Preface

In 1983, Professor Jan Lindhe, University of Gothenburg, Sweden, published the first edition of *Clinical Periodontology*. This was only 2 years after the publication of a textbook on clinical periodontology in Scandinavian languages. It was a pioneer enterprise and began a new era in the study of periodontology. Up to this point, the profession was predominantly oriented towards a treatment philosophy that was based on *deductive thinking*, and very little scientific evidence had been presented.

In this light, the publication of a textbook that was based on *inductive thinking* and hypothesis testing was a true milestone and represented a novelty in teaching undergraduate and graduate students. As the field of clinical periodontology evolved, and more evidence arose from both clinical and preclinical studies, the textbook had to be revised on a regular basis. By and large, every 5 to 8 years a new edition of *Clinical Periodontology* was put together. With every edition, efforts were made to expand the circle of authors in order to obtain more information on evidence-based concepts. The textbook thus became the most internationally recognized source of information in the periodontal community.

About 20–30 years ago, implant dentistry had become an integral part of clinical periodontology. Hence, the fifth edition of *Clinical Periodontology* was substantially expanded to incorporate biological and clinical aspects of implant dentistry. As teeth and implants are to function together as separate or connected units in the same dentition, a profound knowledge of the biology of the tissues surrounding the tooth and the dental implant is of utmost importance. Owing to the large volume of new information, the fifth edition of the now titled *Clinical Periodontology and Implant Dentistry* was split into two volumes, one on *basic concepts* and another on *clinical concepts*. This division into two volumes was maintained for the sixth edition and is also maintained for this, the seventh edition.

In the last 35 years, during which the textbook evolved into the most popular source of reference, periodontology and implant dentistry have become clinical disciplines based on sound scientific evidence. As a new classification of periodontal and peri-implant diseases and conditions emerged after a world workshop staged by the American Academy of Periodontology and the European Federation of Periodontology, it was time, again, to update the textbook.

In this edition, over 90% of the content has been thoroughly revised and condensed for better understanding. Some less essential chapters have been eliminated and others merged to make the text more cohesive. A new and younger generation of authors of international reputation have been invited to contribute. Moreover, the team of Editors has been enlarged to four.

It is our hope that *Lindhe's Clinical Periodontology and Implant Dentistry* remains the key book of reference to guide treatment planning according to sound biological and evidence-based principles rather than opinions based on trial and error philosophies.

Introduction

This chapter provides a brief description of the characteristics of the normal periodontium. It is assumed that the reader has prior knowledge of oral embryology and histology.

The periodontium (peri = around, odontos = tooth) comprises the following tissues: (1) *gingiva*, (2) *periodontal ligament*, (3) *root cementum*, and (4) *alveolar bone proper* (Fig. 1-1). The latter lines the alveolus of the tooth and is continuous with the alveolar bone; on a radiograph it can be called *lamina dura*. The *alveolar process* that extends from the basal bone of the maxilla and mandible consists of the alveolar bone and the *alveolar bone proper*.

The main function of the periodontium is to attach the tooth to the jaw bone and to maintain the integrity of the surface of the masticatory mucosa of the oral cavity. The periodontal ligament, root cementum, and alveolar bone proper, may together be called "the attachment apparatus" or "the supporting tissues of the teeth", constituting a developmental, biologic, and functional unit which undergoes certain changes with age and is, in addition, subjected to morphologic changes related to functional alterations and alterations in the oral environment.

The development of the periodontal tissues occurs during the development and formation of teeth. This process starts early in the embryonic phase when cells from the neural crest (from the neural tube of the embryo) migrate into the first branchial arch. In this position, the neural crest cells form a band of *ectomesenchyme* beneath the epithelium of the stomatodeum (the primitive oral cavity). After the uncommitted neural crest cells have reached their location in the jaw space, the epithelium of the stomatodeum releases factors which initiate epithelial–ectomesenchymal interactions. Once these interactions have occurred, the ectomesenchyme takes the dominant role in the further development. Following the formation of the *dental lamina*, a series of processes are initiated (bud stage, cap stage, bell stage, and root development) which result in the formation of a tooth and its surrounding periodontal tissues, including the alveolar bone proper. During the cap stage, condensation of ectomesenchymal cells appears in relation to the dental epithelium (the dental organ), forming the *dental papilla* that gives rise to

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

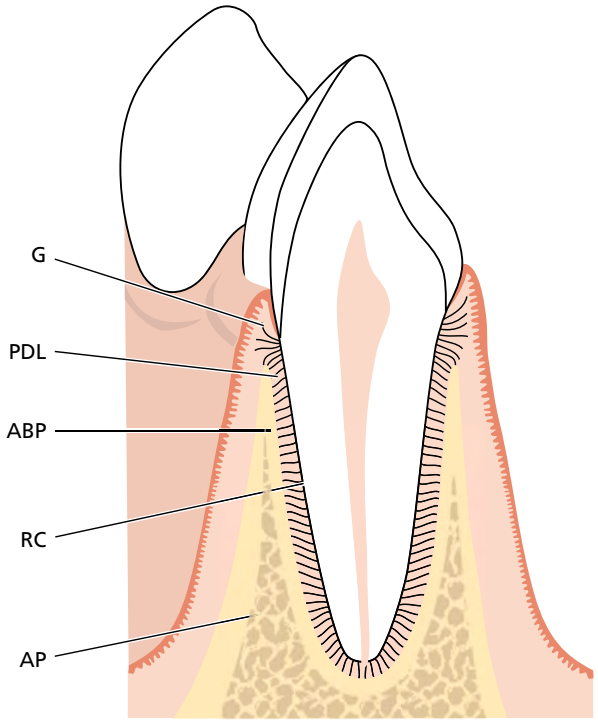

Fig. 1-1 A tooth and its periodontal tissues consisting of gingiva (G), periodontal ligament (PDL), alveolar bone proper (ABP), and root cementum (RC). AP, alveolar process.

Fig. 1-2 Light micrograph of a tooth germ at the cap stage with the dental organ (DO), the dental papilla (DP), and the dental follicle (DF).

the dentin and the pulp, and the *dental follicle* that gives rise to the periodontal supporting tissues (Fig. 1-2). The decisive role played by the ectomesenchyme in this process is further established by the fact that the tissue of the dental papilla apparently also determines the shape and form of the tooth.

If a tooth germ in the bell stage of development is dissected and transplanted to an ectopic site (e.g. the connective tissue of the anterior chamber of the eye), the tooth formation process continues. The crown and the root are formed, and the supporting structures (i.e. cementum, periodontal ligament, and a thin lamina of alveolar bone proper) also develop. Such experiments document that all information necessary for the formation of a tooth and its attachment apparatus resides within the tissues of the dental organ and the surrounding ectomesenchyme. The dental organ is the formative organ of enamel, the dental papilla is the formative organ of the dentin–pulp complex, and the dental follicle is the formative organ of the attachment apparatus (cementum, periodontal ligament, and alveolar bone proper).

The development of the root and the periodontal supporting tissues follows that of the crown. Epithelial cells of the external and internal dental epithelium (the dental organ) proliferate in an apical direction, forming a double layer of cells called *Hertwig's epithelial root sheath*. The odontoblasts forming the dentin of the root differentiate from ectomesenchymal cells in the dental papilla under the inductive influence of the inner epithelial cells (Fig. 1-3). The dentin continues to form in an apical direction, producing the framework of the root. During formation of the root, the periodontal supporting tissues including the acellular extrinsic fiber cementum (AEFC) develop. Some of the events in cementogenesis are still unclear, but the following concept is now generally accepted.

At the start of root dentin formation, the inner cells of Hertwig's epithelial root sheath may synthesize and secrete enamel-related proteins, some of which belong to the amelogenin family. At the end of this process, the epithelial root sheath becomes fenestrated and ectomesenchymal cells from the dental follicle penetrate through these fenestrations and contact the root surface. The ectomesenchymal cells in contact with the root surface differentiate into cementoblasts and start to form cementoid. This cementoid represents the organic matrix of the cementum and consists of a ground substance and collagen fibers, which intermingle with collagen fibers in the not yet fully mineralized outer layer of the dentin. It is assumed that the cementum becomes firmly attached to the dentin through these fiber interactions followed by mineralization of this interface (Fig. 1-4). The formation of the CIFC, which often covers the apical third of the dental roots, differs from that of AEFC

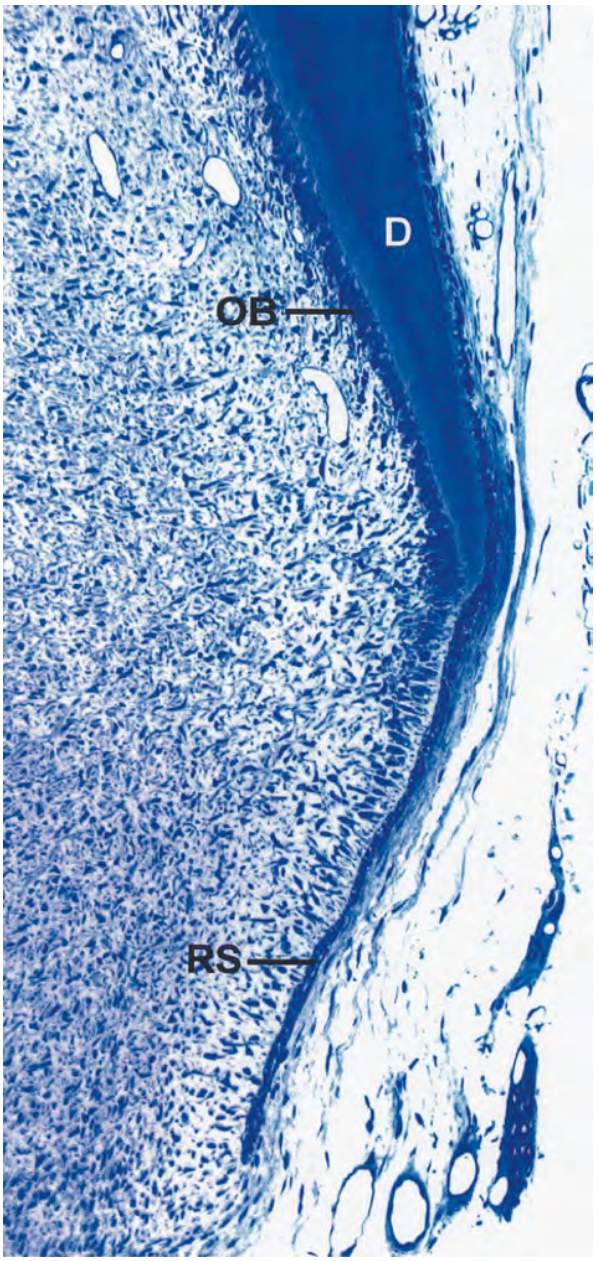

Fig. 1-3 Light micrograph illustrating the edge of a developing tooth root with the Hertwig's epithelial root sheath (RS), odontoblasts (OB), and dentin (D).

as some of the cementoblasts become embedded in the cementum.

The remaining parts of the periodontium are formed by ectomesenchymal cells from the dental follicle lateral to the cementum. Some of them differentiate into periodontal ligament fibroblasts and form the fibers of the periodontal ligament, while others become osteoblasts and form the alveolar bone proper in which the periodontal fibers are anchored. This bony structure has also been term "*bundle bone*". In other words, the bundle bone is also an ectomesenchymal product. It is likely, but still not conclusively documented, that ectomesenchymal cells remain in the mature periodontium and take part in the turnover of this tissue.

Gingiva

Anatomy

The oral mucosa is continuous with the skin of the lips and the mucosa of the soft palate and pharynx. The oral mucosa consists of: (1) the *masticatory mucosa*, which includes the gingiva and the covering of the hard palate; (2) the *specialized mucosa*, which covers the dorsum of the tongue; and (3) the remaining part, called the *lining mucosa*.

The gingiva is that part of the masticatory mucosa which covers the alveolar process and surrounds the cervical portion of the teeth (Fig. 1-5). It consists of an epithelial layer and an underlying connective tissue layer called the *lamina propria*. The gingiva obtains its final shape and texture in conjunction with eruption of the teeth.

In the coronal direction, the coral pink gingiva terminates in the *free gingival margin*, which has a scalloped outline. In the apical direction, the gingiva is continuous with the loose, darker red *alveolar mucosa* (lining mucosa) from which the gingiva is separated by a usually easily recognizable border called either the mucogingival junction, sometimes termed the mucogingival line (Fig. 1-5, arrows). As the hard palate and maxillary alveolar process are covered by a keratinizing mucosa of similar clinical appearance, no mucogingival junction is macroscopically recognizable (Fig. 1-6).

Two parts of the gingiva may be identified (Fig. 1-7): (1) the free gingiva and (2) the attached gingiva. The free gingiva is coral pink, has a dull surface and a firm consistency. It comprises the gingival tissue at the vestibular and lingual/palatal aspects of the teeth. On the vestibular and lingual sides of the teeth, the free gingiva extends from the gingival margin in an apical direction to a structure named *free gingival groove*, which is only observable in approximately one-third of the cases. The attached gingiva is demarcated by the mucogingival junction in the apical direction.

The free gingival margin is often rounded in such a way that a small invagination or sulcus is formed between the tooth and the gingiva. When a periodontal probe is inserted into this invagination and, further apically, towards the cementoenamel junction (CEJ), the gingival tissue is separated from the tooth and a "*gingival pocket*" or "*gingival crevice*" is artificially opened (Fig. 1-8). Thus, in clinically healthy gingiva, there is in fact no "gingival pocket" or "gingival crevice" present, but the gingiva is in close contact with the enamel surface. After complete tooth eruption, the free gingival margin is located on the enamel surface approximately 1.5–2 mm coronal to the CEJ.

The shape of the *interdental gingiva (the interdental papilla)* is determined by the contact relationships between the teeth, the width of the approximal tooth

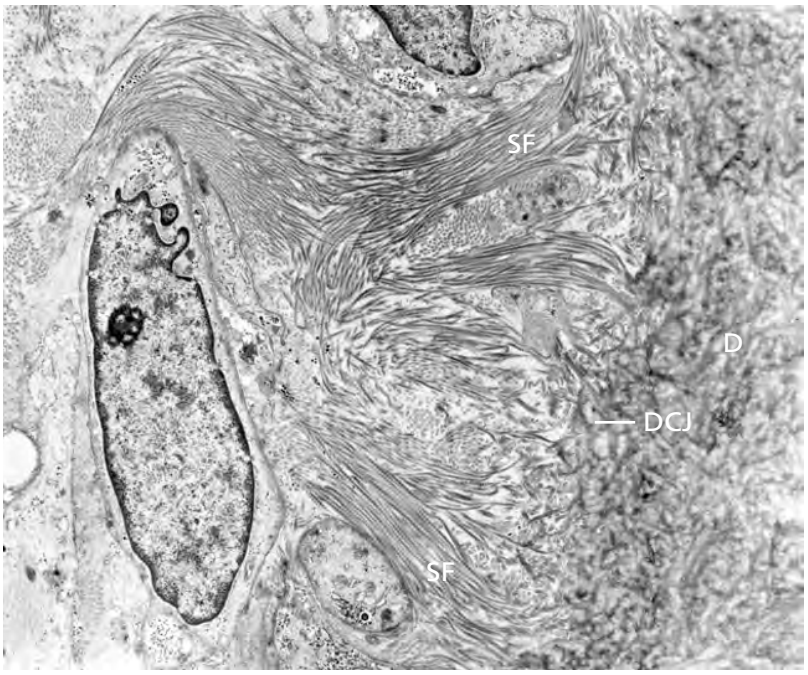

Fig. 1-4 Transmission electron micrograph illustrating the attachment of the future Sharpey's fibers (SF) to the root dentin (D) at a time where the mineralization has reached the dentinocemental junction (DCJ).

Fig. 1-5 Frontal view of the masticatory and lining mucosa. The arrows indicate the mucogingival junction, sometimes also called the mucogingival line.

Fig. 1-6 Masticatory mucosa lining the hard palate. There is no mucogingival line present in the palate, because the hard palate and the maxillary alveolar process are covered by the same type of masticatory mucosa.

surfaces, and the course of the CEJ. In anterior regions of the dentition, the interdental papilla is of pyramidal shape (Fig. 1-9a), while in the molar regions, the papillae are flatter in the buccolingual direction (Fig. 1-9b). Due to the presence of interdental papillae, the free gingival margin follows a more or less accentuated, scalloped course through the dentition.

The interdental region in premolar and molar teeth has two papillae, a vestibular (VP) and a lingual/palatal (LP) papilla, separated by the col region. The col region is lined by a thin non-keratinized epithelium (Fig. 1-10). This epithelium has many features in common with the junctional epithelium.

The attached gingiva is demarcated in the coronal direction by the free gingival groove (Fig. 1-11) or, when such a groove is not present, by a horizontal plane placed at the level of the CEJ. In clinical examinations, it was observed that a free gingival groove is only present in about 30–40% of adults. The free gingival groove is often most pronounced on the vestibular aspect of the teeth, occurring most frequently in the incisor and premolar regions of the mandible, and least frequently in the mandibular molar and maxillary premolar regions.

The attached gingiva extends in the apical direction to the mucogingival junction, where it becomes continuous with the alveolar (lining) mucosa. It is of firm texture, coral pink in color, and often shows small depressions on the surface. The depressions, called "stippling", give the appearance of orange peel. The gingiva is firmly attached to the underlying alveolar bone and cementum by connective

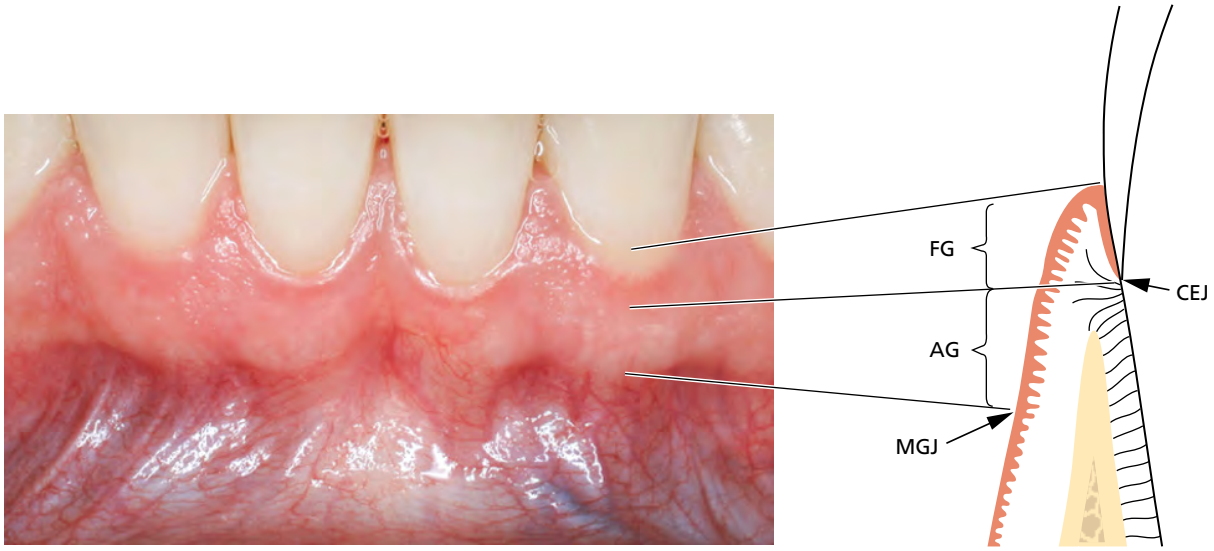

Fig. 1-7 Three parts of the gingiva can be identified: the free gingiva (FG), the interdental gingiva, and the attached gingiva (AG). The mucogingival junction (MGJ) demarcates the gingiva from the alveolar mucosa. CEJ, cementoenamel junction.

Fig. 1-8 A periodontal probe has been inserted into a clinically healthy tooth–gingiva interface and a "gingival crevice" was artificially opened approximately to the level of the cementoenamel junction.

tissue fibers, and is, therefore, comparatively immobile in relation to the underlying tissue. The darker red alveolar mucosa located apical to the mucogingival junction, on the other hand, is loosely bound to the underlying bone. Therefore, in contrast to the attached gingiva, the alveolar mucosa is mobile in relation to the underlying tissue and hence belongs to the lining mucosa.

The width of the gingiva varies in size in different parts of the dentition. In the maxilla (Fig. 1-12a), the vestibular gingiva is generally widest in the area of the incisors and narrowest adjacent to the premolars. In the mandible (Fig. 1-12b), the gingiva on the lingual aspect is particularly narrow in the area of the incisors and wide in the molar region. The range of variation is 1–9 mm. In the mandibular premolar region, the gingiva is extremely narrow (Fig. 1-13).

The result of a study in which the width of the attached gingiva was assessed and related to the

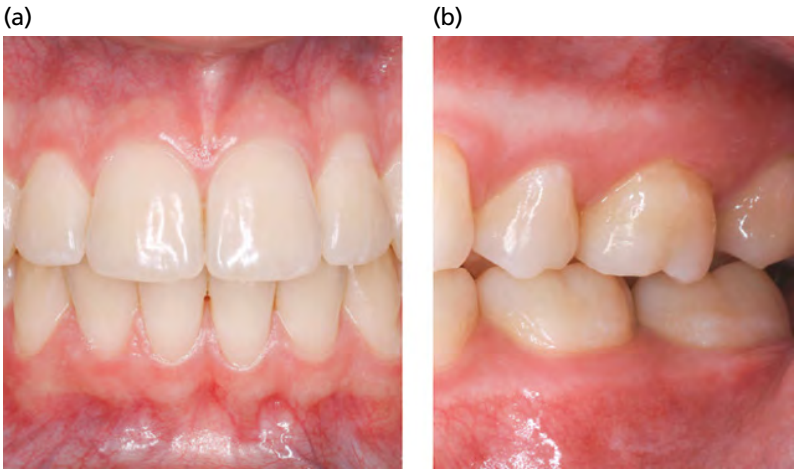

Fig. 1-9 Frontal view showing the shape of the interdental papillae in the anterior (a) and premolar/molar (b) regions.

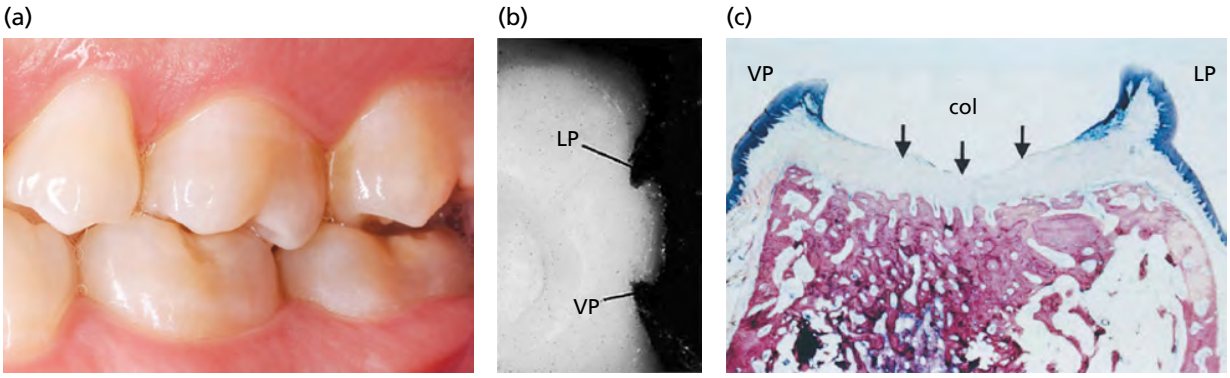

Fig. 1-10 (a) Premolar/molar regions of the dentition exhibit an approximal contact surface. (b) After removal of the distal tooth, a col can be seen between the vestibular (VP) and lingual papillae (LP). (c) Histologically, the bucco-oral section of the col region (arrows) demonstrates a thin non-keratinizing lining between the two papillae.

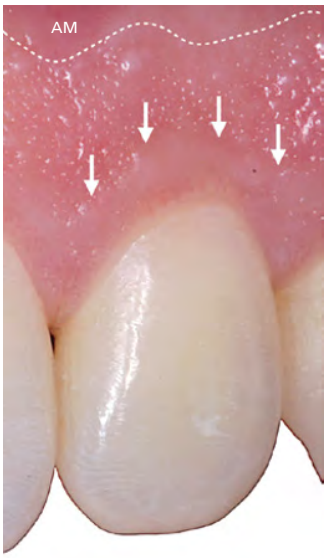

Fig. 1-11 Clinical view on the mucosal tissues. The mucogingival junction (arrows) demarcates the gingiva (masticatory mucosa) from the alveolar (lining) mucosa (AM).

