. 1977; Axelsson & Lindhe 1981), a patient who fails to cooperate during the cause-related phase of therapy should not be exposed to surgical treatment. Even though short-term postoperative infection control entails frequent professional treatments, the long-term responsibility for maintaining good oral hygiene must rest with the patient. Theoretically, even the poorest oral hygiene performance by a patient may be compensated for by frequent recall visits for supportive therapy (e.g. once a week), but it is unrealistic to consider larger groups of patients being maintained in this manner. A typical recall schedule for periodontal patients involves professional consultations for supportive periodontal therapy once every 3–6 months. Patients who cannot maintain satisfactory oral hygiene standards over such a period should normally not be considered to be candidates for periodontal surgery.

Smoking

Although smoking negatively affects wound healing (Siana *et al*. 1989), it may not be considered a contraindication for surgical periodontal treatment. The clinician should be aware, however, that less reduction of PPD, smaller gains in clinical attachment, and less bone regeneration might occur in patients who smoke than in patients who do not smoke (Labriola *et al*. 2005; Javed *et al*. 2012; Patel *et al*. 2012).

General health conditions

It is important to re-evaluate the patient's medical history before any surgical intervention to identify whether there is any medical condition that may preclude periodontal surgery or whether certain

Fig. 32-40 Example of a proximal soft tissue crater, which favors plaque retention and thereby impedes the patient's plaque control.

precautions should be taken, for example prescription of prophylactic antibiotics or the use of local anesthetics without epinephrine. Consultation with the patient's physician should also be considered.

Selection of the surgical technique

Because each of the surgical procedures described is designed to deal with a specific situation or to meet a certain objective, it must be understood that in most patients no single standardized technique alone can be applied when periodontal surgery is undertaken. Therefore, in each surgical field, different techniques are often used and combined in such a way that the overall objectives of the periodontal surgical therapy are met. As a general rule, periodontal surgical techniques that preserve or induce the formation of periodontal tissue should be preferred over those that resect or eliminate tissue.

Gingivectomy

The obvious indication for gingivectomy is the reshaping of abnormal gingival contours such as gingival craters and gingival hyperplasia (see Fig. 32-40). In these cases, the technique is often termed *gingivoplasty*. Gingivectomy as such, is usually not indicated since the external beveled incision will lead to the removal of the entire zone of gingiva. As an alternative, an *internal beveled gingivectomy* may be performed in situations with just soft tissue pockets (pockets not extending beyond the mucogingival junction), without the presence of bony craters or any infrabony lesion (Fig. 32-41). These limitations, combined with the development of surgical methods which have a broader field of application, have led to less frequent use of gingivectomy.

Flap procedures

Flap operations can be used in all cases where surgical treatment of periodontitis is indicated. Periodontal flap procedures are particularly indicated at sites where pockets extend beyond the mucogingival junction and/or where treatment of bony defects and furcation involvements is required.

The advantages of flap operations include:

- Existing gingival tissue is preserved
- Marginal alveolar bone is exposed allowing the identification of bony defects for their adequate treatment
- Furcation areas are exposed, and the degree of involvement and the "tooth–bone" relationship can be identified
- Flap can be repositioned at its original level or shifted apically, thereby making it possible to adjust the gingival margin to the local conditions
- Flap procedure preserves the oral epithelium and hence healing takes place mostly by primary intention. As a consequence, the postoperative period is usually less unpleasant to the patient when compared with gingivectomy.

Classifications of different flap modalities used in the treatment of periodontitis often make distinctions between tissue-eliminating (resective) and tissue-preserving flaps (access/conservative). Furthermore, flaps can be distinguished between those involving both buccal and lingual marginal tissues versus only buccal (standard versus single flaps) and those preserving or not the interdental tissues (standard versus papilla preservation flaps).

From a didactic point of view, it seems appropriate to distinguish periodontal surgical therapy with regard to how to deal with (1) the soft tissue component and (2) the hard tissue component of the periodontal pocket at a specific tooth site (Fig. 32-42).

Depending on the surgical technique used, the soft tissue flap would either be apically positioned at the level of the bone crest (apically positioned flap) or maintained in a coronal position (access and papilla preservation flaps) at the completion of the surgical intervention. The maintenance of the presurgical soft tissue height is of importance from an esthetic point

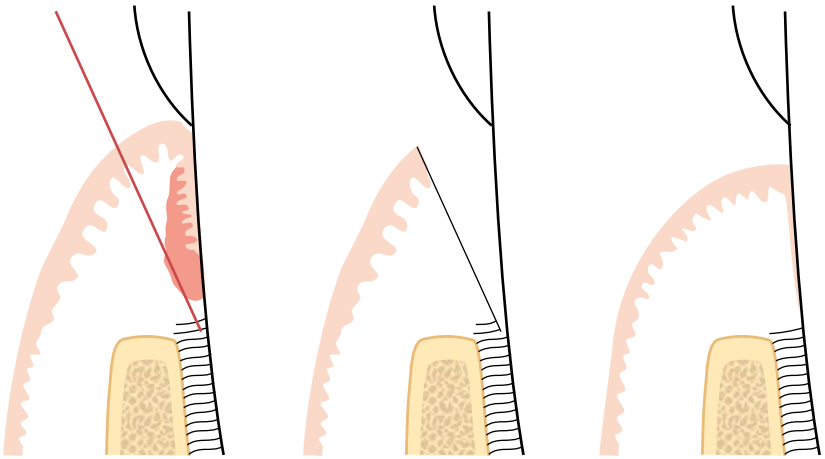

Fig. 32-41 Internal beveled gingivectomy. Schematic illustration of the incision technique in case of the presence of only a minimal zone of gingiva.

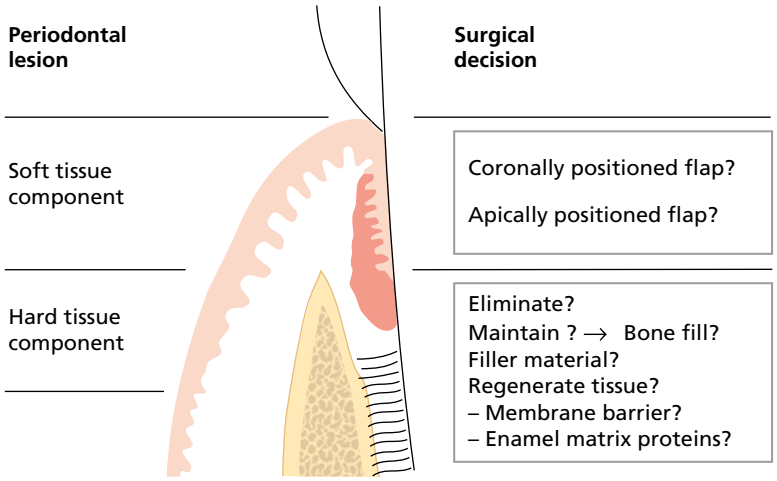

Fig. 32-42 Surgical decisions. Treatment decisions with respect to the soft and the hard tissue component of a periodontal pocket.

of view, particularly in the anterior tooth region. However, long-term results from clinical trials have shown that major differences in the final position of the soft tissue margin are not evident when comparing between access and resective surgical flap procedures. In many patients it may be of significance to position the flap coronally in the anterior tooth region in order to give the patient a prolonged time of adaptation to the inevitable soft tissue recession. In the posterior tooth region, however, an apical position should be the standard.

Independent of flap position, the goal should be to achieve complete soft tissue coverage of the alveolar bone, not only at buccal/lingual sites but also at proximal sites. It is therefore of utmost importance to carefully plan the incisions in such a way that this goal is achieved at the termination of the surgical intervention once the flaps have been re-positioned and sutured

The reported difference in final positioning of the gingival margin between surgical techniques is also dependent on the degree of osseous recontouring performed (Townsend-Olsen *et al*. 1985; Lindhe *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001). During conventional periodontal surgery, one would usually opt for the conversion of an intrabony defect into a suprabony defect, which then is eliminated by apical repositioning of the soft tissue flap(s). Osseous recontouring of angular bony defects and craters is an excisional technique, which should be used with caution and discrimination. However, the therapist is often faced with the dilemma of deciding whether or not to eliminate an angular bony defect. There are a number of factors that should be considered in the treatment decision, such as:

- Esthetics
- Tooth/tooth site involved
- Defect morphology (intrabony component and defect angle)
- Amount of remaining periodontium.

Since alveolar bone supports the soft tissue, bone recontouring will result in recession of the soft tissue margin. For esthetic reasons, one may therefore be restrictive in eliminating interproximal bony defects in the anterior tooth region.

Defect morphology is a variable of significance for repair/regeneration during healing (Rosling *et al*. 1976; Cortellini *et al*. 1993, 1995a). Whereas two- and, especially, three-wall defects may show great potential for repair/regeneration, one-wall defects and interproximal craters will rarely result in such resolution. Further, the removal of intrabony connective tissue/granulation tissue during a surgical procedure will always lead to crestal resorption of bone, especially in sites with thin bony walls. This results in reduction of the vertical dimensions of the bone tissue at the site.

The treatment options available for the hard tissue defect may include:

- Eliminating the osseous defect by resecting bone (osteoplasty and/or ostectomy). In cases of an approximal crater of limited depth, it may often be sufficient to reduce/eliminate the bone wall on the lingual side of the crater, thereby maintaining the bone support for the soft tissue on the facial aspect (see Fig. 32-37). In addition to esthetics, the presence of furcation lesions may limit the extent to which bone recontouring can be performed (Oschenbein 1986).
- Maintaining the area without osseous resection and either using regenerative procedures (these procedures in periodontal therapy are discussed in Chapter 38) or minimally invasive flap procedures aimed to preserve the marginal tissues and provide maximum blood clot stability and protection of self-periodontal regeneration (see detailed description later in this chapter).

Instruments used in periodontal surgery

Surgical procedures used in periodontal therapy often involve specific instruments for the different phases within the surgical intervention:

- Incision and excision (scalpels and knives)
- Deflection and re-adaptation of mucosal flaps (periosteal elevators)
- Removal of adherent fibrous and granulomatous tissue, root debridement (scalers and curettes)
- Removal of dental and osseous tissue (bone rongeurs, chisels, and burs)
- Suturing (sutures and needle holders, suture scissors).

Instruments should be kept in good working condition and maintenance should ensure that scalers, curettes, chisels, and knives are sharp and the hinges of scissors, rongeurs, and needle holders are properly lubricated.

The set of instruments used for the various periodontal surgical procedures should have a comparatively simple design. As a general rule, the number and varieties of instruments should be kept to a minimum and should be stored in sterile "ready-to-use" packs or trays. A commonly used standard tray combines the basic set of instruments used in periodontal surgery, together with periodontal instruments. The instruments listed below are often found on a standard tray (Fig. 32-43):

- Mouth mirrors
- Graduated periodontal probe/explorer
- Nabers (furcation) probe
- Handles for disposable surgical blades
- Mucoperiosteal elevator and tissue retractor
- Scalers and curettes
- Ultrasonic tips
- Tissue pliers
- Tissue scissors
- Needle holder.

Additional equipment may include:

- Syringe for local anesthesia
- Syringe for irrigation
- Aspirator tip
- Physiologic saline
- Plastic instrument

Specific surgical instruments

Knives used for drawing the incisions are available with fixed or replaceable blades. The advantage of disposable blades is that they are always sharp and are manufactured in different shapes (Fig. 32-43). Special handles mount blades in angulated positions, which may facilitate their use for reverse bevel incisions and for harvesting palatal autografts.

The proper healing of the periodontal wound is critical for the success of the operation. It is therefore important that the manipulations of soft tissue flaps are performed with minimum tissue damage. Care should be exercised in the use of periosteal elevators when flaps are deflected and retracted for optimal visibility. Surgical pliers and tissue retractors that pierce the tissues should not be used in the marginal area of the flaps. Needle holders with small beaks and atraumatic sutures should be used.

Scalers and curettes are used in periodontal surgery for both excising the granulation tissue and for scaling and root planing the roots once the area has been accessed after raising the flaps. Rotating fine-grained diamond stones may also be used within infrabony pockets, root concavities, and entrances to furcations (Fig. 32-44). An ultrasonic device with sterile saline solution as coolant may also be used for root debridement during surgery. Continuous irrigation

Fig. 32-43 Set of instruments used for periodontal surgery and included in a standard tray

Fig. 32-44 (a) Examples of rotatory instruments mounted on straight or high-speed handpieces, using either (b) short or long trunk round burrs. (c) Examples of instruments used for bone recontouring (bone chisels and files).

of saline during the instrumentation of the roots is recommended to rinse away the blood and improve the visibility in the surgical field.

Sharp bone chisels or bone rongeurs (Fig. 32-44) are used during resective flap procedures to eliminate non-supportive bone (osteoplasty) or less frequently supportive bone (ostectomy). These instruments are recommended when removing the bone adjacent to the root surfaces because the use of burs may eliminate sound dental tissue, leading to hypersensitivity and loss of cementum. When used, surgical burs should be used with ample rinsing with sterile physiologic saline to ensure cooling and removal of tissue remnants.

Hemorrhage is rarely a problem in periodontal surgery. The characteristic oozing type of bleeding can normally be controlled with a pressure pack (sterile gauze moistened with saline). Bleeding from small vessels can be stopped by clamping and tying using a hemostat and resorbable sutures. If the vessel

is surrounded by bone, bleeding may be stopped by crushing the nutrient canal in which the vessel runs with a blunt instrument.

Visibility in the field of operation is secured by using effective suction. The lumen of the aspirator tip should have a smaller diameter than the rest of the tube, in order to prevent clogging.

The patient's head may be covered by autoclaved cotton draping or sterile disposable plastic/paper draping. The surgeon and all assistants should wear protective sterile gowns, surgical gloves, and protective eyewear.

Step by step flap surgical procedure

Local anesthesia in periodontal surgery

Pain management is an ethical obligation and will improve patient satisfaction (e.g. increased confidence and improved cooperation) as well as recovery and return to function after periodontal surgical procedures. To prevent pain during the performance of a periodontal surgical procedure, the entire area of the dentition scheduled for surgery, the teeth as well as the periodontal tissues, requires proper local anesthesia.

Anesthetics from the chemical group amino amides, e.g. lidocaine, mepivacaine, and articaine, are the "gold standard" for dental local anesthetics in periodontal surgery. In light of the specific need for bone penetration these anesthetics should be administered at high concentrations and with the appropriate additional vasoconstriction since these anesthetic solutions will cause an increase in the local blood flow, thus decreasing the duration of anesthesia. With the addition of vasoconstrictors (e.g. epinephrine >1:100 000 or >5 mg/mL) to dental local anesthetic solutions; the duration is considerably prolonged, the depth of anesthesia may be enhanced, and bleeding during surgery is reduced. In fact, the use of a dental local anesthetic without a vasoconstrictor during a periodontal surgical procedure is counterproductive because of the increased bleeding in the area of surgery and the reduced depth of the anesthesia. However, although the cardiovascular effects of the usually small amounts of epinephrine used during a periodontal surgical procedure are of little practical concern in most individuals, accidental intravascular injections, unusual patient sensitivity, and unanticipated drug interactions (or excessive doses), can result in potentially serious health hazards, and therefore, a careful medical history must be taken before any periodontal surgery. In patients with a history of serious cardiovascular events, only low dosages should be administered or even local anesthetics without a vasoconstrictor can be used.

Injections of dental local anesthetics prior to a periodontal surgical procedure may be routine for the dentist but is often a most unpleasant experience for the patient. Reassurance and psychological support are essential and will increase the patient's confidence in their dentist. The creation of a relaxed atmosphere to decrease the patient's fear in the unusual surgical environment is a useful way of increasing the patient's own defense mechanisms against pain perception (e.g. release of endogenous endorphins).

Anesthesia for periodontal surgery is obtained by nerve block and/or by local infiltration. In cases of flap surgery, complete anesthesia must be attained before commencing the operation because it may be difficult to supplement anesthesia after the bone surface has been exposed. In addition, the pain elicited by needle insertion can be significantly reduced if the mucosa at the puncture site is anesthetized in advance by the use of a suitable topical ointment or spray.

Local infiltration may have a greatly decreased rate of success in areas where inflammation remains in the periodontal tissues. The suggested reason for this is that tissue pH tends to be low in inflamed areas and anesthetic solutions are less potent at low pH because there is a greater proportion of charged cation molecules than uncharged base molecules. Because of this, diffusion of the local anesthetic into the axoplasm is slower, with subsequent delayed onset and decreased efficacy.

As a rule, analgesia of the teeth and the soft and hard tissues of the mandible should be obtained by a mandibular block and/or a mental block. In the anterior region of the mandible, canines and incisors can often be anesthetized by infiltration, but there are often anastomoses over the midline. These anastomoses must be anesthetized by bilateral infiltration or by bilateral mental blocks. The buccal soft tissues of the mandible are anesthetized by local infiltration or by blocking the buccal nerve. Local infiltration, performed as a series of injections in the buccal fold of the treatment area, has of course the added advantage of providing a local ischemic effect if a suitable anesthetic is used.

The lingual periodontal tissues must also be anesthetized. This is accomplished by blocking the lingual nerve and/or by infiltration into the floor of the mouth close to the site of operation. If necessary, to obtain proper ischemia, and only then, supplementary injections may be made in the interdental papillae (intraseptal injections).

Local anesthesia of the teeth and buccal periodontal tissues of the maxilla can easily be obtained by injections into the mucogingival fold of the treatment area. If larger areas of the maxillary dentition are scheduled for surgery, repeated injections (into the mucogingival fold) have to be performed, for example at the central incisor, canine, second premolar, and second molar. In the posterior maxillary region, a tuberosity injection can be used to block the superior alveolar branches of the maxillary nerve. However, because of the vicinity to the pterygoid venous plexus, this type of block anesthesia is not recommended due to the risk of intravenous injection and/or hematoma formation.

The palatal nerves are most easily anesthetized by injections made at right angles to the mucosa and placed about 10 mm apical to the gingival margin adjacent to teeth included in the operation. In cases of advanced bone loss, the pain produced by injecting into the non-resilient palatal mucosa can be

minimized if the injections are performed from the buccal aspect, that is through the interdental gingiva. Sometimes blocks of the nasopalatine nerves and/or the greater palatine nerves can be applied. Supplementary blocking of the greater palatine nerve should be considered, especially for periodontal surgery involving molars.

Incisions and flap elevation

Before incisions are made, a careful periodontal examination should be carried out to identify the teeth on which periodontal surgery should be performed, since flap elevation in teeth with shallow pockets will cause attachment loss and gingival recession. Once all the area is anesthetized, deep bone sounding using a periodontal probe should help the surgeon to identify the areas with deepest pockets and bone defects and thus to properly design the incisions based on the specific objectives of the periodontal surgery.

Scalloped internal beveled horizontal incisions parallel to the gingival margin are the basic incisions in periodontal flap surgery. The amount of scalloping (distance between the incision and the gingival margin) will depend on the surgical technique selection and the objective of the surgery. When the main aim is surgical access for root instrumentation, mainly in anterior maxillary areas, the amount of scalloping should be minimal, and flaps should be repositioned to the same level as before the surgery in order to minimize postoperative gingival recession (access flaps or open flap debridement). Alternatively, when the aim is not only access for deep root instrumentation, but also pocket reduction, the soft tissue component of the periodontal pocket can be excised with the scalloped incision (apically positioned flaps) (Fig. 32-45). This is particularly

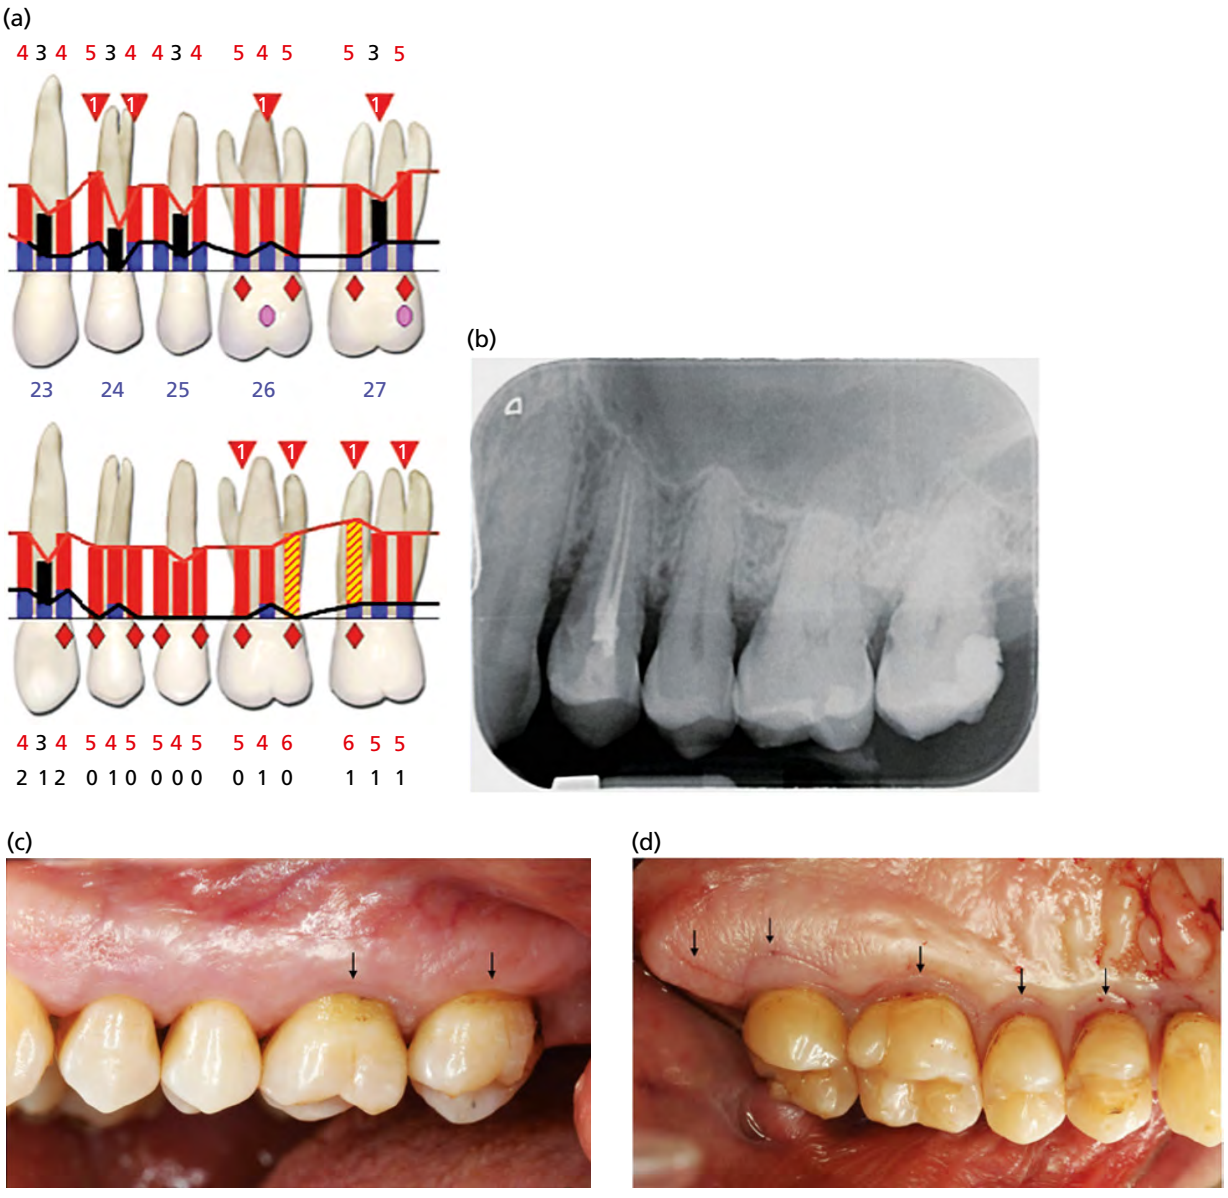

Fig 32-45 Periodontal flap surgery in a posterior maxillary sextant. (a) Preoperative probing depths. Deep probing depth ≥5 mm in interproximal palatal sites. (b) Periapical radiograph depicting horizontal bone loss pattern. (c) Buccal flap design: intracrevicular incision in premolars and minimal scalloping in the molars (see black arrows). (d) Palatal flap design: 2–3 mm scalloping incision and wide parallel incision at the distal wedge (see black arrows)

needed in palatal flaps where the apical positioning of the flaps is impossible and pocket reduction can only be attained by the scalloping during the first incision and by the thinning of the palatal flap. In the buccal flap, depending on the amount of keratinized tissue present, the scalloping can be combined with the apical positioning of the flaps once they have been elevated beyond the mucogingival junction.

As a general rule, periodontal surgeries are planned by sextants, isolating the anterior segment (from cuspid to cuspid) from the posterior areas of the dentition. Surgical designs for anterior periodontal surgeries are conditioned by the expected esthetic outcomes and the presence/absence of bone lesions (infrabony defects or craters). Anterior periodontal surgeries are usually minimally invasive and aim to preserve the interdental soft tissues. These surgical designs will be described independently in this chapter. Posterior periodontal surgeries, however, are usually aimed at pocket reduction and improving the patient's accessibility for plaque control and are frequently designed as apically positioned flaps. The need for vertical releasing incisions in these posterior surgeries will depend on the disease pattern and the degree of periodontal destruction in the mesial and distal teeth of the planned surgery. Distally, buccal and lingual flap incisions are usually followed by distal wedge designs depending on the presence of deep pockets in the distal aspect of the last molar and the amount of keratinized tissue present (Fig. 32-46). Mesially, there is usually no need to use vertical incisions, although the presence of a deep pocket between the cuspid and the first premolar sometimes require a releasing incision to prevent raising the flap mesial to the cuspid and being able at the same time to apically position the flap. Independent of flap position, the goal should be to achieve complete soft tissue coverage of the alveolar bone, not only at buccal/lingual sites but also at proximal sites. It is therefore of utmost importance to carefully plan the incisions in such a way that this goal is achieved at the termination of the surgical intervention. Internal beveled incisions are aimed towards the bone surface and once performed, mucoperiosteal flaps (full thickness) should be elevated with a fine periosteal elevator. Depending on the objective of the surgery,

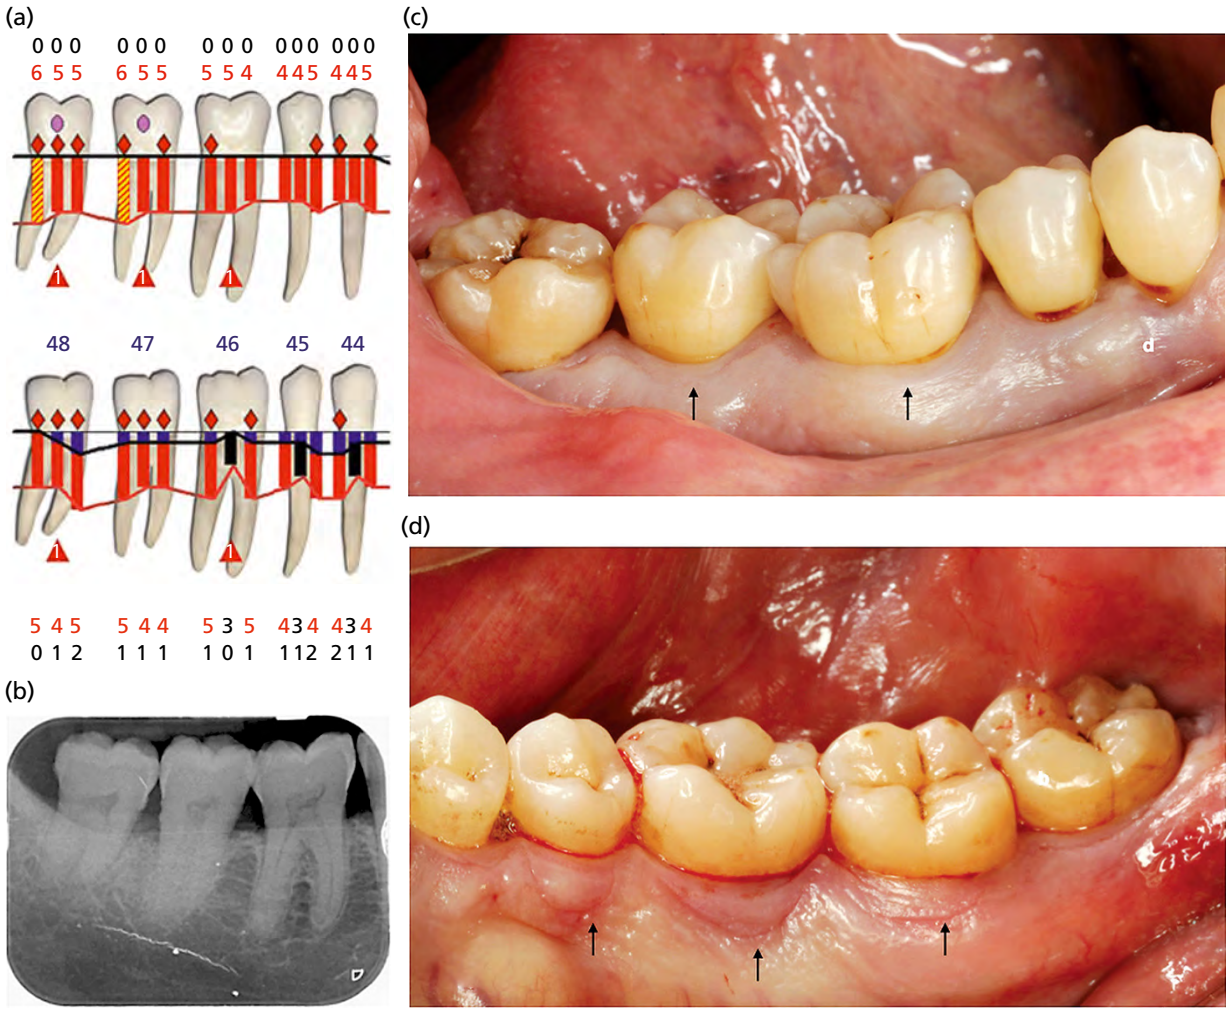

Fig 32-46 Periodontal flap surgery in a posterior mandibular sextant. (a) Preoperative probing depths. Deep probing depth ≥5 mm in interproximal palatal sites. (b) Periapical radiograph depicting horizontal bone loss pattern. (c) Buccal flap design: intracrevicular incision in premolars and minimal scalloping in the molars (see black arrows). the amount of alveolar bone exposed would be minimal in access flap surgeries or extensive in apically positioned flaps that need to elevate the flaps beyond the mucogingival junction (in the buccal flap) (Fig. 32-46).

Bone recontouring

Once the flaps have been raised, the remaining granulation tissue should be removed in order to evaluate the full morphology of the periradicular bone and to decide whether bone recontouring is needed or not, or whether a regenerative procedure is indicated when deep infrabony, crater, or furcation defects are present (see Chapter 38). In posterior sextants, when bone lesions and furcation lesions are not amenable for regeneration (shallow and intermediate craters), they should be eliminated by bone recontouring (osteoplasty and/or ostectomy) (Figs. 32-47, 32-48).

Root instrumentation

Root instrumentation can be performed with hand or ultrasonic instruments according to the operator's preferences. Ultrasonic (sonic) instrumentation offers the additional benefits of improved visibility due to the irrigating effect of the cooling solution (sterile saline). For root instrumentation within intrabony defects, root concavities, and entrances to furcations, the use of rotating fine-grained diamond stones may be used.

An important consideration in periodontal surgery is to make the exposed root surface biologically compatible with a healthy periodontium. In addition to mechanical debridement, agents such as EDTA and enamel matrix proteins (EMD) have been used for root surface conditioning and biomodification. Root surface conditioning is aimed at removing the smear layer and the external hydroxyapatite layers to expose the collagenous matrix of the root cementum. Biomodification with the use of EMD is aimed at preventing the epithelial downgrowth and enhancing cellular responses conducive to new attachment by expressing the cementoblast phenotype of the cells repopulating the treated root surface.

Although in the past root conditioned was carried out by etching the root surface with agents operating at a low pH (e.g. citric acid or tetracycline HCl). This acidic environment may exert immediate necrotizing effects on the surrounding periodontal ligament and other periodontal tissues, and currently these agents have been replaced by EDTA that attains similar effect on the root surface operating at a neutral pH (Blomlöf & Lindskog 1995a, b) (Figs. 32-47, 32-48).

Suturing

At the end of surgery, the flaps should be placed at the intended position and properly adapted to each other and to the tooth surfaces. Preferably, full coverage of the buccal/lingual (palatal) and interdental

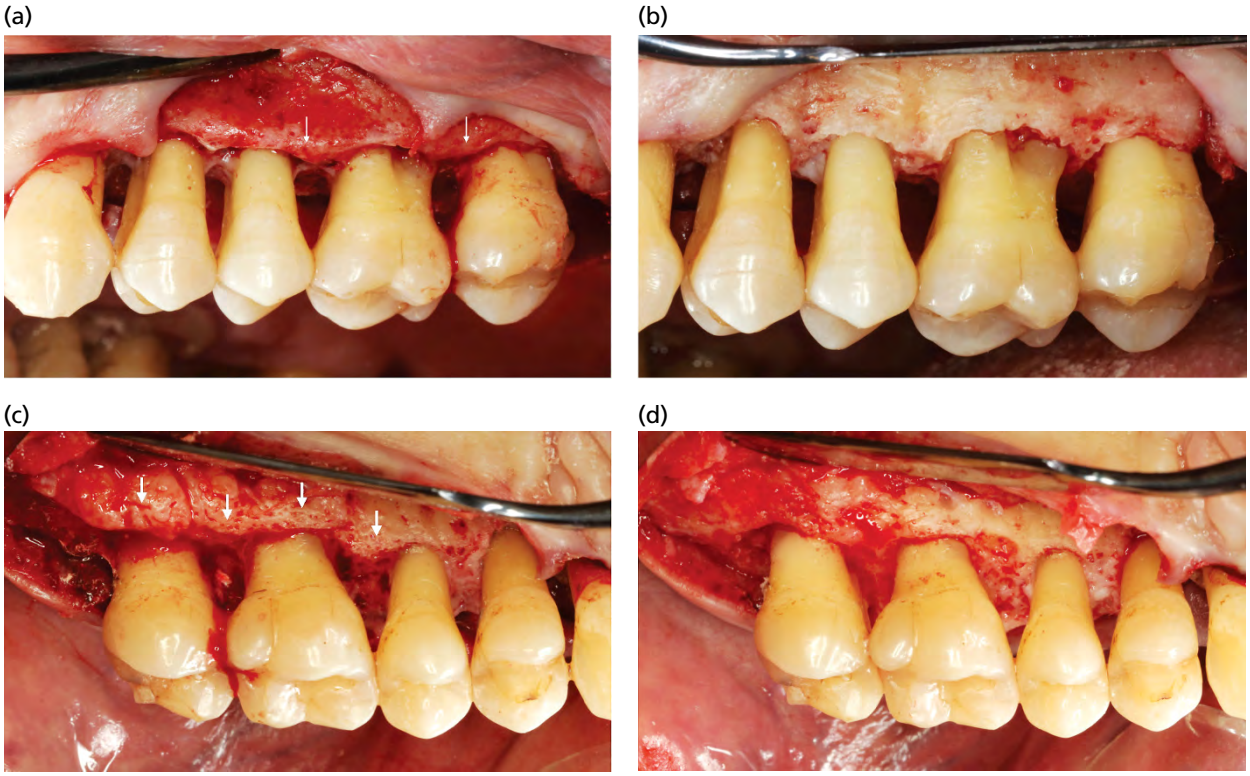

Fig 32-47 (a) Full thickness buccal flap depicting narrow ledges of bone with incipient buccal furcations (white arrows). (d) Wide osteoplasty to eliminate bone balconies and to create interproximal smooth ramps to eliminate craters.

alveolar bone should be obtained by full (primary) closure of the soft tissue flaps. If this can be achieved, healing is by first intention and postoperative bone resorption is minimal. Therefore, prior to suturing, the flap margins should be trimmed to properly fit the buccal and lingual (palatal) bone margin as well as the interproximal areas; excessive soft tissue must be removed. If the amount of flap tissue present is insufficient to cover the interproximal bone, the flaps at the buccal or lingual aspects of the teeth must be recontoured and, in some cases, even displaced coronally. Following proper trimming, the flaps are secured in the correct position by sutures. Sutures should not interfere with incision lines and must not pass through the tissues near the flap margins or too close to a papilla, because this may result in tearing of the tissues (Figs. 32-49, 32-50)

The use of non-irritating, monofilamentous materials is recommended. These materials are non-resorbable and extremely inert, do not adhere to tissues, and are therefore easy to remove. "Wicking", the phenomenon of bacteria moving along or within multistrand (braided) suture materials, should also be avoided. The dimensions usually preferred are 5/0, but even finer suture material (6/0 or 7/0) may be used. Sutures are removed after 7–14 days.

Since the flap tissue following the final preparation is thin, small diameter, curved non-traumatic reverse-cutting needles should be used. Since buccal and lingual/palatal flaps should be adapted around teeth, needles should be shaped as 3/8 of a circle to undertake the flaps without been clotted under the contact points

The three most frequently used sutures in periodontal flap surgery are:

- Interrupted interdental sutures
- Suspensory sutures
- Continuous sutures.

The *interrupted interdental suture* (Fig. 32-51) provides a close interdental adaptation between the buccal and lingual flaps with equal tension on both units. This type of suture is therefore not recommended when the buccal and lingual flaps are repositioned at different levels. When this technique of suturing is employed, the needle is passed through the buccal flap from the external surface, across the interdental area, and through the lingual flap from the internal surface, or vice versa. When closing the suture, care must be taken to avoid tearing the flap tissues.

In order to avoid placing the suture material between the mucosa and the alveolar bone in the interdental area, an alternative technique with the interrupted interdental suture can be used if the flaps have not been elevated beyond the mucogingival line. With the use of a curved needle, the suture is anchored in the attached tissue on the buccal aspect of the proximal site, brought to the lingual side through

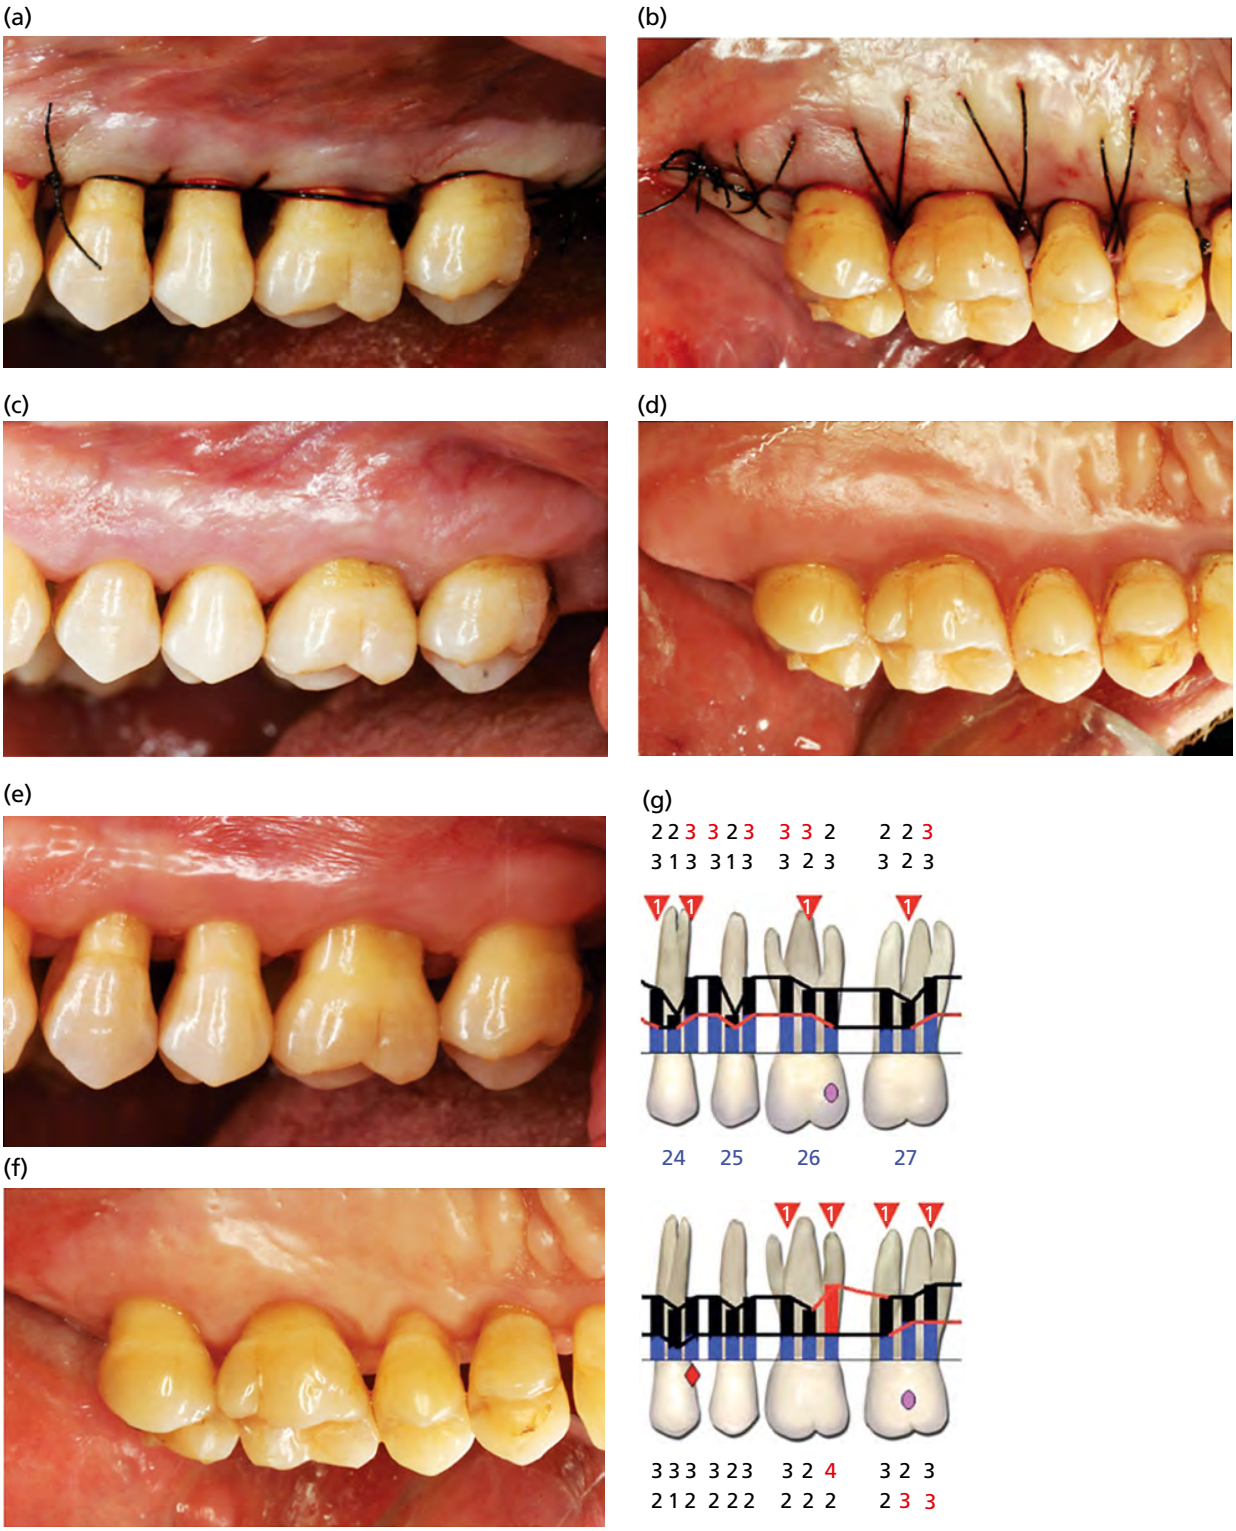

Fig. 32-49 (a) Flap suturing on the buccal side. Continuous anchored suturing to maintain the flap adapted to the bone crest. (b) Flap suturing on the palatal side. the proximal sites, and anchored in the attached tissue on the lingual side. The suture is then brought back to the starting point and tied (Fig. 32-52). Hence, the suture will lie on the surface of the interdental tissue, keeping the soft tissue flaps in close contact with the underlying bone.

In regenerative procedures, which usually require a coronal advancement of the flap, a *modified mattress*

suture may be used as an interdental suture to secure close flap adaptation (Fig. 32-53). As for the interrupted suture, the needle is passed through the buccal flap from the external surface, across the interdental area, and through the lingual flap from the internal surface. The suture is then run back to the buccal side by passing the needle through the lingual and buccal flaps. Thereafter, the suture is brought through the approximal site coronally to the tissue, passed through the loop of the suture on the lingual

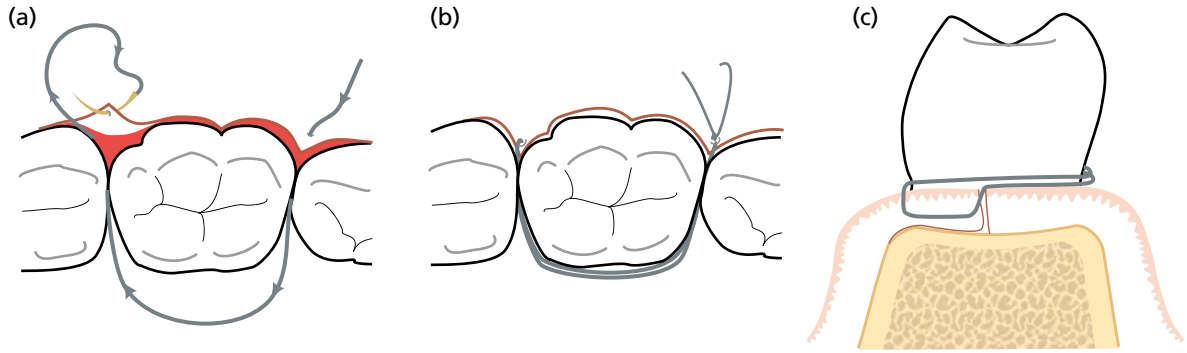

Fig. 32-54 Suturing. (a–c) Suspensory suture.

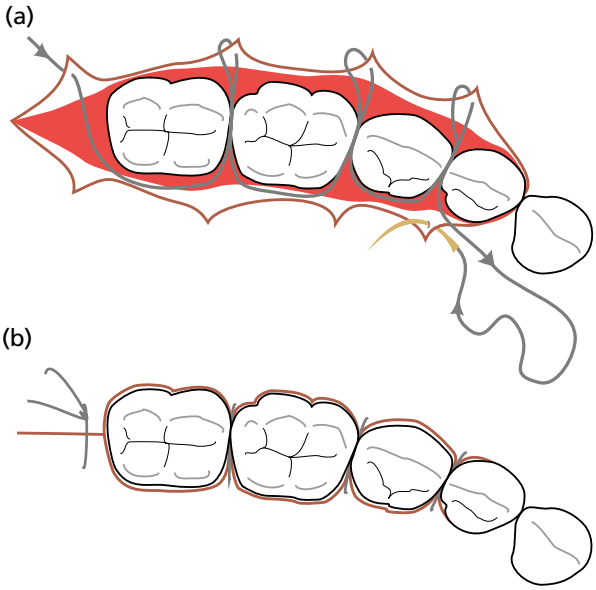

Fig. 32-55 Suturing. (a, b) Continuous suture.

aspect, and then brought back to the starting point on the buccal side and tied.

The *suspensory suture* (Fig. 32-54) is used primarily when the surgical procedure is of limited extent and involves only the tissue of the buccal or lingual aspect of the teeth. It is also the suture of choice when the buccal and lingual flaps are repositioned at different levels. The needle is passed through the buccal flap from its external surface at the mesial side of the tooth, the suture is placed around the lingual surface of the tooth, and the needle is passed through the buccal flap on the distal side of the tooth. The suture is brought back to the starting point via the lingual surface of the tooth and tied. If a lingual flap has been elevated as well, this is secured in the intended position using the same technique.

The *continuous suture* (Fig. 32-55) is commonly used when flaps involving several teeth are to be repositioned apically. When flaps have been elevated on both sides of the teeth, one flap at a time is secured in its correct position. The suturing procedure is started at the mesial/distal aspect of the buccal flap by passing the needle through the flap and across the interdental area. The suture is laid around the lingual surface of the tooth and returned to the buccal side through the next interdental space. The procedure is repeated tooth by tooth until the distal/mesial end of the flap is reached. Thereafter, the needle is passed through the lingual flap, with the suture laid around the buccal aspect of each tooth and through each interproximal space. When the suturing of the lingual flap is completed and the needle has been brought back to the first interdental area, the positions of the flaps are adjusted and secured in their proper positions by closing the suture. Thus, only one knot is needed.

Periodontal dressings are currently seldom used since results from clinical studies have shown that they may be unnecessary and may be usefully replaced by rinsing with chlorhexidine only (Sanz *et al*. 1989; Vaughan & Garnick 1989). Only in situations of bleeding risk during the initial phase of healing (e.g. in patients using anticoagulant medication) are periodontal dressings recommended; they should be soft to allow proper adaptation and must not interfere with healing. Cyanoacrylates have also been used as periodontal dressings with varying success.

Postsurgical care

In order to minimize postoperative pain and discomfort, surgical handling of tissues should be as atraumatic as possible. Care should be taken during surgery to avoid unnecessary tearing of the flaps, to keep the bone moistened, and to secure complete soft tissue coverage of the alveolar bone at suturing. With a carefully performed surgical procedure, most patients will normally experience only minimal postoperative problems. Pain is usually limited to the first days following surgery and is of a level that in most patients can be adequately controlled with drugs normally used for pain control. However, it is important to recognize that pain threshold is subjective and may vary between individuals. It is also important to give the patient information about the postsurgical sequence and communicate that uncomplicated healing is standard. Further, during the early phase of healing, the patient should be instructed to avoid chewing in the area subjected to surgical treatment.

Postoperative plaque control is the most important variable in determining the long-term result of periodontal surgery. Provided proper postoperative infection control levels are established, most surgical treatment techniques will result in conditions that favor the maintenance of a healthy periodontium. Although there are other factors of a more general nature affecting surgical outcome (e.g. the systemic status of the patient at the time of surgery and during healing), disease recurrence is an inevitable complication, regardless of surgical technique used, in patients not given proper postsurgical and maintenance care.

Since self-performed oral hygiene is often associated with pain and discomfort during the immediate postsurgical phase, regularly performed professional tooth cleaning is a more effective means of mechanical infection control following periodontal surgery. In the immediate postsurgical period, self-performed rinsing with a suitable antiplaque agent, for example twice daily rinsing with 0.1–0.2% chlorhexidine solution, is recommended. Although an obvious disadvantage with the use of chlorhexidine is the staining of the teeth and tongue, this is usually not a deterrent for compliance. Nevertheless, it is important to return to and maintain good mechanical oral hygiene measures as soon as possible, particularly since rinsing with chlorhexidine, in contrast to properly performed mechanical oral hygiene, is unlikely to have any influence on subgingival recolonization of plaque.

Maintaining good postsurgical wound stability is another important factor affecting the outcome of some types of periodontal flap surgery. If wound stability is judged an important part of a specific procedure, the procedure itself as well as postsurgical care must include measures to stabilize the healing wound (e.g. adequate suturing technique, protection from mechanical trauma to the marginal tissues during the initial healing phase). If a mucoperiosteal flap is replaced rather than repositioned apically, early apical migration of gingival epithelial cells will occur as a consequence of a break between root surface and healing connective tissue. Hence, maintenance of a tight adaptation of the flap to the root surface is essential and one may therefore consider keeping the sutures in place for longer than the 7–10 days usually prescribed following standard flap surgery.

Following suture removal, the surgically treated area is thoroughly irrigated with a dental spray and the teeth are carefully cleaned with a rubber cup and polishing paste. If the healing is satisfactory for starting mechanical tooth cleaning, the patient is instructed in gentle brushing of the operated area using a soft toothbrush. In this early phase following surgical treatment, the use of interdental brushes is abandoned due to the risk of traumatizing the interdental tissues. Visits are scheduled for supportive care at 2-week intervals to monitor the patient's plaque control closely. During this postoperative maintenance phase, adjustments to the methods for optimal self-performed mechanical cleaning are made depending on the healing status of the tissues. The time interval between visits for supportive care may gradually be increased, depending on the patient's plaque control standard (Figs. 32-49, 32-50).

Specific surgical interventions for papilla management

In the last three decades significant advances have been made in the evolution of flaps. During the early development of guided tissue regeneration, clinically it was felt that access flaps such as the modified Widman flap or the Kirkland modified flap operation would enhance the risk of membrane exposure. Thus, a quest for better flap adaptation and prevention of wound dehiscence began. In particular, the following flaps, aiming at preserving interdental papillary tissues, have been documented (Graziani *et al*. 2018).

Papilla preservation flap

In order to preserve the interdental soft tissues for maximum soft tissue coverage following surgical intervention involving treatment of proximal osseous defects, Takei *et al*. (1985) proposed a surgical approach called the *papilla preservation* technique. This surgical design fully maintained the interdental soft tissues and therefore was mainly indicated for the surgical treatment of anterior tooth regions or in posterior regions when regenerative techniques are used in the treatment of intrabony defects. This surgical design is initiated by intrasulcular incisions at the facial and proximal aspects of the teeth without cutting through the interdental papillae (Fig. 32-56a). Subsequently, an intrasulcular incision is made along the lingual/palatal aspect of the teeth followed with a semilunar incision across each interdental area from the line angles of the teeth. After freeing the interdental papilla carefully from the underlying hard tissues, the detached interdental tissue is pushed through the embrasure with a blunt instrument from the palatal to the buccal side and full thickness flaps are elevated (Fig. 32-56b). After thorough debridement of the root surfaces and bone defects (Fig. 32-57) the flaps are repositioned and sutured using cross mattress sutures (Figs. 32-58, 32-59).

Modified papilla preservation technique

Similarly, the modified papilla preservation technique was designed in order to obtain primary wound closure of the interproximal tissue over barrier membranes placed coronally to the alveolar crest (Cortellini *et al*. 1995b). Conceptually the flap is similar to the papilla preservation technique with an intrasulcular circumferential incision around the involved dentition, but the second incision is straight, instead of semilunar, with a slight internal bevel at the base of the buccal, instead of the palatal, area of the papilla. A mucoperiosteal flap is then elevated to

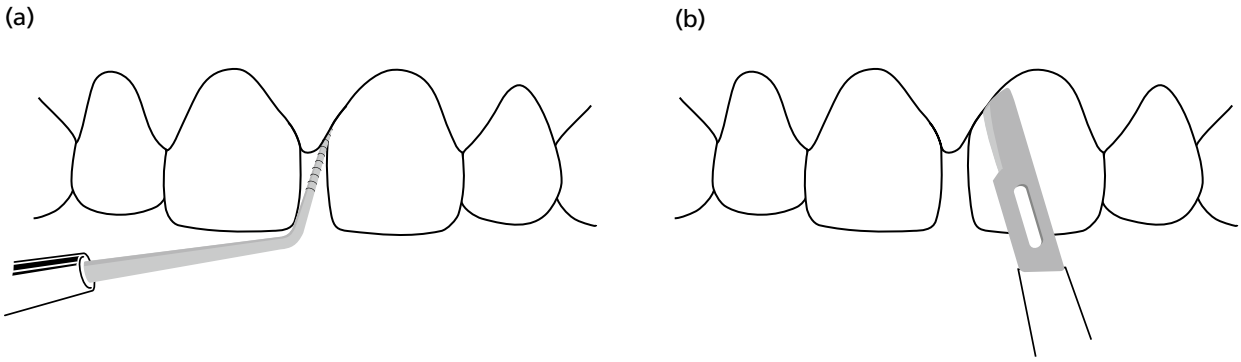

Fig. 32-56 Papilla preservation flap. (a) A deep pocket is present at an approximal tooth site. (b) Intracrevicular incisions are made at the facial and proximal aspects of the teeth.

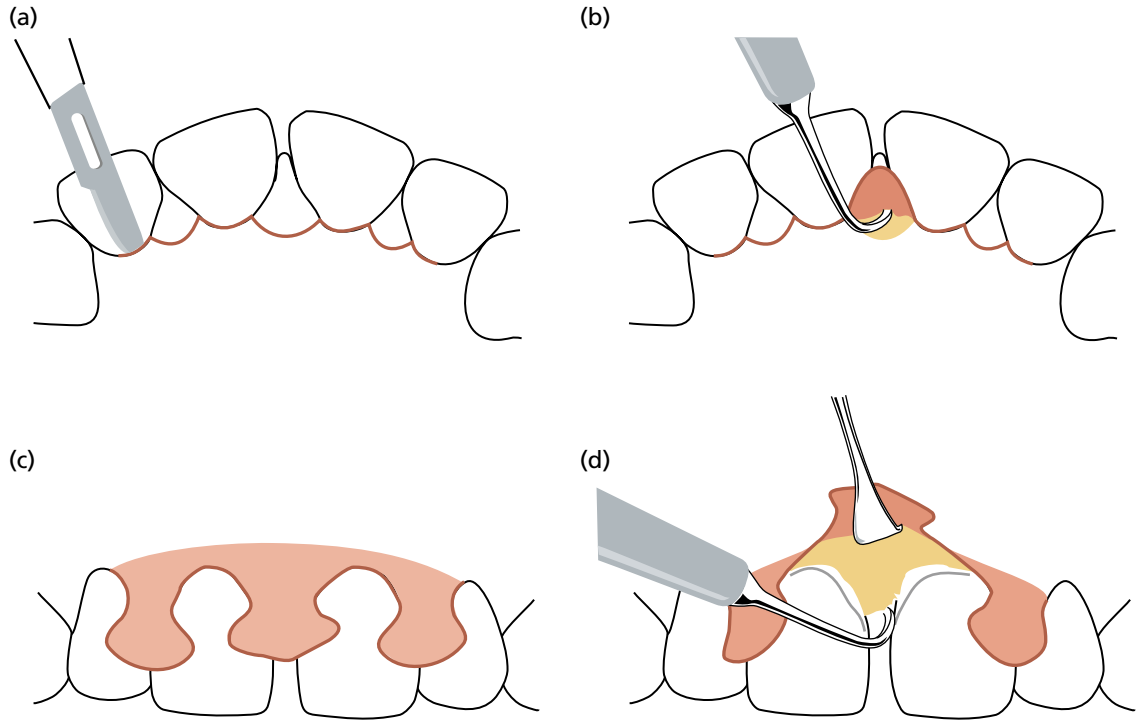

Fig. 32-57 Papilla preservation flap. (a) An intracrevicular incision is made along the lingual/palatal aspect of the teeth with a semilunar incision made across each interdental area. (b) A curette or a papilla elevator is used to carefully free the interdental papilla from the underlying hard tissue. (c, d) Detached interdental tissue is pushed through the embrasure with a blunt instrument to be included in the facial flap.

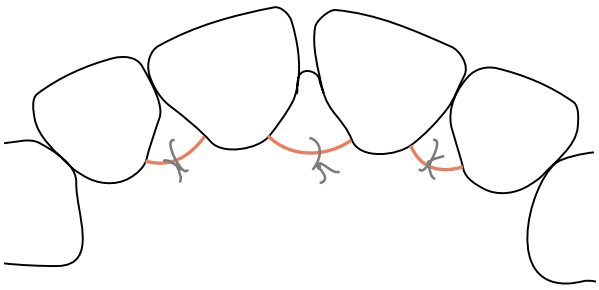

Fig. 32-58 Papilla preservation flap. The flap is replaced, and sutures are placed on the palatal aspect of the interdental areas.

the level of the buccal alveolar crest. The interdental papilla is then separated from the adjacent teeth and underlying alveolar bone and is dissected from buccal towards lingual until it remains pedunculated to the palatal full thickness flap, thus providing direct view of the defect (Fig. 32-60). Moreover, the flap was designed to be coronally repositioned through a split-thickness incision as it has been originally described to interproximally place a non-resorbable titanium-reinforced membrane in order to maintain an adequate supra-alveolar space for regeneration. Flap repositioning is performed through a two-layer suturing consisting of a horizontal internal mattress suture positioned buccally just above the mucogingival line and a vertical internal mattress suture placed between the buccal aspect of the interproximal papilla. Laurell's group then proposed for the latter a modified internal mattress suture for tissue repositioning, which involves a double stabilization both on the buccal and lingual aspect of the flap (Zybutz *et al*. 2000).

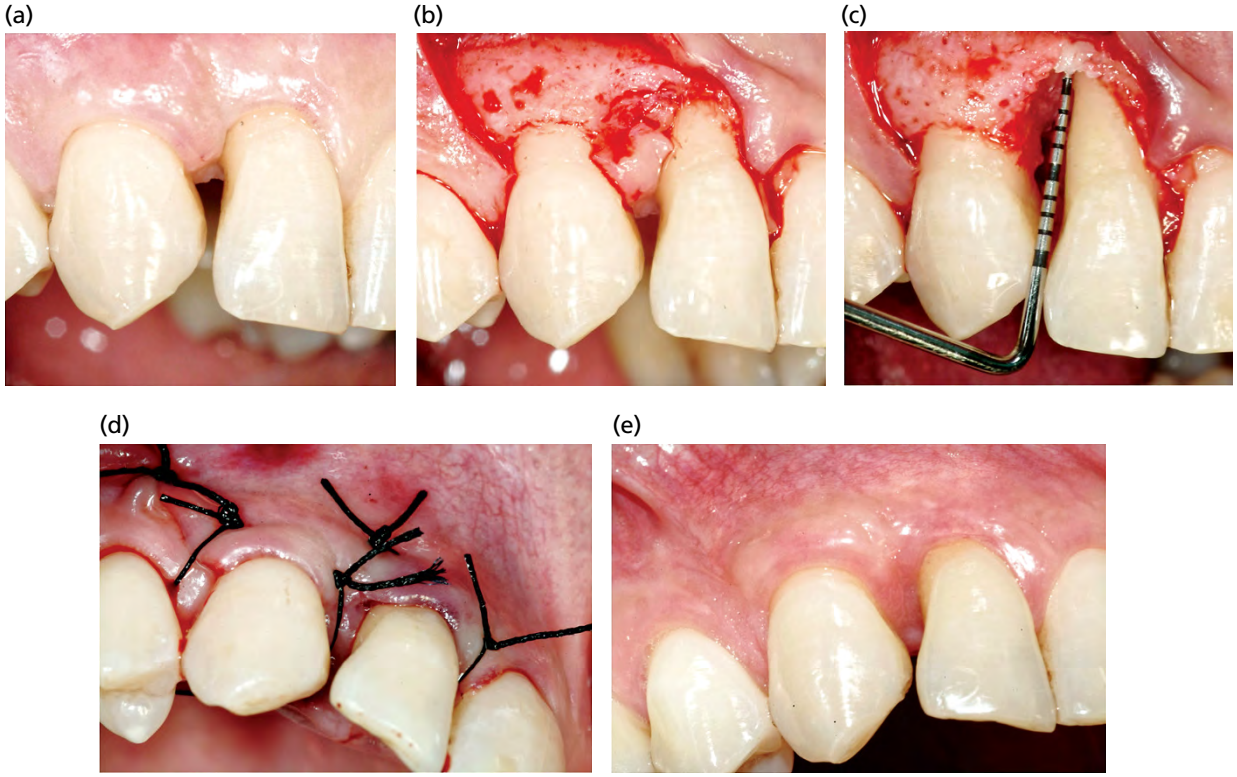

Fig. 32-60 Modified papilla preservation flap. (a) Preoperative buccal view. (b) Buccal incision at the base of the papilla. (c) Flap elevation and defect measurement. (d) Suture. (e) Postoperative buccal view.

Simplified papilla preservation flap

Both the papilla preservation technique and its modification were based on the indication of at least 2 mm of mesiodistal distance among the involved teeth. Thus, it was felt that in cases of reduced interdental spaces, intervention in the posterior regions and when non-supported membranes were used, a different flap should have been implemented. Accordingly, in 1999 the simplified papilla preservation flap was described (Cortellini *et al*. 1999). The flap is characterized by an oblique incision through the papilla going from the gingival margin at the

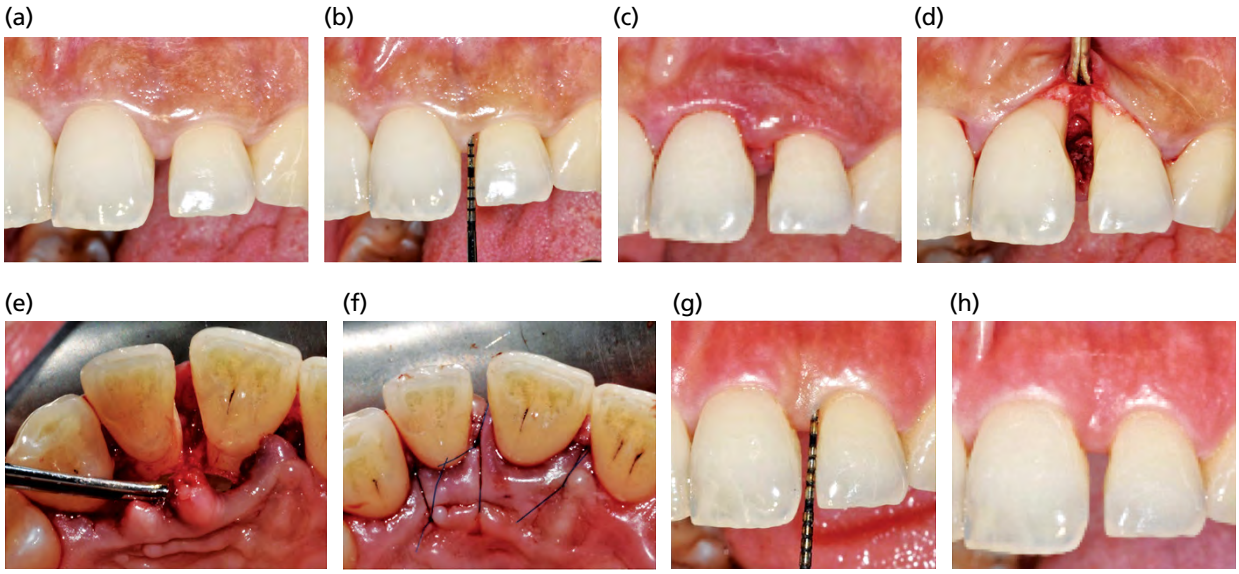

Fig. 32-61 Simplified papilla preservation flap. (a) Preoperative buccal view. (b) Preoperative probing. (c) Incision. (d) Defect exposure. (e) Palatal view. (f) Suture. (g) Postoperative probing. (h) Postoperative view

buccal line angle of the involved tooth towards the mid interproximal portion of the papilla of the adjacent tooth. The incision is performed maintaining the blade parallel to the tooth major axis, and a full-thickness flap is then elevated on the buccal aspect with the exposure of 2–3 mm of the alveolar bone. Then a buccolingual horizontal incision is performed at the base of the papilla extended to the palatal area until the palatal flap is elevated full thickness. The flap is sutured with a horizontal internal mattress suture (Fig. 32-61).

Minimally invasive surgical techniques

Papilla preservation techniques evolved, due to the continuous evolution of regenerative techniques and the advent of amelogenins, towards a more conservative surgical extension in order to favor a reduced postoperative morbidity and higher level of postsurgical attachment gain due to an increased wound stabilization. This involved a higher level of magnification, achieved through loops or microscopes, and a dedicated set of microinstruments. A minimally invasive surgical technique (MIST) was designed to gain access to a three-wall intrabony defect through a papillary incision as in the simplified papilla preservation flap or the modified papilla preservation technique approach (Cortellini & Tonetti 2007). Only the papilla associated with the defect is exclusively elevated through a careful elevation of the buccal and palatal components to a very limited extent up to 1–2 mm of alveolar bone crest. In general, adjunctive vertical release incisions are not performed, nor split incisions of the buccal flap in order to coronally elevate. The papilla is sutured with a single modified internal mattress suture, in order to obtain primary wound closure in the absence of tension (Fig. 32-62).

The concept of minimal invasiveness developed further with the single flap approach (SFA) (Trombelli *et al*. 2009) and the modified-MIST (M-MIST) (Cortellini & Tonetti 2009), both flaps characterized by the elevation of one side exclusively. The indications are mainly: (1) accessibility of the entire anatomical defect through one side only and (2) a defect that is located mainly lingually or buccally. In the SFA the part elevated can be either buccal or lingual according to the anatomical extension of the defect, whereas the M-MIST is mainly buccal, leaving the defects with lingual location to be treated with the MIST. In the M-MIST the extension is kept at a minimum to allow the reflection of a triangular buccal flap to expose the buccal bone crest, then a microblade dissects the supracrestal component of the buccal portion of the papilla from the granulation tissue within the intrabony defect. After degranulation a thorough root instrumentation is performed under the tip of the papilla that is left in place. In the SFA two-layer suturing is employed (internal mattress suture and a single interrupted one) whereas in the M-MIST a single internal modified mattress suture is applied (Fig. 32-63).

The biological rationale of such minimally invasive approaches is to enhance blood clot stability by improving protection of the surgical area. This translates to a higher clinical performance of such flaps compared with conventional flaps in terms of clinical attachment gain (Graziani *et al*. 2012). Accordingly, both flaps have been shown to determine clinical results that are not influenced by the presence of regenerative materials (Cortellini & Tonetti 2011; Trombelli et al. 2012) (Fig. 32-64).

Outcomes of surgical periodontal therapy

Histological healing

Gingivectomy

Within a few days following excision of the inflamed gingival soft tissues coronal to the base of the periodontal pocket, epithelial cells start to migrate over the wound surface. The epithelialization of the gingivectomy wound is usually complete within 7–14 days following surgery (Engler *et al*. 1966; Stahl *et al*. 1968). During the following weeks, a new dentogingival unit is formed (Fig. 32-65). The fibroblasts in the supra-alveolar tissue adjacent to the tooth surface proliferate (Waerhaug 1955) and new connective tissue is laid down. If the wound healing occurs in the vicinity of a plaque-free tooth surface, a free gingival unit will form which has all the characteristics of a normal free gingiva (Hamp *et al*. 1975). The height of the newly formed free gingival unit may vary not only between different parts of the dentition, but also from one tooth surface to another due primarily to anatomic factors.

The re-establishment of a new, free gingival unit by coronal regrowth of tissue from the line of the "gingivectomy" incision implies that sites with so-called "zero pockets" only occasionally occur following gingivectomy. Complete healing of the gingivectomy wound takes 4–5 weeks, although from clinical inspection of the surface of the gingiva, it may appear to be healed after approximately 14 days (Ramfjord *et al*. 1966). Minor remodeling of the alveolar bone crest may also occur postoperatively.

Apically positioned flap

Following osseous surgery for elimination of bony defects and the establishment of "physiologic contours" and repositioning of the soft tissue flaps to the level of the alveolar bone, healing will occur primarily by first intention, especially in areas where proper soft tissue coverage of the alveolar bone has been obtained. During the initial phase of healing, bone resorption of varying degrees almost always occurs in the crestal area of the alveolar bone (Fig. 32-66) (Ramfjord & Costich 1968). The extent of the reduction of the alveolar bone height resulting from this resorption is related to the thickness of the bone in each specific site (Wood *et al*. 1972; Karring *et al*. 1975).

During the phase of tissue regeneration and maturation, a new dentogingival unit will form by coronal growth of the connective tissue. This regrowth occurs in a manner similar to that which characterizes healing following gingivectomy.

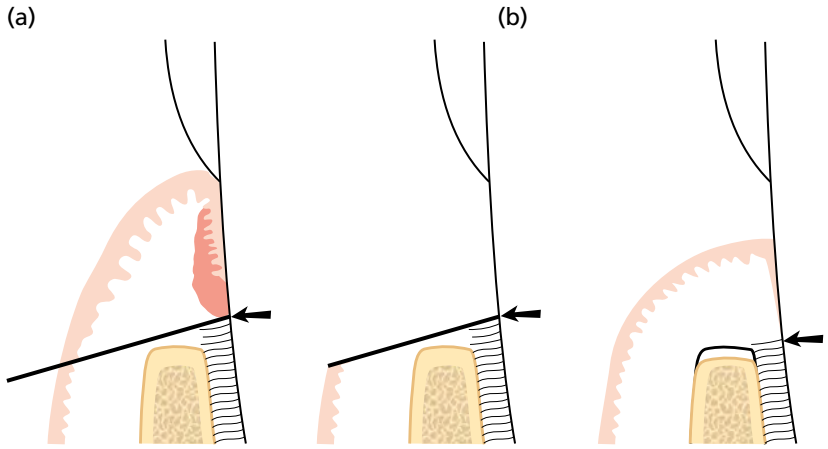

Fig. 32-65 Gingivectomy. Dimensional changes as a result of therapy. (a) Preoperative dimensions and position of the incision line. Black line indicates the location of the primary incision, that is the suprabony pocket is eliminated with the gingivectomy technique; before and after excision of the soft tissue corresponding to the depth of the periodontal pocket. (b) Dimensions following proper healing. Minor resorption of the alveolar bone crest as well as some loss of connective tissue attachment may occur during the healing. The arrows indicate the coronal position of the connective tissue attachment to the root.

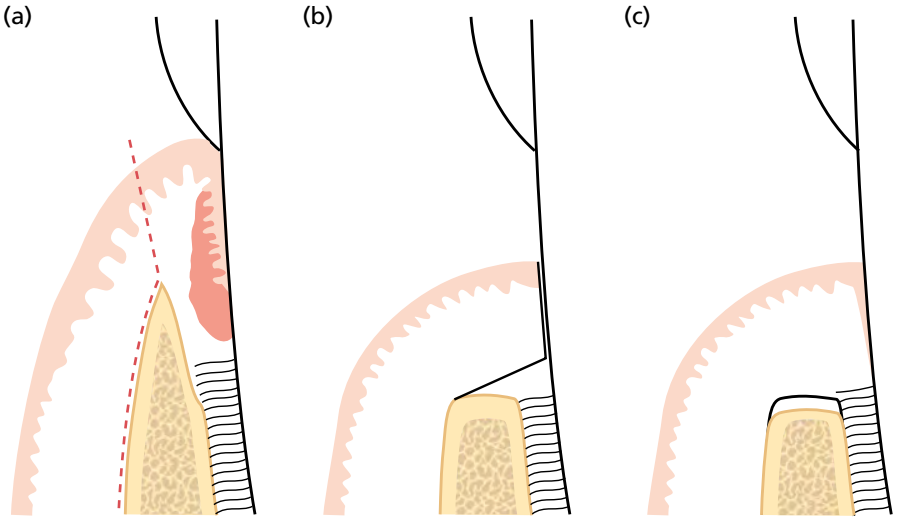

Fig. 32-66 Apically positioned flap. Dimensional changes. (a) Preoperative dimensions. The dashed line indicates the border of the elevated mucoperiosteal flap. (b) Bone recontouring has been completed and the flap repositioned to cover the alveolar bone. (c) Dimensions following healing. Minor resorption of the marginal alveolar bone has occurred as well as some loss of connective tissue attachment.

Modified Widman flap

If a "modified Widman flap" procedure is carried out in an area with a deep infrabony lesion, bone repair may occur within the boundaries of the lesion (Rosling *et al*. 1976; Polson & Heijl 1978). However, crestal bone resorption is also seen. The amount of bone fill obtained is dependent upon (1) the anatomy of the osseous defect (e.g. a three-walled infrabony defect often provides a better mold for bone repair than two-or one-walled defects), (2) the amount of crestal bone resorption, and (3) the extent of chronic inflammation, which may occupy the area of healing. Interposed between the regenerated bone tissue and the root surface, a long junctional epithelium is always found (Fig. 32-67) (Caton & Zander 1976; Caton *et al*. 1980), which is also noted after the modified Kirkland flap procedure. The apical cells of the newly formed junctional epithelium are found at a level on the root that closely coincides with the presurgical attachment level.

Soft tissue recession will take place during the healing phase following a modified Widman flap procedure. Although the major apical shift in the position of the soft tissue margin will occur during the first 6 months following the surgical treatment (Lindhe *et al*. 1987), the soft tissue recession may often continue for >1 year. Factors influencing the degree of soft tissue recession as well as the time period for soft tissue remodeling include the initial height and thickness of the supracrestal flap tissue and the amount of crestal bone resorption.

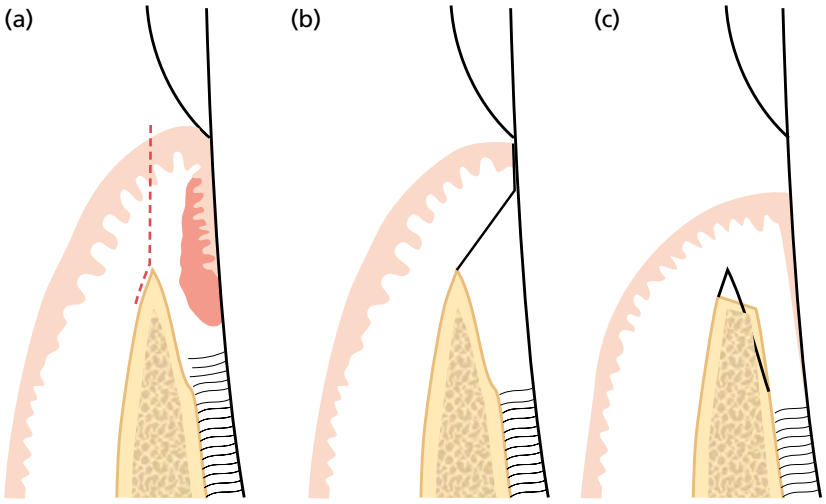

Fig. 32-67 Modified Widman flap. Dimensional changes. (a) Preoperative dimensions. The dashed line indicates the border of the elevated mucoperiosteal flap. (b) Surgery (including curettage of the angular bone defect) is completed with the mucoperiosteal flap repositioned as close as possible to its presurgical position. (c) Dimensions following healing. Osseous repair as well as some crestal bone resorption can be expected during healing with the establishment of a "long" junctional epithelium interposed between the regenerated bone tissue and the root surface. Apical displacement of the soft tissue margin has occurred.