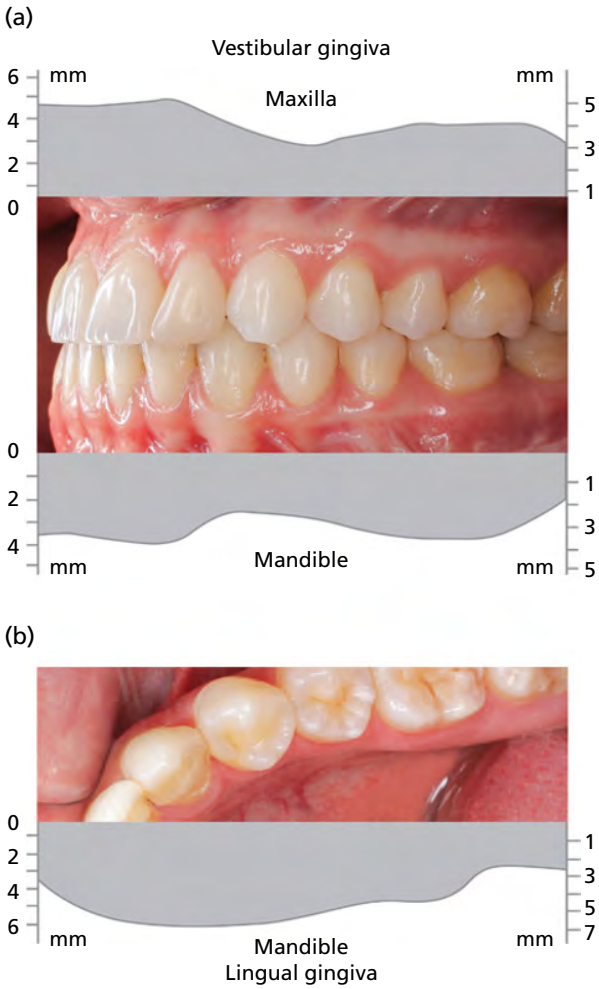

Fig. 1-12 Widths of the vestibular maxillary and mandibular gingivae (a) as well as the lingual extent of the gingiva in the mandible (b). The widths are depicted in millimeters.

age of the patients examined is depicted in Fig. 1-14 (Ainamo *et al*. 1981). The gingiva in the 63-year-olds was significantly wider than in the 40–50-year-olds. Moreover, the width of the gingiva in the 40–50-year-olds was significantly wider than that in 20–30-year-olds. This observation indicates that the width of the gingiva tends to increase with age. As the mucogingival junction remains stable throughout life in relation to the lower border of the mandible, the increasing width of the gingiva may suggest that the teeth erupt slowly throughout life as a result of occlusal wear.

Histology

Oral gingival epithelium

The dentogingival unit is schematically depicted in Fig. 1-15a. The free gingiva comprises all epithelial and connective tissue structures located coronal to a horizontal line placed at the level of the CEJ (Fig. 1-15b). The epithelium covering the free gingiva may be differentiated as follows:

- *Oral gingival epithelium*, which faces the oral cavity
- *Oral sulcular epithelium*, which faces the tooth without being in contact with the tooth surface
- *Junctional epithelium*, which provides the contact between the gingiva and the tooth.

Fig. 1-13 Minimal width of the vestibular gingiva in the premolar region of the mandible. The arrows demonstrate the outline of the mucogingival junction.

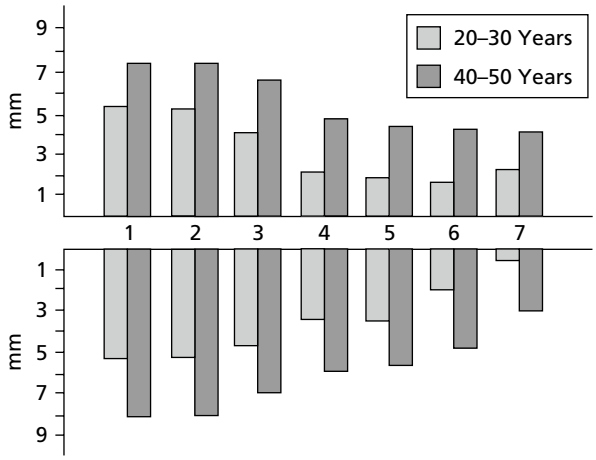

Fig. 1-14 Width of attached gingiva in two age cohorts of 20–30 years and 40–50 years. An increasing width of attached gingiva is recognizable throughout life. (Source: Ainamo & Talari 1976; Ainamo *et al*. 1981. Reproduced with permission from John Wiley & Sons.)

The boundary between the oral gingival epithelium and underlying connective tissue has a wavy course (Fig. 1-15c). The connective tissue portions, which project into the epithelium, are called *connective tissue papillae* and are separated from each other by *epithelial ridges* – so-called *rete pegs*. In non-inflamed gingiva, rete pegs and connective tissue papillae are lacking at the boundary between the junctional epithelium and its underlying connective tissue (Fig. 1-15b). Thus, a characteristic morphologic feature of the oral gingival epithelium and the oral sulcular epithelium is the presence of rete pegs: these structures are lacking in the junctional epithelium.

A wax model, constructed on the basis of magnified serial histologic sections at a magnification of 1:50, shows the subsurface of the oral epithelium of the gingiva after removing the connective tissue (Fig. 1-16). The subsurface of the oral epithelium (i.e. the surface of the epithelium facing the connective tissue) exhibits several depressions corresponding to the connective tissue papillae (see Fig. 1-17), which project into the epithelium. It can be seen that the epithelial projections, which in histologic sections separate the connective tissue papillae, constitute a continuous system of epithelial ridges.

A model of the connective tissue, corresponding to the model of the epithelium shown in Fig. 1-16 yields the connective tissue papillae which project into the space that was occupied by the oral gingival epithelium and by the oral sulcular epithelium at the back of the model (Fig. 1-17). The epithelium has been removed, thereby making the vestibular aspect of the gingival connective tissue visible.

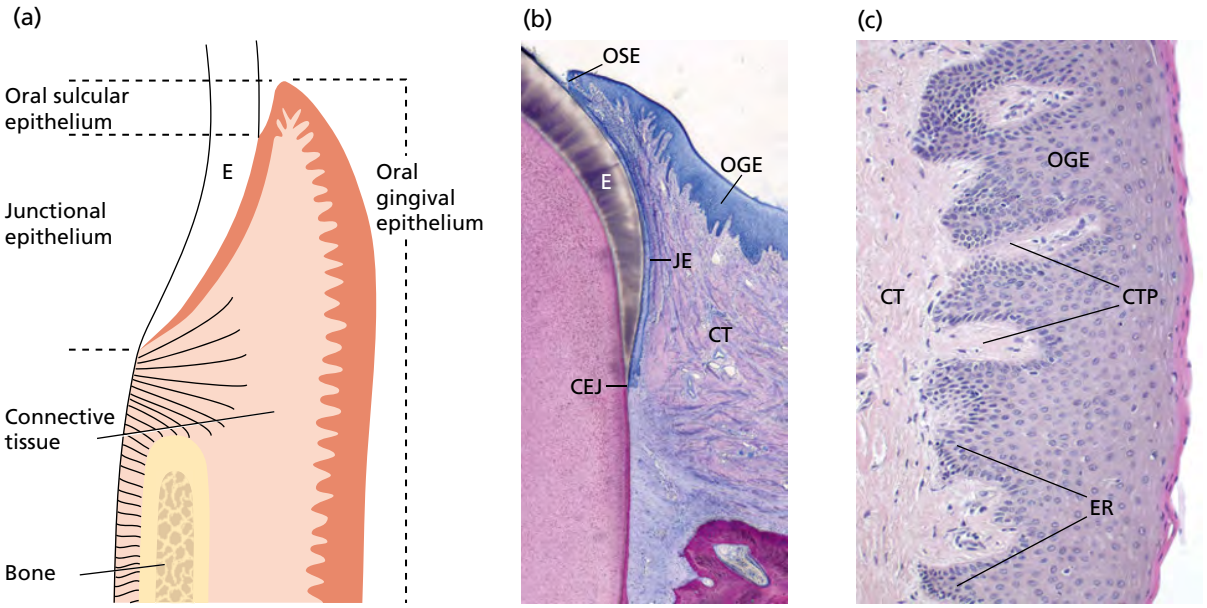

Fig. 1-15 (a) The dentogingival unit. The gingiva consists of three epithelia namely, oral gingival epithelium, oral sulcular epithelium, and junctional epithelium. (b) Histologic section with all the epithelia and soft connective tissue structures (CT). (c) Rete peg configuration (epithelial ridges, ER) interdigitating with the connective tissue papillae (CTP) in masticatory mucosa facing the oral cavity. CEJ, cementoenamel junction; E, enamel; JE, junctional epithelium; OGE, oral gingival epithelium; OSE, oral sulcular epithelium.

Fig. 1-16 Wax model illustrating the surface of the oral gingival epithelium facing the connective tissue following removal from the latter.

Fig. 1-17 Wax model of the connective tissue subjacent to the oral gingival epithelium that had been removed. OE, oral epithelium; OSE, oral sulcular epithelium.

In most adults, the attached gingiva shows a stippling on the surface (Fig. 1-18). The stippling corresponds to depressions on the surface in the areas of fusion between various epithelial ridges. Sometimes, the stippling is conspicuous (see also Fig. 1-11). However, it is not known to which degree the stippling manifests itself in different individuals.

The oral epithelium covering the free gingiva is a *keratinized, stratified, squamous epithelium* which, on the basis of the degree to which the keratin-producing cells are differentiated, can be divided into the following cell layers (Fig. 1-19a):

1. *Basal layer* (stratum basale or stratum germinativum)
2. *Prickle cell layer* (stratum spinosum)
3. *Granular cell layer* (stratum granulosum)
4. *Keratinized cell layer* (stratum corneum).

It should be observed that in the tissue section shown in Fig. 1-19a, cell nuclei are lacking in the outer cell layers. Such an epithelium is denoted *orthokeratinized*. Often, however, the cells of the stratum corneum of the epithelium of human gingiva contain remnants of the nuclei, as seen in Fig. 1-19b. In such a case, the epithelium is denoted *parakeratinized*.

In addition to the keratin-producing cells, which comprise about 90% of the total cell population, the oral gingival epithelium contains the following types of cells:

- *Melanocytes*
- *Langerhans cells*
- *Merkel's cells*
- *Inflammatory cells*.

These cell types are often stellate and have cytoplasmic extensions of various size and appearance. They are also called "clear cells", because in histologic sections, the zone around their nuclei appears lighter than that in the surrounding keratin-producing cells (Fig. 1-20). With the exception of the Merkel's cells, these "clear cells", which do not produce keratin, lack desmosomal attachment to adjacent cells. The melanocytes are pigment-synthesizing cells and are responsible for the melanin pigmentation occasionally seen on the gingiva. However, both lightly and darkly pigmented individuals have melanocytes in the epithelium.

The Langerhans cells are believed to play a role in the defense mechanism of the oral mucosa. It has been suggested that the Langerhans cells react with antigens that are in the process of penetrating the epithelium. An early immunologic response is thereby initiated, inhibiting or preventing further antigen penetration of the tissue. The Merkel's cells have been suggested to have a sensory function.

The cells in the *basal layer* are either cylindric or cuboidal, and are in contact with the *basement membrane* that separates the epithelium from the soft connective tissue (Fig. 1-21). The basal cells possess the ability to divide, that is undergo mitotic cell division. The cells marked with arrows in Fig. 1-21 are in the process of dividing. It is in the basal layer that the epithelium is renewed. Therefore, this layer is also termed *stratum germinativum*, and can be considered the *progenitor cell compartment* of the epithelium.

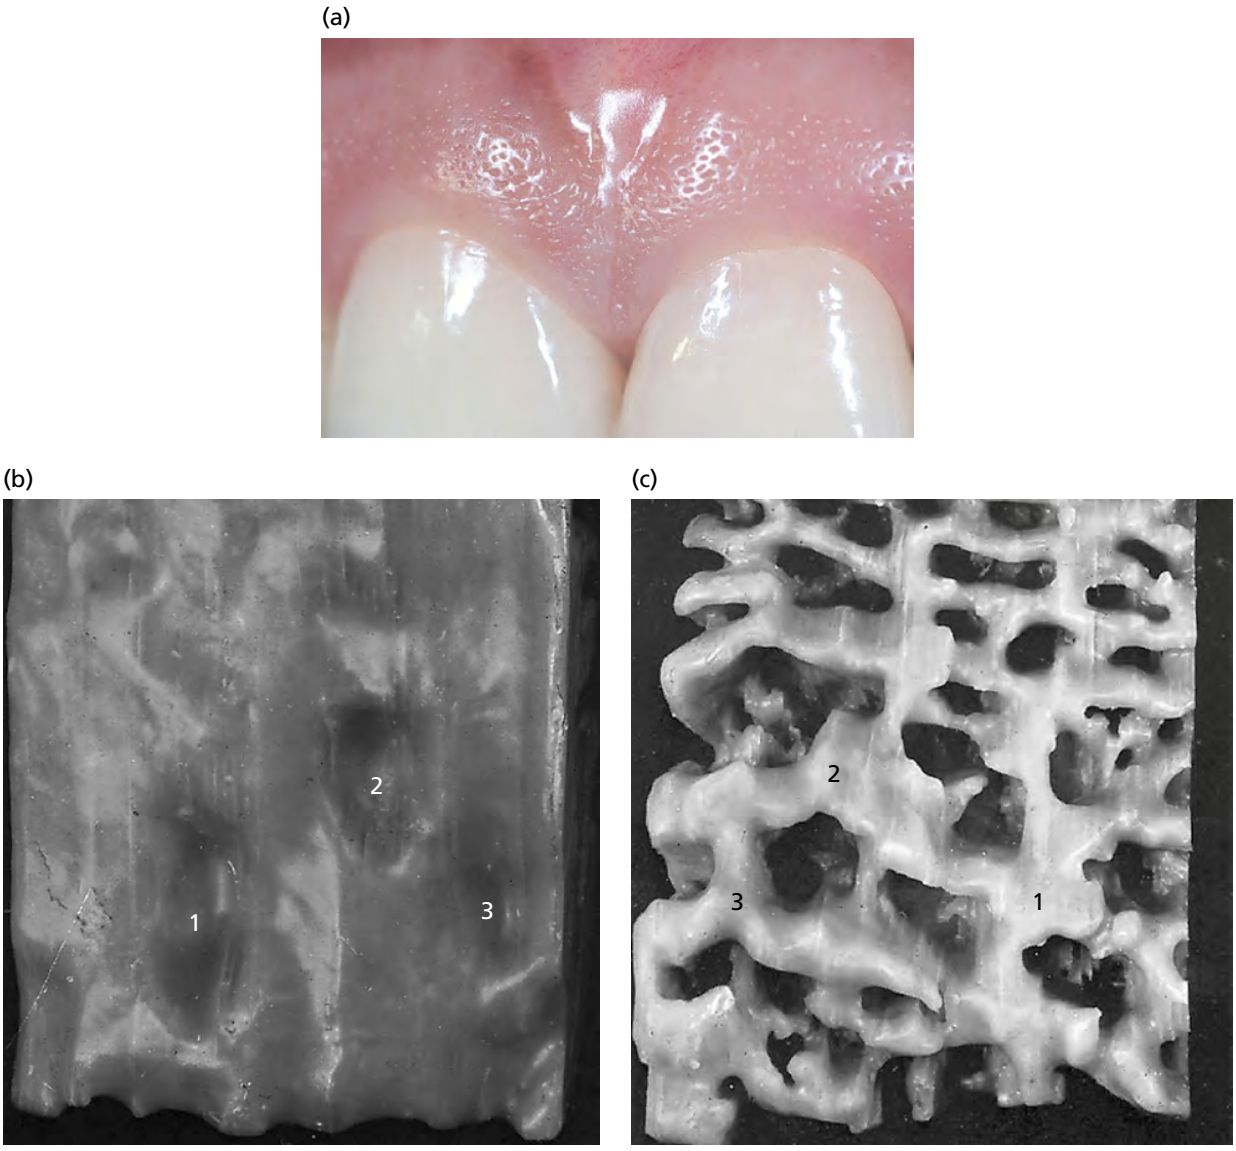

Fig. 1-18 (a) Conspicuous stippling of the masticatory mucosa of the gingiva, as seen macroscopically or clinically. (b) In a magnified model of the oral gingival epithelium of the attached gingiva, the surface exhibits the minute depressions, which give the gingiva its characteristic stippled appearance. (c) In the corresponding surface of the epithelium facing the soft connective tissue, the subsurface of the epithelium is characterized by the presence of epithelial ridges that merge at various locations. The numbers indicate the locations where the epithelial ridges merge and create the depressions seen in (b).

When two daughter cells have been formed by cell division, an adjacent "older" basal cell is pushed into the spinous cell layer and starts, as a *keratinocyte*, to traverse the epithelium (Fig. 1-22). It takes approximately 1 month for a keratinocyte to reach the outer epithelial surface, where it is shed from the stratum corneum. Within a given time, the number of cells which divide in the *basal layer* equals the number of cells which are shed from the surface. Thus, under homeostatic conditions, there is equilibrium between cell renewal and cell loss so that the epithelium maintains a constant thickness. As the basal cell migrates through the epithelium, it becomes flattened with its long axis parallel to the epithelial surface.

The basal cells are found immediately adjacent to the soft connective tissue and are separated from it by the basement membrane, probably produced by the basal cells themselves. Under the light microscope, this membrane appears as a structureless zone approximately 1–2 µm wide and reacts positively to a periodic acid-Schiff (PAS) stain (Fig. 1-23). This positive reaction demonstrates that the basement membrane contains carbohydrates (glycoproteins). The epithelial cells are surrounded by an extracellular substance which also contains protein–polysaccharide complexes.

At the ultrastructural level, the basement membrane has a complex composition (Fig. 1-24). Immediately beneath the basal cells, an approximately 400-Å wide electron-lucent zone can be seen, which is called the *lamina lucida*. Beneath the lamina lucida, an electron-dense zone of approximately the same thickness can be observed. This zone is called *lamina densa*. From the lamina densa, so-called *anchoring fibrils* project in a fan-shaped fashion into the soft connective tissue. The anchoring fibrils are approximately 1 µm

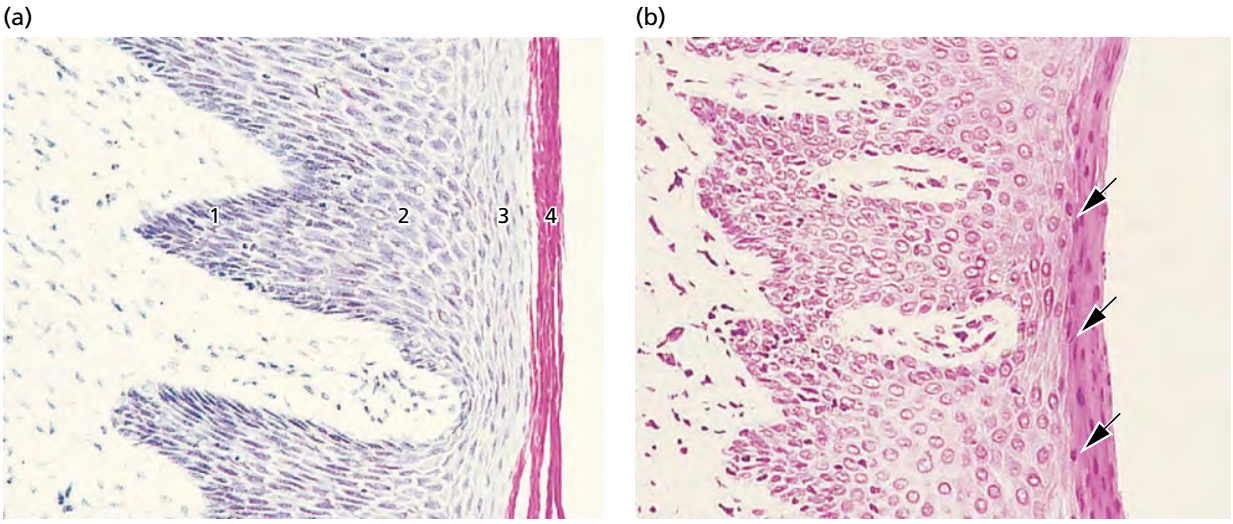

Fig. 1-19 The four layers of the oral gingival epithelium: (1) stratum basale, (2) stratum spinosum, (3) stratum granulosum, and (4) stratum corneum, as seen in the orthokeratinized (a) and parakeratinized (b) epithelium. The arrows indicate the presence of cell nuclei in the case of parakeratinization.

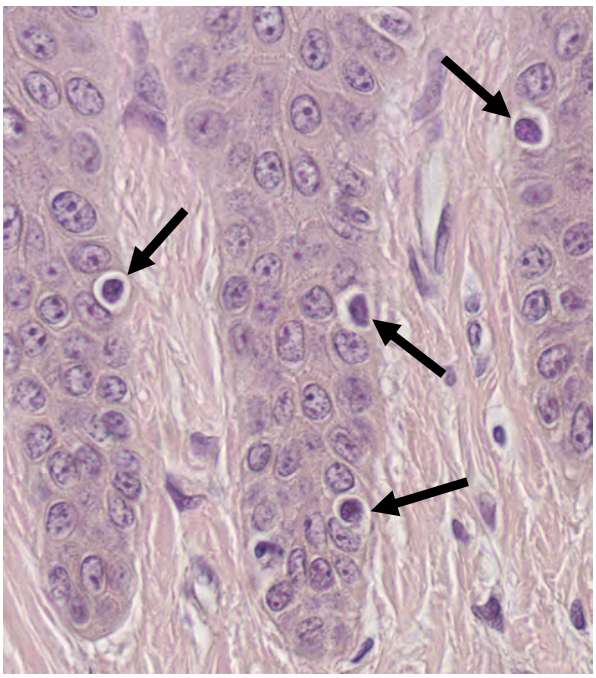

Fig. 1-20 "Clear cells" (arrows) located in or near the stratum basale of the oral gingival epithelium.

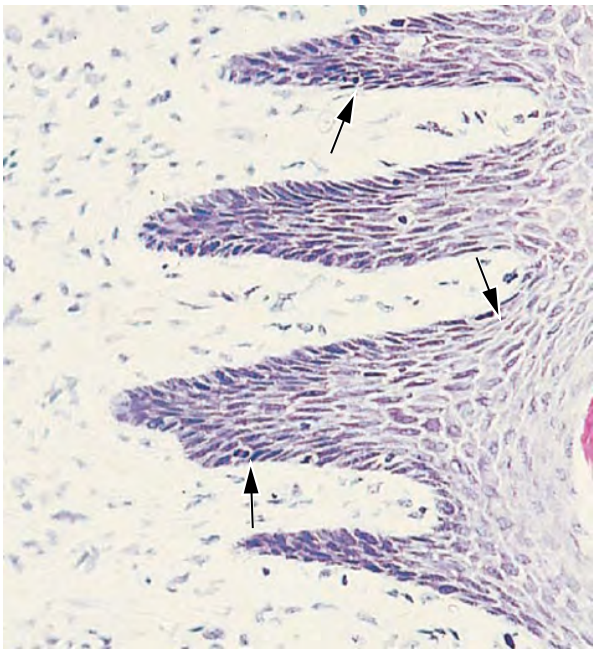

Fig. 1-21 The cells in the basal layer of the oral gingival epithelium are able to divide. The arrows indicate dividing cells.

in length and terminate freely in the soft connective tissue. The basement membrane, which under the light microscope appears as an entity, thus, in the electron micrograph, appears to comprise one lamina lucida and one lamina densa with adjacent anchoring fibrils that interdigitate with the soft connective tissue fibers. The cell membrane of the epithelial cells facing the lamina lucida harbors a number of electron-dense, thicker zones appearing at various intervals along the cell membrane. These structures are called *hemidesmosomes*. The cytoplasmic *tonofilaments* (cytokeratin filaments) in the cell converge towards the hemidesmosomes. The hemidesmosomes are involved in the attachment of the epithelium to the underlying basement membrane.

The stratum spinosum consists of 10–20 layers of relatively large, polyhedral cells, equipped with short cytoplasmic processes resembling spines (Fig. 1-25). These cytoplasmic processes occur at regular intervals and give the cells a prickly appearance. Together with intercellular protein–carbohydrate complexes, cohesion between the cells is provided by numerous "desmosomes" (pairs of hemidesmosomes), which are located between the cytoplasmic processes of adjacent cells. In the transmission electron microscope, the dark-stained structures between the individual epithelial cells represent the *desmosomes* (arrows) (Fig. 1-26). A desmosome may be considered to be two hemidesmosomes facing one another. The

presence of a large number of desmosomes indicates that the cohesion between the epithelial cells is solid.

A schematic drawing of a desmosome is shown in Fig. 1-27. A desmosome can be considered to consist of two adjoining hemidesmosomes separated by a zone containing electron-dense granulated material. Thus, a desmosome comprises the following structural components: (1) the *outer leaflet* of the cell membranes of two adjoining cells; (2) the thick *inner leaflets* of the cell membranes; and (3) the *attachment plaques*, which represent granular and fibrillar material in the cytoplasm.

As mentioned previously, the oral epithelium also contains melanocytes, which are responsible for the production of the pigment melanin (Fig. 1-28). Melanocytes are present in individuals with marked pigmentation of the oral mucosa as well as in individuals in whom no clinical signs of pigmentation can be seen. In this transmission electron micrograph, a melanocyte is present in the lower portion of the stratum spinosum. In contrast to the keratinocytes, this cell contains melanin granules and has no tonofilaments or hemidesmosomes. Note the large number of tonofilaments in the cytoplasm of the adjacent keratinocytes. The inclusion of melanin granules may result in a distinct pigmentation of the oral gingival epithelium and is normally encountered in people with a dark complexion (Fig. 1-29).