Clinical outcomes of surgical periodontal therapy

Surgical periodontal treatment must be seen within the context of a sequential step of treatments in which the surgical options might not be needed in all cases (Graziani *et al*. 2017). To evaluate the performance of surgical interventions it is necessary to highlight the fact that the majority of the long-term studies are derived from iconic studies of the 1970s and 1980s. These pioneering contributions to the understanding of the relative importance of the surgical component of periodontal therapy were generated by the classic longitudinal studies of the Michigan group (Ramfjord and co-workers) and the Gothenburg group (Lindhe and co-workers). Subsequently, several other clinical research centers contributed important data regarding the efficacy of surgical access therapy in comparison to non-surgical periodontal therapy. Nevertheless, some limited information is available in comparing surgical intervention towards repeated surgical instrumentation, that is a second session of non-surgical root instrumentation that should represent the alternative treatment to surgery within the flow of steps of the treatment of periodontitis stage I–III (Sanz *et al*. 2020).

The performance of periodontal surgical treatment is moreover influenced by the bone anatomy associated with the residual pockets and thus recent systematic reviews and meta-analysis will be analyzed (Graziani *et al*. 2012, 2014, 2015; Sanz-Sanchez 2020).

Tooth survival

The amount of tooth loss is the most relevant criterion in an evaluation of the relative importance of surgical periodontal therapy in the overall treatment of periodontal disease. Overall tooth retention after surgery is high if appropriate supportive treatment is provided as shown in a systematic review taking into account long-term results of periodontal surgery on teeth associated with intrabony defects (Graziani *et al*. 2012). Twenty years after 15 patients were treated with an access flap (control group), two patients lost one tooth each (Cortellini *et al*. 2017). When comparing periodontal surgery with repetition of non-surgical instrumentation in residual pockets of 7 mm, more tooth retention was seen in the former in a 13-year follow-up period (0.6 teeth lost versus 1.6, respectively) (Serino *et al*. 2001).

Plaque and gingival inflammation

The most commonly used outcome criteria in clinical research have been resolution of gingivitis (BoP), PPD reduction, and clinical attachment level change. However, with regard to post-treatment plaque accumulation and gingivitis resolution, there is no evidence to suggest that differences exist between non-surgical or surgical treatment or between various surgical procedures.

Probing pocket depth reduction

Periodontal surgical therapy is remarkably effective in reducing PPD. It generally creates greater short-term reduction of probing depth than non-surgically performed scaling and root planing (Sanch-Sanchez *et al* 2020) which are significantly more pronounced in deeper pockets. In moderately deep pockets differences are noted only in the short term. Overall, the differences tend to become less apparent in the long-term follow-ups (over 12 months).

All surgical procedures result in a decrease in PPDs, with greater reduction occurring at the initially deeper sites (Knowles *et al*. 1979; Lindhe *et al*. 1984; Ramfjord *et al*. 1987; Kaldahl *et al*. 1996; Becker

et al. 2001). Flap surgery with bone recontouring (pocket elimination surgery)/resection of the soft tissue component usually results in the most pronounced short-term pocket reduction, whereas the differences tend to disappear 36 months after surgery (Polak *et al*. 2020).

Conservative periodontal surgery, that is, surgical periodontal therapy with no intentional anatomical corrections, results in a reduction of approximately 3 mm in residual pockets associated with intrabony defects, which is confirmed in long-term studies and shows a reduction of 40% in the initial probing depth. In residual pockets associated with suprabony defects or furcation the extent of the reduction is approximately 1.5 mm at 12 and 6 months postoperatively respectively.

Clinical attachment level change

In sites with shallow initial probing depth, both short- and long-term data demonstrate that surgery creates a greater loss of clinical attachment than non-surgical treatment, whereas in sites with initially deep pockets (≥7 mm), a greater gain of clinical attachment is generally obtained (Knowles *et al*. 1979; Lindhe *et al*. 1984; Ramfjord *et al*. 1987; Kaldahl *et al*. 1996; Becker *et al*. 2001).

Based on data generated from a clinical trial comparing non-surgical and surgical (modified Widman flap) approaches to root debridement, Lindhe *et al*. (1982b) developed the concept of *critical probing depth* (CPD) in relation to clinical attachment level change. For each treatment approach, the clinical attachment change was plotted against the initial pocket depth and regression lines were calculated (Fig. 32-68). The

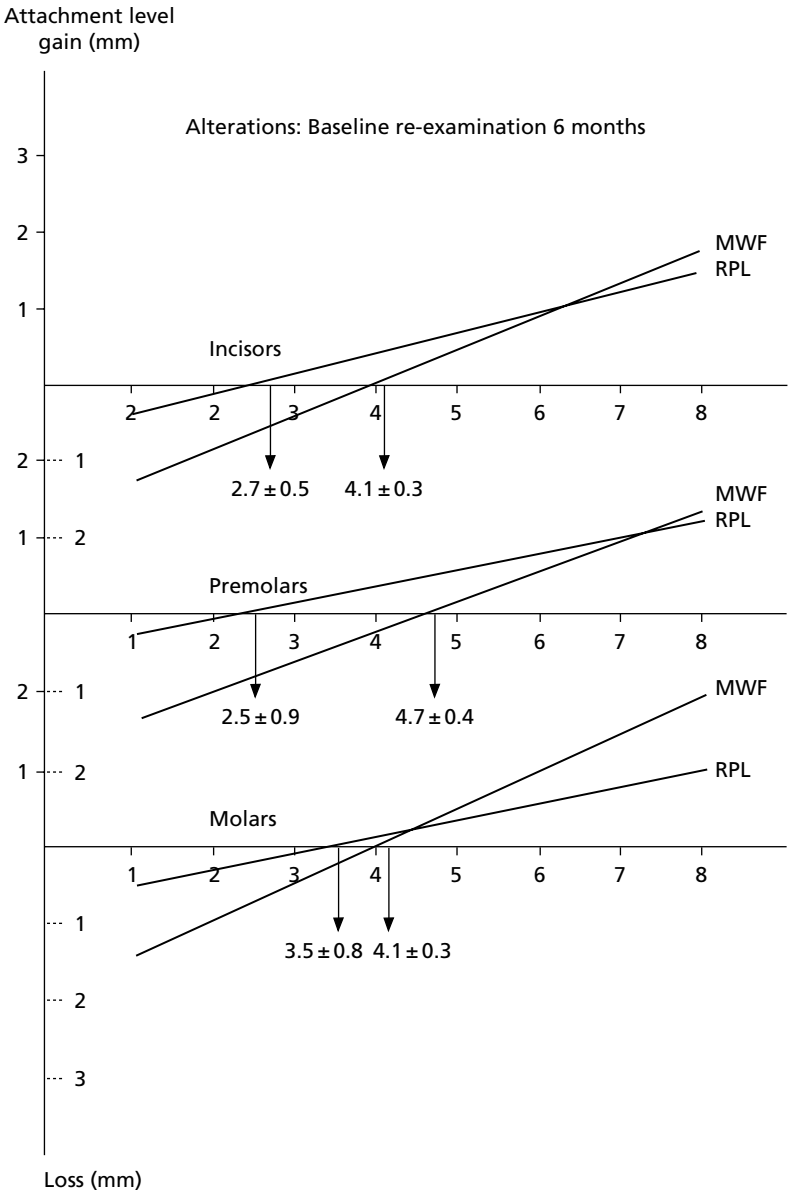

Fig. 32-68 Gain and loss of clinical attachment (y axis) at incisors, premolars, and molars, calculated from measurements taken prior to and 6 months after treatment. The non-surgical approach (RPL) consistently yielded lower critical probing depth values than the surgical approach. RPL, scaling and root planing; MWF, modified Widman flap surgery. (Source: Data from Lindhe *et al*. 1982a. Reproduced with permission from John Wiley & Sons.)

point where the regression line crossed the horizontal axis (initial probing depth) was defined as the CPD, that is, the level of pocket depth below which clinical attachment loss would occur as the result of the treatment procedure performed.

The CPD was consistently found to be greater for the surgical approach than for the non-surgical treatment. Furthermore, at incisors and premolars, the surgical therapy showed superior outcome only when the initial probing depth was >6–7 mm, while at molars the corresponding cut-off point was 4.5 mm. The interpretation of the latter finding is that, in the molar tooth regions, the surgical approach to root debridement offers advantages over the non-surgical approach.

When comparing clinical attachment levels following various types of surgery, either no difference was found between therapies, or flap surgery without osseous/tissue resection produced a greater gain, especially in shallow sites (Polak *et al*. 2020). In addition, there was no difference in the longitudinal maintenance of clinical attachment levels between sites treated non-surgically and those treated surgically, with or without osseous resection (Fig. 32-69).

In residual pockets associated with intrabony defects, surgical therapy resulted in an attachment gain of approximately 2 mm in the long-term. Interestingly, an important flap-dependent gradient indicating that papilla preservation flaps and minimally invasive flaps determined a higher extent of attachment gains compared with conventional open flap debridement in such defects was noted (Graziani *et al*. 2012). In residual pockets associated with suprabony defects and furcation defects, the extent of the gain is modest at around 0.5 mm (Graziani *et al*. 2014, 2015).

Gingival recession

Gingival recession is an inevitable consequence of periodontal therapy. Because it occurs primarily as a result of resolution of the inflammation in the periodontal tissues, it is seen both following non-surgical and surgical therapy. Irrespective of treatment modality used, initially deeper pocket sites will experience more pronounced signs of recession of the gingival margin than sites with shallow initial probing depths (Badersten *et al*. 1984; Lindhe *et al*. 1987; Becker *et al*. 2001) (Fig. 32-69). A general finding in short-term follow-up studies of periodontal therapy is that non-surgically performed scaling and root planing causes less gingival recession than surgical therapy, and that surgical treatment involving osseous and soft tissue resection results in the most pronounced recession (Polak *et al*. 2020). In general, surgical root

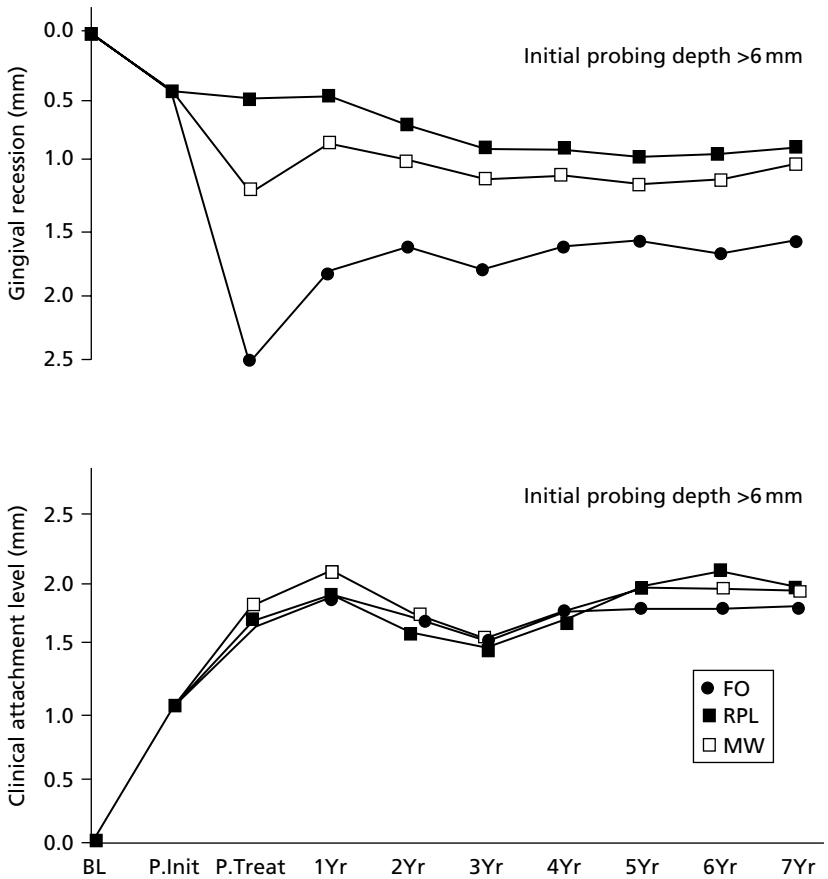

Fig. 32-69 Longitudinal changes over 7 years in recession (top) and clinical attachment levels (bottom) at sites with an initial probing pocket depth of >6 mm following three different periodontal treatment modalities. BL, baseline; FO, flap and osseous surgery; MWF, modified Widman flap procedure; RPL, scaling and root planing. (Source: Data from Kaldahl *et al*. 1996. Reproduced with permission from John Wiley & Sons.)

instrumentation without tissue resection determines approximately 1 mm of recession 12 months after surgery of residual pockets associated with intrabony, suprabony, and furcation defects.

However, data obtained from long-term studies reveal that the initial differences seen in amount of recession between various treatment modalities diminish over time caused by a coronal rebound of the soft tissue margin following surgical treatment (Kaldahl *et al*. 1996; Becker *et al*. 2001) (Fig. 32-67). Lindhe and Nyman (1980) found that after an apically repositioned flap procedure, the buccal gingival margin shifted to a more coronal position (by about 1 mm) during 10–11 years of maintenance. In interdental areas denuded following surgery, van der Velden (1982) found an up growth of around 4 mm of gingival tissue 3 years after surgery, while no significant change in attachment levels was observed. A similar finding was reported by Pontoriero and Carnevale (2001) 1 year after an apically positioned flap procedure for crown lengthening.

Bone fill in angular bone defects

The potential for bone formation in angular defects following surgical access therapy has been demonstrated in a number of studies. Rosling *et al*. (1976) studied the healing of two- and three-wall angular bone defects following a modified Widman flap procedure, including careful curettage of the bone defect and proper root debridement, in 24 patients with multiple osseous defects. Following active treatment, patients assigned to the test group received supportive periodontal care once every 2 weeks for a 2-year period, while the patients in the control group were only recalled once a year for prophylaxis. Re-examination carried out 2 years after therapy demonstrated that the patients who had been subjected to the intensive professional tooth-cleaning regimen had experienced a mean gain of clinical attachment in the angular bone defects amounting to 3.5 mm. Measurements performed on radiographs revealed a marginal bone loss of 0.4 mm, but the remaining portion of the original bone defect (2.8 mm) was refilled with bone (Fig. 32-70)

Similar healing results were reported by Polson and Heijl (1978). They treated 15 defects (two- and three-wall) in nine patients using a modified Widman flap procedure. Following curettage of the bone defect and root planing, the flaps were closed to achieve complete soft tissue coverage of the defect area. All patients were enrolled in a professional tooth-cleaning program. The healing was evaluated at a re-entry operation 6–8 months after the initial surgery. Eleven of the 15 defects had resolved completely. The healing was characterized by a combination of coronal bone regeneration (77% of the initial depth of the defects) and marginal bone resorption (18%). The authors concluded that intrabony defects might predictably remodel after surgical debridement and establishment of optimal plaque control. The results from the studies referred to demonstrate that a significant bone fill may be obtained in two- and three-wall intrabony defects at single-rooted teeth, provided the postoperative supportive care is of very high quality. Two reviews (Laurell *et al*. 1998; Lang 2000), focusing on the outcome of surgical access therapy in angular bone defects, gave additional information regarding expected bone regeneration in angular defects following open-flap debridement (modified Widman flap). In the review by Laurell *et al*. (1998), 13 studies were included, representing a total of 278 treated defects with a mean depth of 4.1 mm. The weighted mean bone fill in the angular defects amounted to 1.1 mm. Lang (2000) reported an analysis of 15 studies providing data generated from

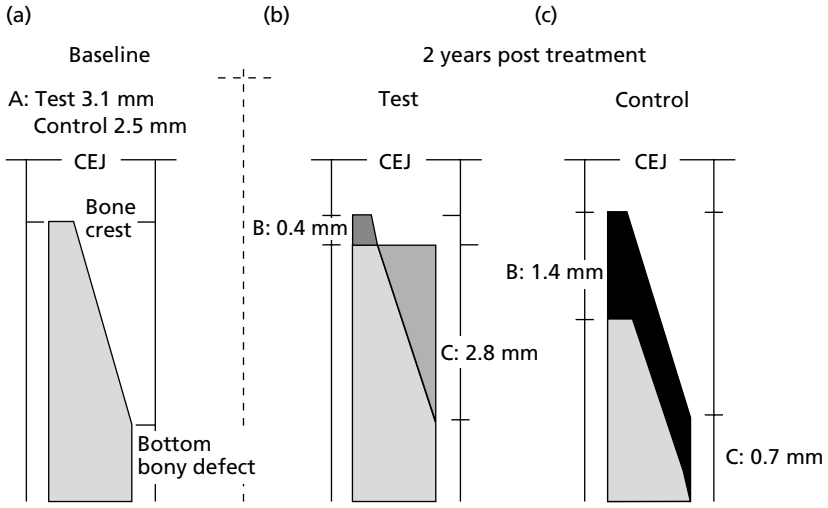

Fig. 32-70 Alterations in the level of the marginal bone crest and the level of the bottom of the bone defects in the test and control groups of the study by Rosling *et al*. (1976a). (a) Distance A denotes the depth of the bone defects at the initial examination; test group 3.1 mm, control 2.5 mm. (b, c) Distance B denotes resorption of the alveolar crest, which amounted to 0.4 mm in the test patients (b) and 1.4 mm in the controls (c). Distance C denotes gain or loss of bone in the apical portion of the defect. There was a refill of bone in the test patients (b) amounting to 2.8 mm, whereas a further 0.7 mm loss of bone occurred in the control patients (c). CEJ, cementoenamel junction. (Source: Data from Rosling *et al*. 1976a. Reproduced with permission from John Wiley & Sons.)

radiographic assessments of the healing of 523 angular bone defects. The analysis yielded a weighted mean of 1.5 mm of bone gain. This data was further confirmed by a recent meta-analysis indicating an average bone fill was 1 mm (Graziani *et al*. 2012).

Factors affecting clinical healing

Periodontal surgical treatment shows heterogenous healing influenced and explained by numerous factors that a clinician should consider when planning an intervention because many of these factors may be changed by the clinician in order to improve the overall surgical prognosis.

Patient factors

Plaque levels

Plaque levels influence healing of surgical debridement significantly. In a landmark study, patients in the test group received, after surgical debridement of intrabony defects, repeated oral hygiene instructions and professional tooth cleaning once every 2 weeks during the postoperative period (Rosling *et al*. 1976). The patients maintained the surgically reduced pocket depth throughout the 2-year follow-up period and important clinical attachment level gains and bone fill were observed for most of the surgical procedures evaluated (Fig. 32-69). Interestingly, the control group that was assessed and polished only once a year (i.e. with high plaque score), showed a significant and important deterioration of clinical attachment level and bone levels.

In a secondary study of a multicenter trial assessing surgical treatment of intrabony defects, the total bacteriological count and the presence of bacteria of the red complex was associated with a lower probability of obtaining important gains of clinical attachment (Heitz-Mayfield *et al*. 2006). The fact that the standard of postoperative oral hygiene is decisive for the outcome of surgical pocket therapy is further underlined by data from a 5-year longitudinal study by Lindhe *et al*. (1984) which showed that patients with a high standard of infection control maintained clinical attachment levels and probing depth reductions following treatment more consistently than patients with poor plaque control. On the other hand, professional tooth cleaning, including subgingival scaling every 3 months, may partly compensate for the negative effects of variations in self-performed plaque control (Ramfjord *et al*. 1982; Isidor & Karring 1986).

Gingival inflammation

The overall level of inflammation influences the outcome of surgical debridement of intrabony defects in terms of attachment gain when full mouth bleeding scores reach >12% (Tonetti *et al*. 1996). Therefore, careful decontamination and reduction of inflammation is needed before surgery.

Smoking

Smoking, despite not being a contraindication for surgery, has an important negative impact on the outcome after periodontal surgery, as shown by the negative influence on both PPD reduction and clinical attachment levels (Labriola *et al*. 2005). Smoking does lessen the impact in both outcomes 6 months after surgery. The chance of obtaining a postsurgical pocket reduction of >3 mm is nearly three times lower in patients who smoke (Scabbia *et al*. 2010).

Local factors

Type of periodontal defect

Periodontal defects are classically divided in intrabony, suprabony, and inter-radicular defects. Most knowledge is derived from the prolific literature on intrabony defects. Conservative surgical debridement of an intrabony defect determines a clinical attachment gain of approximately 1.5 mm and a probing depth reduction of 3 mm, 12 months after surgery (Graziani *et al*. 2012).

Suprabony defects do not heal as well compared with healing achieved after surgical debridement of intrabony defects with a 1.4 probing depth reduction and 0.5 mm of clinical attachment gain (Graziani *et al*. 2014).

Furcation defects also show important reductions in clinical healing if compared with intrabony defects. A meta-analysis analyzing the control group of trials in which periodontal regeneration was applied indicated that the average CAL gain of degree II mandibular furcation was 0.5 mm 6 months after debridement and a PPD reduction of 1.4 mm. This highlights the complexity of surgical access in furcation defects (Graziani *et al*. 2015).

Periodontal defect morphology

The morphology of the defect has important repercussions for healing after surgery. When a residual pocket is associated with an intrabony defect, some factors such as the number of walls of the defect, and the depth and width of the defect, influence significantly the surgical outcome. The deeper the intrabony component the larger is the postsurgical clinical attachment gain in access flaps (Cortellini *et al*. 1998). Three-wall intrabony defects have a 269% higher chance of showing a clinical attachment gain of at least 3 mm than a 1-wall defect after surgical debridement (Tonetti *et al*. 2002). Moreover, the wider the defect, the lower the healing.

Clinician factors

Experience and surgical dexterity

Clinical experience and capabilities have an obvious impact on healing. In a multicenter trial, clinicians operating on identical periodontal defects at baseline with the same surgical access showed a difference of more than 1 mm of clinical attachment gain (Tonetti *et al*. 1998).

Flap choice

The evolution of flap design contributed significantly to the clinical outcome after surgical debridement. The performance of access flaps in intrabony defects changed abruptly within 10 years, indicating an increase in performance of control sites (access flap) of 1 mm between 1996 and 2006 (Tu *et al*. 2008). This has been further confirmed in a meta-analysis indicating that if conservation of the papillary area during surgery is performed, a higher postsurgical clinical attachment gain is achieved (Graziani *et al*. 2012). Papilla preservation flaps appear to improve clinical attachment gain compared with conventional surgery, and also appear to be effective for suprabony defects (Graziani *et al*. 2014). This can be explained by the fact that the choice of papilla preservation flaps increase vascularization, as noted in laser flow doppler studies, which results in improved primary closure and better protection from postsurgical bacterial contamination in the wound (Retzepi *et al*. 2007).

Conclusion

Surgical periodontal therapy is an essential component in the treatment of periodontitis. A clinician must bear in mind that surgery is, however, a specific step of the sequential steps in treatment and is not a single/unique tool for disease resolution. In fact, surgery might not always be required. Knowledge acquired in clinical trials that evaluated the different periodontal regenerative techniques made important developments possible. When advanced flaps were used in the control groups (i.e. without regenerative materials), the performance was superior to the use of conventional flaps. Clearly, some important information, such as the performance of surgical interventions versus non-surgical re-treatment in terms of long-term tooth survival, are still scarce and some decisions are still based on the classic studies from the 1970s. Nevertheless, refined and technique-sensitive periodontal surgical treatment is without doubt a requirement in the armamentarium of a periodontist.

Anatomy

Periodontitis-related bone resorption in multirooted teeth is associated with a very unique anatomical sequela: the exposure of the root separation areas ('furcations') to microbial colonization. The anatomy of the furcation, with concavities, enamel projections, and ridges, often below the gingival margin, favor further microbial accumulation leading to periodontal disease progression and eventually tooth loss. In other words, the periodontal pathogenic process is often 'amplified' in furcation regions, owing to their unique anatomy.

'Periodontal furcation involvement' is defined as destruction of periodontal attachment and bone in the root separation area. This affects maxillary first premolars (normally two-rooted), maxillary molars (normally 3-rooted), and mandibular molars (normally 2-rooted). However, variations in the number of roots exist, and sometimes other teeth such as second premolars or canines may also be affected by furcation involvement (Joseph *et al*. 1996). The 'root complex', defined as the portion of a tooth located apical to the cementoenamel junction, in multirooted teeth is divided into 'root trunk' (undivided region of the root) and 'root cones' (Fig. 33-1). The 'furcation entrance' is the area between the undivided and divided part of the roots, while the 'furcation fornix' is the most coronal portion of the furcation area (Fig. 33-2). 'Degree of separation' is defined as the angle of separation between root cones, while 'divergence' is the distance between two roots. The 'coefficient of separation' is the proportion between length of root cones and length of root complex (Fig. 33-3).

The topography of the furcation area of maxillary and mandibular molars was described in detail in 1988 by Svärdström and Wennström, who showed a complex anatomy consisting of ridges, peaks, and pits (Svärdström & Wennström 1988). First and second maxillary molars generally have three roots (mesiobuccal, distobuccal, and palatal). The distobuccal and palatal roots are usually inclined distally and palatally respectively, while the mesiobuccal root is vertical. The mesiobuccal root has a pronounced

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

concavity in its distal surface, giving it a characteristic hour-glass shape. Out of the three potential furcation entrances in maxillary molars, the mesial is on average 3 mm apical to the cementoenamel junction, while the buccal is 3.5 mm and the distal 5 mm from the cementoenamel junction (Abrams & Trachtenberg 1974). Around 40% of maxillary first premolars have buccal and palatal root cones, and due to a long root trunk, the furcation entrance is on average 8 mm apical to the cementoenamel junction. Mandibular molars usually have two root cones (mesial and distal). The latter is smaller, usually circular in section, and inclined distally, while the mesial has an hour-glass shape and a more pronounced distal concavity (Svärdström & Wennström 1988). The entrance to the furcation region has been measured by several authors in extracted teeth and found to be <1 mm in the majority of molars and <0.75 mm in around half of examined molars (Bower 1979; Chiu *et al*. 1991; Hou *et al*. 1994, 1997) (Fig. 33-4). When compared with the standard width of curettes (0.75–1.0 mm), it is clear how plaque and calculus removal can be particularly challenging in furcation-involved molars (dos Santos *et al*. 2009).

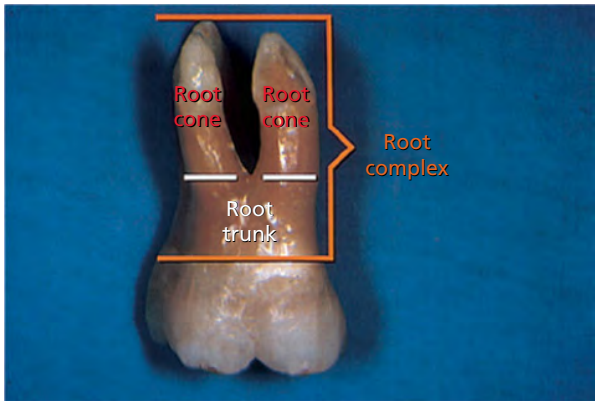

Fig. 33-1 Root complex of a maxillary molar. The root complex is separated into one undivided region (the root trunk) and one divided region (the root cones).

Bifurcation ridges consisting of dentine and/or cementum are found in over half of furcation areas (Everett *et al*. 1958; Burch & Hulen 1974; Bower 1979; Dunlap & Gher 1985; Hou & Tsai 1997) and are divided into two types: buccolingual and mesiodistal or intermediate (IBR) (Everett *et al*. 1958). IBR have been associated with progression of the furcation defect (Gher & Vernino 1980; Hou & Tsai 1997).

Cervical enamel projections are also often found in molars (Masters & Hoskins 1964), especially in Asian populations (Lim *et al*. 2016) (Fig. 33-5). They facilitate plaque accumulation and prevent connective

tissue attachment, thus contributing to the aetiology of furcation lesions (Carnevale *et al*. 1995; Leknes 1997; Al-Shammari *et al*. 2001; Bhusari *et al*. 2013).

Enamel pearls are ectopic globules consisting mostly of enamel and often containing a core of dentine, which adhere to the root surface and particularly to the furcation area (Fig. 33-6). They affect a range of 1–10% of molars in different studies (Moskow & Canut 1990) and are thought to affect attachment and potentially contribute to periodontal furcation pathology.

Diagnosis of furcation involvement

Clinical diagnosis of furcation involvement

Furcation entrances do not lay open in untreated periodontal patients. In most cases they are covered by gingiva. Thus, furcation involvement (FI) cannot be seen by the naked eye but must be probed below the gingival margin. The bizarre anatomy of furcations (Schroeder & Scherle 1987), their curved course, and the fact that furcation entrances of maxillary premolars and molars open into interproximal spaces, require the use of particular curved furcation probes for furcation diagnosis (e.g. Nabers probe) (Fig. 33-7). The probe is placed onto the tooth surface coronally of the gingival margin at the site where a furcation entrance is expected (e.g. lingual of a mandibular molar). The probe is then pushed apically, gently displacing the gingiva in zig-zag movements until the bottom of the sulcus or pocket is reached. If the probe does fall into a pit horizontally, this indicates an FI in most cases (Eickholz & Walter 2018).

Straight rigid periodontal probes (e.g. PCPUNC15) are inappropriate for furcation diagnosis because

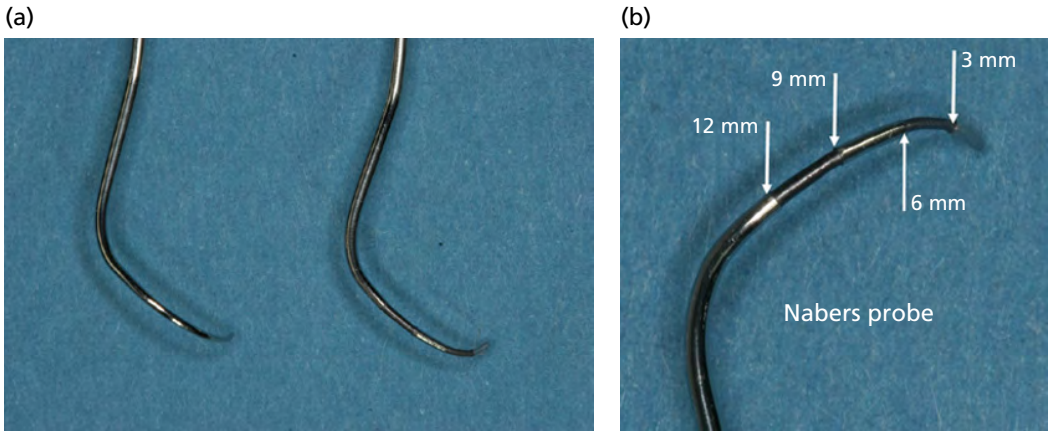

Fig. 33-7 Curved furcation probes. (a) Nabers probes (left, without markings; right, with markings). (b) Markings in 3 mm steps up to 12 mm. (Source: Eickholz & Walter 2018.)

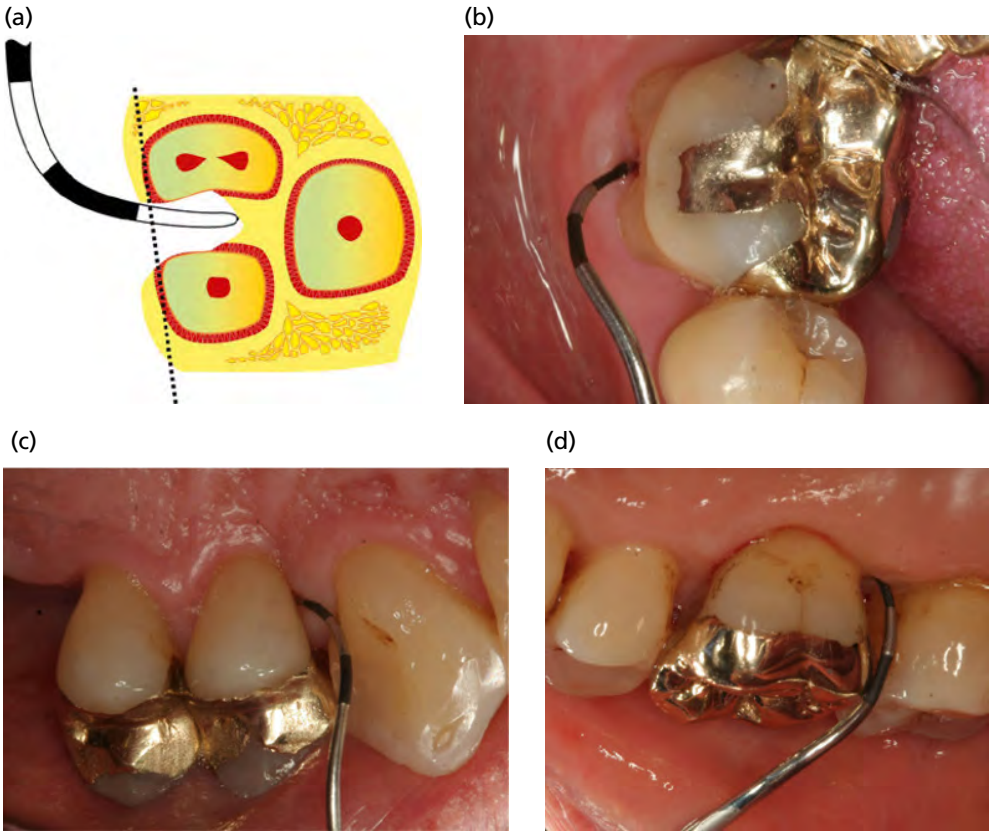

Fig. 33-8 Furcation involvement degree I (Table 33-1) (Eickholz & Staehle 1994; Eickholz & Walter, 2018): horizontal loss of periodontal tissue support up to 3 mm. (a) Schematic (maxillary molar, buccal furcation entrance): horizontal probing/clinical attachment level 2.5 mm (Eickholz & Walter 2018). (b) Buccal tooth 46: the probe does not penetrate more than 3 mm between the two buccal roots. (Source: Eickholz & Walter 2018.) (c) Mesial tooth 24 with neighboring tooth. (Source: Eickholz & Walter 2018.) (d) Distolingual tooth 16 with neighboring tooth. (Source: Eickholz & Walter 2018.)

they fail to follow the curved course of most furcations and can lead to an underestimate of the extent of the FI (Eickholz & Kim 1998).

Classification of furcation involvement

Once an FI has been located, assessing its severity is important. Severity of FI is assessed by probing the furcation in a horizontal direction using a rigid curved probe (e.g. Nabers probe) and measuring the distance from the probe tip to a virtual tangent to the root convexities adjacent to the furcation (Fig. 33-8). Measuring this distance allows assessment of different degrees of FI or the amount of horizontal attachment loss in millimeters (horizontal probing/clinical attachment level: PAL-H/HCAL) (Fig. 33-8). Whereas assessment of the continuous variable horizontal attachment loss provides information on small

changes in interradicular tissues (as they are relevant after regenerative therapy), the classification of interradicular tissue destruction into the *degree/class* of FI provides sufficient information for a prognosis to be given and therapy decisions to be made for the multirooted tooth (Eickholz & Walter 2018).

There are only minor differences in the classifications of FI. The classification by Glickman (1953) provides mainly vague criteria to distinguish classes of FI and also considers radiographic information, which is known to be of low reliability (Glickmann 1953; Ammons & Harrington 2006). The criteria of the Hamp *et al*. (1975) classification are based on clinical measurements (threshold: PAL-H = 3 mm) (Hamp *et al*. 1975).

Degrees III and IV of the Glickman classification describe two severity grades, where the desmodontal fibers are detached from the furcation fornix/dome throughout the complete diameter of the tooth, that is, horizontal "through-and-through" destruction of the periodontal tissue in the furcation (degree III according to Hamp *et al*. 1975; Eickholz & Walter 2018).

The criteria to assign a class III (Hamp *et al*. 1975) to a furcation also have been modified. To assign a class III, Graetz *et al*. (2014) required the tip of the furcation probe to be visible (Nabers) at the opposite furcation. For all other cases of deep, but not completely penetrating horizontal probing, a class II was assigned (Graetz *et al*. 2014). When horizontal probing is more than 6 mm, but does not completely penetrate to the opposite furcation entrance, Walter *et al*. (2009) created a degree II–III (Walter *et al*. 2009; Eickholz & Walter 2018).

Distinction between class II and class III furcation involvement

The distinction between class II (Hamp *et al*. 1975) and through-and-through furcation (class III) is of decisive significance for both prognosis and choice of therapy (Fig. 33-9):

1. Molars with class III furcation defects have a worse long-term prognosis than class II lesions (McGuire & Nunn 1996; Dannewitz *et al*. 2006; Salvi *et al*. 2014; Graetz *et al*. 2015; Dannewitz *et al*. 2016).
2. Whereas buccal and lingual class II lesions can be improved by regenerative therapy, through-and-through furcations do not benefit from regenerative treatment (Sanz *et al*. 2015; Jepsen *et al*. 2020a).

A furcation probe cannot be completely pushed through the whole involved furcation area, particularly from an interproximally located furcation entrance in the presence of adjacent teeth. Nevertheless, hard and soft tissue may be detached from the furcation fornix (i.e. FI class III). Graetz *et al*. (2014) would classify this situation as class II. Walter *et al*. (2009) would classify this situation as class II-III. In these cases, it is recommended that Ammons and Harrington (2006) should be followed: in cases where the clinician may not even be able to pass a periodontal probe completely through the furcation because of interference with the bifurcational ridges or facial/lingual bony margins, the buccal and lingual probing dimensions may be added. If a cumulative probing measurement is obtained that is equal or greater than the buccal/lingual dimension of the tooth at the furcation orifice, the furcation is rated class III (Table 33-1; Fig. 33-10c, d). Thus, underestimation of FI as observed by Walter *et al*. (2009) and Graetz *et al*. (2014) can be avoided (Eickholz & Walter 2018).

The vertical dimension of furcation involvement

The key difficulty in FI is accessing horizontal niches between the roots of multirooted teeth. Thus, the classifications referred to previously primarily consider the horizontal component of attachment/bone loss.

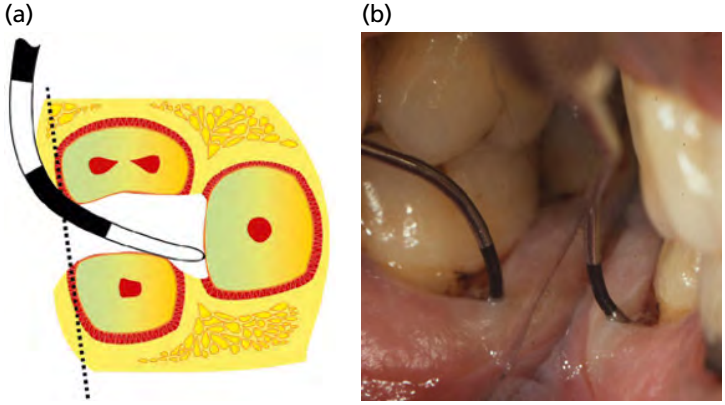

Fig. 33-9 Furcation involvement degree II (Table 33-1) (Hamp *et al*. 1975; Eickholz & Walter, 2018): horizontal loss of support exceeding 3 mm, but not encompassing the total width of the furcation area. (a) Schematic (maxillary molar, buccal furcation entrance): horizontal probing/clinical attachment level 5 mm (Eickholz & Walter 2018). (b) Tooth 47: the 9 mm marking is at the gingival margin. However, the 6 mm marking is at the height of the virtual tangent placed to the roots adjacent to the furcation. (Source: Nibali 2018.)

Table 33-1 Recommended classification of furcation involvement (Sources: Hamp *et al*. 1975; Eickholz & Staehle 1994; Ammons & Harrington 2006; Eickholz & Walter 2018).

Class 0	No furcation involvement
Class I	Horizontal loss of periodontal tissue support up to 3 mm (Eickholz & Staehle 1994) (Fig. 33-8)
Class II	Horizontal loss of support exceeding 3 mm, but not encompassing the total width of the furcation area (Hamp *et al*. 1975) (Fig. 33-9)
Class III	Horizontal "through-and-through" destruction of the periodontal tissue in the furcation. In early class III involvement the opening may be filled with soft tissue and may not be visible. The clinician may not even be able to pass a periodontal probe completely through the furcation because of interference with the bifurcational ridges or facial/lingual bony margins. However, if the clinician adds the buccal and lingual probing dimensions and obtains a cumulative probing measurement that is equal or greater than the buccal/lingual dimension of the tooth at the furcation orifice, the clinician must conclude that a class III furcation exists (Ammons & Harrington 2006) (Fig. 33-10).

However, it is plausible that in addition to horizontal attachment/bone loss, vertical attachment/bone loss in the furcation area plays a role. It has been demonstrated that survival of molars after furcation therapy does not only depend on baseline FI but also on baseline bone loss (Dannewitz *et al*. 2006; Park *et al*. 2009). Thus, a subclassification was proposed that measures the probeable vertical depth from the roof of the furcation apically: (1) subclass A indicates a probeable vertical depth of 1–3 mm, (2) subclass B of 4–6 mm, and (3) subclass C of ≥7 mm. Furcations would thus be classified as IA, IB, IC, IIA, IIB, IIC and IIIA, IIIB, IIIC (Tarnow & Fletcher 1984).

Radiographic diagnosis of furcation involvement

In general, radiographs provide information on the translucency to x-rays of different tissues. The more dense a tissue is (e.g. compact bone), the less translucent it is for x-rays. Thus, both two- and three-dimensional radiographic images primarily provide information on bone in contrast to soft tissue. However, information on connective tissue attachment is also important in diagnosis of FI. Thus, radiographs do tell a substantial part of but not the whole story about FI. This is particularly true after

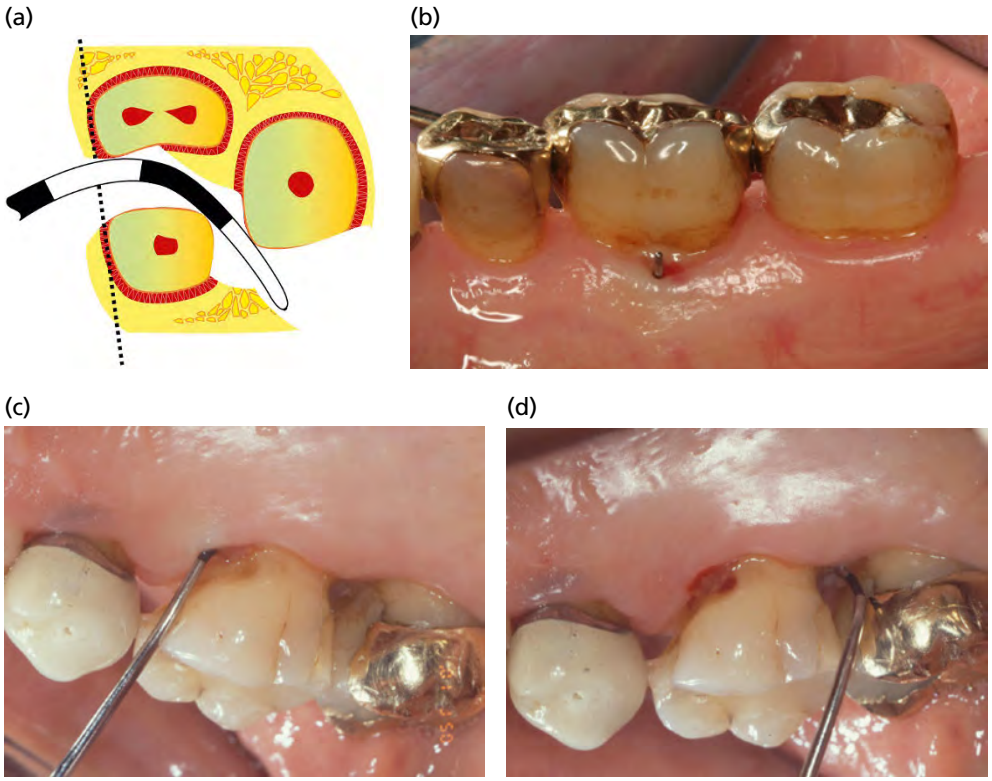

Fig. 33-10 Furcation involvement degree III (Table 33-1) (Ammons & Harrington 2006; Eickholz & Walter 2018): horizontal "through-and-through" destruction of the periodontal tissue in the furcation. (a) Schematic (maxillary molar, buccal to interproximal furcation entrance) (Eickholz & Walter 2018). (b) Tooth 46 (lingual view). (Source: Eickholz & Walter 2018.) (c) Furcation probing at tooth 16 (Eickholz, 2010a): from mesiolingual: probing (PAL-H)/clinical horizontal attachment loss (CAL-H) = 9 mm. (d) Furcation probing at tooth 16 (see part c) (Eickholz 2010a): from distolingual: probing (PAL-H)/clinical horizontal attachment loss (CAL-H) = 6 mm. In tooth 16 the PAL-H/CAL-H measurements add up to 15 mm. At the furcation entrances tooth 16 has a width less than 15 mm. Thus the furcation is through-and-through (degree III; Table 33-1).

regenerative treatment, where new connective tissue attachment may be possible without new bone formation within a furcation (Eickholz & Walter 2018).

Reliable diagnosis of FI is not provided by two-dimensional radiographic techniques (projection radiography, periapical and panoramic radiographs) (Topoll *et al*. 1988). For maxillary premolars the furcation channel is oriented perpendicularly to the central beam. Thus, FI in maxillary premolars cannot be visualized using projection geometry. In three-rooted maxillary molars the furcation channel between the mesio- and distolingual furcation entrance also runs parallel to the plane of the radiographic film or sensor and perpendicular to the central beam. The buccal furcation entrance is in most cases overlapped by the lingual root. Thus, in maxillary molars, two-dimensional radiographs only provide very limited information on interradicular bone. Only in mandibular molars is the furcation channel located perpendicularly to the plane of the film/sensor and parallel to the central beam. Thus, under conditions of orthoradial projection, interradicular bone may be assessed in mandibular molars. However, radiographs only provide information on resorption or density of bone. Reduced bone density may be because of periodontal destruction or reduced bone density caused by loose spongeous structure. Thus, conventional radiographs may only provide hints for a suspicion of FI. This suspicion has to be confirmed or rejected by furcation probing using a curved probe (Eickholz & Walter 2018).

Additionally, radiographs may provide information to judge whether a buccal or lingual class II furcation may benefit from regenerative therapy. In molars with class II FI, a long root trunk, a furcation fornix located coronally to the adjacent interproximal alveolar crest, and a wide furcation are associated with less favorable horizontal attachment gain after guided tissue regeneration (Horwitz *et al*. 2004).

Three-dimensional radiography

Because conventional two-dimensional radiographic imaging may have some clinically relevant drawbacks, it might be useful to analyze distinct clinical situations, particularly in maxillary molar teeth, with a three-dimensional diagnostic approach (Laky *et al*. 2013; Walter *et al*. 2016). Cone beam computed tomography (CBCT) has been validated *in vivo* for the assessment of FI of maxillary molars (Walter *et al*. 2016). CBCT data were found to be accurate in assessing the amount of periodontal tissue loss and in classifying the class of FI in maxillary molars (Walter *et al*. 2009; Walter *et al*. 2010; Walter *et al*. 2016). In addition, the three-dimensional images revealed several findings, such as the surrounding bony support of each maxillary molar root, fusion or proximity of roots, periapical lesions, root-perforations, and/or missing bony walls (Walter *et al*. 2009). The clinical relevance of these radiographic data was analysed regarding the decision-making process for resective or non-resective therapies. These treatment options were classified according to their invasiveness (GoI, graduation of invasiveness): (1) GoI 0, supportive periodontal treatment (SPT); (2) GoI 1, open flap debridement with/without gingivectomy or apically repositioned flap and/or tunneling; (3) GoI 2, root separation; (4) GoI 3, amputation/trisection of a root (with/without root separation or tunnel preparation; (4) GoI 4, amputation/trisection of two roots; and (6) GoI 5, extraction of the entire tooth. They range from minimally invasive SPT to maximally invasive extraction and implant restoration. Significant discrepancies between conventional and CBCT-based treatment approaches were found in most situations, which possibly necessitates intrasurgical changes in the treatment plan in those cases where no CBCT is available (Eickholz & Walter 2018).

However, the findings from a cost analysis indicated the need for a critical appraisal of CBCT applications in upper molars (Walter *et al*. 2012). In most cases with clinically-based GoI ≤1, CBCT imaging seems to have no or only a minor impact on economic benefit and reduces treatment time only slightly, if at all. With more invasive clinically based treatment decisions (>GoI 1), however, the benefits of using CBCT were greater, probably because the indication for tooth extraction is clarified. On the one hand, a straightforward tooth extraction followed by implant placement and restoration is feasible, thereby avoiding explorative periodontal surgeries when the tooth is not maintainable. On the other hand, unnecessary tooth extractions and implant placement in sites where teeth would be maintainable may be avoided. Moreover, root canal treatments in sites planned for GoI 2, 3, or 4 may be prevented, as CBCT revealed morphological variations such as root proximities or root fusions, which precluded the clinically based resective treatment planning (Eickholz & Walter 2018).

The main goal of diagnostic radiology is to keep the radiation dose "as low as reasonably achievable" (ALARA), and this should also be a prerequisite for adequate CBCT application in dentistry, since increased radiation in the dental office may potentially cause malignancies, including thyroid cancer or intracranial meningioma (Hallquist & Nasman 2001; Longstreth *et al*. 2004; Hujoel *et al*. 2006). The potential risks associated with additional radiation exposure are only justified in single cases and have to be evaluated in each individual situation.

Furcations and risk of tooth loss

For the reasons described, plaque removal inside the furcation area is a rather daunting and difficult task, both for the clinician and for patients. It is therefore

plausible to assume that teeth affected by FI, being more exposed to the microbial challenge, will develop periodontal progression more rapidly and will have a higher risk of tooth loss.

Unfortunately, few studies have systematically investigated the relative contribution of FI to tooth loss in untreated populations. A 13-year longitudinal study on a sample of 221 staff members of a Swedish industrial company not receiving a specific periodontal treatment protocol used radiographic mandibular molar interradicular bone destruction for furcation diagnosis, in the absence of clinical data. Only 1.1–2.7% of the molars had bone loss ≥50% of the root trunk. During the follow-up period, bone loss in the furcation area increased from 18% to 32%, and 9% of molars with FI were lost (Bjorn & Hort 1982). A larger study examined a population of 1897 subjects as part of the Study of Health in Pomerania (SHIP) (Nibali *et al*. 2017). All subjects had half-mouth periodontal examinations, including FI measurements with a straight probe in one upper and one lower molar at baseline (total 3267 molars). Fewer than a third of participants reported having had some form of unspecified 'gum treatment' throughout the course of the observational period. In total, 375 subjects (19.8%) lost molars during the follow-up period. As expected, there was a gradient increase in tooth loss prevalence for molars with increasing FI class (respectively 5.6%, 12.7%, 34.0%, and 55.6% of molars without FI, class I FI, class II FI, and class III FI). A strong statistically significant association between FI and tooth loss was detected. The calculated incidence rate ratios (IRR) for molar loss were:

- 1.73 (95% CI = 1.34–2.23, P <0.001) for class I FI compared with no FI at baseline
- 3.88 (95% CI = 2.94–5.11, P <0.001) for class II-–III compared with no FI at baseline.

These results were confirmed in subanalysis of the 72% of subjects who had no periodontal treatment during the course of the study (who could more genuinely be considered 'untreated') (Nibali *et al*. 2017).

Treatment options

The data in the previous section stress the importance of treating molars with FI, in order to avoid tooth loss, which results in the worsening of quality of life for patients. Previous chapters of this book have clearly explained that the mainstay of periodontal treatment consist of patient motivation, oral hygiene instructions, and supra- and subgingival tooth debridement. Furcations are no different. Every effort needs to be made to remove deposits from inside the furcation areas successfully, in order to achieve satisfactory outcomes, with reduction of pocket depths and bleeding on probing, and ideally also of the degree of the FI (horizontal and vertical). However, several studies have shown that removal of subgingival deposits, especially in the furcation area, is challenging and the expected response is not as favorable as in non-furcation sites.

Non-surgical treatment

Both professional root surface debridement and self-performed oral hygiene are very challenging in furcation-involved teeth. This is due to limited access to the usually small furcation entrances (see previously) and to deep difficult-to-reach root concavities present in interradicular areas (Bower 1979; Booker & Loughlin 1985; Eschler & Rapley 1991). Studies have clearly shown that complete plaque and calculus removal in the furcation region is unrealistic (Matia *et al*. 1986; Parashis *et al*. 1993; Kocher *et al*. 1998a,b; Jepsen *et al*. 2011), even for experienced operators (Fleischer *et al*. 1989). Ultrasonic scalers have been shown to be more effective than hand instruments in narrow and deep furcation areas, due to their smaller tips (Matia *et al*. 1986; Leon & Vogel 1987; Sugaya *et al*. 2002). Diamond-coated ultrasonic and sonic scaler tips can also be effective but are more aggressive, removing cementum and dentine (Kocher & Plagmann 1999). Therefore, it is no surprise that studies showed that sites with FI responded consistently less favorably than non-furcated sites to subgingival debridement in terms of pocket depth reduction, clinical attachment gain, and risk of reverting to baseline status (Nordland *et al*. 1987; Loos *et al*. 1988, 1989). These difficulties can be partially overcome by an open-flap approach for furcation debridement (Matia *et al*. 1986; Fleischer *et al*. 1989), but also with the introduction of stronger and thinner curettes and ultrasonic tips, with widths <0.7 mm. Slimline furcation-customized ultrasonic tips and micro-mini curettes are therefore recommended for professional furcation debridement. With the correct use of these newer tools, clinical and radiographic resolution of the furcation lesion may be possible in some cases even following non-surgical therapy only (Fig. 33-11).

Good oral hygiene is crucial for the short- and long-term success of furcation treatment. However, the evidence for efficacy of self-performed oral hygiene tools in the furcation region is very limited. A study suggested that a pointed-end tufted powered brush is more effective than a small-head powered toothbrush in removing plaque in furcal areas (Bader & Williams 1997). For interproximal furcations, we can assume that interdental brushes are more effective than floss, as shown in studies not specific to furcation lesions (Kiger *et al*. 1991). Particularly demanding oral hygiene routines are required for patients to clean class III furcations. However, this has been shown to be achievable under the right circumstances (Hellden *et al*. 1989).

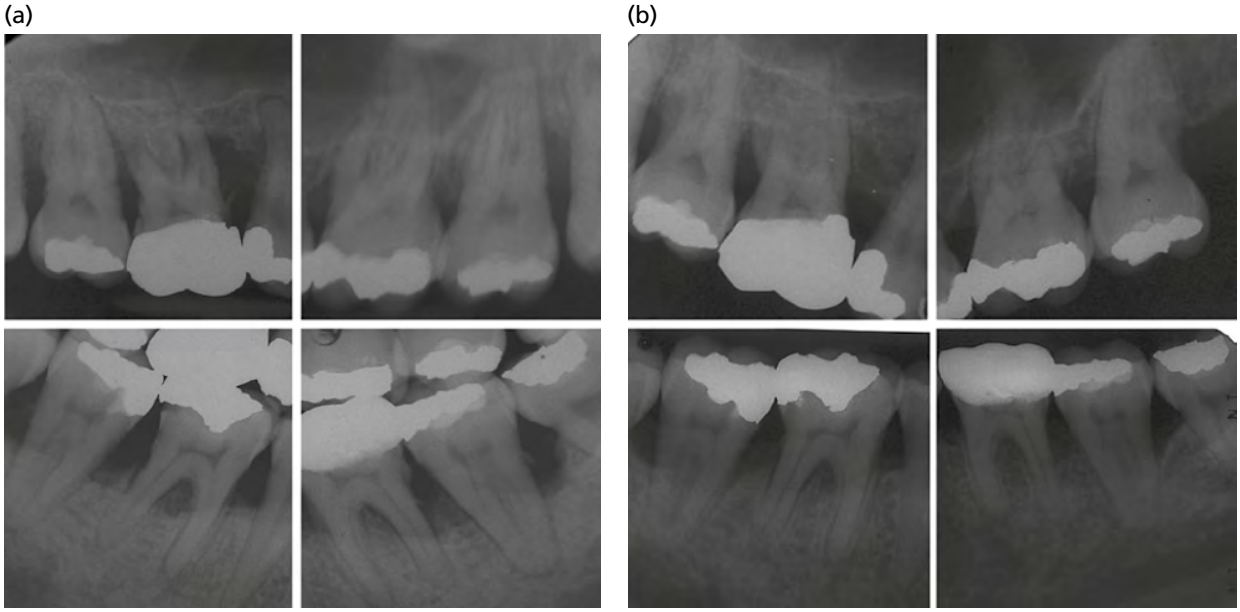

Fig. 33-11 (a) Periapical radiographs of molars of a female 32-year-old aggressive periodontitis patient at periodontal diagnosis. Radiolucency inside the furcation areas is visible, particularly for teeth 16 and 17 (both class II clinical furcation involvement [FI] diagnosis), teeth 26 and 27 (class I FI), tooth 36 (class I FI), and tooth 46 (class II FI), often associated with intrabony defects. (b) Periapical radiographs of the same molars 1 year after initial periodontal therapy (oral hygiene instructions and supra- and subgingival debridement with adjunctive systemic antibiotics and extraction of tooth 28), showing radiographic bone fill in furcation defects and intrabony defects, associated with clinical reduction of FI classes (now only class I for teeth 16 and 17, teeth 26 and 27, and tooth 46).

Corrective surgery in furcation defects

Different surgical strategies are available to address the problem of FI. Access flap surgery aims to improve instrumentation of the furcation area (root surfaces, roof of furcation, osseous lesion) under direct vision (open flap debridement). The elimination of the furcation defect is another option. This can be achieved by removal of the involved root(s) using resective approaches. Alternatively, periodontal tissues that have been destroyed by periodontitis can be regenerated, thereby decreasing the lesion.

Access flap surgery /open flap debridement

Complete removal of subgingival deposits is more difficult in molars than in single-rooted teeth (Brayer *et al*. 1989; Fleischer *et al*. 1989). Thus, after non-surgical treatment, multirooted teeth in many cases exhibit persisting pockets and require additional open flap debridement. Class I FI results in a minor deterioration of prognosis compared with class II and III FI (Nibali *et al*. 2016). Thus, in class I FI there is no need to improve the horizontal component of FI by regenerative treatment. Up to now there is no evidence that the horizontal component of through-and-through FI (class III) may benefit from regenerative treatment (Pontoriero *et al*. 1989; Pontoriero & Lindhe 1995; Jepsen *et al*. 2020a). However, substantial long-term survival of molars with class III FI has been reported after only non-surgical and open flap debridement (OFD) (Dommisch *et al*. 2020).

The clinical performance of access flap surgery (OFD) in the treatment of class II furcation defects has been evaluated (Graziani *et al*. 2015). Based on prospective data of the control groups of randomized clinical trials, most of them with 6 months' duration, the following outcomes could be established: furcation closure after OFD was never reported, mean horizontal bone level (HBL) gain was almost imperceptible, mean horizontal clinical attachment level (HCAL) gain amounted to 1 mm, mean vertical clinical attachment level (VCAL) gain to 0.5 mm, and mean probing pocket depth (PPD) reduction to 1.4 mm. Thus, surgical debridement of class II furcation defects can result in a modest improvement in clinical parameters. However no change in furcation status by horizontal bone fill can be expected.

Resective furcation surgery of furcation defects

Several studies report that molars with class I FI compared with molars without FI have a fair long-term prognosis. However, molars with class II and III have increased long-term tooth loss rates compared with molars without or class I FI. Further, different survival rates according to class of FI, in particular with differences between class II and III, are reported (McGuire & Nunn 1996; Salvi *et al*. 2014; Graetz *et al*. 2015; Dannewitz *et al*. 2016). Under favorable conditions class II FI may be closed or transferred to class I FI by regenerative therapy (regenerative furcation therapy) (Jepsen *et al*. 2020a). Thus, multirooted teeth with class II (unfavorable conditions) and in particular class III FI are the targets of resective treatment.

Resective furcation therapy basically follows two strategies:

1. Elimination of the niche created by FI by removal of roots.
2. Providing access for individual and professional hygiene to the involved furcation.

Further treatment of FI is often required in strategically important teeth that contribute to chewing capability, maintaining the complete or a shortened dental arch (Fig. 33-12) and supporting fixed or removable dental prostheses (Fig. 33-13).

Currently, a root canal treatment and filling is required for all techniques where roots are resected or teeth are separated. If these techniques are to be used, it must be considered that additional treatment (root canal treatment and filling) may result in additional complications. Thus, if a satisfactory root canal filling already exists, this may facilitate the decision for resective furcation therapy. Whereas attempts to keep the pulp of resected teeth vital using calcium hydroxide failed (Haskell & Stanley 1982), a case series using metal trioxide aggregate (MTA) reported promising results for up to 1 year (Tahmooressi *et al*. 2016). Recently, a case series demonstrated the possibility of maintaining severely furcation-involved molars by vital root resection for up to 7 years. Teeth treated were maxillary molars affected by double/triple class II or single/double class III FI and advanced bone loss around one root. Molars were treated with deep pulpotomy using a calcium silicate-based cement before the affected root was removed. All teeth remained vital and presented with healthy and stable periodontal conditions. The authors concluded that root canal therapy and its associated costs and complications can thus be avoided and further trials are warranted (Jepsen *et al*. 2020b).

Root resection/amputation

Root resection (also called root amputation) describes the removal of a root of a multirooted tooth under retention of the respective part of the crown. Root resection is mainly used in maxillary molars to remove one of three roots (Fig. 33-14a–h). When luxating the root to be removed, the molar unit to be retained must not be used for support (Fig. 33-14f), because the molar unit to be retained also may be luxated, which will result postsurgically in increasing mobility and, frequently, tooth loss.

In a maxillary molar resection of one root this leaves approximately 70% of the roots to support 100% of the crown. From a statics point of view, this allows retention of the whole crown and occlusal surface, respectively, without risking overload and fracture. Due to static considerations, roots of mandibular molars are rarely resected. Root resection in a /amputation mandibular molar with two roots would result in 50% of roots left with 100% of the crown, with a strong leverage causing a high risk for fracture. However, in cases where the mandibular molar scheduled for root resection is connected by a crown block or a bridge to neighboring teeth, the leverage of eccentric occlusal forces is compensated (Fig. 33-13). Resecting a root that is creating FI eliminates the respective furcation and the FI. This eliminates the niche and thereby the persisting infection.

If the tooth scheduled for resection has been restored by adhesive composite techniques after root canal treatment, the root canal of the root to be resected should be enlarged in the coronal third and filled by composite material using dentine adhesive (total etch and bond) (Fig. 33-14d). When cutting the root, the root canal is already obliterated by composite avoiding additional restorative measures (Fig. 33-14e).

Hemisection and trisection

Hemisection is the simultaneous removal of a root with the respective part of the crown from a two-rooted tooth (mandibular molar). Trisection is the respective technique in maxillary molars (removal of one or two roots with the respective part of the crown from a three-rooted tooth). Hemisection is the resective technique of choice in teeth that beyond FI exhibit a defect substantially deteriorating the prognosis of one root compared with the other, for example obliterated root canal (Fig. 33-15a), deep bony defect, or apical periodontitis. The tooth is not separated centrally above the furcation but slightly laterally within the root to be removed (Fig. 33-15c). This avoids damage to the root to be retained. Hemisection in many cases creates a gap that may require prosthodontic treatment (Fig. 33-15d–f). However, if there are respective antagonists and the patient is neither functionally nor aesthetically compromised, gaps in the posterior region may be kept.

Restoration of resected molars

Until the 1980s, restorative treatment after root resection followed the paradigm that retention had to be created by root canal posts and teeth had to be stabilized by crown work. The assumption was that root canal filled teeth would become brittle and after root resection the retained tooth units would become instable. At that time, direct restorative materials that allow adhesive connection to enamel and dentine were not available. Providing space for root canal posts requires debridement of more dentine from the root canals than for pure disinfection and filling. This additional debridement of the root canal leads to substantial loss of hard tissues. This may contribute to high rates of long-term failure of resective furcation treatment due to root fractures (18%) compared with periodontal reasons (10%) (Langer *et al*. 1981). Currently, adhesive composite restoration techniques facilitate stabilization of dental hard tissues by direct restorations (Figs. 33-12, 33-14). Avoiding the dogmatic use of root posts may help to reduce the total failure rate (Carnevale *et al*. 1998).

Root separation

Root amputation, hemisection, and trisection entail removal of one or two roots from multirooted teeth to eliminate the respective furcation and FI (Eickholz 2010b). If one of the roots that generates a furcation is compromised by, for example, severe vertical bone loss, an endodontic lesion, root fracture, root perforation, or a fractured root canal instrument, this may support the decision to remove the respective root. However, which procedure may be used if all roots generating a furcation and neighboring an FI have sufficient bony support and have equal prognosis? In such cases the strategy of making the FI niche accessible to individual oral hygiene measures is applied.

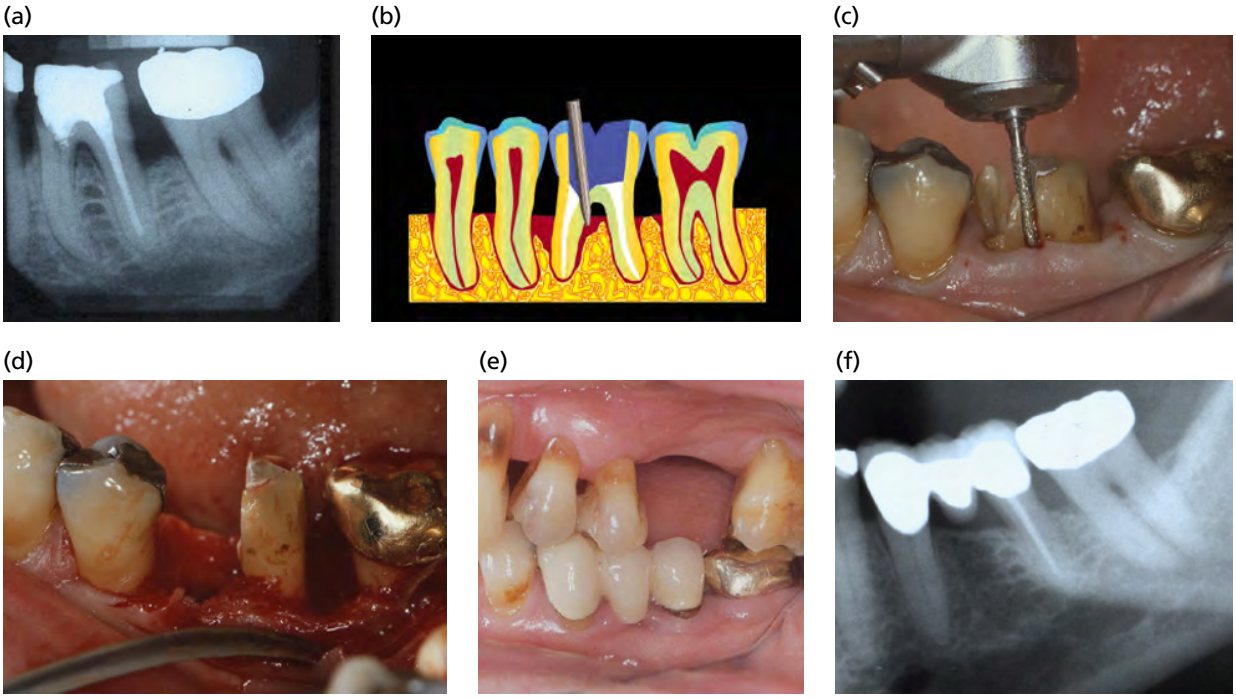

Fig. 33-15 Hemisection at left first mandibular molar (tooth 36). (a) Radiograph after root canal filling. The mesial root canals are obliterated and cannot be debrided. (Source: Eickholz 2011.) (b) Schematic: left first mandibular molar with degree III furcation involvement and infrabony defect at mesial root. Separation of mesial root paramedian of furcation within the root to be removed avoiding damage to the root to be retained. (c) Separation of mesial root. Left second molar exhibits degree III furcation involvement and, thus, is not an appropriate bridge abutment. (Source: Eickholz 2011.) (d) After removal of mesial root. (Source: Eickholz 2011.) (e) Restoration according to traditional paradigm: bridge from distal root of tooth 36 to tooth 35 (clinical view 11 years after surgery). (Source: Eickholz 2011.) (f) Radiograph 11 years after surgery (detail from panoramic radiograph); left second molar still in place despite degree III furcation involvement. (Source: Eickholz 2011.)

In class II and III furcation defects created by two roots with equally good periodontal support and prognosis the furcation niche may be made accessible for individual oral hygiene measures by a so-called root separation (Fig. 33-16). Therefore, a two- or three-rooted tooth is separated into two or three single-rooted tooth units (Fig. 33-16). In contrast to hemisection/trisection for root separation, the roots are separated centrally above the furcation fornix (Fig. 33-16c), because two roots in the mandible and three roots in the maxilla should be retained and, thus, must not be damaged. The furcation is transformed to an interproximal space that can be accessed more easily for individual hygiene measures. Because the grinding bur to separate the roots has a defined diameter that creates a gap between the separated roots (Fig. 33-16c), the interproximal contact has to be recreated restoratively after surgery (Fig. 33-16d–f).

Tunneling

Whereas up-to-date root canal treatment and filling are prerequisites for root resection, hemisection, trisection, and root separation, the tunneling procedure allows the patient access to the furcation area to keep teeth vital. The technique is appropriate particularly for mandibular molars with a mesial and distal root and a buccal and lingual furcation entrance (Fig. 33-17a). Although tunneling maxillary molars is possible in principal, its success depends on the patient's dexterity when using interdental brushes. Opposite each furcation entrance there is a root blocking the straight passage of the brush. In mandibular molars with severe class III FI and a short root trunk, small interdental brushes may pass through the furcation because of already receding gingiva as a result of non-surgical subgingival instrumentation. However, in many cases the channel created by the FI is too narrow or narrowed lingually by a bony wall. In these cases a flap is raised (apically repositioned flap) (Fig. 33-17b, c). After revealing the bone and the furcation defect, interradicular bone is reduced using bone files (Schluger and Sugarman files) sufficiently to facilitate access of interdental brushes after healing (Fig. 33-17b–d). As a rule of thumb, the tunnel should be able to accommodate a Schluger file without edging (Fig. 33-17c). Using rotating instruments carries the risk of irreversibly damaging the root surfaces within the furcation and generating predilection sites for root caries. Finally, the flap is repositioned apically by interradicular and interdental periosteal sutures (Fig. 33-17e). A periodontal dressing should be applied to keep the soft tissues apically and to prevent reclosure of the tunnel. A space holder may keep the tunnel open; a piece of gauze can be used (Fig. 33-17f–h) – the suture is fixed at one end of the gauze (Fig. 33-17f). The periodontal dressing is mixed and one half applied to the gauze (Fig. 33-17g). The needle is then pushed through the tunnel and the gauze, loaded with the dressing, is carefully pulled into the tunnel (Fig. 33-17h). Overhangs should be reduced. However, to facilitate removal 1 week after tunneling at the time of suture removal, the gauze should not be cut too short. The other half of the

periodontal dressing has now become putty and is placed to the buccal and lingual area of the gingival margin (Fig. 33-17i, j). Another technique is to pull and fix an elastic ligature (e.g. Wedjet®) into the furcation (Müller *et al*. 2017).

In the mandible, tunneling has the same indication as root separation. However, tunneling does not require root canal treatment and filling. Tunneling is particularly beneficial for retaining existing and functioning crown and bridge work without damaging restorations, which may occur during root canal treatment.

The aim of tunneling is not elimination of the furcation but facilitating access for a patient's oral hygiene (Fig. 33-17k–n). For tunneling the respective roots should be spread sufficiently and the furcation fornix should be located coronally (short root trunk) to facilitate interradicular professional debridement and individual cleaning. Root caries within the tunnel is the most dreaded complication of this technique (Fig. 33-18). Restoration of such caries is practically impossible. The only putative solutions to this problem are root separation, root resection, trisection/hemisection, or extraction. Patients are advised to

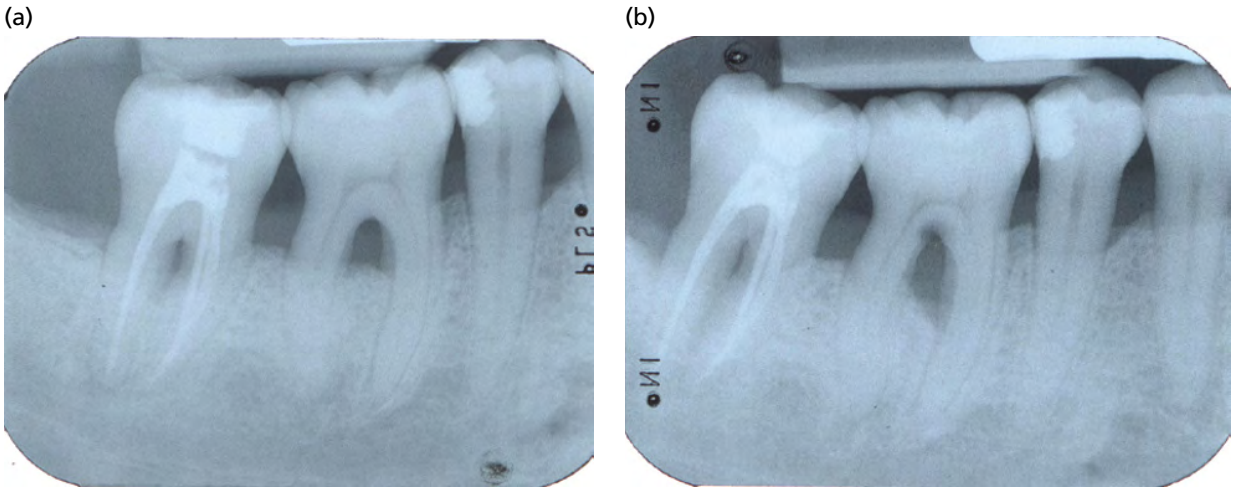

Fig. 33-18 Tunneling of right first and second mandibular molar (teeth 46 und 47). (a) Two months after tunneling. (b) Fifty-six months after tunneling: root caries developed within the furcation fornix of the first molar. Additionally, breakdown of periodontal bone has occurred in the furcation. (Source: Eickholz 2011.)

clean the tunnel meticulously and to apply fluorides on a daily basis into the tunnel to prevent caries. This requirement should be communicated to patients prior to surgery.

Combination of resective techniques

In maxillary molars with class III FI affecting all three furcation entrances, one root may be resected and tunneling performed for the remaining two roots. Alternatively, after resection of one root, the remaining roots may be separated. However, use of such combinations may not be successful. It is important to make sure that there is enough intact periodontium to support the remaining tooth unit (at least 50% remaining bone height) (Park *et al*. 2009).

Prognosis of resective furcation treatment

A recent systematic review evaluated the effect of resective surgical periodontal therapy (root amputation or resection, root separation, tunnel preparation) in periodontitis patients exhibiting class II and III FI and its benefit when compared with non-surgical treatment or open flap debridement. One prospective and six retrospective cohort studies and case series were included, reporting 667 patients contributing 2021 teeth with class II or III FI. Data were highly heterogeneous regarding follow-up and distribution of FI. A total of 1515 teeth survived 4–30.8 years after therapy. Survival ranged from 38% to 94.4% (root amputation or resection, root separation), 62% to 67% (tunnel preparation), 63% to 85% (OFD), and 68% to 80% (scaling and root planing, SRP). Overall, any treatment provided better results for class II than class III FI (Dommisch *et al*. 2020).

In addition to the class of FI prior to therapy and type of restoration, the amount of periodontal support that remains after surgery seems to play a decisive role for prognosis. Teeth with class III FI and little bone loss (Fig. 33-12) or little FI and severe bone loss on average have a good prognosis, whereas multirooted teeth with class III FI and severe bone loss are less suitable for resective surgery (Dannewitz *et al*. 2006). This observation is supported by another group that reports better long-term prognosis in retained tooth units with at least 50% remaining bony support in relation to root length (Park *et al*. 2009).

If performed early enough, root resection, trisection, hemisection, and root separation provide survival rates >90% 10 years after treatment (Carnevale *et al*. 1998). Hemisection of the distal root of mandibular molars provides the worst success rate (75%). Resective surgery facilitates long-term success that is similar to endosseous implants that were inserted in the molar region (>90%) (Fugazzotto 2001). A recent structured review reported that 294 patients contributing 468 teeth lost a total of 105 teeth treated by root amputation or resection, and root separation for class II or III FI (survival 77%). Overall, treatment provided better results for class II FI than class III (Dommisch *et al*. 2020).

After tunneling of seven multirooted teeth (six mandibular molars, one maxillary premolar) and reporting caries within the tunnel 5 years after surgery, this technique had a bad reputation (Hamp *et al*. 1975). A recent structured review revealed that seven of 19 teeth treated by tunnel preparation were lost (survival 63%) (Dommisch *et al*. 2020). Very recent observational studies report slightly better survival rates: in a prospective case series of 32 patients contributing 42 molars with class III FI, 69% survival 5 years after tunnel preparation was observed (Rudiger *et al*. 2019). A retrospective cohort following 102 molars with class III FI in 62 patients at least 5 years after tunnel preparation reported 70% survival with regular SPT positively influencing survival (Nibali *et al*. 2019).

With respect to the heterogeneity of included studies, the lack of randomized controlled trials, and based on the evidence aggregated in this systematic analysis of recent/timely studies on resective surgical periodontal therapy (root amputation or resection,

root separation, tunnel preparation) in class II or III FI, an additional benefit of resective surgery compared with SRP or OFD in class II or III FI cannot be stated. However, in terms of elimination of periodontal inflammation, adjunctive surgical measures (root separation, root resection, tunnel preparation) may be yet justified. A careful case selection with respect to residual circular attachment is strongly suggested (Dommisch *et al*. 2020).

Extraction or palliative furcation treatment

In severely furcation-involved teeth without strategic significance (third molar or second molar in complete dentition or in the presence of the prognostically more favorable first molar), it is questionable whether root canal treatment, surgery, and restorative treatment is worth the effort. In such cases, removal of these teeth may be the most reasonable solution.

However, to surgically treat or extract teeth that are severely affected by FI is difficult to justify to patients who do not feel any pain or discomfort. From the patients' point of view, these teeth still function. If there is no need for new prosthodontic rehabilitation, which includes the FI-affected teeth, what can be offered to the patient? Class II and III FI-affected teeth may be treated with prolonging or palliative treatment: subgingival scaling and an access flap, and be maintained by regular SPT with frequent subgingival re-instrumentation and/or local subgingival antimicrobials. The aim is to slow down progression of periodontal destruction and to prevent loss of the respective tooth in the short and intermediate term. Survival rates after SRP and OFD ranged from 85% to 45% (Dommisch *et al*. 2020).

However, regular SPT is of paramount importance if resective or palliative furcation treatment is to be successful and be stabilized in the long term.

Regenerative surgery of furcation defects

Various surgical regenerative techniques have been proposed for the treatment of furcation defects of periodontitis-affected teeth and, over the past 30 years, they have been evaluated by a large number of clinical trials. Among the techniques, the most frequently described are guided tissue regeneration (GTR), using either resorbable (GTR-res) or non-resorbable (GTR-nonres) membranes, bone replacement grafts (autografts, allografts or xenografts) (BRG), bioactive agents such as enamel matrix derivative (EMD), platelet-derived growth factor (PDGF), platelet-rich plasma, platelet-rich fibrin (PRP/PRF), and combinations of them (Sanz *et al*. 2015; Jepsen & Jepsen 2018).

Evidence from human histology

Exemplary human histology is the ultimate proof for a regenerative healing outcome and is needed to supplement the information obtained from clinical regenerative studies (Machtei 1997). Evidence for periodontal regeneration requires the histological demonstration of restored tooth-supporting tissues, including cementum, periodontal ligament, and alveolar bone over a previously diseased root surface. Even though such outcomes have been demonstrated in well-controlled experimental animal studies for a variety of treatment modalities, when reviewing the histologic evidence for periodontal regeneration in furcations, information derived from human histology was found to be limited (Laugisch *et al*. 2019). Human histology showing regeneration is available for GTR (Gottlow *et al*. 1986; Stoller *et al*. 2001). One study using a combination of GTR-res and BRG (Harris 2002) and two studies using BRG (Camelo *et al*. 2003; Nevins *et al*. 2003) observed new bone, cementum, and connective tissue attachment coronal or limited to the notch area.

Evidence from clinical trials

Outcome measures

A variety of outcome measures can be considered to assess the effectiveness of regenerative furcation therapies (Sanz *et al*. 2015; Jepsen & Jepsen 2018). From a clinical point of view, apart from demonstrated improved long-term tooth retention, complete elimination or reduction of the interradicular defect appears to be the most important outcome, based on the assumption that FI class 0 or I is associated with a decreased long-term tooth loss risk (Nibali *et al*. 2016). Thus, the main outcome variables for studies evaluating the efficacy of regenerative techniques in furcations are change of furcation status (conversion into class I or complete closure) and horizontal hard-tissue fill. As histological evidence for successful furcation regeneration is not a practical outcome variable for controlled clinical trials, changes in direct bone measurements (open measurements: horizontal probing bone level, at surgery, and during re-entry) serve as primary outcome variables for evaluating clinical success, while closed measurements such as clinical attachment level gain (horizontal/vertical probing attachment level), probing depth reduction (horizontal/vertical), and radiographic assessments may serve as secondary outcomes (Machtei 1997). Patient-reported outcomes following regenerative furcation surgery may include postoperative pain, the rate of complications, perceived benefit, and change in quality of life.

Systematic reviews

The efficacy of various regenerative approaches in furcation defects has been evaluated by several systematic reviews with or without meta-analyses

(Jepsen *et al*. 2002; Murphy & Gunsolley 2003; Reynolds *et al*. 2003; Kinaia *et al*. 2011; Chen *et al*. 2013; Avila-Ortiz *et al*. 2015; Panda *et al*. 2019; Jepsen *et al*. 2020a) and has also been addressed in comprehensive narrative reviews (Sanz *et al*. 2015; Jepsen & Jepsen 2018).

By far the most evidence is available for class II furcations (mainly in mandibular molars and to a lesser extent in maxillary buccal defects).

In these systematic reviews, GTR was shown to be significantly superior to OFD for HBL and HCAL gain, PPD reduction, and VCAL gain (Jepsen *et al*. 2002; Kinaia *et al*. 2011; Jepsen *et al*. 2020a). Regarding furcation closure in mandibular defects, the results indicated that GTR plus BRG was the most effective therapeutic approach and that GTR in combination with BRG was superior to OFD and GTR alone (Murphy & Gunsolley 2003; Chen *et al*. 2013; Jepsen *et al*. 2020a).

Based on the best available evidence, by including only randomized clinical trials of at least 12 months' duration, and using Bayesian network meta-analyses to allow for direct and indirect comparisons between various regenerative techniques, it was clearly established that furcation improvement (furcation closure or class I conversion) can be expected for the majority of class II furcation defects (Jepsen *et al*. 2020a) (Table 33-2). BRG resulted in the highest probability of being the best treatment for HBL gain. GTR plus BRG ranked as the best treatment for VCAL gain and PPD reduction.

Long-term outcomes

Long-term data following regenerative therapy in furcation defects are sparse (Figueira *et al*. 2014). Significant gains in horizontal attachment level (2.6 mm) obtained 1 year after GTR were maintained over 4 years with a slight decline at the end of year 3 (Machtei *et al*. 1996). Mean horizontal attachment level gains after the use of non-resorbable and biodegradable barriers could be maintained for 5 years (Eickholz *et al*. 2001). A 10-year follow-up of 18 teeth in nine patients revealed further stability of horizontal attachment level gains between 12 and 120 months. However, two molars were lost in one patient, and another molar lost more than 2 mm of horizontal probing attachment level (Eickholz *et al*. 2006).

	GTR-RES + BRG	3 (20%)	NR

Perspectives

Platelet concentrates

Growth and differentiation factor technologies have been evaluated for their potential to enhance periodontal wound healing/regeneration. Autologous platelet concentrates, such as PRP and PRF, are a source of growth factors that can be applied to the periodontal wound. The adjunctive effect of autologous platelet concentrates for the treatment of furcation defects has been evaluated in a recent systematic review with meta-analysis; significantly superior outcomes compared with open flap debridement were reported for HCAL, and VCAL gain and PPD reduction (Panda *et al*. 2019).

Combined horizontal and vertical bone loss

Little information is available so far on the outcomes of regenerative therapy in molars compromised by the presence of a combination of furcation and intrabony defects, even though such situations are frequently encountered in clinical practice. In a retrospective case series, improvements, defined as tooth retention, reduction in horizontal and vertical FI, decrease in probing depths, and increases in clinical attachment level were reported at 1 year in 100% of maxillary and 92% of mandibular molars (Cortellini *et al*. 2020). Improvements were not observed in molars with baseline hypermobility. Improvement in vertical furcation subclassification was observed in 87.5% of maxillary and in 84.6% of mandibular molars. One-year improvements could be maintained over the 3–16-year follow-up. These results were obtained in cases with an interdental peak of bone and gingival margin coronal to the furcation entrance in well-maintained and compliant subjects. Randomized controlled clinical trials with medium- to long-term follow-up are needed to confirm these findings.

Summary and conclusions

- Various regenerative approaches, including the use of (non)-resorbable barrier membranes, BRG, EMD, and their combinations, have been evaluated in class II furcation defects and have been shown to be superior compared with open flap debridement
- Treatment modalities involving BRG are associated with better performance.
- Furcation improvement (furcation closure or class I conversion) can be expected for the majority of defects.
- Adjunctive regenerative techniques lead to a significant gain of HCAL, VCAL, and reduction of PPD compared with OFD.
- No conclusions can be made for interproximal maxillary class II furcation defects because of lack of studies.

Furcation regeneration: step-by-step procedure (Jepsen & Jepsen 2018)

The suggested treatment sequence is as follows:

1. *Patient selection*. Systemic factors that limit the success of periodontal surgery, such as uncontrolled diabetes and immunocompromised status, must be considered. Poor patient compliance, inadequate oral hygiene, and smoking are the most frequent patient factors limiting the selection of this procedure. Treatment options and alternatives must be presented to the patient and the potential problems and the additional costs should be discussed. Regenerative furcation surgery should be part of a comprehensive treatment plan aiming at complete periodontal and functional rehabilitation.
2. *Tooth selection*. Adequate access to the surgical site and also for future maintenance is extremely important. Molars with class II furcations (mandibular and buccal maxillary FI) are the best candidates to be considered for a regenerative procedure. Based on the available evidence, interproximal maxillary class II furcation defects are significantly less suited, most likely due to limited access. Class III mandibular and maxillary furcations have shown various treatment responses and in general there are no significant differences in treatment outcomes comparing regenerative therapy with conventional surgery. Defect and site characteristics have been identified that have impacts on the outcomes of regenerative furcation surgery (Bowers *et al*. 2003; Horwitz *et al*. 2004; Reddy *et al*. 2015). For example, a thicker phenotype and the absence of soft-tissue recession can positively influence healing following GTR procedures. More favourable outcomes can be expected in sites in which the remaining interproximal bone height is coronal to the entrance of the furcation defect compared with those in which the bone is at or apical to the furcation entrance (Fig. 33-19). Interdental root proximity may impair proper defect debridement. Presence of a root canal filling is not a contraindication to furcation regeneration per se, provided there are no signs of apical pathology.
3. *Regenerative periodontal surgery*. The goal is to obtain sufficient access to the defect for meticulous debridement and application of the regenerative device. In the case of isolated defects, vertical releasing incisions may be used (Fig. 33-20). Alternatively, the flap can be extended laterally (Fig. 33-19). Keratinized tissues should be preserved by intrasulcular incision and the elevation of a full-thickness mucoperiostal flap. Granulation tissue will be removed and the exposed root surfaces carefully cleaned by hand instruments, power-driven scalers (optionally with diamond-coated tips), or rotary instruments. Root anomalies such as enamel projections/pearls should be removed. If EMD is part of the regenerative strategy, it is usually applied following two minutes of root conditioning with EDTA and rinsing with sterile saline. Subsequently a bone graft/substitute can be used to fill the furcation defect. Alternatively, a GTR barrier membrane can be applied, with or

without an additional defect filler (Figs. 33-19, 33-20). The barrier membrane is secured by a resorbable sling suture to cover the furcation entrance and to promote wound and clot stabilization. In order to facilitate complete coverage of the barrier, the periosteum can be cut to allow for a coronal advancement of the flap. The flap is secured in a coronal position by a sling suture and interrupted sutures over the vertical releasing incisions (Fig. 33-20), or interdental sutures in the case of a laterally extended flap (Fig. 33-19). The patient is instructed to abstain from mechanical plaque removal in the surgical area for a period of up to 4 weeks. During this time, chlorhexidine rinses or topical gel applications are used. The patient returns for monitoring of healing after 1 and 2 weeks, when sutures are removed. Interdental hygiene and mechanical plaque removal are re-started after 4 weeks, and the personalized maintenance recall programme will be determined.

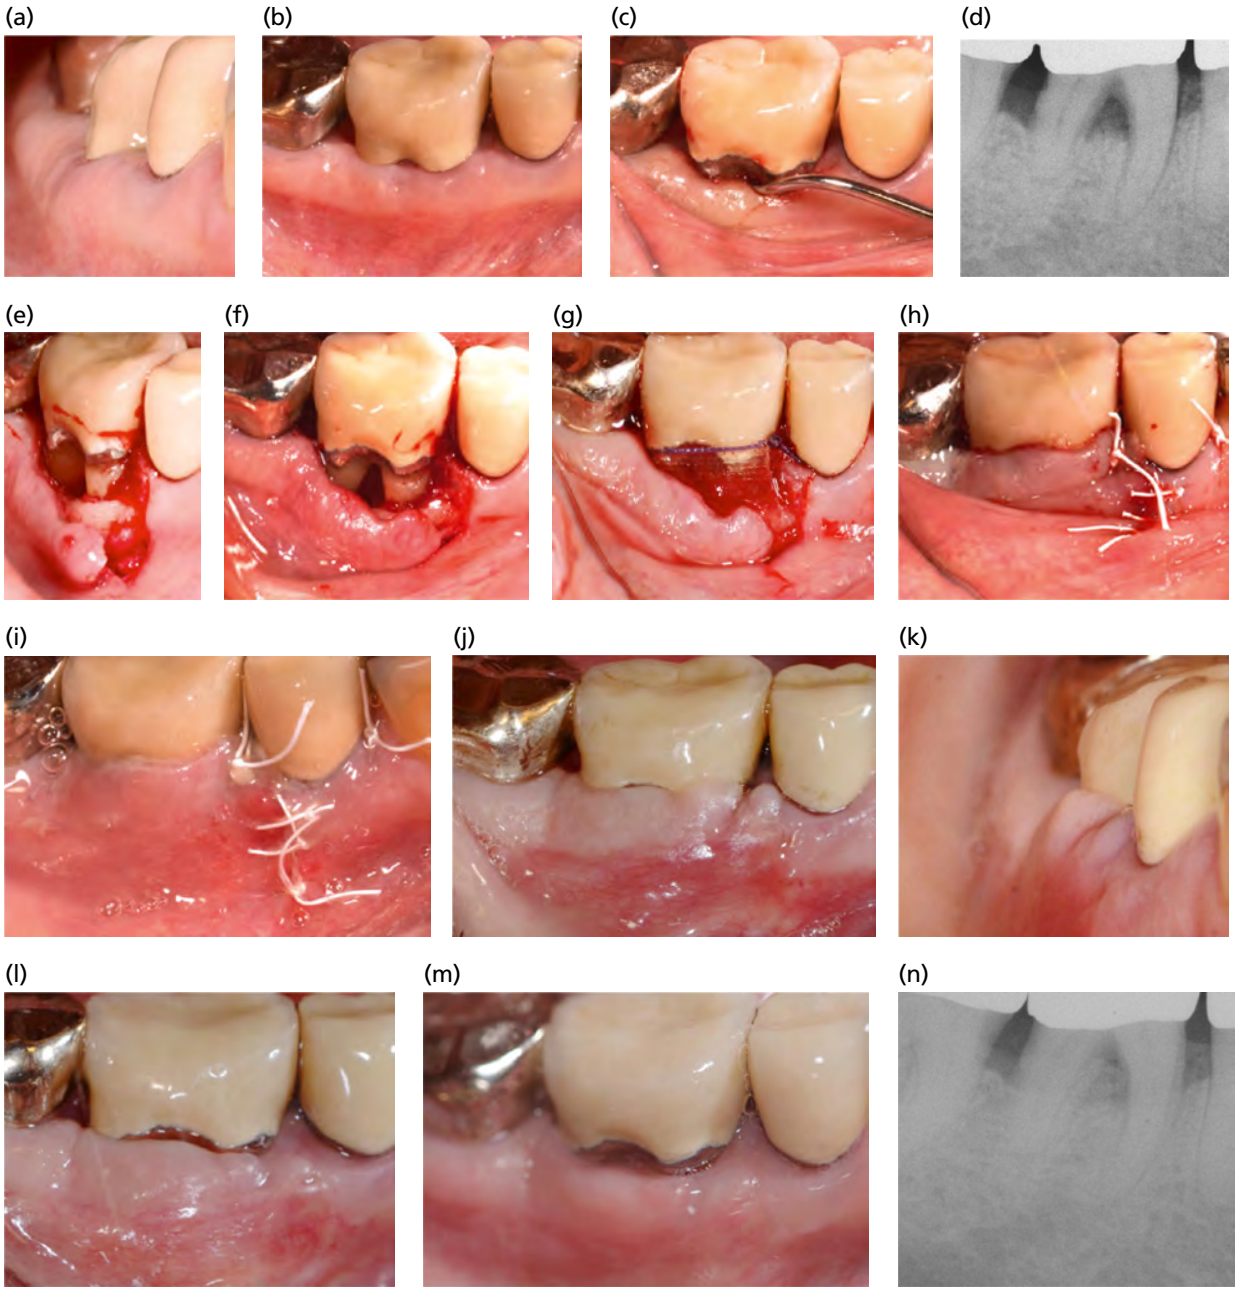

Fig. 33-20 (a, b) Periodontal measurements at baseline tooth 46. Probing depth mesial and distal: 3 mm, furcation class II. Situation 2 months after an acute abscess and mobility grade 2 treated with debridement of the accessible root surfaces and local antimicrobials. (c) Radiograph of tooth 46 with visible furcation defect, proximal bone loss to the level of the furcation and a very short distal root. (l) Clinical view 3 months after surgery. (m) Nine months: vertical and horizontal probing depths: 2 mm. (n) Nine months: radiographic fill of the furcation defect. (Source: Jepsen & Jepsen 2018.)

Decision making (clinical recommendations) in the surgical treatment of class II and III furcation defects (Sanz et al. 2020)

- FI is no reason for tooth extraction.
- It is recommended that molars with class II and III FI and residual pockets after initial non-surgical therapy receive further periodontal therapy.
- It is recommended that mandibular molars with residual pockets associated with class II FI are treated with periodontal regenerative surgery.
- It is suggested that molars with residual pockets associated with maxillary buccal class II FI are treated with periodontal regenerative surgery.
- It is recommended that molars with residual pockets associated with mandibular and maxil-

lary class II FI are treated with periodontal regenerative surgery using EMD alone or bone-derived graft with or without resorbable membranes (Fig. 33-21).

- In maxillary interdental class II FI, non-surgical instrumentation, OFD, periodontal regeneration, root separation, or root resection may be considered.
- In maxillary class III and multiple class II FI in the same tooth, non-surgical instrumentation, OFD, tunneling, root separation, or root resection may be considered.
- In mandibular class III and multiple class II FI in the same tooth, non-surgical instrumentation, OFD, tunneling, root separation, or root resection may be considered (Fig. 33-22).

Long-term maintenance of teeth with furcation involvement

Having covered the different treatment options for molars with FI, it is important to know what to expect from these teeth long-term. Previous chapters have described how long-term longitudinal studies in periodontitis cohorts with SPT reported tooth loss of approximately 0.10 (Hirschfeld & Wasserman 1978), 0.13 (McGuire & Nunn 1986), 0.15 (Eickholz *et al*. 2008), 0.18 (McFall 1982), and up to 0.30 teeth per patient per year (Tsami *et al*. 2009). The classic study by Hirschfeld and Wasserman was perhaps the first to provide some evidence in this field. Following 600 patients during SPT for at least 15 years retrospectively (average 22 years), the authors identified three different groups of patients based on progression pattern: 'well-maintained' (the great majority), 'downhill', and 'extreme downhill'. Of 1464 teeth with FI at baseline, 460 were lost (240 of them by one-sixth of the patients who deteriorated most). Grouping together longitudinal human studies with a follow-up of at least 3 years in patients with chronic periodontitis presenting data on furcation diagnosis and tooth loss, a systematic review identified 14 papers which could be grouped together for meta-analysis (Nibali *et al*. 2016). All these studies included 'active' periodontal therapy (often including different types of surgical procedures), followed by SPT. A total of 8143 molars without FI and a total of 5772 molars with FI were included. Tooth survival ranged from 43% to 100% in the different studies and among teeth reported in these studies, the average

tooth loss/patient/year was 0.1 and 0.2 respectively for molars without and with FI (relative risk [RR] of tooth loss = 2.90, 95% CI = 2.01–4.18). Periodontal progression, endodontic complications, caries, and fractures were reported as main causes of tooth loss (Kuhrau *et al*. 1990; Haney *et al*. 1997; Yukna & Yukna 1997; McLeod *et al*. 1998; Dannewitz *et al*. 2006). The RR of tooth loss increased in parallel with follow-up time, ranging from 1.46 (95% CI = 0.99–2.15, $P = 0.06$) for studies with 5–10 years follow-up, 2.21 (95% CI = 1.79–2.74, $P < 0.0001$) for studies with 10–15 years follow-up and 4.46 (95% CI = 2.62–7.62, $P < 0.0001$) in studies with >15 years follow-up (Nibali *et al*. 2016). With the same gradient effect observed in populations without regular periodontal treatment (Nibali *et al*. 2017), 8%, 18%, and 30% of the total of teeth with furcation class I, II and III respectively were lost in the follow-up period. This resulted in a combined RR of tooth loss of:

- 1.67 (95% CI = 1.14–2.43, $P = 0.008$) for FI class II versus class I
- 1.83 (95% CI = 1.37–2.45, $P < 0.0001$) for FI class III versus class II
- 3.13 (95% CI=2.30–4.24, $P < 0.0001$) for FI class III versus class I.

Tooth loss by vertical furcation component

Retrospective analysis of 200 molars followed up for 10 years of supportive therapy after conservative periodontal surgery with limited osseous surgery showed that vertical furcation subclassification with a modification of the classification proposed by Tarnow and Fletcher (1984) was associated with a higher incidence of tooth loss for class II FI with bone loss up to the coronal third, middle third, or apical third of the root (respectively 9%, 33%, and 77% tooth loss at 10 years). In agreement with this study, similar results were observed in another retrospective cohort of 200 patients with chronic periodontitis (Tonetti *et al*. 2017), where both the horizontal and the vertical furcation components were associated with increased risk of tooth loss during SPT in a multivariable model (Nibali *et al*. 2018; Tonetti *et al*. 2017).

Although it is not possible to completely disentangle the relative contribution of PPD or bleeding on probing to tooth loss from the mere presence of FI, it is clear that FI at least doubles the risk of long-term tooth loss, and probably more when no regular periodontal treatment is carried out. This clearly highlights the importance of improving our efficacy for the treatment of FI-involved teeth. One could assume that, with improvements in regenerative treatment of FI, these figures could potentially improve in the future. However, it is already clear that in patients undergoing comprehensive periodontal treatment, most molars affected by FI respond well to periodontal treatment. It is important to highlight that, even in the presence of class III FI, only 30% of molars were lost with up to 15 years of follow-up in reviewed studies (Nibali *et al*. 2016). The importance of strict SPT for the survival of teeth affected by FI, as for periodontitis cases in general, is paramount (Pretzl *et al*. 2008; Nibali *et al*. 2019). Therefore, although data need to be gathered on other important outcomes such as oral-health related quality of life or systemic inflammation, treatment of teeth affected by FI needs to be considered an important part of periodontal care.

Chapter 34

Non-Surgical Therapy of Peri-Implant Mucositis and Peri-Implantitis

Lisa Heitz-Mayfield[1], Giovanni E. Salvi[2], and Frank Schwarz[3]

Introduction

Peri-implant diseases are inflammatory conditions of the tissues surrounding implants, caused by an imbalance between the peri-implant biofilm and the host response to the biofilm, resulting in dysbiosis and tissue destruction. Chapter 20 describes the histopathologic features of peri-implant mucositis and peri-implantitis, while Chapter 9 outlines the nature of peri-implant biofilms in health and disease.

Peri-implant mucositis is a reversible plaque-associated inflammatory condition of the soft tissues surrounding the implant (Salvi *et al*. 2012; Schwarz *et al*. 2018a). Clinical signs of peri-implant mucositis are bleeding on gentle probing (BoP) without loss of supporting bone. Redness and swelling of the peri-implant mucosa and increased probing depths (PDs), as compared to previous measurements, may also be observed (Heitz-Mayfield & Salvi 2018) (Fig. 34.1).

Peri-implantitis is a plaque-associated pathologic condition characterized by inflammation of the soft tissues surrounding the implant and progressive bone loss (Berglundh *et al*. 2018a). Clinical signs of peri-implantitis are BoP and radiographic bone loss in comparison to previous bone levels. Redness, swelling, suppuration, and deep PDs (≥6 mm) are commonly observed at implants diagnosed with peri-implantitis (Berglundh *et al*. 2018a,b; Schwarz *et al*. 2018b) (Fig. 34.2).

Peri-implant diseases are common conditions with an estimated patient prevalence of 43% (CI: 32%–54%) for peri-implant mucositis and 22% (CI:14%–30%) for peri-implantitis (Derks & Tomasi 2015). Peri-implant mucositis is considered to be the precursor to peri-implantitis, and non-surgical treatment of peri-implant mucositis is a prerequisite for the prevention of peri-implantitis (Jepsen *et al*. 2015). If left untreated peri-implantitis may lead to implant loss. Therefore, effective measures to treat peri-implant diseases have been a focus of attention in recent years.

It is essential that the clinician regularly monitors the peri-implant tissues, by peri-implant probing, and provides treatment of peri-implant disease at an early stage using non-surgical therapy. Distinguishing

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Fig 34.1 Peri-implant mucositis. Clinical signs of peri-implant mucositis with presence of bleeding on gentle probing with an increased probing depth (5 mm) compared with a previous examination. There was no loss of supporting bone.

between peri-implant mucositis and incipient peri-implantitis may be challenging. This is in part due to difficulties in evaluating radiographic bone levels at implants related to angulation and measurement error, further emphasizing the importance of regular monitoring and early intervention. Effective measures to treat peri-implant diseases require an anti-infective approach by supra- and submucosal biofilm removal with the goal of resolving inflammation and preventing disease progression.

Successful treatment of peri-implant mucositis is defined as resolution of inflammation assessed by the absence of BoP. Successful treatment of peri-implantitis is defined using composite success criteria, for example peri-implant PD of ≤5 mm, absence of bleeding or suppuration on probing, and no additional bone loss.

If peri-implant disease is detected at an early stage, non-surgical therapy may result in a successful outcome. Whereas surgical intervention is usually required for treatment of advanced peri-implantitis (see Chapter 35), non-surgical therapy should always be the first stage of treatment and includes professional biofilm removal and oral hygiene instruction (Jepsen *et al*. 2019).

Non-surgical treatment strategies include various methods of professional biofilm removal such as debridement using hand or ultrasonic instruments, air-polishing (biofilm removal using a mixture of compressed air, water, and a fine abrasive powder), or laser irradiation. Adjunctive measures such as antimicrobial photodynamic therapy (use of low-powered laser irradiation with a photosensitizer), delivery of local antimicrobial agents, or prescription of probiotics may also be used, albeit with no additional benefit. Implant surface, material, and topography may influence biofilm formation and the choice of decontamination method. This chapter outlines anti-infective non-surgical treatment strategies for peri-implant mucositis and peri-implantitis (Fig. 34.3).

Non-surgical therapy of peri-implant mucositis

Following a comprehensive examination and diagnosis, an assessment and appropriate management of modifiable risk factors/indicators (such as cigarette smoking, periodontitis, uncontrolled diabetes mellitus) should precede treatment. Figure 34.3a outlines

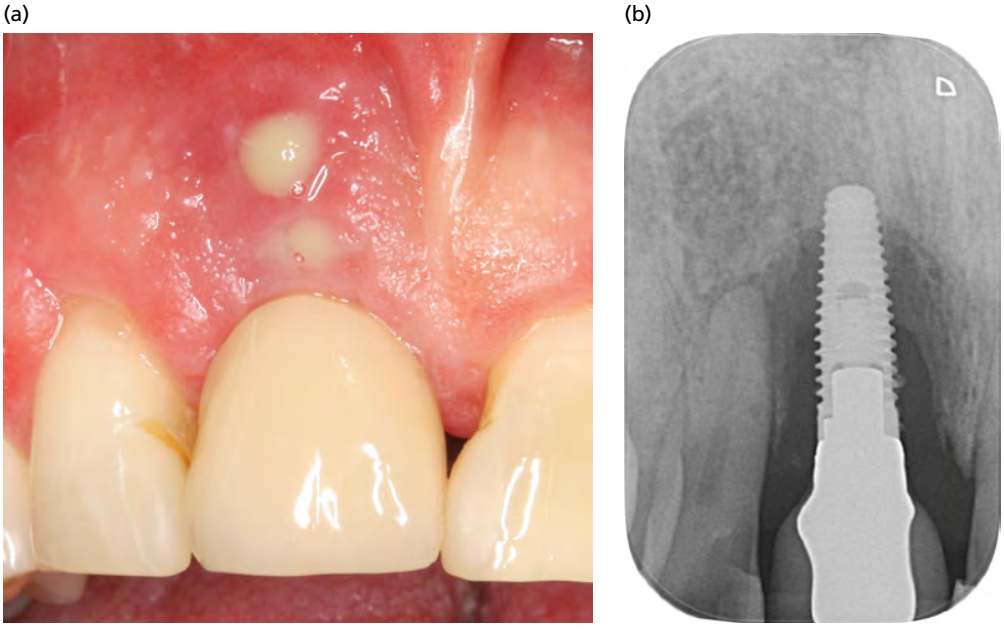

Fig 34.2 (a) Peri-implantitis. Clinical signs of peri-implantitis with suppuration on probing in addition to the presence of a draining sinus on the buccal peri-implant mucosa. Deep probing depths >8 mm. (b) A periapical radiograph of the implant shows advanced peri-implant bone loss to within 2 mm of the apex of the implant.

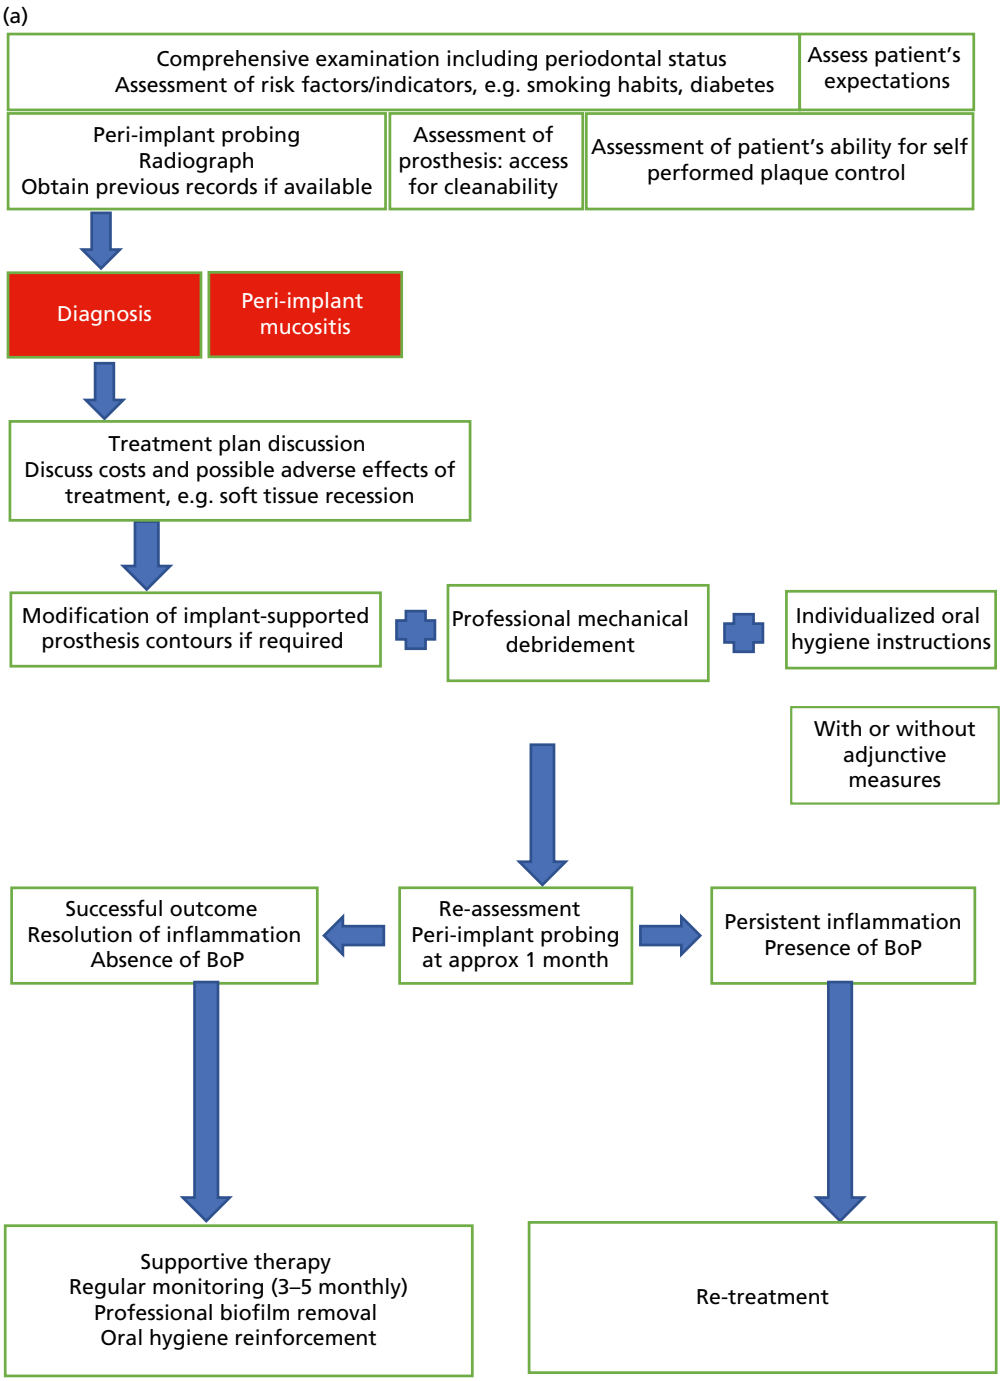

Fig 34.3 (a) Flow-chart outlining the recommended non-surgical treatment sequence for management of peri-implant mucositis.

the steps involved and treatment options available for non-surgical therapy of peri-implant mucositis.

Assessment of the implant-supported prosthesis

The contours of the implant-supported prosthesis and the position of the restoration margin relative to the peri-implant mucosal margin play an important role in the outcome of peri-implant mucositis treatment.

The prosthesis design and access for cleanability as well as the patient's ability for self-performed plaque control should be carefully assessed as part of the non-surgical phase of therapy. Modification of the contours of the prosthesis to allow adequate access for use of oral hygiene aids has been shown to improve treatment outcomes following mechanical non-surgical treatment of peri-implant mucositis (de Tapia *et al*. 2019). Furthermore, improved treatment outcomes at implants with supramucosal restorative margins have been shown following non-surgical treatment of peri-implant mucositis (Heitz-Mayfield *et al*. 2011; Chan *et al*. 2019).

Hence a careful assessment of the contours of the prosthesis and the access for biofilm removal and peri-implant monitoring is important. Modification of the prosthesis may require minor adjustments or may involve redesigning and remaking the prosthesis to eliminate plaque retentive factors and facilitate access for oral hygiene measures (Fig. 34.4). The fit of

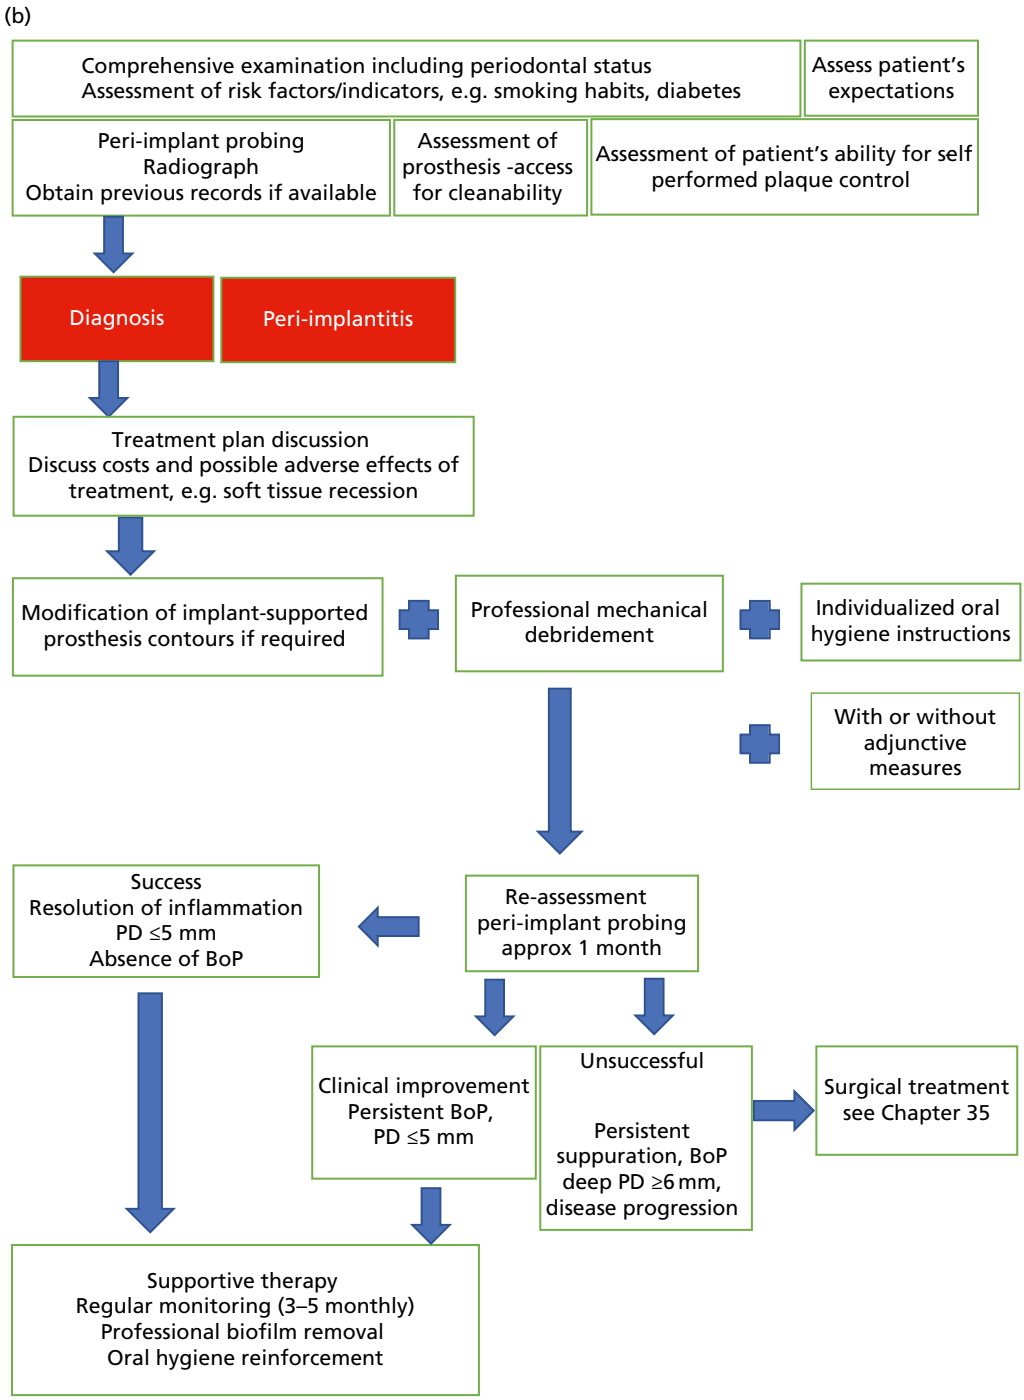

Fig 34.3 (Continued) (b) Flow-chart outlining the recommended non-surgical treatment sequence for management of peri-implantitis.

the implant-supported prosthesis and the tightness of the retention screws should also be assessed for integrity as poor fit or screws with inadequate torque may increase biofilm accumulation.

Cemented prostheses should also be carefully assessed for the presence of excess luting cement which is a risk indicator for peri-implant mucositis (Jepsen *et al*. 2015). Where presence of submucosal luting cement is detected it should be removed.

Oral hygiene measures for self-performed biofilm removal

Oral hygiene measures using either manual or powered toothbrushes are effective for self-performed biofilm removal at implant-supported prostheses (Salvi & Ramseier 2015; Allocca *et al*. 2018). Various interproximal brushes have also been evaluated and found to be effective (Chongcharoen *et al*. 2012). Selection of the appropriate oral hygiene aids, including the use of dental floss or interproximal brushes, should be tailored to suit the aptitude of each individual patient (Fig. 34.5).

Where there is minimal (<2 mm) or lack of keratinized attached peri-implant mucosa patients may have difficulty in performing oral hygiene due to discomfort when brushing (Fig. 34.6), and more frequent supportive care, or augmentation of the keratinized peri-implant mucosa, may be considered (Roccuzzo *et al*. 2016).

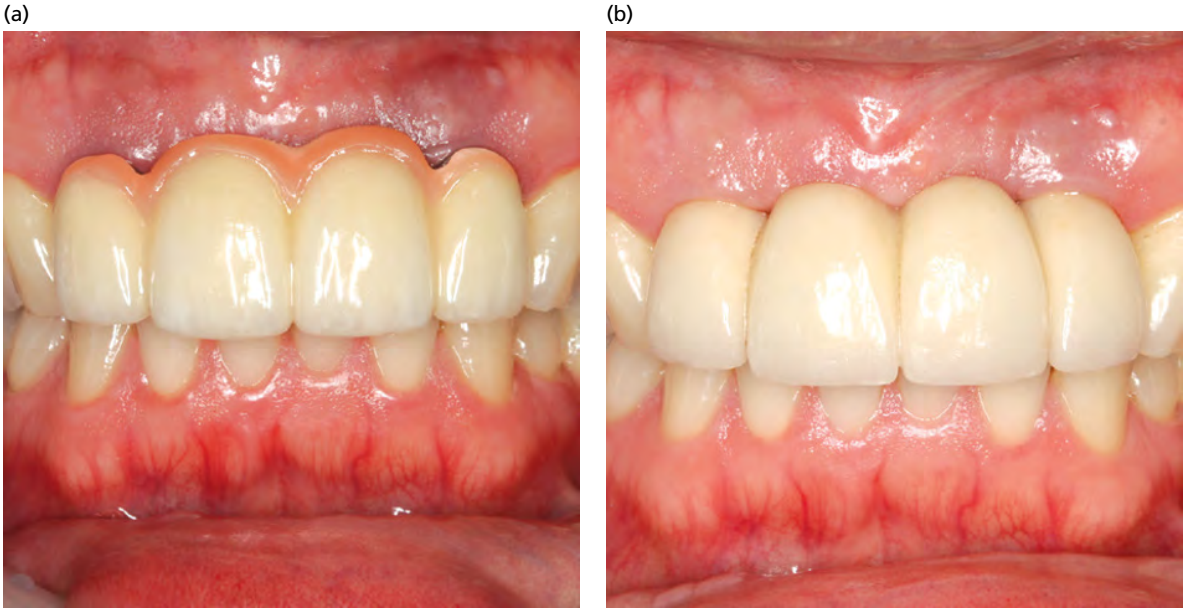

Fig 34.4 (a) Implant-supported prosthesis with inadequate access for cleanability of the implants. The labial flange of the prosthesis prevents access for biofilm removal and monitoring of the implants in position 12 and 22. (b) The implant-supported prosthesis was re-designed and remade without a labial flange to allow good access for cleanability and monitoring at the implants in position 12 and 22.

Professional mechanical debridement (supra- and submucosal calculus and biofilm removal)

Hand instrumentation

Hand instrumentation including the use of steel, titanium, carbon-fiber or plastic curettes, and/or ultrasonic instruments with a variety of tips may be used for removal of supra- and submucosal calculus and biofilm deposits (Fig. 34.7a). Instruments which cause minimal alteration to the surface of the transmucosal components of the implant/restoration should be used. Prophylaxis using a rubber cup and polishing paste may also be used for supramucosal biofilm removal (Fig. 34.7b).

Air-polishing

Air-polishing is an alternative to hand or ultrasonic instrumentation for supra- and submucosal biofilm removal at titanium implants (Tastepe *et al*. 2012). The powders used mainly consist of either amino acid glycine, sodium bicarbonate, or erythritol and are effective in biofilm removal from machined or structured titanium and zirconia implants without causing major surface changes (Schwarz *et al*. 2009b; John *et al*. 2016) (Fig. 34.8).

A systematic review, including five studies, found that glycine powder air-polishing used as either an adjunct to hand instrumentation or as a monotherapy was as effective as hand instrumentation for peri-implant mucositis treatment (Schwarz et al. 2015a).

Adjunctive measures for peri-implant mucositis treatment

Adjunctive measures including application of local antimicrobials, diode laser irradiation, photodynamic therapy, and probiotics have been investigated. However, adjunctive measures have not been found to improve the efficacy of professionally administered mechanical biofilm removal in resolving inflammation (Table 34-1).

Adjunctive local antimicrobials/antiseptics

There is conflicting evidence regarding an additional benefit of local antimicrobials/antiseptics for peri-implant mucositis treatment. In patients diagnosed with peri-implant mucositis, delivery of 0.12% chlorhexidine gluconate solution into peri-implant pockets, after mechanical debridement using plastic curettes, was compared with the submucosal delivery of placebo solution (Menezes *et al*. 2016). In addition, the patients were prescribed a twice daily mouth rinse with a chlorhexidine or placebo solution for 2 weeks (Menezes *et al*. 2016). At the 6-month follow-up, no statistically significant difference in the number

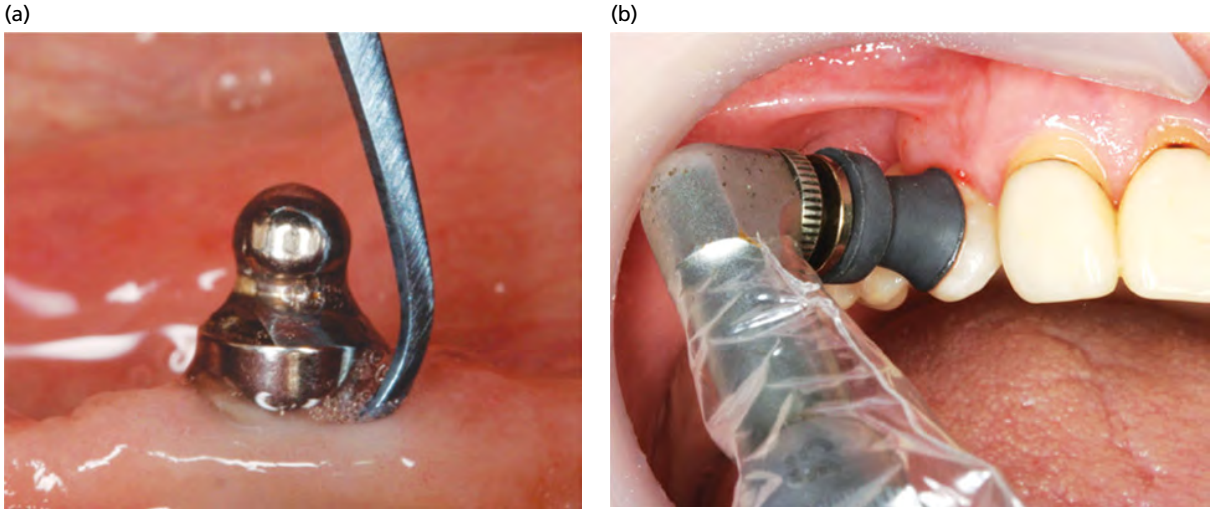

Fig. 34.7 (a) A titanium curette used to remove supra-and submucosal biofilm at an implant overdenture abutment. (b) Prophylaxis using a rubber cup and polishing paste for biofilm removal in the non-surgical treatment of peri-implant mucositis.

Fig. 34.8 An air-polishing device used for supra- and submucosal biofilm removal for non-surgical treatment of peri-implant mucositis.

of BoP-positive implant sites was found between the antiseptic and placebo groups (Menezes *et al*. 2016).

Heitz-Mayfield *et al*. (2011) reported in a study treating 29 peri-implant mucositis patients that non-surgical debridement using titanium curettes and self-performed plaque control was effective in treating peri-implant mucositis and that the adjunctive application of chlorhexidine digluconate gel, applied daily using a toothbrush, did not enhance treatment outcomes. At 3 months, 38% of implants treated had complete disease resolution (absence of BoP) (Heitz-Mayfield *et al*. 2011) (Table 34-1).

In contrast, Hallström *et al*. (2017) reported an additional improvement in treatment outcomes when adjunctive 0.2% chlorhexidine-containing gel was applied daily with a toothbrush. The effects of daily application of a 0.2% chlorhexidine-containing gel as a supplement to oral hygiene instructions and mechanical debridement were investigated in a 12-week randomized control trial in patients diagnosed with peri-implant mucositis (Hallström *et al*. 2017). The daily use of the chlorhexidine-containing gel resulted in statistically significantly lower BoP scores and less residual PD of ≥4 mm after 4 and 12 weeks compared with the application of a placebo gel (Hallström *et al*. 2017).

The clinical effects of a mouth-rinse containing 0.03% chlorhexidine and 0.05% cetylpyridinium chloride as an adjunct to professionally and patient-administered mechanical plaque removal was assessed in the management of peri-implant mucositis over 12 months (Pulcini *et al*. 2019). At the 12-month follow-up, twice daily rinsing with the antiseptic solution was not more effective compared with rinsing with a placebo solution. Complete resolution of BoP-positive sites was achieved in 58% of cases following rinsing with the antiseptic solution and 50% of cases following rinsing with placebo (Pulcini *et al*. 2019).

The application of a chloramine-containing gel was investigated as an adjunct to mechanical debridement in the management of patients diagnosed with peri-implant mucositis (Iorio-Siciliano *et al*. 2020). The chloramine-containing gel was applied to the implants of the test group while the control group received a placebo gel. The gels were applied five times for 30 seconds prior to mechanical ultrasonic debridement. The 6-month outcomes of this randomized clinical trial failed to show statistically significant differences in PDs and BoP scores when comparing test and control groups. Complete elimination of sites with BoP was achieved in 45% of test and 32% of control implants at 6 months (Iorio-Siciliano *et al*. 2020) (Table 34-1).

Table 34-1 Studies reporting disease resolution (absence of bleeding on probing) following treatment of peri-implant mucositis.

Author	Treatment	Study design	*n*	Follow-up	Disease resolution (absence BoP)	Comments
Heitz-Mayfield 2011	MD +/- CHX gel	RCT	29 patients	3 months	38% implants/patients	No added benefit of CHX
Schwarz 2015c	MD + CHX	Case series	17 patients 24 implants	6 months	5 of 17 patients 53% patients	Zirconia implants
John *et al*. 2017 (same as Schwarz 2015c)	MD + CHX	Case series	14 patients	Median 34 months	7 of 14 patients 50% patients	Two-piece zirconium implants
Pulcini *et al*. 2019	MD + CHX-CET MD	RCT	24 patients 22 patients	12 months	58.3% implants 50% implants	Some advantage of CHX/CET at buccal sites only
Iorio-Siciliano *et al*. 2020	MD + chloramine MD + placebo	RCT	46 patients 68 implants	6 months	45% implants 32% implants	No significant difference between groups
Aimetti 2019	MD + diode laser MD	RCT	110 patients 110 implants	3 months	35% implants 31% implants	No advantage of diode laser

BoP, bleeding on probing; CET, cetylpyridinium chloride; CHX, chlorhexidine; MD, mechanical debridement; RCT, randomized controlled trial.

Adjunctive probiotics

It has been suggested that daily oral administration of probiotic bacteria may support the formation of bacterial biofilms compatible with peri-implant health and therefore improve clinical, microbiological, and host-derived parameters when administered as adjuncts to non-surgical mechanical therapy of peri-implant mucositis. There is conflicting evidence regarding the clinical benefit of adjunctive probiotic treatment. Flichy-Fernández *et al*. (2015) reported positive effects following prophylaxis and daily oral probiotic containing *Lactobacillus reuteri* for 30 days at implants diagnosed with peri-implant mucositis. Daily oral probiotics showed an additional PD reduction of 1.09 ± 0.90 mm compared with adjunctive delivery of placebo tablets at 6 months (Flichy-Fernández *et al*. 2015). These results, however, should be interpreted with caution due to the fact that parameters reflecting changes in mucosal inflammation (i.e. BoP) were not reported.

In another study, *L. reuteri* administered for 30 days in conjunction with full-mouth mechanical debridement showed an improvement in clinical parameters at implants diagnosed with mucositis or peri-implantitis for up to 90 days (Galofre *et al*. 2018). Delivery of *L. reuteri*, however, yielded a significant decrease in the bacterial load of *Porphyromonas gingivalis* only at implants with peri-implant mucositis (Galofre *et al*. 2018).

However, outcomes from randomised controlled trials (Hallström *et al*. 2016, Pena *et al*. 2019), failed to demonstrate beneficial effects of adjunctive probiotics in the management of peri-implant mucositis. Therefore the available evidence for use of adjunctive probiotics is limited and inconclusive.

Adjunctive laser irradiation

The adjunctive use of diode (980 nm) laser irradiation for peri-implant mucositis treatment was investigated in a randomized controlled study including 220 patients, each with one implant diagnosed with peri-implant mucositis. Three months following treatment of peri-implant mucositis disease resolution (absence of BoP) was observed at 31% of the implants treated with mechanical debridement alone and 34% of implants treated by the laser in conjunction with mechanical debridement (Aimetti *et al*. 2019) (Table 34-1). Therefore, the diode laser treatment was not shown to provide any additional benefit compared with mechanical debridement (curettes and ultrasonic devices) alone.

Adjunctive antimicrobial photodynamic therapy (aPDT)

A randomized controlled trial in 54 patients who smoked with peri-implant mucositis found that antimicrobial photodynamic therapy as an adjunct to mechanical therapy resulted in additional clinical benefits, 3 months after treatment, in terms of PD reduction compared with mechanical debridement alone (Javed *et al*. 2017). The number of sites with residual BoP, however, was similar between treatment groups indicating that adjunctive aPDT has a limited benefit.

Adjunctive systemic antimicrobials

Adjunctive systemic antimicrobials are not recommended for the treatment of peri-implant mucositis because they do not provide additional clinical benefits and there is a risk of adverse effects (Hallström *et al*. 2012).

Zirconia implants

Most studies evaluating treatment of peri-implant mucositis have included titanium implants. There is limited data available regarding treatment of peri-implant mucositis at zirconia implants. One case series including 17 patients with zirconia implants diagnosed with peri-implant mucositis which were treated with mechanical debridement and local chlorhexidine application found that nine of the 17 (52.9%) patients achieved disease resolution (absence of BoP) 6 months following treatment (Schwarz *et al*. 2015c).

Conclusion

Adjunctive measures to mechanical debridement have not been found to improve the efficacy of professionally administered mechanical biofilm removal in peri-implant mucositis treatment (Schwarz *et al*. 2015b). Glycine powder air-polishing used as a monotherapy is as effective as hand instrumentation for peri-implant mucositis treatment (Schwarz et al. 2015a). Significant clinical improvements in terms of reduction in the number of sites with BoP and a reduction in PDs can be achieved following treatment of peri-implant mucositis. However, complete resolution of inflammation is not achieved in the majority of cases (Table 34-1). Therefore, regular monitoring and regular professional mechanical biofilm removal in addition to daily self-performed plaque control is considered the standard of care and should be performed to treat peri-implant mucositis and prevent progression to peri-implantitis (Fig. 34.3a).

Non-surgical therapy of peri-implantitis

Once a diagnosis of peri-implantitis has been made, treatment should proceed without delay.

In cases of incipient bone loss, non-surgical therapy may be successful in resolving peri-implantitis. However, where there is more advanced bone loss, while clinical improvements (PD and BoP reduction)

are frequently observed, non-surgical treatment alone is usually ineffective in resolving the inflammation and arresting disease progression in the majority of cases. The limitation of non-surgical treatment of peri-implantitis is related to the difficulty in accessing the implant surface due to the topography, presence of implant threads, and anatomy of the surrounding area. Surgical management (see Chapter 35) is recommended where deep PDs and bleeding and/or suppuration remain following non-surgical treatment. Non-surgical treatment should, however, be performed as a first treatment phase and prior to surgical management in order to reduce the level of inflammation and ensure that the patient's self-performed oral hygiene is optimized prior to surgery.

Non-surgical therapy of peri-implantitis (Fig. 34.3b) involves the same treatment sequence as for the treatment of peri-implant mucositis. Following a comprehensive examination and diagnosis an assessment and reduction of modifiable risk factors/indicators such as cigarette smoking, periodontitis, and uncontrolled diabetes mellitus should precede treatment. Treatment includes an assessment of cleanability and fit of the prosthesis and modification as required, followed by oral hygiene instructions and professional mechanical debridement to remove calculus and biofilm deposits. Re-evaluation at approximately 4–6 weeks following non-surgical treatment will enable the clinician to evaluate the response to treatment. Where clinical improvements are observed (reduction in PDs of ≤5 mm and resolution of BoP), the patient should be provided with a structured supportive care program which entails regular monitoring and professional removal of biofilm. If there is persistent inflammation (BoP/suppuration) with remaining deep PDs of ≥6 mm, surgical treatment (see Chapter 35) is recommended (Fig. 34.3b).

Professional mechanical debridement

Instrumentation including the use of steel, titanium, carbon-fiber, and/or ultrasonic instruments or Er:YAG laser irradiation may be used for removal of supra- and submucosal calculus and biofilm deposits. Air polishing may be used to remove non-mineralized deposits. Care should be taken when instrumenting deep peri-implant pockets, regardless of the method chosen, due to the inability to visualize the implant topography. Adjunctive measures include the use of local antimicrobials, antimicrobial photodynamic therapy, and probiotics. Cost-effectiveness and patient preference should be considered when choosing the method for non-surgical biofilm removal.

Laser irradiation

The Er:YAG (erbium-doped: yttrium, aluminium and garnet) laser is the most commonly investigated laser for peri-implantitis treatment. Its emission wavelength (2940 nm) is highly absorbed by water, allowing effective removal of non-mineralized and mineralized biofilms without damaging the implant surface or causing major thermal side effects to the adjacent tissues (Aoki *et al*. 2004) (Fig. 34.9).

The histological characteristics of wound healing following Er:YAG laser application for the non-surgical treatment of peri-implantitis have been evaluated in both experimental animal and clinical studies (Schwarz *et al*. 2009a). Non-surgical therapy using either Er:YAG laser, an ultrasonic device, or plastic curettes and local application of metronidazole gel was evaluated in an experimental animal study. After 3 months of healing, biopsies showed similar inflammatory cell infiltrates in all treatment groups with minimal re-osseointegration (new bone-to-implant contact) following non-surgical treatment (Schwarz *et al*. 2006c).

The observation that a single course of non-surgical instrumentation using an Er:YAG laser may not be effective in obtaining complete disease resolution was confirmed in a clinical study including a total of 12 patients each with one implant diagnosed with peri-implantitis (Schwarz *et al*. 2006b). Examination of tissue biopsies obtained following non-surgical treatment during subsequent open flap surgery at implant sites revealed a mixed chronic inflammatory cell infiltrate (macrophages, lymphocytes, and plasma cells) which was encapsulated by irregular bundles of fibrous connective tissue showing an increased proliferation of vascular structures (Schwarz *et al*. 2006b).

These results confirmed the findings of controlled clinical studies (Schwarz *et al*. 2005, 2006a) which compared Er:YAG laser monotherapy with mechanical debridement (plastic curettes + chlorhexidine digluconate irrigation) for the non-surgical treatment of moderate and advanced peri-implantitis lesions. After 3 and 6 months of healing, Er:YAG laser treatment revealed a significantly greater mean BoP reduction than the mechanical debridement using plastic curettes. However, at 12 months both treatment groups had a slight increase in BoP which was most pronounced at initially deep sites (PD >7 mm) (Schwarz *et al*. 2006a).

In conclusion, Er:YAG laser irradiation has not been shown to provide additional benefits in terms of disease resolution compared with mechanical debridement alone.

Air-polishing

Air-polishing using glycine powder, for removal of supra- and submucosal biofilm at implants diagnosed with peri-implantitis (Fig. 34.10), has been shown in a meta-analysis to provide a greater improvement in reduction of BoP (weighted mean BoP reduction of −23.83%; 95% CI [−47.47, −0.20]) compared with either mechanical debridement with or without local antiseptic therapy or to Er:YAG laser treatment (Schwarz *et al*. 2015a).

However, as complete disease resolution is infrequently obtained after therapy, a strict follow-up is

essential to determine the need for additional treatment (Schwarz *et al*. 2016).

Adjunctive antimicrobial photodynamic therapy (aPDT)

Adjunctive antimicrobial PDT in conjunction with mechanical debridement may represent an alternative treatment for peri-implantitis as clinical and microbiological improvements have been reported following treatment. In cases of incipient peri-implantitis (defined as PD of 4–6 mm with BoP and ≤2 mm bone loss), non-surgical mechanical debridement (titanium curettes and air-polishing with glycine powder) with adjunctive use of PDT resulted in similar clinical, microbiological, and host-derived outcomes as with the adjunctive use of minocycline microspheres (Schär *et al*. 2013; Bassetti *et al*. 2014). Complete elimination of sites with BoP was achieved in 31.6% of patients with adjunctive aPDT application at the 12-month follow-up (Table 34-2).

Although the application of aPDT has been investigated as an additional approach for decontamination of implants affected by peri-implantitis, a recent summary of available evidence reported

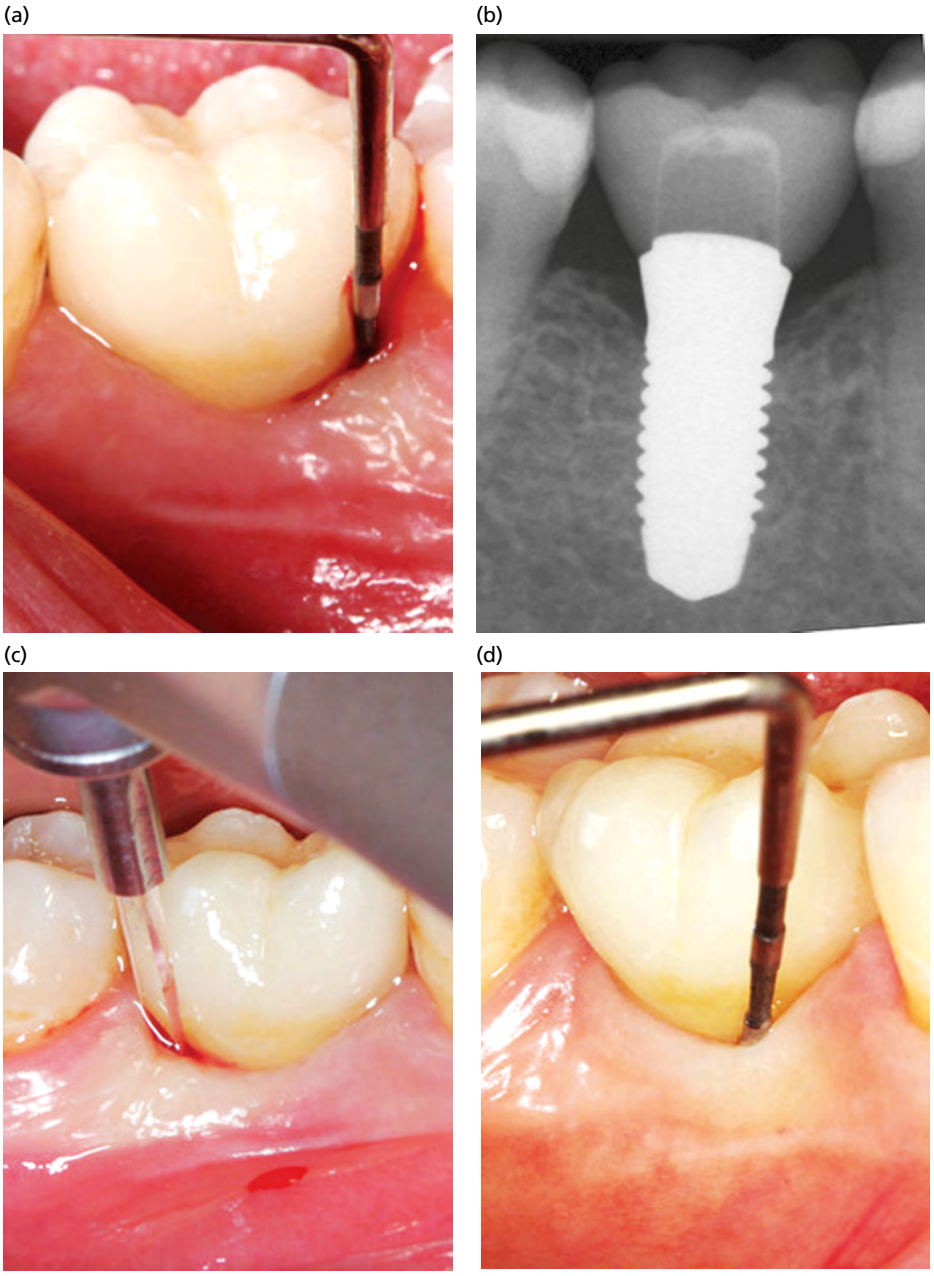

Fig. 34.9 Non-surgical treatment of incipient peri-implantitis at a zirconia implant using an Er:YAG laser. (a) Clinical signs (bleeding on probing and increased probing depth) of incipient peri-implantitis at a zirconia implant. (b) Radiographic appearance of a zirconia implant with incipient bone loss at the mesial and distal aspects. inconclusive results on its application as an adjunct to mechanical debridement alone (Chambrone *et al*. 2018).

Adjunctive local antimicrobials

Improvements in clinical and microbiological parameters have been reported following non-surgical mechanical debridement and adjunctive delivery of chlorhexidine (Machtei *et al*. 2012) and local non-resorbable and resorbable antimicrobials (Buchter *et al*. 2004; Renvert *et al*. 2004, 2006, 2008; Persson *et al*. 2006; Salvi *et al*. 2007) for treatment of peri-implantitis.

Repeated placement of chlorhexidine chips as an adjunct to non-surgical mechanical debridement was investigated in patients diagnosed with peri-implantitis, defined as a PD of 6–10 mm combined with bone loss ≥2 mm (Machtei *et al*. 2012). This randomized clinical study included seven applications of chlorhexidine chips and results indicated significant improvements in clinical parameters at 6 months (Machtei *et al*. 2012). However, absence of BoP was achieved in only 57.5% of implant sites treated with repeated chlorhexidine chip application (Machtei *et al*. 2012) (Table 34-2).

Mechanical implant surface debridement in conjunction with the placement of non-resorbable tetracycline-impregnated fibers yielded statistically significant clinical changes with respect to the reduction in mean PD from 6.0 to 4.1 mm and BoP scores after 12 months (Mombelli *et al*. 2001). The resorbable tetracycline-impregnated fibers are no longer commercially available.

The clinical and microbiological effects of locally delivered minocycline microspheres as an adjunct to non-surgical mechanical debridement using carbon fiber currettes was investigated in a case series of peri-implantitis lesions (Persson *et al*. 2006; Salvi *et al*. 2007) (Fig. 34.11). Significant reductions in levels of *Tanerella forsythia*, *Porphyromonas gingivalis*, and *Treponema denticola* were observed up to 6 months (Persson *et al*. 2006). Although the results indicated significant reductions in the percentage of sites with BoP and in pocket PD over 12 months, disease resolution was not achieved in all cases and the need for additional surgical intervention could not be excluded (Salvi *et al*. 2007).

In a comparative study, the clinical adjunctive effects of repeated local delivery of minocycline microspheres was compared with that of chlorhexidine gel application in patients with peri-implantitis (Renvert *et al*. 2008). Adjunctive minocycline microsphere delivery resulted in a statistically greater reduction in PDs and number of sites with BoP compared with that of chlorhexidine gel application (Renvert *et al*. 2008).

The adjunctive clinical benefits of a chloramine-containing solution to mechanical debridement alone was also tested in a randomized clinical trial with a split-mouth design in 16 patients diagnosed with peri-implantitis (Roos-Jansaker *et al*. 2017). At the 3-month follow-up, significant reductions in BoP-positive sites and PDs were observed in both groups when compared with baseline. No statistically significant differences, however, were observed between groups indicating that non-surgical mechanical debridement alone was equally effective in the reduction of mucosal inflammation and other clinical parameters compared with non-surgical mechanical debridement with adjunctive application of chloramine (Roos-Jansaker *et al*. 2017).

Adjunctive systemic antimicrobials

A randomized placebo-controlled study did not find any clinical advantage of adjunctive systemic antimicrobials for non-surgical treatment of advanced peri-implantitis (Shibli *et al*. 2019), with only half of the patients achieving a successful treatment outcome (PD of <5 mm, no BoP, no further bone loss). Therefore, the adjunctive use of systemic

antimicrobials is not supported for non-surgical treatment of peri-implantitis.

Zirconia implants

There is limited data available regarding treatment of peri-implantitis at zirconia implants. In a case series, 17 patients diagnosed with peri-implantitis received treatment with Er:YAG laser monotherapy followed by supramucosal plaque removal and local pocket irrigation with chlorhexidine. At 6 months disease resolution (absence of BoP and absence of PD of ≥6 mm) was obtained in the five of 17 (29.4%) patients (Schwarz *et al*. 2015c). At 3 years, resolution of peri-implant mucositis was obtained in seven of 14 (50.0%) patients and resolution of peri-implantitis in five of 13 (38.5%) patients investigated (Fig. 34.9). Based on this limited data, it can be concluded that non-surgical treatment at zirconia implants may result in clinical improvements; however, complete disease resolution is not achieved in all cases (John *et al*. 2017).

Conclusion

Treatment of peri-implantitis requires an anti-infective approach which includes professional non-surgical mechanical removal of supra-and submucosal peri-implant biofilm and regular self-performed biofilm control. The goal of treatment is to resolve inflammation and prevent disease progression. Clinical improvements such as a reduction in the number of sites with BoP and a reduction in PDs can frequently be achieved following non-surgical treatment of peri-implantitis. However, complete resolution of inflammation is not achieved in the majority of peri-implantitis cases. Various techniques for professional mechanical debridement are available. Glycine powder air-polishing has been demonstrated to provide some advantage in BoP reduction compared with either mechanical debridement with or without local antiseptic therapy or to Er:YAG laser treatment (Schwarz *et al*. 2015b). Adjunctive measures may be used; however, no significant clinical benefit over mechanical debridement alone has been shown.

Regular monitoring of peri-implant tissues and detection of incipient peri-implantitis is essential as non-surgical therapy may be successful in treating peri-implantitis in its early stages. In more advanced stages of peri-implantitis non-surgical management is often unsuccessful in the resolution of inflammation and surgical intervention is frequently required.

Chapter 35

Surgical Treatment of Peri-Implantitis

Tord Berglundh[1], Jan Derks[1], Niklaus P. Lang[2], and Jan Lindhe[1]

[1]Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden
[2]Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland

Introduction and goals of surgical therapy

Peri-implantitis is characterized by inflammation in the peri-implant mucosa and loss of peri-implant bone (see Chapter 20). If left untreated, the disease may progress with further marginal bone loss and, in the end, result in implant loss. It is therefore imperative that the tissues around implants be monitored at regular intervals to identify biological complications and to treat disease at an early stage. The overall goal of treatment of peri-implantitis is to resolve inflammation in the peri-implant mucosa and to preserve supporting hard and soft tissues. The parameters to be considered in the evaluation of outcomes of treatment are reduction of bleeding on probing (BoP), reduction of probing depth (PD), and preservation or gain of crestal bone assessed in radiographs.

Peri-implantitis is typically associated with osseous defects involving the full circumference of the implant. Depending on the width of the ridge, buccal and lingual bone walls may remain, resulting in a crater-like defect. Conversely, in sites with a narrow ridge, buccal and lingual bone walls will be lost during progression of peri-implantitis. Thus, sites with peri-implantitis often present with open ("one-wall"), angular bone defects on the mesial and the distal aspects of the implant (Fig. 35-1).

In line with treatment concepts of periodontitis, a step-by-step strategy should be applied in the treatment of peri-implantitis. While non-surgical treatment procedures should be considered as an initial step in the management of the disease, data indicate that such methods may be ineffective in resolving moderate and severe forms of peri-implantitis (for details see Chapter 34). Thus, if clinical signs of pathology persist in peri-implant tissues following initial therapy, that is, BoP and/or suppuration in combination with deep pocketing, surgical therapy is required. The specific goal of surgical treatment of peri-implantitis is to obtain access to the implant surface for debridement and decontamination in order to achieve resolution of the inflammatory lesion (Lindhe & Meyle 2008). A prerequisite for surgical treatment of peri-implantitis, however, is an appropriate level of self-performed infection control.

Surgical therapy of an implant site presenting with peri-implantitis is shown in Figs. 35-2 and 35-3. Clinical signs of inflammation, PD of 7 mm in combination with BoP were detected at the initial examination (Fig. 35-2). The radiograph revealed the presence of angular bone defects. Flap elevation allowed access to the area and inflamed tissues were removed

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

from the defects (Fig. 35-3). Mechanical debridement of the implant surface was performed using a rotating titanium brush and small pieces of gauze soaked in saline. Flaps were replaced and sutured in their original position (access flap). A supportive therapy

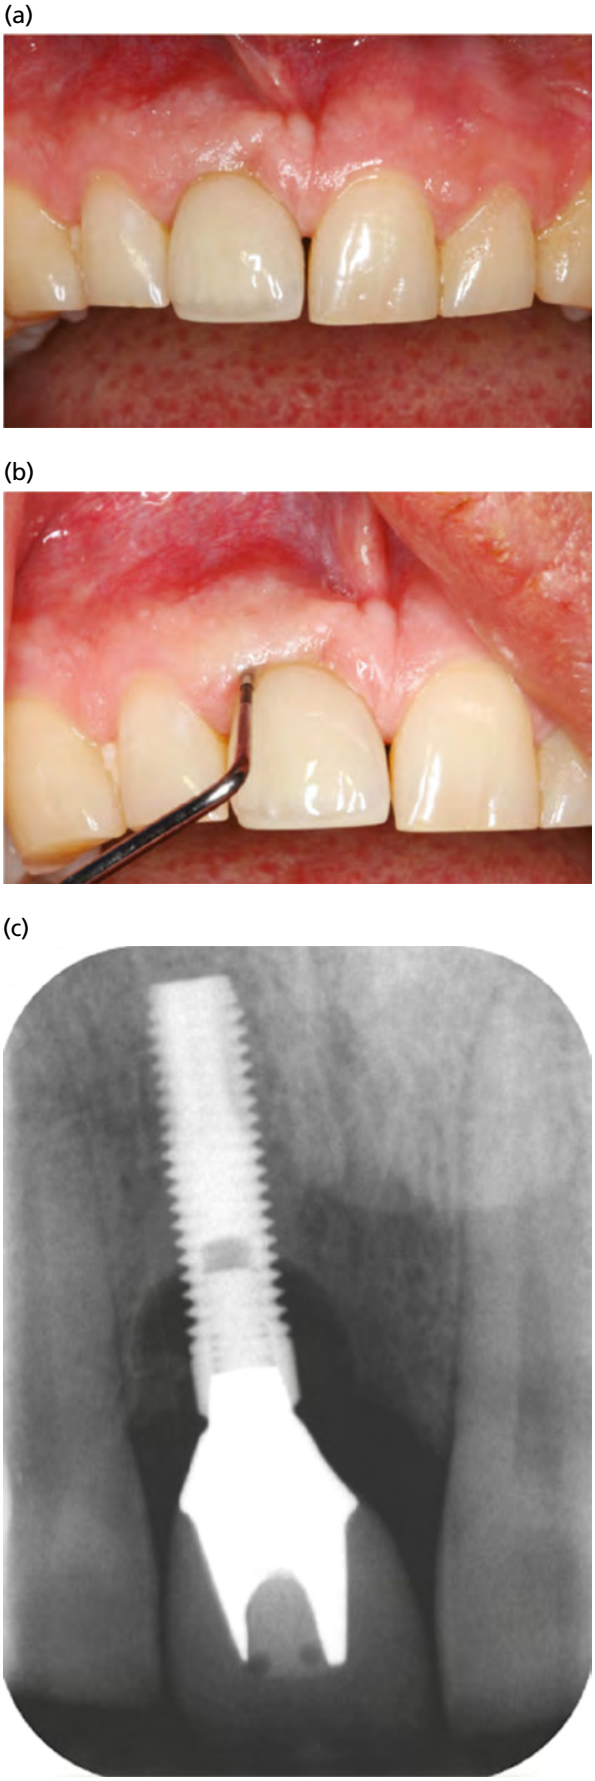

Fig. 35-2 Clinical photographs (a, b) and radiograph (c) from an implant site presenting with peri-implantitis. (b) Note the probing depth of 7 mm and the angular bone defects (c).

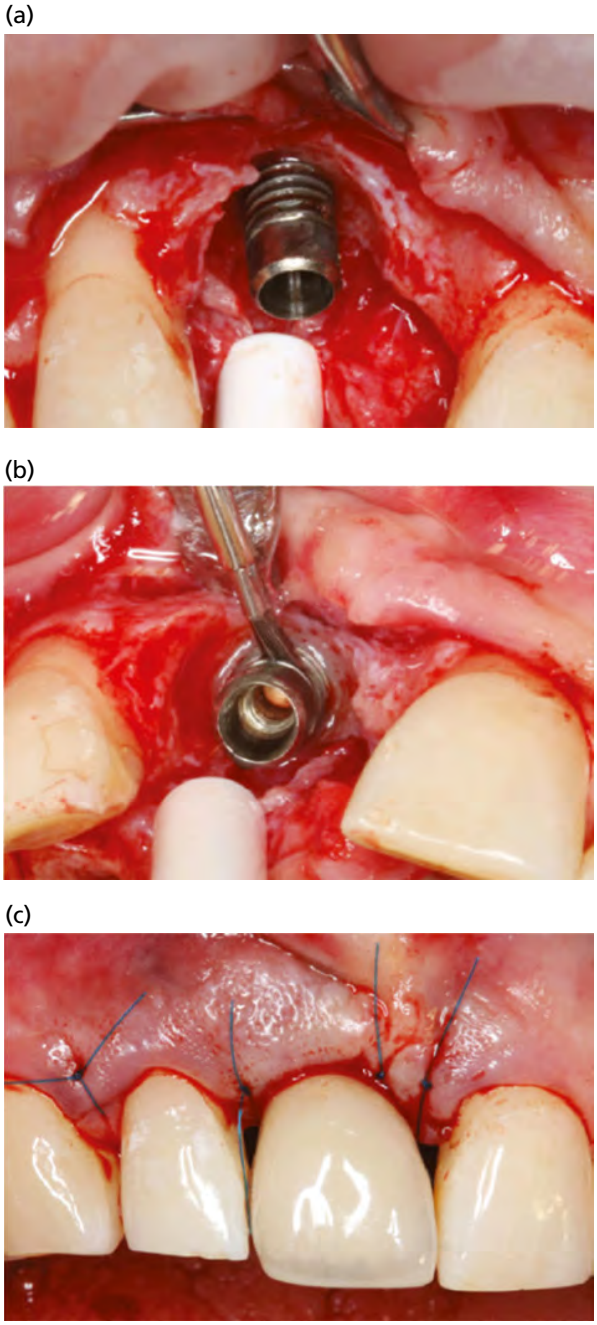

Fig. 35-3 (a) Implant site shown in Fig. 35-2 after flap elevation and removal of inflamed tissues. Note the absence of the buccal bone wall. (b) Decontamination of the implant surface was performed using a rotating titanium brush under saline irrigation. (c) Flaps were replaced and sutured.

program with supervised infection control was subsequently provided.

At the 12-month follow-up after surgery, PD was reduced and clinical signs of inflammation were absent (Fig. 35-4).