As indicated previously, the keratinocytes undergo continuous differentiation and specialization when traversing the epithelium from the basal layer to the

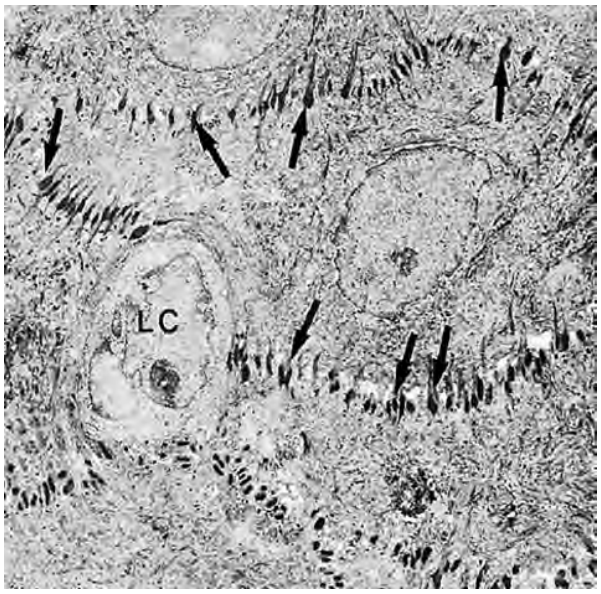

Fig. 1-26 Transmission electron micrograph of stratum spinosum highlighting (arrows) desmosomes between neighboring cells. The light cell (LC) harbors no hemidesmosomes and is, therefore, not a keratinocyte but rather a "clear cell".

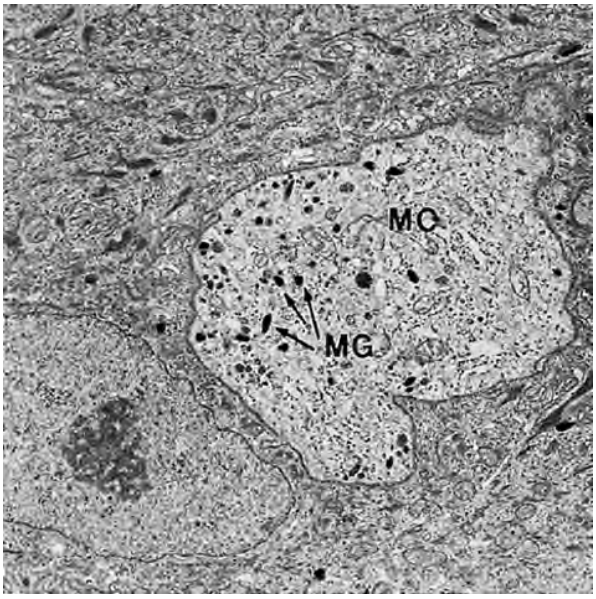

Fig. 1-28 Transmission electron micrograph illustrating a melanocyte (MC) surrounded by keratinocytes in the oral gingival epithelium. MG (arrows) points to melanin granules.

epithelial surface (Fig. 1-30). From the basal layer (stratum basale) to the granular layer (stratum granulosum) both the number of tonofilaments in the cytoplasm and the number of desmosomes increase. In contrast, the number of organelles, such as mitochondria, lamellae of rough endoplasmic reticulum, and Golgi complexes decrease in the keratinocytes on their way from the basal layer towards the surface. In the stratum granulosum, electron-dense *keratohyalin bodies* and clusters of glycogen-containing granules start to appear. Such granules are believed to be related to the synthesis of keratin.

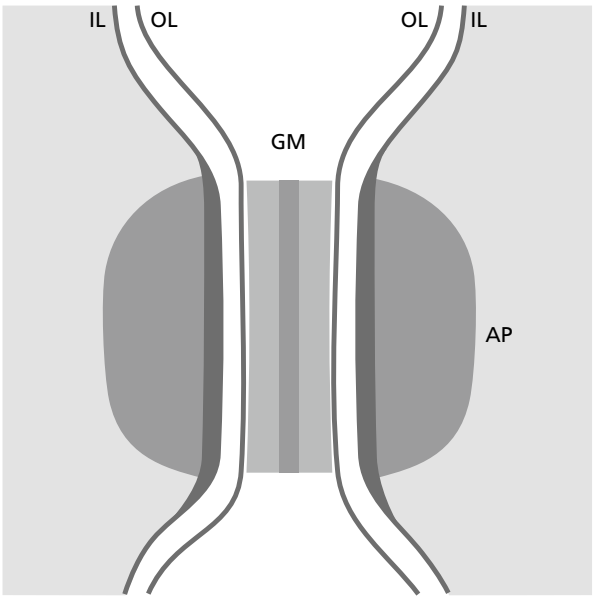

Fig. 1-27 The composition of a desmosome. AP, attachment plaque; GM, granulated material; IL, inner leaflets; OL, outer leaflets.

There is an abrupt transition of the cells from the stratum granulosum to the stratum corneum (Fig. 1-31). This is indicative of a very sudden keratinization of the cytoplasm of the keratinocyte and its conversion into a horny squame. The cytoplasm of the cells in the stratum corneum is filled with keratin and the entire apparatus for protein synthesis and energy production, that is the nucleus, the mitochondria, the endoplasmic reticulum, and the Golgi complex, is lost. In a parakeratinized epithelium, however, the cells of the stratum corneum contain remnants of nuclei. Keratinization is considered a process of differentiation rather than degeneration. It is a process of protein synthesis which requires energy and is dependent on functional cells (i.e. cells containing a nucleus and a normal set of organelles).

In contrast to the oral gingival epithelium, the epithelium of the alveolar (lining) mucosa has no stratum corneum. Cells containing nuclei can be identified in all layers, from the basal layer to the surface of the epithelium (Fig. 1-32).

Dentogingival epithelium

The tissue components of the dentogingival region achieve their final structural characteristics in conjunction with the eruption of the teeth. This is illustrated in Fig. 1-33a–d.

When the enamel of the tooth is fully developed, the enamel-producing cells (ameloblasts) become reduced in height, produce a basal lamina, and form, together with cells from the outer enamel epithelium, the so-called reduced enamel epithelium. The basal lamina lies in direct contact with the enamel. The contact between this lamina and the epithelial cells is maintained by hemidesmosomes. The reduced enamel epithelium surrounds the crown of the tooth

Fig. 1-29 The frontal view of the gingiva and alveolar mucosa. Distinct pigmentation of the oral gingival epithelium can be seen because of inclusion of melanin granules.

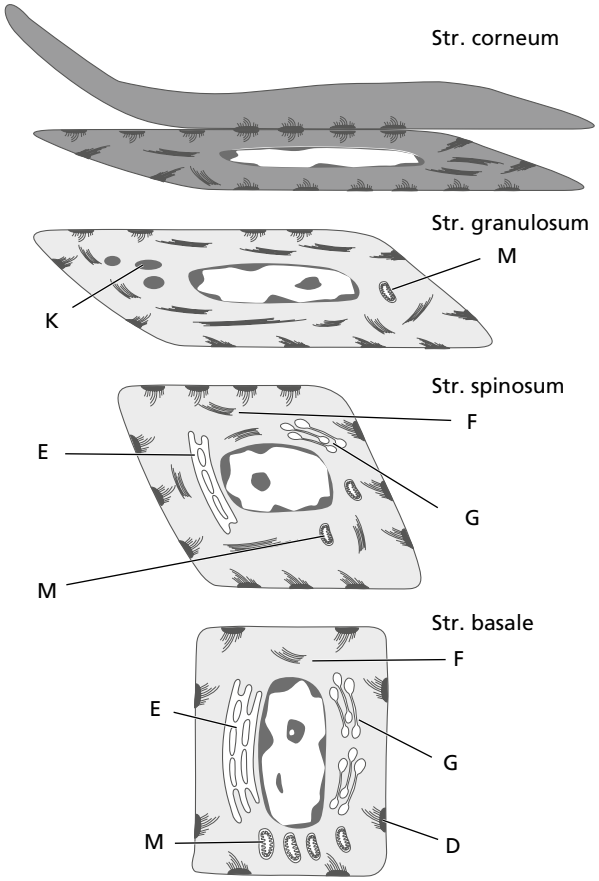

Fig. 1-30 A keratinized stratified squamous epithelium. From the basal layer to the epithelial surface, the keratinocytes undergo continuous differentiation and specialization. The many changes the cells undergo are indicated in this diagram. D, desmosomes; E, rough endoplasmic reticulum; F, tonofilaments; G, Golgi complexes; K, keratohyalin bodies; M, mitochondria.

from the moment the enamel is properly mineralized until the tooth starts to erupt (Fig. 1-33a).

As the erupting tooth approaches the oral epithelium, the cells of the outer layer of the reduced enamel epithelium, as well as the cells of the basal layer of the oral epithelium, show increased mitotic activity and start to migrate into the underlying connective tissue. The migrating epithelium produces an epithelial mass between the oral epithelium and

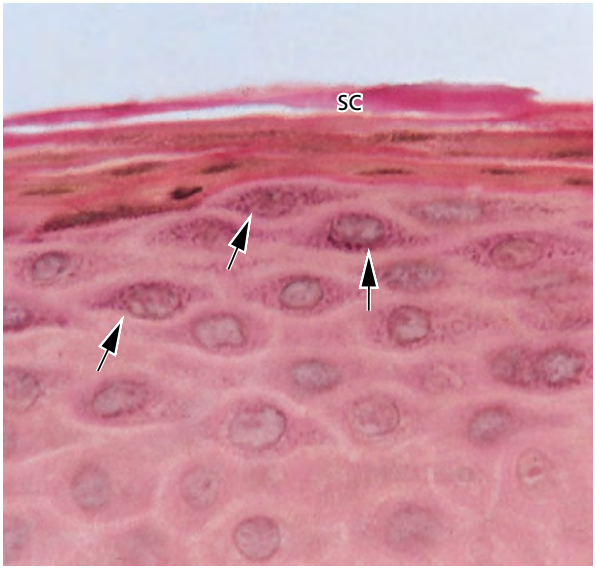

Fig. 1-31 Photomicrograph of the stratum granulosum and stratum corneum (SC). Keratohyalin granules (arrows) are seen in the stratum granulosum.

the reduced enamel epithelium so that the tooth can erupt without bleeding. The former ameloblasts do not divide (Fig. 1-33b).

When the tooth has penetrated into the oral cavity, large portions immediately apical to the incisal area of the enamel are covered by a transformed reduced enamel epithelium, which is now termed *junctional epithelium* and that contains only a few layers of cells. The cervical region of the enamel, however, is still covered by reduced ameloblasts and outer cells of the reduced enamel epithelium (Fig. 1-33c).

During the later phases of tooth eruption, all cells of the reduced enamel epithelium are replaced by *junctional epithelium*. This epithelium is continuous with the oral epithelium and provides the attachment between the tooth and the gingiva (Fig. 1-33d). If the free gingiva is excised after the tooth has fully erupted, a new junctional epithelium, indistinguishable from that found following tooth eruption, will develop during healing. The fact that this new junctional epithelium has developed from the oral epithelium indicates that the cells of the oral epithelium

Fig. 1-32 Photomicrograph illustrating a portion of the epithelium of the alveolar (lining) mucosa and the adjacent soft connective tissue. The epithelium of the alveolar mucosa has no stratum corneum.

possess the ability to differentiate into cells of the junctional epithelium.

Figure 1-34 is a histologic section through the border area between the tooth and the gingiva, that is the *dentogingival region*. The oral sulcular epithelium covers the shallow groove, the gingival sulcus, located between the enamel and the top of the free gingiva. The junctional epithelium differs morphologically from the oral sulcular epithelium and oral epithelium, while the latter two are structurally very similar. Although individual variation may occur, the junctional epithelium is usually widest in its coronal portion (about 15–20 cells) but becomes thinner (3–4 cells) towards the CEJ. The borderline between the junctional epithelium and the underlying connective tissue does not have epithelial rete pegs, except when inflamed.

The junctional epithelium has a free surface at the bottom of the *gingival sulcus* (Fig. 1-35). Like the oral sulcular epithelium and the oral gingival epithelium, the junctional epithelium is continuously renewed through cell division in the basal layer. The cells migrate to the base of the gingival sulcus from where they are shed. The cells of the oral sulcular

epithelium are cuboidal and the surface of this epithelium is non-keratinized.

The cells of the junctional epithelium are arranged into one basal layer and several suprabasal layers (Fig. 1-36a). The basal cells as well as the suprabasal cells are flattened with their long axis parallel to the tooth surface (Fig. 1-36b).

There are distinct differences between the oral sulcular epithelium, the oral gingival epithelium, and the junctional epithelium:

- The size of the cells in the junctional epithelium is, relative to the tissue volume, larger than in the oral gingival epithelium.
- The intercellular space in the junctional epithelium is, relative to the tissue volume, comparatively wider than in the oral gingival epithelium.
- The number of desmosomes is smaller in the junctional epithelium than in the oral gingival epithelium.

Between the enamel and the junctional epithelium, one electron-dense zone and one electron-lucent zone can be seen (Fig. 1-36c). The electron-lucent zone is in contact with the cells of the junctional epithelium. These two zones have a structure very similar to that of the lamina densa and lamina lucida in the basement membrane area (i.e. the epithelium–connective tissue interface) described in Fig. 1-24. Furthermore, as seen in Fig. 1-36d, the cell membrane of the junctional epithelial cells harbors hemidesmosomes towards the enamel and towards the soft connective tissue. Thus, the interface between the enamel and the junctional epithelium is somehow similar to the interface between the epithelium and the connective tissue.

In a schematic drawing (Fig. 1-37), it can be seen that the electron-dense zone between the junctional epithelium and the enamel can be considered a continuation of the lamina densa in the basement membrane of the connective tissue side. Similarly, the electron-lucent zone can be considered a continuation of the lamina lucida. It should be noted, however, that at variance with the epithelium–connective tissue interface, there are no anchoring fibrils attached to the lamina densa-like structure adjacent to the enamel. On the other hand, like the basal cells adjacent to the basement membrane (at the connective tissue interface), the cells of the junctional epithelium facing the lamina lucida-like structure harbor hemidesmosomes. Thus, the interface between the junctional epithelium and the enamel is structurally very similar to the epithelium–connective tissue interface, which means that the junctional epithelium is not only in contact with the enamel but is actually physically attached to the tooth via hemidesmosomes.

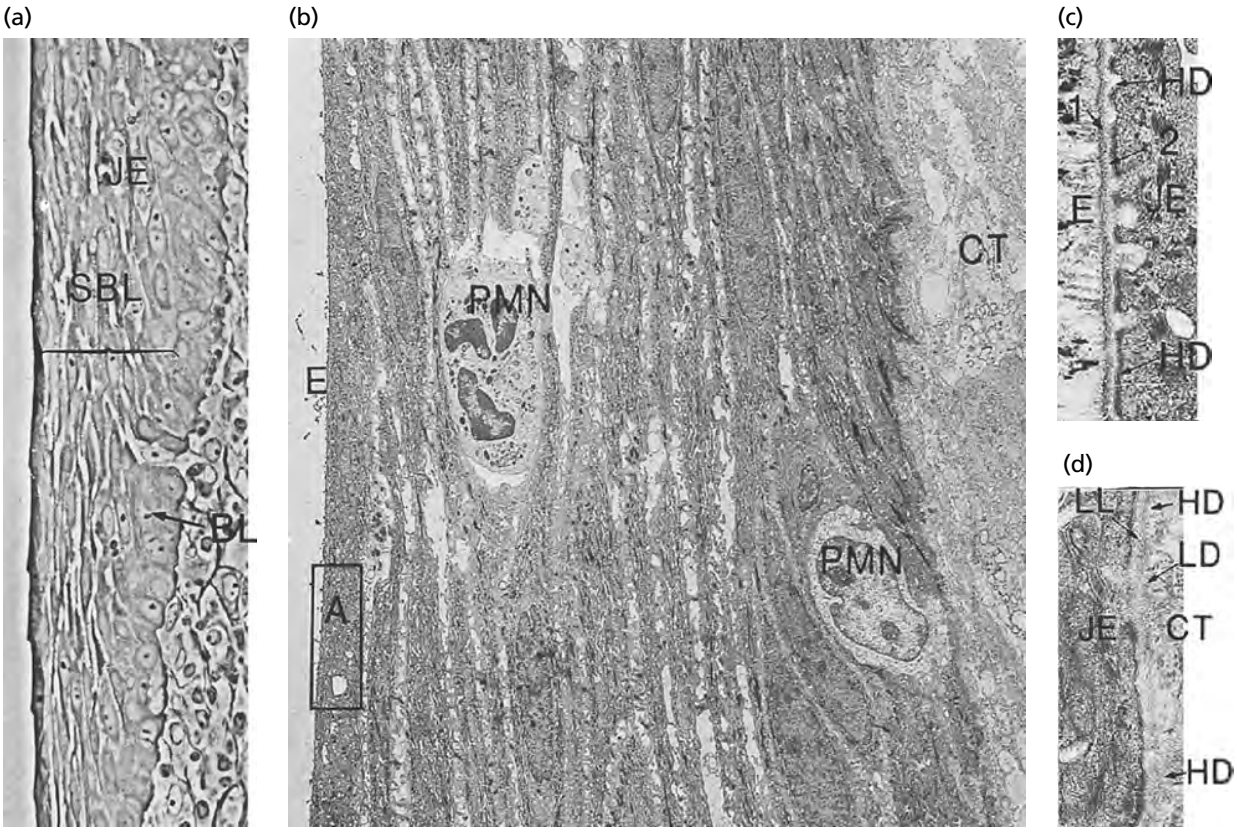

Fig. 1-36 Light (a) and transmission electron (b-d) micrographs illustrating different characteristics of the junctional epithelium (JE). Note the comparatively wide intercellular spaces between the oblong cells of the junctional epithelium, and the presence of two neutrophilic granulocytes (PMN) which are traversing the epithelium (b). The framed area (A) in (b) is shown in a higher magnification in (c), from which it can be seen that the basal cells of the junctional epithelium are not in direct contact with the enamel (E). Between the enamel and the junctional epithelium, one electron-dense zone (1) and one electron-lucent zone (2) can be seen. Likewise, an electron-dense (LD, lamina densa) and an electron-lucent (LL, lamina lucida) zone is present in the basement membrane constituting the epithelium-connective tissue interface (d). Hemidesmosomes (HD) are part of both the basal lamina and the basement membrane. BL, basal layer; CT, soft connective tissue; E, enamel space; PMN, polymorphonuclear leukocytes; SBL, suprabasal layer.

Lamina propria

The predominant tissue component of the gingiva is the connective tissue (lamina propria). The major components of the connective tissue are *collagen fibers* (around 60% of connective tissue volume), *fibroblasts* (around 5%), and *vessels and nerves* (around 35%), which are embedded in an amorphous extracellular matrix containing non-collagenous proteins (Fig. 1-38).

Cells

The different types of cells present in the connective tissue are: (1) *fibroblasts*, (2) *mast cells*, (3) *macrophages*, and (4) *inflammatory cells*.

The *fibroblast* is the predominant connective tissue cell (65% of the total cell population). The fibroblast is engaged in the production of various types of fibers found in the connective tissue but is also instrumental in the synthesis of the connective tissue matrix. The fibroblast is a spindle-shaped or stellate cell with an oval-shaped nucleus containing one or more nucleoli (Fig. 1-39). The cytoplasm contains a well-developed rough endoplasmic reticulum with ribosomes. The Golgi complex is usually of considerable size and the mitochondria are large and numerous. Furthermore, the cytoplasm contains many fine filaments, which resemble tonofilaments.

The *mast cell* is responsible for the production of components of the matrix (Fig. 1-40). This cell also produces vasoactive substances, which can affect the function of the microvascular system and control the flow of blood through the tissue. The cytoplasm is characterized by the presence of a large number of vesicles of varying size. These vesicles contain biologically active substances such as proteolytic enzymes, histamine, and heparin. The Golgi complex is well-developed, while rough endoplasmic reticulum structures are scarce. A large number of small cytoplasmic projections (i.e. microvilli) are present along the periphery of the cell.

The *macrophage* has a number of different phagocytic and synthetic functions in the tissue (Fig. 1-41). They are derived from circulating blood monocytes, which migrate into the tissue, play an important role in our immune system, and respond to necrotic tissue and foreign bodies in the form of microorganisms or biomaterials. The nucleus is characterized by numerous invaginations of varying size. A zone

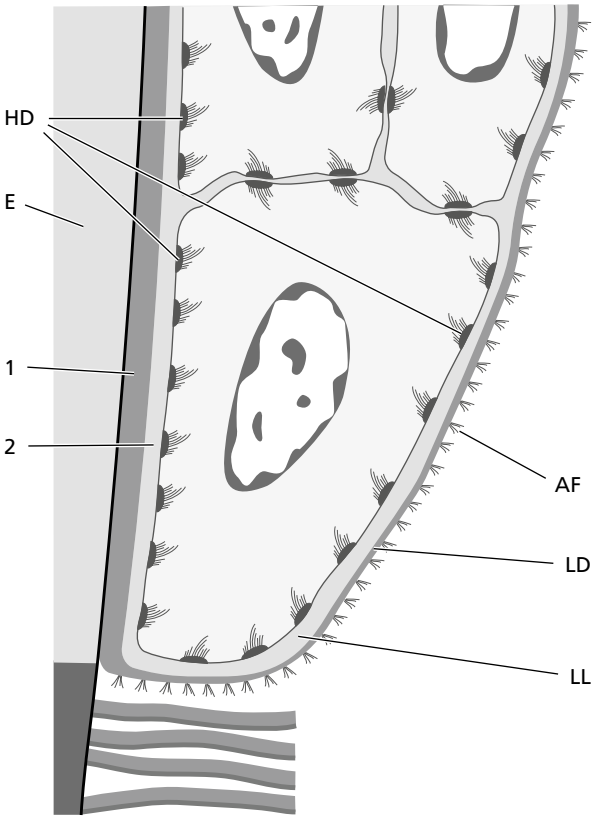

Fig. 1-37 The most apically positioned cell in the junctional epithelium. The enamel (E) is depicted to the left. The electron-dense zone (1) represents the lamina densa (LD), whereas the electron-lucent zone (2) represents the lamina lucida (LL) of the basal lamina at the epithelium–enamel interface. Anchoring fibrils (AF) are present only in the basement membrane where the epithelial cells face the soft connective tissue. Hemidesmosomes (HD), however, are part of both the basal lamina and the basement membrane.

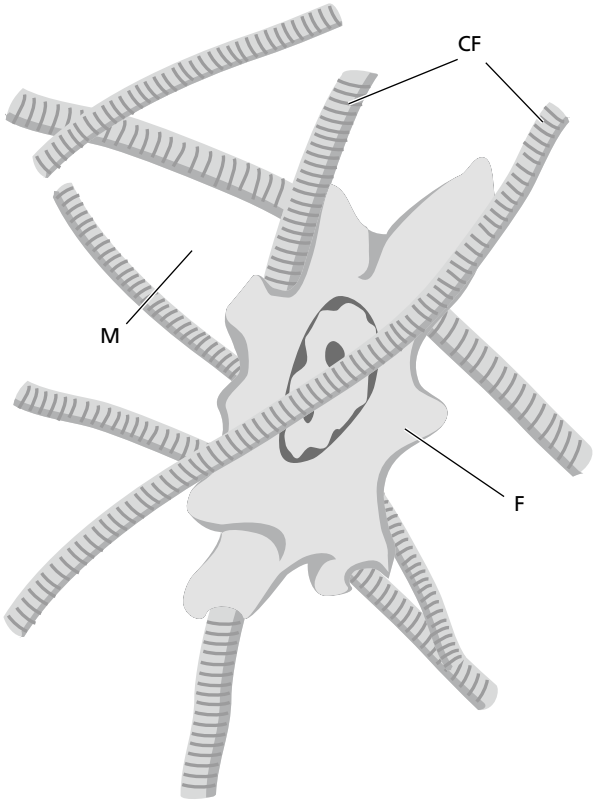

Fig. 1-38 A fibroblast (F) residing in a network of connective tissue fibrils (CF). The intervening space is filled with non-collagenous extracellular matrix (M), which constitutes the "environment" for the cell.

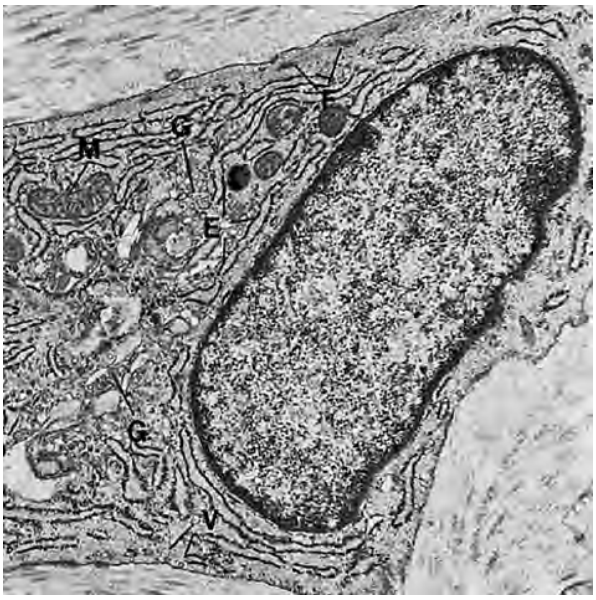

Fig. 1-39 Transmission electron micrograph illustrating a part of a fibroblast. A well-developed rough endoplasmic reticulum (E), a Golgi complex (G), and numerous large mitochondria (M) and vesicles (V) constitute the cytoplasm. At the cell periphery, many fine filaments (F) resembling tonofilaments can be seen.