Implant surface decontamination

One of the greatest challenges in the treatment of peri-implantitis is implant surface decontamination. As illustrated in the scanning electron micrographs in Fig. 35-5, the target surface of an implant affected by peri-implantitis exhibits a complex biofilm with microorganisms residing in compartments resulting from different implant surface modifications. Although the removal of the biofilm is a prerequisite for achieving the goal of resolution of the peri-implantitis lesion, complete elimination of biofilm appears to be difficult. Results from preclinical and clinical studies, however, have demonstrated that resolution of peri-implantitis lesions can indeed occur following implant surface decontamination using a mechanical approach.

Evidence of complete resolution of peri-implantitis lesions following mechanical debridement was presented in a preclinical study by Albouy *et al*. (2011). Experimental peri-implantitis around different types of implants was produced according to techniques previously described (Lindhe *et al*. 1992) (see Chapter 20). The surgical therapy was carried out without adjunctive use of systemic antibiotics or local antimicrobial agents. The histologic examination of biopsies obtained at 6 months after surgery revealed complete resolution of the lesions at most implant sites. In another preclinical evaluation, Almohandes *et al*. (2019) used the same decontamination protocol in the treatment of experimentally induced peri-implantitis and, after healing, consistently observed re-osseointegration at previously contaminated surfaces (Fig. 35-6).

The feasibility of treatment of peri-implantitis through surgical decontamination of implant surfaces using gauzes soaked in saline has been evaluated clinically. At a 12-month examination following surgical therapy of peri-implantitis in 24 patients, Heitz-Mayfield *et al*. (2012) reported that a significant reduction of PD, BoP, and suppuration had occurred. While 47% of the implant sites exhibited complete resolution of disease, 92% of the sites showed stable crestal bone levels or bone gain. In a retrospective evaluation, 2–11 years following surgical therapy of peri-implantitis, Berglundh *et al*. (2018) found that 71% of all implant sites displayed stable bone levels and that clinical signs of inflammation were reduced. The adjunctive use of a local antiseptic to the surgical decontamination protocol has been evaluated in controlled studies but not been found beneficial. Thus, in a study including 100 subjects, Carcuac *et al*. (2016) found that the local administration of the antiseptic agent (0.2% solution of chlorhexidine digluconate) did not improve 1-year outcomes when compared with the use of saline alone. De Waal *et al*. (2015) compared two different concentrations of chlorhexidine solutions (0.12% versus 2%) as part of the surgical treatment of peri-implantitis in 44 subjects. While 1-year outcomes were in line with other reports in terms of PD reductions and absence of additional bone loss, no relevant differences between study groups were observed. Taken together, there is currently a lack of evidence suggesting the benefit of the adjunctive use of antiseptic or antimicrobial agents in the surgical decontamination of implant surfaces.

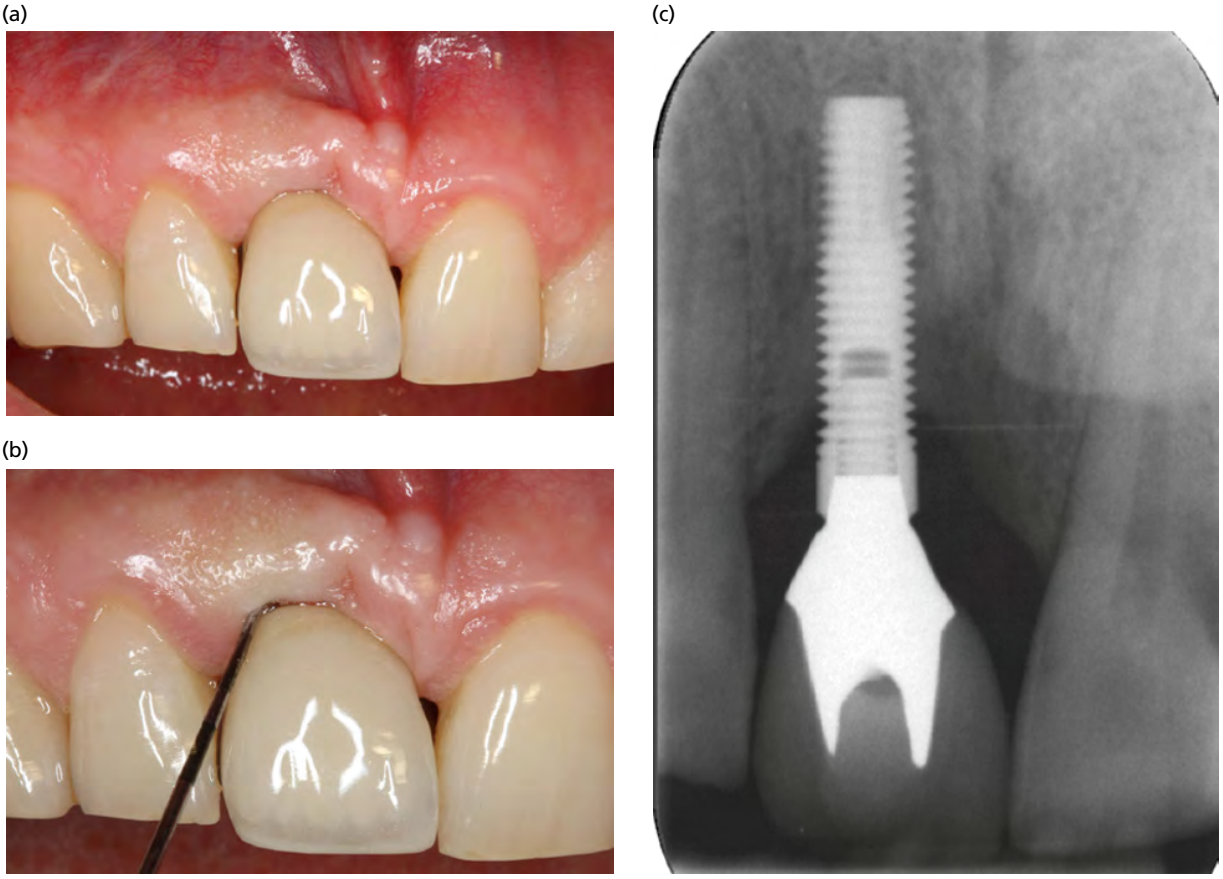

Fig. 35-4 Implant site shown in Figs. 35-2 and 35-3 at 12 months after surgical therapy. (a, b) Note the reduced probing depth and absence of clinical signs of inflammation. (c) The radiograph indicates some fill of the bone defects relative to baseline.

Data from preclinical and clinical evaluations of other methods of decontamination, including air abrasive devices and lasers are limited. The effect of rotating or oscillating titanium brushes on implant surfaces and on postsurgical outcomes has been assessed in *in vitro;* and in clinical studies. Thus, Cha *et al*. (2019) observed that, while instrumentation with an ultrasonic metal instrument resulted in pronounced alterations of the micro- and macrostructure of the implant surface, rotating titanium brushes were able to access all parts of the threaded area without causing major structural damage. Clinical efficacy of the concept was evaluated by Tapia *et al*. (2019), who supplemented surgical decontamination with an oscillating titanium brush in a test group including 15 subjects. Clinical and radiographic outcomes at 12 months were superior to findings from the control group, in which decontamination was performed by the use of a plastic ultrasonic scaler, only. In contrast, there is a lack of data, preclinical or clinical, demonstrating benefits of the use of air abrasives or lasers for surface decontamination during surgical treatment of peri-implantitis.

Aggressive mechanical techniques, often referred to as "implantoplasty", have been suggested to achieve implant surface decontamination. Such procedures have included grinding of the implant surface and removal of threads from the titanium cylinder together with polishing of rough implant surfaces. Results from one study with a 3-year follow-up after surgical therapy indicated some benefit when using such "implant-resective techniques" on titanium plasma-sprayed (TPS) surface implants (Romeo *et al*. 2007). In this context, however, the risks involved in implant grinding procedures – potential damage to the peri-implant bone caused by overheating as well as spreading of metal particles – must be considered.

The outcome of decontamination procedures during surgical treatment of peri-implantitis is influenced by implant surface characteristics. Thus, data presented in preclinical studies by Albouy *et al*. (2011), Carcuac *et al*. (2015), and Almohandes *et al*. (2019) revealed that the resolution of experimental peri-implantitis lesions was influenced by implant surface characteristics, consistently favoring turned or less complex surfaces. Results presented in clinical studies support the concept that the response to treatment is influenced by implant surface-specific features. Roccuzzo *et al*. (2017), in a study including 24 patients with peri-implantitis around implants with either a rough TPS or moderately rough surface (sandblasted large-grit acid-etched [SLA]), reported that reduction of PD and BoP was more pronounced at implants with the SLA surface than those with the TPS surface. Implants with TPS surfaces also demonstrated significantly higher frequencies of disease recurrence during the 7-year follow-up period after

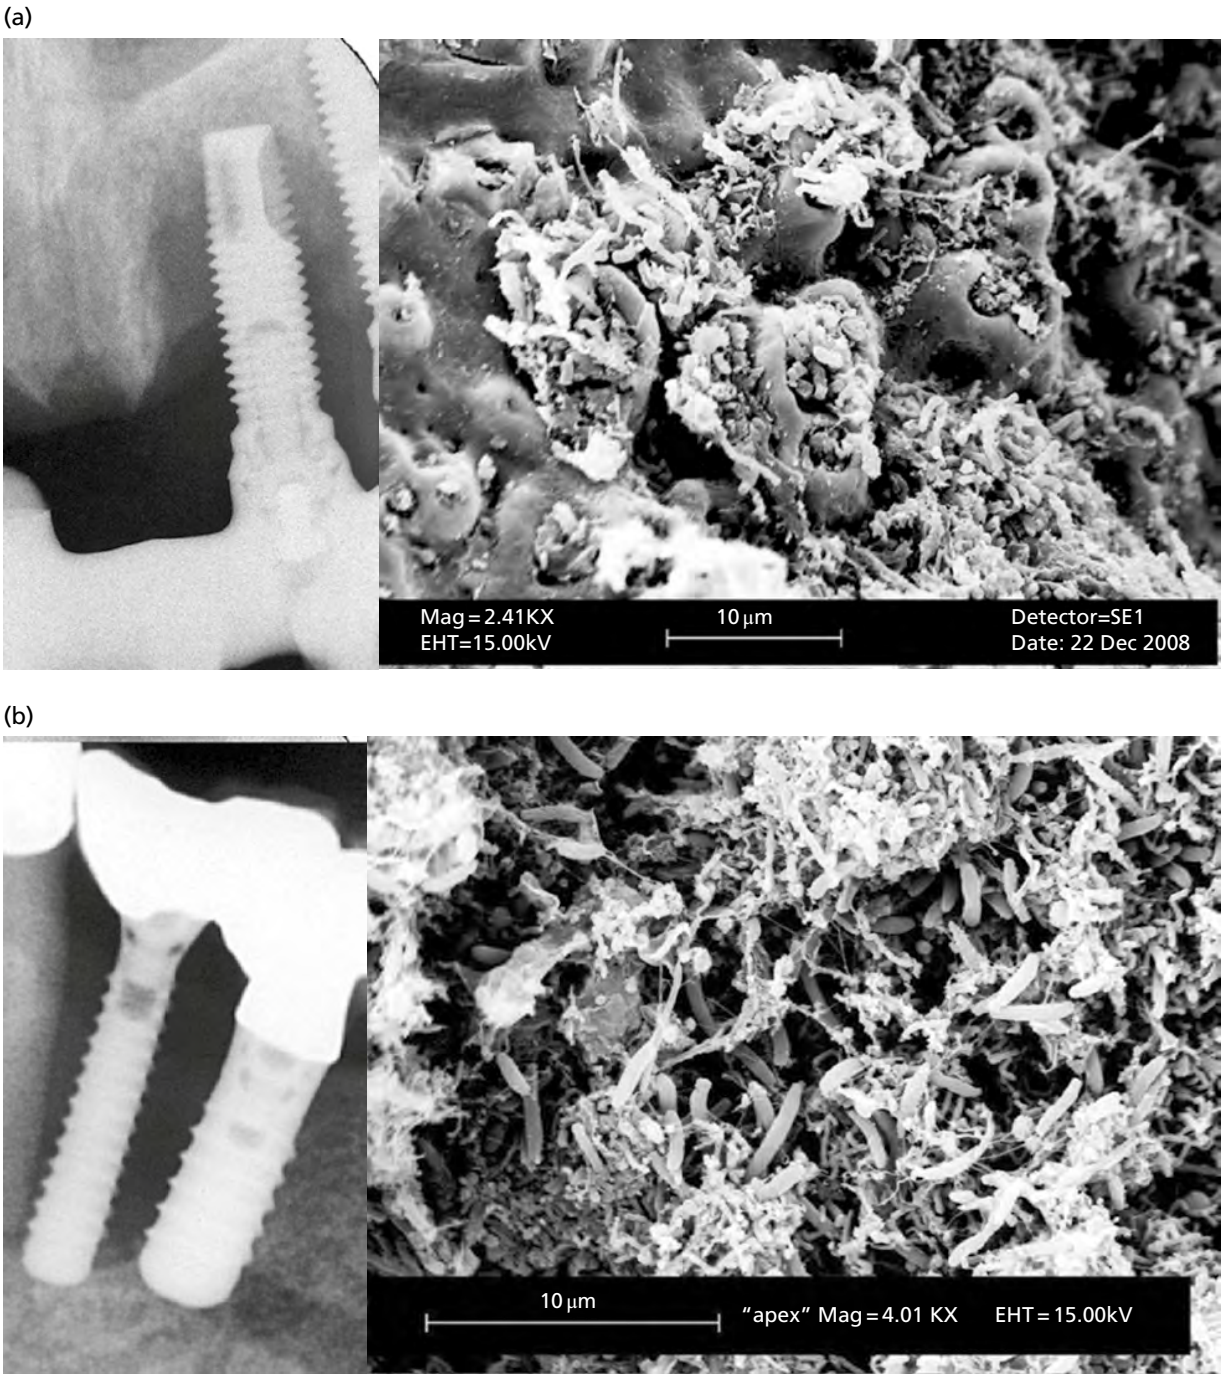

Fig. 35-5 The two implants affected by advanced peri-implantitis (a, b) were surgically removed. The high magnification of the scanning electron micrographs of the explanted implants reveals microorganisms of various morphotypes occupying compartments of the modified implant surfaces.

surgical treatment. Carcuac *et al*. (2017) evaluated 83 patients 3 years after surgical therapy of advanced peri-implantitis. Absence of additional bone loss following treatment was observed in 82% of implants with turned surfaces and in 49% of the implants with modified surface characteristics.

Taken together, there is ample evidence that resolution of peri-implantitis following anti-infective therapy is feasible and that implant surface characteristics have a profound impact on short- and long-term outcomes of surgical treatment of peri-implantitis.

Pocket elimination/reduction procedures

In addition to the decontamination procedures in conjunction with surgical treatment of peri-implantitis, the configuration of the bony defect that surrounds the implant has to be addressed. Similar to the planning of treatment of angular bone defects at periodontally involved sites, the surgical protocol for the treatment of peri-implantitis comprises pocket elimination/reduction or reconstructive procedures.

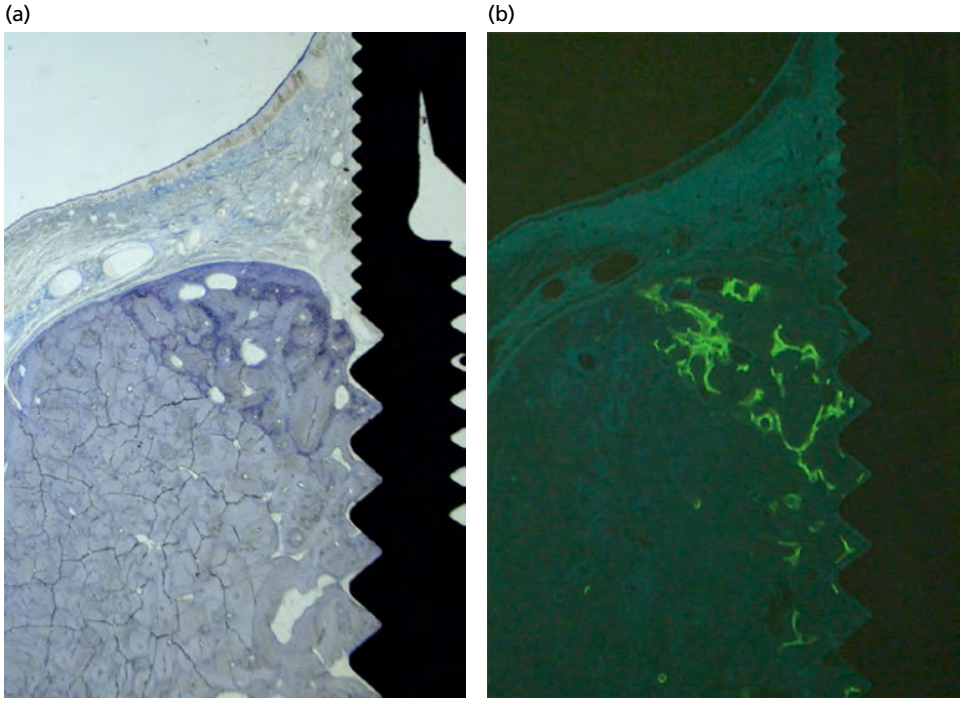

Fig. 35-6 (a) Histological ground section prepared from an implant site following 6 months of healing after treatment of peri-implantitis. Note the newly formed bone and high degree of re-osseointegration to the previously contaminated implant surface. (b) Micrograph including a fluorochrome marker indicating the original bone defect and newly formed bone following treatment.

Preclinical data

Surgical treatment of peri-implantitis including pocket elimination/reduction procedures has been evaluated in numerous preclinical studies. Persson *et al*. (1999) induced experimental peri-implantitis in dogs according to the model described by Lindhe *et al*. (1992). The subsequent treatment included (1) systemic administration of antibiotics, (2) elevation of full thickness flaps at the experimental sites and curettage of the hard tissue defect, (3) mechanical debridement of the exposed portion of the implants, and (4) flap management and closure of the soft tissue wound. Radiographs and biopsies were obtained after 7 months of submerged healing. The analysis of the radiographs indicated a complete bone fill in the hard tissue defects (Fig. 35-7). Histologic analysis of the biopsy sections revealed that treatment had resulted in a complete resolution of the soft tissue inflammation and the formation of substantial amounts of new bone in the previous hard tissue defects (Fig. 35-8).

Applying the same experimental model as Persson *et al*. (1999) did earlier, subsequent studies demonstrated that resolution of peri-implantitis was also possible without the use of systemic antimicrobial therapy. Thus, Albouy *et al*. (2011) and Carcuac *et al*. (2015) reported that radiographic bone fill and resolution of the soft tissue inflammation occurred and that outcomes of treatment were influenced by implant surface characteristics. This observation is in line with findings presented by Almohandes *et al*. (2019), using the same experimental set-up as described above. While pronounced radiographic defect fill and re-osseointegration at previously contaminated surfaces were observed overall (Fig. 35-6), outcomes

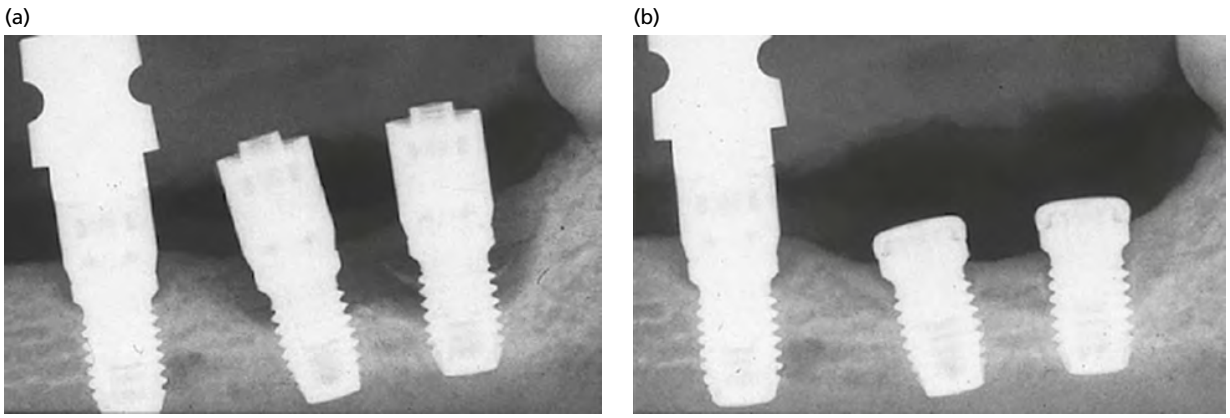

Fig. 35-7 Radiographs obtained from two sites exposed to experimental peri-implantitis. (a) Sites at 7 months of submerged healing after treatment of peri-implantitis. (b) Note the bone fill in the previous osseous defects.

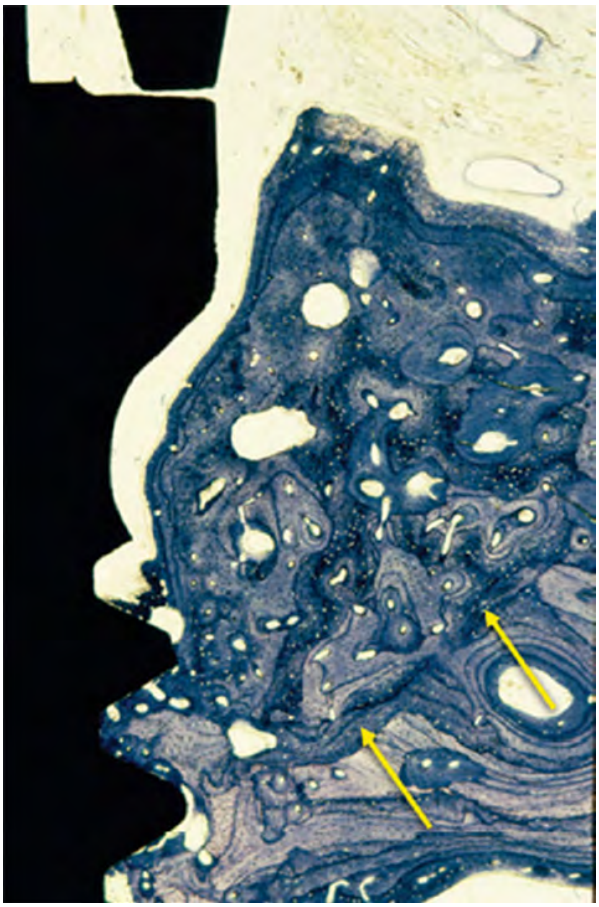

Fig. 35-8 Ground section following 7 months of submerged healing after treatment of peri-implantitis. Note the newly formed bone in the hard tissue defects (arrows).

were better at implants with smooth surfaces than implants with moderately rough surfaces.

Clinical data

Clinical studies evaluating surgical therapy of peri-implantitis applying a pocket elimination/reduction technique are illustrated in Table 35-1. The studies reported a pronounced reduction of PD and clinical signs of inflammation (BoP) and preservation of crestal bone levels at follow-up examinations ranging from 1 year to 5 years post-treatment.

In a retrospective analysis of 50 subjects treated for advanced peri-implantitis, Berglundh *et al*. (2018) observed a mean reduction of PD of 2.6 mm after an observation period of 2–11 years. A mean additional bone loss of 0.1 mm was noted. In line with preclinical data discussed earlier, outcomes were strongly influenced by implant surface characteristics. Thus, at implants with turned surfaces, mean reduction of PD amounted to 2.9 mm and a mean bone gain of 0.1 mm was recorded. These findings are in agreement with data presented in a prospective 5-year study by Heitz-Mayfield *et al*. (2018). It was reported that the reduction of PD and BoP was on average 2.8 mm and 42%, respectively. An additional and clinically relevant observation in the study by Heitz-Mayfield *et al*. (2018) was the substantial soft tissue recession of 1.8 mm that had occurred at the buccal aspect of the treated implants. A case illustrating soft tissue recession after surgical treatment of peri-implantitis is presented in Fig. 35-9.

Table 35-1 Clinical studies evaluating surgical therapy of peri-implantitis: pocket elimination/reduction procedures.

Study	Sample and follow-up	Inclusion criteria	Surgical procedures	Outcomes	Comments
Serino & Turri (2011) Sweden, case series	29 patients, 2 years	BoP + PD ≥6 mm Marginal bone loss ≥2 mm	Pocket elimination	Implant loss: 7 out of 86 implants Implants *in situ*: PD ≥6 mm & BoP+: 14 out of 79 implants	Systemic antibiotics prescribed. REC and PROMs not reported
De Waal *et al*. (2015), Netherlands, RCT	44 patients, 1 year	BoP + PD ≥5 mm Marginal bone loss ≥2 mm	Pocket elimination Decontamination with 0.12% chlorhexidine solution (+ 0.05% cetylpyridinium chloride)	MBL: 0.0 mm PD: -2.1 mm BoP: -28%	No systemic antibiotics prescribed. REC and PROMs not reported.
			Pocket elimination Decontamination with 2% chlorhexidine solution	MBL: 0.3 mm PD: -1.7 mm BoP: -21%	
Carcuac et al. (2017), Sweden, RCT.	83 patients, 3 years	BoP + PD ≥6 mm Marginal bone loss >3 mm	Pocket elimination	Absence of additional bone loss >0.5 mm: 44% Implants *in situ*: MBL: 0.5 mm PD: -2.4 mm BoP: -47%	REC and PROMs not reported.
			Pocket elimination and systemic antibiotics	Absence of additional bone loss >0.5 mm: 68% Implants *in situ*: MBL: -0.3 mm PD: -3.0 mm BoP: -34%

Fig. 35-9 (a, b) Implant demonstrating deep probing depth (9 mm), clinical signs of inflammation, and a reduced bone level. (c, d) Surgical access and decontamination of the implant surface followed by flap closure. (e) After 12 months of healing the peri-implant tissues display no signs of inflammation and shallow probing depth (3 mm). Note the soft tissue recession on the buccal aspect of the implant. (f) The 12-month radiograph indicates stable marginal bone levels relative to baseline.

The majority of studies in Table 35-1 described treatment protocols that included the administration of systemic antibiotics. Carcuac *et al*. (2017) reported 3-year outcomes of a randomized controlled trial evaluating the effect of a 10-day regimen of amoxicillin in conjunction with surgery. Out of the initially enrolled 100 subjects, 83 were available for the final assessment. Overall, the authors observed a reduction of PD and BoP as well as unchanged marginal bone levels following surgery. Outcomes were, however, significantly better at implants with turned surfaces than those with modified surfaces. In addition, a short-term benefit, which was limited to the first year of follow-up, of the adjunctive use of systemic antibiotics was observed for cases with modified surface implants, whereas no such benefit was seen in cases with turned surface implants. Thus, decisions on using systemic antibiotics as an adjunct to surgical therapy of peri-implantitis should be based on a careful analysis of the surface characteristics of the target implants and the fact that potential benefits are not sustained over time. The impact of implant surface characteristics on long-term outcomes following surgical treatment of peri-implantitis were further highlighted by the 5-year follow-up data presented by Carcuac *et al*. (2020). It was observed that, while the risk for recurrence of disease following the first year after treatment was 17% for implants with non-modified (turned) surfaces, the corresponding proportion for implants with modified surfaces was 52%.

Reconstructive procedures

The main goal of treatment of peri-implantitis is to resolve soft tissue inflammation and to prevent further crestal bone loss. An additional goal when using a reconstructive approach in surgical therapy is to restore the tissue damage that was caused by the disease. Whereas the management of peri-implant bone defects is considered a main component of reconstructive procedures, a clinical focus may also include the preservation of the soft tissue dimensions around the target implant following treatment. Thus, reconstructive procedures aiming at minimizing mucosal recession and promoting fill of the osseous defect may therefore be of particular relevance in sites located in the esthetic zone.

Another desirable outcome of reconstructive therapy of peri-implantitis is re-osseointegration. The finding in radiographs of bone fill of the osseous defect around the implant following surgical therapy, however, should not be taken to indicate that re-osseointegration has occurred. The term re-osseointegration can be defined as the establishment of *de novo* bone formation and *de novo* osseointegration to a portion of an implant that during the development of peri-implantitis suffered loss of bone–implant contact and became exposed to microbial colonization. Assessments of re-osseointegration require histological analysis (Fig. 35-6). In the clinical setting, a vast number of procedures have been proposed to promote bone fill of peri-implantitis-related bone defects. It is currently not known, however, if the use of bone grafts/substitutes or barrier membranes improves treatment outcomes following surgical therapy of peri-implantitis (Tomasi *et al*. 2019).

Preclinical data

Assessment of bone–implant contact requires histologic examination, which calls for the use of preclinical research models. As described in Chapter 20, experimental peri-implantitis can predictably be produced using well-established techniques (Lindhe *et al*. 1992) and different reconstructive treatment protocols can be applied accordingly. Re-osseointegration has been evaluated in a number of preclinical studies (e.g. Wetzel *et al*. 1999; Persson *et al*. 2001, 2004; Namgoong *et al*. 2015) and was found to be dependent on implant surface characteristics. Almohandes *et al*. (2019) in a study on treatment of experimentally induced peri-implantitis observed that radiographic bone fill occurred in the osseous defects surrounding the implants. In addition, histological evaluations performed 6 months after reconstructive surgery revealed evidence of re-osseointegration. The frequency of sites demonstrating re-osseointegration, however, varied depending on implant surface modification. Thus, 96% (23 out of 24) of the implants with a smooth surface exhibited re-osseointegration, while the corresponding figure for the implants with a moderately rough surface was 54% (13 out of 24) (Fig. 35-6). The results presented by Almohandes *et al*. (2019) indicate that the decontamination procedure was effective in removing the biofilm on implants with a smooth surface, but also that the surface became conducive for *de novo* bone formation.

Reconstructive techniques including the application of bone replacement grafts and/or membranes at peri-implantitis-related bone defects have also been compared in preclinical research. Almohandes *et al*. (2019) used bone replacement graft alone or in combination with membranes to reconstruct the experimentally induced peri-implant defects. While neither of the test groups demonstrated any benefit over empty controls at smooth-surface implants, the use of grafting material resulted in improved radiographic bone levels at implants with moderately rough surfaces. The additional use of a membrane did not result in improved outcomes. Overall differences between groups, however, were small and outweighed by the aforementioned differences observed between different types of surface characteristics.

Clinical data

Evidence on the use of different techniques for reconstruction of peri-implantitis-associated bone defects is limited. This is highlighted by the low number of studies using adequate controls. In a systematic review presented by Tomasi *et al*. (2019), only three publications comparing the adjunctive use of either bone replacement grafts (Wohlfahrt *et al*. 2012;

Table 35-2 Clinical studies evaluating surgical therapy of peri-implantitis: reconstructive procedures.

Study	Sample and follow-up	Inclusion criteria	Surgical procedures	Outcomes	Comments
Roos-Jansåker *et al*. (2007), Sweden, case series	36 patients, 1 year	BoP + Bone loss ≥1.8 mm	Hydroxyapatite and membrane	MBL: –1.5 mm REC: 1.3 mm PD: –2.9 mm BoP: –60%	Systemic antibiotics prescribed. PROMs not reported.

BoP, bleeding on probing; MBL, marginal bone level; PD, probing pocket depth; RCT, randomized controlled trial; REC, soft tissue recession; PROMs, patient-reported outcome measures.

Jepsen *et al*. 2016) or enamel matrix proteins (Isehed *et al*. 2016) to access flap alone were included. No controlled study evaluating the use of membranes was identified. Clinical studies on reconstructive procedures at peri-implantitis-affected sites are depicted in Table 35-2.

Results of the controlled studies, in particular studies evaluating bone replacement grafts (Wohlfahrt *et al*. 2012; Jepsen *et al*. 2016), indicated better radiographic outcomes in the test groups. Using a meta-analysis, Tomasi *et al*. (2019) observed an additional defect fill of 57% and a difference in crestal bone gain of 1.7 mm for the reconstructive procedures. Figure 35-10 illustrates a reconstructive procedure at an anteriorly positioned implant affected by advanced peri-implantitis. Radiographic bone fill and improved crestal bone levels are identified on the 12-month radiograph.

In contrast to the reported findings on radiographs, benefits in terms of clinical measures such as PD and BoP following reconstructive procedures have yet to be demonstrated (Tomasi *et al*. 2019). In addition, the effect of different techniques on esthetic outcomes (e.g. soft tissue recession) or on patient satisfaction has not been evaluated.

Long-term observations on outcomes following reconstructive surgical therapy of peri-implantitis demonstrated that the procedure is safe and effective in reducing peri-implant inflammation. Roccuzzo *et al*. (2017) used a bone replacement graft to reconstruct peri-implant bone defects and followed 26 patients for 7 years. The mean reduction of PD at the final examination was >3 mm. These data are in line with assessments of overall improvements presented in the systematic review by Tomasi *et al*. (2019). At 12 months, a PD reduction of 2.8 mm and a soft tissue

Fig. 35-10 (a, b) Implant demonstrating deep probing depth (9 mm), clinical signs of inflammation, and a reduced bone level. recession of 0.7 mm were estimated on the basis of the available evidence. Potential factors that influence outcomes following reconstructive therapy are (1) the type/quality of surface decontamination (Tapia *et al*. 2019), (2) the configuration of the bone defect (Schwarz *et al*. 2012), and (3) implant surface characteristics (Roccuzzo *et al*. 2017).

Conclusion

Pocket elimination/reduction procedures are effective in managing peri-implantitis. While the benefit of the adjunctive use of local antiseptic/antimicrobial agents for decontamination purposes remains to be demonstrated, the use of systemic antibiotics was shown to result in short-term improved outcomes after surgery. This benefit, however, was found to be limited to implants with modified implant surfaces and to the first year after treatment, only. Data from preclinical research suggest that re-osseointegration at previously contaminated implant surfaces is possible but depends on implant surface characteristics and the level of decontamination. While radiographic outcomes may be improved following the use of reconstructive techniques, clinical and patient-perceived benefits of the use of bone replacement grafts and/or membranes remain to be demonstrated. In general, treatment outcomes following surgical therapy of peri-implantitis appear to be highly dependent on implant surface characteristics, favoring smooth surface implants.

Chapter 36

Systemic Antibiotics in Periodontal Therapy

Magda Feres[1] and David Herrera[2]

[1] Department of Periodontology, Dental Research Division, Guarulhos University, Guarulhos, São Paulo, Brazil and The Forsyth Institute, Cambridge, MA, USA

Introduction

Antibiotics are substances produced by a plethora of microorganisms such as bacteria (e.g., *Streptomyces* species) and fungi (e.g., *Penicillium* species) that selectively suppress the growth of other microorganisms and eventually may kill them (Fleming 2001; Watve *et al*. 2001; Mohr 2016). However, the term "antibiotics" is now extended to include synthetic or semisynthetic antimicrobial agents, such as sulfonamides and imidazoles, which are not produced by microbes (Mohr 2016). The modern era of antimicrobial therapy began with the production of penicillin in 1941, when this compound, discovered by Fleming in 1928, was finally mass produced and made available for clinical use (Chambers & Sande 1996). The outstanding success of penicillin in treating various infections quickly encouraged pharmaceutical laboratories to search for new antibiotics, produced from microorganisms isolated from soil samples; further successes came quickly (Chain 1972). Since then, hundreds of natural, semisynthetic, and synthetic antibiotics have been identified (Mohr 2016), and many of these drugs are essential in the treatment of numerous infections.

The widespread use of antibiotics over the past 80 years has led to the emergence of microorganisms tolerant to certain drugs, which is a primary reason for their failure to treat some infectious diseases, including life-threatening conditions (WHO 2014, 2015). A microorganism that survives exposure to an antimicrobial agent may become resistant to that agent, either by selecting for a mutation in its genome or by activating the expression of previously existing antibiotic-resistant genes. These resistant genes may be transferred within or between species, giving rise

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

to a new bacterial population tolerant to that agent (Davies & Davies 2010; Soares *et al*. 2012; Sekyere & Asante 2018). The emergence of side-effects is another disadvantage in the use of systemic antibiotics and must also be considered in the context of the risk–benefit evaluation of such therapies.

Considering the infectious nature of periodontitis, systemic antibiotics have been extensively studied as adjuncts in periodontal treatment (Herrera *et al*. 2002; Haffajee *et al*. 2003b; Sgolastra *et al*. 2012a, b, 2014; Zandbergen *et al*. 2013, 2016; Feres *et al*. 2015; Keestra *et al*. 2015a, b; Rabelo *et al*. 2015; Santos *et al*. 2015; Grellmann *et al*. 2016; Assem *et al*. 2017; Souto *et al*. 2018; Teughels *et al*. 2020). The recommendation for the use of antibiotics to treat periodontal infections should follow the same principles used for the treatment of any other infection in the body, that is: the risks need to be clearly offset by benefits to the patient – benefits that could not be otherwise achieved or which would be achieved with much greater difficulty or risk by other means. The aim of this chapter is to discuss the use of systemic antibiotics in the treatment of periodontitis, in an endeavor to provide clinicians with guidance on the use of these agents in daily clinical practice.

Microbiological basis for periodontal treatment

The idea of using antimicrobial agents in the management of periodontal diseases is based on the premise that these are infections triggered and magnified by microorganisms that colonize the oral cavity, above or below the gingival margin. Understanding the composition of the periodontal microbiota in health and in disease is essential for establishing effective periodontal treatments.

The long search for periodontal pathogens and the concept of beneficial species

Researchers first suggested a specific bacterial etiology for periodontal diseases during the golden era of medical bacteriology (1880–1920), when the etiologic agents of important bacterial infections, such as cholera and anthrax, were isolated (Socransky & Haffajee 1994). Regrettably, technical difficulties in evaluating the complex periodontal microbiota colonized by several strict anaerobes and fastidious pathogens have delayed a more accurate description of the subgingival microbial composition (Socransky *et al*. 1987). Despite these difficulties, the collective efforts of pioneer microbiologists using mainly open-ended culture techniques led to the isolation and identification of several important periodontal pathogens (Newman *et al*. 1976; Slots, 1976; Loesche *et al*. 1982, 1985; Keyes & Rams 1983; Moore *et al*. 1985; Socransky *et al*. 1988a, b; Haffajee & Socransky 1994; Marsh 1994; Zambon 1996; Riviere *et al*. 1996, 1997). This knowledge was significantly expanded after the introduction of target molecular diagnostic techniques in the 1980s and 1990s, such as monoclonal antibodies, enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and DNA probes (Dzink *et al*. 1983; Bonta *et al*. 1985; Zappa *et al*. 1990; Socransky *et al*. 1991; Watanabe & Frommel 1993; Gmur & Guggenheim 1994; Socransky *et al*. 1994; Ellwood *et al*. 1997; Socransky *et al*. 1998; Mombelli *et al*. 1999). One of these techniques, checkerboard DNA–DNA hybridization (Socransky *et al*. 1994), allowed for the quantification of many bacterial species in hundreds of thousands of plaque samples and introduced the concept of microbial complexes in 1998 (Socransky *et al*., 1998, 1999; Ximénez-Fyvie *et al*. 2000a, b, 2006; Colombo *et al*. 2002; Socransky & Haffajee 2002, 2005; Haffajee *et al*. 2004, 2005, 2006, 2008a, b; López *et al*. 2004; Teles *et al*. 2006; Faveri *et al*. 2009; da Silva-Boghossian *et al*. 2011; Uzel *et al*. 2011; Feres *et al*. 2015; Feres *et al*. 2016; Maciel *et al*. 2016). More recently, open-ended DNA sequencing technologies, including next-generation sequencing (NGS), opened up the possibilities of identifying all microorganisms in a given sample, including those that have never been cultivated before, revealing an even broader diversity within the periodontal microbiome (Paster *et al*. 2001; Griffen *et al*. 2012; Liu *et al*. 2012; Abusleme *et al*. 2013; Wang *et al*. 2013; Duran-Pinedo *et al*. 2014; Galimanas *et al*. 2014; Li *et al*. 2014; Camelo-Castillo *et al*. 2015; Chen *et al*. 2015; Kirst *et al*. 2015; Park *et al*. 2015; Pozhitkov *et al*. 2015; Dabdoub *et al*. 2016; Ganesan *et al*. 2017; Chen *et al*. 2018a; Shi *et al*. 2018; Pérez-Chaparro *et al*. 2018; Tsai *et al*. 2018; Schulz *et al*. 2019; Wei *et al*. 2019; Feres *et al*. 2020b; Ikeda *et al*. 2020). The labor-intensive work of the abovementioned microbiologists revealed that only a limited number of organisms are associated with the etiopathogenesis of periodontitis and that several other species colonizing the oral cavity were host-compatible or beneficial. The species considered "true" pathogens were those found in higher levels and proportions in patients with periodontitis than in healthy individuals (association studies), and were reduced in sites and patients who responded well to periodontal treatment (elimination/suppression studies), namely: *Porphyromonas gingivalis*, *Treponema denticola*, *Tannerella forsythia* (red complex pathogens), *Eubacterium nodatum*, and several *Fusobacteria*, *Prevotella*, and *Campylobacter* species (orange complex species), as well as *Eikenella corrodens*, *Selenomonas sputigena*, *Aggregatibacter actinomycetemcomitans*, and *Treponema socranskii*. The data provided by the studies using NGS confirmed previous knowledge of the role of these classic pathogenic species in the pathobiology of periodontal diseases and identified other taxa, such as *Filifactor alocis*, *Eubacterium saphenum*, *Dialister invisus*, and several other species from the genera *Treponema* and *Desulfobulbus*, as possible new pathogens (Pérez-Chaparro *et al*. 2014; Feres *et al*. 2020c) (Fig. 36-1). A recently introduced concept suggests that certain periodontal pathogens, named "keystone pathogens", are able to evade host

response and mediate the conversion of the whole microbial community into dysbiosis. The broad disturbance of this community would cause and/or sustain the process of periodontal breakdown. *P. gingivalis* has been identified as a main keystone pathogen (Hajishengallis 2011; Hajishengallis & Lamont 2012; Hajishengallis *et al*. 2011).

Conversely, other microorganisms were considered host compatible as they were found elevated in periodontal health and increased in proportions after therapy. These included *Veillonella parvula* and *Actinomyces odontolyticus* (purple complex) and several species from the genera *Actinomyces*, *Streptococcus* (yellow complex), and *Capnocytophaga* (green complex) (Socransky *et al*. 1988a, b, 1998; Haffajee *et al*. 2006; Faveri *et al*. 2009; Teles *et al*. 2006, 2013). Species from the genera *Rothia*, *Neisseria*, *Leptotrichia*, *Corynebacterium*, and *Kingella* have also been recently associated with periodontal health (Feres *et al*. 2020c) (Fig. 36-2).

The accumulated knowledge about the composition of the subgingival microbiota in periodontal health and in periodontitis suggest that successful treatment would require a profound ecological change in the entire oral cavity. This may not be easy to achieve, especially considering that these microorganisms do not live in isolation but are part of complex microbial communities named biofilms.

Understanding the target: bacterial biofilms

Besides the great advance in our knowledge about the composition of the periodontal microbiota in the past 50 years, the notion that periodontitis is caused by bacteria growing in biofilms led to a big breakthrough in our understanding of treatment success and failure. Bill Costerton, the father of biofilm science, defined biofilm as "matrix-enclosed bacterial populations adherent to each other and to a solid (non-shedding) surface" (Costerton 1999). This definition has been refined to also include shedding surfaces (Hall-Stoodley *et al*. 2004). Thus, the term biofilm has come to encompass not only the bacterial communities attached to the tooth or other artificial surfaces in the mouth, but also those on the tongue and other oral soft tissues.

Biofilms are complex structures that may function as a physiological integrated community and provide several advantages to colonizing species, such as protection from undesirable environmental conditions (e.g. oxygen levels), antibiotics, and host defenses (Costerton *et al*. 1999; Marsh & Devine 2011). Most of the cells in biofilms are alive and may be spatially organized in patterns that facilitate metabolic cooperation. The presence of strict anaerobe pathogens in highly oxygenated niches of the oral cavity is a good example of biofilm protection. While in the subgingival environment these species are located in the outer layer of the biofilm, lining the epithelium (Kolenbrander *et al*. 2006; Zijnge *et al*. 2010), in the niches exposed to oxygen, the strict anaerobes are protected from oxygen within the deep layers of the biofilm (Marsh 1994). This explains how shallow pockets, tongue, saliva, oral mucosa, and the supragingival biofilm of subjects with periodontitis are highly colonized with several strict anaerobe periodontal pathogens, such as those from the red and orange complexes (Riviere *et al*. 1996, 1997;

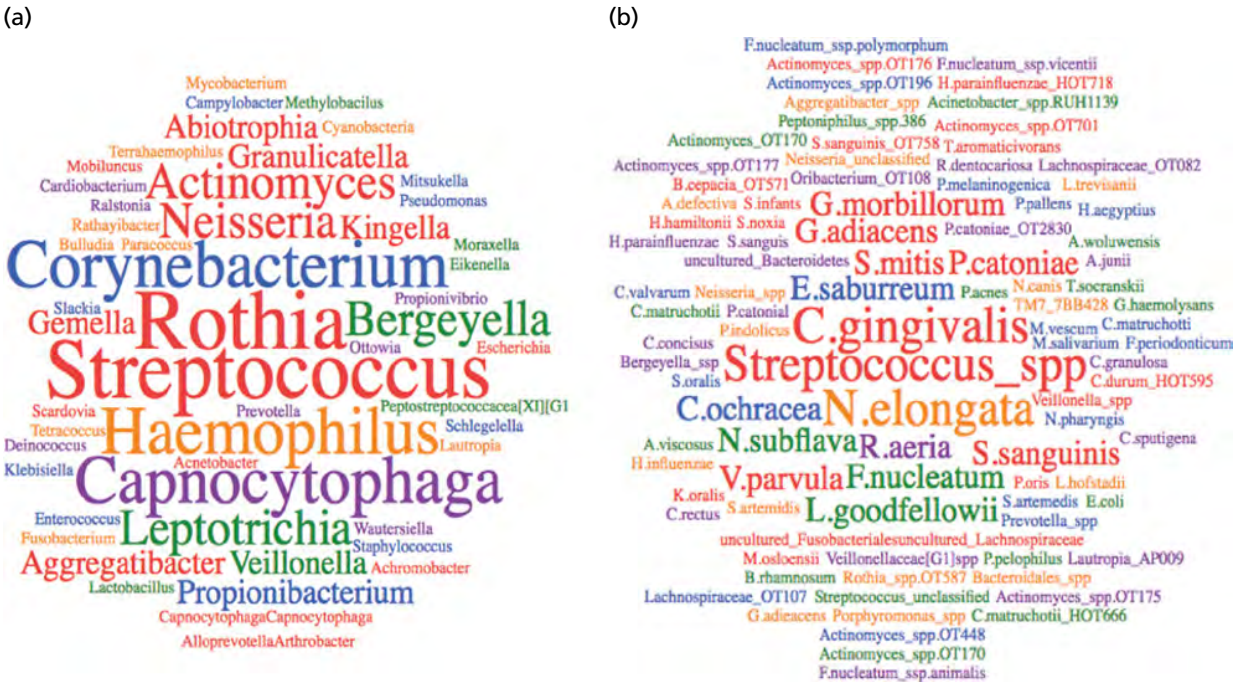

Fig. 36-2 Word clouds of the *genera* (a) and *species* (b) increased in periodontal health, according to the data from the association studies using next-generation sequencing (16S and metagenomic techniques). (Source: Adapted from Feres *et al*. 2020c. Reproduced with permission from John Wiley & Sons.)

Ximénez-Fyvie *et al*. 2000a, b; Mager *et al*. 2003; Beikler *et al*. 2004; Socransky & Haffajee 2005; Faveri *et al*. 2006a; Haffajee *et al*. 2008b). These findings impact treatment decisions, because they suggest that not only deep pockets, but also shallow pockets, and all other oral surfaces of patients with periodontitis demand biofilm-control treatment. If not eliminated or reduced, pathogens residing in the profound layers of different oxygenated niches in the oral cavity may be a source of recolonization of recently treated pockets.

The development of mixed biofilms is normally guided by the environmental conditions, nutrient availability, and the coaggregation (i.e. specific bindings) patterns of colonizing microorganisms. Determining the biogeography of microorganisms within biofilms is not simple, but the sequence of subgingival colonization has been suggested by a few authors (Socransky *et al*. 1998; Socransky & Haffajee 2005; Kolenbrander *et al*. 2006; Zijnge *et al*. 2010; Teles *et al*. 2012). The overall results of these studies suggested that the early colonizers are mostly host-compatible species such as *V. parvula* and species from the genera *Streptococcus*, *Capnocytophaga*, and *Actinomyces* (mostly members of the yellow, green, and purple complexes). Orange complex microorganisms from the genera *Fusobacterium*, *Prevotella*, and *Campylobacter* function as a bridge between the early colonizers and the late colonizers from the red complex (*P. gingivalis*, *T. forsythia*, and *T. denticola*). Other newly identified pathogens from the genera *Porphyromonas* and *Treponema* would probably colonize the biofilm later, but the pattern of colonization of other putative pathogens such as those from the genera *Filifactor*, *Dialister*, and *Desulfobulbus*, is still unknown.

The final stage of equilibrium between microorganisms and the environment within a biofilm is called the climax community (Socransky & Haffajee 2005). It is extremely difficult to change the composition of a climax community due to a biofilm property named resilience – the ability for survival, recovery, and adaptation. In periodontal health, resilience is a beneficial mechanism because it prevents small challenges to the healthy biofilm that may result in dysbiosis and, consequently, disease (Rosier *et al*. 2018). Regrettably, the climax community associated with disease is also extremely stable, especially in the nutrient-rich environment of severe periodontitis. In this case, resilience has a negative impact on treatment outcome as it helps the climax community return to its original dysbiotic composition, especially if the biofilm is only mildly disturbed by therapy. This may lead to disease recurrence.

Microorganisms living in biofilms may be 10 to 1000 times more resistant to the effects of antimicrobials than their planktonic (i.e. non-attached) counterparts (Costerton *et al*. 1999). The main mechanisms of resistance include: (1) limited drug diffusion into the inner layers of the biofilm through the extracellular matrix; (2) low level of bacterial metabolic activity inside the biofilm, which may reduce the efficacy of antibiotics that target processes that occur in actively growing bacteria; (3) post-treatment presence of dormant cells called "persistants", which are not induced by antibiotic administration but may resist antibiotic

inactivation and help to re-establish the original composition of the climax community; (4) inactivation of antibiotic molecules in the biofilm matrix by entrapped degrading enzymes; and (5) overexpression of resistant genes by sessile (i.e. attached) cells. It is not clear how many of these mechanisms happen concomitantly in the subgingival environment, but the compelling body of evidence showing that biofilms offer substantial protection against antimicrobials and host response has led to an overall consensus that systemic antibiotics should always be combined with the mechanical disruption of the biofilm (Herrera *et al*. 2008; Sanz *et al*. 2008)

Rationale for the use of adjunctive systemic antibiotics in periodontal treatment

The main clinical goals of periodontal treatment include reductions in probing depth (PD), bleeding on probing (BoP) and suppuration, and gains in clinical attachment level (CAL). In addition, and most importantly, treatment should prevent further disease progression. Numerous interventional studies, conducted over the past decades, have demonstrated that these results are attained when treatment is able to produce a rapid and marked reduction in levels and proportions of the abovementioned periodontal pathogens and an oral recolonization by a new climax community with higher proportions of host-compatible microorganisms (Cugini *et al*. 2000; De Soete *et al*. 2001; Socransky & Haffajee 2002; Colombo *et al*. 2005; Haffajee *et al*. 2006; Teles *et al*. 2006; Matarazzo *et al*. 2008; Mestnik *et al*. 2010; da Silva-Boghossian *et al*. 2011; Silva *et al*. 2011; Uzel *et al*. 2011; Faveri *et al*. 2014; Soares *et al*. 2014; Feres *et al*. 2015, 2016; Tamashiro *et al*. 2016) (Fig. 36-3). This is not an easy undertaking, especially considering the protective effect of the biofilm and its high potential of recovery (resilience). Hypothetically, systemic antibiotics may be useful tools in achieving these ecological changes.

Mechanical periodontal therapy and its limitations

Subgingival instrumentation, usually delivered as scaling and root planing (SRP) is the gold standard treatment for periodontitis and it improves all periodontal clinical parameters (Badersten *et al*. 1981; Pihlstrom *et al*. 1983; Ramfjord *et al*. 1987; Cobb 2002; Heitz-Mayfield *et al*. 2002; Hung & Douglass 2002). These clinical benefits are associated with a decrease in total counts of bacteria and also with a reduction in specific pathogens and a concomitant increase in host-compatible species (Hinrichs *et al*. 1985; Sbordone *et al*. 1990; Pedrazzoli *et al*. 1991; Ali *et al*. 1992; Haffajee *et al*. 1997, 2008a; Shiloah *et al*. 1997; Cugini *et al*. 2000; Fujise *et al*. 2002; Carvalho *et al*. 2005; Colombo *et al*. 2005; Haffajee *et al*. 2006; Ioannou *et al*. 2009; Knöfler *et al*. 2011; Rosalem *et al*. 2011; Silva *et al*. 2011; Feres *et al*. 2015, 2016; Mombelli 2018). Interestingly, although SRP does not target specific microorganisms, it leads to the recolonization of recently scaled sites with a microbiota more compatible with health. This is probably due to the typical post-treatment sequence of recolonization. The host-compatible species are the first to recolonize the recently instrumented tooth surfaces, while the main pathogens are late colonizers. These species, especially those from the red complex, are fastidious in nature and require several types of nutrients to grow, many of them produced by the inflammatory process associated with periodontitis. It has been proposed that periodontal treatment has a direct effect on biofilm and calculus and an indirect effect in the local host tissue. If an effective SRP is followed by adequate

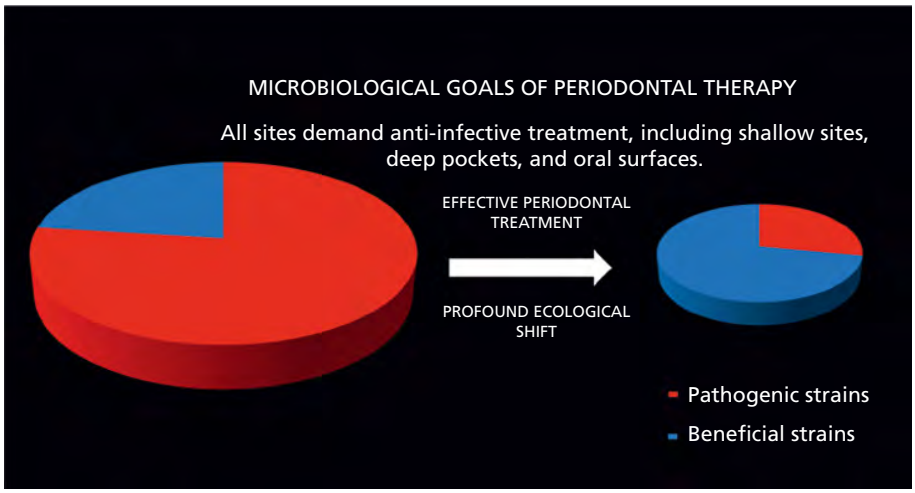

Fig. 36-3 Microbiological goals of periodontal therapy. It is important to highlight that treatment success depends on a profound change in the composition of the subgingival biofilm throughout the oral cavity, from a disease-related (dysbiosis) to a health-related (homeostasis) ecology. In order to obtain periodontal clinical stability, treatment must be able to lead to a reduction in the levels and proportions of pathogens and the concomitant increase in proportions of bacteria associated with periodontal health.

plaque control, the reduction in tissue inflammation is reached, together with low levels of gingival crevicular fluid, which represents an important source of nutrients for many fastidious pathogens (Socransky & Haffajee 2002; Socransky *et al*. 2004; Uzel *et al*. 2011; Teles *et al*. 2013). This new healthy environment prevents biofilm colonization by high proportions of pathogens due to restriction of nutrition and other bacterial growth requirements. Unfortunately, the clinical and microbiological improvements obtained after SRP are not always sustained over time, particularly in severe cases with the presence of many deep pockets and a severely dysbiotic biofilm. Thus, other forms of periodontal therapies, including local and systemic antimicrobials, have been proposed in conjunction with SRP with the objective of improving the clinical and microbiological outcomes of this treatment.

Local versus systemic antimicrobials

Antimicrobials for the treatment of periodontitis may be delivered locally or administered systemically. The concept of controlled local antimicrobial delivery in the treatment of periodontitis was introduced in 1979 by Max Goodson and co-workers (Goodson *et al*. 1979). The idea was rather appealing as the agents are directly applied at the infection site in very high concentrations, while systemic antimicrobials must navigate through multiple membranes surfaces within the body (e.g. gastrointestinal tract, endothelial, and epithelial surfaces) before reaching the gingival crevicular fluid and saliva. Locally delivered antimicrobials also cause fewer side effects than drugs prescribed systemically and have a reduced chance of developing bacterial resistance to the medications. Thus, different antibiotics and antiseptics (tetracycline, minocycline, doxycycline, metronidazole, piperacillin, tazobactam, chlorhexidine, etc.), delivered through different systems (non-resorbable polymer fibers, gels, chip of hydrolyzed gelatin) have been tested in the treatment of periodontitis (Herrera *et al*. 2020). The overall results suggest a beneficial effect of the adjunctive use of these products at a local level, but the outcomes, in general, were not as good as expected (for review, see Chapter 37). This may be partially explained by limitations of the release kinetics of the carrier systems and the complexity of the infection being treated. In order to effectively change the climax community associated with periodontitis, the antimicrobial agent must be released subgingivally over a long period of time (at least 7–10 days) in a controlled concentration. Regrettably, very few systems present with such kinetics. In addition, as discussed earlier in this chapter, the dysbiosis associated with periodontitis affects the whole oral cavity, including shallow sites, saliva, tongue, and cheeks. Thus, it is somehow expected that the use of locally delivered antimicrobials restricted to a subset of deep subgingival sites would be particularly limited. Therefore, local antimicrobial therapy has been recommended during the maintenance phase for treating remaining and isolated active pockets (Heasman *et al*. 2001; Hussein *et al*. 2007; Herrera *et al*. 2020).

The systemic administration of antibiotics mitigates some of the limitations of local delivery. The agents reach all the oral surfaces and fluids for a prolonged period of time and may reach periodontal pathogens that eventually invade the host's tissues (Rudney *et al*. 2005; Kim *et al*. 2010). The disadvantages of systemic administration over local delivery include adverse drug reactions (Slots & Rams 1990), uncertain patient compliance (Loesche *et al*. 1993; Guerrero *et al*. 2007), lower concentration of the drug at subgingival sites (Goodson 1994) and the increased risk of developing bacterial resistance (WHO 2015; Tacconelli *et al*. 2018). Several systemic antibiotics have been used as adjuncts to mechanical periodontal treatment with different degrees of success. The literature is reviewed in the following sections.

Systemic antibiotics in periodontal therapy

Should systemic antimicrobial therapy be aimed at specific pathogens?

The idea of using systemic antibiotics to target/eliminate specific pathogens from the subgingival biofilm is based on the historical attempt to parallel the pathobiology of periodontitis with that of classic infections and on evidences showing that a well-recognized pathogen, *A. actinomycetemcomitans*, is effectively reduced by a specific combination of antibiotics. These principles are summarized below.

The notion that periodontitis is associated with specific pathogens may have led to misinterpretations concerning its pathobiology and mode of treatment. Classic infections, such as syphilis and tuberculosis, are normally caused by an exogenous microorganism, but periodontitis is a complex disease associated with mainly endogenous pathogens that may trigger and/or promote tissue destruction in susceptible hosts (Haffajee & Socransky 1994; Teles *et al*. 2013). Several periodontal pathogens are involved in disease onset and progression concomitantly, and pathogens may be found in healthy individuals, albeit in low levels and proportions (Socransky & Haffajee 2005). The presence of pathogens in healthy individuals is not unique to periodontal diseases; they occur in virtually any infection, including the most classic ones. In classic infections, once disease is established, the accurate diagnosis of the causative agent and their sensitivities to different antibiotics are essential in order to ensure the effective elimination of the agent and, consequently, cure. In periodontitis, environmental factors may lead to the selection or overgrowth of different pathogens, including opportunistic (or accessory species) (Socransky & Haffajee, 2005; Darveau 2010;

Hajishengallis 2011; Hajishengallis & Lamont 2012) and possibly some yet unidentified/unnamed organisms (Pérez-Chaparro *et al*. 2014; Feres *et al*. 2020c). A microbial diagnosis would have limited value for treatment in this case, since the detection of one pathogen would not rule out the presence of others. In addition, a negative test does not mean the pathogen is absent, but simply means it was not detected in the sites sampled. And, finally, we should bear in mind that, as suggested previously in this chapter, effective periodontal treatment demands a striking change in the biofilm climax community, from a microbial profile associated with disease to a microbial profile compatible with health, rather than on the elimination of one or a few pathogens.

An argument that supported the notion that antibiotic therapy in periodontics should be driven by the presence of specific pathogens came from a series of elegantly designed studies carried out by van Winkelhoff and co-workers in the 1980s and 1990s. These authors convincingly demonstrated that the combination of metronidazole (MTZ) and amoxicillin (AMX) could reduce or eliminate *A. actinomycetemcomitans* from periodontal and oral sites in patients with periodontitis, and these reductions were associated with important clinical improvements (Christersson *et al*. 1985; van Winkelhoff *et al*. 1989, 1992; Goené *et al*. 1990; Renvert *et al*. 1990; Berglundh *et al*. 1998; Flemmig *et al*. 1998; Winkel *et al*. 1998). These findings reinforced the idea that specific antibiotics should only be prescribed in cases of periodontitis associated with specific pathogens. However, data from later clinical studies has challenged this notion by showing that patients not initially colonized by *A. actinomycetemcomitans* also benefited from the combination of MTZ plus AMX (MTZ+AMX) (Dannewitz *et al*. 2007; Mombelli *et al*. 2013), most probably due to the effect of these agents in inhibiting other important pathogens and in changing the microbiological profile towards health (Haffajee *et al*. 2006; Mestnik *et al*. 2010; Soares *et al*. 2014; Faveri *et al*. 2014; Feres *et al*. 2015; Tamashiro *et al*. 2016; Duarte *et al*. 2018). Indeed, a recent systematic review concluded that there is no compelling evidence in the literature that baseline detection of *A. actinomycetemcomitans* should be used as a criterion for prescribing adjunctive antibiotics, although the authors acknowledge the limitations of their review, because of the limited information available (Nibali *et al*. 2019). Conversely, some studies and/or secondary analysis indicated that patients with specific microbial profiles benefit more from adjunctive systemic antibiotics (Guerrero *et al*. 2014) and that targeting specific species or clonotypes (e.g. *A. actinomycetemcomitans* JP2) would be relevant in certain patients/conditions (van Winkelhoff *et al*. 1989, 1992; Haubek *et al*. 2008). In addition, the keystone pathogen hypothesis associating *P. gingivalis* with disease onset (Hajishengallis & Lamont 2014) rekindled the idea of a possible important role of targeting specific pathogens.

In summary, there is still controversy on the need for identifying a specific periodontal pathogen to achieve treatment success, and consequently, baseline microbiological tests are not routinely used in daily clinical practice and most randomized clinical trials (RCTs) in periodontology have not chosen patients and/or antibiotics according to specific microbial profiles.

Which antimicrobial(s) would provide the most predictable results? A historical perspective

The first clinical studies on the effect of systemic antimicrobials in periodontal treatment were conducted in the 1970s and 1980s. Most of those studies used tetracycline for treating young subjects with periodontal destruction localized in first molars and incisors, who did not respond to mechanical treatment: a condition at that time named localized juvenile periodontitis (later known as localized aggressive periodontitis, and currently molar/incisor pattern periodontitis). These studies showed that a regimen of 1 g/day of tetracycline HCl for 2–4 weeks enhanced the resolution of gingival inflammation and led to gains in CAL and alveolar bone (Lindhe & Liljenberg 1984; Novak *et al*. 1988, 1991). The two lipid soluble analogs, doxycycline and minocycline, which seemed to achieve higher gingival fluid levels with a lower dose regimen of 100–200 mg/day for 7–21 days (Ciancio *et al*. 1980, 1982; Pascale *et al*. 1986), also led to important clinical improvements in young subjects (Mandell & Socransky 1988; Müller *et al*. 1993). However, tetracycline and its analogs did not show similar benefits in adults (Listgarten & Helldén 1978; Helldén *et al*. 1979; Scopp *et al*. 1980; Ng & Bissada 1998).

Many results obtained with the tetracyclines, especially in young patients, seemed promising, and hence, during the 1980s and 1990s, several antibiotics were tested for their use in the treatment of periodontitis, culminating with the publication of the two first systematic reviews with meta-analyses on this topic at the beginning of the 2000s (Herrera *et al*. 2002; Haffajee *et al*. 2003b), which were presented at the European and World Workshops in Periodontology, respectively. Over 10 different antimicrobials or combination of drugs were included in the meta-analyses, and both studies suggested that the adjunctive use of systemic antibiotics to SRP provided some additional benefit over SRP alone in terms of CAL gain and PD reduction, especially in younger patients and in patients with severe/aggressive/"active" disease and/or specific microbiological profiles. Although neither study could assign superiority to any particular antibiotic due to insufficient numbers of studies for each agent tested, differences in study protocols, and small sample sizes, the body of evidence suggested that some antibiotics were more effective than others, and this information impacted the next round of studies in this area. It should be noted that

the majority of studies provided data up to 6 months post-treatment, and that the most recent literature encompassing studies with 1 year or more of follow-up converged on the use of three particular drugs/combinations: MTZ, MTZ+AMX and azithromycin (AZI) (Feres *et al*. 2015; Teughels *et al*. 2020).

Metronidazole

MTZ is a nitroimidazole compound discovered in the late 1950s, when researchers at Rhone-Poulenc Research Laboratories in France were trying to create a synthetic product from a *Streptomyces* spp. that would have activity against *Trichomonas vaginalis* (Freeman *et al*. 1997). Thus, MTZ was found initially to be effective against certain protozoan pathogens. Its antibacterial activity was discovered by accident in 1962, when a patient with *T. vaginalis* and acute ulcerative gingivitis had a "double cure" after a week of treatment with MTZ (Shinn, 1962). This clinical observation led to studies that established MTZ as an important bactericidal antimicrobial for anaerobic infections in the body (Falagas & Gorbach 1995; Stupnicki *et al*. 1996; Freeman *et al*. 1997), including the oral cavity (Proctor & Baker 1971; Loesche *et al*. 1982). MTZ can be considered a prodrug in the sense that it requires metabolic activation by anaerobic organisms; hence, all aerobic organisms are intrinsically resistant to this agent. The selective efficacy of MTZ against obligate anaerobes makes it particularly appealing for the treatment of periodontitis, considering that most periodontal pathogens are strict anaerobes, such as the three red complex species (*P. gingivalis, T. forsythia*, and *T. denticola)*.

Lindhe and co-workers (Lindhe *et al*. 1983a) were the first to observe that systemic MTZ (200 mg) taken four times a day for 14 days, in combination with mechanical therapy, was more effective in improving clinical parameters and reducing *spirochetes* than controls who received SRP alone. But it was Walter Loesche and co-workers who carried out the seminal clinical studies showing the benefits of MTZ for patient with periodontitis, especially in reducing the need for periodontal surgery (Loesche *et al*. 1987, 1991, 1992, 1996). Later, other RCTs demonstrated the effect of these agents in improving several periodontal clinical parameters and the composition of the subgingival microbiota (Feres *et al*. 2001, 2012; Sigusch *et al*. 2001; Carvalho *et al*. 2004, 2005; Xajigeorgiou *et al*. 2006; Matarazzo *et al*. 2008; Rooney *et al*. 2002; Silva *et al*. 2011; Preus *et al*. 2013; Soares *et al*. 2014).

Amoxicillin

AMX is a semisynthetic penicillin. The discovery of penicillin in 1928 and the beginning of its clinical use in 1941 represented a real turning point in human history. For the first time, patients desperately ill with staphylococcal and streptococcal infections could be cured. Cephalosporins and penicillins are the main classes of ß-lactam antibiotics. They are bactericidal agents and kill susceptible bacteria by inhibiting the synthesis of the bacterial peptidoglycan cell wall (Spratt 1978; Yocum *et al*. 1980). Because penicillin has a narrow spectrum of antimicrobial activity, research for alternative drugs with a broader range of antimicrobial activity led to the discovery of AMX by scientists at Beecham Research Laboratories, in 1972 (Gordon *et al*. 1972). The most important mechanism of resistance is β-lactamase-mediated hydrolysis of the β-lactam ring, resulting in inactivation of the antibiotic. A small proportion of the subgingival microbiota seems to be resistant to AMX (Sutter *et al*. 1983; Walker *et al*. 1983; Feres *et al*. 2002; Ardila *et al*. 2010; Rams *et al*. 2014), but an important number of patients will harbor, at least, one β-lactamase producing bacterial species (Herrera *et al*. 2000b).

Penicillin has not shown encouraging clinical results in the treatment of periodontitis, probably due to its antimicrobial effect being limited to aerobic microorganisms (Kinder *et al*. 1986; Drawz & Bonomo 2010), and only a few studies have described the clinical and microbiological outcomes of AMX, as an adjunct, in periodontal treatment (Feres *et al*. 2001; Matisko & Bissada 1993; Abu Fanas *et al*. 1991; Winkel *et al*. 1999). Feres *et al*. (2001) showed beneficial changes in clinical parameters and in the subgingival microbial composition in nine adults with periodontitis, treated by means of SRP and systemic AMX for 14 days. These changes were very striking during antibiotic administration and up to 14 days after the antibiotic was withdrawn, and most of the benefits were maintained for up to 1 year. However, of concern was the fact that the proportions of the *Actinomyces* species were reduced right after treatment and remained low up to 1-year post-therapy. This was considered an unwanted outcome of treatment, since these are host-compatible organisms that one expects to increase in proportion after treatment.

Metronidazole plus amoxicillin

Although AMX was not established as a drug of choice in the treatment of periodontitis, the important studies led by A.J. van Winkelhoff suggested that the combined use of AMX and MTZ could be a potent tool in the treatment of periodontitis, especially in patients harboring *A. actinomycetemcomitans* (van Winkelhoff *et al*. 1989, 1992; Pavicic *et al*. 1992, 1994). Many years later, the first placebo-controlled RCT demonstrating the benefits of the combination of AMX and MTZ in treating young adults with aggressive periodontitis was published (Guerrero *et al*. 2005), and this information was confirmed by other studies (Xajigeorgiou *et al*. 2006; Mestnik *et al*. 2010, 2012; Yek *et al*. 2010; Aimetti *et al*. 2012; Casarin *et al*. 2012). Similar benefits were also shown in adults with severe periodontitis (Moeintaghavi *et al*. 2007; Cionca *et al*. 2009, 2010;

Silva *et al*. 2011; Feres *et al*. 2012; Goodson *et al*. 2012; Feres *et al*. 2015; Harks *et al*. 2015; Usin *et al*. 2016; Saleh *et al*. 2016; Cosgarea *et al*. 2016, 2017; Borges *et al*. 2017; Mombelli *et al*. 2017; Rebeis *et al*. 2019) and in very young patients with localized disease (Beliveau *et al*. 2012; Merchant *et al*. 2014; Burgess *et al*. 2017; Rebeis *et al*. 2019), colonized or not by *A. actinomycetemcomitans*. These agents also showed added benefits in smokers (Matarazzo *et al*. 2008; Theodoro *et al*. 2018) and in patients with diabetes (Miranda *et al*. 2014; Tamashiro *et al*. 2016). Microbiological studies, evaluating 40 bacterial species, showed that the improvements in clinical parameters were associated, not only with a reduction in *A. actinomycetemcomitans*, but with a broader beneficial change in the subgingival microbial composition, as will be described later in this chapter (Haffajee *et al*. 2006; Matarazzo *et al*. 2008; Mestnik *et al*. 2010; Casarin *et al*. 2012; Soares *et al*. 2014; Feres *et al*. 2015; Miranda *et al*. 2014; Tamashiro *et al*. 2016).

Azithromycin

AZI is a relatively new macrolide that, due to excellent pharmacological properties, emerged as a promising drug in medicine in the early 1990s (Schönwald *et al*. 1990; Balmes *et al*. 1991; Hoepelman & Schneider 1995) and, more recently, in dentistry (Herrera *et al*. 2000a; Mascarenhas *et al*. 2005; Haffajee *et al*. 2006; Dastoor *et al*. 2007; Gomi *et al*. 2007; Haas *et al*. 2008, 2012; Yashima *et al*. 2009; Oteo *et al*. 2010; Botero *et al*. 2013; Martande *et al*. 2016). AZI is a semisynthetic, bacteriostatic, wide-spectrum antibiotic, rapidly absorbed by cells, such as leucocytes and fibroblasts, which helps to quickly bring the drug to the site of inflammation and to maintain its concentration 10–100 times higher in tissues than in serum (Hoepelman & Schneider 1995). In addition, AZI is slowly released to the tissues, which increases its half-life (Gladue *et al*. 1989; Gladue & Snider 1990). This favorable pharmacokinetic property allows AZI to be administered only once a day (500 mg) for short periods of time (from 3 to 6 days) (Henry *et al*. 2003). This simple dosage protocol and the low incidence of side-effects reported with the use of this antibiotic facilitate patient adherence to treatment, which represents a major advantage of AZI over MTZ, alone or in combination with AMX. Nonetheless, despite the good pharmacological properties and its easy dosage regimen, the results of RCTs assessing the clinical and microbiological effects of AZI in periodontal treatment diverged considerably. Whereas some authors demonstrated that AZI could enhance the outcomes of subgingival instrumentation of patients with periodontitis (Dastoor *et al*. 2007; Gomi *et al*. 2007; Haas *et al*. 2008; Haas *et al*. 2012; Botero *et al*. 2013; Martande *et al*. 2016), smokers (Mascarenhas *et al*. 2005), or in cases of mild/moderate periodontitis (Haffajee *et al*. 2007; Oteo *et al*. 2010; Smith *et al*. 2002), others could not show important benefits (Sampaio *et al*. 2011; Emingil *et al*. 2012; Han *et al*. 2012; Morales *et al*. 2018).

Which antimicrobial(s) would provide the most predictable results? Weighting the evidence: clinical outcomes in randomized clinical trials and systematic reviews

RCTs and systematic reviews with meta-analysis represent the highest level of evidence to assess the clinical effectiveness of a new intervention (Bero & Rennie 1995; Cook *et al*. 1995; Liberati *et al*. 2009; Spieth *et al*. 2016). These studies are the main pillars of what has been named "evidence-based clinical practice" (Bero & Rennie 1995; Cook *et al*. 1995; Bahtsevani *et al*. 2004). Thus, this section will present the results of such studies, in an attempt to determine the weight of evidence for the use of different systemic antimicrobials in the treatment of periodontitis.

RCTs testing adjunctive systemic antimicrobials in periodontal treatment have evaluated a variety of different agents or combinations. The majority of these studies have presented data for up to 6 months of follow-up and fewer provided longer term (≥1 year) data (Herrera *et al*. 2002; Haffajee *et al*. 2003b; Feres *et al*. 2015; Teughels *et al*. 2020). In general, clinical guidelines suggest that the best evidence for the use of a new treatment comes from studies with at least 1 year of follow-up and more than 100 patients (Hadorn *et al*. 1996). Nonetheless, such data are not always available in the literature, due to difficulties in selecting patients with less prevalent conditions and in retaining patients in studies for long periods of time. Thus, in periodontology, RCTs with at least 6 months of follow-up are normally accepted as good evidence to support the use of new treatment protocols (Herrera *et al*. 2002). Twenty-eight placebo-controlled (Al-Joburi *et al*. 1989; Bain *et al*. 1994; Berglundh *et al*. 1998; Rooney *et al*. 2002; Guerrero *et al*. 2005; Haas *et al*. 2008; Cionca *et al*. 2009; Mestnik *et al*. 2010; Oteo *et al*. 2010; Basegmez *et al*. 2011; Sampaio *et al*. 2011; Heller *et al*. 2011; Pradeep and Kathariya, 2011; Aimetti *et al*. 2012; Casarin *et al*. 2012; Emingil *et al*. 2012; Feres *et al*. 2012; Han *et al*. 2012; Pradeep *et al*. 2012; Preus *et al*. 2013; Ardila *et al*. 2015; Harks *et al*. 2015; Martande *et al*. 2016; Taiete *et al*. 2016; Andere *et al*. 2017; Borges *et al*. 2017; Cosgarea *et al*. 2017; Morales *et al*. 2018) and 19 non-placebo controlled RCTs (Lindhe *et al*. 1983b; Saxén & Asikainen 1993; Flemmig *et al*. 1998; Palmer *et al*. 1999; Ramberg *et al*. 2001; Blandino *et al*. 2004; Vergani *et al*. 2004; Ehmke *et al*. 2005; Mascarenhas *et al*. 2005; Xajigeorgiou *et al*. 2006; Gomi *et al*. 2007; Haffajee *et al*. 2007; Kaner *et al*. 2007; Guentsch *et al*. 2008; Yashima *et al*. 2009; Yek *et al*. 2010; Beliveau *et al*. 2012; Goodson *et al*. 2012; Jentsch *et al*. 2016), with at least 6 months of follow-up, have described the clinical outcomes of systemic antibiotics as adjuncts to SRP or subgingival mechanical instrumentation in periodontal treatment in systemically healthy individuals.

A recent systematic review, presented at the XVI European Workshop in Periodontology (2019), has evaluated the results of the 28 placebo-controlled studies available, which were reported in 34 publications (Teughels *et al*. 2020). The following agents were tested: MTZ+AMX ($n=17$), AZI ($n=7$), MTZ ($n=4$), spiramycin ($n=2$), clarithromycin (CLAR, $n=2$), moxifloxacin (MOX, $n=1$), AMX ($n=1$), minocycline (MINO, $n=1$), tetracycline ($n=1$), and ornidazole ($n=1$). Overall, the results of the meta-analysis, including 24 studies, suggested that antibiotics, adjunctive to SRP, led to a statistically significant additional full-mouth PD reduction and CAL gain, in agreement with observations from previous systematic reviews (Herrera *et al*. 2002, 2008; Haffajee *et al*. 2003b; Sgolastra *et al*. 2012a, b, 2014; Zandbergen *et al*. 2013, 2016; Keestra *et al*. 2015a, b; Rabelo *et al*. 2015). The level of evidence varied substantially among the different antibiotics studied. MTZ+AMX was the only adjunct supported by a high level of evidence, based on the results of 11 placebo-controlled RCTs, seven of them providing data for up to 1 or 2 years year of follow-up (Berglundh *et al*. 1998; Mestnik *et al*. 2010; Feres *et al*. 2012; Preus *et al*. 2013; Harks *et al*. 2015; Cosgarea *et al*. 2016; Borges *et al*. 2017). This treatment protocol led to statistically significant benefits over those obtained with SRP-only in all clinical outcomes evaluated, including PD reduction (primary outcome variable) and CAL gain in full-mouth and in initially moderately deep and deep pockets, percentage of pocket closure (sites changing from PD ≥4 to PD ≤3 mm) and frequency of pockets ≥4, 5, 6, and 7 mm, as well as of sites showing BoP. The level of evidence for the benefits brought about by the adjunctive use of MTZ and AZI was assessed as moderate, but the results for MTZ were more consistent. Although only two studies evaluated MTZ (Feres *et al*. 2012; Preus *et al*. 2013), the results were quite consistent in showing benefits of this agent, while the findings of the seven studies that assessed AZI were somewhat controversial. While three studies showed a significant benefit in CAL gain (Oteo *et al*. 2010; Emingil *et al*. 2012; Martande *et al*. 2016), another four studies described none or minor benefits for this parameter with the adjunctive use of AZI (Haas *et al*. 2008; Sampaio *et al*. 2011; Han *et al*. 2012; Morales *et al*. 2018). The level of evidence for CLAR, MINO, and MOX was considered low.