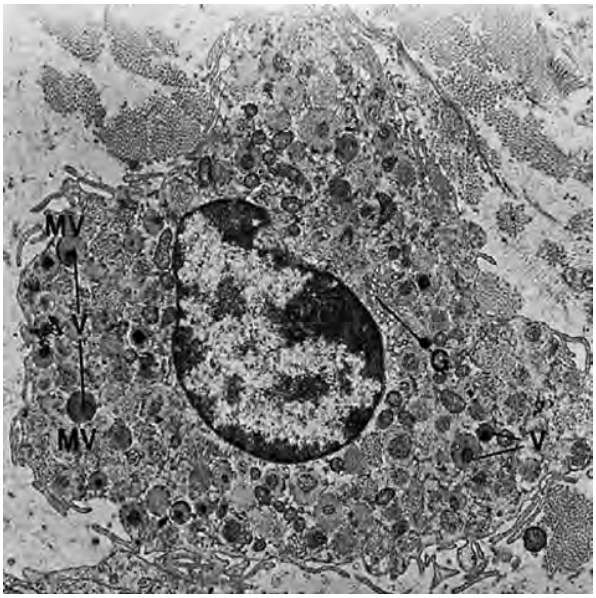

Fig. 1-40 Transmission electron micrograph showing a mast cell. The cytoplasm contains a well-developed Golgi complex (G) and a large number of vesicles (V). Many microvilli (MV), small cytoplasmic projections, can be seen extending from the cell periphery.

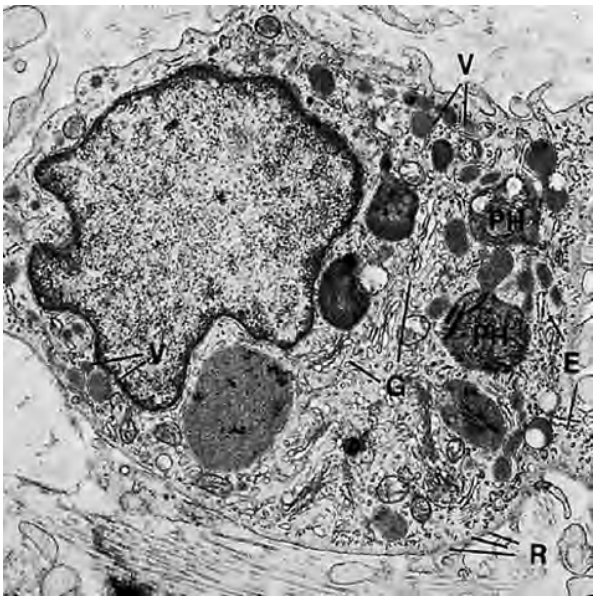

Fig. 1-41 Transmission electron micrograph demonstrating a macrophage. E, rough endoplasmic reticulum; G, Golgi complex; PH, phagosomes; R, ribosomes; V, vesicles.

of electron-dense chromatin condensations can be seen along the periphery of the nucleus. The Golgi complex is well developed and numerous vesicles of varying size are present in the cytoplasm. Rough endoplasmic reticulum is scarce, but a certain number of free ribosomes are evenly distributed in the cytoplasm. Remnants of phagocytosed material, called phagosomes, are often found in lysosomal vesicles. In the periphery of the cell, a large number of microvilli of varying size can be seen. Macrophages are particularly numerous in inflamed tissue.

Besides fibroblasts, mast cells, and macrophages, the connective tissue also harbors *inflammatory cells* of various types, for example neutrophilic granulocytes, lymphocytes, and plasma cells (Fig. 1-42).

The *neutrophilic granulocytes*, also called *polymorphonuclear leukocytes*, have a characteristic appearance (Fig. 1-42a). The nucleus is lobulated and numerous lysosomes, containing lysosomal enzymes, are found in the cytoplasm.

The *lymphocytes* (Fig. 1-42b) are characterized by an oval to spherical nucleus containing localized areas of electron-dense chromatin. The narrow border of cytoplasm surrounding the nucleus contains numerous free ribosomes, a few mitochondria, and, in localized areas, rough endoplasmic reticulum. Lysosomes are also present in the cytoplasm.

The *plasma cells* (Fig. 1-42c) contain an eccentrically located spherical nucleus with radially deployed electron-dense chromatin. Rough endoplasmic reticulum is abundantly found randomly distributed in the cytoplasm. In addition, the cytoplasm contains numerous mitochondria and a well-developed Golgi complex.

Fibers

The connective tissue fibers are produced by the fibroblasts and can be divided into: (1) *collagen fibers*, (2) *reticulin fibers*, (3) *oxytalan fibers*, and (4) *elastic fibers*.

The *collagen fibers* predominate in the gingival connective tissue and constitute the most essential components of the periodontium. The collagen fibrils have a characteristic cross-banding with a periodicity of 700 Å between the individual dark bands (Fig. 1-43).

Figure 1-44 illustrates some important features of the synthesis and the composition of collagen fibers produced by fibroblasts. The smallest unit, the collagen molecule, is often referred to as *tropocollagen*. A

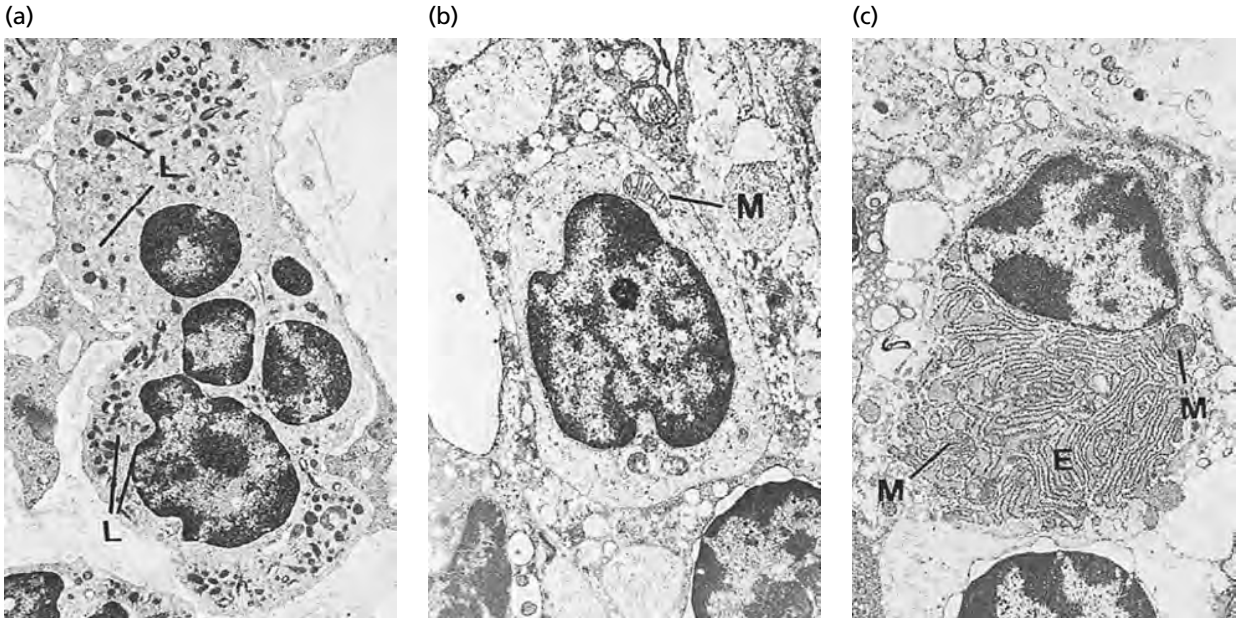

Fig. 1-42 Transmission electron micrographs showing a polymorphonuclear leukocyte (a), a lymphocyte (b), and a plasma cell (c). E, rough endoplasmic reticulum; L, lysosomes; M, mitochondria.

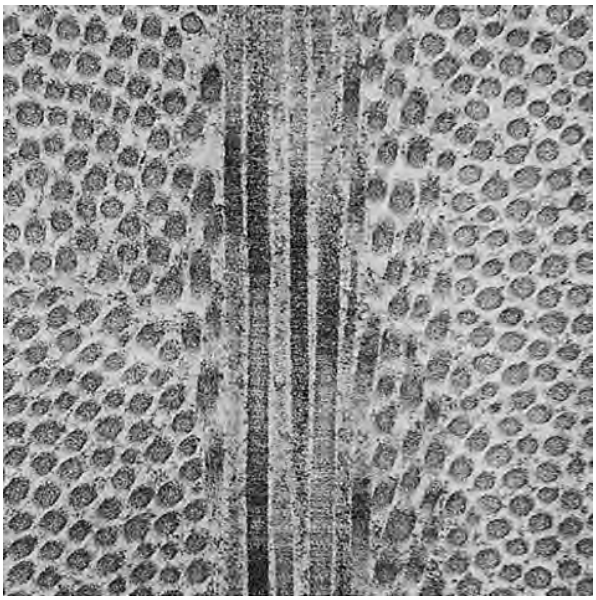

Fig. 1-43 Transmission electron micrograph demonstrating cross-sections and longitudinal sections of collagen fibrils.

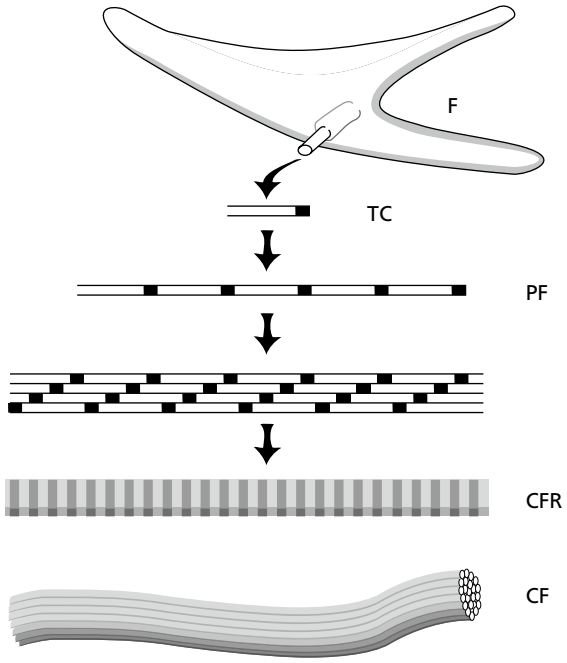

Fig. 1-44 Some important features of the synthesis and composition of collagen fibers (CF) produced by fibroblasts (F). CFR, collagen fibril; PF, protofibril; TC, tropocollagen molecule.

tropocollagen molecule, is approximately 3000 Å long and has a diameter of 15 Å. It consists of three polypeptide chains intertwined to form a helix. Each chain contains about 1000 amino acids. One-third of these are glycine and about 20% proline and hydroxyproline, the latter being found almost exclusively in collagen. Tropocollagen synthesis takes place inside the fibroblast from which the tropocollagen molecule is secreted into the extracellular space. Thus, the polymerization of tropocollagen molecules to collagen fibrils takes place in the extracellular compartment. First, tropocollagen molecules are aggregated longitudinally to form *protofibrils*, which are subsequently laterally aggregated parallel to *collagen fibrils*, with the tropocollagen molecules overlapping by about 25% of their length. Due to the fact that special refraction conditions develop after staining at the sites where the tropocollagen molecules adjoin, a cross-banding with a periodicity of approximately 640 Å is seen in the transmission electron microscope. The *collagen fibers* are bundles of collagen fibrils, aligned in such a way that the fibers also exhibit a cross-banding with a periodicity of 640 Å. In the tissue, the fibers are usually arranged in bundles. As the collagen fibers mature, covalent cross-links are formed between the tropocollagen molecules, resulting in an age-related reduction in collagen solubility.

Reticulin fibers exhibit argyrophilic staining properties and are numerous in the tissue adjacent to the basement membrane (Fig. 1-45). However, reticulin fibers also occur in large numbers in the loose connective tissue surrounding the blood vessels. Thus, reticulin fibers are present at the epithelium–connective tissue and the endothelium–connective tissue interfaces.

Oxytalan fibers are scarce in the gingiva but numerous in the periodontal ligament (Fig. 1-46). They are composed of long thin fibrils with a diameter of approximately 150 Å. These connective tissue fibers can be demonstrated under light microscopy only after previous oxidation with peracetic acid.

Fig. 1-45 Light micrograph showing reticulin fibers adjacent to the basement membrane between epithelium and soft connective tissue. Argyrophilic staining produces a black staining of the reticulin fibers (arrows).

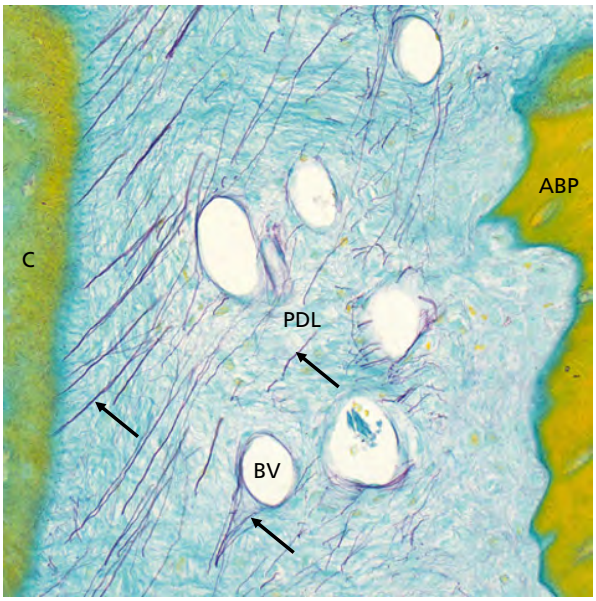

Fig. 1-46 Light micrograph demonstrating oxytalan fibers (arrows) in the periodontal ligament (PDL). Note that the oxytalan fibers insert into the cementum (C) and are associated with blood vessels (BV). ABP, alveolar bone proper.

The photomicrograph illustrates oxytalan fibers in the periodontal ligament, where they have a course mainly parallel to the long axis of the tooth and insert into cementum. Oxytalan fibers are elastic in nature and are largely associated with blood vessels. They may have a function in mechanotransduction.

Elastic fibers in the connective tissue of the gingiva and periodontal ligament are only present in association with blood vessels. However, the lamina propria and submucosa of the alveolar (lining) mucosa contain numerous elastic fibers (Fig. 1-47).

Although many of the collagen fibers in the gingiva and the periodontal ligament are irregularly or randomly distributed, most tend to be arranged in groups of bundles with a distinct orientation. According to their insertion and course in the tissue, the oriented bundles in the gingiva can be divided into the following groups (Fig. 1-48):

1. *Circular fibers* are fiber bundles which run their course in the free gingiva and encircle the tooth in a cuff-like fashion.
2. *Dentogingival fibers* are embedded in the cementum of the supra-alveolar portion of the root and project out from the AEFC in a fan-like configuration into the free gingival tissue of the facial, lingual, and interproximal surfaces.
3. *Dentoperiosteal fibers* are embedded in the same portion of the cementum as the dentogingival fibers but run their course apically over the vestibular and lingual bone crest and terminate in the tissue of the attached gingiva. In the border area between the free and attached gingiva, the epithelium often lacks support from underlying oriented collagen fiber bundles. In this area, the free gingival groove may sometimes be observed.

Fig. 1-47 Light micrograph illustrating elastic fibers (arrows) in the lamina propria and submucosa of the alveolar mucosa. The gingiva (G) seen coronal to the mucogingival junction (MGJ) contains no elastic fibers except in association with the blood vessels.

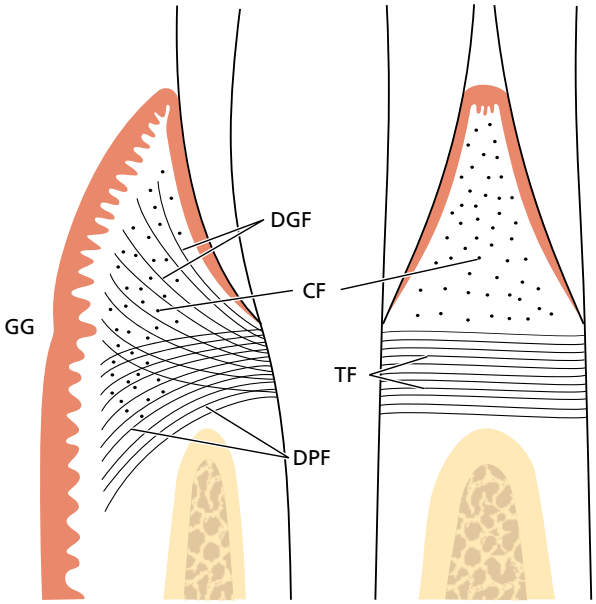

Fig. 1-48 The arrangement of collagen fiber bundles in the gingiva in a buccolingual (left) and mesiodistal (right) section. CF, circular fibers; DGF, dentogingival fibers; DPF, dentoperiosteal fibers; GG, gingival groove; TF, trans-septal fibers.

4. *Trans-septal fibers* extend between the supra-alveolar cementum of approximating teeth. The transseptal fibers run straight across the interdental septum and are embedded in the AEFC of adjacent teeth.

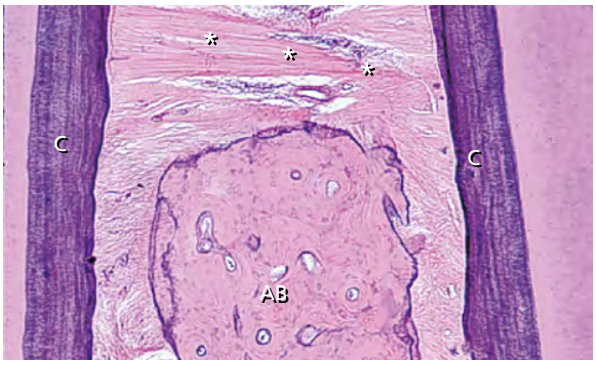

Fig. 1-49 Histologic section illustrating the orientation of the trans-septal fiber bundles (asterisks) in the supra-alveolar portion of the interdental area. The trans-septal fibers are embedded in acellular extrinsic fiber cementum (C) and also in the crest of the alveolar bone (AB).

It should be observed that, besides connecting the cementum of adjacent teeth, the trans-septal fibers also connect the supra-alveolar cementum with the crest of the alveolar bone (Fig. 1-49). The four groups of collagen fiber bundles shown in Fig. 1-48 reinforce the gingiva and provide the resilience and tone which is necessary for maintaining its architectural form and the integrity of the dentogingival attachment.

Extracellular matrix

The extracellular *matrix* of the connective tissue is produced mainly by the fibroblasts, although some constituents are produced by mast cells and others are derived from the blood. The matrix is the medium in which the connective tissue cells are embedded and it is essential for the maintenance of the normal function of the connective tissue. Thus, the transportation of water, electrolytes, nutrients, metabolites, etc., to and from the individual connective tissue cells occurs within the matrix. The main constituents of the connective tissue matrix are protein–carbohydrate macromolecules. These complexes are normally divided into *proteoglycans* and *glycoproteins*. The proteoglycans contain *glycosaminoglycans* as the carbohydrate units (hyaluronan sulfate, heparan sulfate, etc.), which are attached to one or more protein chains via covalent bonds. The carbohydrate component is always predominant in the proteoglycans. The glycosaminoglycan, called hyaluronan or "hyaluronic acid", is probably not bound to protein. The glycoproteins (fibronectin, osteonectin, etc.) also contain polysaccharides, but these macromolecules are different from glycosaminoglycans. The protein component predominates in glycoproteins. In the macromolecules, mono- or oligo-saccharides are connected to one or more protein chains via covalent bonds.

Normal function of the connective tissue depends on the presence of proteoglycans and glycosaminoglycans. The carbohydrate moieties of the proteoglycans, the glycosaminoglycans, are large, flexible, chains of negatively charged molecules, each of which occupies a rather large space. In such a space, smaller molecules, for example water and electrolytes, can be incorporated, while larger molecules are prevented from entering. The proteoglycans thereby regulate diffusion and fluid flow through the matrix and are important determinants for the fluid content of the tissue and the maintenance of the osmotic pressure. In other words, the proteoglycans act as a molecule filter and, in addition, play an important role in the regulation of cell migration (movement) in the tissue. Due to their structure and hydration, the macromolecules resist deformation, thereby serving as regulators of the consistency of the connective tissue. If the gingiva is suppressed, the macromolecules become deformed. When the pressure is eliminated, the macromolecules regain their original form. Thus, the macromolecules are important for the resilience of the gingiva.

Epithelial–mesenchymal interactions

During the embryonic development of various organs, a mutual inductive influence occurs between the epithelium and the connective tissue. The development of the teeth is a characteristic example of this phenomenon. The connective tissue is, on the one hand, a determining factor for normal development of the tooth bud, while, on the other hand, the enamel epithelia exert a definite influence on the development of the mesenchymal components of the teeth.

It has been suggested that tissue differentiation in the adult organism can be influenced by environmental factors. The skin and mucous membranes, for instance, often display increased keratinization and hyperplasia of the epithelium in areas which are exposed to mechanical stimulation. Thus, the tissues seem to adapt to environmental stimuli. The presence of keratinized epithelium on the masticatory mucosa has been considered to represent an adaptation to mechanical irritation released by mastication. However, research has demonstrated that the characteristic features of the epithelium in such areas are genetically determined. Some pertinent observations are discussed below.

In an experimental study, separate tissue flaps of the buccal gingiva and alveolar mucosa adjacent to premolar teeth were transposed by a surgical procedure (Karring *et al*. 1971). An area in a monkey where the gingiva and the alveolar mucosa have been transposed is shown in Fig. 1-50. The alveolar mucosa is placed in close contact with the teeth, while the gingiva is positioned in the area of the alveolar mucosa.

Four months later, the same area as seen in Fig. 1-50 shows that the transplanted gingiva has retained its characteristic morphologic features of a masticatory mucosa, despite the fact that the transplanted gingiva is mobile in relation to the underlying bone (Fig. 1-51). A narrow zone of new keratinized gingiva has formed between the alveolar mucosa and the teeth.

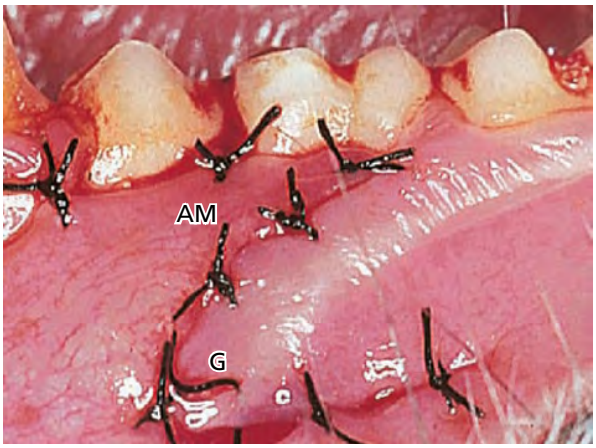

Fig. 1-50 A buccal site in a monkey where the gingiva (G) and the alveolar mucosa (AM) have been surgically transposed.

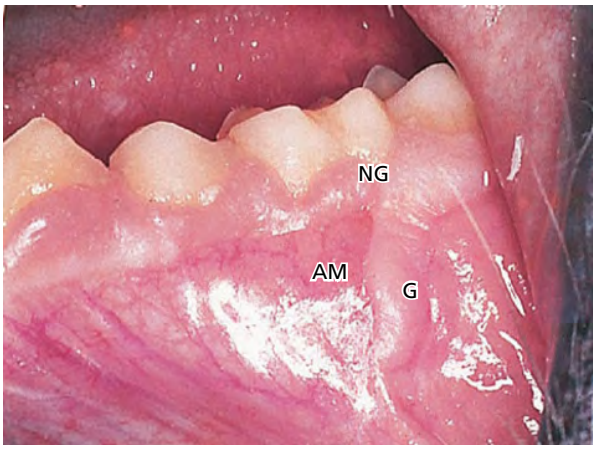

Fig. 1-51 The same area as seen in Fig. 1-50, but 4 months later. The transplanted gingiva (G) has retained its characteristic morphologic features and a narrow zone of new keratinized gingiva (NG) has formed between the alveolar mucosa (AM) and the teeth.

A histologic section through the transplanted gingiva seen in Fig. 1-51 is shown in Fig. 1-52. Since elastic fibers are lacking in the gingival connective tissue but are numerous in the connective tissue of the alveolar mucosa, the transplanted gingival tissue can readily be identified. The epithelium covering the transplanted gingival tissue exhibits a distinct keratin layer on the surface, and the configuration of the epithelium–connective tissue interface (i.e. rete pegs and connective tissue papillae) is similar to that of normal non-transplanted gingiva. Thus, the heterotopically located gingival tissue has maintained its original specificity. This observation demonstrates that the characteristics of the gingiva are genetically determined rather than being the result of functional adaptation to environmental stimuli.

After surgery, the alveolar mucosa transplant was positioned in close contact with the teeth, as seen in Fig. 1-50. After healing, a narrow zone of keratinized gingiva developed coronal to the alveolar mucosa transplant (see Fig. 1-51). This zone of new gingiva is covered by keratinized epithelium and the connective tissue contains no purple-stained elastic fibers (Fig. 1-53). In addition, it is important to note that the junction between keratinized and non-keratinized epithelium corresponds exactly to the junction between "elastic" and "non-elastic" connective tissue. The connective tissue of the new gingiva has regenerated from the connective tissue of the supraalveolar and periodontal ligament compartments and has separated the alveolar mucosal transplant from the tooth (see Fig. 1-54). It is likely that the epithelium which covers the new gingiva has migrated from the adjacent epithelium of the alveolar mucosa. This indicates that it is the connective tissue that determines the quality of the epithelium.