A rather relevant clinical benefit, that has been consistently demonstrated in patients treated with adjunctive MTZ+AMX, and to a lesser extent with MTZ, is the efficacy of these agents in reducing residual pockets, above the reduction obtained with mechanical treatment only (Guerrero *et al*. 2005; Cionca *et al*. 2009; Feres *et al*. 2012; Mestnik *et al*. 2012; Mombelli *et al*. 2013; Miranda *et al*. 2014; Borges *et al*. 2017; Cosgarea *et al*. 2017). These results have direct clinical implications, since a robust long-term risk assessment study showed that the presence of nine or more sites with PD ≥5 mm or of at least one site with PD ≥6 mm after treatment were associated with future disease progression in a population of 172 subjects treated for periodontitis, and in periodontal maintenance for an average period of 11.3 years (Matuliene *et al*. 2008). Other authors have also discussed the association between the presence of residual pockets, with and/or without BoP, and the lack of periodontal stability (Claffey & Egelberg 1995; Renvert & Persson 2002; Lang & Tonetti, 2003; Cionca *et al*. 2009; Feres *et al*. 2012; Borges *et al*. 2017; Graetz *et al*. 2017; Tonetti *et al*. 2018). Figure 36-4 provides a clear representation of the prominent effect of MTZ+AMX, and to a lesser extent MTZ, in reducing the number of sites with PD ≥5 mm at 6- and 12-months post-therapy (Teughels *et al*. 2020).

Additional interesting findings regarding the effect of antibiotics in reducing deep sites have been recently published. The presence of, at most, four sites with PD ≥5 mm, which has been proposed as a clinical endpoint for active periodontal treatment in clinical trials (Feres *et al*. 2012, 2020a), were reported by the six RCTs with 1–2 years of follow-up that tested MTZ+AMX (Feres *et al*. 2012; Mestnik *et al*. 2012; Harks *et al*. 2015; Tamashiro *et al*. 2016; Cosgarea *et al*. 2017; Borges *et al*. 2017). Taken together, these studies showed that 53–72% of the patients taking MTZ+AMX were able to achieve this clinical outcome, as opposed to 6.6–36.5% of the patients receiving mechanical treatment only. One study (Feres *et al*. 2012), comparing MTZ+AMX and MTZ, reported similar benefits for these two agents: 61.6% of the patients treated by SRP and MTZ achieved the clinical endpoint for treatment, 67.7% of those treated by means of SRP and MTZ+AMX, and 22.5% with SRP alone.

In summary, the available evidence has demonstrated an added clinical benefit of MTZ+AMX, and to a lesser extent of MTZ alone, in reducing the number of residual sites, which may impact the long-term clinical stability of treated periodontitis patients, together with the advantage of reducing the need for periodontal surgeries. Indeed, the reduced need for periodontal surgeries with the use of adjunctive MTZ was suggested by Walter Loesche almost 30 years ago (Loesche *et al*. 1987, 1991) and this same effect has recently been confirmed, for MTZ+AMX, in an elegantly designed RCT (Mombelli *et al*. 2015).

Which antimicrobial(s) would provide the most predictable results? Microbiological impact

The clinical benefits achieved with the adjunctive use of MTZ alone, or MTZ+AMX to SRP, are closely associated with the striking effect of these treatment protocols in reducing specific periodontal pathogens and in changing the subgingival microbial profile associated with disease to a profile compatible with periodontal health (Haffajee *et al*. 2006; Cionca *et al*. 2009; Mestnik *et al*. 2010; Heller *et al*. 2011; Silva

et al. 2011; Casarin *et al*. 2012; Miranda *et al*. 2014; Soares *et al*. 2014; Feres *et al*. 2015; Tamashiro *et al*. 2016; Usin *et al*. 2016; Mombelli *et al*. 2017). Figure 36-5 describes the mean proportions of microbial complexes at 1-year post-treatment in subgingival biofilm samples taken from subjects with severe periodontitis treated with: (1) SRP alone ($n = 55$); (2) SRP combined with 400 mg of MTZ, three times daily for 14 days ($n = 45$); or (3) SRP with 400 mg of MTZ + 500 mg of AMX, three times daily for 14 days ($n = 54$) (Feres *et al*. 2015). Nine subgingival biofilm samples were taken from each subject at each time point (baseline and at 3 and 6 months and 1-year post-treatment) and individually analyzed to determine their content of 40 bacterial species by checkerboard DNA–DNA hybridization. The overall proportions of the complexes harboring the pathogens (red and orange) decreased, while those harboring beneficial species increased over the course of the study, in all treatment groups. At 1-year post-treatment, subjects taking antibiotics exhibited a microbial profile more compatible with periodontal health than the control group, treated by SRP alone. Antibiotic treated subjects presented lower proportions of red and orange complexes, in comparison with those receiving SRP only, whereas subjects taking MTZ+AMX had an additional benefit, which was higher proportions of the host compatible *Actinomyces* spp., in comparison with the other two treatments (Fig. 36-5).

As mentioned in the first section of this chapter, the introduction of NGS technologies to study the oral microbiota has allowed a systematic evaluation of the periodontal microbiome, including the effects of treatments in the whole bacterial community. Thirteen interventional studies to date have assessed post-treatment changes occurring in the subgingival microbiome using sequencing techniques (Sakamoto *et al*. 2004; Valenza *et al*. 2009; Jünemann *et al*. 2012; Laksmana *et al*. 2012; Shi *et al*. 2015; Bizzarro *et al*. 2016; Martelli *et al*. 2016; Belstrøm *et al*. 2017; Han *et al*. 2017; Hagenfeld *et al*. 2018; Liu *et al*. 2018; Chen *et al*. 2018b; Feres *et al*. 2020b), including two RCTs (Bizzarro *et al*. 2016; Hagenfeld *et al*. 2018). SRP was the standard treatment in all studies, and systemic MTZ+AMX was used as adjunct in five investigations (Valenza *et al*. 2009; Jünemann *et al*. 2012; Laksmana *et al*. 2012; Bizzarro *et al*. 2016; Hagenfeld *et al*. 2018). Because the studies using these techniques were too diverse in terms of patients included, treatments used, and follow-up time periods, it is still difficult to draw definitive conclusions in terms of the effects of specific treatment protocols in changing abundance of these species. The results of the two RCTs and one clinical study that directly compared mechanical treatment alone or with adjunctive MTZ+AMX, revealed a more beneficial change in the microbiome when the antibiotics were used (Jünemann *et al*. 2012; Bizzarro *et al*. 2016; Hagenfeld *et al*. 2018). All three studies showed that antibiotics were more effective than SRP alone in reducing the proportions of species from the genera *Porphyromonas* and *Treponema* and in fostering host-compatible species from the genera *Veillonella* and *Haemophillus*. Other genera more affected by systemic antibiotics than by mechanical treatment alone were *Synergistetes*, *Filifactor*, and *Tannerella*, all three of them comprising pathogens. The study of Bizzarro *et al*. (2016) was the only one to provide microbiological data up to 1-year post-treatment for 37 patients. Although some rebound was observed, most of the beneficial effects of the antibiotics on the microbiome were maintained over time. Hagenfeld *et al*. (2018) included the larger sample size and provided data for 96 subjects up to 2 months post-treatment. These authors showed a clear compositional separation for samples taken before and after treatment in the antibiotic group, but not in subjects receiving subgingival instrumentation alone. These differences before and after antibiotic treatment in hierarchical clustering seemed to be associated with the striking and significant reductions in genera harboring periodontal pathogens and a concomitant increase in those harboring health-associated species. This trend was not observed with subgingival instrumentation alone. Although the results of these studies have provided an initial view of the effects of treatment in modulating the dysbiotic microbiome observed in periodontitis, it is essential to conduct further clinical trials evaluating many patients and individual samples to extend the current knowledge in this field.

The overall changes in biofilms achieved with MTZ+AMX intake may be due to a series of ecological benefits: (1) the effect of these antimicrobials in reducing the numbers of major periodontal pathogens, such as the impact of MTZ on *P. gingivalis* and other strict anaerobes, and of MTZ+AMX on *A. actinomycetemcomitans* (van Winkelhoff *et al*. 1989; Goené *et al*. 1990; van Winkelhoff *et al*. 1992; Berglundh *et al*. 1998; Flemmig *et al*. 1998; Winkel *et al*. 1998); (2) these antimicrobials could potentially control periodontal pathogens present on the other oral surfaces, tissues, fluids, epithelial cells, and connective tissue; and (3) the broad-spectrum activity of AMX might potentiate the effect of SRP, leading to a more rapid and profound reduction of the bacterial load in the subgingival space.

Another possible role of the antibiotics administrated at the initial phase (step 2) of periodontal therapy is to suppress the overgrowth of species, such as some proteolytic pathogens, that could benefit from tissue damage during subgingival scaling (Feres *et al*. 2015). This would diminish inflammation in the local tissues during healing, which, in turn, would hinder an increase in the proportions of these same pathogens, a common event in microbial ecology, where colonizing species affect the habitat, and the habitat affects the colonizing organisms (Socransky & Haffajee 2002). The combination of all these effects would allow a recolonization of the recently scaled pockets by the host-compatible initial colonizers, preventing the species of the red complex (and possibly

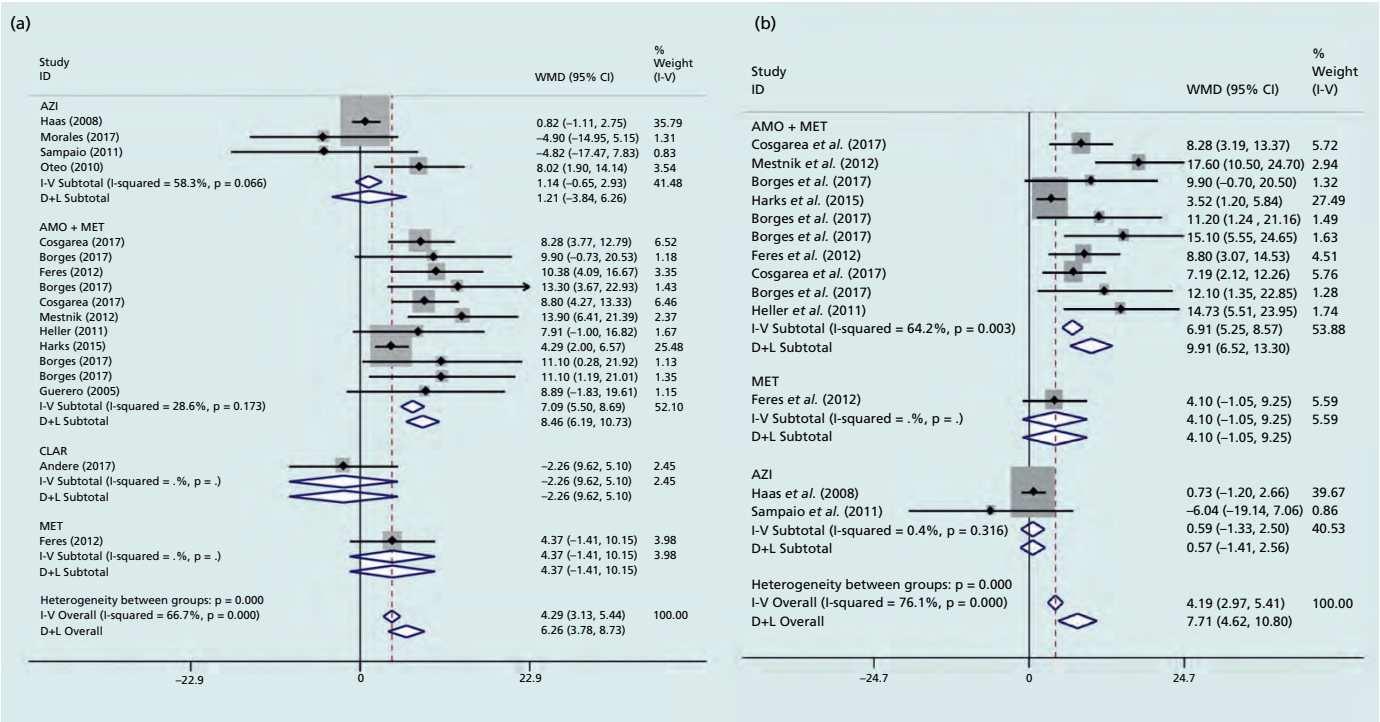

Fig. 36-4 Forest plot: meta-analysis for change in frequency of pockets ≥5 mm, 6 months (a) and 12 months (b), all types of periodontitis. (Source: Adapted from Teughels *et al*. 2020. AZI, azithromycin; AMO, amoxicillin; MET, metronidazole; CLAR, clarithromycin.

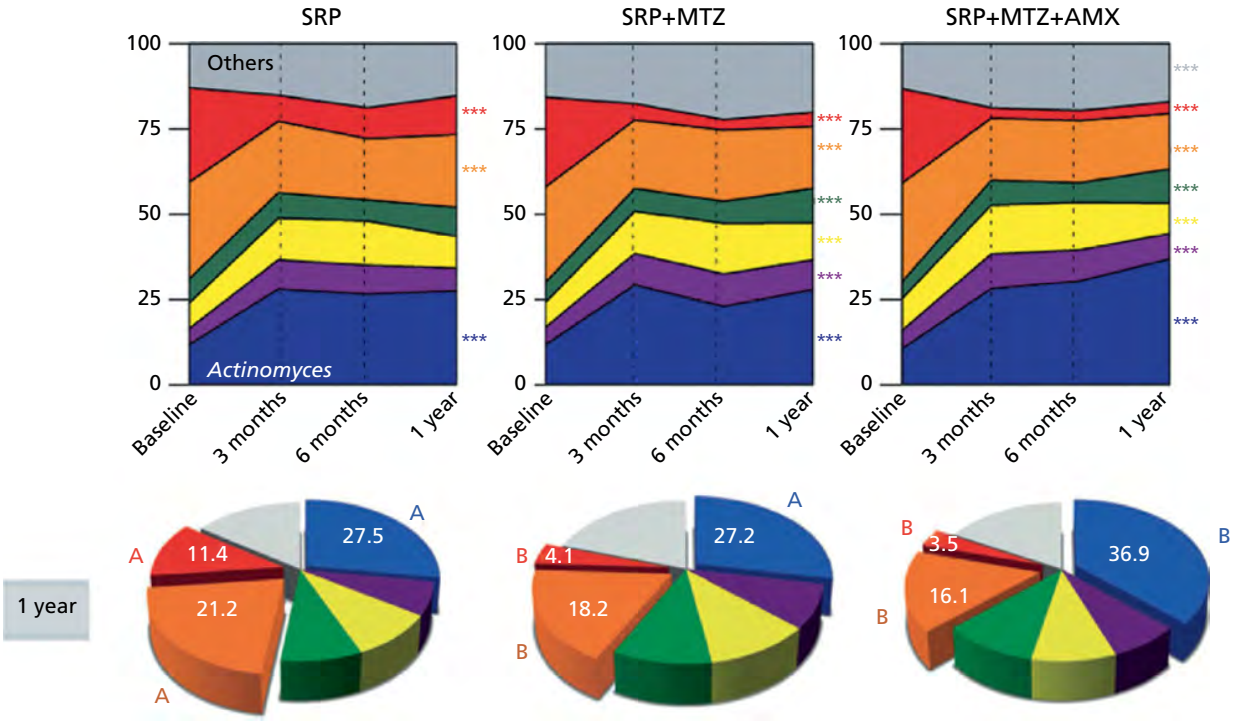

Fig. 36-5 Cumulative mean proportions of microbial complexes, as well as pie charts describing the mean proportions of microbial complexes at 1-year post-treatment, in subgingival biofilm samples taken from subjects with severe periodontitis treated with scaling and root planing (SRP) alone or with adjunctive systemic metronidazole (MTZ) or MTZ plus amoxicillin (AMX). The colors represent the different complexes described by Socransky *et al*. (1998). The grey color ('Others') represents species that did not fall into any complex, and *Actinomyces* spp. are represented in blue. The significance of differences among time points was determined using repeated-measures analysis of variance (***P <0.001). The significance of differences among groups at 1-year post-treatment was determined using one-way analysis of variance and Tukey's multiple comparison tests (different letters indicate significant differences between pairs of groups, P <0.05). (Source: Adapted from Feres *et al*. 2015. Reproduced with permission from John Wiley & Sons.)

other pathogens) from recolonizing in high numbers and proportions (Feres *et al*. 2015; Soares *et al*. 2014; Tamashiro *et al*. 2016; Hagenfeld *et al*. 2018; Feres *et al*. 2020b).

Which subjects would benefit most from systemic antimicrobial therapy?

As indicated in the previous section, there is consistent evidence from the literature showing that the adjunctive use of systemic antimicrobials improves the outcomes of SRP. It is also clear from the results of the available studies that not all patients with periodontitis equally benefit from these agents. Hence, in order to properly use systemic antimicrobials in the treatment of periodontitis, it is crucial to define which patients would consistently benefit from this adjunctive treatment.

Pioneer studies using tetracycline (Lindhe & Liljenberg 1984; Novak *et al*. 1988, 1991) and doxycycline (Pascale *et al*. 1986; Mandell & Socransky 1988) and later, MTZ+AMX (Beliveau *et al*. 2012; Merchant *et al*. 2014; Miller *et al*. 2017; Burgess *et al*. 2017), in the treatment of young subjects with localized (juvenile or aggressive) periodontitis, clearly indicated the benefits of systemic antimicrobials in the treatment of these patients. Most of them would be classified today as periodontitis with a molar-incisor pattern. Apparently, this therapeutic benefit is largely associated with the reduction of *A. actinomycetemcomitans*, which is difficult to control by mechanical treatment only (Christersson *et al*. 1985; Renvert *et al*. 1990; Winkel *et al*. 1998). At least two studies suggested that young subjects with periodontitis are highly colonized by *A. actinomycetemcomitans*, and the levels and proportions of this pathogen may decrease with increasing age (Rodenburg *et al*. 1990; Faveri *et al*. 2009). Thus, very young subjects with periodontal destruction should be treated with adjunctive antimicrobials, with the best evidence for MTZ+AMX.

The use of adjunctive antibiotics in the treatment of young adults and adults has been a subject of continuous debate. Some clinical studies have suggested that only adults colonized by *A. actinomycetemcomitans* should be treated with MTZ+AMX (van Winkelhoff *et al*. 1989; Pavicic *et al*. 1992, 1994; van Winkelhoff *et al*. 1992; Flemmig *et al*. 1998), while MTZ demonstrated a good effect in patients colonized by *P. gingivalis* or those refractory to treatment (Winkel *et al*. 1997; Soder *et al*. 1999). However, at least four RCTs showed that adults not colonized by *A. actinomycetemcomitans* also benefited from adjunctive MTZ+AMX (Winkel *et al*. 2001; Rooney *et al*. 2002; Cionca *et al*. 2010; Mombelli *et al*. 2013), although patients colonized by this species at baseline benefited the most from this treatment protocol (Flemmig

et al. 1998; Winkel *et al*. 2001). A recent systematic review indicated that SRP with MTZ+AMX was more effective than SRP alone in reducing pockets (PD ≥5 mm), irrespective of *A. actinomycetemcomitans* detection at baseline (Nibali *et al*. 2019). As alluded in the previous section, MTZ+AMX, and also MTZ, promote a broad rebiosis in the subgingival microbial biofilm that seems to go beyond their effects in controlling *A. actinomycetemcomitans*. The benefits in the biofilm composition include a striking reduction in several periodontal pathogens from the red and orange complexes and some newly identified taxa, and an increase in the proportions of host-compatibles species (Haffajee *et al*. 2006; Mestnik *et al*. 2010; Silva *et al*. 2011; Soares *et al*. 2014; Tamashiro *et al*. 2016; Hagenfeld *et al*. 2018; Feres *et al*. 2020b) (Fig. 36-5). Altogether, these data indicate a lack of evidence that the decision-making regarding antibiotic prescription should be based on the colonization of specific microorganisms. Determining clinical parameters/profiles that may guide this therapeutic decision may be an alternative practical approach.

In 1999, two main clinical categories of periodontitis (phenotypes) were described: aggressive and chronic (Armitage 1999). Since then, innumerous studies have explored specific differences in the subgingival microbial composition between chronic and aggressive periodontitis. The abovementioned pioneer investigations showing high prevalence and levels of *A. actinomycetemcomitans* in young patients with aggressive periodontitis contributed to the formation of the long-lasting notion in the periodontal field that only young patients with aggressive periodontitis would benefit from adjunctive antibiotics. Nonetheless, over the years, clear differences in the pathobiology of these two clinical conditions were not confirmed. A recent systematic review evaluated 56 studies that compared microbiological data of chronic and aggressive patients and concluded that, to date, no species or groups of microorganisms were unique to or could differentiate between these two disease categories (Montenegro *et al*. 2020). Other studies also failed to show distinct immune-inflammatory responses of subjects with chronic and aggressive periodontitis (Duarte *et al*. 2015; Amaral *et al*. 2019). Indeed, the most recent systematic review and meta-analysis on the effects of antibiotics in periodontal treatment described significant benefits with the use of these agents, specifically for MTZ+AMX, but these benefits did not differ between aggressive and chronic periodontitis (Teughels *et al*. 2020). These findings supported the current classification scheme for periodontal diseases and conditions that grouped aggressive and chronic periodontitis in one single condition named periodontitis (Papapanou *et al*. 2018; Tonetti *et al*. 2018). This classification scheme applies a staging and grading system that allows the assessment of several dimensions of the disease, including severity/past destruction, complexity of treatment, and risk for future disease progression, based on grade modifiers (e.g. smoking and diabetes). It represents a central paradigm-shifting in the periodontal field and an important step towards personalized care (for review, see Chapter 16). Thus, researchers and clinicians should now make an effort to extrapolate the results of the available studies, entirely based on chronic and aggressive periodontitis, to treat patients that will, from now on, be classified according to stages and grades. A detailed evaluation of the inclusion criteria and baseline data of the RCTs testing systemic antibiotics for periodontal treatment suggest that most studies included patients with generalized stage III and stage IV periodontitis. Very few studies have assessed patients with mild or moderate disease (Dastoor *et al*. 2007; Haffajee *et al*. 2007; Oteo *et al*. 2010; Preus *et al*. 2017), and the additional benefits of antibiotics in those cases were not so evident. Additionally, patients with less severe disease and shallower pockets respond well to mechanical treatment alone (Jepsen & Jepsen 2016). Thus, the current literature indicates that systemic antibiotics in adult patients should be restricted for those with generalized stage III and stage IV periodontitis.

Another aspect to be considered when defining the adjunctive use of antibiotics in the treatment plan is the presence of a risk factor/grade modifier, e.g. smoking and diabetes. Smokers are a group of individuals who might particularly benefit from systemic antibiotics because they respond less favorably to mechanical periodontal treatment (Haffajee & Socransky 2001; Labriola *et al*. 2005; Heasman *et al*. 2006; Johnson & Guthmiller 2007). Apparently, it is more difficult to reduce periodontal pathogens and to foster the growth of host-compatible species in smokers than in non-smokers (Darby *et al*. 2005; Mascarenhas *et al*. 2005; Grossi *et al*. 2007; Matarazzo *et al*. 2008; Meulman *et al*. 2012), most probably because of their impaired immune system and inflammatory response (Kinane & Chestnutt 2000; Palmer *et al*. 2005; Ryder 2007; Mouzakiti *et al*. 2012). Some clinical studies have suggested that AZI (Mascarenhas *et al*. 2005), MTZ (Soder *et al*. 1999) or MTZ+AMX (Pahkla *et al*. 2006; Matarazzo *et al*. 2008) may improve the outcomes of mechanical treatment of smokers, with MTZ+AMX showing the most encouraging results (Matarazzo *et al*. 2008). However, smokers do not seem to respond as well as non-smokers to these agents as they exhibit more residual pockets and less mean reduction in PD and CAL than non-smokers after being treated with SRP plus MTZ+AMX (Faveri *et al*. 2014). This impaired clinical response of smokers to different periodontal treatments seem to be associated with a lack of reduction in the levels and proportions of the putative pathogens from the orange complex, in particular *Fusobacterium* spp. (Matarazzo *et al*. 2008).

Systemic antibiotics have also been proposed in the treatment of patients with diabetes mellitus, a major risk factor for periodontitis. Patients with diabetes present increased prevalence and severity of

periodontal destruction, compared with systemically healthy individuals (Llambes *et al*. 2015), although they do not seem to have a poorer clinical response to treatment when compared with non-diabetic patients (Duarte *et al*. 2018). SRP provides significant clinical benefits in the treatment of diabetic patients, but many of these patients still present a high number of residual pockets as well as high proportions of periodontal pathogens after mechanical treatment alone (Santos *et al*. 2013; Tamashiro *et al*. 2016). Thus, there has been an increasing interest in studying adjunctive therapies that could improve the clinical and microbiological outcomes of SRP in these patients, including systemic antibiotics (Grellmann *et al*. 2016; Souto *et al*. 2018). Nonetheless, only a few RCTs to date have assessed the effects of adjunctive antibiotics in the treatment of diabetic patients, and the most widely studied agent is doxycycline. There was a general belief that doxycycline could provide benefits for diabetic patients due to its ability to inhibit matrix metalloproteinase activity, but the results from RCTs using this agent were not very encouraging (Singh *et al*. 2008; Al-Zahrani *et al*. 2009; Gaikwad *et al*. 2013; Al-Zahrani *et al*. 2014; Tsalikis *et al*. 2014). A systematic review, with a meta-analysis of five studies, has suggested only a modest benefit from the use of adjunctive antibiotics in PD reduction and in mean percentage of sites with BoP in diabetic patients (Grellmann *et al*. 2016). Three of these studies tested doxycycline, including one that used low-dose doxycycline, which does not present antimicrobial effects. In 2014, the first RCT on the effects of MTZ+AMX in the treatment of patients with type 2 diabetes was published (Miranda *et al*. 2014). The results of that study and of a subsequent paper reporting the 2-year follow-up of these patients (Tamashiro *et al*. 2016) showed important additional clinical and microbiological benefits in the test group. For up to 2 years post-treatment, the antibiotic-treated subjects presented an average of 10 less residual sites with PD ≥5 mm, than those who received SRP alone, and 76% of the subjects in the antibiotic-treated group reached the clinical endpoint for treatment "≤4 sites with PD ≥5 mm" (Feres *et al*. 2020a), as opposed to only 22% of the subjects treated by means of SRP-only. Furthermore, MTZ+AMX intake was the only significant predictor for subjects achieving this clinical endpoint at 2 years with an odds ratio (OR) of 20.9 (P <0.001). The important reduction in the number of residual pockets with the use of MTZ+AMX and, consequently, in the need for surgical interventions, may represent a major benefit for patients with diabetes. Besides the stress and financial costs associated with surgical procedures, diabetic subjects have a lower healing capacity, which may hamper or complicate their recovery from surgeries (Tsourdi *et al*. 2013; Miranda *et al*. 2014).

In summary, the current literature suggests that some patient groups may benefit the most from systemic antibiotics: (1) young subjects, especially those with periodontitis with a molar-incisor pattern; (2) adult patients with generalized stage III and stage IV periodontitis; and (3) those cases associated with grade modifiers (e.g. diabetes). A future challenge will be to define which individuals, among those presenting stages III and IV periodontitis, would benefit even further from treatment. A recent analysis in 345 patients treated or not with adjunctive MTZ+AMX and followed for 2 years suggested that patients <55 years of age, or with ≥35% sites with PD ≥5 mm, or with a mean CAL level >5 mm at baseline, would benefit the most from this treatment protocol. Patients presenting at least one of these clinical features, who took MTZ+AMX, showed a greater reduction in median CAL after 2 years, when compared with those not taking antibiotics (Eickholz *et al*. 2019). Further analysis of this type should be conducted in order to better understand the proper and most efficient use of antibiotics in periodontal treatment.

Protocols of use of systemic antimicrobials in periodontics

Defining clear protocols of administration of systemic antibiotics in periodontal treatment is crucial to optimize the effects of these agents and to develop personalized treatments. The main questions to be addressed are: (1) what is the ideal dose and duration of the antibiotic(s); (2) in which step of the periodontal treatment should the antibiotic(s) be prescribed; and (3) if antibiotics should be combined with other treatment protocols to improve efficacy. These questions are addressed in the following sections.

What is the ideal dose and duration of the antimicrobial(s)?

The optimal dose and duration of systemic antibiotics for the treatment of periodontitis have not yet been fully established. These are very important parameters because they may directly impact the desirable (e.g. infection control) and undesirable (e.g. side effects and emergence of bacterial resistance) impacts of the agents. For example, an antibiotic taken above the optimal dose may lead to an increase in the side effects of the drug, whereas an under-dose use may not eliminate the target species but yield bacterial tolerance to the drug.

The dose and duration of adjunctive antibiotics in periodontal treatment have varied significantly since the pioneer studies conducted in the 1970s. In those initial studies, tetracyclines were normally prescribed at a dose of 1 g/day for 2–4 weeks (Slots & Rosling 1983; Lindhe & Liljenberg 1984; Kornman & Robertson 1985; Mandell *et al*. 1986; Novak *et al*. 1988; Novak *et al*. 1991) and doxycycline or MINO were prescribed at a dose of 100 or 200 mg/day for 7–21 days (Ciancio *et al*. 1980, 1982; Mandell & Socransky 1988; Müller *et al*. 1993; Xajigeorgiou *et al*. 2006). The recently introduced AZI is usually prescribed at a dose of 500 mg/day for 3–5 days (Smith *et al*. 2002; Mascarenhas *et al*. 2005; Dastoor *et al*. 2007; Yashima

et al. 2009; Oteo *et al*. 2010; Sampaio *et al*. 2011; Haas *et al*. 2012; Han *et al*. 2012; Feres *et al*. 2015; Teughels *et al*. 2020), while MTZ and AMX, or MTZ alone, have been administered for 3, 7, 10, or 14 days (Feres *et al*. 2015; Teughels *et al*. 2020). The dose of MTZ varies substantially (e.g. 200, 250, 400, and 500 mg/three times daily), while AMX seems to be an exception as it has normally been prescribed at a dose of 500 mg three times daily, although the pioneer studies by van Winkelhoff and colleagues used a dose of 375 mg (Pavicic *et al*. 1994).

Only a few studies to date have directly compared different durations of antibiotic intake in periodontal treatment, and they have all assessed MTZ+AMX. Two RCTs tested MTZ+AMX for 3 or 7 days (Cosgarea *et al*. 2016; Boia *et al*. 2019). While Cosgarea *et al*. (2016, 2017) showed similar benefits with both protocols, Boia *et al*. (2019) observed that 7 days of antibiotic intake was more effective than 3 days in improving clinical parameters and reducing several periodontal pathogens. Borges *et al*. (2017) compared 7 and 14 days of MTZ+AMX administration and two different dosages of MTZ (250 and 400 mg) in the treatment of adults with severe periodontitis and provided data for up to 1 year of follow-up. The duration of antibiotic intake had a greater impact on treatment outcomes than the dose of MTZ, and no differences in side effects were observed with the different protocols tested. The authors concluded that adjunctive use of 400 or 250 mg of MTZ plus 500 mg of AMX three times daily for 14 days offered statistically significant and clinically relevant benefits over those achieved with SRP alone. The added benefits of the 7-day regimen in this population were less evident. However, it should be highlighted that studies using 7 days of MTZ+AMX administration have also provided clinical important advantages over SRP alone (Guerrero *et al*. 2005; Xajigeorgiou *et al*. 2006; Cionca *et al*. 2009; Yek *et al*. 2010; Aimetti *et al*. 2012; Harks *et al*. 2015). Differences in severity of disease may partially explain the efficacy of MTZ+AMX administered during different periods of time. For example, Harks *et al*. (2015) showed that 7 days of adjunctive MTZ (400 mg) + AMX (500 mg), three times a day, provided results similar to those observed in the 14-days group of Borges *et al*. (2017): approximately 60% of the subjects in both studies achieved the clinical endpoint of "≤4 sites with PD ≥5 mm" (Feres *et al*. 2020a) post-treatment. Nonetheless, the population treated by Harks *et al*. (2015) had less severe disease than that treated by Borges *et al*. (2017).

In which phase of the mechanical treatment should the antimicrobial be prescribed?

Two different questions, related to the ideal timing for systemic antimicrobial prescription in periodontal treatment, should be addressed: (1) should it be administered during the active phase of therapy or after re-evaluation (i.e. 3 or 6 months after active treatment), and (2) should it be administered on the first or last day of the SRP procedure?

To date, no RCT has directly compared the effects of systemic antibiotics administered during the active phase of therapy or after re-evaluation. Two previous investigations, one retrospective study (Kaner *et al*. 2007), and a RCT (Griffiths *et al*. 2011), have indirectly addressed this topic, and the results of both studies suggested greater clinical benefits when MTZ+AMX was prescribed at the initial phase of therapy, than after the re-evaluation. Similarly, two clinical studies described the effects of MTZ+AMX either during or after the initial phase of treatment, in young patients with periodontitis with molar/incisor pattern (Beliveau *et al*. 2012), or in adults with generalized stage III and stage IV periodontitis (Mombelli *et al*. 2015). Both studies indicated that MTZ+AMX given at the active phase of treatment allowed for better clinical improvements early in the course of treatment and was thus associated with a reduction in the need for additional interventions.

When assessing if the drugs should be administered at the first or after the last session of SRP, no RCT has directly addressed this question, but there is a strong biological reason for administering the antibiotics immediately after the subgingival mechanical disruption of biofilm (Herrera *et al*. 2008), and the consensus of the European Workshop clearly suggested that biofilm disruption should precede antibiotic prescription, that disruption should be accomplished in a short period of time (limited time between appointments), and the prescription should start immediately after the last session of debridement (Sanz *et al*. 2008). The main advantage of such protocol is to reduce the protective effect of the biofilm before the drug is delivered to the site of infection. Indeed, most RCTs have used this strategy, either by starting antibiotic intake 1 or 2 days after full-mouth SRP (Guerrero *et al*. 2005; Harks *et al*. 2015) or after the first session of full-mouth debridement followed by quadrant-wise scaling (Carvalho *et al*. 2004; Matarazzo *et al*. 2008; Silva *et al*. 2011; Feres *et al*. 2012; Goodson *et al*. 2012; Mestnik *et al*. 2012; Borges *et al*. 2017).

The abovementioned observations, suggesting that antibiotics should be administered during the active phase of treatment and right after disruption of the subgingival biofilm, are in line with the notion, already strengthened in this chapter, that a rapid and striking reduction in the subgingival microbiota would be necessary in order to obtain the most beneficial recolonization possible of the recently scaled pockets. Milder and sequential perturbations to the mature biofilm might not be enough to change its highly stable and resilient climax community (Socransky & Haffajee 2002). More assertive treatments applied at once, such as the association of SRP and systemic antibiotics during the initial therapy (step 2), may have greater potential to create an entirely new and stable climax community, similar to that observed in health.

Should antimicrobials be combined with other treatment protocols to improve its efficacy?

Some studies have shown important clinical and/or microbiological benefits when the administration of systemic antibiotics, more specifically MTZ or MTZ+AMX, are combined with a weekly professional removal of the supragingival biofilm for 3 months or with chemical control of biofilm by means of chlorhexidine rinsing for 2 months (Haffajee *et al*. 2003a; Carvalho *et al*. 2004, 2005; Feres *et al*. 2012; Soares *et al*. 2014). These data are in line with previous publications suggesting that strict mechanical (Nyman *et al*. 1975; Rosling *et al*. 1976; Lindhe *et al*. 1982a, b; Westfelt *et al*. 1983; Ximenez-Fyvie *et al*. 2000) or chemical (Faveri *et al*. 2006b; Feres *et al*. 2009) control of supragingival plaque, during and after mechanical treatment, positively impact clinical parameters and the composition of the subgingival biofilm. These favorable results may be attributed to preventing periodontal pathogen migration to recently scaled pockets, as it has been recognized that several of these species may colonize the supragingival environment (Ximenez-Fyvie *et al*. 2000). An indirect effect may be related to the reduction of inflammation on the adjacent periodontal tissues, and the consequent reduction on the availability of nutrients necessary for the multiplication of proteolytic pathogens (Socransky & Haffajee 2002). In addition, the beneficial effects of chlorhexidine rinsing in changing the subgingival microbial composition, when used in combination with SRP (Feres *et al*. 2009) or with MTZ+AMX (Soares *et al*. 2014) may be correlated to the effect of this antiseptic in reducing periodontal pathogen reservoirs, that are not reached by the mechanical removal of supragingival biofilm, such as the tongue (Faveri *et al*. 2006a), saliva and, oral mucosa (Mager *et al*. 2003).

Finally, it should be highlighted that all RCTs published to date, showing benefits for systemic antimicrobials in clinical and microbiological periodontal parameters, have enrolled patients in a regular maintenance program after initial treatment. Thus, keeping patients under periodontal maintenance with low levels of biofilm is mandatory to assure long-term periodontal stability.

Use of systemic antimicrobials: associated risks

Adverse events/reactions

The use of systemic antibiotics is frequently associated with unwanted/side effects for the individual patient. The systematic review by Teughels *et al*. (2020) included RCTs with 6 months or more of follow-up. Twenty-five of the included studies reported information on adverse events and/or patient reported outcome measures (PROMs), and 22 of them described some of the following events: "nausea/stomach upset/vomiting", "diarrhea/gastrointestinal disturbance", "metallic taste", "oral ulceration", "dizziness", "fever", "headache", "periodontal abscess", "general unwellness (e.g. irritability)" and "allergic reactions". It was concluded that, in general, these side effects were more frequently reported in the antimicrobial (ranging from 0% to 36.36%) than in the placebo (ranging from 0% to 20%) groups and that the highest frequency of each listed side effects was always reported for MTZ+AMX.

Relevant differences in the frequency, type, and severity of adverse effects are evident when comparing different drugs (for review, see Hersh & Moore 2008). Overall, penicillins present low frequency and severity of unwanted effects, being considered among the safest drugs; however, they may induce hypersensitivity reactions, which can be mild (just a skin rash), but may also induce anaphylactic reactions in sensitized patients, which can be life-threatening. Tetracyclines are also considered as very safe, and associated side effects normally affect the digestive tract (pain, vomiting, or diarrhea), although deposition in calcified areas may induce tooth discoloration. AZI, as most macrolides, presents low frequency of adverse events and, when happening, they are usually mild and affecting the digestive tract. Clindamycin and MTZ have been associated with antibiotic-associated colitis and other, less relevant, gastrointestinal problems. In addition, MTZ has been associated with nausea, headache, anorexia and vomiting, especially if combined with alcohol intake (known as Antabuse-like effect) (Mergenhagen *et al*. 2020), peripheral neuropathies, and some carcinogenic risks have been suggested (Adil *et al*. 2018).

Emergence of resistant strains/global increase in antibiotic resistance

Antibacterial drugs have been available for human use since the beginning of the twentieth century, and rapidly became a much used, successful treatment. However, since they started to be used, there were warnings that bacteria could become resistant to antibiotics, as stated by Alexander Fleming during his Nobel Prize speech in 1945. Development of resistance is a normal evolutionary process, but it is clearly and dramatically accelerated by selective pressure derived from widespread and inappropriate use. The increase in bacterial resistance, together with the lack of development of new antimicrobial drugs, is now becoming a major global public health problem, that may challenge global health at completely unseen level (WHO 2014).

Recently, a report requested by the European Centre for Disease Prevention and Control estimated the magnitude of the problem in the European Union and in the European Economic Area (Cassini *et al*. 2019): in 2015, 671 689 infections with antibiotic-resistant bacteria were estimated, with 33 110 attributable deaths and 874 541

disability-adjusted life-years (DALYs). The burden was highest in infants and older people, and had increased since 2007.

Excessive and incorrect use of systemic antimicrobials contributes to the emergence of specific-drug-resistant and multidrug-resistant bacterial species (WHO 2014; Elias *et al*. 2017). It should be noted that the antimicrobial resistance profiles of periodontal pathogens are higher in populations with higher frequencies of exposure to systemic antimicrobials (van Winkelhoff *et al*. 2005). This has led to a call for controls on the use of systemic antimicrobial drugs and, when prescriptions are necessary, that they are used judiciously. For this reason, the "Proposals for EU guidelines on the prudent use of antimicrobials in humans" (ECDC 2017) were developed and published in 2017. Among the general recommendations made for all health professionals, the following are listed: "ensure that appropriate microbiological samples are taken before starting antimicrobial treatment"; "avoid antimicrobial combinations unless there is a clear indication outlined in the guidelines"; "select an antimicrobial in accordance with relevant guidelines, at an appropriate dose, for the shortest effective duration and with appropriate route of administration (preferably oral if possible)"; "select an antimicrobial with a spectrum of activity as narrow as possible". Although, to date, there is no compelling evidence to support the need for microbiological testing to prescribe systemic adjunctive antibiotics in periodontal treatment, more research in this area should be conducted. Similarly, other systemic drugs should be investigated as alternatives to the combination of MTZ and the large spectrum AMX.

Concluding remarks and recommendations for clinical practice

The ecological concepts and clinical data discussed in this chapter support the notion that certain systemic antimicrobial protocols can enhance the effects of periodontal therapy and thus are important adjunctive tools in the treatment of periodontitis. However, there are risks associated with antibiotic intake, such as the worldwide increase in antibiotic resistance and the unwanted systemic effects of these agents. A recently published clinical practice guideline, derived from the consensus report by the European Federation of Periodontology (Sanz *et al*. 2020) has concluded the following, when answering the question "Does adjunctive systemically administered antibiotics improve the clinical outcome of non-surgical periodontal therapy?: (1) due to concerns about patient health and the impact of systemic antibiotic use on public health, its routine use as an adjunct to subgingival debridement in patients with periodontitis is not recommended; (2) the adjunctive use of specific systemic antibiotics may be considered for specific patient categories (e.g. generalized periodontitis stage III in young adults)". Thus, the decision to use an antibiotic to treat periodontitis should be based on an accurate risk–benefit evaluation, based on a thorough evaluation of the RCTs and systematic reviews available. According to the most recent literature discussed in different sections of this chapter, the patients who benefit the most from adjunctive systemic antibiotics are those with generalized stage III and stage IV periodontitis (systemically healthy or with diabetes mellitus), and patients presenting with periodontitis with a molar-incisor pattern.

At present, the most thoroughly documented antibiotic protocol in periodontal therapy is MTZ+AMX. Other agents, including AZI and especially, MTZ, may be considered (Teughels *et al*. 2020), but more studies are necessary in order to establish the real benefits of these agents in clinical practice. The duration and dosage of the MTZ+AMX treatment have been tested by a few RCTs and still needs further assessment (Cosgarea *et al*. 2016; Borges *et al*. 2017; Boia *et al*. 2019). The available literature also suggests that, when indicated, systemic antibiotic intake should start immediately after subgingival biofilm disruption and should not be postponed to the maintenance phase (Kaner *et al*. 2007; Griffiths *et al*. 2011; Beliveau *et al*. 2012).

Finally, the recommendations for prescribers, suggested by the European Centre for Disease Prevention and Control (ECDC 2017), are also relevant for clinicians when deciding whether or not to use systemic antibiotics as adjuncts in periodontal treatment, and for information on how to use them. Of special relevance are those specific recommendations for dentists: "Dentists should prescribe antimicrobials in accordance with guidelines. Antimicrobials should not be used by dentists or other healthcare professionals as a substitute for dental operative intervention". Thus, systemic antibiotics must never replace subgingival instrumentation (e.g. SRP) or be used to compensate for a poorly performed instrumentation.

General principles of local drug delivery

Rationale of local drug delivery

Treatment of periodontitis is routinely based on dental biofilm control, with oral hygiene and supra- and subgingival biofilm instrumentation as main elements (Graziani *et al*. 2017). Given the bacterial etiology and the inflammatory pathogenesis of periodontitis, the adjunctive use of locally applied or systemic administration of antimicrobials and/or host response-modulating medications has been proposed. Localized therapy has received significant attention because of the site-specific pattern of destruction of periodontal infections and the potential side effects of systemic antimicrobials and host-modulating agents. Another important rationale for the development of effective ways to locally apply medications into the periodontal pockets comes from the fact that systemic administration of many medications (and antibiotics in particular) results in marginally effective local concentrations of free, active drug in the periodontal pocket and surrounding tissues.

There are three basic routes to localized adjunctive pharmacologic periodontal therapy:

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

1. *Mouth rinses, toothpaste, or varnishes*. Rinses are useful for supragingival biofilm control, modulation of gingival inflammation, and potentially for recolonization of the subgingival environment following periodontal treatment. Their major limitation, in the context of pharmacologic therapy of periodontitis, is that they do not gain access to the subgingival environment and therefore do not reach the desired site of action (Pitcher *et al*. 1980) (see also Chapter 29).
2. *Subgingival irrigation*. Irrigation solutions placed directly into periodontal pockets initially reach effective concentrations in the area, but the flow of the gingival crevicular fluid (GCF), which is replaced about 40 times per hour, leads to rapid clearance of subgingivally placed drugs. Clearance of a medication locally placed in a periodontal pocket follows exponential kinetics and it has been calculated that the concentration of a highly concentrated irrigating solution of a non-substantive (non-binding) drug becomes ineffective about 15 minutes following application. This time can be prolonged by the application of substantive drugs, such as tetracyclines or chlorhexidine, that bind to the root surface and/or the soft tissue wall of the periodontal pocket and thus establish a drug reservoir that can be slowly released to counteract the clearance by the GCF flow. Limitations on reservoir volume, however, limit the duration of the possible pharmacologic effect. Thus, efficient delivery of pharmacologic agents into the periodontal microenvironment is difficult to achieve using rinses and irrigating solutions.
3. *Periodontal application of local, sustained-release delivery systems*. Goodson, a pharmacologist who in the early 1970s pioneered the field of local delivery to treat periodontitis (Goodson *et al*. 1979), pointed out that successful pharmacologic control of the periodontal microbiota would require:
   - The delivery of an intrinsically efficacious drug to the site of action (periodontal pocket and surrounding tissues).
   - A concentration of the drug higher than the minimum efficacious concentration.
   - The maintenance of this concentration long enough for the effect to occur.

These three principles (namely, site, concentration, and time) are the key parameters in the optimization of local pharmacologic treatment (Goodson 1989, 1996).

Subgingival pharmacokinetics

The action of an intrinsically efficacious drug in a body site is dependent upon the bioavailability of free active medication at the desired location: here, specifically, the periodontal pocket and the neighboring soft and hard tissues. From a pharmacologic standpoint, the periodontal pocket is a challenging microenvironment: it is characterized by the rapid flow of GCF, has a small resting volume, and has an uneven topography. Periodontal pockets are uneven in terms of depth, width, presence of furcation involvements, composition and amounts of subgingival biofilm, and calculus deposits. These characteristics translate into specific difficulties for the design of periodontal local delivery devices.

Clearance of a drug placed into a periodontal pocket follows the exponential function:

$$C_{(t)} = C_{(0)} e^{-t\frac{F}{V}}$$

where $C_{(t)}$ is the concentration of the drug as a function of time (t), $C_{(0)}$ is the initial concentration obtained in the GCF, F is the GCF flow rate, and V is the resting fluid volume of the pocket.

Using an estimated periodontal pocket volume of 0.5 µL (Binder *et al*. 1987) and a GCF flow rate of 20 µL/h (Goodson 1989), the half-time (the time that it takes to reach half of the initial concentration) for a non-substantive medication placed in the periodontal pocket will be 0.017 hours (or about 1 minute). From these calculations, Goodson (1989) concluded that the subgingival irrigation route is theoretically feasible only for very potent (i.e. antimicrobials that can act at very low concentrations) substantive drugs. In the case of a substantive compound, the exponential function can be rewritten by introducing a multiplicative constant K into the denominator of the exponential term to account for binding of the drug to the root surface (and/or periodontal pocket wall):

$$C_{(t)} = C_{(0)} e^{-t\frac{F}{KV}}$$

where K is the affinity constant, which is experimentally estimated from the determined clearance half-time. This equation can be conveniently rearranged to estimate the effect of the various parameters on the duration of the desired therapeutic effect:

$$t_{(MIC)} = \frac{KV}{F} \ln \frac{C_{(0)}}{C_{(MIC)}}$$

where $C_{(MIC)}$ is the minimum inhibitory concentration (MIC) and $t_{(MIC)}$ is the time taken to reach the MIC or the expected time of antibacterial action.

From this relation, it is apparent that the time over which a therapeutic effect is observed ($t_{(MIC)}$) will be longer when the:

- Volume of the pocket is large.
- GCF flow rate is low.
- Affinity constant for the drug is higher, that is a highly substantive drugs is used.
- Initial concentration is very high, that is the drug has good solubility in the applied vehicle.
- Minimum inhibitory concentration (MIC) is low, that is a very potent agent is used.

While the first two parameters relate to the specific disease state of each tooth and thus cannot be easily modified without intervention, the remaining three parameters relate to the choice of drug. Preclinical data related to the *in vitro* antimicrobial susceptibility profile and pharmacokinetic data are at the base of the rationale choice of the active agent.

Development of subgingival delivery devices

To overcome the challenges represented by the pharmacokinetic parameters of the local microenvironment, Goodson designed a first generation of local drug delivery devices for application into periodontal pockets. The concept was to constantly replenish the free drug in the periodontal pocket that is cleared by the GCF flow with the release of drug from a drug reservoir placed into the periodontal pocket (Goodson *et al*. 1979). These devices consisted of permeable hollow cellulose acetate fibers (with an internal thickness of 200 μm) filled with a 20% tetracycline–HCl solution. The fiber was tied around the crevice of the pocket, pressed into the subgingival environment, and removed after 24 hours. In spite of the short duration of application, an important effect on the composition of the subgingival microbiota was observed. A subsequent clinical study compared hollow fibers, left in place for 2 days, with scaling and root planing (SRP). Microbial and clinical parameters improved, but less than in the SRP group (Lindhe *et al*. 1979). These early attempts produced limited clinical outcomes and this was explained by the insufficient duration of drug delivery. Subsequent efforts focused on leaving the delivery device longer in the periodontal pocket, but it became apparent that these devices were exhausted relatively quickly (Addy *et al*. 1982; Coventry & Newman 1982).

Better release profiles were obtained with a second generation of devices characterized by a monolithic design (drug crystals interspersed within an inert matrix), such as acrylic strips or extruded ethylene vinyl acetate fibers (Addy *et al*. 1982; Goodson *et al*. 1983). In particular, following placement of 0.5-mm diameter 25% tetracycline fibers, GCF concentrations in the order of 500–1500 μg/mL were reported (Tonetti *et al*. 1990). Parallel efforts with bioresorbable matrices focused on chlorhexidine in cellulose acetate (Soskolne *et al*. 1983) and on release platforms made of hydroxypropylcellulose (Noguchi *et al*. 1984) or collagen matrices (Minabe *et al*. 1989a, b).

Studies have estimated that the resting fluid volume of a 5-mm pocket is about 0.5 μL (or 0.5 mm^3). While deeper pockets and pockets around dental implants (that also include a sizeable mucosal tunnel) may have a significantly larger volume, these data indicate that any subgingival delivery device needs to be able to expand the pocket volume, in order to establish a large enough drug reservoir that will be able to release free drug over time to counteract the GCF clearance. Early attempts using dimensionally stable acrylic strips or tetracycline fibers achieved pocket expansion.

Phase I and II studies with these devices reported improvements in the microbiota and clinical parameters (Addy & Langeroudi 1984; Goodson *et al*. 1985a, b). The pivotal trial required for regulatory clearance by the USA Food and Drug Administration (FDA) of 25% tetracycline–HCl ethylene vinyl acetate fibers was the first multicenter trial in the field of periodontology to be conducted under stringent quality control and was a stepping stone towards modern clinical trial design and execution in dentistry (Goodson *et al*. 1991a, b).

Over the following three decades, several local antimicrobial delivery devices have been developed and have undergone clinical testing for safety and effectiveness to satisfy clearance by the local regulatory agencies, in order to be available in the market. These products will be presented in the next sections.

Antimicrobial effects of subgingival delivery devices

Early studies, mandated by regulatory agencies to provide proof of efficacy of the locally delivered antimicrobial alone, showed consistent suppression of total bacterial loads and frequency of detection of target pathogens. Later studies, however, showed that better clinical and microbiologic outcomes were obtained by combining mechanical instrumentation with local delivery of the antimicrobial. This established the key role of mechanical instrumentation in successful clinical strategies for application of local delivery devices (Johnson *et al*. 2002).

Clinical studies evaluating microbiologic outcomes of local delivery devices, used in combination with mechanical instrumentation (e.g. SRP), have shown drastic reductions in both total bacterial load and periodontal pathogens counts and detection. With the most effective devices (those delivering high concentrations of intrinsically efficacious antimicrobials for >1 week), suppression of 99–99.9% of total microbial load was reported, leading to effective disinfection of the treated periodontal pocket. After exhaustion of the drug reservoir, however, rapid recolonization was observed. Three possible sources for this recolonization were hypothesized: (1) Regrowth from the residual microbiota from within the periodontal pocket; (2) recolonization from other intraoral areas of infection; (3) re-infection of the patient from other subjects.

Different studies addressed the source of recolonization. The pivotal study by the Goodson group in 1988 led to FDA approval of tetracycline fibers (Goodson *et al*. 1991a, b). They employed tetracycline fibers and SRP, with or without chlorhexidine mouth rinsing, to complete the treatment of the subjects. The hypothesis was that the intraoral antibacterial effect of chlorhexidine would modulate

bacterial recolonization of tetracycline fiber-treated pockets. Results showed that chlorhexidine mouth rinsing over a 28-day period led to significant reductions of the bacterial recolonization profiles for three target pathogens. The data were interpreted as an indication that the overall oral ecology of the patient was a critical determinant of success with this therapeutic modality. This concept was further assessed by a study conducted at the University of Berne. Subjects with generalized periodontitis, who were *Porphyromonas gingivalis* positive, were enrolled into a controlled randomized clinical trial (RCT) testing two extreme forms of therapy: localized treatment of two isolated pockets (with the rest of the dentition being monitored over the study period) and full-mouth disinfection of the whole dentition by tetracycline fiber application, SRP, and chlorhexidine mouth rinsing for 4 weeks. Clinical and radiographic outcomes showed greater improvement in the index teeth of the full-mouth disinfection group compared with the index teeth of the localized treatment group (Mombelli *et al*. 1996, 1997; Fourmousis *et al*. 1998). Most importantly, while similar levels of pocket disinfection were achieved for total bacterial counts, at the time of tetracycline fiber removal, the recolonization kinetics showed rapid return towards baseline bacterial levels in the localized treatment group (Fig. 37-1). Persistent, stable suppression of bacterial levels was observed in the full-mouth disinfection group. Interestingly, early recolonization kinetics predicted clinical (reduction of pocket depth and bleeding on probing) and radiographic (hard and soft tissue subtraction analysis) outcomes 3 and 6 months later. Several important conclusions were drawn from these studies and these represent important strategic elements for the rationale use of local delivery devices:

1. Effective subgingival delivery devices have the potential to dramatically change the microbial profile of treated periodontal pockets. Recolonization, however, is a critical phenomenon that may undermine clinical benefit.
2. Bacteria present in other areas of the mouth are the major source of recolonization and need to be addressed by improved oral hygiene measures, treatment of the whole dentition and, perhaps, antimicrobial mouth rinsing.
3. Subgingival delivery devices are not a promising treatment for subjects who are unable or unwilling to achieve improved (optimal) oral hygiene levels.

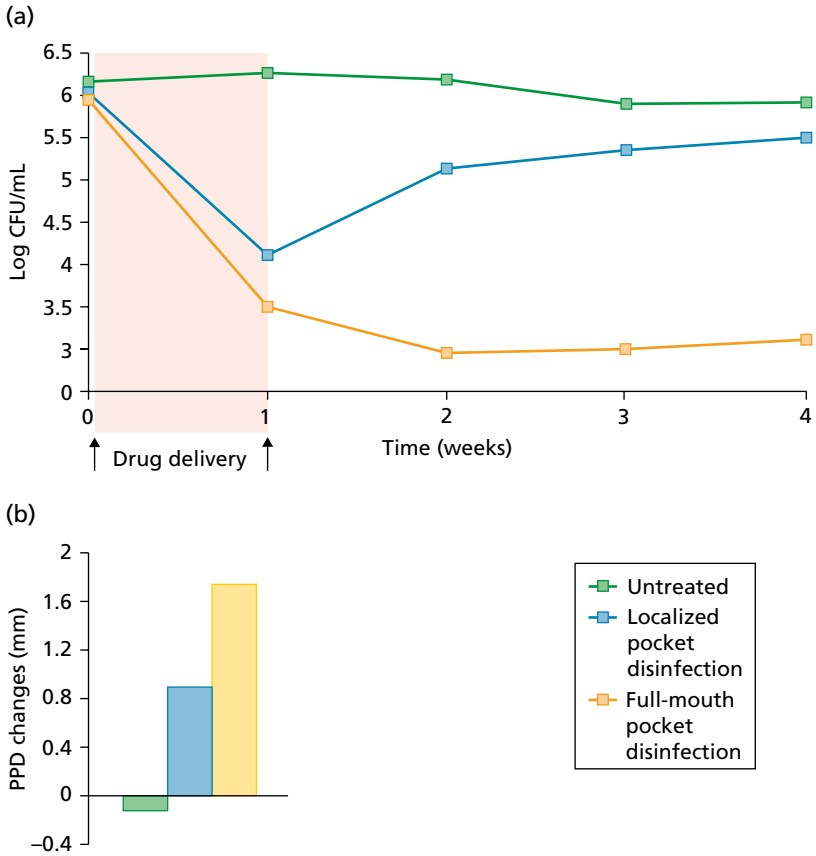

Fig. 37-1 (a) Kinetics of change following local drug delivery with tetracycline fibers in untreated sites; localized treated areas (only two teeth treated in subjects with widespread periodontitis and *P. gingivalis* infection); and full-mouth pocket disinfection (all pockets treated plus chlorhexidine mouth rinse in subjects with widespread periodontitis and *P. gingivalis* infection). Note the different patterns of recolonization. The vertical axis displays total colony forming units (CFU) (Log10)/mL. (b) Changes in probing depths at 6 months for the three groups displayed in (a). Note the greater pocket depth reductions (PPD) observed in the full-mouth pocket disinfection group.

Local antimicrobial delivery for the treatment of periodontitis

Efficacy of subgingival delivery devices

Several clinical studies have assessed the effects of locally delivered antimicrobials in fibers, gels, chips, or microspheres, mainly in untreated patients, but also in treated sites with poor response or with recurrent disease, and their results have been summarized in different systematic reviews (Hanes & Purvis 2003; Bonito *et al*. 2005; Matesanz-Pérez *et al*. 2013; Smiley *et al*. 2015). More recently, a systematic review (Herrera *et al*. 2020) was presented at the XVI European Workshop on Periodontology, for the development of a Clinical Practice Guideline (CPG) in periodontal therapy for periodontitis in stages I–III (Sanz *et al*. 2020). The present section will follow the results of the latter work, which is based on 6-month RCTs, in which the adjunctive use of locally delivered antimicrobials is compared with SRP, alone or plus a placebo, in split-mouth or parallel studies, and probing pocket depth (PPD) changes were considered the primary outcome.

Characteristics of the available studies

A total of 50 studies (described in 59 papers) were identified: 38 were single-blinded; 26 had a parallel design and 23 a split-mouth design, with one combining both (Jeffcoat *et al.* 1998); 33 were single-center studies, while 11 included two or more centers; most studies were performed at university clinics (41), while three took place exclusively at private clinics, and one combined both types of settings (Bogren *et al.* 2008). Studies were carried out in 16 different countries from four continents. The most typical study duration was 6 months (30), followed by 9 months (7) and 12 months (10); only three studies reported more than 12-month follow-up data (in addition, an extension of a 6-month study reported 60-month data in a subset of the original population; Wilson *et al.* 1997). In 22 studies, periodontitis was defined as chronic or adult; in 11 studies, the terminology used was recurrent/refractory/relapsing in already treated patients or patients in supportive periodontal care (SPC), while in five studies the only definition of disease was "periodontitis" and it was not reported in nine studies. In two studies, two groups were included: both aggressive and chronic periodontitis (Agan *et al*. 2006), and untreated and recurrent (Eickholz *et al*. 2002). In just one study, additional microbiological criteria were used (Jones *et al*. 1994). With regards to the extension of the disease, in two studies it was considered as localized and in four as generalized, while it was not reported in 45 studies. For severity, in 20 studies it was "moderate–severe" or "advanced", while in two it was "severe" or "advanced", and in another two "mild" or "initial to moderate". Twenty-six studies did not report on the severity of the disease (Table 37-1).

Seventeen studies used a full-mouth approach to assess clinical outcome variables, either by evaluating all sites, or a group of sites according to a part of the mouth (e.g. a quadrant) or according to a clinical criterion (e.g. PPD >4 mm); in contrast, 36 studies selected some specific sites/teeth for evaluation, based on clinical, radiological, or biomarker criteria, including furcation lesion sites (Tonetti *et al*. 1998; Tomasi *et al*. 2008; Dannewitz *et al*. 2009; Tomasi & Wennstrom 2011). In three studies, both full-mouth and partial-mouth evaluations were reported (Timmerman *et al*. 1996; Gonçalves *et al*. 2004).

In most cases, the studies described periodontal therapies which were rendered before the main intervention, and in common for all study groups, including oral hygiene instructions alone (n=15) or in combination with supragingival professional mechanical plaque removal (PMPR) (n=12) or with SRP (n=4); in some studies, the intervention was PMPR alone (n=3), and in 16 studies, no such an intervention was mentioned. The study intervention was local SRP in 19 studies, full-mouth SRP in 22 studies, while supragingival PMPR was the main mechanical therapy in two studies (Heasman *et al*. 2001; Gonzales *et al*. 2011). Forty-eight out of the 50 studies clearly explained that the local antimicrobial was placed/delivered immediately after instrumentation, with two exceptions: in one study, it was placed before instrumentation (Tonetti *et al*. 1998), and SRP was rendered at fiber removal; and in other study, it was placed 1 week after instrumentation (Flemmig *et al*. 1996). Forty-three studies had SRP alone as main control group, while eight had a vehicle control (placebo), with three of the studies presenting both control groups. Four studies presented an additional untreated control, while one study presented two SRP alone controls, one in adjacent sites and another in remote sites (Henderson *et al*. 2002).

Tested products/formulations

The test groups with commercialized local antimicrobials aimed to assess: Actisite (n=10), Arestin (8), Atridox (4), Aureomycin (1), Chlosite (2), Dentomycin (1) and Periocline (2) (same formulation with different brand names), Elyzol (7), Ligosan (3), PerioChip (11), Periofilm (1); among those not commercially available, were chitosan (1), chitosan with metronidazole (1), minocycline powder (1), tetracycline strips, just using one (1), or multiple (1). Brand names are used to avoid confusion but information on composition can be found in Table 37-2.

The number of applications varied among products and study protocols, just one application being the most frequent, in 34 study groups; two applications were performed in 10 study groups and more than two in five. In six study groups, one initial application was performed, while a second (three studies) or a third one (three studies) was decided based on the dislodging on the first application or on the presence of pockets. When more than one application was scheduled, the protocols were highly heterogeneous. In some cases (16 study groups), a cyanoacrylate or periodontal dressing was used after the local antimicrobial application that was kept in place for 3–13 days; dislodging of the antimicrobial or dressing was recorded in 12 study groups.

Table 37-1 Randomized clinical trials of at least 6-month duration, evaluating locally delivered antimicrobials: description of characteristic of periodontitis (type, extension, and severity) and the distribution, number, and criteria for the evaluated teeth/sites.

*Full mouth assessment, with only four selected sites treated with local antimicrobial.

Table 37-2 Brand names and product description of the tested products, in alphabetic order, and relevant information on availability (in 2019) in the European and other markets.

Descriptive name	Brand name(s)	Manufacturer	Composition	Information on availability*
Actisite	Actisite	ALZA Corporation, Palo Alto, CA, USA	500 µg/cm tetracycline hydrochloride loaded in 0.5 cm-diameter ethylene vinyl acetate co-polymer fiber (23 cm, 12.7 mg of tetracycline)	No availability
Arestin	Arestin	OraPharma, Warminster, PA, USA	1 mg minocycline microencapsulated in poly(glycolide-co-DL-lactide)	Israel, Poland, UK, USA
Atridox	Atridox	Block Drug, Jersey City, NJ, USA; Atrix Laboratories Inc., Fort Collins, CO, USA	8.8–10% doxycycline hyclate in a biodegradable liquid polymer gel	Canada, UK, USA
Aureomycin	Aureomycin	Lederle, UK	3% tetracycline ointment	Not specific for dentistry
Chlosite	Chlosite	Ghimas, Casalecchio di Reno, Bologna, Italy	0.5% chlorhexidine digluconate and 1.0% chlorhexidine dihydrochloride in a xanthan-based syringeable gel system	Austria, Georgia, Germany, Israel, Italy, The Netherlands, Poland, Russia, Spain
Dentomycin	Dentomycin	Atrix Laboratories, Germany	2% minocycline hydrochloride dihydrate	Poland, UK
	Periocline	Sunstar, Osaka, Japan	2% minocycline hydrochloride, 0.5 g in microcapsules gel	France, Ireland
Elyzol	Elyzol	Dumex, Copenhagen, Denmark	40% metronidazole benzoate corresponding to 25% metronidazole in a mixture of glycerol mono-oleate and sesame oil	Italy, UK
Ligosan	Ligosan, Adjusan	Kulzer (Germany)	15% doxycycline-hyclate in a polyethylene glycolactid/glycolid copolymer gel	Austria, Germany, Hungary, Italy, Poland, Spain (Ligosan), The Netherlands (Adjusan)
Minocycline powder	Not available	Not available	1 mg minocycline hydrochloride microencapsulated in a biodegradable polymer, poly(glycolide-co-DL-lactide)	Not commercially available.
Periochip	Periochip	Dexcel Pharma, Israel	2.5 mg of chlorhexidine gluconate in a bioabsorbable chip of hydrolysed gelatine	Austria, Germany, Greece, Ireland, Israel, Italy, The Netherlands, Poland, Singapore, Switzerland, Ukraine, UK, USA
Periofilm	Periofilm, Gelcide	MedTechDental, Switzerland	Powder (sodium piperacillin 100 mg and sodium tazobactam 12.5 mg) plus liquid (amino-alkyl-methacrylate copolymer, ammonium methacrylate co- polymer, ethanol 95 %, and purified water)	Croatia, France, Italy, Lithuania, Poland, Switzerland
Tetracycline strip	Not available	ALZA Corporation, Palo Alto, CA, USA	Tetracycline hydrochloride loaded in ethylene vinyl acetate co-polymer strips (0.65 mm thick, 1 mm wide, 5 cm length, 13.5 mg tetracycline)	Not commercially available

* Direct information from 22 European countries (Austria, *Azerbaijan, Belgium*, Croatia, *Denmark*, *Finland*, Germany, Lithuania, Hungary, Ireland, Israel, Italy, The Netherlands, Poland, *Portugal*, *Serbia*, *Slovenia*, Spain, Switzerland, *Turkey*, Ukraine, UK) and from some manufacturers. None of the listed products was available in 2019 in the countries shown in italics in the previous sentence.

Overall efficacy of locally delivered antimicrobials

The overall meta-analysis, combining all test groups, demonstrated statistically significant PPD reductions and clinical attachment level (CAL) gains, with weighted mean differences (WMD) in 6–9 month studies, of 0.365 mm and 0.263 mm, respectively, when compared with control groups. In addition, minor or no adverse effects were observed, with no differences between test and control groups. However, significant heterogeneity was observed in most of the analyses. These results were similar to those reported in the previously mentioned systematic reviews (Bonito *et al*. 2005; Hanes & Purvis, 2003; Matesanz-Pérez *et al*. 2013; Smiley *et al*. 2015), with additional PPD reductions ranging between 0.3 mm and 0.6 mm. Overall, systematic reviews demonstrate that locally delivered antimicrobials, as adjuncts to SRP, can improve the clinical outcomes of mechanical treatment alone or with a placebo.

It is important to highlight that, among the sources of heterogeneity, relevant aspects of the study design can have a significant impact on the results of the studies. In the systematic review by Herrera *et al*. (2020), and using meta-regression, the following factors were identified: with statistically significant impact, study design (with larger benefits for split-mouth studies, as compared with parallel studies) and the type of assessment (with larger benefits for partial-mouth assessments, as compared with full-mouth evaluation); studies on treated patients tended to achieve larger PPD reductions (as compared with studies in untreated patients), and studies with placebo tended to achieve smaller benefits, as compared with those in which the control group was SRP alone.

Efficacy of specific locally delivered antimicrobials (in alphabetic order)

Actisite (ALZA Corporation, Palo Alto, CA, USA). Tetracycline has been included in non-resorbable plastic co-polymers, and other vehicles, and clinically tested. The most extensively tested tetracycline-releasing device is the Actisite periodontal fiber. This currently unavailable product consists of a monolithic thread of a biologically inert, non-resorbable plastic co-polymer (ethylene and vinyl-acetate) containing 25% tetracycline–HCl powder. The fiber is packed into the periodontal pocket, secured with a thin layer of cyanoacrylate adhesive, and left in place for 7–12 days (Goodson *et al*. 1983, 1991b). The continuous delivery of tetracycline maintains a local concentration of the active drug in excess of 1000 mg/L throughout that period. In the reference systematic review (Herrera *et al*. 2020), seven studies (with 255 control and 257 test patients) with Actisite were included in the primary analysis (PPD changes after 6–9 months), demonstrating a statistically significant added benefit (WMD) of 0.729 mm (95% confidence interval [CI] 0.696; 0.761, P <0.001) with no heterogeneity.

Arestin (OraPharma, Warminster, PA, USA). It is composed of 1 mg minocycline microencapsulated in poly(glycolide-co-DL-lactide). In the reference systematic review (Herrera *et al*. 2020), six studies (with 567 control and 564 test patients) were included in the primary analysis (PPD changes after 6–9 months), demonstrating an additional reduction (WMD) of 0.279 mm (95% CI 0.203; 0.356, P <0.001) with no heterogeneity.

Atridox (Block Drug, Jersey City, NJ, USA; Atrix Laboratories Inc., Fort Collins, CO, USA). It is a 8.8–10% doxycycline hyclate in a biodegradable liquid polymer gel, with a two-syringe mixing system. One syringe contains the delivery vehicle, flowable bioabsorbable poly(DL-lactide) dissolved in N-methyl-2-pyrrolidone, and the other a doxycycline hyclate powder. In the reference systematic review (Herrera *et al*. 2020), two studies (with 19 control and 19 test patients) were included in the primary analysis (PPD changes after 6–9 months), demonstrating a statistically significant added benefit (WMD) of 0.800 mm (95% CI 0.084; 1.516, P = 0.026) with no heterogeneity.

Chlosite (Ghimas, Casalecchio di Reno, Bologna, Italy). It is composed of 0.5% chlorhexidine digluconate and 1.0% chlorhexidine dihydrochloride, in a xanthan-based syringeable gel system. In the reference systematic review (Herrera *et al*. 2020), two studies (with 109 control and 108 test patients) were included in the primary analysis (PPD changes after 6–9 months), not showing statistically significant added benefits (WMD = 0.486 mm, 95% CI -0.238; 1.211, P = 0.188) with significant heterogeneity (P = 0.002) (Fig. 37-2).

Dentomycin (Dentomycin, Cyanamid, Lederle Division, Wayne, NJ, USA; Dentomycin, Atrix Laboratories, Germany; Periocline, Sunstar, Osaka, Japan). It is 2% minocycline hydrochloride dihydrate, presented in a 5 g microcapsule gel. In the reference systematic review (Herrera *et al*. 2020), two studies (with 65 control and 41 test patients) were included in the primary analysis (PPD changes after 6–9 months), not showing statistically significant added benefits (WMD = 0.377 mm, 95% CI -0.036; 0.790, P = 0.073) with no heterogeneity.

Elyzol (Dumex, Copenhagen, Denmark). It is a 40% metronidazole benzoate, corresponding to 25% metronidazole, in a mixture of glycerol mono-oleate and sesame oil. Dialysis tubing, acrylic strips, and poly-OH-butyric acid strips have been tested as solid devices for delivery of metronidazole. The most extensively used device for metronidazole application is Elyzol Dental Gel, which is applied with a syringe into the pocket, and its viscosity should increase after placement. In the reference systematic review (Herrera *et al*. 2020), five studies (with 136 control and 135 test patients) were included in the primary analysis (PPD changes after 6–9 months), not showing statistically significant added benefits (WMD = 0.140 mm, 95% CI -0.041; 0.322, P = 0.130) with no heterogeneity.

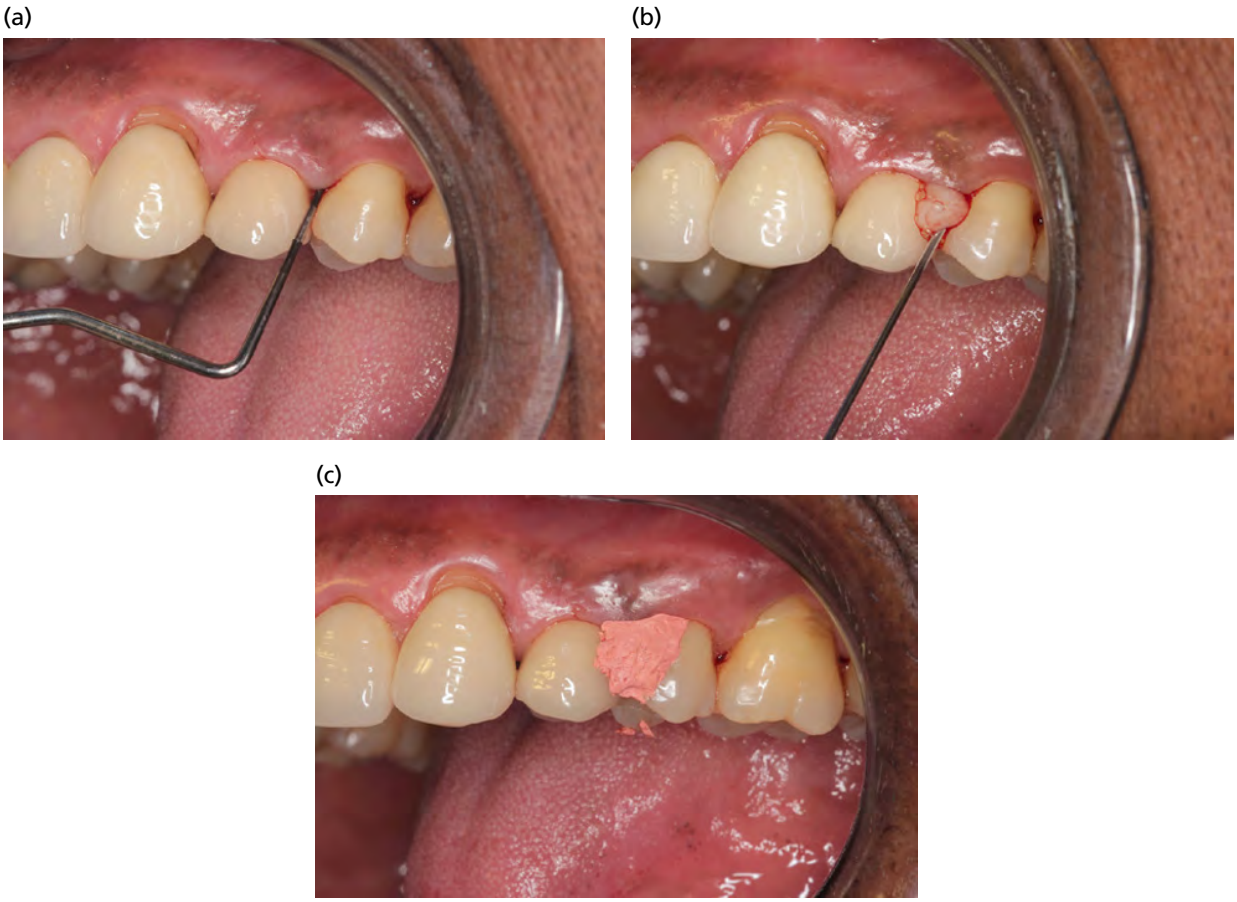

Fig. 37-2 Adjunctive use of chlorhexidine in a xanthan-based syringeable gel system, (a) Deep pocket in the mesiobuccal aspect of tooth number 25. (b) Insertion of the gel with a syringe. (c) Placement of a periodontal dressing to protect the treated area. (Source: Courtesy of Dr. Paula Matesanz.)

Ligosan (also Adjusan, Kulzer, Germany). It is a 15% doxycycline-hyclate in a polyethylene glycolactid/glycolid copolymer gel. In the reference systematic review (Herrera *et al*. 2020), three studies (with 236 control and 232 test patients) were included in the primary analysis (PPD changes after 6–9 months), demonstrating a statistically significant added benefit (WMD) of 0.525 mm (95% CI 0.283; 0.767, P <0.001), with no heterogeneity.

PerioChip (Dexcel Pharma, Israel). It is composed of 2.5 mg of chlorhexidine gluconate in a bioabsorbable chip of hydrolysed gelatine. In the reference systematic review (Herrera *et al*. 2020), nine studies (with 718 control and 719 test patients) were included in the primary analysis (PPD changes after 6–9 months), demonstrating a statistically significant added benefit (WMD) of 0.230 mm (95% CI 0.120; 0.341, P <0.001), with significant heterogeneity (P <0.001) (Fig. 37-3).