The development of the new gingival tissue in contact with the teeth is illustrated in a schematic drawing (Fig. 1-54). Granulation tissue has proliferated coronally along the root surface and has separated the alveolar mucosa transplant from its original contact with the tooth surface (Fig. 1-54a). Epithelial

Fig. 1-52 Histologic section through the transplanted gingiva (G) seen in Fig. 1-51. The transposed gingiva exhibits a keratinized epithelium (between arrowheads) and lacks elastic fibers in the lamina propria. In contrast, elastic fibers are numerous (arrows) in the connective tissue of the alveolar mucosa (AM) adjacent to the lamina propria of the gingiva. The elastic fibers are purple-stained.

vcells have migrated from the alveolar mucosal transplant to the newly formed gingival connective tissue (Fig. 1-54b). Thus, the newly formed gingiva has become covered with a keratinized epithelium that originated from the non-keratinized epithelium of the alveolar mucosa. This implies that the newly

Fig. 1-53 Histologic section through the coronal portion of the area of transplantation seen in Fig. 1-51 showing the transplanted gingival tissue (G) in the lower portion of the photomicrograph and a newly formed narrow zone of gingiva (NG) between the teeth and the transplanted alveolar mucosa (AM, between arrowheads). Note that the junctions between keratinized and non-keratinized epithelium (arrowheads) correspond exactly to the junction between "elastic" (arrows) and "non-elastic" connective tissue. The elastic fibers are purple-stained.

formed gingival connective tissue possesses the ability to induce changes in the differentiation of the epithelium originating from the alveolar mucosa. This epithelium, which is normally non-keratinized, apparently differentiates to keratinized epithelium because of stimuli arising from the newly formed gingival connective tissue.

In another experimental study, the role of the soft connective tissue in determining the type of epithelium was further studied (Karring *et al*. 1975). In this experiment, free connective tissue grafts, without epithelium, were transplanted from either the keratinized gingiva or the non-keratinized alveolar mucosa into pouches created in the soft connective tissue of the alveolar mucosa (Fig. 1-55). The transplants were placed as close as possible to the overlying epithelium, which was removed after 3–4 weeks to allow epithelialization from the surrounding non-keratinized alveolar mucosa. The gingival connective tissue grafts became covered with keratinized epithelium, which displayed the same characteristics as those of normal gingival epithelium (Fig. 1-56). In contrast, the alveolar mucosa transplants were covered with non-keratinized epithelium.

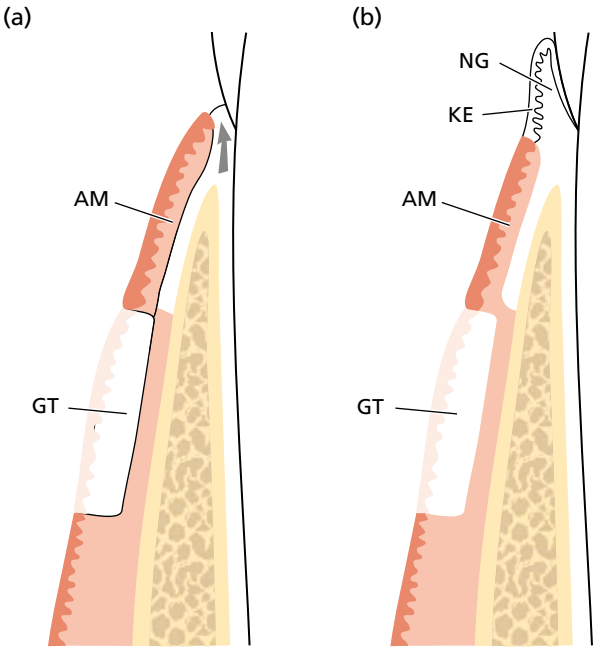

Fig. 1-54 The development of the new, narrow zone of keratinized gingiva seen in Figs. 1-51 and 1-53. (a) Granulation tissue has proliferated coronally along the root surface (arrow) and has separated the alveolar mucosa transplant (AM) from its original contact with the tooth surface. (b) Epithelial cells have migrated from the alveolar mucosal transplant (AM) to the newly formed gingival connective tissue (NG) where they transformed into keratinized epithelial cells (KE). GT, gingival transplant.

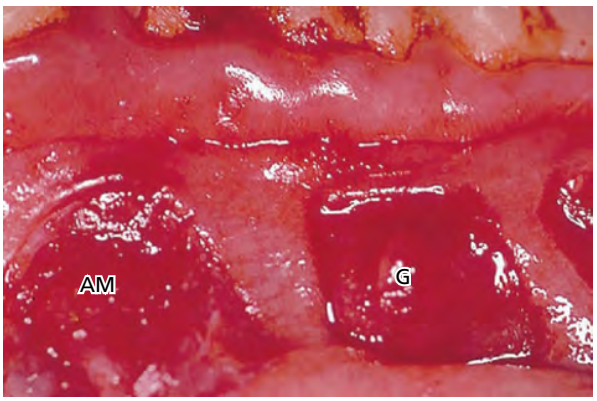

Fig. 1-55 A portion of gingival connective tissue (G) and alveolar mucosal connective tissue (AM) which, after transplantation, has healed into wound areas in the alveolar mucosa. Epithelialization of these transplants can only occur through migration of epithelial cells from the surrounding alveolar mucosa.

Histological sections through the area of the transplanted gingival connective tissue (Fig. 1-57) show that:

- Transplanted gingival connective tissue is covered by keratinized epithelium.
- Epithelium–connective tissue interface has the same wavy course (i.e. rete pegs and connective tissue papillae) as seen in the pristine gingiva.

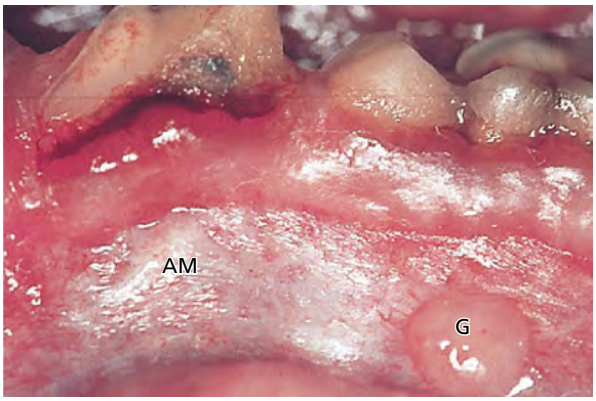

Fig. 1-56 The transplanted gingival connective tissue (G) after re-epithelialization. This tissue portion has attained an appearance similar to that of the normal gingiva, indicating that this connective tissue is now covered by keratinized epithelium. The transplanted connective tissue from the alveolar mucosa (AM) is covered by non-keratinized epithelium and has the same appearance as the surrounding alveolar mucosa.

At a higher magnification, the distinct relationship between keratinized epithelium and "inelastic" connective tissue, and between non-keratinized epithelium and "elastic" connective tissue is evident (Fig. 1-57c, d). The establishment of such a close relationship during healing implies that the transplanted gingival connective tissue possesses the ability to alter the differentiation of epithelial cells, as previously suggested (Fig. 1-54). While starting as non-keratinizing cells, the cells of the epithelium of the alveolar mucosa have evidently become keratinizing cells. This means that the specificity of the gingival epithelium is determined by genetic factors inherent in the connective tissue.

Periodontal ligament

The periodontal ligament is the soft, richly vascular and cellular connective tissue that surrounds the roots of the teeth and joins the root cementum with the socket wall. In the coronal direction, the periodontal ligament is continuous with the lamina propria of the gingiva and is demarcated from the gingiva by the collagen fiber bundles which connect the alveolar bone crest to the root (the alveolar crest fibers).

On radiographs, two types of alveolar bone can be distinguished (Fig. 1-58):

1. The part of the alveolar process which covers the alveolus, denoted "lamina dura".
2. The portion of the alveolar process which, on the radiograph, has the appearance of a meshwork, denoted "trabecular bone".

The periodontal ligament is situated in the space between the roots of the teeth and the bone of the socket wall. The alveolar bone surrounds the tooth from the apex to a level approximately 1 mm apical to the CEJ. The coronal border of the bone is called the *bone crest*.

The periodontal ligament space has the shape of an hourglass and is narrowest at the mid-root level. The width of the periodontal ligament is approximately 0.2 mm and depends on type of species, age, distance from the CEJ, and function. The presence of a periodontal ligament permits forces, elicited during masticatory function and other tooth contacts, to be distributed to and absorbed by the alveolar process via the alveolar bone proper. The periodontal ligament is also essential for the mobility of the teeth. Tooth mobility is to a large extent determined by the width and height of the periodontal ligament (see Chapters 13 and 43).

The tooth is joined to the bone by bundles of collagen fibers that can be divided into the following main groups according to their location and arrangement (Fig. 1-59):

1. *Alveolar crest fibers*
2. *Horizontal fibers*
3. *Oblique fibers*
4. *Apical fibers*.

The periodontal ligament and the root cementum develop from the loose connective tissue (the dental follicle), which surrounds the tooth bud. The principal fiber bundles of the periodontal ligament develop from coronal to apical, while the root develops and the tooth erupts. The various stages in the organization of the periodontal ligament, which forms concomitantly with the development of the root and the eruption of the tooth, is illustrated in Fig. 1-60.

The tooth bud is formed in a crypt of the bone (Fig. 1-60a). The collagen fibers produced by the fibroblasts in the loose connective tissue around the tooth bud are embedded, during the process of their maturation, into the newly formed cementum immediately apical to the CEJ. These fiber bundles oriented towards the coronal portion of the bone crypt will later form the dentogingival, the dentoperiosteal, and the trans-septal fiber groups, which belong to the oriented fibers of the gingiva (see Fig. 1-48).

The true periodontal ligament fibers, the *principal fibers*, develop in conjunction with the eruption of the tooth (Fig. 1-60b). First, fibers can be identified entering the most marginal portion of the alveolar bone. Later, more apically positioned bundles of oriented collagen fibers are seen (Fig. 1-60c).

The orientation of the collagen fiber bundles alters continuously during the phase of tooth eruption. First, when the tooth has reached contact in occlusion and is fully in function, the fibers of the periodontal ligament associate into groups of well-oriented dentoalveolar collagen fibers (Fig. 1-60d). These collagen structures undergo constant remodeling (i.e. resorption of old and formation of new fibers).

The development of the principal fibers of the periodontal ligament is illustrated in Fig. 1-61. First, small,

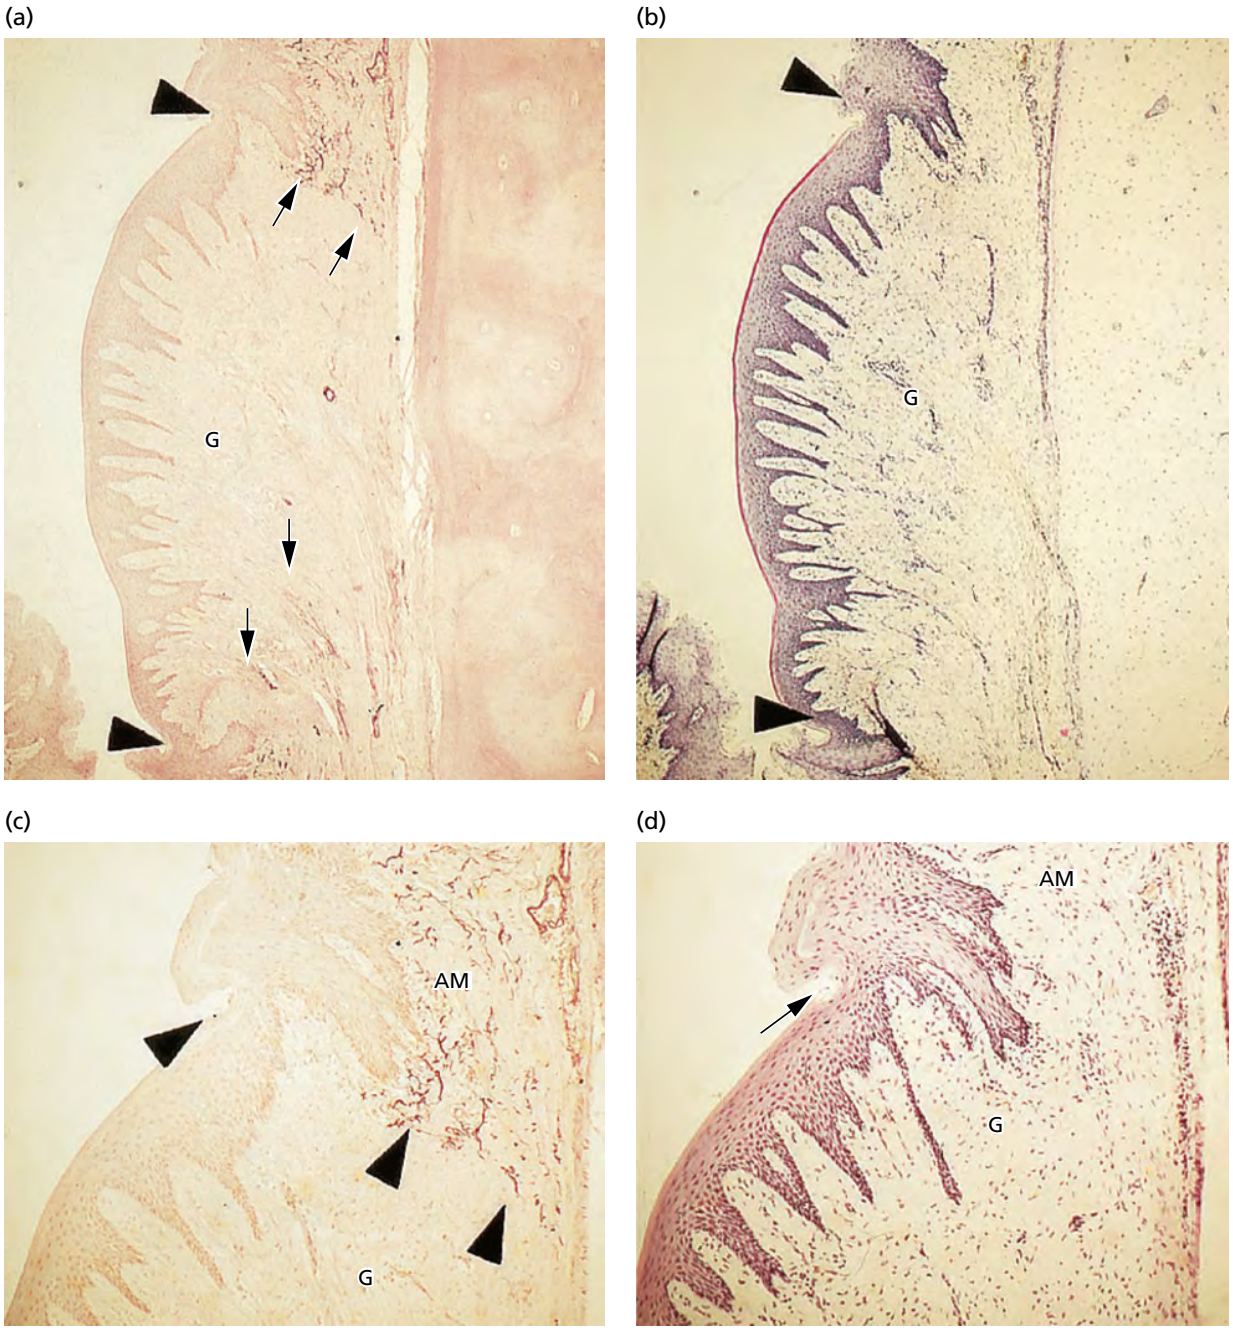

Fig. 1-57 Two histologic sections through the area of the transplanted gingival connective tissue. Sections were stained for elastic fibers (arrows) (a, c) and with hematoxylin and eosin (b, d) and are illustrated at medium (a, b) and high (c, d) magnifications. (a, b) The tissue in the middle (between arrowheads) without elastic fibers is the transplanted gingival connective tissue covered with a keratinized epithelium. (c) Note that the purple-stained elastic fibers in the connective tissue of the alveolar mucosa (AM) (2 arrowheads) end where the connective tissue of the gingiva (G) begins. (d) The arrow indicates the site where the keratinized epithelium adjacent to the gingival connective tissue meets the non-keratinized epithelium over the alveolar mucosa.

fine, brush-like collagenous fiber stubs arise from the root cementum and project into the periodontal ligament space (Fig. 1-61a). At this stage, the surface of the bone is covered by osteoblasts and only a small number of radiating, thin fiber stubs can be seen.

Later on, the number and thickness of fibers embedded in the bone increase (Fig. 1-61b). These fibers radiate towards the loose connective tissue in the mid-portion of the periodontal ligament space, which contains more or less randomly oriented collagen fibers. The fibers originating from the cementum are still short, while those entering the bone gradually lengthen. The terminal portions of these fibers carry finger-like projections.

The fibers originating from the cementum subsequently increase in length and thickness and fuse in the periodontal ligament space with the fibers originating from the alveolar bone (Fig. 1-61c). When the tooth, following eruption, reaches contact in occlusion and starts to function, the principal fibers become organized into bundles and run continuously from the bone to the cementum.

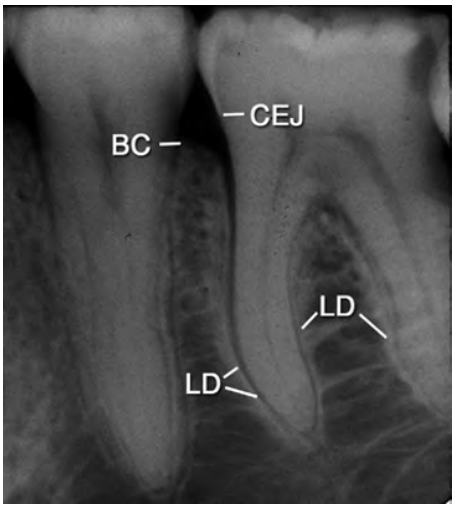

Fig. 1-58 Radiograph of a mandibular premolar region. Two types of alveolar bone can be distinguished: the lamina dura (LD) is that part of the alveolar process that covers the alveolus, whereas the trabecular bone, which has the appearance of a meshwork, constitutes the rest of the alveolar process. The coronal border of the bone is called bone crest (BC). The distance between the bone crest and the cementoenamel junction (CEJ) measures approximately 1 mm.

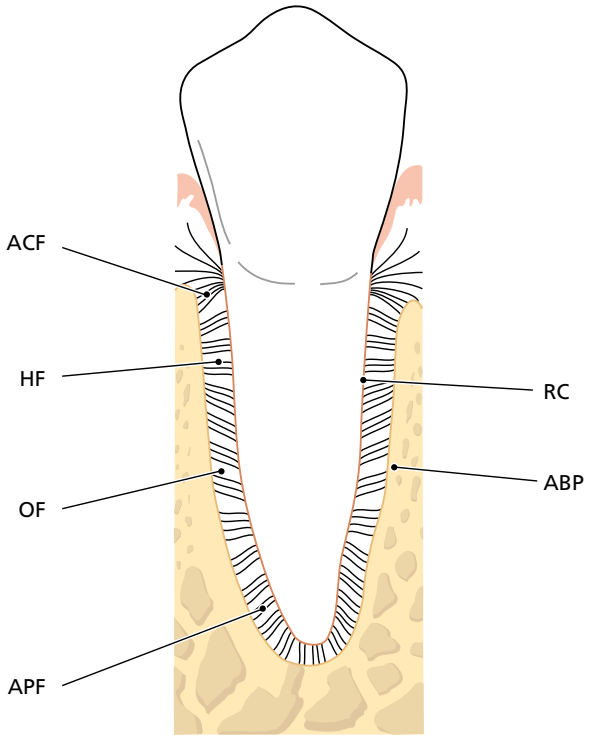

Fig. 1-59 This schematic drawing illustrates how the periodontal ligament is situated between the alveolar bone proper (ABP) and the root cementum (RC) and indicates the groups of collagen fibers that join the tooth to the surrounding bone. From coronal to apical, these groups of fibers constitute the alveolar crest fibers (ACF), the horizontal fibers (HF), the oblique fibers (OF), and the apical fibers (APF).

A histologic section shows how the principal fibers of the periodontal ligament run continuously from the root cementum to the alveolar bone proper (Fig. 1-62a). The principal fibers embedded in the cementum (*Sharpey's fibers*) have a smaller diameter, but are more numerous than those embedded in the alveolar bone proper (also called Sharpey's fibers).

Under polarized light, the Sharpey's fibers can be seen penetrating not only the cementum but also the entire width of the alveolar bone proper (Fig. 1-62b). The periodontal ligament also contains a few elastic fibers associated with the blood vessels. Oxytalan fibers (see Fig. 1-46) are also present in the periodontal ligament. They have a mainly apico-occlusal orientation and are located in the ligament closer to the root than to the alveolar bone. Very often, they insert into the cementum. Their function may be related to mechanotransduction.

The cells of the periodontal ligament are: *fibroblasts*, *osteoblasts*, *cementoblasts*, *osteoclasts*, odontoclasts,

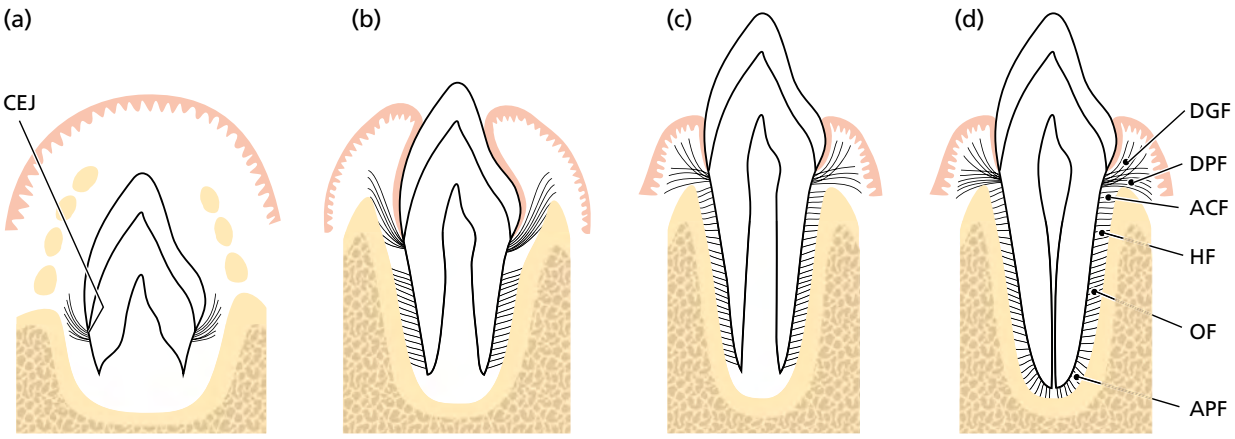

Fig. 1-60 The various stages in the organization of the periodontal ligament, while the tooth root(s) develop and the tooth erupts. (a) Tooth bud with a short root portion developed and before eruption into the oral cavity. (b) The tooth during eruption into the oral cavity. (c) The tooth has reached the occlusal plane but root formation is not complete yet. (d) The tooth in occlusion with closed root apex. The development of the collagen fibers inserting into the cementum starts in closest proximity to the cementoenamel junction (CEJ). The principal fiber bundles of the periodontal ligament develop from coronal to apical, while the root develops and the tooth erupts. First, the dentogingival fibers (DGF) and the dentoperiosteal fibers (DPF) develop, followed by the alveolar crest fibers (ACF), the horizontal fibers (HF), the oblique fibers (OF), and finally the apical fibers (APF).

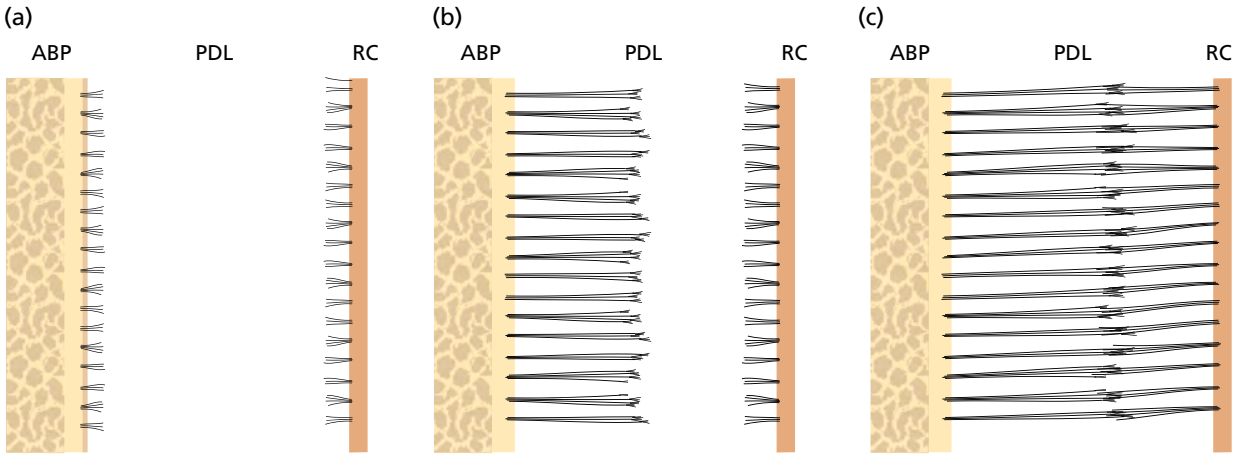

Fig. 1-61 The development of the principal periodontal ligament fibers. (a) First, short, brush-like collagenous fiber stubs embedded in the root cementum (RC) and alveolar bone proper (ABP) project into the periodontal ligament (PDL) space. (b) Later, the short fiber stubs gradually extend into the periodontal ligament space. (c) The collagen fibers originating from the root cementum and bone increase in length and thickness and fuse to form the principal periodontal ligament fibers.