Periofilm (also marketed as Gelcide, MedTechDental, Switzerland). It is a mixture of a powder (sodium piperacillin 100 mg and sodium tazobactam 12.5 mg) and a liquid (amino-alkyl-methacrylate copolymer, ammonium methacrylate co-polymer, ethanol 95%, and purified water). In the reference systematic review (Herrera *et al*. 2020), only one study (with 14 control and 18 test patients) was included in the primary analysis (PPD changes after 6–9 months), with no added benefits (WMD) of -0.100 mm (95% CI -1.053; 0.853, P = 0.837).

Efficacy of other locally delivered antimicrobials

Aureomycin (Lederle, UK). It is a 3% tetracycline ointment, not specifically developed for dentistry. In the reference systematic review (Herrera *et al*. 2020), only one study (with 18 control and 18 test patients) was included in the primary analysis (PPD changes after 6–9 months), not showing statistically significant added benefits (WMD = 0.6 mm, 95% CI -0.339; 1.539, P = 0.219). There are reasonable doubts to include this product in the category of sustained-release local antimicrobials.

Tetracycline strip (ALZA Corporation, Palo Alto, CA, USA). It is tetracycline hydrochloride loaded in ethylene vinyl acetate co-polymer strips (0.65 mm thick, 1 mm wide, 5 cm length, 13.5 mg tetracycline), and it has never been marketed. In the reference systematic review (Herrera *et al*. 2020), only one study (with 24 control and 24 test patients) was included in the primary analysis (PPD changes after 6–9 months), demonstrating an additional reduction (WMD) of

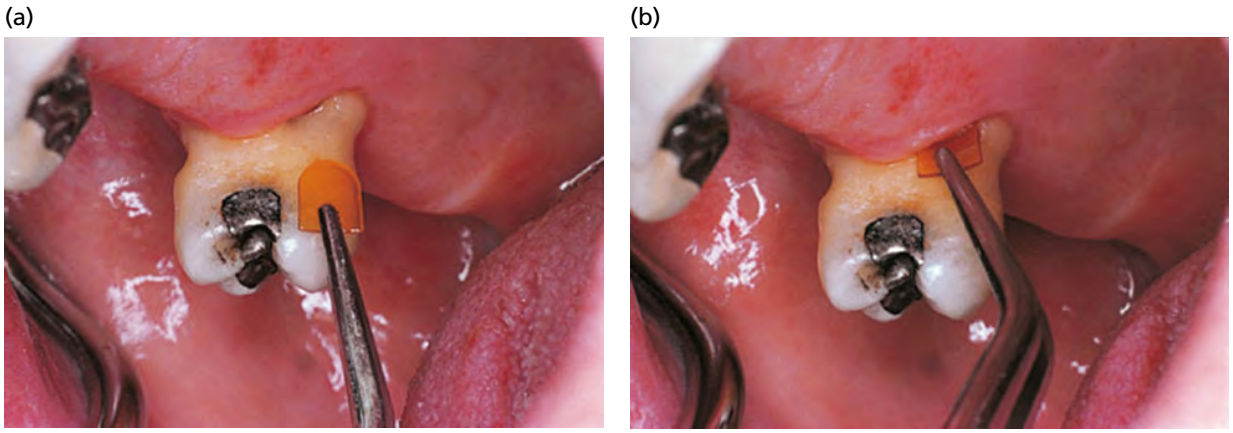

Fig. 37-3 (a) Chlorhexidine chip. (b) Insertion of a chlorhexidine chip into a residual pocket mesial of an upper molar with a furcation involvement.

0.44 mm (95% CI -0.025; 0.905, $P = 0.064$) for the application of one strip, and 0.48 mm (95% CI 0.087; 0.873, $P = 0.017$) for the application of multiple strips.

Azithromycin gel. At 0.5%, it has been tested in at least two studies from the same research group (Pradeep *et al*. 2008, 2013), but it was not included in the reference systematic review due to the limited follow up (Pradeep *et al*. 2008), or because the inclusion criteria restricted the selected sample to smokers (Pradeep *et al*. 2013). There are reasonable doubts to include this product within the category of sustained-release local antimicrobials.

Chlorhexidine varnish. It has been tested by a research group in different investigations (Cosyn *et al*. 2006, 2007). There are reasonable doubts to include this product and the protocol tested within the category of sustained-release local antimicrobials.

Selection of the most effective locally delivered antimicrobial

Based on the individual analysis of each product, it is difficult to provide a global assessment of the use of sustained-released local antimicrobials because each product has unique properties. In addition, the variable availability of these products in different countries makes it more difficult to provide consistent recommendations. Usability should also be considered; some products are very easy to apply, while others are less user-friendly. Some need repeated application, while others must be removed after 7–10 days and/or be protected by using a dressing or cyanoacrylate on the treated area. The use of antiseptics, such as chlorhexidine, which have fewer risks, rather than the use of antibiotics, is also a consideration. However, they are not as effective when compared with products based on doxycycline, minocycline, or tetracycline. The cost–benefit ratio of these technologies should also be considered. Henke *et al*. (2001) suggested that the increased cost of initial therapy is compensated by fewer surgical interventions; however, more consistent analyses are needed, similar to those already available for peri-implant diseases (Listl *et al*. 2015). A cost-effectiveness analysis concluded that systemic antimicrobials are more cost-effective than locally delivered antimicrobials (Heasman *et al*. 2011).

Ideally, to understand which products are most effective, a direct comparison is preferable. However, in the reference systematic review (Herrera *et al*. 2020), only two studies included more than one local antimicrobial test group, comparing Actisite, Dentomycin, and Elyzol Dental Gel (where better results were reported for Actisite) (Kinane & Radvar 1999) or Elyzol and Aureomycin (reporting similar results) (Lie *et al*. 1998). Few other direct comparisons are available. Salvi *et al*. (2002), assessed Atridox, Elyzol Dental Gel, and PerioChip, concluding that Atridox provided the best results.

Indications for locally delivered, sustained-release antimicrobials

Studies assessing the adjunctive benefits of local delivery devices to mechanical instrumentation have identified a range of clinical conditions where the addition of these devices may lead to improved outcomes (Tonetti *et al*. 1994; Tonetti, 1998; Greenstein & Tonetti 2000; Matesanz-Pérez *et al*. 2013) including special local conditions and special patient groups.

Clinical indications: deep, localized pockets

Because the majority of untreated shallow (4–5 mm) pockets are expected to heal with mechanical instrumentation alone, local antimicrobials are of potential benefit for deeper pockets (6–8 mm range). Furthermore, incorporation of local delivery devices into the treatment armamentarium requires reconciliation of the localized nature of the treatment target (the periodontal pocket) with the overall ecologic determinants of clinical outcomes in light of

available treatment alternatives. In general, adjunctive treatment with local antimicrobials is favored when there are relatively few residual pockets and systemic delivery of the antimicrobial may not be warranted.

Clinical indications: localized residual pockets

Deep localized pockets may be found after treatment, either non-responding sites or disease recurrence during SPC. In the reference systematic review (Herrera *et al*. 2020), 11 studies defined the disease condition as recurrent or "refractory" or relapsing, in already treated patients or in patients SPC. For the assessment of the same product (Chlosite), some authors selected non-responding or refractory sites (Matesanz *et al*. 2013), while others recruited untreated patients (Paolantonio *et al*. 2009), with poorer response in non-responding/refractory cases, which could be explained by a larger potential for healing in untreated sites (Harrel & Nunn 2001), or by specific microbiological profiles or immunological conditions in non-responding/refractory cases (Haffajee *et al*. 2004). However, in the overall evaluation, studies on treated patients tended to achieve larger PPD reductions (as compared with studies in untreated patients). Despite the fact that non-responding sites after therapy or recurrent disease during SPC may represent a reasonable indication for local antimicrobials (because only local sites/teeth may be affected), limited attention has been paid to differential outcomes in those cases, as compared with untreated patients, even when both types of patients were included in the same study (Eickholz *et al*. 2002).

Clinical indications: residual pockets in sites with furcation involvement

Few studies have addressed the management of furcation defects with local antimicrobials. Short-term adjunctive benefits in controlling gingival inflammation as well as improvements in probing depths and CALs have been reported (Tonetti *et al*. 1998; Tomasi *et al*. 2008; Dannewitz *et al*. 2009; Tomasi & Wennstrom, 2011). Interestingly, but perhaps not unexpectedly, the benefits did not persist medium to long term in these difficult anatomic areas.

Clinical indications: residual pockets in the aesthetic zone

Another potentially important application is when residual pockets are present in the so-called aesthetic zone, where a surgical intervention may compromise aesthetics and/or phonetics. Lastly, application of local delivery devices seems to be a rational choice at sites with deep pockets and persistent bleeding on probing that are associated with intrabony defects after completion of the cause-related phase of therapy. As these sites are likely to be treated with periodontal regeneration and the outcome of periodontal regeneration is negatively affected by the degree of bacterial contamination and spectrum of pathogens persisting into the lesion (Heitz-Mayfield *et al*. 2006), local drug delivery may be an important means of pocket disinfection before regenerative periodontal surgery.

Patient indications: special patient categories

From a clinical standpoint, important attenuations of the expected benefits of non-surgical and surgical treatment have been observed in high-risk groups. These include smokers and subjects with diabetes, significant co-morbidities, or erratic compliance with oral hygiene and/or long-term adherence to the necessary SPC program. The effect of adjunctive local drug delivery has been assessed in such subjects, and although very limited and initial evidence is available, it may open new possible indications for the use of local antimicrobials:

- Studies have reported that the adjunctive effect of local drug delivery may not be adversely affected by cigarette smoking (Ryder *et al*. 1999). In a planned secondary analysis of a multicenter trial, assessing the adjunctive benefits of minocycline microspheres, the enhanced response to local delivery device application was greatest among smokers (Paquette *et al*. 2003).
- Older patients as well as those with concomitant self-reported cardiovascular disease have also been reported to respond better to adjunctive local delivery than to mechanical instrumentation alone (Lessem & Hanlon 2004). Local drug delivery may contribute to better control of periodontitis in subjects with relative or absolute contraindications to surgical intervention.
- Lastly, in patients with diabetes and periodontitis, recent RCTs have shown benefits in the control of gingival inflammation and better clinical outcomes from the application of adjunctive local drug delivery with respect to subgingival instrumentation alone (Agarwal *et al*. 2017)

Locally or systemically delivered antimicrobials

Very limited information on a direct comparison of local or systemic antimicrobials is available. For patients with chronic periodontitis, one study reported better results for SRP supplemented with Elyzol than adjunctive systemic metronidazole (Noyan *et al*. 1997). For patients with aggressive periodontitis, SRP plus amoxicillin and metronidazole provided better clinical results after 6 months than PerioChip (Kaner *et al*. 2007).

Summary

Local drug delivery into the periodontal pocket is an effective treatment adjunct to mechanical instrumentation. Clinical application requires the use of a well-designed technology platform that is able to counteract GCF clearance of the locally applied antimicrobial and maintain effective concentrations for long enough for the desired pharmacologic effect to occur. Pocket disinfection is feasible, but recolonization is a critical phenomenon that needs to be prevented with a specific clinical strategy: optimal supragingival hygiene, full-mouth approach, and/or use of an antiseptic mouth rinse. Clinical applications range from the management of few residual pockets in otherwise healthy subjects to the management of residual lesions in groups at high risk because of age, smoking, frailty, or the presence of important co-morbidities.

The main limitation of these recommendations is the limited quality of the available RCTs. Although some methodological aspects, such as blinding and randomization, were acceptable in most cases, the global risk of bias was considered as high in most of the included publications in the reference systematic review (Herrera *et al*. 2020), and only three of them were classified as having a moderate risk of bias (Eickholz *et al*. 2002; Killeen *et al*. 2016; Tabenski *et al*. 2017). In addition, when combining data (meta-analyses), statistically significant heterogeneity was observed for most of the analyses, which limits the results of the systematic review. Furthermore, the risk of bias in selected studies may have been increased by the participation of the manufacturing companies in most studies, either through sponsorship or by inclusion of their personnel in the research teams.

The European Federation of Periodontology (EFP) S3 Level Clinical Practice Guideline on the Treatment of Stage I–III Periodontitis (Sanz *et al.* 2020) has assessed the role of local delivery of antiseptics (chlorhexidine) and antibiotics, based on the systematic review by Herrera *et al.* (2020). After due consideration, a consensus was reached on the following clinical recommendation: "specific locally administered sustained release chlorhexidine and antibiotics, as an adjunct to subgingival instrumentation, in patients with stage I–III periodontitis may be considered" (Sanz *et al.* 2020).

Local antimicrobial delivery for the treatment of peri-implant diseases

Clinical rationale

Prevention and control of biofilm-induced inflammation at the transmucosal portion of dental implants is particularly challenging due to the special limitations in effectiveness of professional mechanical plaque removal, in both peri-implant mucositis (Schwarz *et al*. 2015a) and peri-implantitis (Schwarz *et al*. 2015b). The adjunctive use of local antimicrobials has long been suggested as a potential approach to overcome some of the limitations. The use of local delivery devices has been tested in early proof of principle studies with some success. Potential uses for locally delivered antimicrobials furthermore include the treatment of peri-implant infections (Mombelli *et al*. 2001; Renvert *et al*. 2006). The sulcus around dental implants shares some of the pharmacokinetic characteristics of periodontal pockets: the presence of a high flow rate of peri-implant sulcus fluid, a relatively small resting volume, and difficulty of access of mouth rinses and dentifrices to the submucosal environment where the biofilm accumulates.

Efficacy of subgingival delivery devices in peri-implant diseases

Very limited information is available on the use of locally delivered antimicrobials (tetracycline fibers) in peri-implant mucositis (Schenk *et al*. 1997), and its relevance has been considered as small (Schwarz *et al*. 2015a, b).

In the non-surgical therapy of peri-implantitis, the early proof of principle studies showed some efficacy of adjunctive locally delivered antimicrobials (Mombelli *et al*. 2001; Salvi *et al*. 2007). More recently, different studies have been conducted assessing minocycline microspheres (Renvert *et al*. 2006, 2008), chlorhexidine chips (Machtei *et al*. 2012), or doxycycline gel (Buchter *et al*. 2004), and systematic reviews on effective interventions for peri-implantitis have globally assessed their impact (Esposito *et al*. 2012; Muthukuru *et al*. 2012; Schwarz *et al*. 2015b; de Almeida *et al*. 2017), identifying some initial evidence that local delivery, combined with subgingival instrumentation, may be of greater benefit than subgingival instrumentation alone. These studies, however, failed to identify decisive clinical benefits from the adjunctive application of local delivery devices to control peri-implant dysbiosis and further studies are necessary in this area. Network meta-analyses have also explored the relative potential of various adjuncts to peri-implant debridement/biofilm removal alone and again have not been able to recommend strategies to better control peri-implantitis (Faggion *et al*. 2014).

Indications for locally delivered, sustained-release antimicrobials in peri-implantitis

Given the limited evidence of efficacy, the adjunctive application of local delivery of antimicrobials is best limited to selected cases and in the context of better control of peri-implant mucosal tissue inflammation during the preparation phase of surgical (resective or regenerative) therapy. In some specific cases, the local adjunctive antimicrobial effect may provide significant short-term anti-inflammatory benefits (Fig. 37-4).

Summary

Local drug delivery as an adjunct to mechanical debridement for the management of peri-implant diseases, and peri-implantitis in particular, is potentially interesting. For a specific application, the relatively low intrinsic efficacy of mechanical debridement alone may render this treatment modality an important adjunct. More research is necessary to fully understand the benefits and indications.

Introduction

The advances in the understanding of the biology of wound healing and periodontal regenerative technologies are applied to improve long-term clinical outcomes of teeth that are periodontally compromised by intrabony or interradicular defects. The treatment objective is to obtain shallow, maintainable pockets by reconstruction of the destroyed attachment apparatus and thereby also limit recession of the gingival margin. In general, periodontal regeneration is selected to obtain: (1) an increase in the periodontal attachment of a severely compromised tooth; (2) a decrease in deep pockets to a more maintainable range; and (3) a reduction of the vertical and horizontal component of furcation defects. Current approaches, however, remain technique sensitive and clinical success requires application of meticulous diagnostic and treatment strategies.

Classification and diagnosis of periodontal osseous defects

Site-specific periodontal breakdown compromises the long-term prognosis of teeth by producing three types of defects: suprabony (or horizontal) defects, infrabony (or vertical) defects, and interradicular (or furcation) defects.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

According to the classification by Goldman and Cohen (1958), suprabony defects are those where the base of the pocket is located coronal to the alveolar crest. This chapter does not deal with suprabony defects.

Infrabony defects, on the other hand, are defined by the apical location of the base of the pocket with respect to the residual alveolar crest. With regard to infrabony defects, two types can be recognized: intrabony defects and craters. Intrabony defects are bony defects whose infrabony component affects primarily one tooth, while in craters the defect affects two adjacent root surfaces to a similar extent. Intrabony defects (Fig. 38-1) have been classified according to their morphology in terms of residual bony walls, width of the defect (or radiographic angle), and topographic extension around the tooth. Three-wall, two-wall, and one-wall defects have been defined on the basis of the number of residual alveolar bone walls. This represents the primary classification system. Frequently, intrabony defects present a complex anatomy consisting of a three-wall component in the most apical portion of the defect, and two- and/or one-wall components in the more superficial portions. Hemiseptal defects, that is vertical defects in the presence of adjacent roots and where half of a septum remains on one tooth, represent a special case of one-wall defects. Several authors have also used descriptive terms to define special morphologic characteristics: funnel-shaped defects, moat-like defects, trenches, etc.

Of particular interest is a special morphology: the crater (Fig. 38-1). It is defined as a cup- or bowl-shaped defect in the interdental alveolar bone with bone loss nearly equal from the roots of two contiguous teeth and a more coronal position of the buccal and lingual alveolar crest; the facial and lingual/palatal walls may be of unequal height. This defect can be considered to be the result of the apical spread of periodontitis along two adjacent roots in a relatively narrow (mesiodistally) interproximal area. Notably, all the definitions above are not based on radiographic assessments, but on the actual morphology of the defects after flap elevation. Conditions entailing pathologic resorption of bone within the furcation of a multirooted tooth, defined as furcation invasions, are also classed as periodontal bony defects; the reader is referred to Chapter 33 for a discussion of the anatomy and classification of furcations.

The diagnosis of the presence and the morphology of periodontal osseous lesions represents a major clinical challenge. It is primarily performed by combining clinical information derived from the evaluation of the attachment level with information derived from diagnostic-quality parallel-technique intraoral radiographs. A precise knowledge of root anatomy and its variations is also important for the diagnosis of periodontal osseous defects, and interradicular defects in particular. Diagnostic-quality radiographs provide additional information on the morphology of the alveolar bone resorption. In this context, interpretation of the radiographic image of the interdental septum is complicated, since the radiograph provides a two-dimensional image of a three-dimensional anatomy consisting of superimposed structures, including alveolar bone, hard tooth substances, and soft tissue. This complexity of the visualized structures means that a certain amount of tissue destruction must occur before it can be radiographically detected, often rendering incipient bone lesions obscure. Furthermore, even advanced lesions may be masked by the presence of superimposed structures. It is therefore generally stated that radiographic diagnosis has a high positive predictability (i.e. the visualized lesions are indeed there) but a low negative predictability (i.e. the absence of radiographically detectable bone loss does not exclude the presence of an osseous lesion).

Clinical attachment level (CAL), on the other hand, is a highly sensitive diagnostic tool; its combination with radiographs, therefore, confers a higher degree of accuracy to the diagnostic approach (Tonetti *et al*. 1993b). In particular, the site-specific comparison of radiographic bone loss with clinical attachment loss allows the clinician to make a qualified guess of the true osseous architecture, whose exact morphology, however, can only be established after flap elevation. Detection of the defect, its location and extension, along with its major morphologic features, should be performed before flap elevation. A further aid to this end is the use of transgingival probing or bone sounding.

Clinical indications

Periodontal treatment, either surgical or non-surgical, results in recession of the gingival margin after healing (Isidor *et al*. 1984). In advanced cases of periodontitis, this may lead to poor esthetics in the front areas of the dentition, in particular when applying surgical procedures with osseous recountouring for the eradication of bone defects. In addition, osseous resection applied to sites with severe bone destruction and deep intrabony defects may result in unacceptable removal of residual supporting bone to the involved and neighboring teeth. Treatment of such cases without bone contouring, on the other hand, may result in residual pockets inaccessible to proper cleaning during post-treatment maintenance. These problems can be avoided or reduced by applying regenerative surgical procedures to restore the lost periodontal attachment in the bone defects. Thus, the indication for applying regenerative periodontal therapy is often based on the anatomy of bone destruction and on esthetic considerations, besides the fact that the function or long-term prognosis of the treated teeth may be improved. Case reports exist demonstrating that "hopeless" teeth with deep vertical defects, increased tooth mobility or through-and-through furcations can be successfully treated with regenerative periodontal

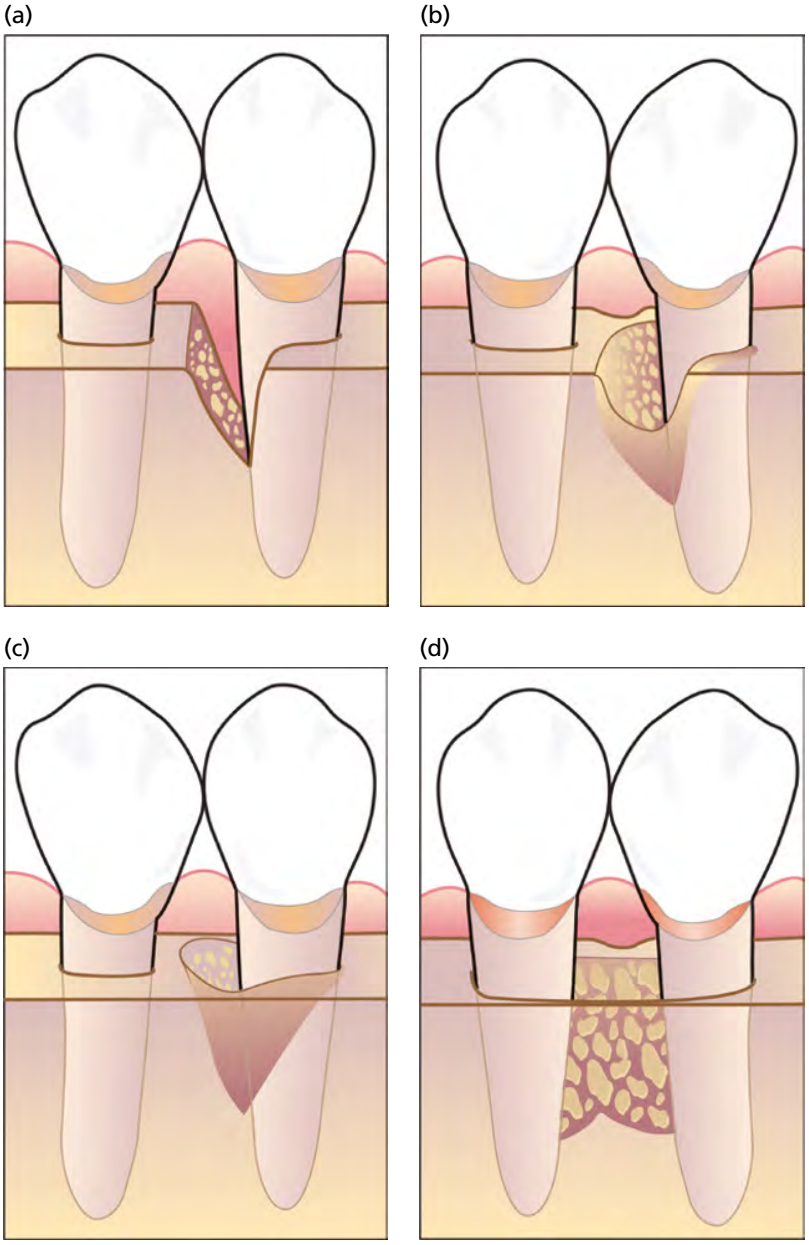

Fig. 38-1 Infrabony defects. (a) One-wall intrabony defect; (b) two-wall intrabony defect; (c) three-wall intrabony defect; (d) interproximal crater. (Source: Papapanou & Tonetti 2000. Reproduced with permission from John Wiley & Sons.)

therapy (Gottlow *et al*. 1986). Teeth with deep pockets associated with deep intrabony defects are considered a clinical challenge. Most authors have classified such teeth as having either a questionable or a hopeless prognosis. Key elements supporting these opinions are the complex interplay of reduced residual periodontal attachment, deep pocketing, functional demands, and frequently the resulting tooth hypermobility (Lang & Tonetti 1996; McGuire & Nunn 1996a, b; Kwok & Caton 2007). It is therefore clear that the possibility of changing the prognosis of a tooth from "questionable" or "hopeless" to "fair" or "favorable" would greatly help clinicians and patients in the difficult job of maintaining teeth over time, and the possibility of gaining periodontal support would help improve patient comfort and function. A randomized controlled clinical trial reported 92% survival at 5 years and 88% at 10 years of "hopeless" teeth treated with periodontal regeneration (Cortellini *et al*. 2011, 2020b). A recent meta-analysis concluded that application of regenerative materials in combination with papillary preservation flaps should be considered the treatment of choice for residual pockets with deep (≥3 mm) intrabony defects (Nibali *et al*. 2020). The XVI European Workshop in Periodontology in periodontology developed clinical guidelines using the format of a structured consensus development conference. From the conference came a strong recommendation "to treat teeth with residual deep pockets associated with intrabony defects 3 mm or deeper with periodontal regenerative surgery" (Sanz *et al*. 2020).

Other indications for regenerative periodontal therapy include furcation-involved teeth. The furcation area is often inaccessible to adequate instrumentation and frequently the roots present concavities and furrows that make proper cleaning of the area impossible after access or resective surgery. Considering the long-term results and complications

reported following treatment of furcation involvements by traditional surgical therapy (Hamp *et al*. 1975; Bühler 1988), the long-term prognosis of furcation-involved teeth can be improved considerably by successful regenerative periodontal therapy. The EFP 2019 workshop expressed a consensus on a recommendation "to treat mandibular molars with residual pockets associated with class II furcation involvement with periodontal regenerative surgery"; and a suggestion "to treat molars with residual pockets associated with maxillary buccal class II furcation involvement with periodontal regenerative surgery" (Sanz *et al*. 2020).

Long-term effects and benefits of regeneration

A pertinent question with respect to regenerative treatment is whether or not the achieved attachment level gains can be maintained over an extended period of time. In a long-term follow-up study, Gottlow *et al*. (1992) assessed the stability of new attachment gained through guided tissue regeneration (GTR) procedures. Eighty sites in 39 patients, which 6 months after surgery exhibited a gain of clinical attachment of ≥2 mm (2–7 mm), were monitored over an additional period of 1–5 years. Of the 80 sites, 65 were monitored for 2 years, 40 for 3 years, 17 for 4 years, and nine for 5 years. The results of this study and those of other trials indicate that attachment gain obtained following GTR treatment can be maintained on a long-term basis (Becker & Becker 1993; McClain & Schallhorn 1993).

An investigation of intrabony defects demonstrated that the stability of sites treated with GTR was dependent on patient participation in a recall program, and on the absence of bacterial plaque, bleeding on probing (BoP), and re-infection of the treated sites with periodontal pathogens (Cortellini *et al*. 1994). The susceptibility to disease recurrence at sites treated with non-bioresorbable barrier membranes was assessed in a study comparing long-term changes in attachment levels at regenerated and non-regenerated sites in the same patient (Cortellini *et al*. 1996a). Results indicated that there was a high degree of concordance in the clinical outcomes (stability versus recurrence of attachment loss) within the same patient, suggesting that patient factors, rather than site factors, including the specifics of the histologic type of expected wound healing, are associated with disease recurrence. Among patient factors, compliance with oral hygiene, smoking habits, and susceptibility to disease progression were the major determinants of stability of the treated sites, rather than the employed treatment modality.

Support for a limited impact of the histologic type of healing comes from an experimental study. In a study in monkeys (Kostopoulos & Karring 1994), periodontal breakdown was produced by the placement and retention of orthodontic elastics on experimental teeth until 50% bone loss was recorded. The experimental teeth were endodontically treated and subjected to a flap operation, and all granulation tissue was removed. The crowns of the teeth were resected at the level of the cementoenamel junction and a barrier membrane was placed to cover the roots before they were submerged. Following 4 weeks of healing, the membranes were removed. At the same time, the contralateral teeth that served as controls were endodontically treated and subjected to a sham operation during which the crowns were resected at the level of the cementoenamel junction. Artificial composite crowns were then placed on both the experimental and the control roots. The sites were allowed to heal for 3 months during which period careful plaque control was performed. At the end of this period, cotton-floss ligatures were placed on both experimental and control teeth to induce periodontal tissue breakdown. After another 6 months, the animals were sacrificed. With respect to attachment level, bone level, probing pocket depth (PPD), and gingival recession, similar results were recorded in the histologic specimens of experimental (Fig. 38-2) and control (Fig. 38-3) teeth.

Fig. 38-2 Microphotograph of test specimen with a reformed connective tissue attachment. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut root surface to the level indicated by the arrow.

This indicates that the new connective tissue attachment formed with GTR is no more susceptible to periodontitis than the naturally existing periodontium.

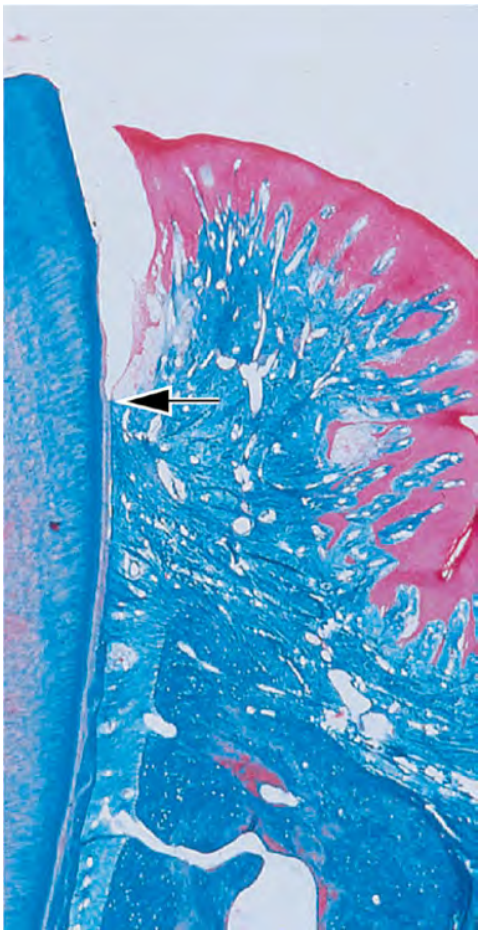

Fig. 38-3 Microphotograph of control specimen with a naturally existing periodontium. After 6 months of ligature-induced periodontitis, loss of attachment has occurred from the coronal cut tooth surface to the level indicated by the arrow.

Other long-term studies show that, if the patient participates in a professionally delivered supportive periodontal care program and maintains good oral hygiene, the regenerated attachment can be maintained long term (Christgau *et al*. 1997; Sculean *et al*. 2006, 2008; Eickholz *et al*. 2007; Slotte *et al*. 2007; Nickles *et al*. 2009; Pretzl *et al*. 2009; Nygaard-Østby *et al*. 2010).

Few investigations have looked at the long-term effects of periodontal regeneration on tooth survival. Cortellini and Tonetti (2004) performed a Kaplan–Mayer analysis of tooth survival following periodontal regenerative treatment in a sample of 175 patients followed up for 2–16 years (average 8 ± 3.4 years) in a specialist environment. In this study, 96% of teeth treated with periodontal regeneration survived. Of interest was the observation that tooth loss was observed among only the 32% of the population who smoked (tooth survival was 89% among smokers and 100% among non-smokers). CALs were located at the same level or coronal to the pretreatment levels in 92% of cases up to 15 years after treatment (Table 38-1, Fig. 38-4).

The potential clinical benefits of periodontal regeneration are best illustrated in a consecutive case series of strategic abutments severely compromised by the presence of deep intrabony defects with associated deep pockets, which were followed up for up to 8 years following regenerative treatment (Tonetti *et al*. 1996b; Cortellini *et al*. 1999b). At baseline, the periodontal defect rendered these teeth unsuitable as abutments to be included in a reconstruction. In all cases, periodontal regeneration with barrier membranes was able to change the clinical prognosis by providing both a 30% increase in radiographic bone support and shallow, maintainable PPD. These outcomes remained stable during the follow-up period (Fig. 38-5). A systematic review (Kao *et al*. 2015) concluded that

Table 38-1 Survival analysis of regenerated periodontal attachment over a 16-year follow-up period in 175 subjects treated with periodontal regeneration. In this survival analysis, the event is represented by clinical attachment level (CAL) loss of ≥2 mm from the level of attachment obtained at completion of healing 1 year after regeneration. No substantial recurrence of periodontitis (CAL loss) was observed in 92% of treated cases who participated in a secondary prevention program.

Time at risk (years)	Number of CAL loss ≥2 mm	Censored	Effective sample size	Conditional probability of CAL loss (%)	Survival (%)
0–2	2	0	175	1.1	100
2–4	3	0	166	1.7	98.9

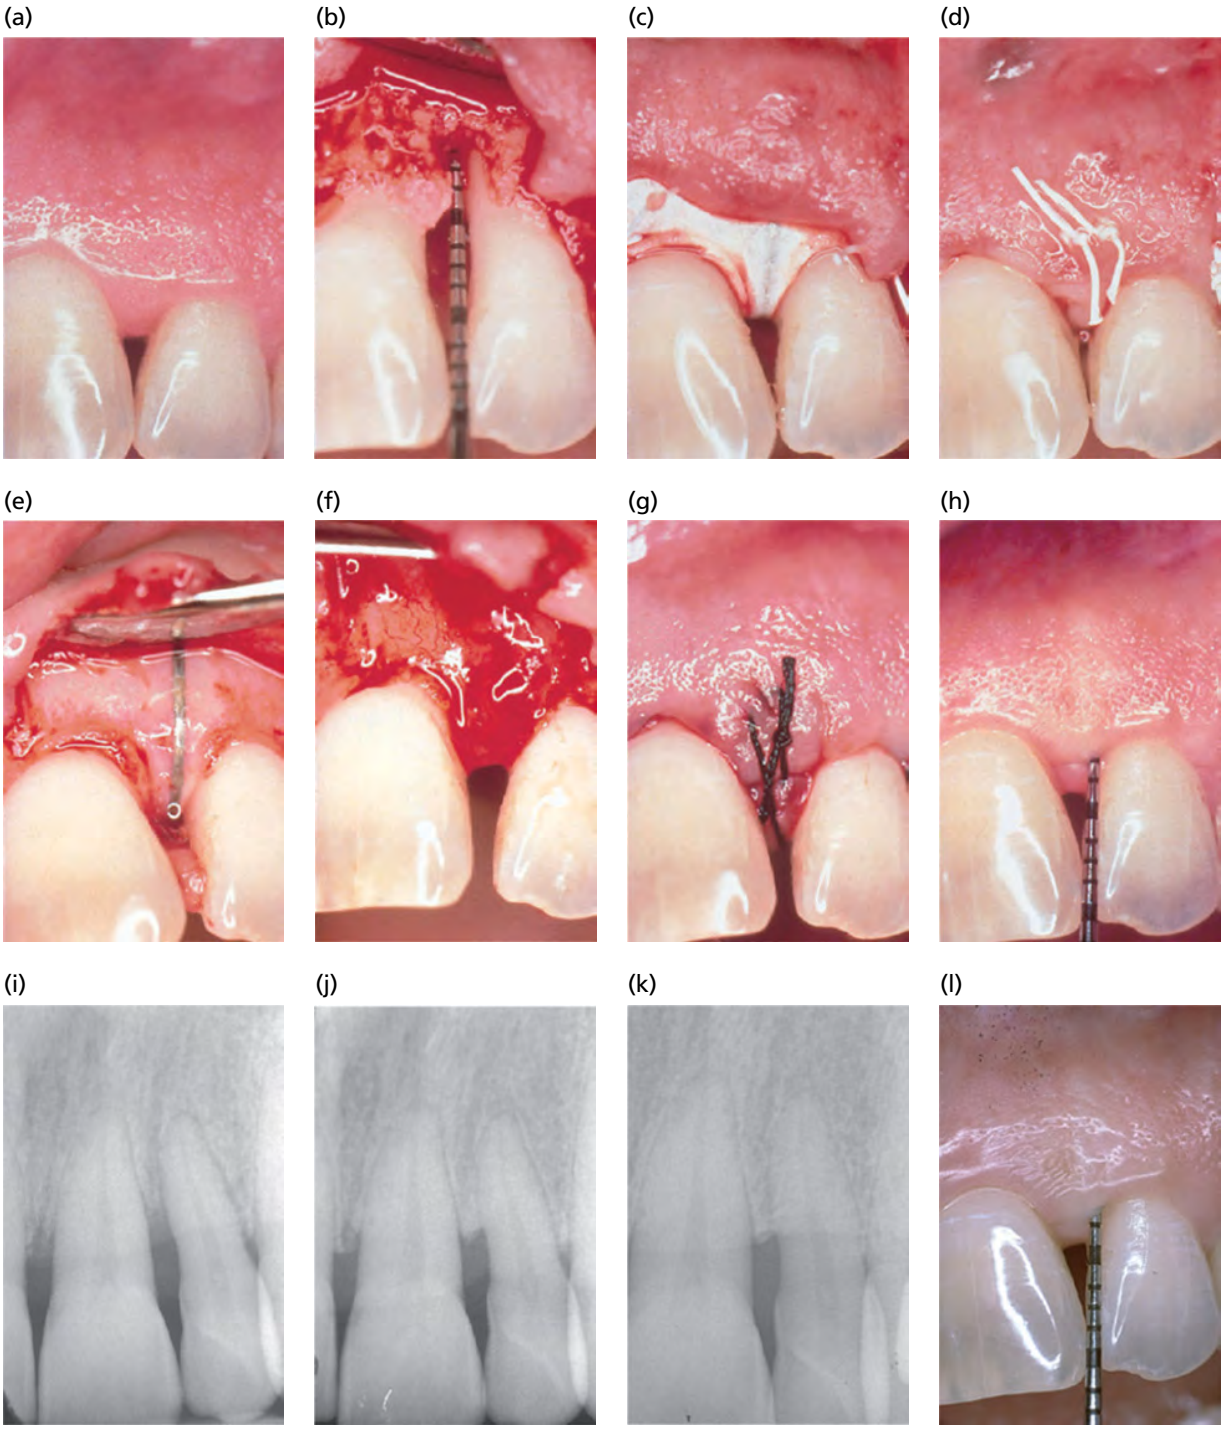

Fig. 38-4 (a, b) Left maxillary lateral incisor with a deep interproximal intrabony defect on the mesial surface. (c) Flaps are raised according to the modified papilla preservation technique, and a titanium-reinforced barrier membrane is placed over the defect. (d) By coronal displacement of the flap and preservation of the interdental papilla, the membrane is completely covered. (e, f) After 6 weeks of uneventful postoperative healing, the membrane was removed and (g) the newly formed tissue was completely covered. (h) At 1 year, residual probing pocket depth was 2 mm and no buccal or interdental recession had occurred. (i) Baseline radiograph showed radiolucency approaching the apex of the tooth, but after 1 year the intrabony defect is resolved and some supracrestal bone apposition seems to have occurred (j). Radiograph taken at 6 years confirms the supracrestal bone regeneration (k) and the clinical image showed the integrity of the interdental papilla with optimal preservation of the esthetic appearance (l).

improvements in clinical parameters obtained with periodontal regeneration are maintainable up to 10 years, even in severely compromised teeth, consistent with a favorable/good long-term prognosis.

A recent long-term randomized controlled trial (RCT) demonstrated that clinical benefits from periodontal regeneration can be maintained up to 20 years (Cortellini *et al*. 2017). In this study, survival of the regenerated teeth in well-maintained patients was 100% compared with 85.7% in the flap control group. Flap-treated sites had greater odds ratios (OR) for recurrences and higher costs of re-intervention than regenerated sites over a 20-year follow-up period with supportive periodontal care (SPC). Residual

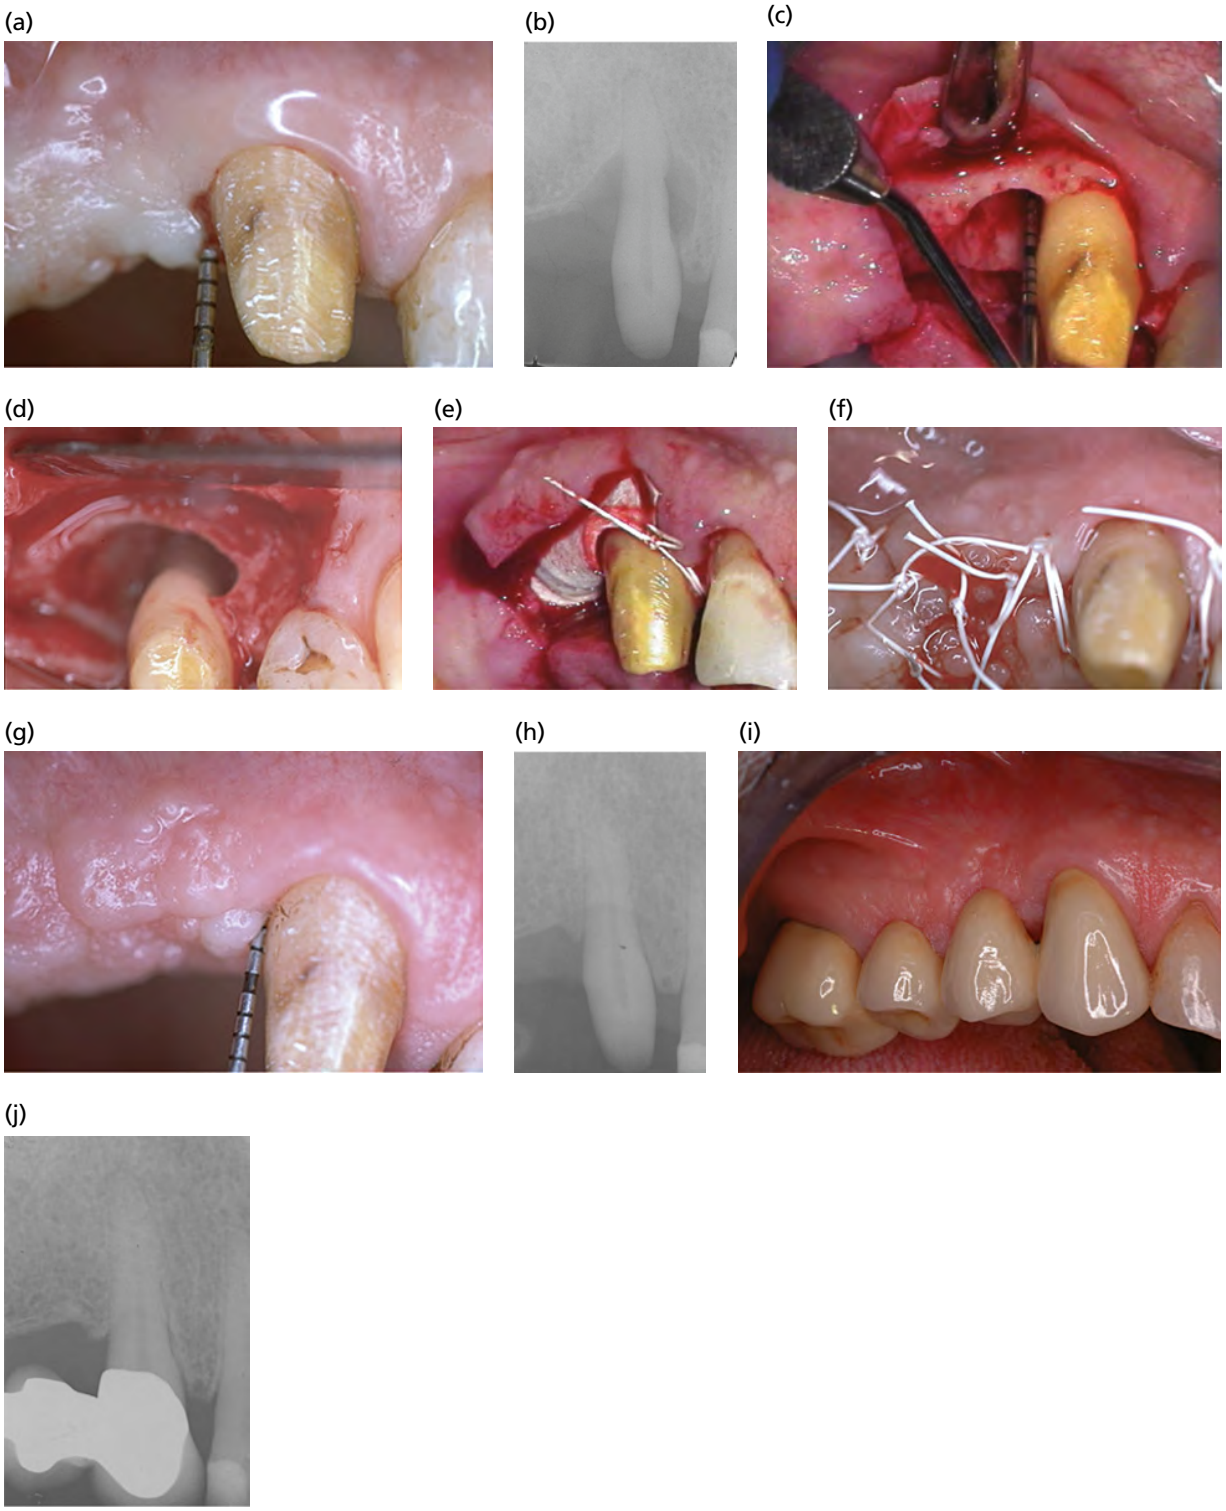

Fig. 38-5 Clinical benefits of periodontal regeneration. Patient presented with periodontally compromised mesial abutment of the bridge: a 10-mm pocket was associated with a 10-mm intrabony defect extending on three of the four surfaces of the tooth (a–d). A barrier membrane was positioned and secured around the root of the tooth (e). Primary closure with internal mattress sutures was achieved (f) and maintained during the healing period. At 1 year, periodontal probing showed a shallow maintainable pocket (3 mm) (g) and the complete resolution of the defect (h). Clinical and radiographic stability of the outcome is shown 10 years following regenerative therapy (i, j): stability of the gingival margin, shallow pockets, good esthetics, and good periodontal support for the abutment are evident.

pocket depth at 1 year, more frequently detected in the flap-treated sites, was significantly correlated with the number of recurrences ($P = 0.002$).

A randomized controlled clinical trial reported 88% survival at 10 years of "hopeless" teeth treated with periodontal regeneration (Cortellini *et al*. 2020b). The control group was treated with extraction and replacement of hopeless teeth with implant or teeth supported reconstructions. Complication-free survival was not significantly different: 6.7–9.1 years for

periodontal regeneration and 7.3–9.1 years for extraction and replacement ($P = 0.788$). Recurrence analysis showed that the 95% confidence interval of the costs was significantly lower for periodontal regeneration compared with extraction and replacement throughout the whole 10-year period. Patient-reported outcomes and oral health-related quality-of-life measurements improved in both groups. The authors concluded that periodontal regeneration can change the prognosis of hopeless teeth and is a less costly alternative to tooth extraction and replacement. The complexity of the treatment limits widespread application to the most complex cases but provides powerful proof of principle for the benefits of periodontal regeneration in deep intrabony defects.

A few studies have evaluated the long-term prognosis for furcation defects treated with regenerative therapy. Sixteen mandibular class II furcation defects, following coronal flap positioning and citric acid root biomodification with and without implantation of demineralized freeze-dried bone allografts (DFDBAs), were determined to be completely resolved with bone fill assessed by re-entry surgery. They were re-evaluated after 4–5 years (Haney *et al*. 1997), when 12 of the 16 sites exhibited recurrent class II furcations and all 16 sites demonstrated probable buccal furcation defects. The investigators concluded that these findings question the long-term stability of bone regeneration in furcations following coronally advanced flap procedures. A similar benefit has been reported following use of combination therapy (barrier membranes and DFDBA) in teeth compromised by class II furcation defects (Bowers *et al*. 2003): 92% of the class II defects were either closed or transformed into class I and thus at lower risk of tooth loss 1 year after therapy (McGuire & Nunn 1996a, b). A recent systematic review (Jepsen *et al*. 2020) investigated the clinical performance of regenerative periodontal surgery in the treatment of furcation defects versus open flap debridement (OFD) and compared different regenerative modalities. Authors concluded that regenerative surgery of class II furcations is superior to OFD. The likelihood of obtaining furcation closure or conversion to class I is significantly higher (OR = 20.91; 90% CI = 5.81, 69.41) for regenerative techniques than for OFD. Treatment modalities involving bone replacement graft are associated with higher performance.

The long-term stability of mandibular furcation defects regenerated following GTR alone or in combination with root surface biomodification with citric acid and bone grafting was also evaluated by McClain and Schallhorn (1993). Of the 57% of the furcation defects that were assessed as completely filled at 6 and 12 months, only 29% were completely filled after 4–6 years. However, 74% of the furcations treated with GTR in combination with the placement of DFDBA were completely filled at both the short- and long-term evaluation, suggesting that the results obtained with the combined procedure were more stable over time. Long-term results of GTR treatment of mandibular class II furcations with expanded polytetrafluoroethylene (e-PTFE) membranes were also reported by Machtei *et al*. (1996). The teeth were followed up for 4 years and compared with non-furcated molars. Improvements assessed in vertical (V-CAL) and horizontal CAL (H-CAL) after treatment were also maintained after 4 years, suggesting that changes obtained in class II furcation defects by GTR are stable. Only 9% of the treated defects were unstable, which was similar to the percentage observed for non-furcated molars. Good oral hygiene, as reflected in low plaque scores and elimination of periodontal pathogens, was closely related to the long-term stability. On the basis of these results, it was concluded that furcation defects treated with membrane barriers can be maintained in health for at least 4 years, provided good oral hygiene and frequent recall visits are established. Dannewitz *et al*. (2016), in a 10-year follow-up study, concluded that long-term retention of molars is possible. With active periodontal therapy, followed by supportive periodontal therapy, even teeth with an initial bone loss of more than 60% and/or through-and-through furcations can usually be retained for more than 10 years. Patient-related factors influencing molar loss are: age, female gender, smoking, and diabetes, while among tooth-related factors, class III furcation involvement, initial bone loss, endodontic treatment, and residual PPD at T1 played a significant role.

The survival rate of furcated teeth treated with regenerative therapy has been investigated in a few studies. Yukna and Yukna (1997) reported a 100% survival rate after an average observation period of 6.6 years in 26 mandibular and maxillary furcated molars treated with synthetic bone graft and coronally advanced flap. Eickholz and Hausmann (2002) reported a 100% survival rate after 60 months in 10 mandibular and 10 maxillary furcated molars treated with barriers. A survival rate of 98.1% was reported by Dannewitz *et al*. (2006) after a 107-month observation period of 29 maxillary and 24 mandibular furcated molars treated with GTR. Eickholz *et al*. (2006) reported an 83.3% survival rate after 10 years in 18 mandibular and maxillary molars treated with barriers.

Summary: Several clinical studies addressing the long-term effects of periodontal regeneration show that, if the patient participates in a professionally delivered supportive periodontal care program and maintains good oral hygiene, the regenerated attachment can be maintained long term. Risk factors for attachment loss are those associated with disease recurrence: poor compliance with supportive periodontal care, poor oral hygiene, and cigarette smoking. In addition, most treated teeth affected by intrabony defects or furcation involvement can be maintained over long periods of time provided proper supportive periodontal and home care is undertaken.

Evidence for clinical efficacy and effectiveness

Questions of efficacy relate to the added benefit of a treatment modality under ideal experimental conditions (such as those of a highly controlled research center environment). Effectiveness, on the other hand, relates to the benefit that can be achieved in a regular clinical setting where the procedure is likely to be performed in relation to morbidity and adverse events. Besides efficiency considerations, both evidence for efficacy and effectiveness need to be available in order to provide support for the adoption of a novel approach in clinical practice.

The clinical efficacy of periodontal regenerative procedures has been extensively evaluated in randomized controlled clinical trials that have compared the regenerative procedure with a standard approach. To limit sample size and study duration, these trials have utilized surrogate outcomes – CAL changes, decrease in PPD, furcation closure or radiographic measurements – rather than changes in tooth survival. These surrogate outcomes, however, are considered to be adequate proxies of the true outcome represented by tooth survival: persistence of deep pockets or furcation involvement are associated with a higher risk of periodontal breakdown and tooth extraction.

The majority of clinical trials have been small single-center studies. The evidence from these studies has been summarized in meta-analyses performed on data retrieved by systematic reviews of the published literature. In 2002, 2003, and 2008, the European Workshop on Periodontology and the Workshop on Emerging Technologies in Periodontics provided much of the systematic assessment of the evidence for currently available technologies. These include the use of barrier membranes (GTR), bone replacement grafts (BRGs), and biologically active regenerative materials, as well as the application of combination therapy. The clinical evidence must be interpreted in the context of the biologic mechanisms and evidence for regeneration discussed in Chapter 21.

The evidence for clinical efficacy of barrier membranes has been assessed in the systematic reviews and meta-analyses performed by Needleman *et al*. (2002, 2006), Jepsen *et al*. (2002), Murphy and Gunsolley (2003), and Kinaia (2011).

For intrabony defects, 26 controlled trials with 867 intrabony defects were included (Murphy & Gunsolley 2003). The application of barrier membranes resulted in an additional CAL gain of >1 mm compared with that with an access flap approach control (Fig. 38-6). A more recent meta-analysis (Needleman *et al*. 2006) was performed on 17 RCTs (16 studies testing GTR alone and two testing GTR + bone substitutes). For CAL change, the mean difference between GTR and OFD was 1.22 mm (95% CI random effects 0.80–1.64) and for GTR + bone substitutes was 1.25 mm (95% CI 0.89–1.61). The authors highlighted that GTR showed a significant benefit when comparing the numbers of sites failing to gain 2 mm of attachment, with a risk ratio of 0.54 (95% CI random effects 0.31–0.96). The number needed to treat (NNT) for GTR to achieve one extra site gaining 2 mm or more of attachment over OPD was therefore eight (95% CI 5–33), based on an incidence of 28% of sites in the control group failing to gain 2 mm or more of attachment. For baseline incidences in the range of the control groups of 3% and 55%, the NNT would be 71 and four, respectively. The authors concluded that GTR has a greater effect on probing measures of periodontal treatment than OPD, including improved attachment gain, reduced PPD, less increase in gingival recession, and more gain in hard tissue probing

at re-entry surgery. However, there was marked variability between the studies and the clinical relevance of these changes is unknown.

For class II furcation defects, 15 controlled trials with 376 involved teeth were included (Murphy & Gunsolley 2003). Membrane application resulted in additional vertical and horizontal (depth of the furcation involvement) CAL gains (Fig. 38-7). A meta-analysis of re-entry studies on the treatment of class II molar furcation involvement (Kinaia *et al*. 2011) was performed on 13 controlled clinical trials. There was a significant improvement for bioresorbable versus non-bioresorbable membranes mainly in vertical bone fill (0.77–0.33 mm; 95% CI 0.13–1.41). Non-bioresorbable membranes showed significant improvement in vertical probing reduction (0.75–0.31 mm; 95% CI 0.14–1.35), attachment gain (1.41–0.46 mm; 95% CI 0.50–2.31), horizontal bone fill (1.16–0.29 mm; 95% CI 0.59–1.73), and vertical bone fill (0.58–0.11 mm; 95% CI 0.35–0.80) over OFD. Bioresorbable membranes showed significant reduction in vertical probing depth (0.73–0.16 mm; 95% CI 0.42–1.05), attachment gain (0.88–0.16 mm; 95% CI 0.55–1.20), horizontal bone fill (0.98–0.12 mm; 95% CI 0.74–1.21), and vertical bone fill (0.78–0.19 mm; 95% CI 0.42–1.15) over OFD. These data alone, however, did not present conclusive evidence of efficacy as the possibility of bias arising from a possible tendency to report studies with positive results could not be ruled out. Multicenter studies were designed to assess efficacy conclusively. These were performed in a private practice environment in order to assess also the generalizability of the benefit to this specific setting (effectiveness). The results of large prospective multicenter studies in private practice settings (Tonetti *et al*. 1998, 2004b; Cortellini *et al*. 2001) conclusively support the additional benefit of membranes in improving CAL in intrabony defects, and thus their efficacy and effectiveness. More limited evidence is also available for combination therapy (BRG + barrier membranes) in furcation defects (Bowers *et al*. 2003).

The efficacy of BRG materials has been assessed in two systematic reviews (Trombelli *et al*. 2002; Reynolds *et al*. 2003). As these two systematic reviews used significantly different criteria for study inclusion, their results do not fully overlap. Trombelli *et al*. (2002), who included only controlled studies that reported changes in CAL as the primary outcome, concluded that there was insufficient evidence to support the clinical use of BRG materials in intrabony defects, since: (1) there was significant heterogeneity among the included studies; (2) the size of the adjunctive effect was small; and (3) there were differences that did not allow pooling of results obtained with different materials. In the other meta-analysis for intrabony defects, 27 controlled trials with 797 intrabony defects were included (Reynolds *et al*. 2003). The application of BRG resulted in an additional CAL gain of 0.5 mm compared with an access flap approach control (Fig. 38-8). Greater additional benefits from the application of BRG were observed whenever hard tissue measurements (bone fill or defect resolution) were utilized as outcome measures.

For furcation defects, the lack of consistent comparisons did not allow a meaningful assessment of the potential benefits of the use of BRGs alone (Reynolds *et al*. 2003). No large multicenter trials have provided definitive support for efficacy and/or effectiveness of the use of BRGs.

The evidence for clinical efficacy of biologically active regenerative materials has been summarized in meta-analyses for enamel matrix derivatives (EMDs) (Trombelli *et al*. 2002; Giannobile & Somerman 2003; Esposito *et al*. 2009; Koop *et al*. 2012), for growth factors (Darby & Morris 2013), and for platelet concentrate (Del Fabbro *et al*. 2011) in the treatment of intrabony defects only.

The outcomes of eight studies including 444 defects have indicated that EMD application provides additional benefits of a magnitude of 0.75 mm in terms of CAL gain (Giannobile & Somerman 2003). These data are in accordance with those of a large practice-based multicenter trial that demonstrated both efficacy and effectiveness of EMDs in intrabony defects (Tonetti *et al*. 2002). The meta-analysis by Esposito *et al*. (2009) included 13 trials. A meta-analysis including nine

trials showed that EMD-treated sites displayed statistically significant CAL improvements (mean difference 1.1 mm; 95% CI 0.61–1.55) and PPD reduction (0.9 mm; 95% CI 0.44–1.31) when compared with placebo- or control-treated sites, although a high degree of heterogeneity was found. Approximately nine patients needed to be treated (NNT) for one to gain 2 mm or more probing attachment level (PAL) over the control group, based on a prevalence in the control group of 25%. No differences in tooth loss or esthetic appearance as judged by the patients were observed. When evaluating only trials at a low risk of bias in a sensitivity analysis (four trials), the effect size for PAL was 0.62 mm (95% CI 0.28–0.96), which was <1.1 mm for the overall result.

A more recent meta-analysis (Koop *et al*. 2012) on 20 RCTs showed a significant additional gain in CAL of 1.30 mm of EMD-treated sites compared with OFD, ethylenediaminetetra-acetic acid (EDTA), or placebo (Fig. 38-9).

The systematic review by Darby and Morris (2013) reported a meta-analysis on two studies on the use of recombinant human platelet-derived growth factor-BB (rhPDGF-BB). Sites treated with rhPDGF-BB had greater CAL gain of around 1 mm, a greater percentage bone fill of around 40%, and an increased rate of bone growth of around 2 mm compared with sites treated with an osseoconductive control, beta-tricalcium phosphate (β-TCP).

Del Fabbro *et al*. (2011) in a meta-analysis on 10 studies reported a significantly greater CAL gain in cases treated with platelet-rich plasma (PRP) compared with control sites (mean adjusted percentage difference 5.50%; 95% CI 1.32–9.67%; $P = 0.01$). The mean weighted CAL gain difference was 0.50 mm (95% CI 0.12–0.88 mm).

Combination therapy has been explored in two recent meta-analyses. Trombelli and Farina (2008) evaluated the clinical effects of bioactive agents when used in addition to OFD either alone or in association with grafts and/or barrier membranes. The authors concluded that there was evidence to support the use of EMDs either alone or in combination with grafts to effectively treat intraosseous defects and the additional use of a graft seems to enhance the clinical outcome of EMDs; the combined use of rhPDGF-BB and P-15 with a graft biomaterial has shown beneficial effects in intraosseous defects; contrasting results were reported for PRP and graft combinations. Tu *et al*. (2010) explored the additional treatment effect of barriers or bone grafts to EMDs in 28 studies. EMD plus bone grafts and EMD plus membranes attained

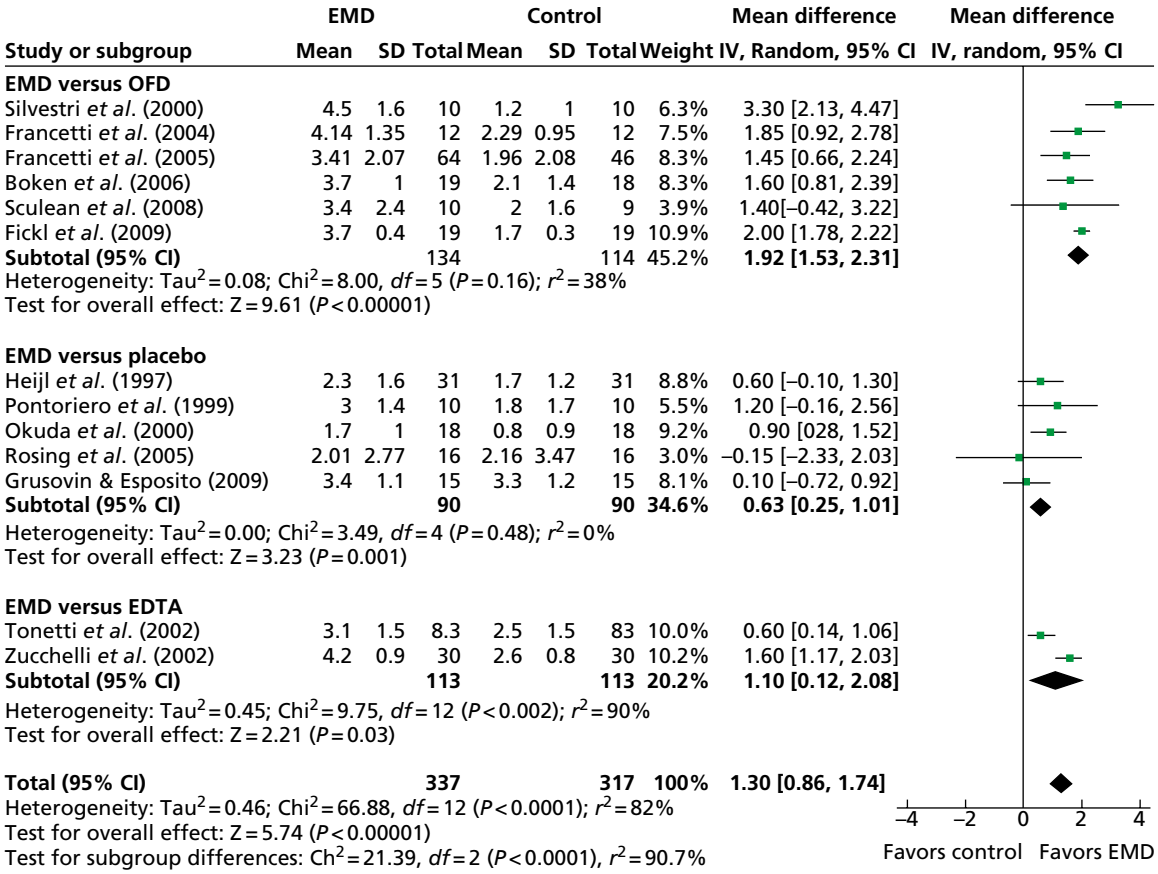

Fig. 38-9 Meta-analysis of intrabony defect studies. Comparison of enamel matrix derivatives (EMDs) versus control: change in clinical attachment level after 1 year. CI, confidence interval; EDTA, ethylene–diamine–tetra-acetic acid; IV, inverse variance; Total, number of patients. (Source: Koop *et al*. 2012. Reproduced with permission from John Wiley & Sons.)

0.24 mm and 0.07 mm more PPD reduction than EMD alone, respectively. EMD plus bone grafts and EMD plus membranes attained 0.46 mm and 0.15 mm more CAL gain, respectively. When different types of bone grafts and barrier membranes were treated separately, EMD with bovine bone grafts showed greater treatment effects. The authors concluded that there was little evidence to support the additional benefits of EMDs in conjunction with other regenerative materials.

Comparative studies between different regenerative approaches have been analyzed in a systematic review by Esposito *et al*. (2009) including six studies. The authors did not find any difference between EMDs and barriers in terms of CAL gain and PPD reduction. These data are supported by two large practice-based multicenter trials (Silvestri *et al*. 2003; Sanz *et al*. 2004). The Sanz *et al*. (2004) study, however, reported a significantly higher prevalence of complications in the barrier-treated group compared with the EMD-treated one. More recently, Tu *et al*. (2012) compared GTR, EMDs, and their use in conjunction with other regenerative materials with a Bayesian network meta-analysis of 53 RCTs. The authors found small differences between regenerative therapies which were non-significant statistically and clinically. GTR and GTR-related combination therapies achieved greater PPD reduction than EMDs and EMD-related combination therapies. Combination therapies achieved slightly greater CAL gain than the use of EMDs or GTR alone. The authors concluded that combination therapies performed better than single therapies, but the additional benefits were small. The same conclusions were reached by Koop *et al*. (2012).

Recent systematic reviews have confirmed the potential for clinical improvements of different regenerative materials. Kao *et al*. (2015) concluded that biologics (EMD and rhPDGF-BB plus b-tricalcium phosphate), demineralized freeze-dried bone allograft and GTR with membranes are superior to OFD procedures in improving clinical parameters in the treatment of intrabony defects. Nibali *et al*. (2020) concluded that all regenerative procedures provided adjunctive benefit in term of CAL gain (1.34 mm; 0.95–1.73) compared with OFD alone. Both EMD and GTR were superior to OFD alone in improving CAL (1.27 mm; 0.79–1.74 mm and 1.43 mm; 0.76–2.22 respectively), although with moderate–high heterogeneity. Among biomaterials, the addition of deproteinized bovine bone mineral (DBBM) improved the clinical outcomes of both GTR with resorbable barriers and EMD. Papillary preservation flaps enhanced the clinical outcomes.

Patient, defect, and tooth prognostic factors

The results reported in the meta-analyses discussed in the previous section indicate that clinical improvements beyond those from flap surgery can be obtained by treating periodontal defects with regenerative therapies, but they also suggest a great variability in clinical outcomes among the different studies. In addition, it is apparent from the results that the complete resolution of the intrabony component of the defect and of the horizontal component of a furcation is observed in only a minority of sites. Regeneration, in fact, is an advanced healing event that occurs when the systemic and local conditions are favorable and when therapy is properly applied. A significant "center effect" was consistently observed in five randomized multicenter studies (Tonetti *et al*. 1998, 2003, 2004a; Cortellini *et al*. 2001; Sanz *et al*. 2004). The center variability, defined as the difference in CAL between the best and the worst center, had a highly significant impact on the outcomes, greater than the impact of the tested regenerative materials (Table 38-2).

The observed variability among centers may depend on differences in the enrolled patients in terms of socioeconomic background, form of periodontal disease, response to therapy, and persistence of specific pathogens; or differences in clinical experience, surgical skills, and clinical organization of the clinicians. In addition, a series of prognostic factors associated with the clinical outcomes has been identified using multivariate approaches (Tonetti *et al*. 1993a, 1995, 1996a; Cortellini *et al*. 1994; Machtei *et al*. 1994; Falk *et al*. 1997; Cortellini & Tonetti 2000b). The main sources of clinical variability are patient-, defect-, and surgery-associated factors (Cortellini & Bowers 1995; Cortellini & Tonetti 2000a). Attention has focused on some important patient, defect, and tooth factors.

Patient factors

Periodontal infection

Periodontal regeneration does not treat periodontitis, but rather is an approach for regenerating defects that have developed as a result of periodontitis. Therefore, appropriate periodontal treatment should always be completed before periodontal regeneration is initiated. In this context, that is in patients who have undergone a cycle of cause-related periodontal therapy to the satisfaction of the treating clinician, evidence suggests that the level of control of periodontitis achieved before a periodontal regenerative procedure is initiated is associated with outcomes: the persistence of poor plaque control, high levels of bleeding upon probing, as well as the persistence of high loads of total bacteria or of specific microbial pathogens (or complexes of pathogens) have all been associated in a dose-dependent manner with poor clinical outcomes (Tonetti *et al*. 1993a, 1995; Cortellini *et al*. 1994, 1995a, b; Machtei *et al*. 1994, 2003; Silvestri *et al*. 2003; Heitz-Mayfield *et al*. 2006).

The level of self-performed plaque control has a great and dose-dependent effect on the outcome of periodontal regeneration. Better CAL gains were observed in patients with optimal levels of plaque control as compared with those in patients with less ideal oral hygiene (Cortellini *et al*. 1994, 1995a, b; Tonetti *et al*. 1995, 1996a). Patients with plaque on <10% of the tooth surfaces (full-mouth plaque score [FMPS]) had a gain of CAL which was 1.89 mm greater than that observed in patients with a FMPS of >20% (Tonetti *et al*. 1995).

Although not formally tested for efficacy in randomized trials, achieving high levels of plaque control and suppression of the pathogenic microflora through behavioral intervention and intensive antiinfective periodontal therapy are generally advocated before proceeding with periodontal regeneration. Furthermore, some proof of principle investigations

have assessed the adjunctive effect of using an antibiotic locally delivered within the wound area or in the regenerative material (Yukna & Sepe 1982; Sanders *et al*. 1983; Machtei *et al*. 2003; Stavropoulos *et al*. 2003). Results showed consistently better outcomes in the groups that received the systemic/local antibiotic. At present, however, no regenerative device with enhanced antimicrobial activity is commercially available. Local contamination of the defect-associated pocket should be as low as possible (Heitz-Mayfield *et al*. 2006). Presence of BoP (i.e. bacteria) should be controlled with additional gentle root planing and eventually with the additional use of local antimicrobials (Tunkel *et al*. 2002; Hanes & Purvis 2003).

Smoking

A retrospective study found that cigarette smokers displayed significantly impaired regenerative outcomes compared with non-smokers (Tonetti *et al*. 1995). Data showed that cigarette smoking was associated with reduced CAL gains. The CAL gain in subjects smoking more than 10 cigarettes/day was 2.1 ± 1.2 mm versus 5.2 ± 1.9 mm in non-smokers (Tonetti *et al*. 1995). Thereafter, a series of investigations has confirmed that cigarette smoking displays a dose-dependent detrimental effect on CAL gains in intrabony defects (Cortellini *et al*. 1995b, 2001; Falk *et al*. 1997; Trombelli *et al*. 1997, 1998; Ehmke *et al*. 2003; Stavropoulos *et al*. 2004) and furcations (Luepke *et al*. 1997; Bowers *et al*. 2003; Machtei *et al*. 2003). A meta-analysis (Patel *et al*. 2012) concluded that smoking has a negative effect on bone regeneration after periodontal treatment. Patients should be advised that their smoking habit may result in poorer bone regeneration after periodontal treatment. Although no formal evidence is available, it is generally suggested that smoking cessation counseling should be initiated in the context of cause-related periodontal therapy, and that patients who are unable to quit the habit should be informed of the possibility of reduced outcomes and of the need to abstain from smoking during the perioperative and early healing period.

Other patient factors

It has been suggested that other patient factors, such as age, genetics, systemic conditions or stress levels, may be associated with suboptimal regenerative outcomes. In the light of lack of evidence, however, no action is required with the exception of considering the patient characteristics that represent a contraindication to surgery (e.g. uncontrolled diabetes or unstable, severe diseases).

Clinical relevance of patient factors

The data discussed above indicate that patient factors play an important role in regenerative periodontal therapy (Fig. 38-10). Some of these factors can be modified by appropriate interventions in some patients. These interventions should be performed before periodontal regenerative therapy. Whenever modification is not possible, reduced outcomes in terms of extent and predictability should be considered.

Defect factors

Type of defect

With the currently available periodontal regenerative technologies, there is no evidence that suprabony (horizontal) defects, supracrestal components of intrabony defects, or class III furcation involvements can be predictably treated with regenerative approaches. This limitation is also true for interdental craters, thus limiting the type of defects that can be treated to intrabony defects and class II furcation defects.

Morphology of the defect

Defect morphology plays a major role in healing following periodontal regenerative treatment of intrabony defects (Papapanou & Tonetti 2000). This was demonstrated in studies showing that the depth and width of the intrabony component of the defect influenced the amount of CAL and bone gained at 1 year.

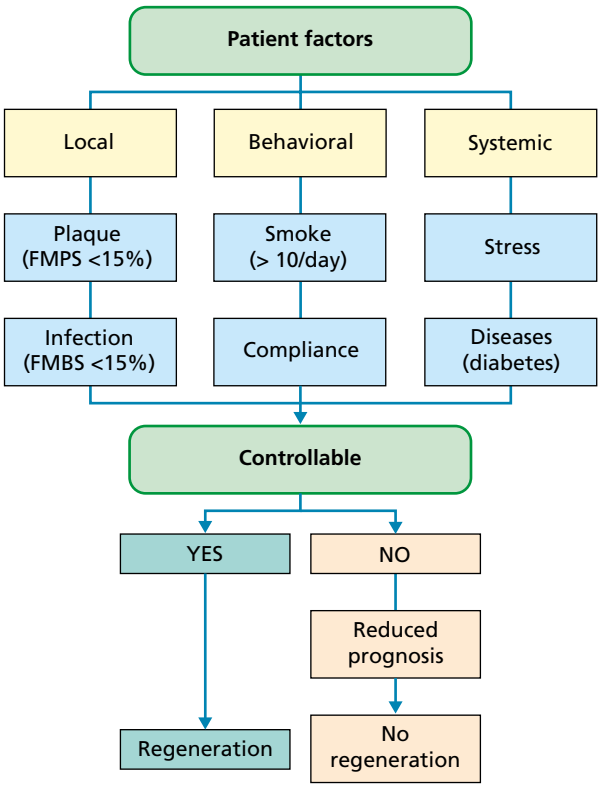

Fig. 38-10 Patient selection criteria. It can be seen that control of local, behavioral, and systemic patient characteristics may improve the treatment outcomes. FMPS, full mouth plaque score; FMBS, full mouth bleeding score. (Source: Adapted from Cortellini & Bowers 1995. Reproduced with permission from John Wiley & Sons.

The deeper the defect, the greater was the amount of clinical improvements (Tonetti *et al*. 1993a, 1996a; Garrett *et al*, 1988; Ehmke *et al*. 2003; Silvestri *et al*. 2003).

In a controlled study, however, it was demonstrated that deep and shallow defects have the "same potential" for regeneration (Cortellini *et al*. 1998). Deep defects (>3 mm) resulted in larger linear CAL gain than shallow defects (3.7 ± 1.7 mm versus 2.2 ± 1.3 mm), but the percentage of CAL gain as related to the baseline defect depth was similar in deep (76.7 ± 27.7%) and in shallow (75.8 ± 45%) defects.

Another important morphologic characteristic of the defect is the *width* of the intrabony component, measured as the angle that the bony wall of the defect forms with the long axis of the tooth (Steffensen & Weber 1989). Wider defects have been associated with reduced CAL and bone gain at 1 year (Tonetti *et al*. 1993a, 1996a; Garrett *et al*. 1988). In a study on 242 intrabony defects treated with membranes, Cortellini and Tonetti (1999) demonstrated that defects with a radiographic angle of ≤25° gained consistently more attachment (1.6 mm on average) than defects with an angle of ≥37°. Two follow-up studies addressed the significance of the baseline radiographic angle of the intrabony defect following the use of either EMDs (Tsitoura *et al*. 2004) or a combination of BRG with a barrier membrane (Linares *et al*. 2006). The impact of the width of the baseline radiographic angle was confirmed for the non-space-making biologic mediator, but not for the more stable combination therapy. These data are consistent with the notion that the choice of the regenerative technology may partially overcome negative morphologic characteristics of intrabony defects. An earlier secondary analysis of a controlled clinical trial using titanium-reinforced membranes (Tonetti *et al*. 1996a) indicated that the relevance of defect morphology parameters may be diminished with the use of supported membranes.

It was also shown that the number of residual bony walls was related to the outcomes of various regenerative approaches (Goldman & Cohen 1958; Schallhorn *et al*. 1970). This issue as related to GTR therapy was addressed in three investigations (Selvig *et al*. 1993; Tonetti *et al*. 1993a, 1996a). In one study, the reported 1-year mean CAL gain was 0.8 ± 0.3 mm. This gain corresponded to the depth of the three-wall intrabony component of the defect (Selvig *et al*. 1993). In contrast, in the other two investigations, CAL gain was not related to the defect configuration in terms of one-wall, two-wall, and three-wall subcomponents (Tonetti *et al*. 1993a, 1996a). A total of 70 defects were examined in these two latter studies, utilizing a multivariate approach. The treatment resulted in mean attachment gains of 4.1 ± 2.5 mm and 5.3 ± 2.2 mm, and it was observed that the most coronal portion of the defects, which is the most susceptible to negative influences from the oral environment, was often incompletely filled with bone, irrespective of whether these were one-wall, two-wall, or three-wall defects.

Thus, these studies questioned the impact of the number of residual bony walls of the defect on the clinical outcomes of periodontal regeneration with membranes and suggested that location of the one-wall subcomponent (the one most likely to be the most superficial) may have acted as a confounder in other studies and be an important predictor of the outcomes. The number of walls was not significant when titanium barriers (Tonetti *et al*. 1996a) or combination therapy (Tonetti *et al*. 2004a, b) were used, but were significant when bioresorbable barriers (Falk *et al*. 1997; Silvestri *et al*. 2003) and EMDs were used (Tonetti *et al*. 2002; Silvestri *et al*. 2003). In particular, a secondary analysis of a multicenter trial showed that, in intrabony defects, the added benefit of EMDs was greater in three-wall defects compared with one-wall defects (Tonetti *et al*. 2002, 2004a).

These data also questioned the suitability of the gel formulation of EMDs for the treatment of defects with a non-supporting anatomy (wide defects with missing bony walls). More recently, however, two studies demonstrated a reduced impact of the number of residual bony walls and of defect width on the outcomes obtained with EMDs when a minimally invasive surgical technique (MIST) was used (Cortellini *et al*. 2008; Cortellini & Tonetti 2009a). This finding clearly differs from the evidence discussed previously of a strong impact of the defect anatomy in terms of residual bony walls and defect width on the clinical outcomes observed in previous studies in which EMDs were used under conventional large and intrinsically less stable papilla preservation flaps (Tonetti *et al*. 2002, 2004a).

Tooth factors

The endodontic status of the tooth has been suggested as a potential relevant factor in periodontal therapy. Emerging evidence (see Chapter 41) indicates that root canal-treated teeth may respond differently to periodontal therapy. A clinical study of 208 consecutive patients with one intrabony defect each demonstrated that properly performed root canal treatment does not negatively affect the healing response and the long-term stability of deep intrabony defects treated with membranes (Cortellini & Tonetti 2000b).

Tooth mobility has long been considered an important factor for periodontal regeneration (Sanders *et al*. 1983). A multivariate analysis of a multicenter controlled clinical trial demonstrated that tooth hypermobility was negatively and dose-dependently associated with the clinical outcomes of regeneration (Cortellini *et al*. 2001). Although significant, the size of the effect was small, within the range of physiologic mobility. Another secondary analysis of three previously reported trials assessed the regenerative outcomes for hypermobile teeth (Trejo & Weltman 2004). This report indicated that teeth with baseline

mobility amounting to <1 mm horizontally could be successfully treated with periodontal regeneration. Although no intervention trial has been performed to date, these results are generally considered supportive of an approach that does not base the prognosis of the tooth or the regenerative procedure on tooth mobility, but rather considers splinting hypermobile teeth before periodontal regenerative surgery.

Conclusion: Based on these results, it can be concluded that deep and narrow intrabony defects at either vital or endodontically treated teeth are the ones in which the most significant and predictable outcomes can be achieved with GTR treatment. Number of walls and width of the defect are influential when non-supportive biomaterials are used. The influence of defect anatomy appears to be reduced to some extent when a more stable flap design is applied. Severe, uncontrolled dental hypermobility (Miller class II or higher) may impair the regenerative outcomes. Significant clinical improvements can be expected only in patients with optimal plaque control, with reduced levels of periodontal contamination, and who are non-smokers.

Factors affecting the clinical outcomes in furcations

Significant evidence has demonstrated that treatment of maxillary class II furcations and maxillary and mandibular class III furcation involvements with regeneration is unpredictable, while clinical improvements can be expected for mandibular class II furcations. The great variability in clinical outcomes following treatment of mandibular class II furcations with regeneration is probably related to the factors discussed relative to intrabony defects.

Regarding tooth/defect factors, it was shown that first and second mandibular molars and buccal and lingual furcations respond equally well to GTR treatment (Pontoriero *et al*. 1988; Machtei *et al*. 1994). It was also demonstrated that the preoperative horizontal pocket depth directly correlates with the magnitude of attachment gain and bone formation in the furcation area (Machtei *et al*. 1993, 1994; Horwitz *et al*. 2004). The deeper the baseline horizontal pocket, the greater the H-CAL and bone gain. The anatomy of the furcations in terms of height, width, depth, and volume, however, did not correlate with the clinical outcome (Machtei *et al*. 1994). Horwitz *et al*. (2004) demonstrated that a long root trunk, a wide furcation entrance, and a furcation fornix coronal to the alveolar crest have negative influences on the success of therapy. Anderegg *et al*. (1995) demonstrated that sites with a gingival thickness of >1 mm exhibited less gingival recession postsurgery than sites with a gingival thickness of <1 mm. Bowers *et al*. (2003) reported that increases in presurgical PAL-H were associated with monotonic decreases in the percentage of sites demonstrating complete clinical closure, with only 53% of lesions of ≥5 mm responding with complete closure. Similarly, significant reductions in the frequency of clinical closure were associated with increases in the distance between the roof of the furcation and the crest of the bone, roof of the furcation and base of the defect, and depth of the horizontal defect and the divergence of the roots. The authors concluded that the highest frequency of clinical furcation closure was observed in early class II defects. Tsao *et al*. (2006a) treated class II furcations in lower molars with either OFD alone or with additional use of bone graft or bone graft plus a collagen barrier. Among the anatomic factors, only the baseline vertical depth was found to affect the clinical outcomes in terms of vertical CAL gain. The most influential factor was the type of surgical treatment: the regenerative procedures performed better than the flap alone.

Relevance of the surgical approach

At the beginning of the 1980s, the need to modify standard periodontal surgical procedures to favor periodontal regeneration became apparent. In particular, the need to preserve soft tissues in order to attempt primary closure of the interdental space to contain grafts or coronally advanced flaps to cover furcation entrances led to the development of specific flap designs for periodontal regeneration (Takei *et al*. 1985; Gantes & Garret 1991).

In fact, graft exfoliation and membrane exposure with consequent bacterial contamination during healing represented the major complications of periodontal regenerative procedures at the time. Membrane exposure was reported to be a major complication with a prevalence of 50–100% (Becker *et al*. 1988; Cortellini *et al*. 1990, 1993a; Selvig *et al*. 1992, 1993; Murphy 1995a; De Sanctis *et al*. 1996a, b; Falk *et al*. 1997; Trombelli *et al*. 1997; Mayfield *et al*. 1998). Cortellini *et al*. (1995c, d) reported that the prevalence of membrane exposure could be greatly reduced with the use of access flaps specifically designed to preserve the interdental tissues (modified papilla preservation technique) (Fig. 38-11).

Many studies have shown that the exposed membranes are contaminated with bacteria (Selvig *et al*. 1990, 1992; Grevstad & Leknes 1992; Machtei *et al*. 1993; Mombelli *et al*. 1993; Tempro & Nalbandian 1993; Nowzari & Slots 1994; Novaes *et al*. 1995; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). Contamination of exposed non-bioresorbable as well as bioresorbable membranes was associated with lower PAL gains in intrabony defects (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). The impaired clinical results in some studies were associated with high counts of bacteria and with the presence of *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* (Machtei *et al*. 1994; Nowzari & Slots 1994; Nowzari *et al*. 1995).

Bacterial contamination of the regenerative biomaterials may occur during surgery, but also during the postoperative healing phase. Bacteria from the

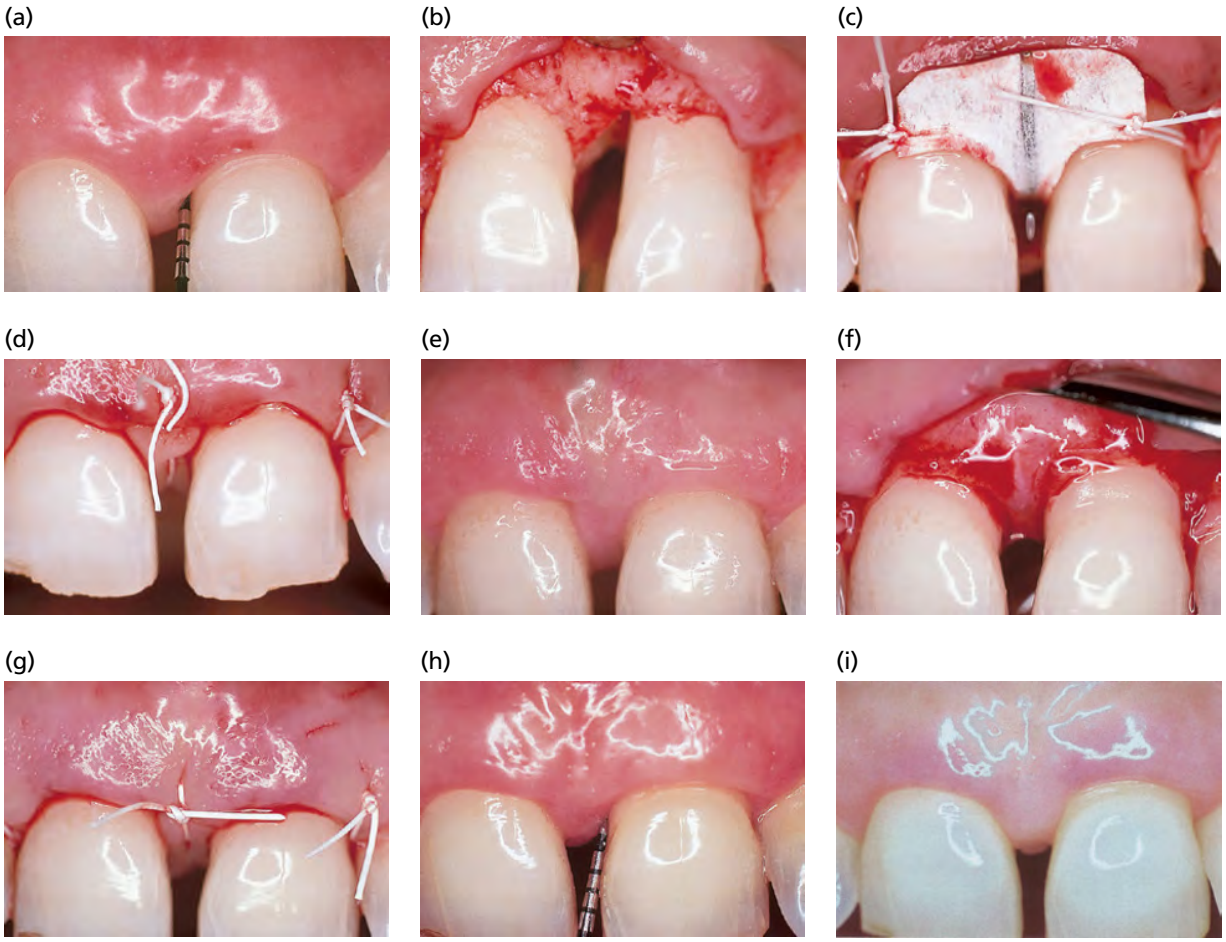

Fig. 38-11 (a) Left maxillary central incisor with a 10-mm pocket depth and 11 mm of clinical attachment loss on the mesial surface. A diastema is present between the two central incisors. (b) Full thickness buccal and palatal flaps have been raised and an intrabony defect can be seen. The interdental papilla has been incised on the buccal aspect and elevated with the palatal flap (modified papilla preservation technique). (c) Titanium-reinforced e-PTFE barrier membrane has been placed and fixed close to the level of the cementoenamel junction. (d) Membrane is completely covered. This primary closure has been obtained by preserving the interdental papilla and by coronal displacement of the buccal tissue flap. (e) At 6 weeks, the membrane is completely covered with healthy tissue. (f) After membrane removal at 6 weeks, dense newly formed tissue is evident in the defect and in the supracrestal space maintained by the titanium-reinforced membrane. (g) Newly formed tissue is completely covered by the raised and well-preserved tissue flaps. (h) Clinical photograph after 1 year showed a 4-mm residual pocket depth. A gain of clinical attachment of 6 mm was recorded, and no recession had occurred compared with baseline. (i) Ten-year clinical photograph showing the optimal preservation of the interdental tissues.

oral cavity may colonize the implanted biomaterials. Frequently, this results in recession of the gingival tissues, which allows colonization of the material further apically. The significance of bacterial contamination was addressed in an investigation in monkeys (Sander & Karring 1995). The findings of this study showed that new attachment and bone formation occurred consistently when bacteria were prevented from invading the membrane and the wound during healing.

In order to prevent wound infection, some investigators have administered systemic antibiotics to patients before and during the first weeks after membrane application (Demolon *et al*. 1993; Nowzari & Slots 1994). However, despite the application of systemic antibiotics, postoperative wound infection related to implanted barrier membranes was noted. This indicates that either the drug administered is not directed against the microorganisms responsible for the wound infection, or that the drug does not reach the infected site at a concentration sufficiently high enough to inhibit the target microorganisms. An improved effect on periodontal healing after GTR in association with local application of metronidazole was reported by Sander *et al*. (1994). Twelve patients each with two similar intrabony defects participated in this intraindividual study. Metronidazole in a gel form was placed in the test defects and on the membrane prior to wound closure, while the control defects were treated with a membrane alone. Six months following membrane removal the medium gain in PAL, presented as a percentage of the initial defect depth, was 92% for the test defects versus 50% for the control defects. Other clinical parameters, like plaque index, BoP, PPD reduction, and recession of the gingival margin, were similar in the test and control sites. Although local or systemic antibiotics may reduce the bacterial load on exposed membranes,

they seem ineffective in preventing the formation of a microbial biofilm (Frandsen *et al*. 1994; Nowzari *et al*. 1995). In addition to the erythema and swelling related to such infection of the wound, more severe postoperative complications such as suppuration, sloughing or perforation of the flap, membrane exfoliation, and postoperative pain have been reported (Murphy 1995a, b).

Another important issue associated with the clinical results is the coverage of the regenerated tissue after removal of a non-bioresorbable membrane. Many authors have reported that the frequent occurrence of a gingival dehiscence over the membrane is likely to result in insufficient protection of the interdental regenerated tissue (Becker *et al*. 1988; Selvig *et al*. 1992; Cortellini *et al*. 1993a; Tonetti *et al*. 1993a). Exposure of the regenerated tissue to the oral environment introduces the risk of mechanical and infectious insults that in turn may prevent complete maturation of the regenerated tissue into a new connective tissue attachment. In fact, incomplete coverage of the regenerated tissue was associated with reduced attachment and bone gain at 1 year (Tonetti *et al*. 1993a). The positioning of a saddle-shaped free gingival graft over the regenerated interdental tissue (Fig. 38-12) was suggested to offer better coverage and protection than a dehiscent gingival flap (Cortellini *et al*. 1995a). In this randomized controlled study (Cortellini *et al*. 1995a) more gain of attachment was observed in the 14 sites where a free gingival graft was positioned after membrane removal (5.0 ± 2.1 mm), than in the 14 sites where conventional protection of the regenerated tissue was accomplished (3.7 ± 2.1 mm).

The systematic assessment of the relevant factors associated with variability of periodontal regenerative outcomes performed at the beginning of the 1990s (Tonetti *et al*. 1993a, 1995, 1996a; Machtei *et al*. 1994; Falk *et al*. 1997) provided further evidence that surgical factors had a great impact on regeneration and led the way to the development of procedures specifically designed for periodontal regeneration. In general, the development of new procedures was aimed at complete tissue preservation in order to achieve and maintain primary closure on top of the applied regenerative material during the critical stages of healing and to save space for blood clot formation and maturation. Specifically, flap designs attempted to achieve passive primary closure of the flap combined with optimal wound stability. In fact, basic and clinical research indicate that, among many, absolute requirements for regeneration include the presence of space for the formation of the blood clot at the interface between the flap and root surface (Haney *et al*. 1993; Sigurdsson *et al*. 1994, Cortellini *et al*. 1995b, c; Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al*. 2004), the stability of the blood clot to maintain a continuity with the root surface and thereby prevent the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993), and protection of the soft tissue of the treated area to avoid bacterial contamination (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b; Sanz *et al*. 2004).

Development of periodontal regenerative medicine in the last 25 years has followed two distinct, though totally interlaced, paths. The interest of researchers has so far focused on regenerative materials and products on the one hand and on novel surgical approaches on the other hand.

Surgical approach to intrabony defects

Papilla preservation flaps

The modified papilla preservation technique (MPPT) was developed in order to increase the space for regeneration and to achieve and maintain primary closure of the flap in the interdental area (Cortellini *et al*. 1995c, d). This approach combines special soft tissue management with the use of a self-supporting titanium-reinforced membrane capable of maintaining a supra-alveolar space for regeneration. The MPPT allows primary closure of the interdental space, resulting in better protection of the membrane from the oral environment (Cortellini *et al*. 1995d). The technique involves the elevation of a full-thickness palatal flap which includes the entire interdental papilla. The buccal flap is mobilized with vertical and periosteal incisions, coronally positioned to cover the membrane, and sutured to the palatal flap through a horizontal internal crossed mattress suture over the membrane. Primary closure between the flap and the interdental papilla is obtained with a second internal mattress suture. Representative cases are shown in Figs. 38-4 and 38-11.

In a randomized controlled clinical study of 45 patients (Cortellini *et al*. 1995c), significantly greater attachment gain was obtained with the MPPT (5.3 ± 2.2 mm) in comparison with either conventional GTR (4.1 ± 1.9 mm) or flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes. In this study, 100% of the sites were closed on top of a titanium-reinforced membrane and 73% remained closed for up to 6 weeks, when the barrier membrane was removed. This study provided proof of principle of the benefit of specific flap designs for periodontal regeneration. The MPPT has been successfully applied in multicenter randomized clinical trials designed to test the generalizability of the added benefits of regenerative approaches in deep intrabony defects (Tonetti *et al*. 1998, 2002, 2004b; Cortellini *et al*. 2001).

A meta-analysis (Murphy & Gunsolley 2003) showed the existence of a trend associating better clinical outcomes with flap designs and closing techniques considered conducive to the achievement and maintenance of primary closure of the flap (Figs. 38-13, 38-14). A similar trend was observed by

Fig. 38-12 Clinical case illustrating the management of the most common complication following application of a non-bioresorbable barrier membrane: membrane exposure and consequent loss of interdental soft tissue. Upon completion of cause-related periodontal therapy, regenerative periodontal surgery was performed to resolve a deep pocket associated with a deep intrabony defect (a, b). The 7-mm intrabony defect was accessed with a modified papilla preservation flap (c) and a non-bioresorbable barrier membrane was placed (d). Primary closure with multilayered sutures was obtained, but 5 weeks after surgery, the membrane became exposed to the oral cavity (e). Upon membrane removal (f), a newly regenerated tissue completely filled the space below the membrane, but inadequate soft tissue was available to completely cover the regenerated tissue in the interdental space. In order to protect the maturation of this tissue, a saddle-shaped interdental free gingival graft was harvested from the palate and shaped to precisely fit the interdental area (g). The graft healed well on the highly vascularized recipient bed and allowed good healing of the interdental tissues. Nine years after completion of therapy, the clinical and radiographic outcomes show healing with shallow probing depths and elimination of the defect (h, i).

Graziani *et al*. (2011) in their meta-analysis of flap surgery studies, where papilla preservation flaps performed better than conventional flap surgery.

The reported MPPT can be successfully applied in sites where the interdental space width is at least 2 mm at the most coronal portion of the papilla. When interdental sites are narrower, the reported technique is difficult to apply. In order to overcome this problem, a different papilla preservation procedure (the simplified papilla preservation flap [SPPF]) has been

proposed for narrow interdental spaces (Cortellini *et al*. 1999a). This approach includes an oblique incision across the defect-associated papilla, starting from the buccal angle of the defect-associated tooth and continuing to the mid-interdental part of the papilla at the adjacent tooth under the contact point. In this way, the papilla is cut into two equal parts of which the buccal part is elevated with the buccal flap and the lingual part with the lingual flap. In the cited study, 100% of the narrow interdental papillae could be closed on top of bioresorbable barriers, and 67% maintained primary closure over time, resulting in 4.9 ± 1.8 mm of CAL gain. This approach has been successfully applied in different multicenter RCTs designed to test the generalizability of the added benefits of using barrier membranes on deep intrabony defects (Tonetti *et al*. 1998, 2002, 2004b; Cortellini *et al*. 2001).

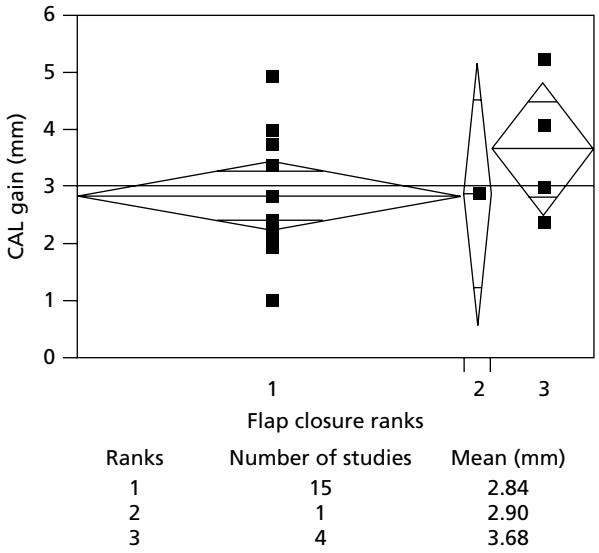

Fig. 38-13 Means of intrabony defect studies examining the relationship between flap closure technique ranking and gain in clinical attachment level (CAL) (in mm) considering only e-PTFE barrier types. Groupings were not statistically different from one another. (Source: Murphy & Gunsolley 2003. Reproduced with permission from John Wiley & Sons.)

In the cited studies, GTR therapy of deep intrabony defects performed by different clinicians on various patient populations resulted in both greater amounts and improved predictability of CAL gain than access flap alone. The issue of soft tissue manipulation to obtain stable protection of the regeneration site has been further explored by applying a microsurgical approach in the regenerative therapy of deep intrabony defects (Fig. 38-15). In a patient cohort study of 26 patients with 26 intrabony defects treated with papilla preservation techniques, primary closure on the barrier was obtained in 100% of the cases and maintained over time in 92.3% of the sites (Cortellini & Tonetti 2001). Treatment resulted in large CAL gain (5.4 ± 1.2 mm) and minimal gingival recession (0.4 ± 0.7 mm). Thus, the improved vision and better soft tissue handling improved the predictability of periodontal regeneration.

Today, the use of papilla preservation flap designs and closure techniques has become the standard approach for regenerative periodontal surgery. In a recent meta-analyses, Graziani *et al*. (2012) and Nibali *et al*. (2020) concluded that papillary preservation flaps enhanced the clinical outcomes of both access flap and regenerative surgery. The consensus panel of the XVI European Workshop in Periodontology *recommended* the use of specific flap designs with maximum preservation of interdental soft tissue such as papilla preservation flaps for the regenerative treatment of residual deep pockets associated with an intrabony defect (Sanz *et al*. 2020). The panel also *recommended* limiting flap elevation, under some specific circumstances, to optimize wound stability

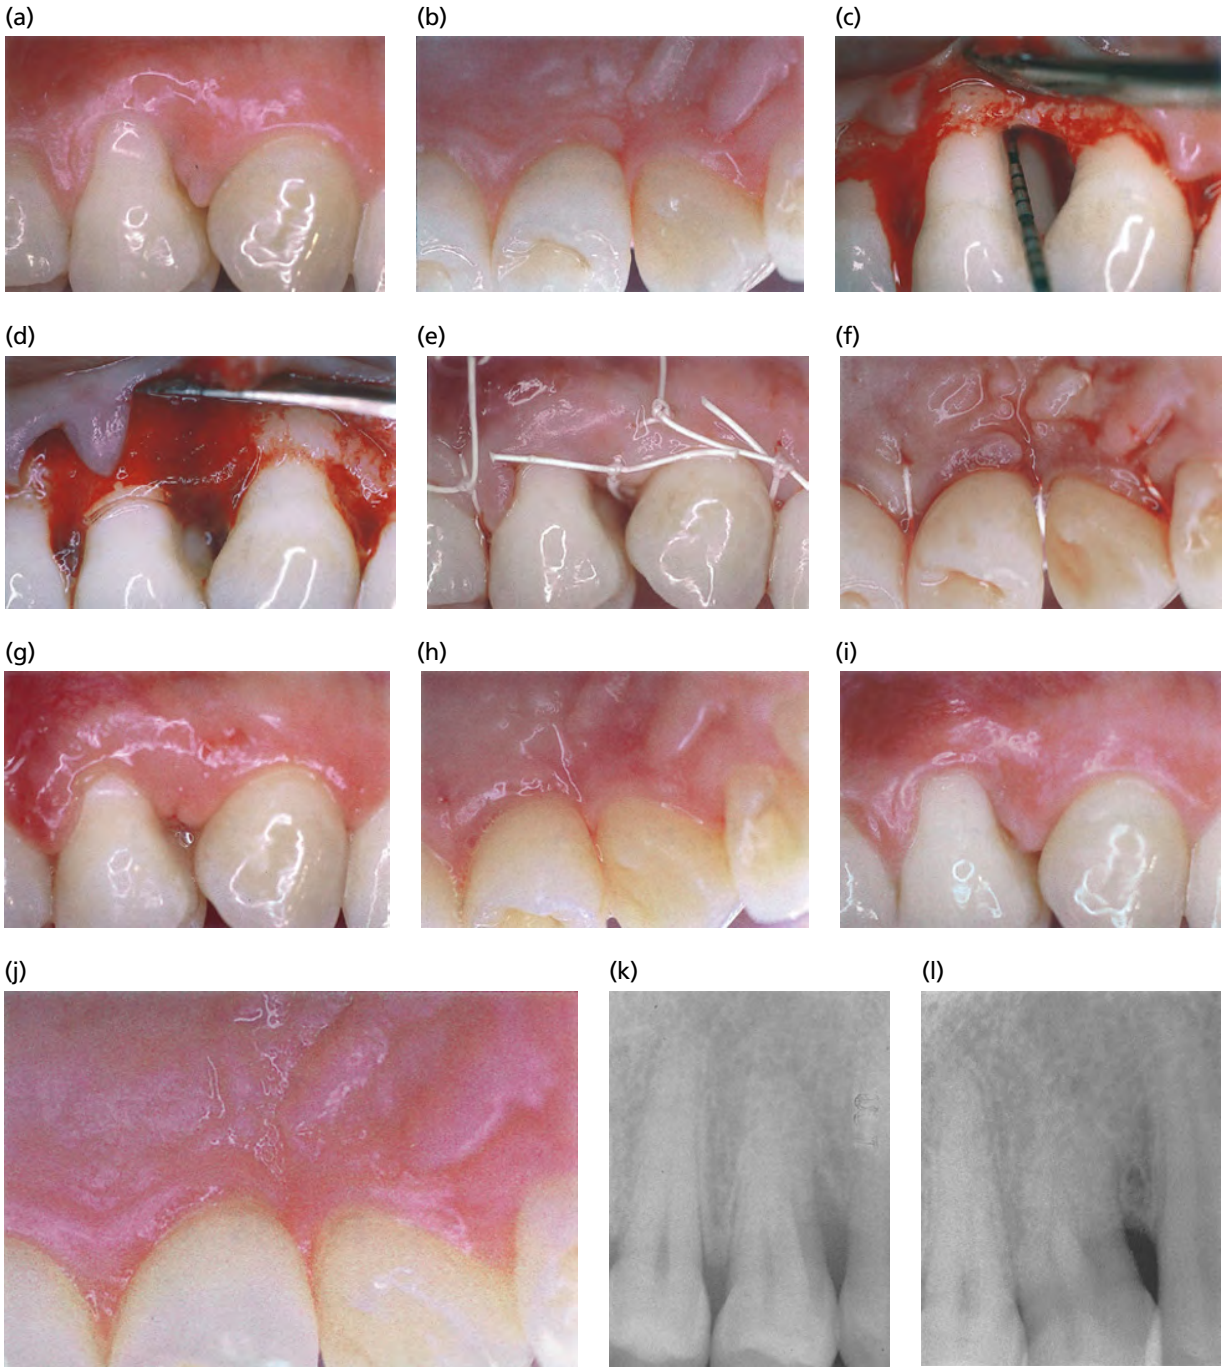

Fig. 38-15 (a) Right first maxillary premolar with a 7-mm pocket on the mesial surface. The interdental space (b) is very narrow (>2 mm), and is accessed with a simplified papilla preservation flap using a microsurgical approach (operative microscope and microsurgical instruments). The 5-mm deep intrabony defect (c) is covered with a bioresorbable barrier membrane (d). Primary closure of the flap over the membrane (e, f) is maintained over time (g, h). After 1 year, the interdental papilla is completely preserved and the residual pocket depth is 3 mm (i, j). The radiograph taken at baseline (k) compared with that taken 1 year after treatment (l) shows that the intrabony defect has healed completely.

and reduce morbidity according to the principles of minimally invasive surgery, that will be discussed in the next paragraphs.

Modified papilla preservation technique

The rationale for developing this technique was to achieve and maintain primary closure of the flap in the interdental space over the membrane (Cortellini *et al*. 1995d) (Figs. 38-16, 38-17, 38-18). Access to the interdental defect is achieved with a horizontal incision traced in the buccal keratinized gingiva at the base of the papilla and connected to mesiodistal buccal intrasulcular incisions. After elevation of a full-thickness buccal flap, the residual interdental tissues are dissected from the neighboring teeth and the underlying bone, and elevated towards the palatal aspect. A full-thickness palatal flap, including the interdental papilla, is elevated and the interdental defect exposed. Following debridement of the defect,

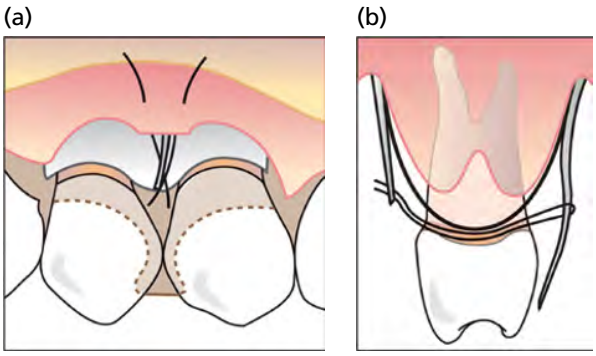

Fig. 38-16 Suture to obtain coronal positioning of the buccal flap: schematic illustration of the crossed horizontal internal mattress suture between the base of the palatal papilla and the buccal flap immediately coronal to the mucogingival junction. Note that the suture crosses above the titanium reinforcement of the membrane. (a) Buccal view; (b) mesiodistal view. (Source: Cortellini *et al*. 1995d. Reproduced with permission from John Wiley & Sons.)

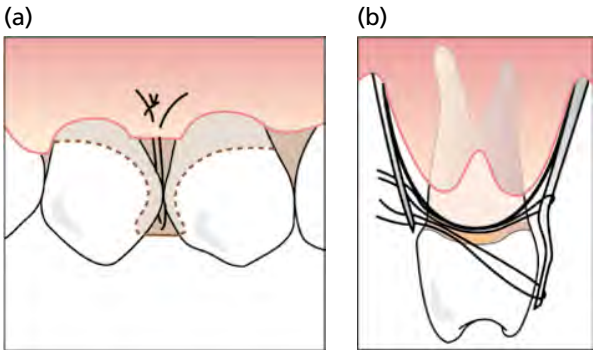

Fig. 38-17 Suture to obtain tension-free primary closure of the interdental space: schematic illustration of the vertical internal mattress suture between the most coronal portion of the palatal flap (which includes the interdental papilla) and the most coronal portion of the buccal flap. (a) Buccal view; (b) mesiodistal view. (Source: Cortellini *et al*. 1995d. Reproduced with permission from John Wiley & Sons.)

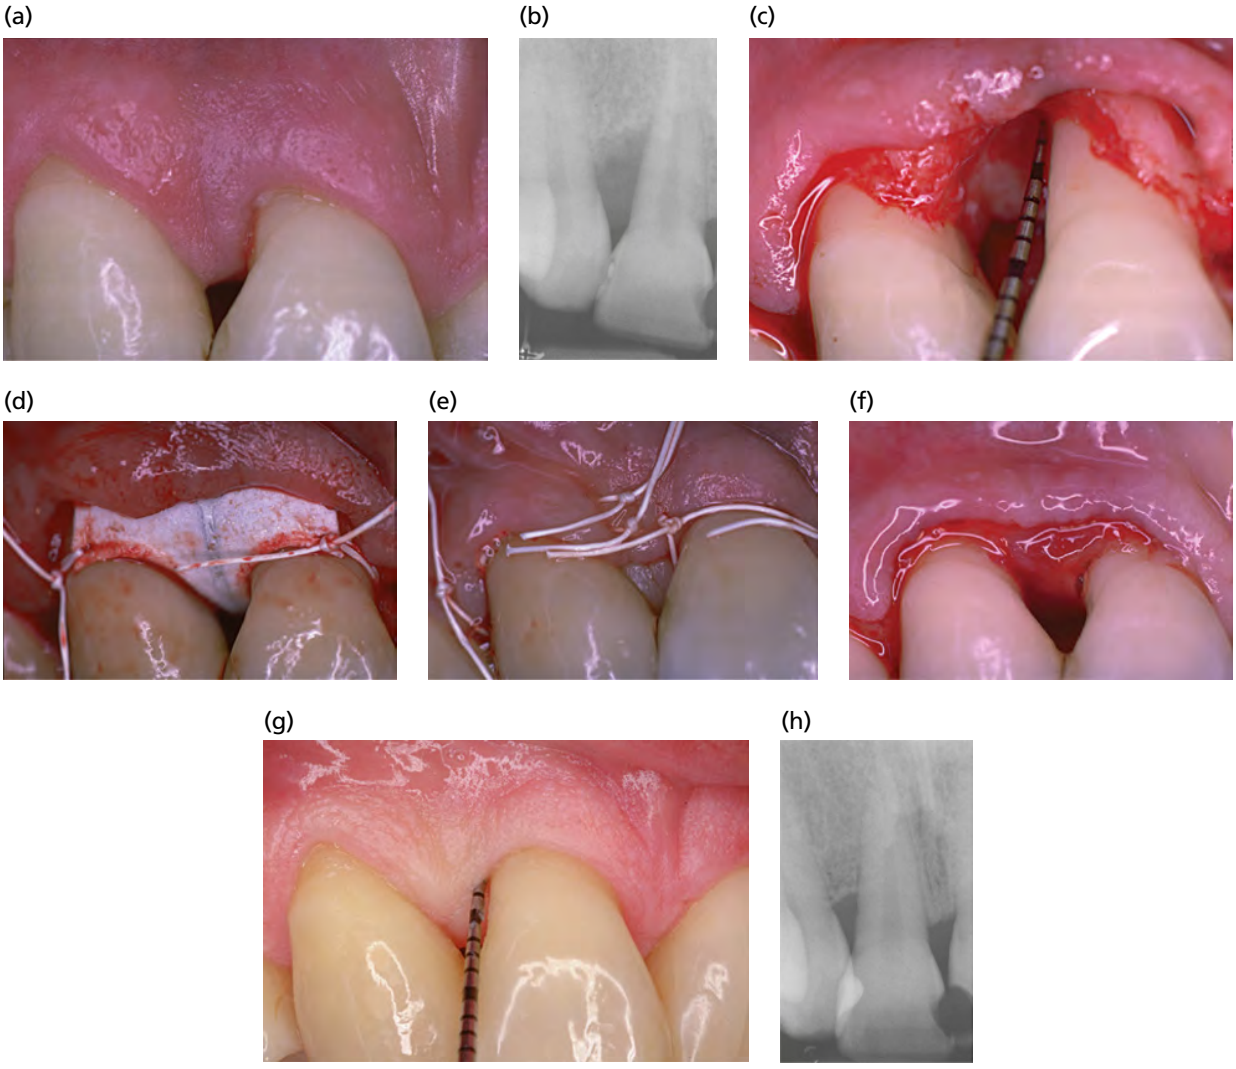

Fig. 38-18 Clinical case illustrating the modified papilla preservation technique (MPPT) used to completely close the interdental space above a barrier membrane. Following completion of initial cause-related therapy, an 8-mm pocket associated with 2 mm of recession of the gingival margin was present on the distal aspect of the central incisor (a). A wide intrabony defect was detectable on the radiograph (b). Defect was accessed with the MPPT, keeping the whole interdental tissue connected with the palatal flap. A 7-mm intrabony defect was uncovered (c). Following root debridement, a titanium-reinforced barrier membrane was positioned (d). Primary closure of the interdental space was obtained by suturing back the papilla preservation flap using a multilayered suturing technique aimed at coronal advancement of the flap, complete relief of wound tension, and good flap stability (e). Six weeks later, the same flap was elevated in order to remove the membrane that had remained completely submerged for the whole time. New tissue filled the space maintained beneath the membrane (f). Following completion of healing (1 year), a 3-mm probing depth and fill of the intrabony defect were observed. The results were maintained over time as indicated by the clinical and radiographic appearance 6 years after regeneration (g, h).

the buccal flap is mobilized with vertical and periosteal incisions, when needed.

This technique was originally designed for use in combination with self-supporting barrier membranes. In fact, the suturing technique requires a supportive (or supported) membrane to be effective (Figs. 38-16, 38-17). To obtain primary closure of the interdental space over the membrane, a first suture (horizontal internal crossed mattress suture) is placed beneath the mucoperiosteal flaps between the base of the palatal papilla and the buccal flap. The interdental portion of this suture hangs on top of the membrane, allowing the coronal displacement of the buccal flap. This suture relieves all the tension in the flaps. To ensure primary passive closure of the interdental tissues over the membrane, a second suture (vertical internal mattress suture) is placed between the buccal aspect of the interdental papilla (i.e. the most coronal portion of the palatal flap, which includes the interdental papilla) and the most coronal portion of the buccal flap. This suture is free of tension.

An alternative type of suture to close the interdental tissues has been proposed by Dr Lars Laurell. This modified internal mattress suture starts from the external surface of the buccal flap, crosses the interdental area, and runs through the lingual flap at the base of the papilla. The suture runs back through the external surface of the lingual flap and the internal surface of the buccal flap, about 3 mm distant from the first two bites. Finally, the suture is passed through the interdental area above the papillary tissues, passed through the loop of the suture on the lingual side, and brought back to the buccal side, where it is tied. This suture is very effective in ensuring stability and primary closure of the interdental tissues.

In a randomized controlled clinical study of 45 patients (Cortellini *et al*. 1995c), significantly greater PAL was gained with the MPPT (5.3 ± 2.2 mm) in comparison with either conventional GTR (4.1 ± 1.9 mm) or access flap surgery (2.5 ± 0.8 mm), demonstrating that a modified surgical approach can result in improved clinical outcomes. The sites accessed with the MPPT showed primary closure of the flap in all but one case, and no gingival dehiscence until membrane removal in 73% of the cases.

This surgical approach has also been used in combination with non-supported bioresorbable barrier membranes (Cortellini *et al*. 1996c), with positive results. CAL gains at 1 year were 4.5 ± 1.2 mm. In all the cases, primary closure of the flap was achieved and about 80% of the sites maintained primary closure over time (Fig. 38-19). It should be underlined, however, that the horizontal internal crossed mattress suture most probably caused an apical displacement of the interdental portion of the membrane, thereby reducing the space for regeneration.

The MPPT can be successfully applied in conjunction with a variety of regenerative materials, including biologically active materials such as EMDs (Tonetti *et al*. 2002) (Fig. 38-20) or growth factors and BRGs (Fig. 38-21) (Tonetti *et al*. 2004b; Cortellini & Tonetti 2005).

The surgical access of the interdental space with the MPPT is technically very demanding, but it has been reported to be very effective and applicable to wide interdental spaces (>2 mm at the interdental tissue level), especially in the anterior dentition. In properly selected cases, large attachment gain and consistent reduction of PPD associated with no or minimal recession of the interdental papilla can be consistently expected. It is, therefore, indicated in cases in whom esthetics are particularly important.

Simplified papilla preservation flap

To overcome some of the technical problems encountered with the MPPT (difficult application in narrow interdental spaces and in posterior areas, suturing technique not appropriate for use with non-supportive barriers), a different approach, the SPPF (Figs. 38-15, 38-22) was subsequently developed (Cortellini *et al*. 1999a).

This simplified approach to the interdental papilla includes a first incision across the defect-associated papilla, starting from the gingival margin at the buccal-line angle of the involved tooth and extending to the mid-interdental portion of the papilla under the contact point of the adjacent tooth. This oblique incision is carried out by keeping the blade parallel to the long axis of the teeth in order to avoid excessive thinning of the remaining interdental tissues. The first oblique interdental incision is continued intrasulcularly in the buccal aspect of the teeth neighboring the defect. After elevation of a full-thickness buccal flap, the remaining tissues of the papilla are carefully dissected from the neighboring teeth and the underlying bone crest. The interdental papillary tissues at the defect site are gently elevated along with the lingual/palatal flap to fully expose the interdental defect. Following defect debridement and root planing, vertical releasing incisions and/or periosteal incisions are performed, when needed, to improve the mobility of the buccal flap. After application of a barrier membrane, primary closure of the interdental tissues above the membrane is attempted in the absence of tension, with the following sutures:

1. A first horizontal internal mattress suture (offset mattress suture) is positioned in the defect-associated interdental space running from the base (near to the mucogingival junction) of the keratinized tissue at the mid-buccal aspect of the tooth not involved with the defect to a symmetrical location at the base of the lingual/palatal flap. This suture rubs against the interdental root surface, hangs on the residual interdental bone crest, and is anchored to the lingual/palatal flap. When tied, it allows the coronal positioning of the buccal flap. Importantly, this suture, lying on the interdental bone crest,

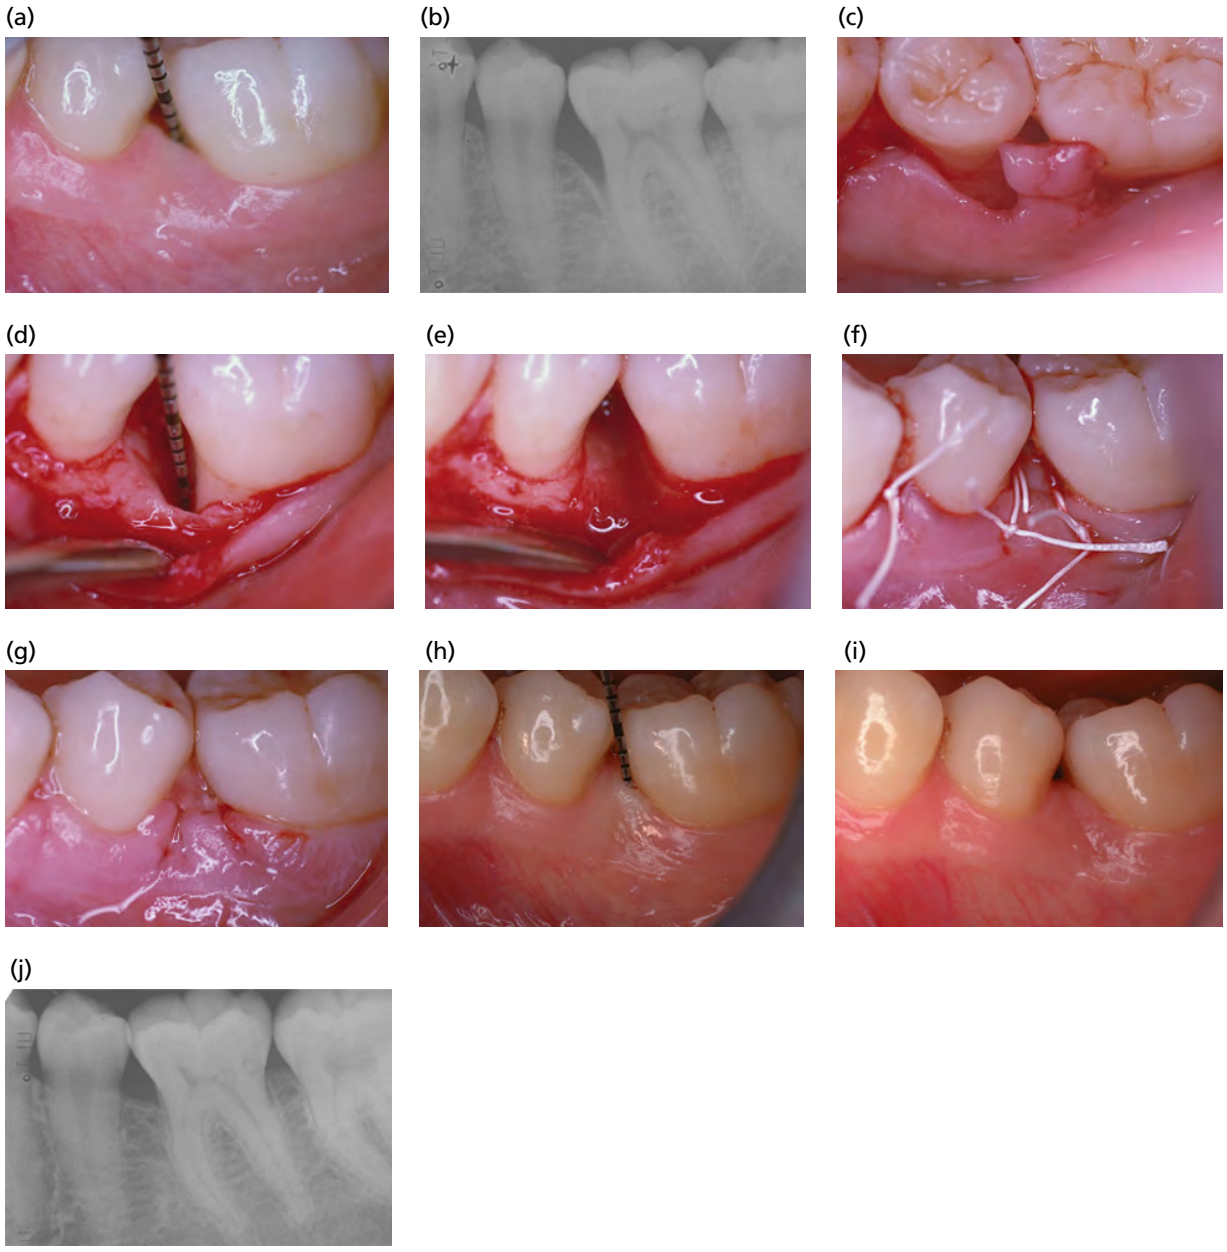

Fig. 38-19 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) to a case treated with a bioresorbable barrier membrane. An 8-mm pocket associated with an intrabony defect persisted on the mesial aspect of the lower first molar following completion of initial cause-related therapy (a, b). The defect was accessed with the MPPT. Note the papilla preserved attached to the lingual flap (c) as well as the presence of a 7-mm intrabony defect (d). Following root debridement, a bioresorbable barrier membrane was positioned and secured around the root of the tooth with bioresorbable sutures (e). Primary closure of the interdental space was obtained with multilayered sutures (f) and was fully maintained at the 1-week suture removal appointment (g). At 6 years, probing depths were 2–3 mm, the soft tissue profile was conducive to optimal self-performed oral hygiene measures, and the radiograph showed elimination of the defect (h–j).

does not cause any compression at the mid-portion of the membrane, therefore preventing its collapse into the defect.

2. The interdental tissues above the membrane are then sutured to obtain primary closure with one of the following approaches: one interrupted suture whenever the interdental space is narrow and the interdental tissues thin; two interrupted sutures when the interdental space is wider and the interdental tissues thicker; an internal vertical/oblique mattress suture when the interdental space is wide and the interdental tissues are thick.

Special care has to be paid to ensure that the first horizontal mattress suture relieves all the tension in the flaps, and to obtain primary passive closure of the interdental tissues over the membrane with the second suture. When tension is observed, the sutures should be removed and the primary passive closure attempted again.

This approach has been preliminarily tested in combination with bioresorbable barrier membranes in a case series of 18 deep intrabony defects (Cortellini *et al*. 1999a). The average CAL gain observed at 1 year was 4.9 ± 1.8 mm. In all the cases

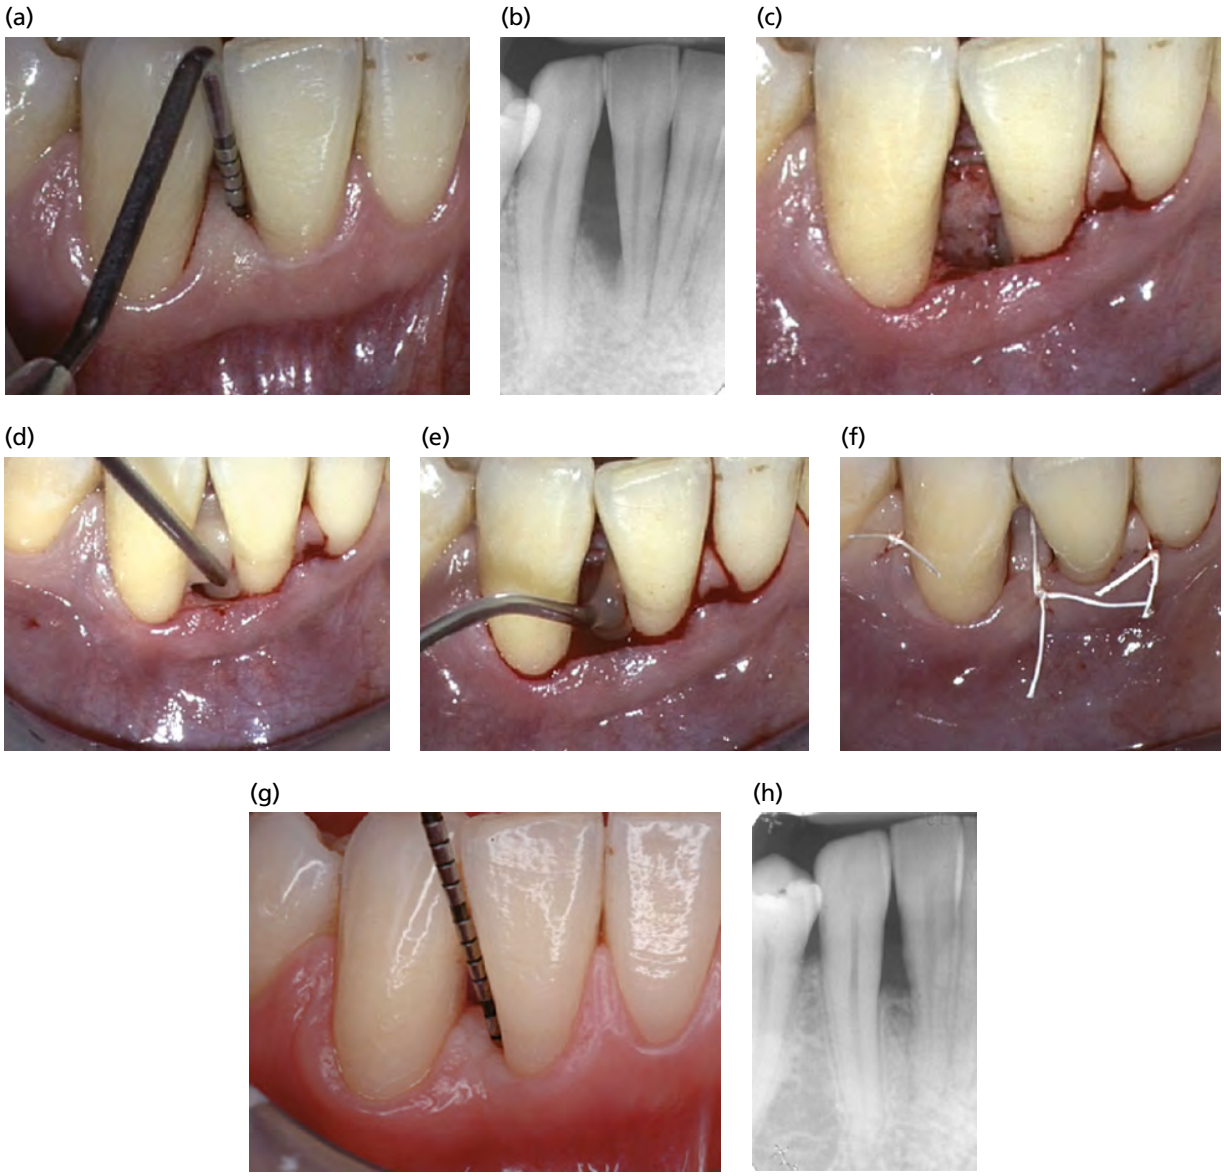

Fig. 38-20 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) in conjunction with the application of enamel matrix derivatives (EMDs). (a) A 10-mm pocket was detectable on the distal aspect of the lower lateral incisor following successful completion of initial cause-related therapy. (b) The radiograph showed the presence of a deep intrabony defect extending to the apical third of the root. The defect was accessed with the MPPT (c) with limited mesial and distal extension of the flap. Following careful debridement, the root was conditioned with an EDTA gel according to the manufacturer's instructions for the application of EMDs (d). After rinsing and drying of the defect and root surface, the EMD gel was applied to the root surface and to fill the defect (e), and flaps were sutured with a multilayer technique to achieve primary closure in the absence of tension (f). (g, h) One year following regenerative surgery, shallow pockets and radiographic resolution of the defect were apparent.

it was possible to obtain primary closure of the flap over the membrane, and 67% of the sites maintained primary closure over time. This approach was tested in a multicenter controlled randomized clinical trial involving 11 clinicians from seven different countries and a total of 136 defects (Tonetti *et al*. 1998). The average CAL gain observed at 1 year in the 69 defects treated with the SPPF and a bioresorbable barrier membrane was 3 ± 1.6 mm. More than 60% of the treated sites maintained primary closure over time. It is important to underline that these results were obtained by different clinicians treating different populations of patients and defects, including those with narrow spaces and involving the posterior areas of the mouth. The SPPF was successfully applied in conjunction with a variety of regenerative materials, including biologically active materials such as EMDs (Tonetti *et al*. 2002) (Fig. 38-23) and BRG (Fig. 38-24) (Cortellini & Tonetti 2004; Tonetti *et al*. 2004b).

Minimally invasive surgical technique (MIST)

More recently there has been a growing interest in a friendlier, patient-oriented surgery and clinical investigators have focused their interest on the development of less invasive approaches. Harrel and Rees

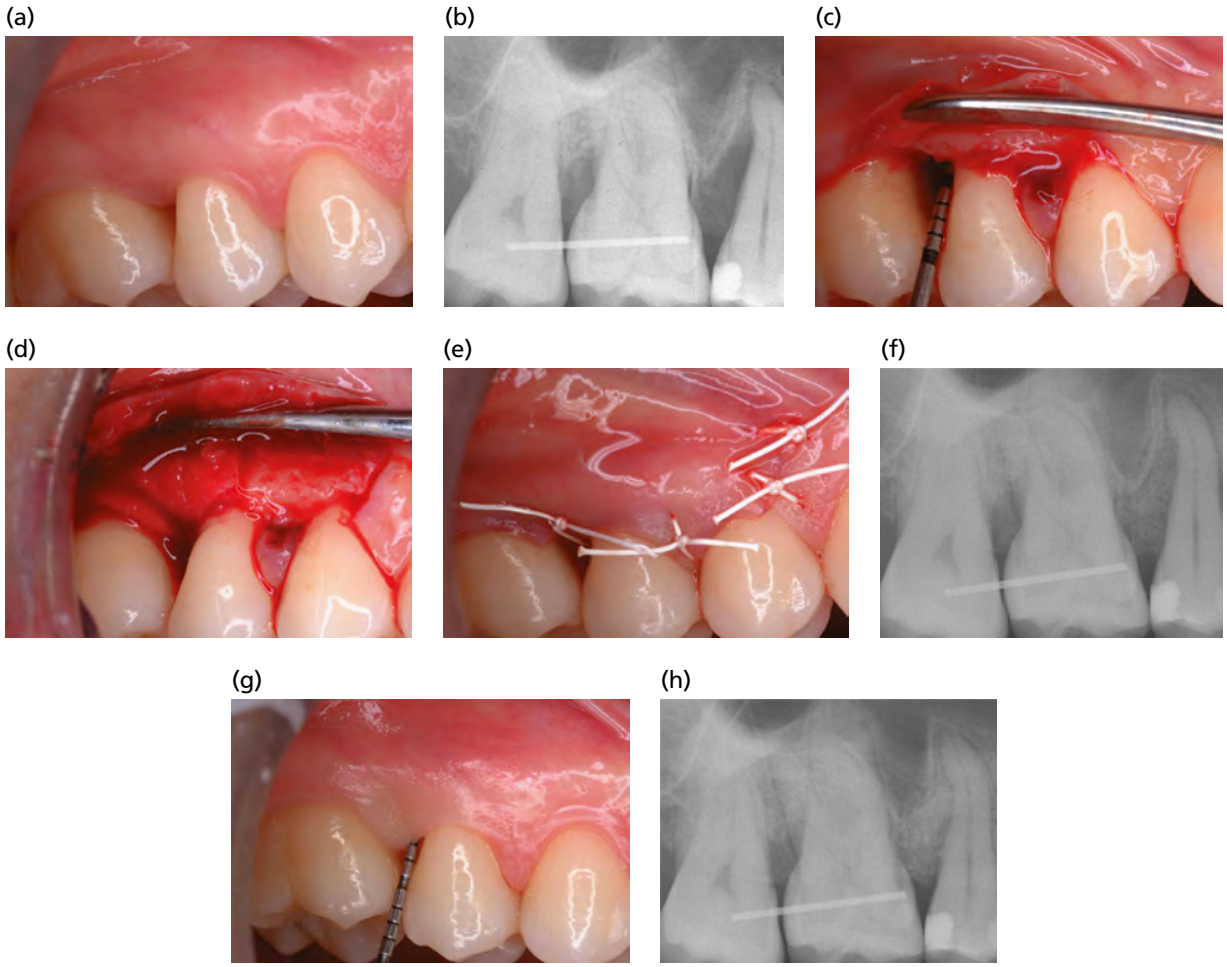

Fig. 38-21 Clinical case illustrating the application of the modified papilla preservation technique (MPPT) in conjunction with a bone replacement graft (BRG) in combination with a bioresorbable membrane. After completion of initial cause-related therapy, a 9-mm pocket associated with an intrabony defect was present on the distal aspect of the upper second premolar (a, b). The defect reached the apical portion of the root and had a 9-mm intrabony component (c). Following careful root debridement, a bioresorbable membrane was adapted to the local anatomy and was positioned to contain the defect. A BRG was subsequently inserted under the membrane to provide additional support for the membrane and for the soft tissues (d). Primary closure was achieved with a single internal mattress suture (e). The control radiograph taken upon completion of the surgery showed the presence of the radio-opaque BRG in the defect (f). At 1-year follow-up, a 3-mm probing depth associated with resolution of the intrabony component of the defect was apparent (g, h). Note that the radio-opaque BRG particles are still detectable but appear embedded in newly formed mineralized tissue.

(1995) proposed the minimally invasive surgery (MIS) approach with the aim of producing minimal wounds, minimal flap reflection, and gentle handling of the soft and hard tissues (Harrel & Nunn 2001; Harrel *et al*. 2005). In order to provide even greater wound stability and to further limit patient morbidity, a papilla preservation flap can be used in the context of a minimally invasive, high-power magnification-assisted surgical technique (Cortellini & Tonetti 2007a). Such a minimally invasive approach is particularly suited for treatment in conjunction with biologically active agents such as EMDs or growth factors and/or grafting materials.

The defect-associated interdental papilla is accessed either with the SPPF (Cortellini *et al*. 1999a) or the MPPT (Cortellini *et al*. 1995d). The SPPF is performed whenever the width of the interdental space is 2 mm or narrower, while the MPPT is applied at interdental sites wider than 2 mm. The interdental incision (SPPF or MPPT) is extended to the buccal and lingual aspects of the two teeth adjacent to the defect. These incisions are strictly intrasulcular to preserve all the height and width of the gingiva, and their mesiodistal extension is kept to a minimum to allow the coronoapical elevation of a very small full-thickness flap with the objective of exposing just 1–2 mm of the defect-associated residual bone crest. When possible, only the defect-associated papilla is accessed and vertical releasing incisions are avoided. With these general rules in mind, different clinical pictures can be encountered in different defects.

The shortest mesiodistal extension of the incision and the minimal flap reflection occurs when the intrabony defect is a pure three-wall, or has shallow two- and/or one-wall subcomponents allocated entirely in the interdental area. In these instances, the mesiodistal incision involves only the defect-associated papilla and part of the buccal and lingual

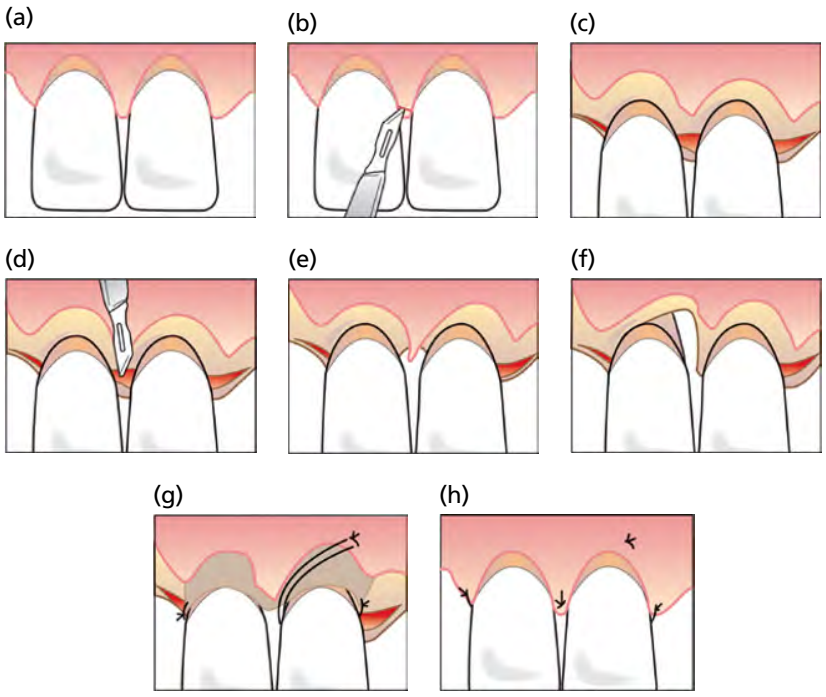

Fig. 38-22 (a) Presurgical appearance of the area to be accessed with a simplified papilla preservation flap (SPPF). The defect is located on the mesial aspect of the maxillary right lateral incisor. (b) First oblique incision in the defect-associated papilla begins at the gingival margin of the mesiobuccal line angle of the lateral incisor. The blade is kept parallel to the long axis of the tooth and reaches the mid-point of the distal surface of the central incisor just below the contact point. (c) First oblique incision continues intrasulcularly in the buccal aspect of the lateral and central incisors, extending to the adjacent papillae, and a buccal full-thickness flap is elevated to expose 2–3 mm of bone. Note the defect-associated papilla is still in place. (d) Buccolingual horizontal incision at the base of the papilla is as close as possible to the interproximal bone crest. Care is taken to avoid a lingual/palatal perforation. (e) Intrasulcular interdental incisions continue in the palatal aspect of the incisors to the adjacent partially dissected papillae. A full-thickness palatal flap including the interdental papilla is elevated. (f) Intrabony defect following debridement. Note the position of the bone crest on the distal aspect of the central incisor. (g) Membrane is positioned to cover the defect and 2–3 mm of remaining bone and secured to neighboring teeth. A horizontal internal mattress suture runs from the base of the keratinized tissue at the mid-buccal side of the central incisor to a symmetric location at the base of the palatal flap. This suture causes no direct compression of the mid-portion of the membrane, preventing its collapse into the defect. (h) Primary closure and complete coverage of the membrane are obtained. (Source: Cortellini *et al*. 1999a. Reproduced with permission from John Wiley & Sons.)

aspects of the two teeth neighboring the defect. The full-thickness flap is elevated minimally, just enough to expose the buccal and lingual bone crest delineating the defect in the interdental area (Fig. 38-25).

A larger coronoapical elevation of the full-thickness flap is necessary when the coronal portion of the intrabony defect has a deep two-wall component. The coronoapical extension of the flap is kept to a minimum at the aspect where the bony wall is preserved (either buccally or lingually), and extends more apically at the site where the bony wall is missing (lingually or buccally), the objective being to reach and expose 1–2 mm of the residual bone crest (Fig. 38-26).

When a deep one-wall defect is approached, the full-thickness flap is elevated to the same extent on both the buccal and the lingual aspects.

When the position of the residual buccal/lingual bony wall(s) is very deep and difficult or impossible to reach with the previously described minimal incision of the defect-associated interdental space, the flap(s) is (are) further extended mesially or distally and one extra interdental space is involved to obtain a larger flap reflection. The same approach is used when the bony defect also extends to the buccal or the palatal side of the involved tooth, or when it involves the two interdental spaces of the same tooth (Fig. 38-27) or two approximal teeth (Fig. 38-28). In the latter instance, a second interdental papilla is accessed, either with an SPPF or an MPPT, according to the indication. Vertical releasing incisions are performed when flap reflection causes tension at the extremities of the flap(s). The vertical releasing incisions are always kept very short and within the attached gingiva (never involving the mucogingival junction). The overall aim of this approach is to avoid using vertical incisions whenever possible or to reduce their number and extent to a minimum when there is a clear indication for them. Periosteal incisions are never performed.

The defects are debrided with the combined use of mini-curettes and power-driven instruments, and the roots carefully planed. During the instrumentation, the flaps are slightly reflected and carefully protected with periosteal elevators and frequent saline irrigations. At the end of instrumentation, the biologically active agent is applied, and then the flaps are repositioned.

The suturing approach in most instances consists of a single modified internal mattress suture at the defect-associated interdental area to achieve primary closure

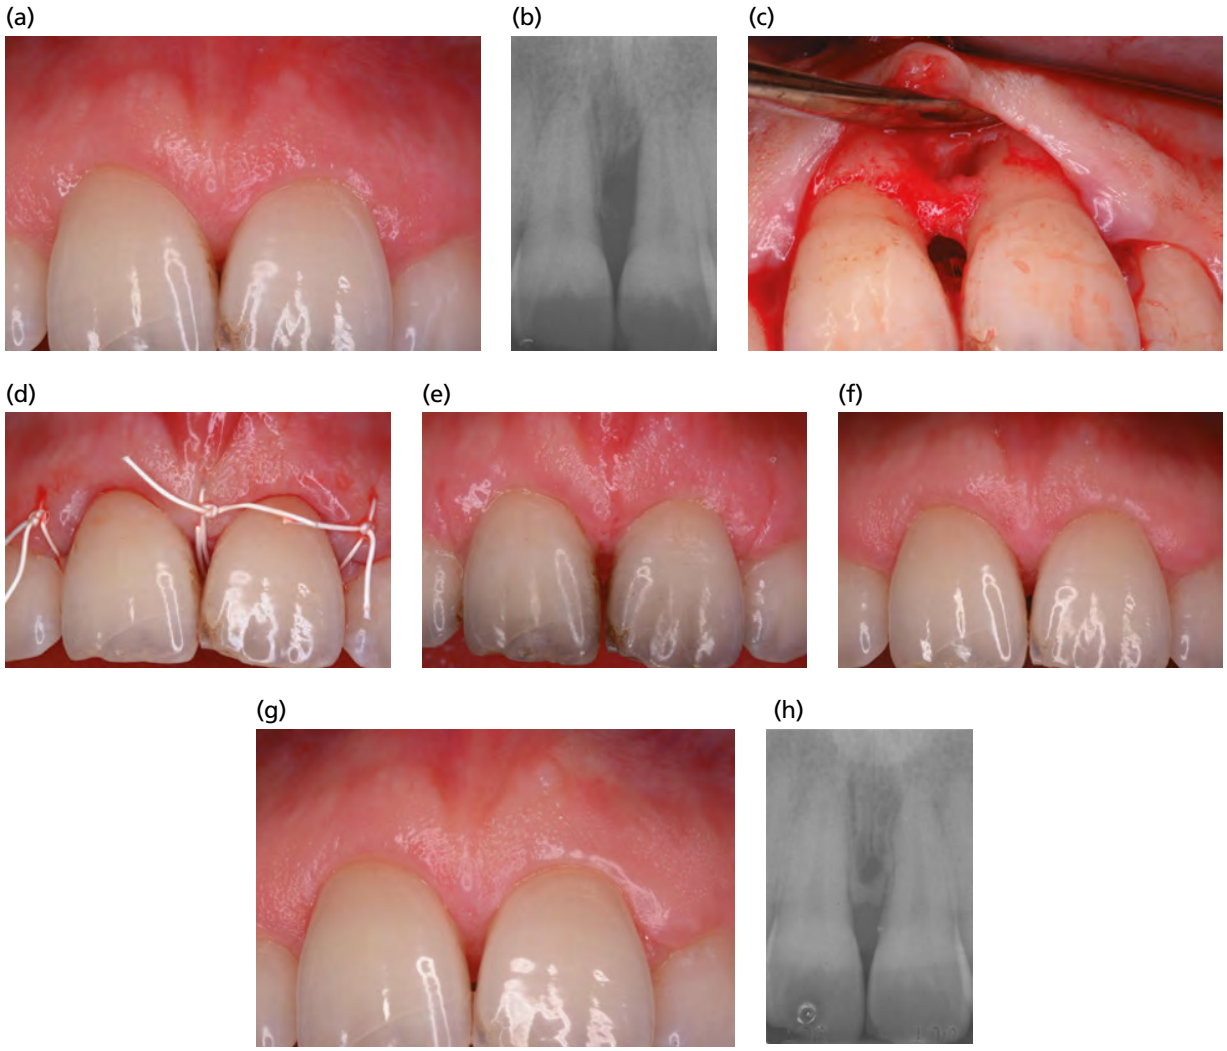

Fig. 38-23 Clinical case illustrating the clinical application of the simplified papilla preservation flap (SFFP) in conjunction with the application of a biologically active regenerative material (enamel matrix derivatives [EMDs] in gel form). At re-evaluation following completion of successful initial cause-related therapy, an 8-mm pocket was detected on the mesial palatal aspect of the left central incisor (a). An angular defect was evidenced on a periapical radiograph (b). The complex anatomy of the defect was apparent following access to the defect with the modified papilla preservation technique (MPPT): a buccal fenestration was apparent with the majority of the defect extending palatally to the apical third of the root (c). Following application of the EMDs, primary closure of the flap was achieved with a multilayered suture (d). At the 1-week suture removal appointment, excellent maturation of the soft tissue healing was apparent (e). At 6 months, a well-represented interdental papilla was present thanks to both the papilla preservation approach and the presence of a bony bridge that assisted in soft tissue support, in spite of the gel formulation of the EMDs (f). Clinical and radiographic outcomes at 1 year showed preservation of excellent esthetics and elimination of the defect (g, h). Probing depths were in the 2–3 mm range.

of the papilla in the absence of any tension (Cortellini & Tonetti 2001, 2005). When a second interdental space has been accessed, the same suturing technique is used to obtain primary closure in this area. Vertical releasing incisions are sutured with simple passing sutures. The buccal and lingual flaps are repositioned at their original level, without any coronal displacement to avoid any additional tension in the healing area.

All the surgical procedures can be performed with the aid of an operating microscope or magnifying loupes at a magnification of ×4 to ×16 (Cortellini & Tonetti 2001, 2005). Microsurgical instruments are utilized whenever needed as a complement to the normal set of periodontal instruments.

This approach has been preliminary tested in two case series with a total of 53 deep intrabony defects (Cortellini & Tonetti 2007a, b). One-year results showed clinically significant improvements (CAL gain of 4.8 ± 1.9 mm with 88.7 ± 20.7% clinical resolution of the defect) and greatly reduced patient morbidity. The same approach was successfully applied to multiple intrabony defects in 20 patients (Cortellini *et al*. 2008). The 44 treated defects gained on average 4.4 ± 1.4 mm of clinical attachment and 73% of defects showed CAL improvements of ≥4 mm. This corresponded to an 83 ± 20% resolution of the defect (15 defects were completely filled). Residual PPDs were 2.5 ± 0.6 mm. A minimal increase of 0.2 ± 0.6 mm in gingival recession between baseline and 1 year was recorded.

A recent controlled clinical study of 30 patients compared MIST plus EMD to MIST alone (Ribeiro

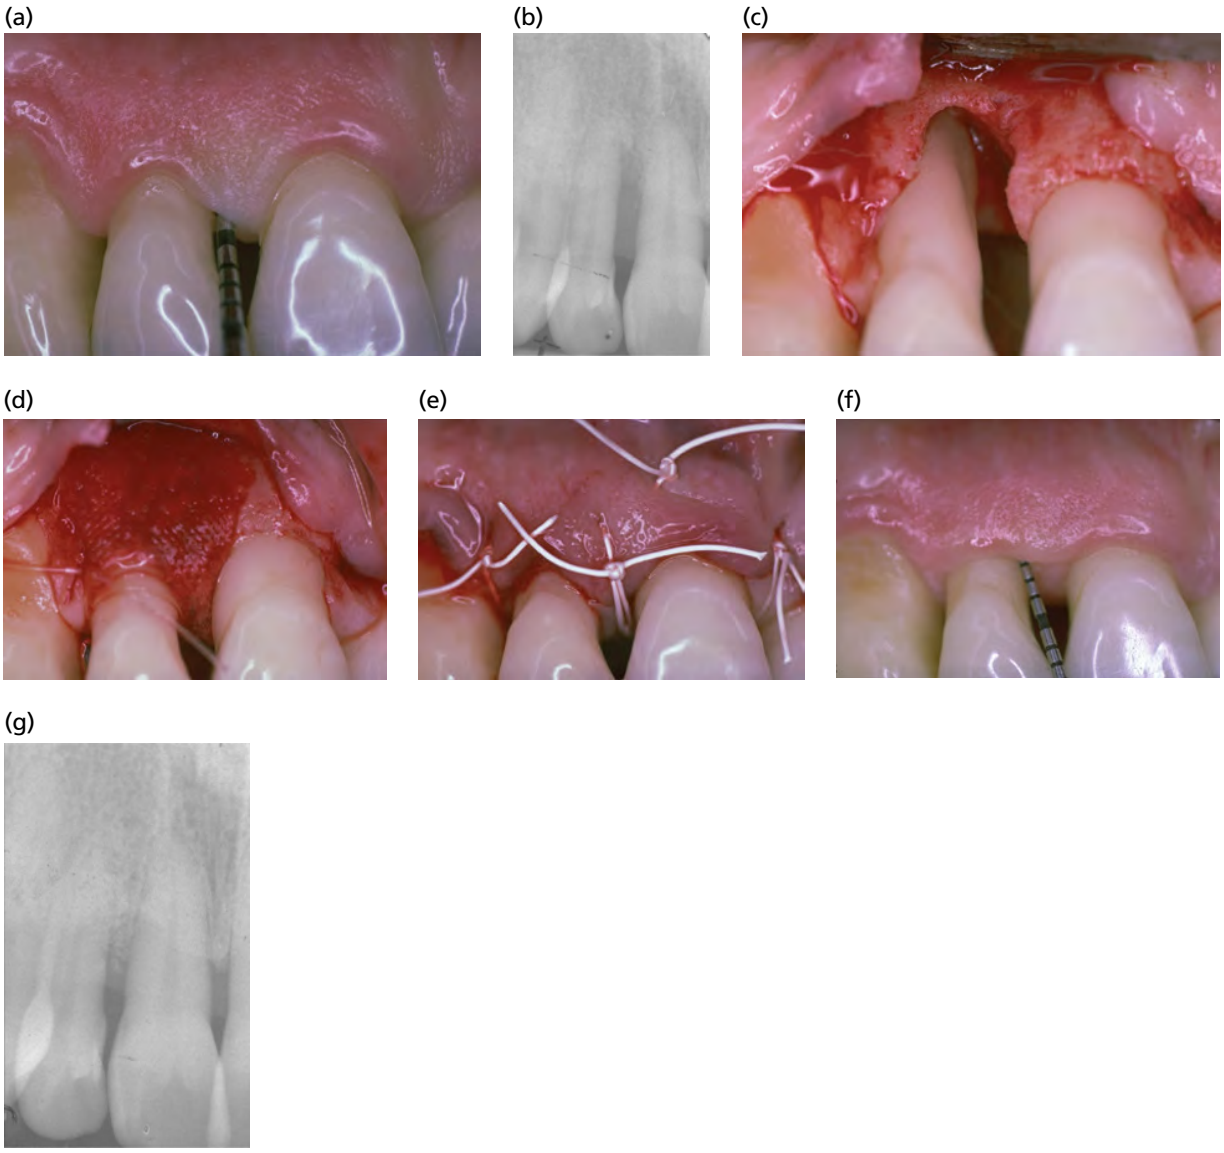

Fig. 38-24 Clinical case illustrating the application of the simplified papilla preservation flap (SPPF) in combination with a bioresorbable barrier membrane applied in combination with a bone replacement graft (BRG). At re-evaluation, a 9-mm pocket was detected on the mesial aspect of the lateral incisor (a). The radiograph showed the presence of a deep intrabony defect (b). Following access with a SPPF, a predominantly two-wall intrabony defect was exposed (c). After careful root instrumentation, a bioresorbable membrane was placed on top of a BRG (d). Primary closure of the flap was obtained with a multilayered suture approach (e). At 6 years, shallow probing depths were present (f); note the moderate increase in recession of the gingival margin. The radiograph at 6 years showed elimination of the defect but persistence of mineralized granules of the BRG embedded in the newly formed mineralized tissue (g).

et al. 2011a). The authors reported significant PPD reduction, CAL gain, and radiographic bone gain at 3 and 6 months in both groups. No differences were detected between therapies at any time point. It was concluded that the use of EMDs did not improve the outcome of the MIST for the treatment of intrabony defects.