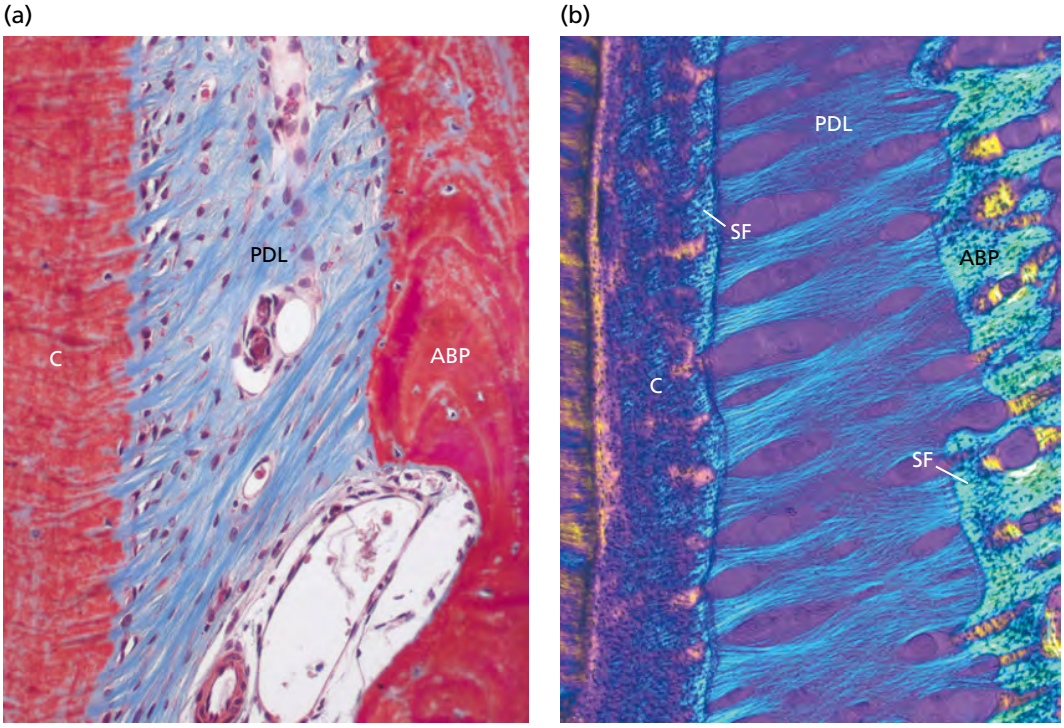

Fig. 1-62 Histologic sections viewed under transmitted (a) and polarized (b) light illustrating how the principal periodontal ligament (PDL) fibers run between the root cementum (C) and the alveolar bone proper (ABP). The collagen fibers inserting into both root cementum and bone are called Sharpey's fibers (SF).

histiocytes as well as *epithelial cells*, *nerve fibers*, *and blood vessels*. The fibroblasts are aligned along the principal fibers, while cementoblasts line the surface of the cementum and the osteoblasts line the bone surface.

Clusters of epithelial cells in the periodontal ligament, called the *epithelial cell rests of Malassez* (ERM), represent remnants of the Hertwig's epithelial root sheath (Fig. 1-63a). The epithelial cell rests are situated in the periodontal ligament at a distance of 15–75 µm from the cementum on the root surface. One large group of such epithelial cell rests is seen in a higher magnification in Fig. 1-63b.

In the transmission electron microscope, it can be seen that the epithelial cell rests are surrounded by a basement membrane and that the cell membranes of the epithelial cells exhibit the presence of desmosomes as well as hemidesmosomes (Fig. 1-64). The epithelial cells contain only a few mitochondria and have a poorly developed endoplasmic reticulum. This means that they are vital, but resting, cells with minute metabolism.

When the periodontal ligament is cut tangential to the root surface, it becomes evident that the epithelial cell rests of Malassez, which in ordinary histologic sections appear as isolated groups of epithelial

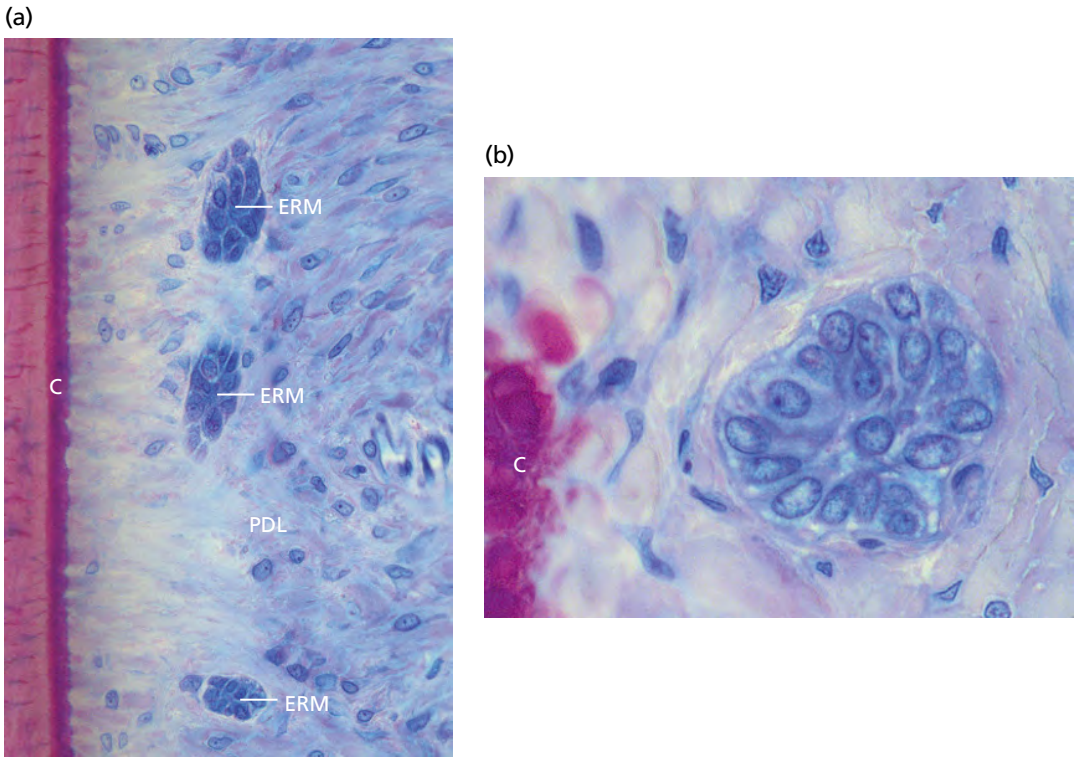

Fig. 1-63 (a) Light micrograph showing three clusters of epithelial cells, called the epithelial cell rests of Malassez (ERM), in the periodontal ligament (PDL) close to the cementum (C) surface. (b) Higher magnification of a large cluster of epithelial cell rests of Malassez near the cementum surface.

cells, in fact form a continuous network of epithelial cells surrounding the root (Fig. 1-65). Their function is unknown at present. Yet, it has been shown that the epithelial network is in contact with the junctional epithelium. Moreover, nerve endings are in contact

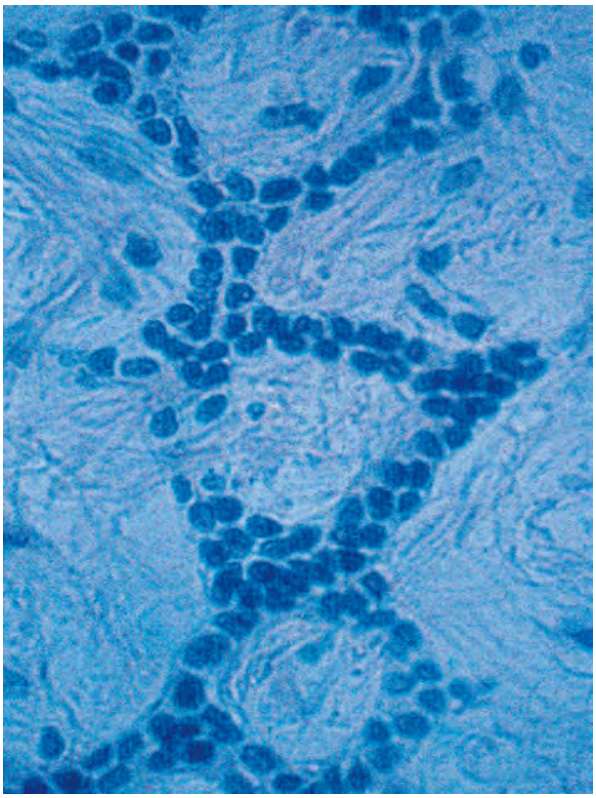

Fig. 1-65 Photomicrograph of a periodontal ligament removed from an extracted tooth and sectioned tangential to the root surface showing that the epithelial cell rests of Malassez form a continuous network of epithelial cells surrounding the root.

with both the epithelial cell rests of Malassez and the junctional epithelium.

Root cementum

The cementum is a specialized mineralized tissue covering the root surfaces and, occasionally, small portions of the crown of the teeth. It may also extend into the root canal. In humans and unlike bone, the cementum contains no blood or lymph vessels, has no innervation, does not undergo physiologic resorption or remodeling, but is characterized by continuing deposition throughout life. Like other mineralized tissues, it contains collagen fibrils embedded in an organic matrix. Its mineral content, which is mainly hydroxyapatite, is about 65% by weight, a little more than that of bone (60%). The various cementum types serve different functions. One cementum type attaches the principal periodontal ligament fibers to the root. Another cementum type contributes to the process of repair after damage to the root surface and may also serve to adjust the tooth position to new requirements.

Different forms of cementum have been described:

1. *Acellular afibrillar cementum* (AAC) is found mainly at the cervical portion of the enamel.
2. *Acellular extrinsic fiber cementum* (AEFC) is found in the coronal and middle portions of the root and contains mainly bundles of Sharpey's fibers. This type of cementum is an important part of the attachment apparatus and connects the tooth with the bundle bone (alveolar bone proper). It may be termed "attachment cementum".
3. *Cellular mixed stratified cementum* (CMSC) occurs in the apical third of the roots and in the furcations. It contains both extrinsic and intrinsic fibers as well as cementocytes. It may be termed "reactive cementum", as it reacts more readily to mechanical strain.
4. *Cellular intrinsic fiber cementum* (CIFC) is found mainly in resorption lacunae and it contains intrinsic fibers and cementocytes. It may be called "reparative cementum".

Histological examples of the tooth attachment apparatus are shown in Fig. 1-66. Viewed under polarized light (Fig. 1-66a), it can be seen that the principal collagen fibers of the periodontal ligament span between the root covered with cementum and the alveolar process covered with bundle bone. The portions of the principal fibers of the periodontal ligament that are embedded in the root cementum and in the bundle bone are called Sharpey's fibers. Oxytalan fibers are particularly found in the periodontal

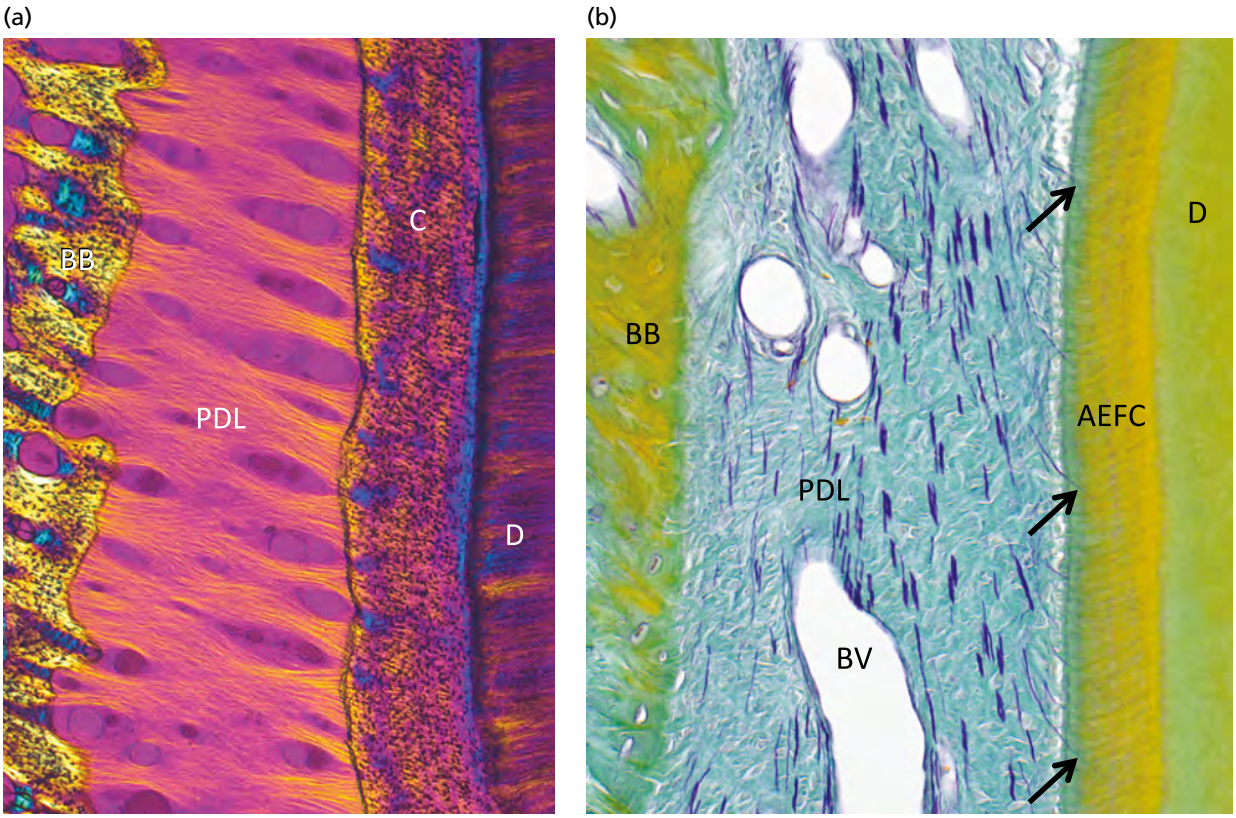

Fig. 1-66 Photomicrographs illustrating the tooth attachment apparatus. (a) Viewed under polarized light, it can be seen that the principal collagen fibers of the periodontal ligament (PDL) span between the root covered with cementum (C) and the socket wall covered with alveolar bone proper or bundle bone (BB). (b) When a paraffin section is stained with the oxone-aldehyde-fuchsin-Halmi technique, oxytalan fibers show an apicocoronal arrangement with some fibers inserting (arrows) into the acellular extrinsic fiber cementum (AEFC). Many oxytalan fibers are associated with blood vessels (BV). D, dentin.

ligament (Fig. 1-66b). They run parallel to the root with some fibers bending to cementum where they attach. Many oxytalan fibers are seen around the blood vessels in the periodontal ligament. Oxytalan fibers may have a function in mechanotransduction between the root and the periodontal ligament.

Acellular afibrillar cementum

The AAC prevails in the region of the CEJ where it covers minor areas of the cervical enamel (Fig.1-67a). It neither contains cells nor collagen fibrils. It may form isolated patches on the enamel or be contiguous with the AEFC. The AAC may form when the reduced enamel epithelium recedes or focally disintegrates so that the exposed enamel surface comes into contact with the surrounding soft connective tissue. In the transmission electron microscope, the AAC extends from the AEFC in the coronal direction (Fig. 1-67b). The layered appearance of the AAC is indicative of periods of deposition and rest. The function of the AAC is unclear.

Acellular extrinsic fiber cementum

The AEFC is formed concomitantly with the formation of the root dentin. At the beginning of root development, the Hertwig's epithelial root sheath, which lines the newly formed predentin, becomes fragmented. Cementoblasts then begin to synthesize collagen fibers that are implanted roughly at a right angle to the root surface. During the continuous formation of AEFC, portions of these short collagen fibers adjacent to the root become embedded in the mineralized cementum. Figure 1-68 shows the advancement of mineralization of the AEFC. Short collagenous fibers, resembling fringes and constituting the future Sharpey's fibers, cover the root surface and protrude from the dentin into the periodontal ligament space (Fig. 1-68a). A cementum layer is not visible yet. Later, however, a layer of mineralized cementum, into which the bases of the short collagen fibers are embedded as Sharpey's fibers, is discernible (Fig. 1-68b). When the tooth approaches the occlusal level, the short collagen fibers become elongated and eventually merge with the collagen fibers protruding from bone into the periodontal ligament (Fig. 1-68c) (see also Fig. 1-61).

These micrographs demonstrate that the Sharpey's fibers in the cementum are a direct continuation of the principal fibers in the periodontal ligament and the supra-alveolar connective tissue. The AEFC increases throughout life with a very slow growth rate of 1.5–4.0 µm/year. On mesial root surfaces, the growth is slower than on distal root surfaces, a phenomenon related to the mesial drift of the teeth.

A scanning electron micrograph of a non-decalcified fracture surface of acellular extrinsic fiber cement demonstrates how the extrinsic fibers attach to the dentin, traverse the mineralized cementum layer as Sharpey's fibers, and leave the cementum layer as the principal collagen fibers of the periodontal ligament (Fig. 1-69a). In an ultrathin tissue section, it can be seen that the Sharpey's fibers (i.e. the extrinsic collagen fibers of AEFC) pass from the dentin surface through the mineralized cementum layer and continue

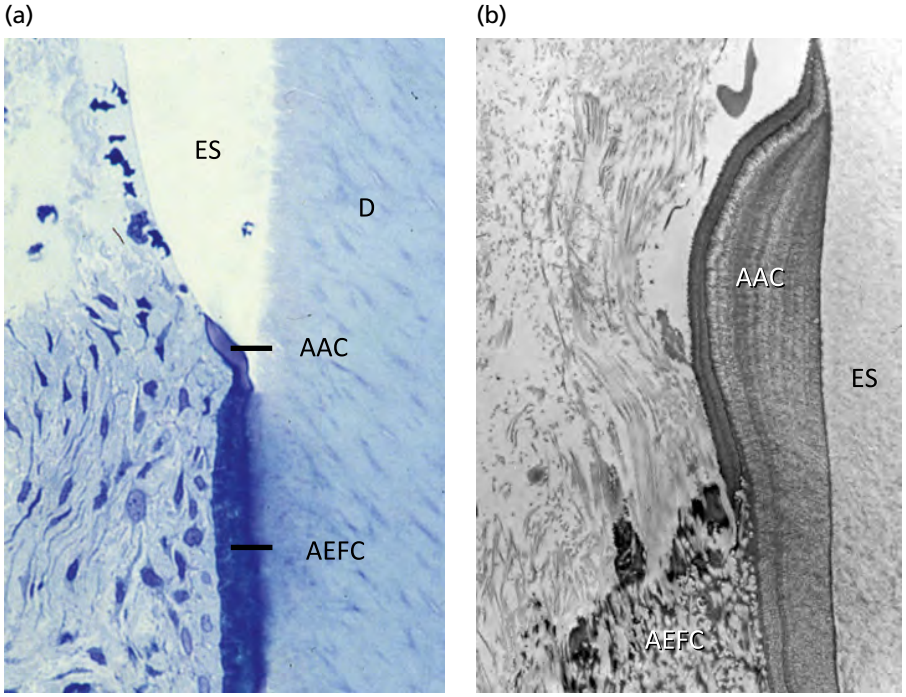

Fig. 1-67 Light (a) and transmission electron (b) micrographs illustrating the morphology of acellular afibrillar cementum (AAC), which prevails in the region of the cementoenamel junction. The moderately electron-dense material in the enamel space (ES) adjacent to the AAC represents residual enamel matrix. AEFC, acellular extrinsic fiber cementum; D, dentin.

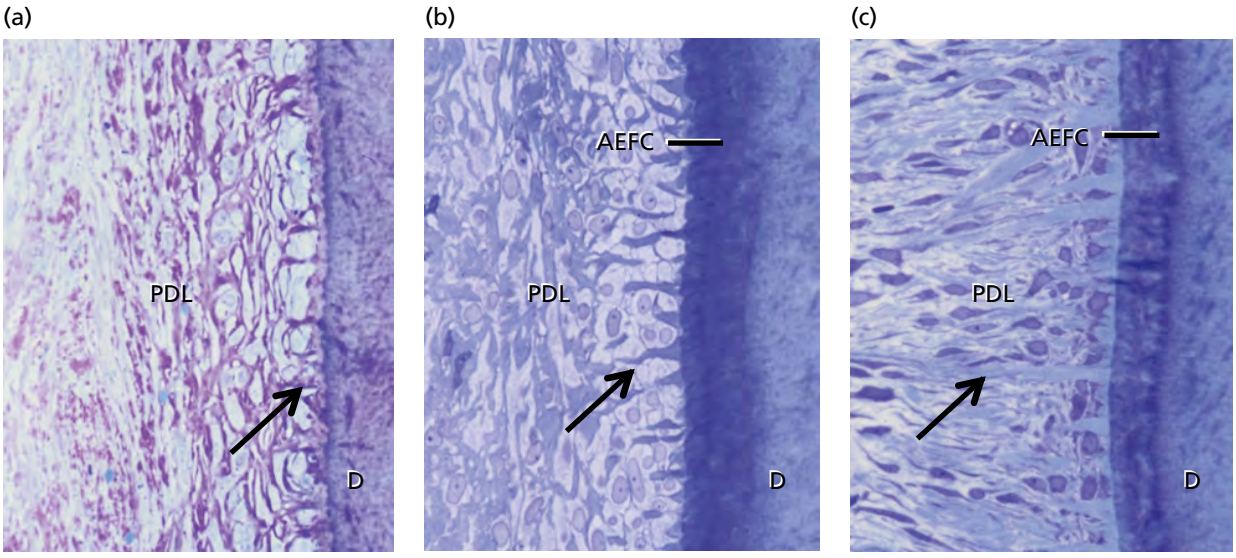

Fig. 1-68 These photomicrographs illustrate the developmental stages of the acellular extrinsic fiber cementum (AEFC). (a) Short collagenous fiber stubs (arrow), the future Sharpey's fibers, protrude from the dentin (D) surface into the periodontal ligament (PDL) before a cementum layer is discernible. (b) Later, the bases of the short collagen fibers (arrow) are embedded in the mineralized cementum. (c) Even later, most collagen fibers are now elongated (arrows) and continue into the periodontal ligament space.

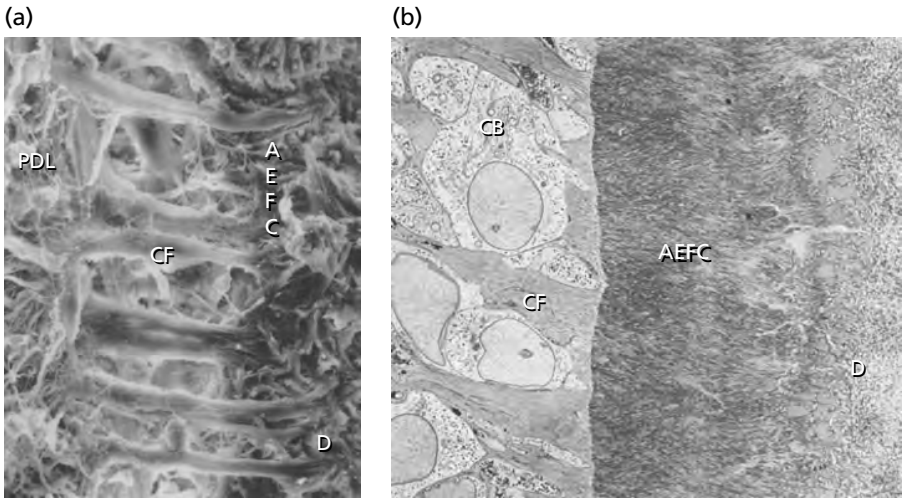

Fig. 1-69 Scanning (a) and transmission (b) electron micrographs illustrating acellular extrinsic fiber cementum (AEFC). Collagen fibers (CF), leaving the cementum layer at the mineralization front, continue into the periodontal ligament (PDL) space. Cementoblasts (CB) occupy the spaces between the protruding collagen fibers. (a) Fracture of a non-decalcified sample. (b) Ultrathin section of a decalcified sample. D, dentin.

outside the cementum as principal collagen fibers into the periodontal ligament (Fig. 1-69b). A higher magnification demonstrates how the Sharpey's fibers leave the cementum at the mineralization front and continue as principal periodontal ligament fibers (Fig. 1-70a). Cementoblasts occupy the space between the densely packed collagen fibrils. The characteristic cross-banding of the collagen fibrils is masked in the cementum because of the presence of non-collagenous proteins. Mineralization occurs by the deposition of hydroxyapatite crystals, first within the collagen fibers, later upon the fiber surface, and finally in the interfibrillar matrix. High-resolution immunolabeling of AEFC at the mineralization front shows the distribution of bone sialoprotein, a non-collagenous protein involved in the regulation of mineralization of collagen-based hard tissues (Fig. 1-70b). Gold particles label the interfibrillar matrix of the mineralized cementum, whereas the unmasked collagen fibrils that leave the cementum and extend into the periodontal ligament space are not labeled.

Cellular mixed stratified cementum

In contrast to AEFC, CIFC contains cells and intrinsic fibers. It is built up of alternating layers of AEFC and CIFC (Fig. 1-71a). While the extrinsic Sharpey's fibers traverse the cementum layer and leave it at the mineralization front, the intrinsic fibers reside completely within the cementum. The cells that are incorporated into the cementum are called *cementocytes*. The CMSC is laid down throughout the functional period of the tooth. The stratification of CMSC is usually irregular. CMSC is found at the mid-root and apical

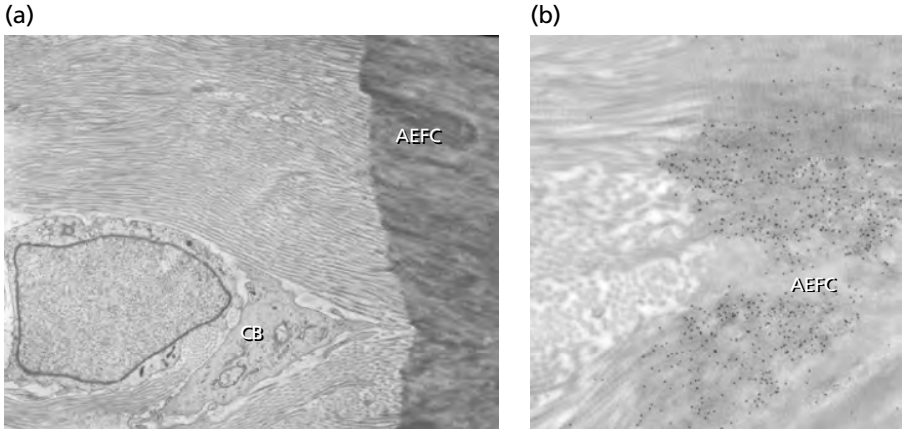

Fig. 1-70 Transmission electron micrographs of acellular extrinsic fiber cementum (AEFC) at the mineralization front. (a) The Sharpey's fibers leave the cementum at the mineralization front and continue as principal periodontal ligament fibers. Cementoblasts (CB) occupy the space between the densely packed collagen fibrils. (b) High-resolution immunohistochemistry with immunogold labeling for bone sialoprotein shows (small black dots) that this non-collagenous protein is mainly present in the interfibrillar matrix of cementum.

root surfaces and in the furcations. The cementum becomes considerably wider in the apical portion of the root than in the cervical portion. In the apical root portion, the cementum is often 150–250 µm wide or even more. The cementum often contains incremental lines, indicating alternating periods of formation and rest.

Cellular intrinsic fiber cementum

This cementum type is either part of the CMSC or is found alone at sites on the root surface undergoing repair after root resorption. Cementocytes are numerous and reside in lacunae in the mineralized matrix (Fig. 1-71b). Cementocytes communicate with each other through a network of cytoplasmic processes running through canaliculi in the cementum. Most cell processes point to the cementum surface. The cementocytes also communicate with the cementoblasts on the surface through cytoplasmic processes. The presence of cementocytes allows transportation of nutrients and waste products through the cementum and contributes to the maintenance of the vitality of this mineralized tissue.

The cementoid, the not yet mineralized cementum matrix, is lined by the cementoblast. They are large, cuboidal cells with a round, euchromatin-rich nucleus. The abundance of rough endoplasmic reticulum indicates that these cells are highly active and produce proteins that are secreted into the extracellular space. They elaborate a cementoid seam consisting of a collagenous matrix that later mineralizes.

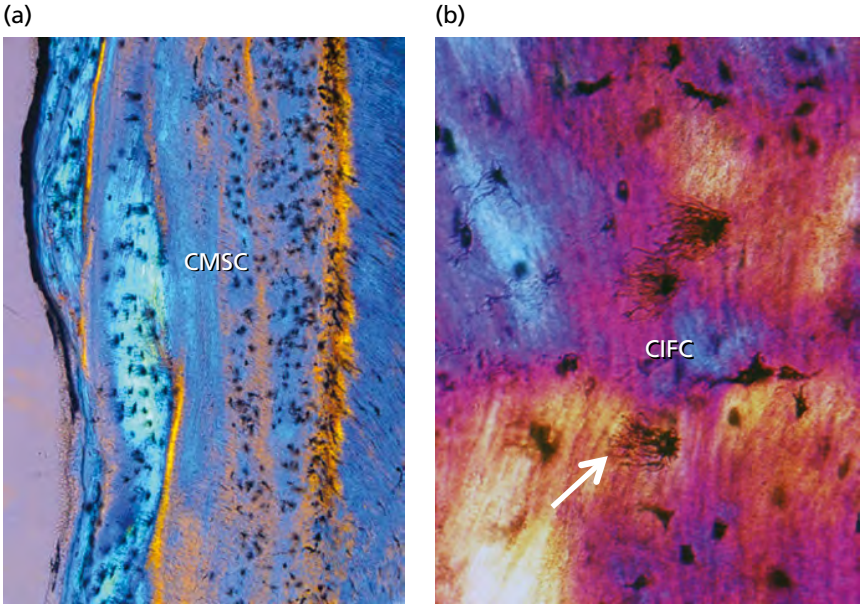

Fig. 1-71 Ground sections viewed under polarized light illustrating (a) cellular mixed stratified cementum (CMSC) and (b) cellular intrinsic fiber cementum (CIFC). The black cells are cementocytes that reside in lacunae in the CIFC. The arrow points to cytoplasmic processes.

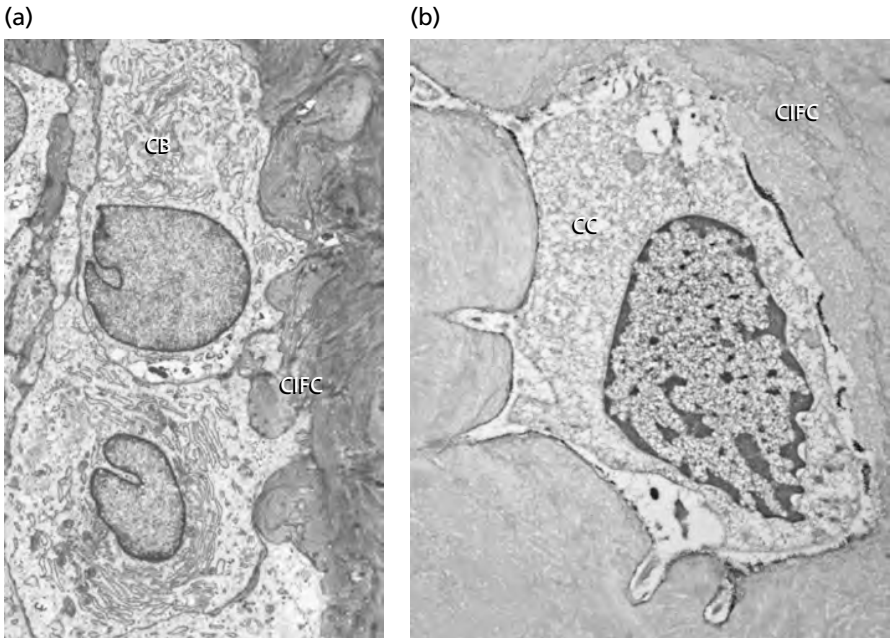

Fig. 1-72 Transmission electron micrographs illustrating (a) the surface of the cellular intrinsic fiber cementum (CIFC) covered with cementoblasts (CB) and (b) a cementocyte (CC) in its lacuna and surrounded by mineralized matrix.

Generally, the AEFC is more mineralized than CMSC and CIFC. Sometimes only the periphery of the Sharpey's fibers of the CMSC is mineralized, leaving an unmineralized core within the fiber. The cementocytes are cementoblasts that become entrapped in the cementum matrix. They are present in lacunae from which several canaliculi traverse the cementum matrix and communicate with neighboring cementocytes (Fig. 1-72b). Cementocyte lacunae in deeper portions of the cementum often appear empty, which may be attributed to the fact that the critical distance for exchange of metabolites is surpassed.

Bone of the alveolar process

Macroscopic anatomy

The alveolar process is defined as the parts of the maxilla and the mandible that form and support the sockets of the teeth. The alveolar process extends from the basal bone of the jaws and develops in conjunction with the development and eruption of the teeth (see Fig. 1-60). The alveolar process consists of bone that is formed both by cells from the dental follicle (to produce the alveolar bone proper) and cells which are independent of this follicle (to produce the alveolar bone). Together with the root cementum and the periodontal ligament, the alveolar bone proper constitutes the attachment apparatus of the teeth, the main function of which is to distribute forces generated by, for example, mastication and other tooth contacts.

In a cross-section through the alveolar process (pars alveolaris) of the maxilla at the mid-root level of the teeth, it can be seen that the bone which covers the root surfaces is considerably thicker at the palatal than at the buccal aspect of the jaw (Fig. 1-73). Anatomically, the walls of the sockets (alveolar bone proper; arrows), as well as the outer walls of the alveolar process are made up of *cortical bone*. The area enclosed by the cortical bone walls is occupied by *cancellous (spongy) bone*. Thus, the cancellous bone occupies most of the interdental septa but only a relatively small portion of the buccal and palatal bone walls. The cancellous bone contains *bone trabeculae*, the architecture and size of which are partly genetically determined and partly the result of the forces to which the teeth are exposed during function. Note how the bone on the buccal and palatal aspects of the alveolar process varies in thickness from one region to another.

In the mandible, the bone lining the wall of the sockets (alveolar bone proper) is often continuous with the compact or cortical bone at the lingual and buccal aspects of the alveolar process (Fig. 1-74). Note how the bone on the vestibular and lingual aspects of the alveolar process varies in thickness from one region to another. In the incisor and premolar regions, the bone plate at the buccal aspects of the teeth is considerably thinner than at the lingual aspect. In the molar region, the bone is thicker at the buccal aspect than at the lingual aspect.

At the buccal aspect, particularly in the front region, of the jaws, the bone coverage of the roots is occasionally very thin or entirely missing (Fig. 1-75). An area without bone coverage in the marginal portion of the root is called *dehiscence*. If some bone is present in the most coronal portion of the buccal bone but the defect is located more apically, it is denoted *fenestration*. These defects often occur where a tooth during eruption is displaced out of the arch and are more frequent over anterior than posterior teeth. The root in such defects is covered only by a soft connective tissue attachment and overlying mucosa.

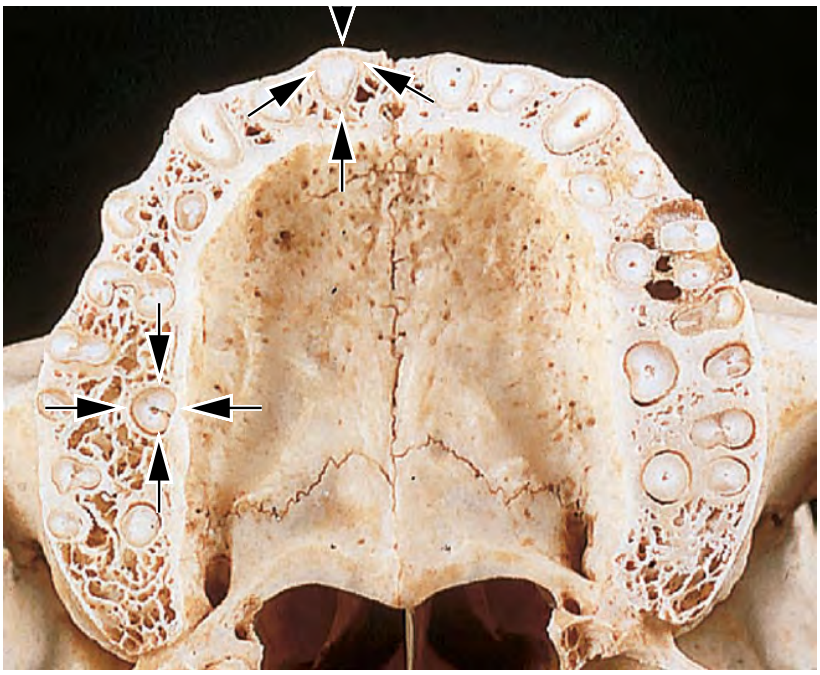

Fig. 1-73 Cross-section through the alveolar process (pars alveolaris) of the maxilla at the mid-root level of the teeth. The arrows indicate the walls of the sockets, the alveolar bone proper.

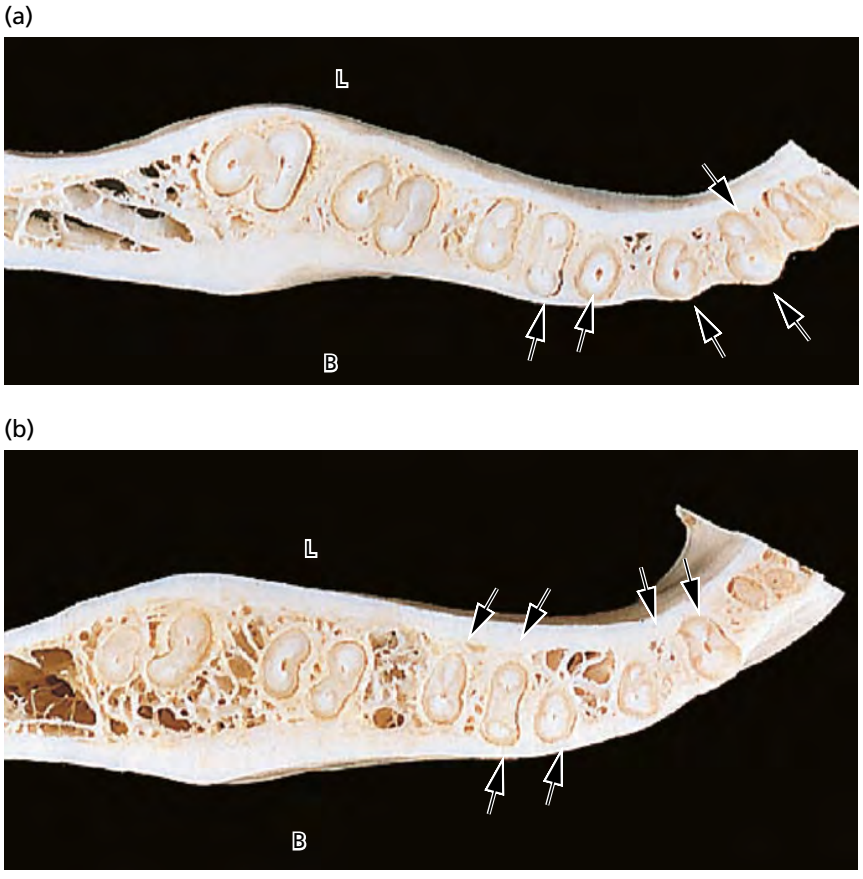

Fig. 1-74 Cross-sections through the mandibular alveolar process at levels corresponding to the coronal (a) and apical (b) thirds of the roots. Arrows indicate the bone of the alveolar process. B, buccal; L, lingual.

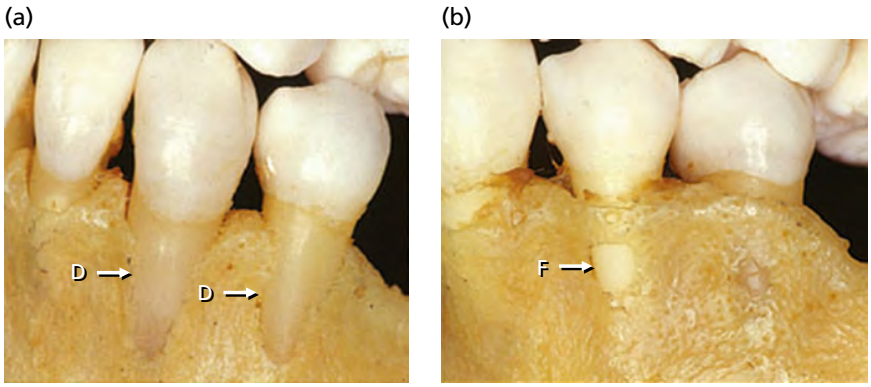

Fig. 1-75 Buccal aspect of the jaws. The bone coverage of the roots is occasionally very thin or entirely missing. (a) A dehiscence (D) is an area without bone coverage in the marginal portion of the root. (b) A fenestration (F) is a bone defect where some bone is present coronal to the defect region.

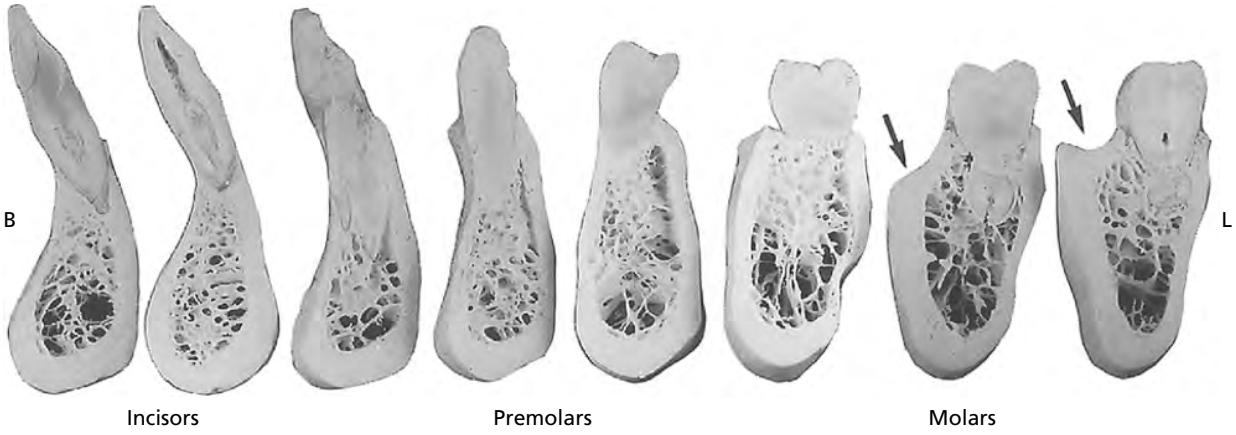

Fig. 1-76 Vertical sections through various regions of the mandibular dentition. The bone wall at the buccal (B) and lingual (L) aspects of the teeth varies considerably in thickness. The arrows indicate a shelf-like bone process at the buccal aspect of the second and third molars.

Vertical sections through various regions of the mandibular dentition show how the bone wall thickness varies considerably at the vestibular and lingual aspects of the teeth, for example from the premolar to the molar region (Fig. 1-76). Note, for instance, how the presence of the oblique line (*linea obliqua*) results in a shelf-like bone process at the buccal aspect of the second and third molars.

Microscopic anatomy

In a histologic section through the interproximal septum between two premolars, the dense alveolar bone proper is seen facing the periodontal ligament of the two teeth, while cancellous bone occupies the area between the alveolar bone proper (Fig. 1-77).

The mineralized bone in the furcation area, as well as in the interproximal septum (Fig. 1-77), is made up of lamellar bone (including circumferential lamellae, concentric lamellae osteons, and interstitial lamellae), while the bone marrow contains adipocytes and vascular structures (Fig. 1-78).

The mineralized bone facing the periodontal ligament, the alveolar bone proper or the bundle bone, is about 250–500 µm wide (Fig. 1-79). The alveolar bone proper is made up of lamellar bone including circumferential lamellae. As stated above, the alveolar bone proper, together with the periodontal ligament and the cementum, is responsible for the attachment between the tooth and the skeleton. Unlike the alveolar bone proper, the alveolar bone is a tissue of mesenchymal origin and it is not considered as part of the genuine attachment apparatus. Both alveolar bone and alveolar bone proper may, as a result of altered functional demands, undergo adaptive changes.

The composition of the hard tissue in the furcation area is illustrated in a schematic drawing in Fig. 1-80. The lamellar bone includes three brown osteons with a blood vessel in the centrally located Haversian canal. An interstitial lamella is located between the osteons and represents an old and partly remodeled osteon. The alveolar bone proper lines the lamellae and is represented by the dark lines. Sharpey's fibers insert into the alveolar bone proper.

Osteons constitute the building blocks of lamellar bone (Fig. 1-81). In the center of an osteon is the Haversian canal, which harbors a blood vessel. The space between the osteons is filled with so-called interstitial lamellae, remnants of older osteons. The osteons are not only structural, but also metabolic units. Thus, the nutrition of the bone cells (osteoblasts, osteocytes, osteoclasts) is secured by the blood

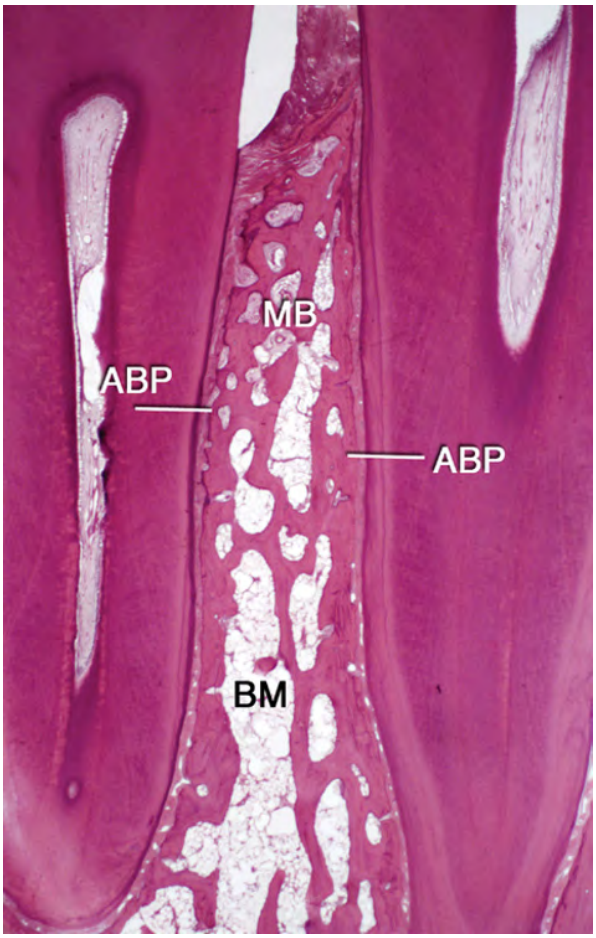

Fig. 1-77 Histologic section illustrating the bone of the interproximal septum between two premolars. The alveolar bone proper (ABP) is facing the periodontal ligament of the two teeth. BM, bone marrow; MB, mineralized matrix of cancellous bone.

vessels in the Haversian canals and the vessels in the so-called Volkmann canals.

The borderline region between the alveolar bone proper, the bundle bone, and the alveolar bone, highlights the characteristic features of the two types

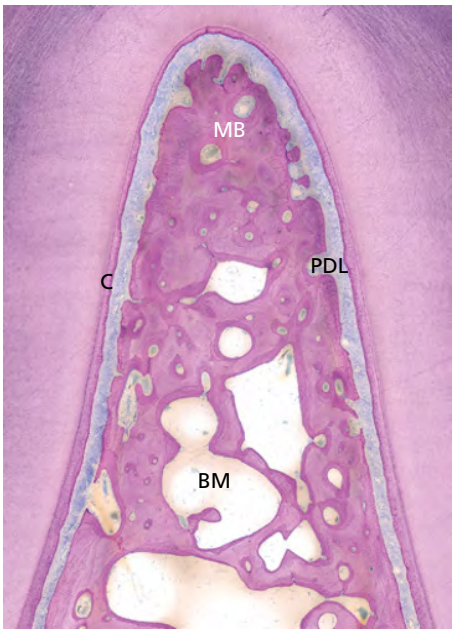

Fig. 1-78 Histologic section showing the bone tissue within the furcation area of a mandibular molar. BM, bone marrow; C, root cementum; MB, mineralized bone; PDL, periodontal ligament.

of bone (Fig. 1-82). The alveolar bone is lamellar in nature and thus composed of osteons, which include a Haversian canal with blood vessels in the center of each osteon. In contrast, the alveolar bone proper is not made up of osteons. It contains Sharpey's fibers, resting lines, and many osteocytes but no blood vessels. Also, the osteon contains a large number of osteocytes. They reside in lacunae within the lamellar bone and connect to each other via canaliculi that contain cytoplasmic protrusions of the osteocytes (Fig. 1-83). Canaliculi also connect the peripheral osteocytes with the osteoblasts on the bone surface (Fig. 1-84).

Osteocytes possess many cytoplasmic processes that radiate in different directions (Fig. 1-85) and

communicate with each other (Fig. 1-86) and with osteoblasts or bone lining cells on the bone surface (Fig. 1-84) via long and delicate cytoplasmic processes situated within the canaliculi. The resulting canalicular–lacunar system is essential for cell metabolism by allowing diffusion of nutrients and waste products. The surface between the osteocytes, with their cytoplasmic processes on one side and the mineralized matrix on the other, is very large. It has been calculated that the interface between cells and matrix in a cube of bone, $10 \times 10 \times 10$ cm, amounts to approximately

Fig. 1-87 Histologic section illustrating bone. Osteoblasts (arrows) are sandwiched between the bone matrix and the periosteum (P). The inner surface of bone, facing bone marrow, is covered with the endosteum (E).