Modified Minimally Invasive Surgical Technique (M-MIST)

A development of this technique, the modified minimally invasive surgical technique (M-MIST) (Cortellini & Tonetti 2009b) has been tested (Fig. 38-29). The M-MIST was designed especially to improve flap stability and to provide self-ability to maintain space for regeneration. The surgical approach consists of a tiny interdental access through which only a buccal triangular flap is elevated, while the papilla is left in place, connected to the root of the crest-associated tooth with its supracrestal fibers (see Fig. 38-5). Access to the defect is gained through the tiny buccal triangular flap: from the buccal "window", the soft tissue filling the defect (i.e. the so-called granulation tissues) is sharply dissected from the papillary supracrestal connective tissue and from the bony walls with a microblade, and removed with a mini-curette. Then, the root surface is carefully debrided with hand and mechanical instruments. The supracrestal fibers of the defect-associated papilla and the palatal tissues are left untouched. The minimal wound and

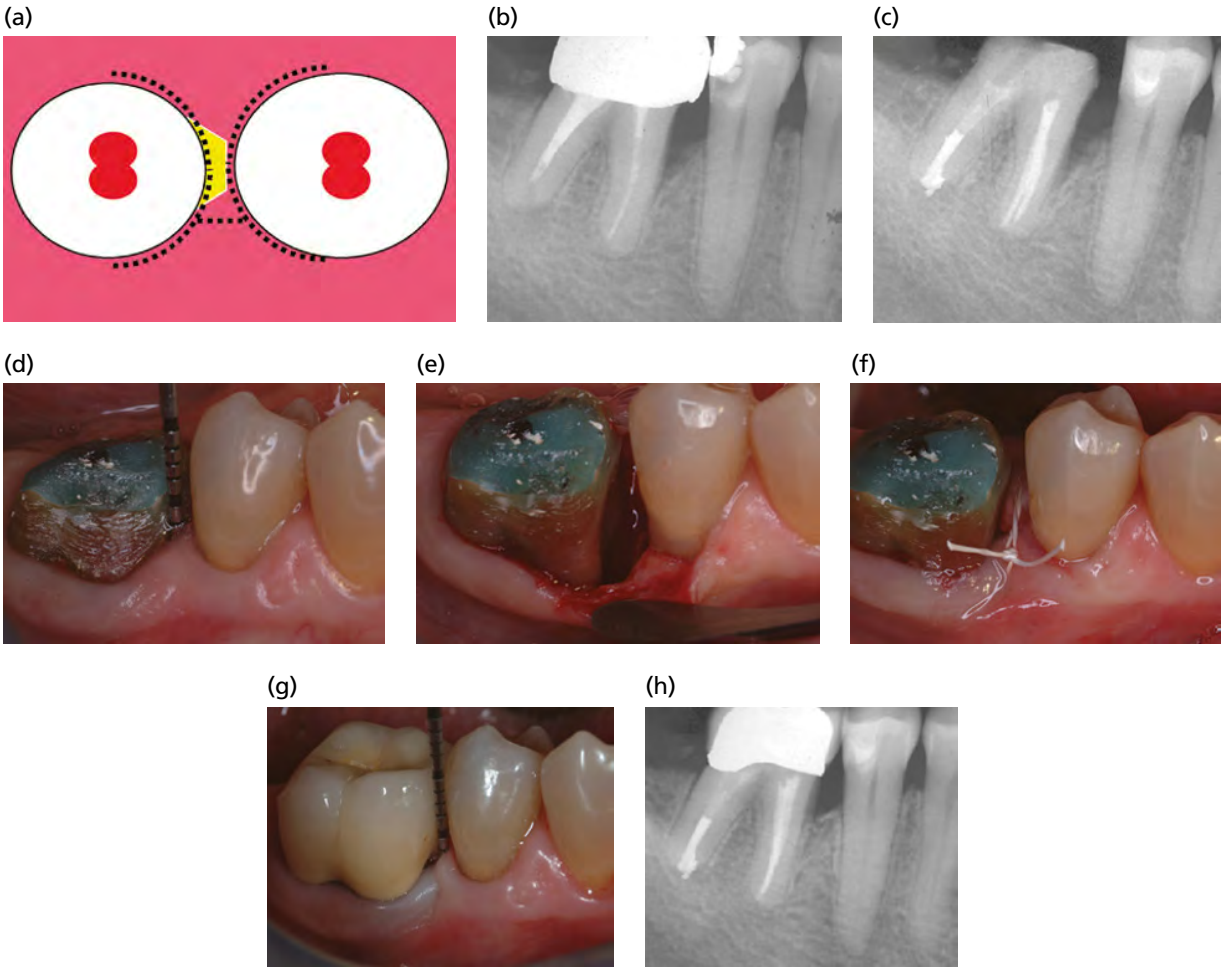

Fig. 38-25 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental three-wall defect. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the interdental space associated with the defect. Mesiodistal extension of the flap was limited to the buccal aspect of the teeth adjacent to the defect in order to optimize wound stability (a). The baseline radiograph showed the presence of dental diseases (periapical infection and caries) that needed to be controlled during the initial cause-related phase of therapy (b). At re-evaluation, an 8-mm pocket associated with the presence of a deep intrabony defect was detected on the mesial aspect of the first molar (c, d). The defect was accessed in a minimally invasive fashion using the MPPT. The three-wall intrabony defect was exposed and carefully debrided (e). After application of enamel matrix derivatives, primary closure was obtained with a single modified internal mattress suture (f). One-year outcomes showed shallow probing depths and almost complete resolution of the defect (g, h).

the minimal flap elevation allows for preservation of most of the vessels providing the blood supply to the interdental tissues, with obvious advantages for the healing process of the interdental wound. This surgical approach with its novel design ensures self-support to the interdentally soft tissues through the "hanging" papilla, thereby enhancing space provision. The flap is extremely stable since most of the soft tissue around the bony defect is not incised or elevated, thereby enhancing blood clot stability. Minimal flap trauma, integrity of the blood supply, and absolute passivity in the suturing technique ensures primary closure of the interdental wound in the majority of the cases, thereby preventing bacterial contamination. The suturing approach is based on the use of a single internal modified mattress suture. Additional sutures can be applied to further increase primary closure, when needed. The reduced buccal access, however, means this approach is not applicable to very deep defects that involve the lingual side of a tooth for which the diseased root surface is not easily accessible for instrumentation from the small buccal window (Cortellini & Tonetti 2009b).

Recently, a three-arm randomized controlled clinical trial was designed to compare the clinical efficacy of the M-MIST alone versus M-MIST combined with EMD and EMD plus bone mineral derived xenograph (BMDX), in the treatment of isolated, interdental intrabony defects (Cortellini & Tonetti 2011). The study was performed on 45 deep isolated intrabony defects accessed with the M-MIST and randomly assigned to three experimental groups: 15 to M-MIST alone, 15 to M-MIST + EMD, and 15 to M-MIST + EMD–BMDX (Fig. 38-30). The differences between baseline and 1 year were statistically significant in the three groups for PPD reduction (P >0.0001, student t-test) as well as CAL gain (P >0.0001). Comparisons between the three groups showed no statistically

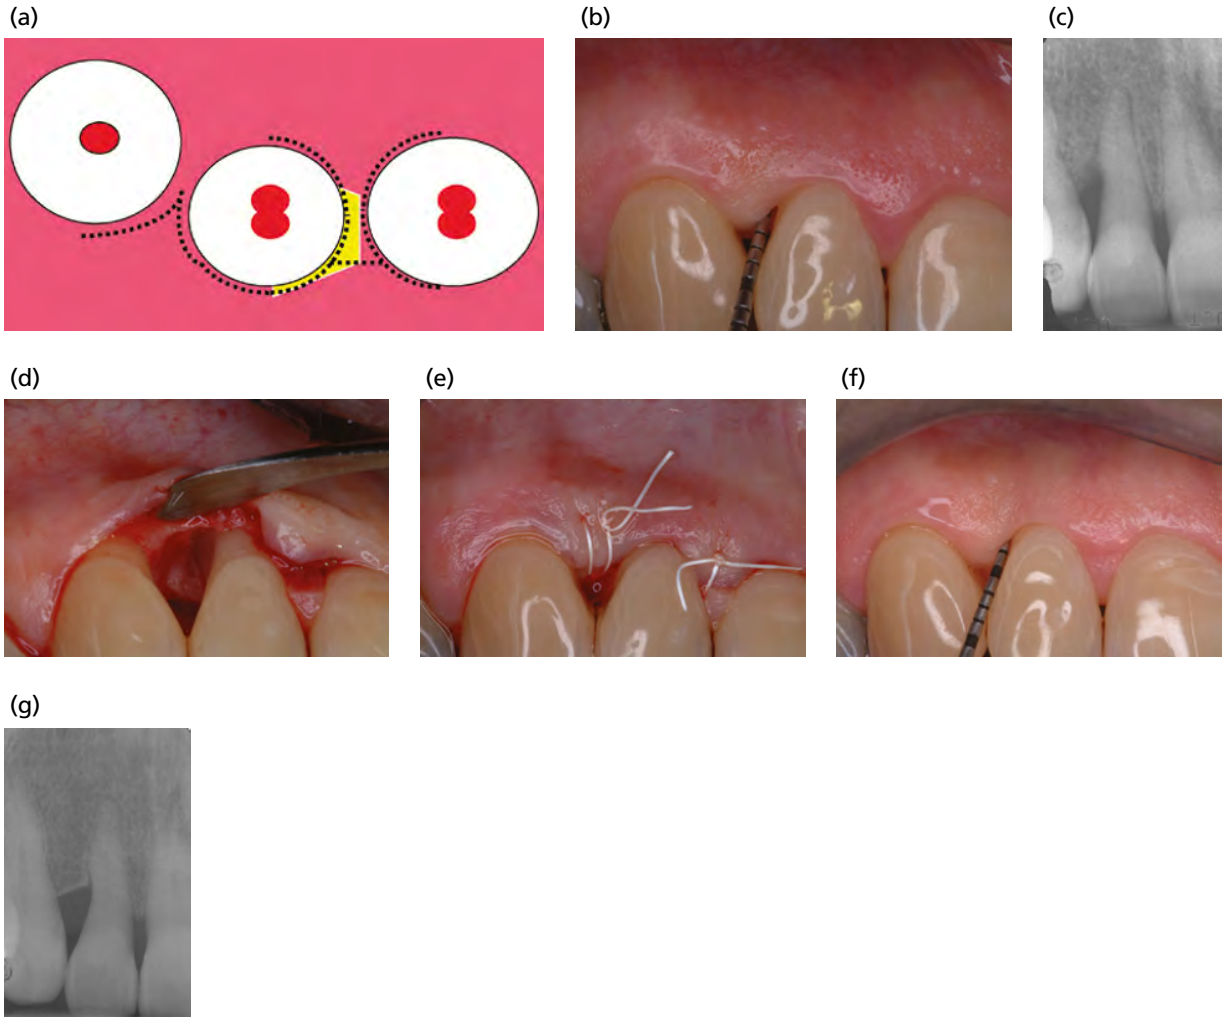

Fig. 38-26 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in an isolated interdental defect extending towards the buccal aspect of the tooth. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the interdental space associated with the defect. Mesiodistal extension of the flap was limited to the buccal aspect of the teeth adjacent to the defect and to the interdental aspect adjacent to the buccal extension of the defect in order to optimize wound stability (a). Following completion of successful initial cause-related therapy, a 6-mm pocket associated with an intrabony defect was detected on the distal aspect of the lateral incisor (b, c). The attachment loss extended to the buccal aspect of the lateral incisor, suggesting the need to obtain access to the buccal aspect of this tooth. The defect was therefore accessed with a minimally invasive approach using the MPPT to access the interdental area and extending the incision to the papilla between the lateral and central incisors to ensure adequate access to the defect (d). Primary closure was obtained with a modified internal mattress suture and a simple passing suture (e). One-year outcomes showed shallow probing depths, good preservation of the soft tissue heights, and resolution of the defect (f, g).

significant difference in any of the measured clinical outcomes. In particular, CAL gain of 4.1 ± 1.4 mm was observed in the M-MIST control group, 4.1 ± 1.2 mm in the EMD group, and 3.7 ± 1.3 mm in the EMD + BMDX group. The percentage radiographic bone fills of the intrabony component were 77 ± 19%, 71 ± 18%, and 78 ± 27%, respectively. This initial controlled study could detect a true difference in CAL of 0.96 mm between the treatment groups. However, the fact that the outcomes among the three groups could not be discriminated raises a series of hypotheses that focus on the intrinsic healing potential of a wound when ideal conditions are provided with the surgical approach. In other words, the outcomes of this study lay down the challenge to clinicians of possibly achieving substantial clinical improvements without the use of products or materials. An independent study (Trombelli *et al*. 2010) reported similar outcomes with no difference between a single flap approach (SFA) alone and SFA plus a bioresorbable barrier and hydroxyapatite. The study was conducted on 24 patients/defects. Authors reported five sites in the SFA + HA/GTR group showing incomplete closure at week 2, which resolved spontaneously. There were no statistically significant or clinically meaningful differences in mean (+/− SD) clinical attachment gain (4.7 +/−2.5 versus 4.4 +/− 1.5 mm), probing depth reduction (5.3 +/−2.4 versus 5.3 +/−1.5 mm), and gingival recession increase (0.4 +/−1.4 versus 0.8 +/−0.8 mm) between the SFA + HA/GTR and SFA groups. Mishra *et al*. (2013) evaluated the efficacy of the M-MIST alone versus M-MIST with local delivery of rhPDGF-BB gel in the treatment of 24 intrabony defects. Gain in CAL and

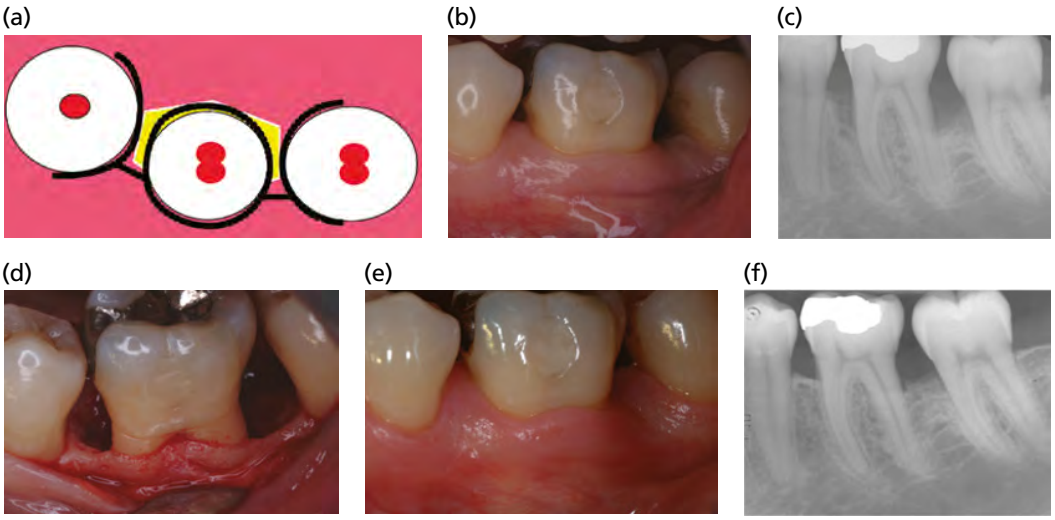

Fig. 38-27 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving both interdental spaces of the same tooth. The schematic diagram shows the extent of the incision performed according to the principles of the modified papilla preservation technique (MPPT) in the two interdental spaces associated with the defects. Mesiodistal extension of the flap was limited to the two interdental papillae associated with the defects (a) and reached the line angle of the two adjacent teeth in order to limit the loss of wound stability, while allowing adequate access to the defects. The clinical and radiographic appearance at baseline highlighted the good control of inflammation obtained following completion of initial cause-related therapy and the presence of deep mesial and distal pockets with associated intrabony defects (b, c). Both the mesial and distal defects were accessed with papilla preservation flaps, the defects were debrided, and the root surfaces were carefully instrumented (d). Following application of enamel matrix derivatives in the well-contained defects, primary closure of the flap was achieved by modified internal mattress sutures. At 1-year follow-up, shallow pockets, preservation of soft tissues, and elimination of the defects were apparent (e, f).

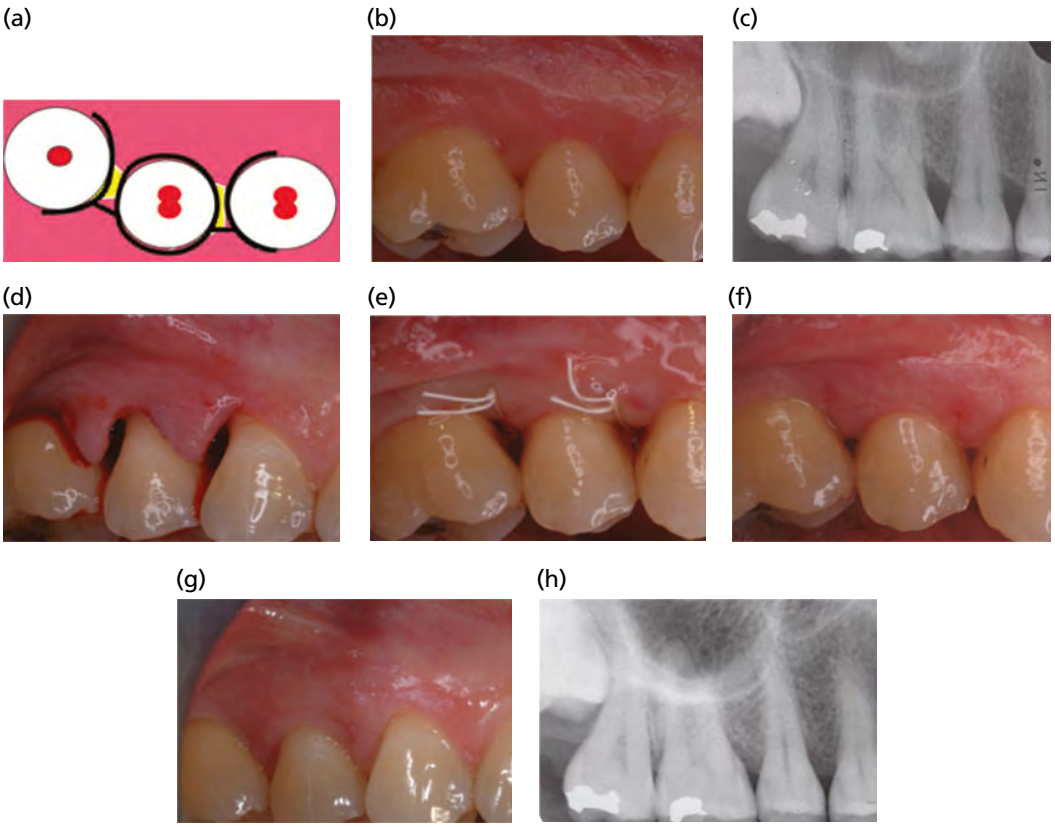

Fig. 38-28 Clinical illustration of the use of the minimally invasive surgical technique (MIST) in intrabony defects involving two adjacent teeth. The schematic diagram shows the extent of the incision performed according to the principles of the papilla preservation flaps in the two interdental spaces associated with the defects. Mesiodistal extension of the flap was limited to the two interdental papillae associated with the defects (a) and reached the line angle of the two adjacent teeth in order to limit the loss of wound stability and to limit flap extension. After successful initial cause-related therapy, two defects were present on the mesial aspect of the first molar and second premolar (b, c). Simplified papilla preservation flaps (SPPF) were used to access the defects (d). Incisions were stopped at the distal line angle of the first premolar and on the buccal aspect of the first molar. Root debridement and application of enamel matrix proteins in gel form were performed before primary closure of the flap with two modified internal vertical mattress sutures (e). Excellent early healing in the absence of pain or discomfort was evident at the 1-week suture removal (f). At 1-year follow-up, absence of inflammation, shallow probing depths, and resolution of the defects were evident (g, h).

Fig. 38-29 Clinical case treated with the modified minimally invasive procedure (M-MIST). A 10-mm pocket mesial to the upper right cuspid (a) was associated with a deep intrabony defect reaching the mid third of the root (b). The area was accessed with the M-MIST procedure (c). The buccal flap was minimally elevated to the mid-buccal contour of the cuspid and the lateral incisor. The defect-associated interdental papilla was left untouched and the lingual flap was not elevated. The intrabony defect and the exposed root surface were instrumented through the small buccal surgical "window". A single modified internal mattress suture was positioned to close the area (d). No regenerative material was placed into the defect, leaving the natural blood clot alone to fill the intrabony component. Integrity of the primary closure of the wound was maintained after 1 week (e). One-year clinical photograph showed a 3-mm normal sulcus, associated with a 7-mm clinical attachment gain and no increase in gingival recession (f). One-year radiograph showed the complete resolution of the intrabony component of the defect (g).

linear bone growth was 3 ± 0.89 mm and 1.89 ± 0.6 mm in test group and 2.64 ± 0.67 mm and 1.85 ± 1.18 mm in control group, respectively, and did not show statistical significance. Authors concluded that the improvement in both groups could be attributed to the novel surgical technique rather than addition of rhPDGF-BB.

In a recent study, Schincaglia *et al*. (2015) reported similar clinical outcomes when treating intrabony defects with a flap based on the elevation of the defect associated papilla versus a flap designed to keep the papilla in place (SFA). The regenerative material applied was rhPDGF-BB and β-TCP. A recent systematic review on MIS applied to intrabony defects (Barbato *et al*. 2020) concluded that MIS represents a reliable treatment for isolated intrabony defect. Another meta-analysis (Liu *et al*. 2016) suggested no significant difference in treatment of intrabony defects between the MIS plus biomaterials group and the MIS alone group, indicating that it is important to take costs and benefits into consideration when a decision is made about a therapeutic approach.

Entire Papilla Preservation Technique (EPP)

Recently, a novel technique, the entire papilla preservation technique (EPP) has been proposed (Aslan *et al*. 2017a, b) for treatment of isolated intrabony defects. The EPP technique is a tunnel-like approach of the defect-associated interdental papilla (Fig 38-31). Following a buccal intracrevicular incision, a bevelled vertical releasing incision is performed in the buccal gingiva of the neighbouring interdental space and extended just beyond the mucogingival line to provide appropriate mechanical

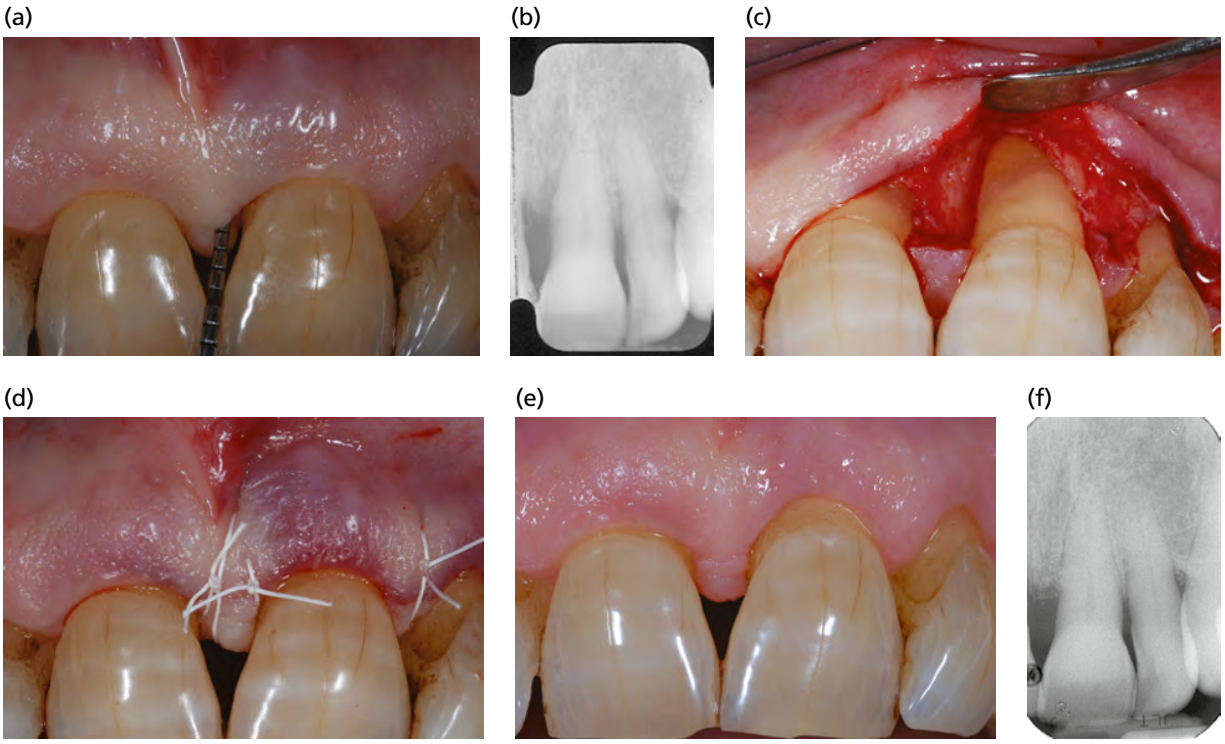

Fig. 38-30 Clinical case treated with the modified minimally invasive procedure (M-MIST) + enamel matrix derivatives (EMDs) + Bio-Oss®. A 7-mm attachment loss was associated with a 6-mm pocket depth at the mesial side of the left upper central incisor (a). The intrabony defect was evident on the baseline radiograph (b). The area was accessed with the M-MIST approach. The flap was extended to the distal interdental space to uncover the buccal bone dehiscence (c). The flap was sutured after positioning of EMDs and grafting material (d). Clinical photograph (e) and radiograph (f) at 1 year showed the resolution of the periodontal lesion.

access to the intrabony defect. A microsurgical periosteal elevator is used to elevate a buccal full-thickness mucoperiosteal flap extending from the vertical incision to the defect-associated papilla. A specifically designed angled tunnel elevator facilitates the interdental tunnel preparation under the papillary tissue. Utmost care is taken to elevate the full thickness of the interdental papilla up to the intact lingual bone crest. Granulation tissue is removed from the inner aspect of the defect-associated interdental papilla. Excessive thinning of the papilla must be avoided to avoid compromising the blood supply. The granulation tissue is then removed with a mini-curette and the root surface debrided and planed. Regenerative materials like EMD and/or bone substitutes can be placed into the intrabony defect. A collagen barrier can be utilized to contain the biomaterial. Sutures are applied for optimal wound closure of the surgical area. A recent RCT (Aslan *et al*. 2020) on 30 patients compared the EPP alone versus EPP and amelogenins. The authors reported 100% primary closure of the flap maintained through the early wound healing; a highly significant CAL gain of 6.3 ± 2.5 mm and PD reduction of 6.5 ± 2.65 mm was observed in the EPP + EMD group, while CAL gain and PD reduction were 5.83 ± 1.12 mm and 6.2 ± 1.33 mm, respectively in the EPP group. A slight statistically not significant increase in gingival recession of 0.2 ± 0.25 mm and 0.36 ± 0.54 mm was reported. EPP is an advanced flap procedure, based on the concepts of microsurgery and MIS, that requires competence and surgical skills and cannot be extended to any intrabony defect. The application of EPP is indicated in isolated interproximal intrabony defects. The ample involvement of the palatal side of a tooth makes this approach not applicable. It is a matter of fact that a 2-wall intrabony defect with a missing buccal bony wall and a relatively well-preserved lingual wall is the best indication for EPP.

Technical implications

The studies cited in the previous section propose three different minimally invasive approaches to intrabony defects (Cortellini 2012). The MIS (Harrel & Rees1995) and the MIST (Cortellini & Tonetti 2007a, b) include the elevation of the interdental papillary tissues to uncover the interdental space, gaining complete access to the intrabony defect; the M-MIST (Cortellini & Tonetti 2009a) in which the access to the defect is gained through the reflection of a small buccal flap, without elevation of the interdental papilla (Figs. 38-27, 38-28, 38-29, 38-30); the EPP that is based on a tunnel-like approach with no incision of the interdental papilla (Aslan *et al*. 2017a). The major problem to be overcome when applying MIS is the visibility and manipulation of the surgical field. This issue is clearly enhanced in the M-MIST and EPP approaches. High magnification and direct optimal illumination can help in solving the problem. Thereby, the adoption of magnifying devices, like loops or operating microscopes, are strongly recommended. Traditionally, dental surgeons are taught

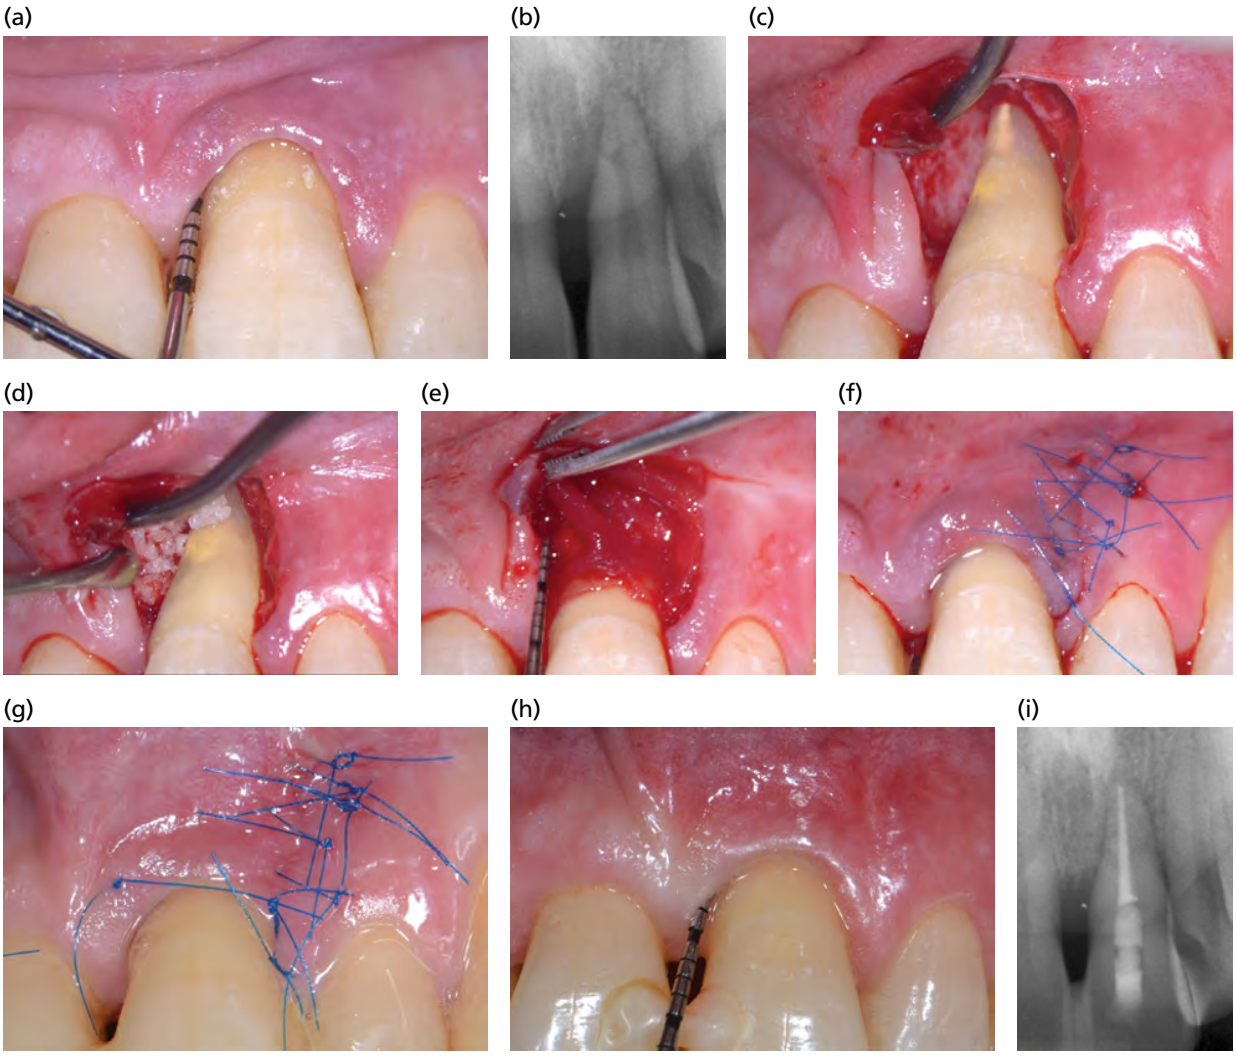

Fig. 38-31 Clinical case treated with the entire papilla preservation technique (EPP). Probing depth of 10 mm, with a 13 mm clinical attachment level (CAL) (a) is associated with bone destruction involving the apex (b). Access to the defect using the EPP technique by avoiding an incision over the defect-associated papilla (c). Note the osseous defect involving the apex. Application of bone substitutes to fill the defect (d). Application of a collagen membrane to cover the defect (e). Primary wound closure is obtained with microsurgical suturing technique (f). Primary closure maintained 7 days postoperatively, when sutures are removed (g). Clinical condition at 1-year examination. The probe indicates a 3 mm residual probing depth and 7 mm CAL gain (h), associated with the mineralization of the intrabony component of the defect (i). (Source: Courtesy Dr. Serhat Aslan.)

to raise large flaps to completely expose the area of interest. In reality, visibility of the defect is restricted by the residual bony walls that surround the defect. The elevation of a flap to the edge of the residual bony walls should therefore be sufficient to visualize the defect: over-reflection of the flaps does not increase defect visibility. However, the minimal flap reflection narrows the angle of vision and especially the light penetration into the surgical field. In addition, the soft tissue manipulation during instrumentation requires more care since the flaps, which are not fully reflected, lie very close to the working field. Use of small instruments, like small periosteal elevators and tiny tissue players, is mandatory for soft and hard tissue manipulation. Microblades, mini- or microcurettes, and miniscissors allow for full control over the incision, debridement, and refinement of the surgical area, and sutures from 6-0 to 8-0 are mandatory for wound closure.

Flap design for furcation involvement

Flap design for buccal and lingual mandibular and buccal maxillary class II furcations, the so-called "key hole", were described more than 20 years ago and have not been substantially modified since (Pontoriero *et al*. 1988; Andersson *et al*. 1994; Jepsen *et al*. 2004). Following intrasulcular incisions, a mucoperiosteal flap is raised at the buccal or lingual aspect of the alveolar process (Fig. 38-32). The root surfaces are carefully scaled and planed using hand and power-driven instruments and rotating, flame-shaped diamond burs. Remaining granulation tissue in the furcation area is carefully removed to expose the surface of the alveolar bone.

The regenerative material of choice (a non-bioresorbable or a bioresorbable barrier, a bone graft, a biologically active agent, or a combination approach) is positioned at the furcation area (Fig. 38-33). When

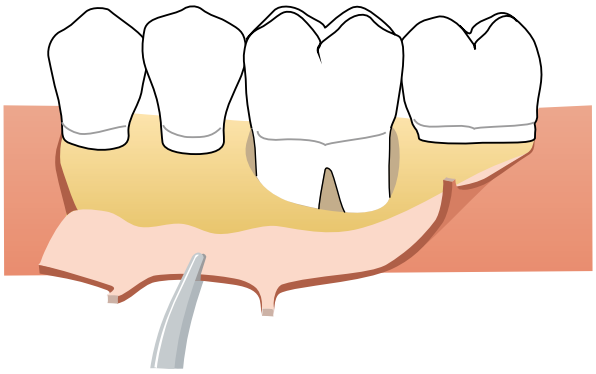

Fig. 38-32 Furcation involvement: step-by-step approach. Following marginal incisions and vertical releasing incisions on the buccal aspect of the jaw, buccal and lingual full-thickness flaps are elevated.

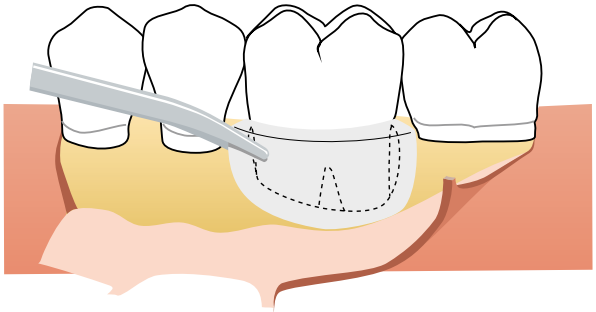

Fig. 38-33 Furcation involvement: step-by-step approach. The barrier material is placed in such a way that it completely covers the defect and extends over at least 3 mm of bone beyond the defect margin.

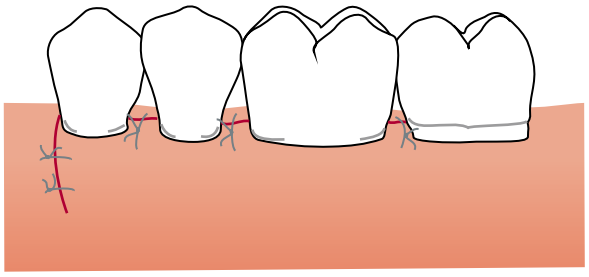

Fig. 38-34 Furcation involvement: step-by-step approach. The elevated tissue flaps are coronally displaced and sutured in such a way that the border of the barrier material is at least 2 mm below the flap margin.

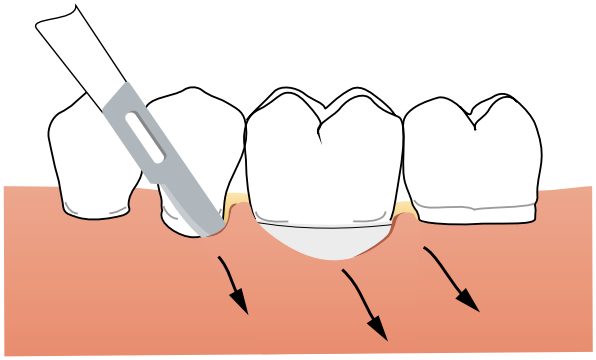

Fig. 38-35 Furcation involvement: step-by-step approach. In order to remove the barrier material, an incision is made extending one tooth mesially and distally to the border of the barrier. After reflecting the covering tissue flaps, the barrier can be removed without compromising the newly regenerated tissue.

a barrier is used, it is adjusted to cover the entrance (buccal or lingual) of the furcation area, the adjacent root surfaces (from the distobuccal/lingual line angle of the distal root to the mesiobuccal/lingual line angle of the mesial root), and a 4–5-mm wide surface of the alveolar bone apical to the bone crest. The membrane can be retained in position by sutures placed around the crown of the molar using a sling technique. When a graft is preferred, it is positioned to completely fill the furcation area and slightly overfill the entrance. Biologically active agents are delivered into the furcation area. A combination approach requires the positioning of different biomaterials according to the properties of each material.

Following placement of the regenerative material, the mucoperiosteal flap is repositioned to completely cover the furcation and the biomaterials (Fig. 38-34). A periosteal incision can be made, when needed, to coronally advance the flap. The flap is secured with interdental or sling sutures. The sutures are removed 7–15 days after surgery. When a non-bioresorbable barrier is positioned, a second surgical procedure to remove the barrier is performed after a healing period of about 6 weeks (Fig. 38-35).

The surgical technique has been carefully refined and revised by McClain and Schallhorn (2000). Their surgical technique is especially designed for combination therapy (barrier plus grafting material) and is based on a common core, modified as necessary for specific situations. This common core employs a sulcular incision full-thickness envelope flap with maximum retention of gingival and papillary tissues and sufficient exposure of the defect for adequate visualization and access for debridement. If recession has occurred and/or coronal flap positioning is required for membrane coverage, periosteal separation is also performed.

The defect is debrided and the root surface planed to remove plaque, accretions, enamel projections, and other root surface alterations (grooves, notches, caries, etc.) employing ultrasonic or sonic, hand and rotary (fine diamond and/or finishing burs) instrumentation. Odontoplasty and/or osteoplasty are performed if required for adequate access to the defect, including intraradicular or furcation fundus concavities, and/or for reduction of enamel projections. Adequate root preparation is considered critical to a successful outcome.

The bone graft is prepared (typically by DFDBA) in a dappen dish with hydration with sterile saline or local anesthetic solution and, if there is no contraindication, combined with tetracycline (125 mg/0.25 g of DFDBA). After mixing, the dappen dish is covered with a sterile, moistened gauze to prevent drying of the graft. The appropriate membrane is selected and trimmed to fit into the desired position, and then placed on sterile gauze. Care is taken to prevent

membrane contamination via contact with the lips, tongue, mucosa, or saliva.

The area is thoroughly cleansed and isolated, and the root surface at the regenerative site is treated with citric acid (pH 1) for 3 minutes using cotton pellets, with care taken to contain the solution to the root and bone surface. The pellets are removed and the site inspected for any residual cotton fibers prior to flushing it with sterile water or saline. Intramarrow penetration is then performed with a 1/4 round bur if a sclerotic bone surface exists in the graft site. The ligament surface is "scraped" with a periodontal probe to remove any eschar and to stimulate bleeding, and the DFDBA is packed firmly into the defect using an overfill approach, along with covering the root trunk and combination or confluent intrabony, dehiscence or horizontal/crestal osseous defects. The custom-made membrane is placed over the graft and secured as appropriate. After rechecking to be sure adequate graft material remains in the desired area, the flap is positioned to cover the membrane and secured with non-bioresorbable sutures (typically Gore sutures). Throughout the root conditioning and subsequent treatment to closure, the site remains isolated to avoid saliva contamination.

If a non-bioresorbable membrane is used, it is removed at 6–8 weeks postoperatively by employing minor flap reflection, de-epithelialization of the internal aspect of the flap adjacent to the membrane, gentle removal (peeling) of the membrane outward from the site, and flap positioning to cover the regenerated tissues as feasible. Closure with sutures is then accomplished with non-bioresorbable sutures.

Flap design for combined furcation and intrabony defects

Compromised molars are frequently characterized by the presence of deep pockets and by a pattern of periodontal breakdown that involves both apical and interradicular spread of attachment and bone loss. The anatomy of bone destruction, thereby, can result in a combination of horizontal breakdown in the furcation area and vertical breakdown around the single roots. The vertical extension of the periodontal breakdown seems to be an important predictor of survival of teeth with furcation involvement (Tonetti *et al*. 2017). Clinical studies have demonstrated the potential for clinical improvements of both the horizontal and vertical furcation components, reporting encouraging results (Jepsen *et al*. 2002). The peculiar anatomy of a combined furcation and intrabony defect requires a surgical approach which is different with respect to the traditional buccal or lingual flap for a key-hole defect. Cortellini *et al*. (2020a) proposed the application of papilla preservation flaps (PPF) following the positive experience with regeneration of intrabony components. The design of PPF is selected upon the width of the interdental space. A horizontal incision according to the principles of the MPPT (Cortellini *et al*. 1995d) is traced at the buccal aspect of the defect-associated papilla when the width of the interdental space is greater than 2 mm, while a diagonal incision is applied when the interdental space is 2 mm or narrower (SPPF; Cortellini *et al*. 1999). Flaps are designed to obtain adequate access to the defect limiting as much as possible flap extension and thus preserving optimal wound stability according to the concepts of MIS, as previously described for intrabony defects (Cortellini 2012) and as exemplified in Figs. 38-36 and 38-37. In particular, the choice of how far to extend the flap in a mesiodistal and buccolingual direction is dependent upon the anatomy of the combined bony and furcation defect. Whenever possible, only the full thickness buccal flap is elevated (M-MIST; Cortellini & Tonetti 2009b) and the defect/furcation debrided through the buccal window. When the defect extends toward the oral aspect of the tooth, the preserved papilla is elevated along with the full thickness lingual flap (MIST, MIS; Cortellini & Tonetti 2007a). The full thickness flaps are elevated to expose the crest of bone surrounding the intrabony defect and to gain access to the involved interradicular space. Vertical releasing incisions are traced only when needed to gain access. Defects and furcation area are thoroughly debrided with a combination of microcurettes and fine sonic tips. In the presence of furrows, the roof of the furcation is further instrumented with the aid of diamond tips mounted on a sonic device. Cleanliness of the furcation roof is carefully inspected at ×30 magnification with the aid of micromirrors. The exposed root surfaces can be treated with the application of EDTA gel for 2 minutes then carefully rinsed with sterile water. A single modified internal mattress suture (6-0 or 7-0 e-PTFE) is applied at the preserved papilla and left loose to keep the flaps reflected. EMD and/or bone substitutes can be applied in the defects and the sutures tightened to obtain passive primary closure of the flaps

A pilot study on 49 subjects with furcated molars and deep intrabony defects showed that significant clinical improvements can be achieved by applying periodontal regeneration in both maxillary and mandibular molars (Cortellini *et al*. 2020a). The benefits included improvement in vertical CALs, decrease in PPDs, and improvements in horizontal and vertical furcation involvement. These surrogate outcomes also translated into excellent tooth retention observed during the follow-up period. At 1 year, 100% of maxillary and 92% of mandibular molars showed improvements. Improvements were not observed in molars with baseline hypermobility: two mandibular molars with hypermobility were extracted at the 1-year follow up. Improvement in the vertical component was observed in 87.5% of maxillary and in 84.6% of mandibular molars. One-year improvements could be maintained over the 3–16-year follow-up. These results were obtained in cases with an interdental peak of bone coronal to the furcation roof

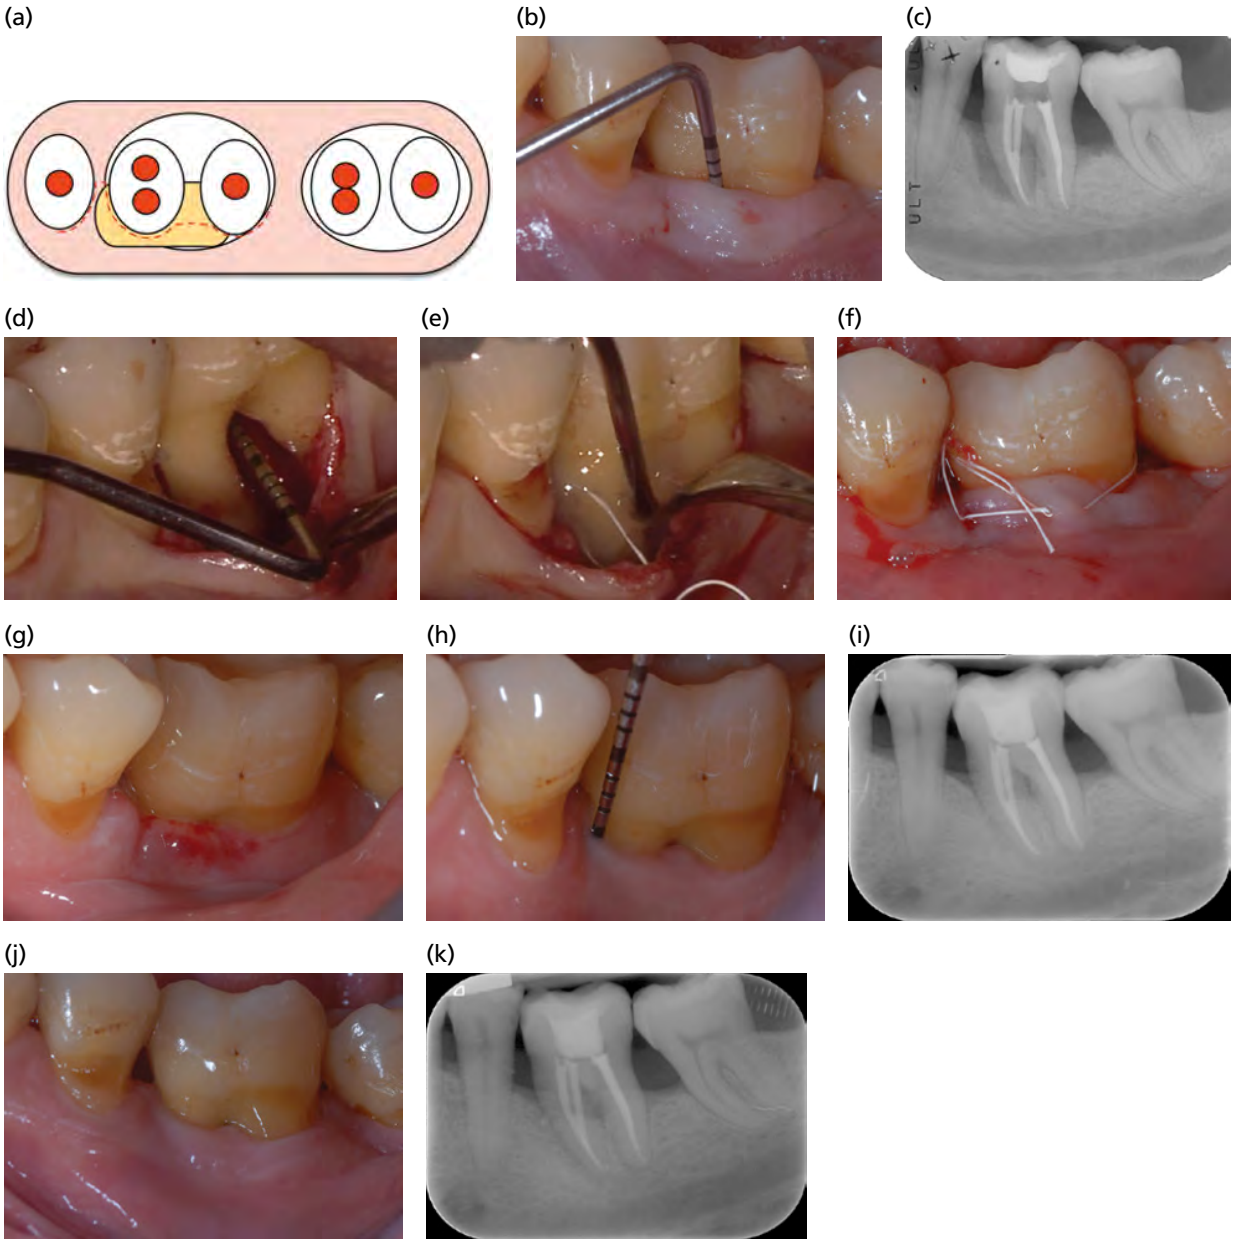

Fig. 38-36 Clinical illustration of the use of papilla preservation flap (PPF) and modified minimally invasive surgical technique (M-MIST) in a case presenting with a combined deep class II buccal furcation and intrabony defect involving the lower left first molar. The schematic diagram (a) shows the extent of the incision involving the mesial interdental space associated with the defects and the elevation of the sole buccal flap. Distal extension of the flap was limited to the buccal side of the distal root of the molar. A 12 mm pocket was detected before surgery (b) associated with a deep intrabony defect and a deep class II furcation (c, d). EMD was delivered on the debrided root surface (e) and the flap was closed with an internal mattress modified suture (f). One week after surgery, sutures were removed; primary intention closure of the wound was maintained (g). At 1 year a 4 mm probing depth and a class I shallow furcation involvement was detected (h, i). The clinical outcomes are maintained at 5-year follow up (j, k)

and gingival margin coronal to the furcation entrance in well-maintained and compliant subjects.

Postoperative regimen

The postoperative regimen prescribed to the patients is aimed at controlling wound infection or contamination as well as mechanical trauma to the treated sites. A meta-analysis indicated that differences in regenerative outcomes can be expected based on the postoperative care protocol: more frequent, intensive regimens were associated with better CAL gain in intrabony defects (Murphy & Gunsolley 2003) (Fig. 38-38). It generally includes the prescription of systemic antibiotics (doxycycline or amoxicillin) in the immediate postoperative period (1 week), 0.2 or 0.12% chlorhexidine mouth rinsing b.i.d. or t.i.d., and weekly professional tooth cleaning until the membrane is in place. Professional tooth cleaning consists of supragingival prophylaxis with a rubber cup and chlorhexidine gel. Patients are generally advised not to perform mechanical oral hygiene and not to chew in the treated area.

Non-bioresorbable membranes are removed 4–6 weeks after placement, following elevation of partial-thickness flaps. Patients are re-instructed to

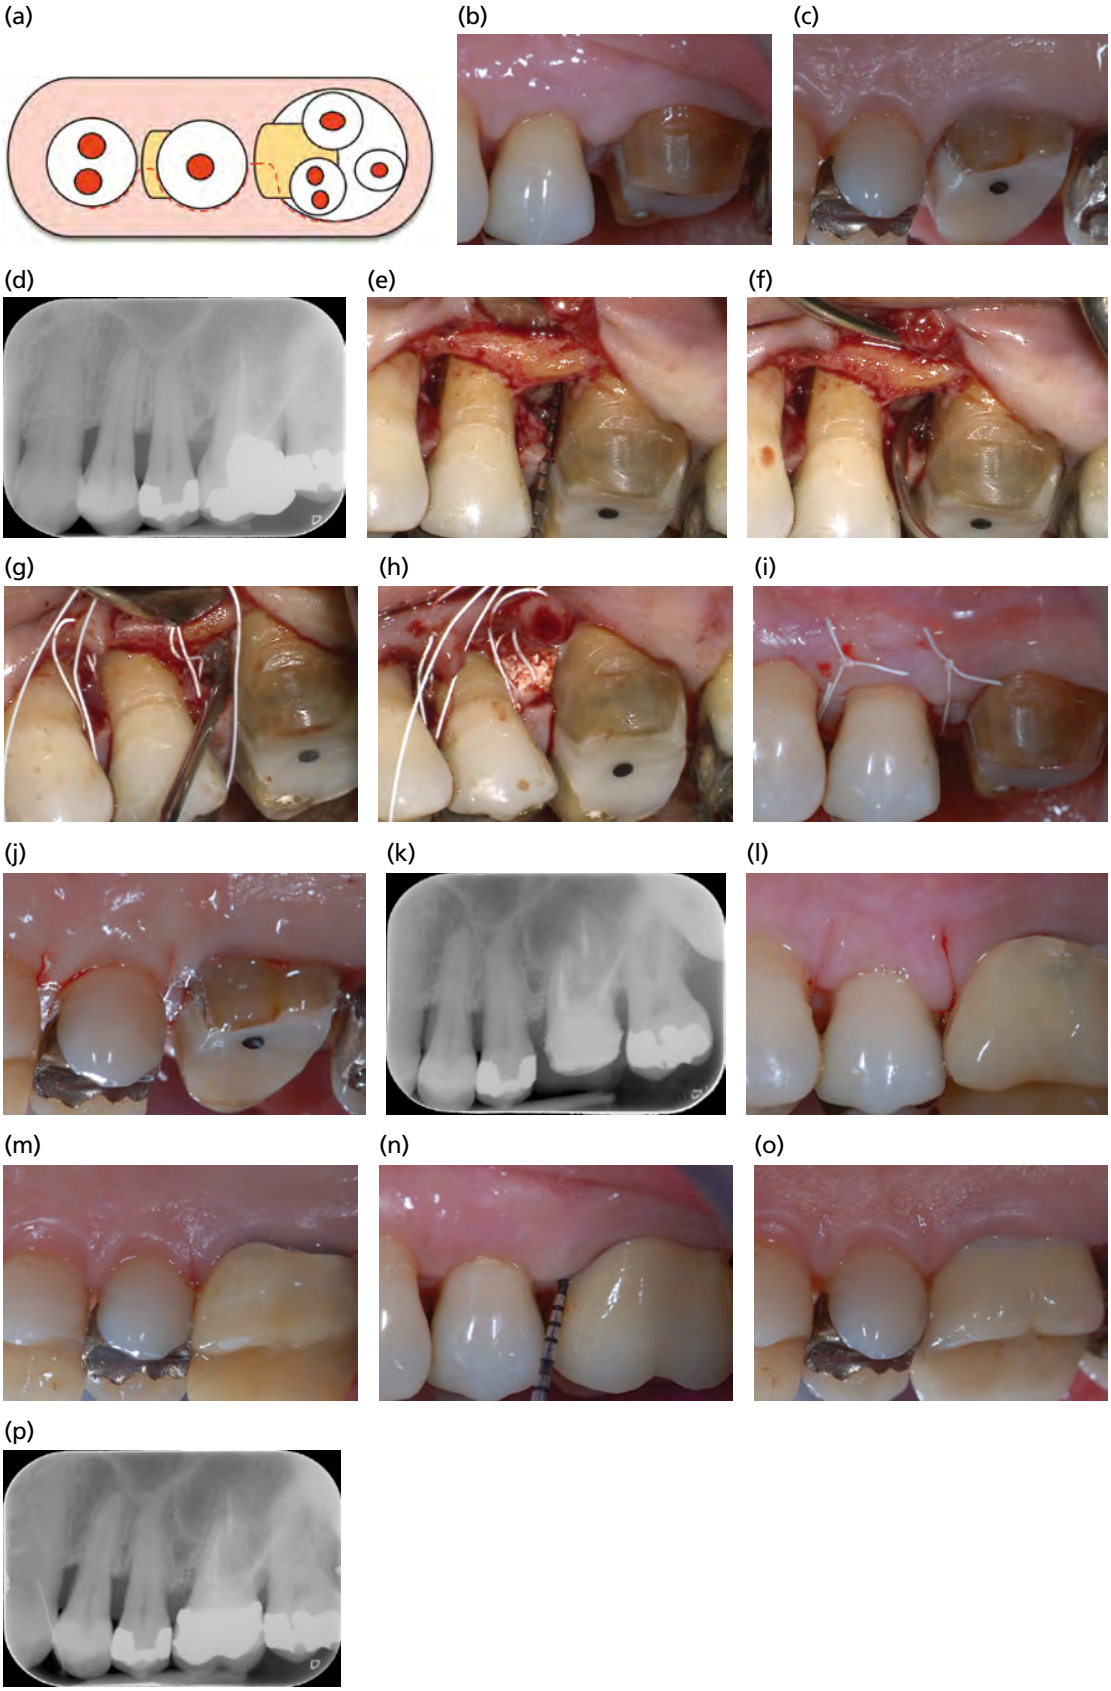

Fig. 38-37 Clinical illustration of the use of papilla preservation flap (PPF) and modifiedminimally invasive surgical technique (M-MIST) in a case presenting with a combined deep class II buccal furcation and intrabony defect involving the upper left first molar. In this case an intrabony defect was present on the second premolar. The schematic diagram (a) shows the extent of the incision involving the interdental space mesial to the premolar and the one between the bicuspid and the molar. In this case, the flap was elevated only on the buccal side. Preoperative images of the surgical area (b, c) and the radiograph (d) showing the intrabony defects mesial to the premolar and the molar. A 5 mm intrabony defect and a class II furcation are evident at the mesial side of the molar (e, f). Enamel matrix derivatives (g) and bovine bone mineral (h) were delivered into the defect area (e) and the flap was closed with internal mattress modified sutures (i, j). Postoperative radiograph showing the biomaterial in place (k). One week after surgery sutures were removed; primary intention closure of the wound was maintained (l, m). At 1 year, a 4 mm probing depth and no furcation involvement was detected (n, o). The 1-year radiograph shows the mineralization of the defects (p).

rinse b.i.d. or t.i.d. with chlorhexidine, not to perform mechanical oral hygiene, and not to chew in the treated area for 3–4 weeks. In this period, weekly professional control and prophylaxis are recommended. When bioresorbable membrane, BRG, or biologically active regenerative materials are used, the period of tight infection control is extended for 6–8 weeks. After this period, patients are re-instructed to resume mechanical oral hygiene gradually, including interdental cleaning, and to discontinue chlorhexidine. Patients are then enrolled in a monthly periodontal care program for 1 year. Probing or deep scaling in the treated area is generally avoided before the 1-year follow-up visit.

Postoperative period and local side effects

From the very beginning of the "guided tissue regeneration era", the frequent occurrence of complications, in particular barrier exposure, was apparent. Complications occurred in almost 100% of the cases in the prepapilla preservation techniques period (Becker *et al*. 1988; Cortellini *et al*. 1990, 1993a, b; Selvig *et al*. 1992; Falk *et al*. 1997; Trombelli *et al*. 1997; Murphy 1995a, b; Mayfield *et al*. 1998) but negative occurrences reportedly reduced to amounts ranging from 50% to 6% when PPF were adopted (Cortellini *et al*. 1995a, c, 1996b, 1999a, 2001; Tonetti *et al*. 1998, 2002, 2004a; Cortellini & Tonetti 2000a, 2005; Machtei 2001; Murphy & Gunsolley 2003). A consistent decrease of complications was observed when barriers were not incorporated into the surgical procedure. In particular, the adoption of EMDs largely reduced the prevalence of complications (Tonetti *et al*. 2002; Sanz *et al*. 2004; Esposito *et al*. 2009). Sanz *et al*. (2004) showed that all sites treated with membranes showed at least one surgical complication during healing, while a complication was observed in only 6% of sites treated with EMDs. This study indicates that some regenerative materials/procedures may be less technique-sensitive than others.

The development of MIS has greatly reduced the amount of complications and side effects in the postoperative period. Primary closure of the flap was reported in 100% of cases treated with MIST and was maintained in single sites in 95% of cases at 1 week (Cortellini & Tonetti 2007a, b) and in multiple sites in 100% of cases (Cortellini *et al*. 2008). Edema was noted in few cases (Cortellini and Tonetti 2007a, b; Cortellini *et al*. 2008). No postsurgical hematoma, suppuration, flap dehiscence, presence of granulation tissue, or other complications were reported in any of the treated sites (Cortellini & Tonetti 2007a, b; Cortellini *et al*. 2008). Root sensitivity was not a frequent occurrence: it was reported at 1 week by about 20% of the patients but this percentage rapidly decreased in the following weeks, with only one patient still reporting some root sensitivity at 6 weeks (Cortellini & Tonetti 2007b). Ribeiro *et al*. (2011a) reported that the extent of root hypersensitivity and edema was very discreet and no patients developed hematoma.

When applying M-MIST, Cortellini and Tonetti (2009b) reported primary closure obtained and maintained in 100% of cases. In a second controlled study (Cortellini & Tonetti 2011), one M-MIST/EMD/BMDX-treated site presented at suture removal (week 1) with a slight discontinuity of the interdental wound. At week 2, the gap appeared to have closed. No edema, hematoma or suppuration was noted in any of the treated sites in these studies (Cortellini & Tonetti 2009a, 2011).

Surgical and postsurgical morbidity

To date, little consideration has been given to critical elements that could contribute to the patient's assessment of the cost–benefit ratio of GTR procedures.

These include postoperative pain, discomfort, complications, and the perceived benefits from the treatment. A parallel group, randomized, multicenter, and controlled clinical trial designed to test the efficacy of GTR versus flap surgery alone assessed these patient issues (Cortellini *et al*. 2001). During the procedure, 30.4% of the test group and 28.6% of the controls reported moderate pain, and subjects in the test group estimated the hardship of the procedure as 24 ± 25 units on a visual analog scale (VAS from 0 to 100, with 0 = no hardship and 100 = unbearable hardship) and subjects in the control group 22 ± 23 VAS. Surgery with membranes required longer chair time than flap surgery alone (on average 20 minutes longer). Among the postoperative complications, edema was most prevalent at week 1 and most frequently associated with the GTR treatment, while postoperative pain was reported by fewer than 50% of both the test and control patients. Pain intensity was described as mild and lasted on average 14.1 ± 15.6 hours in the test patients and 24.7 ± 39.1 hours in the controls. Postoperative morbidity was limited to a minority of subjects: 35.7% of the test patients and 32.1% of the controls reported that the procedures interfered with daily activities for an average of 2.7 ± 2.3 days in the test group and 2.4 ± 1.3 days in the control group. These data indicate that GTR adds almost 30 minutes to a flap procedure and is followed by a greater prevalence of postsurgical edema, while no difference was observed between GTR and flap surgery alone in terms of postoperative pain, discomfort, and interference with daily activities.

No comparative study has reported the morbidity associated with the various regenerative approaches. Reports of multicenter trials on the application of EMDs or barrier membranes using the same methodology, however, show similar results for the two regenerative materials (Tonetti *et al*. 1998, 2004a; Cortellini *et al*. 2001).

Morbidity of the regenerative procedure was tested on a population treated with MIST and EMDs. Patients were questioned at the end of surgery and at week 1 about the intraoperative and postoperative period, respectively, and reported no pain (Cortellini & Tonetti 2007a). Three of the 13 patients reported very limited discomfort in the first 2 days of the first postoperative week. Seventy-seven percent of the patients described the first postoperative week as uneventful, reporting no feeling of having been surgically treated after the second postoperative day.

In a large case cohort of 40 patients treated with MIST and EMDs (Cortellini & Tonetti 2007b), none of the patients reported intraoperative pain or discomfort and 70% did not experience any postoperative pain. The subjects reporting pain described it as being very moderate (VAS 19 ± 10, with 0 = no pain and 100 = unbearable pain). In these patients, pain lasted for 26 ± 17 hours on average. Home consumption of analgesic tablets was 1 ± 2 on average. Twenty-three patients did not use any pain killer in addition to the first two compulsory tablets that were administered in the practice immediately after the surgery and 6 hours later. Seven of the 12 patients (17.5%) reporting pain also experienced some discomfort (VAS 28 ± 11, with 0 = no discomfort and 100 = unbearable discomfort) that lasted for 36 ± 17 hours on average. Only three patients reported some interference with daily activities (work and sport) for 1–3 days.

In a second case cohort study of MIST and EMDs on multiple adjacent intrabony defects (Cortellini *et al*. 2008), 14 of the 20 patients did not experience any postoperative pain. The six subjects reporting pain described it as being very mild (VAS 19 ± 9) and lasting for 21 ± 5 hours on average. Home consumption of painkillers was 0.9 ± 1.0. Nine patients did not use any analgesic in addition to the first two compulsory tablets. Ten patients experienced mild discomfort (VAS 21 ± 10) that lasted for 20 ± 9 hours on average. Only four patients reported some interference with daily activities (work and sport) for 1–3 days.

Ribeiro *et al*. (2011b) reported that the extent of discomfort/pain experienced during therapy with MIST and EMDs was very limited. In addition, the extent of discomfort during the first postoperative week was very discreet, and no patients developed high fever or reported any interference with daily activities. The quantity of analgesic medication taken by patients was minimal (fewer than one analgesic medication per patient).

In a case cohort study where 15 patients were treated with M-MIST and EMDs (Cortellini & Tonetti 2009b), none of the patients reported intraoperative or significant postoperative pain. Three of the patients reported very limited discomfort in the first 2 days after surgery. Fourteen described the first postoperative week as uneventful, reporting no feeling of having been surgically treated after the second postoperative day.

In a controlled study of the additional benefit from EMDs or EMD/BMDX with M-MIST compared with M-MIST alone (Cortellini & Tonetti 2011), none of the 45 patients reported having experienced intra- and postoperative pain. Slight discomfort was reported by three patients in the M-MIST group (average VAS 10.7 ± 2.1), by two patients in the M-MIST/EMD group (VAS 11.5 ± 0.7), and by four patients in the M-MIST/EMD/BMDX group (VAS 12.3 ± 3.1). Few patients needed pain control medications: three patients from the M-MIST group (average number of tablets 0.4 ± 0.7; maximum 2), four patients from the M-MIST/EMD group (average 0.3 ± 0.6; maximum 2), and four patients from the M-MIST/ EMD/BMDX group (average 0.5 ± 1; maximum 3).

Table 38-3 gives some of the surgical and postsurgical parameters used in four studies. Two studies concerned the application of traditional large PPF (MPPT and SPPF) with bioresorbable barriers (Cortellini *et al*. 2001) or EMDs (Tonetti *et al*. 2004b). The other two studies concerned the MIST (Cortellini *et al*. 2007b) and the M-MIST (Cortellini & Tonetti 2011) in

Table 38-3 Comparison between clinical studies of conventional versus those of minimally invasive surgery.

	Cortellini *et al*. (2001)	Tonetti *et al*. (2004b)	Cortellini *et al*. (2007b)	Cortellini & Tonetti (2011)
Regenerative approach	SPPF/MPPT + bioresorbable barrier	SPPF/MPPT+ EMD	MIST + EMD	M-MIST + EMD
Number of patients	56	83	40	15
Chair time (minutes)[a]	99 ± 46	80 ± 34	58 ± 11	54.2 ± 7.4
Interference with daily activity[b]	35.7%	29.5%	7.5%	0
Subjects with postoperative discomfort[b]	53.6%	47.5%	17.5%	13.3%
Subjects with postoperative pain[b]	46%	50%	30%	0
Pain intensity[c]	28.1 ± 2.5	28 ± 20	19 ± 10	–
Number of pain killers[d]	4.1 ± 2.5	4.3 ± 4.5	1.1 ± 2	0.3 ± 0.6

[a] Chair time measured from delivery of anesthesia to completion of the regenerative surgical procedures.
[b] Percentage of subjects reporting postoperative interference with daily activities, discomfort, and pain, as questioned at 1-week recall visit.
[c] Intensity of pain measured with a visual analog scale (VAS).
[d] Number of pain killers taken in addition to the two compulsory ones delivered at the end of surgery.
SPPF, simplified papilla preservation flap; MPPT, modified papilla preservation technique; MIST, minimally invasive surgical technique; M-MIST, modified minimally invasive surgical technique; EMD, enamel matrix derivative; bioresorbable barrier, polylactic and polyglycolic acid barrier.

combination with EMDs. This historical comparison clearly shows differences in most of the parameters between the four studies. Surgical chair time was the longest when large PPF and barriers were applied, shorter when large PPF were combined with EMDs, and by far the shortest when M-MIST and EMDs were used. The number of subjects reporting postoperative interference with daily activities, discomfort, and pain was similar in the two PPF studies, much reduced in the MIST study, and very limited or none in the M-MIST study; similarly, pain intensity and consumption of pain killers was very low in both studies. The reported outcomes indicate that postoperative discomfort and pain apparently are not influenced by the type of regenerative material, but are by the type of surgical approach: a more friendly, shorter chair time, MIS is associated with fewer postoperative problems. These considerations may prompt clinicians to adopt more patient-friendly approaches whenever possible.

Materials for regenerative surgery

In the area of materials and products, three different regenerative concepts have been explored: barrier membranes (GTR), grafts and wound-healing modifiers, plus many combinations of those (Cortellini & Tonetti 2015). A recent meta-analysis on intrabony defects (Nibali *et al*. 2020) concluded that both EMD and GTR were superior to OFD alone in improving CAL (1.27 mm; 0.79–1.74 mm and 1.43 mm; 0.76–2.22 respectively). Among biomaterials, the addition of DBBM improved the clinical outcomes of both GTR with resorbable barriers and EMD. PPFs enhanced the clinical outcomes. Another meta-analysis on furcations (Jepsen *et al*. 2020) concluded that furcation closure ranged between 0% and 60% (10 trials), and class I conversion from 29% to 100% (six trials). Regenerative techniques were superior to OFD for furcation improvement (closure/conversion, OR = 20.9; 90% CI = 5.81, 69.41), horizontal CAL gain (1.6 mm), vertical CAL gain (1.3 mm), and PPD reduction (1.3 mm). BRG resulted in the highest probability (61%) of being the best treatment for horizontal bone level gain. Non-resorbable membranes in combination with BRG ranked as the best treatment for vertical CAL gain (probability 75%) and PPD reduction (probability 56%).

The consensus panel of the XVI European Workshop on Periodontology recommended the use of either barrier membranes or EMD with or without the addition of bone-derived grafts to promote healing of residual deep pockets associated with a deep intrabony defect (Sanz *et al*. 2020). As for the regenerative treatment of residual deep pockets associated with class II mandibular and maxillary buccal furcation involvement the panel *recommended* the use of EMD alone or bone-derived graft with or without resorbable membranes

An detailed analysis of the different regenerative materials follows in the next section.

Barrier materials for regenerative surgery

In the first GTR attempts, a bacterial filter produced from cellulose acetate (Millipore®) was used as an occlusive membrane (Nyman *et al*. 1982; Gottlow *et al*. 1984; Magnusson *et al*. 1985). Although this type of membrane served its purpose, it was not ideal for clinical application.

Non-bioresorbable materials

Later studies have utilized membranes of e-PTFE specially designed for periodontal regeneration (Gore Tex Periodontal Material®). The basic molecule of this material consists of a carbon–carbon bond

with four attached fluorine atoms to form a polymer. It is inert and does not result in any tissue reaction when implanted in the body. This type of membrane persists after healing and must be removed in a second operation. Membranes of e-PTFE have been used successfully in animal experiments and in several clinical studies. From such studies it was found that for a barrier material to function optimally, it has to meet certain essential design criteria:

- Biocompatibility to assure good tissue acceptance. The material should not elicit an immune response, sensitization, or chronic inflammation that may interfere with healing and present a hazard to the patient. Biocompatibility, however, is a relative term since practically no materials are completely inert.
- Acts as a barrier to exclude undesirable cell types from entering the secluded space adjacent to the root surface. It is also considered to be an advantage that the material allows the passage of nutrients and gases.
- Tissue integration that allows the tissue to grow into the material without completely penetrating it. The goal of tissue integration is to prevent rapid epithelial downgrowth on the outer surface of the material or encapsulation of the material, and to provide stability to the overlying flap. The importance of tissue integration was demonstrated in a study in monkeys (Warrer *et al*. 1992) in which bioresorbable membranes of polylactic acid, a synthetic polymer, were used to treat circumferential periodontal defects. Due to the lack of tissue integration, the membranes in this study became surrounded by an epithelial layer and were often encapsulated and exfoliated.
- Capable of creating and maintaining a space adjacent to the root surface. This allows the blood clot to form at the interface between the flap and root surface (Haney *et al*. 1993; Sigurdsson *et al*. 1994; Cortellini *et al*. 1995c, d; Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al*. 2004). Some materials may be so soft and flexible that they collapse into the defect. Other materials are too stiff and may perforate the overlying tissue.
- Provide stability to the blood clot to maintain continuity with the root surface, thereby preventing the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993).

Bioresorbable materials

In recent years, natural or synthetic bioresorbable barrier materials for GTR have been introduced in order to avoid the second surgery necessary for removal of non-bioresorbable materials. Barrier materials of collagen from different species and from different anatomic sites have been tested in animals and in humans (Blumenthal 1988; Pitaru *et al*. 1988; Tanner *et al*. 1988; Paul *et al*. 1992; Blumenthal 1993; Wang *et al*. 1994; Camelo *et al*. 1998; Mellonig 2000). Often the collagen used is a cross-linked variety of porcine or bovine origin. When a collagen membrane is implanted in the human body, it is resorbed by the enzymatic activity of macrophages and polymorphonuclear leukocytes (Tatakis *et al*. 1999). Successful treatment with these barrier materials has been demonstrated, but the results of studies vary. Several complications, such as early degradation, epithelial down-growth along the material, and premature loss of the material, have been reported. The varying results are probably due to differences in the properties of the material and the handling of the material at the time of implantation. Although probably very minimal, there is a risk that infectious agents from animal products can be transmitted to humans, and autoimmunization has also been mentioned as a risk.

Barrier materials of polylactic acid or co-polymers of polylactic acid and polyglycolic acid were evaluated in animal and human studies and are now commonly used (Magnusson *et al*. 1988; Caffesse *et al*. 1994; Caton *et al*. 1994; Gottlow *et al*. 1994; Laurell *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995a; Cortellini *et al*. 1996c, 2001; Hürzeler *et al*. 1997; Tonetti *et al*. 1998; Sculean *et al*. 1999a). These materials are biocompatible, but by definition they are not inert since some tissue reaction may be expected during degradation. The materials are degraded by hydrolysis and eliminated from the organism through the Krebs cycle as carbon dioxide and water (Tatakis *et al*. 1999).

The types of barrier materials that have been tested differ both in configuration and design. It appears that a number of bioresorbable materials meet to a varying extent the requirements of a good barrier listed above. Indeed, there are several studies (Hugoson *et al*. 1995; Cortellini *et al*. 1996b; Smith MacDonald *et al*. 1998; Tonetti *et al*. 1998; Cortellini & Tonetti 2000a, 2005) indicating that similar satisfactory results can be obtained with bioresorbable barrier materials of polylactic and polyglycolic acid as with non-bioresorbable materials.

Membranes for intrabony defects

Early evidence that GTR treatment of deep intrabony defects may produce clinical improvements in terms of CAL was presented in several case reports (Nyman *et al*. 1982; Gottlow *et al*. 1986; Becker *et al*. 1988; Schallhorn & McClain 1988; Cortellini *et al*. 1990). In recent years, a considerable number of clinical investigations have reported on intrabony defects treated with GTR (see Table 38-4). In these studies, the issue of evaluating the predictability of the clinical outcomes following application of GTR procedures was addressed. Table 38-4 gives the results for a total of 1283 intrabony defects treated with GTR. The weighted mean of the reported results indicates

Table 38-4 Clinical outcomes of guided tissue regeneration (GTR) treatment of deep intrabony defects.

Study	Membranes	Number	Gains in CAL ± SD (mm)	Residual PPD ± SD (mm)

CAL, clinical attachment level; e-PTFE, expanded polytetrafluoroethylene; FGG, free gingival graft; ITM, interproximal tissue maintenance; PPD, probing pocket depth; SD, standard deviation.

a mean CAL gain of 3.8 ± 1.7 mm (95% CI 3.7–4.0 mm) (Cortellini & Tonetti 2000a). The reported CAL gains following GTR treatment were significantly larger than those obtained with conventional flap surgery. A review 40 studies on flap surgery with a weighted mean of 1172 defects reported CAL gains of 1.8 ± 1.4 mm (95% CI of 1.6–1.9 mm) (Lang 2000). A more recent review and meta-analysis of 27 trials on access flap surgery included 647 subjects and 734 defects (Graziani *et al*. 2011). Twelve months after flap surgery, tooth survival was 98% (IQ 96.77–100%), CAL gain was 1.65 mm (95% CI 1.37–1.94; P <0.0001), PPD reduction was 2.80 mm (CI 2.43–3.18; P <0.0001), and recession increase 1.26 mm (CI 0.94–1.49; P <0.0001).

Different types of non-bioresorbable (Fig. 38-39) and bioresorbable (Fig. 38-40) barrier materials were used in the clinical studies summarized in Table 38-4. Analysis of the results reported in some of the published studies (Proestakis *et al*. 1992; Cortellini *et al*. 1993a, 1995b, c, 1996b; Cortellini & Pini-Prato 1994; Laurell *et al*. 1994; Mattson *et al*. 1995; Mellado *et al*. 1995; Tonetti *et al*. 1996b) provides important information regarding the predictability of GTR in intrabony defects. CAL gains of 2–3 mm were observed in 29.2% of the defects, of 4–5 mm in 35.4% of the defects, and of ≥6 mm in 24.9% of the defects. Only in 10.5% of the treated defects was the gain <2 mm, while no change or attachment loss was observed in two cases.

In some of the investigations, changes in bone levels were also reported (Becker *et al*. 1988; Handelsman *et al*. 1991; Kersten *et al*. 1992; Cortellini *et al*. 1993a, b; Selvig *et al*. 1993). Bone gains ranged between 1.1 and 4.3 mm and correlated with the reported CAL gains. In a study by Tonetti *et al*. (1993b), 1 year after GTR the bone was found to be located 1.5 mm apically to the position of the attained CAL.

Another important parameter related to the outcome of regenerative procedures is the residual pocket depth. In the studies in Table 38-4, shallow pockets were consistently found at 1 year. The weighted mean residual pocket depth was 3.4 ± 1.2 mm (95% CI 2.3–3.5 mm).

The reported outcomes indicate that GTR procedures predictably result in clinical improvements in intrabony defects beyond those of flap surgery (see Fig. 38-6). This was further confirmed in 11 controlled randomized clinical trials in which GTR was compared with conventional flap surgery (Table 38-5). A total of 267 defects were treated with flap surgery and 317 with GTR. In nine of the 11 investigations, GTR resulted in a statistically significantly greater PAL gain when compared with flap surgery. Similar results were also observed for residual pocket depth.

Membranes for furcation involvement