250 m^2. This enormous surface of exchange serves as a regulator for, for example, serum calcium and serum phosphate levels via hormonal control mechanisms.

All active bone-forming sites harbor osteoblasts, which are sandwiched between the bone matrix and the periosteum (Fig. 1-87). On the "inner surface" of the bone, that is in the bone marrow space, there is an endosteum, which has features similar to those of the periosteum.

The alveolar bone is constantly renewed in response to functional demands. The teeth erupt and migrate in a mesial direction throughout life to compensate for attrition. Such movement of the teeth implies remodeling of the alveolar bone. During the process of remodeling, the bone trabeculae are continuously resorbed and reformed, and the cortical bone mass is removed and replaced by new bone. The resting line in the mineralized bone matrix documents phases of bone formation and rest (Fig. 1-88). During breakdown of the cortical bone, resorption canals are formed by osteoclasts. Such canals, which contain a blood vessel in the center, are subsequently refilled with new bone by the formation of lamellae arranged in concentric layers around the blood vessel (Fig. 1-88).

The resorption of bone is always associated with *osteoclasts* (Fig. 1-89). These cells are large, multinucleated cells specialized in the breakdown of matrix and minerals. The osteoclasts are hematopoetic cells (derived from monocytes in the bone marrow). Hard tissue resorption occurs by the release of acid products (lactic acid, etc.), which form an acidic environment in which the mineral salts become dissolved. Remaining organic substances are eliminated by

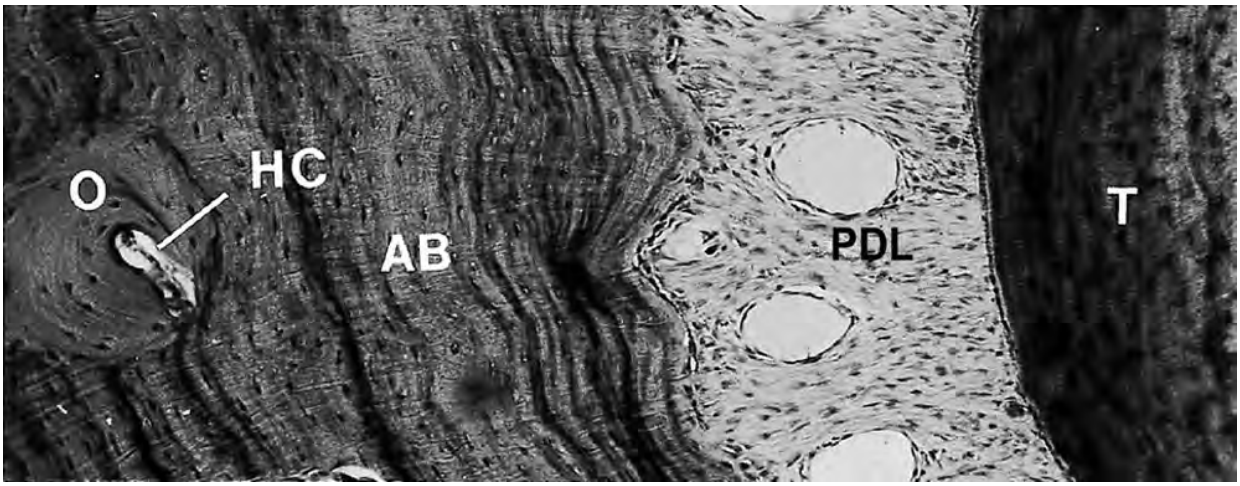

Fig. 1-88 Micrograph of a horizontal section illustrating the tooth attachment apparatus consisting of the tooth (T), the periodontal ligament (PDL), and alveolar bone proper (AB). Numerous resting lines in the alveolar bone proper (AB) document phases of active bone formation and rest. A new osteon (O) with a central Haversian canal (HC) demarcates the border to the lamellar alveolar bone.

proteolytic enzymes and osteoclastic phagocytosis. Actively resorbing osteoclasts adhere to the bone surface through receptors and produce lacunar pits called *Howship's lacunae*. The osteoclasts are mobile and capable of migrating over the bone surface.

Bone multicellular units are always present in bone tissue undergoing active remodeling (Fig. 1-90). The bone multicellular unit has one resorption front characterized by the presence of osteoclasts and one formation front characterized by the presence of osteoblasts.

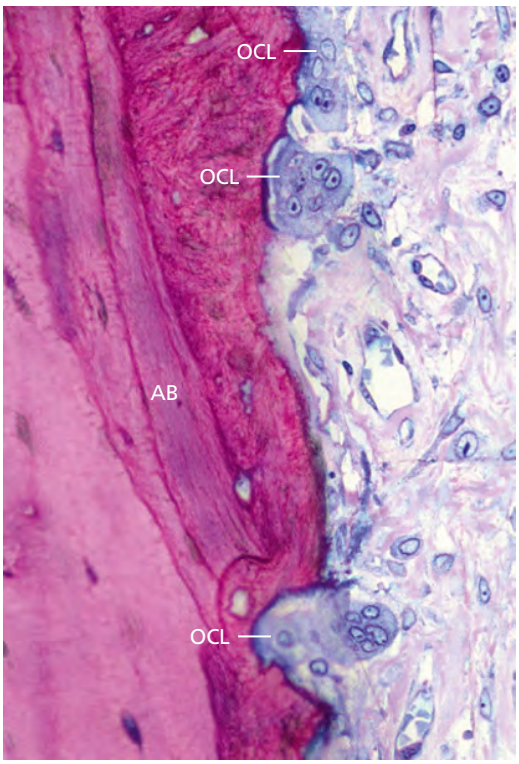

Fig. 1-89 Micrograph illustrating three resorption sites lined with osteoclasts (OCL) on the surface of the alveolar bone (AB).

Both the cortical and cancellous alveolar bone are constantly undergoing remodeling (i.e. resorption followed by formation) in response to tooth drifting and changes in functional forces acting on the teeth. Figure 1-91 illustrates the remodeling sequence. Remodeling of the trabecular bone starts with resorption of the bone surface by osteoclasts (Fig. 1-91a). After a short period, osteoblasts start depositing new bone (Fig. 1-91b) and finally a new bone multicellular unit is formed, clearly delineated by a reversal line (Fig. 1-91c).

Collagen fibers of the periodontal ligament insert in the mineralized bone which lines the wall of the tooth socket (Fig. 1-92). This bone, called alveolar bone proper or bundle bone, has a high turnover rate. The portions of the collagen fibers which are inserted inside the bundle bone are called Sharpey's fibers. These fibers are mineralized at their periphery, but often have a non-mineralized central core. The collagen fiber bundles inserting in the bundle bone generally have a larger diameter and are less numerous than the corresponding fiber bundles in the cementum on the opposite side of the periodontal ligament. Individual bundles of fibers can be followed all the way from the alveolar bone to the cementum. However, despite being in the same bundle of fibers, the collagen adjacent to the bone is always less mature than that adjacent to the cementum. The collagen on the tooth side has a low turnover rate. Thus, while the collagen adjacent to the bone is renewed relatively rapidly, the collagen adjacent to the root surface is renewed slowly or not at all.

Blood supply of the periodontium

The blood supply of the teeth and the periodontal tissues is illustrated in Fig. 1-93. The *dental artery* (arteria dentalis), which is a branch of the *superior* or *inferior* alveolar artery (arteria alveolaris inferior), dismisses

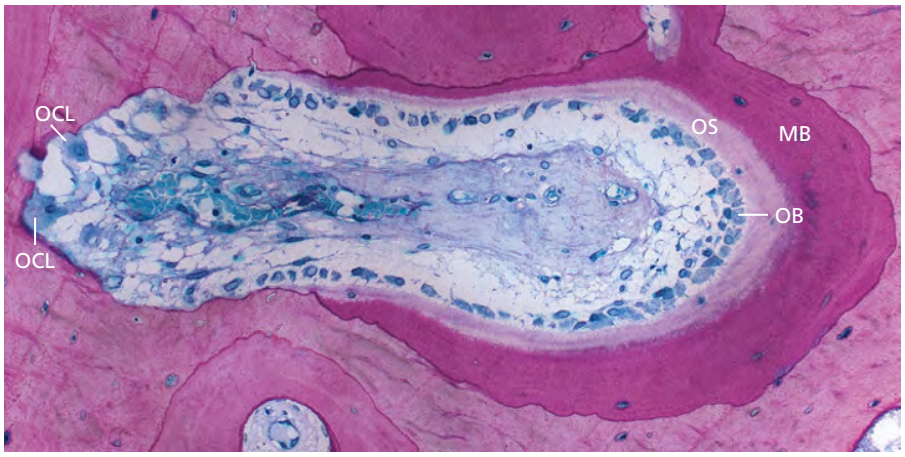

Fig. 1-90 Histologic section of compact bone illustrating a bone multicellular unit characterized by the presence of osteoclasts (OCL) at the resorption front and osteoblasts (OB) at the formation front. MB, mineralized bone matrix; OS, osteoid.

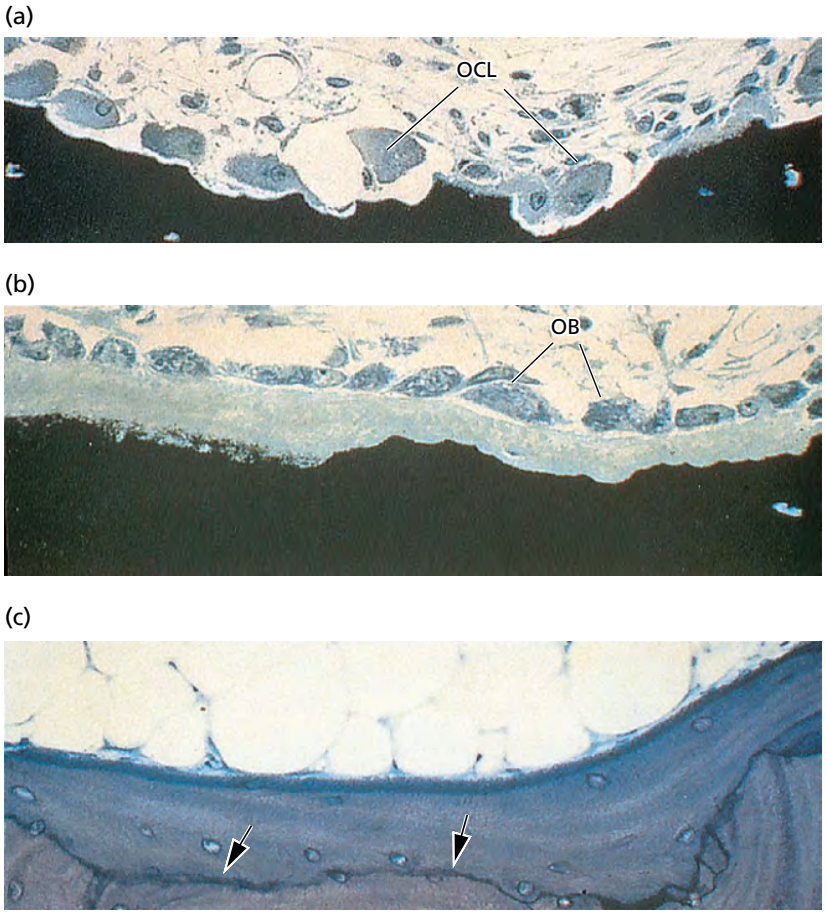

Fig. 1-91 Histologic sections illustrating the sequence of bone remodeling with (a) bone resorption by osteoclasts (OCL), (b) bone matrix deposition and mineralization by osteoblasts (OB), and (c) rest. A reversal line (cement line) (arrows) demarcates the new from the old bone.

the *intraseptal artery* (arteria interseptalis) before it enters the tooth socket. The terminal branches of the *intraseptal artery* (*rami perforantes*) penetrate the alveolar bone proper in canals at all levels of the socket (see Fig. 1-77). They anastomose in the periodontal ligament space, together with blood vessels originating from the apical portion of the periodontal ligament and with other terminal branches from the intraseptal artery. Before the dental artery enters the root canal it puts out branches which supply the apical portion of the periodontal ligament.

The blood supply of the teeth and the periodontal tissues is illustrated in Fig. 1-94. The gingiva receives its blood supply mainly through *supraperiosteal* blood vessels which are terminal branches of the *sublingual artery* (arteria sublingualis), the *mental artery* (arteria mentalis), the *buccal artery* (arteria buccalis), the *facial artery* (arteria facialis), the *greater palatine artery*

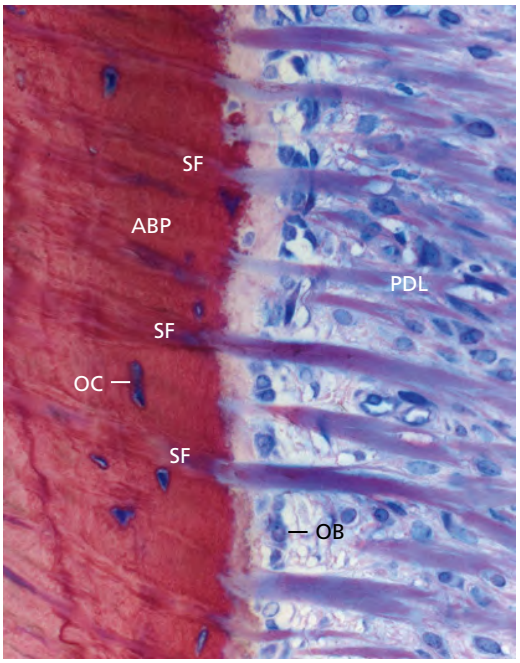

Fig. 1-92 Micrograph illustrating the insertion of periodontal ligament (PDL) fibers in the alveolar bone proper (ABP) or bundle bone that lines the wall of the tooth socket. Sharpey's fibers (SF) traverse the bundle bone, osteoblasts (OB) line the bone surface, and osteocytes (OC) are present in their lacunae surrounded by the mineralized bone matrix.

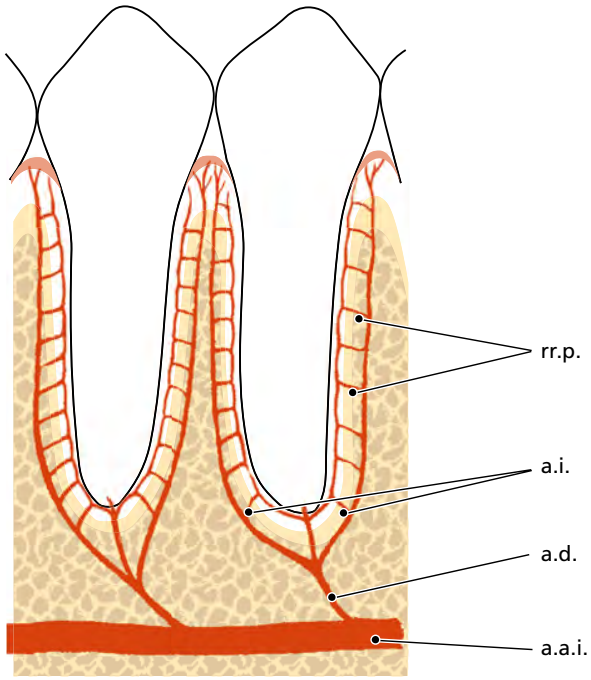

Fig. 1-93 The blood supply to the teeth and the periodontal tissues. a.a.i., superior or inferior alveolar artery; a.d., dental artery; a.i., intraseptal artery; rr.p., terminal branches of the intraseptal artery.

(arteria palatina major), the *infraorbital artery* (arteria infraorbitalis), and the *posterior superior dental artery* (arteria dentalis superior posterioris). The greater palatine artery, which is a terminal branch of the *ascending palatine artery* (from the *maxillary*, "internal maxillary", artery), runs through the *greater palatine canal* to the palate (Fig. 1-95). As this artery runs in a frontal direction, it puts out branches which supply the gingiva and the masticatory mucosa of the palate.

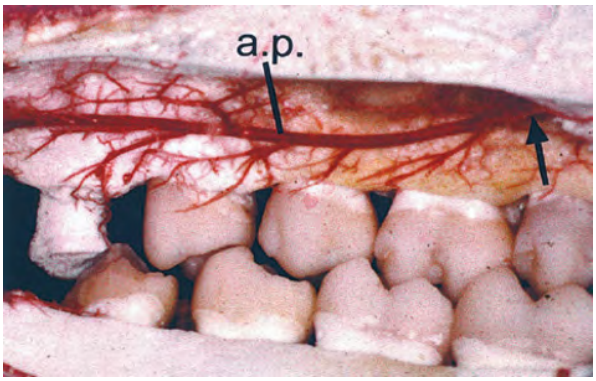

Fig. 1-95 The course of the greater palatine artery (a.p.) in a monkey specimen that was perfused with plastic at sacrifice. Subsequently, the soft tissue was dissolved. The arrow indicates the greater palatine canal.

The various arteries are often considered to supply certain well-defined regions of the dentition. In reality, however, there are numerous anastomoses present between the different arteries (Fig. 1-96). Thus, the *entire system of blood vessels*, rather than individual groups of vessels, should be regarded as the unit supplying the soft and hard tissues of the maxilla and the mandible.

The blood supply of the vestibular gingiva is mainly through *supraperiosteal* blood vessels (Fig. 1-97). Another sample preparation demonstrates that blood vessels originating from vessels in the periodontal ligament pass the alveolar bone crest and contribute to the blood supply of the free gingiva (Fig. 1-98).

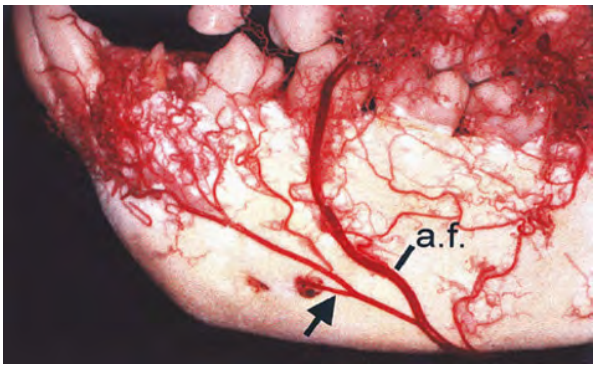

Fig. 1-96 An anastomosis (arrow) between the facial artery (a.f.) and the blood vessels of the mandible.

Fig. 1-97 Illustration of a vestibular segment of the maxilla and mandible from a monkey that was perfused with plastic at sacrifice. Note that the blood supply of the vestibular gingiva is mainly through supraperiosteal blood vessels (arrows).

In a cleared specimen (Fig. 1-99), the blood vessel distribution is clearly visible. During their course towards the free gingiva, the supraperiosteal blood vessels put forth numerous branches to the *subepithelial plexus*, located immediately beneath the oral gingival epithelium of the free and attached gingiva. This subepithelial plexus in turn yields thin *capillary loops* to each of the connective tissue papillae projecting into the oral gingival epithelium (seen at higher magnification in Fig. 1-100). The number of such capillary loops is constant over a very long time and is not altered by application of epinephrine or histamine to the gingival margin. This implies that the blood vessels of the lateral portions of the gingiva, even under normal circumstances, are fully utilized and that the blood flow to the free gingiva is regulated entirely by velocity alterations. In the free gingiva, the supraperiosteal blood vessels anastomose with blood vessels from the periodontal ligament and the bone. Beneath the junctional epithelium is a plexus of blood vessels termed the *dentogingival plexus*. The blood vessels in this plexus have a thickness of approximately 40 µm, which means that they are mainly venules. In healthy gingiva, no capillary loops occur in the dentogingival plexus. When cut parallel to the subsurface of the

Fig. 1-98 Blood vessels (arrows) originating from vessels in the periodontal ligament pass the alveolar bone crest and contribute to the blood supply of the free gingiva.

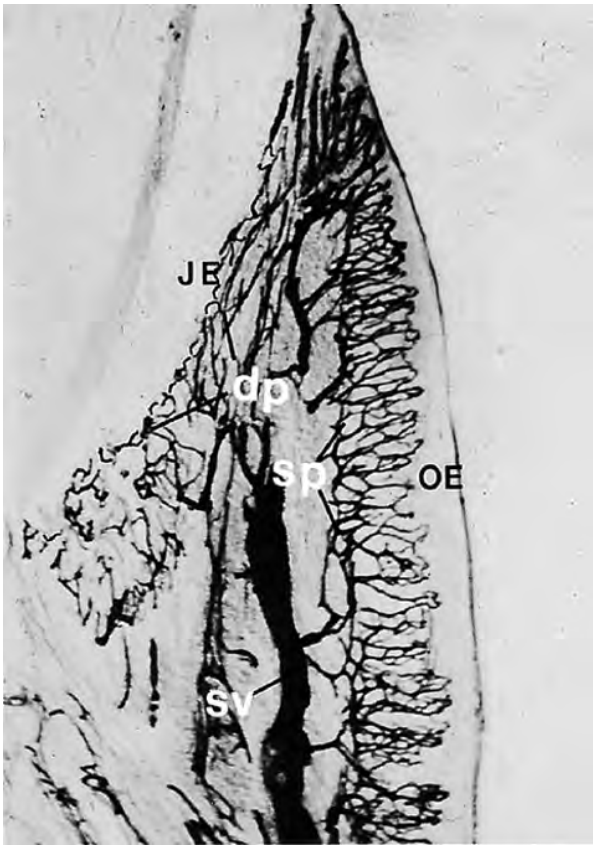

Fig. 1-99 Blood vessels in the gingiva in a specimen from a monkey perfused with ink at the time of sacrifice. Subsequently, the specimen was treated to make the tissue transparent (cleared specimen). The tooth is to the left. dp, dentogingival plexus; JE, junctional epithelium; OE, oral gingival epithelium; sp, subepithelial plexus; sv, supraperiosteal blood vessels.

junctional epithelium, it can be seen that the dentogingival plexus consists of a fine-meshed network of blood vessels (Fig. 1-101).

A summary of the blood vessels in the free gingiva is shown in a three-dimensional schematic drawing

Fig. 1-100 Higher magnification of a cleared specimen illustrating how the subepithelial plexus (s.p.), beneath the oral gingival epithelium of the free and attached gingiva, yields thin capillary loops to each connective tissue papilla. These capillary loops have a diameter of approximately 7 µm, which means they are the size of true capillaries.

Fig. 1-101 Higher magnification of a cleared specimen illustrating the dentogingival plexus in a section parallel to the subsurface of the junctional epithelium. The dentogingival plexus consists of a fine-meshed network of blood vessels. In the upper portion of the image, capillary loops belonging to the subepithelial plexus can be seen beneath the oral sulcular epithelium.

(Fig. 1-102). As stated earlier, the main blood supply of the free gingiva derives from the *supraperiosteal* blood vessels which, in the gingiva, anastomose with blood vessels from the *alveolar bone* and *periodontal ligament*. The subepithelial plexus of vessels adjacent to the oral gingival epithelium can be clearly seen. Likewise, the dentogingival plexus can be seen beneath the junctional epithelium. Under normal conditions, the dentogingival plexus comprises a fine-meshed network without capillary loops.

The blood vessels of the periodontal ligament derive from (1) branches of the dental artery, (2) branches of the interalveolar and interradicular arteries, and (3) the supraperiosteal arteries. Figure 1-103 illustrates how the vessels arising from the intraseptal artery in the alveolar bone run through the Volkmann's canals into the periodontal ligament, where they anastomose. In a section cut parallel to the root surface (Fig. 1-104), it can be seen that, after entering the periodontal ligament, the blood vessels anastomose and form a polyhedral network which surrounds the root like a stocking. The majority of the blood vessels in the periodontal ligament are found close to the alveolar bone. In the coronal portion of the periodontal ligament, blood vessels run in a coronal direction, passing the alveolar bone crest, into the free gingiva (see also Fig. 1-98).

The blood supply of the periodontium is summarized in a schematic drawing (Fig. 1-105). The blood

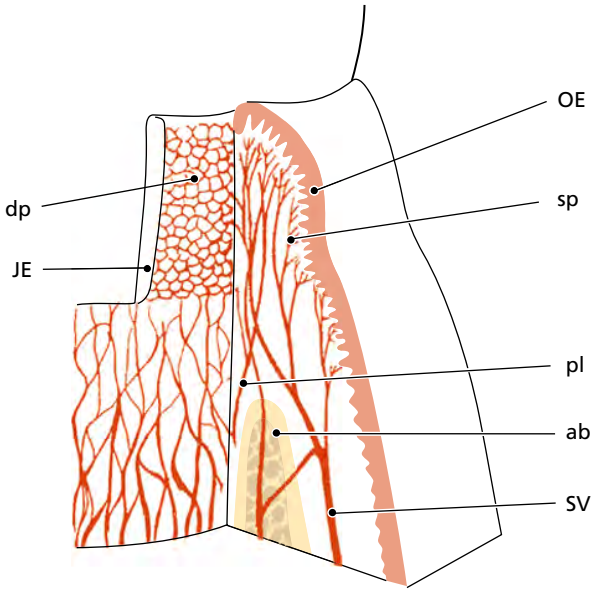

Fig. 1-102 The blood supply to the free gingiva. The main blood supply to the free gingiva derives from the supraperiosteal blood vessels (SV). To the right, the oral gingival epithelium (OE) is depicted with its underlying subepithelial plexus of vessels (sp). To the left, beneath the junctional epithelium (JE), the dentogingival plexus (dp) can be seen, which, under normal conditions, comprises a fine-meshed network without capillary loops. ab, alveolar bone; pdl, periodontal ligament.

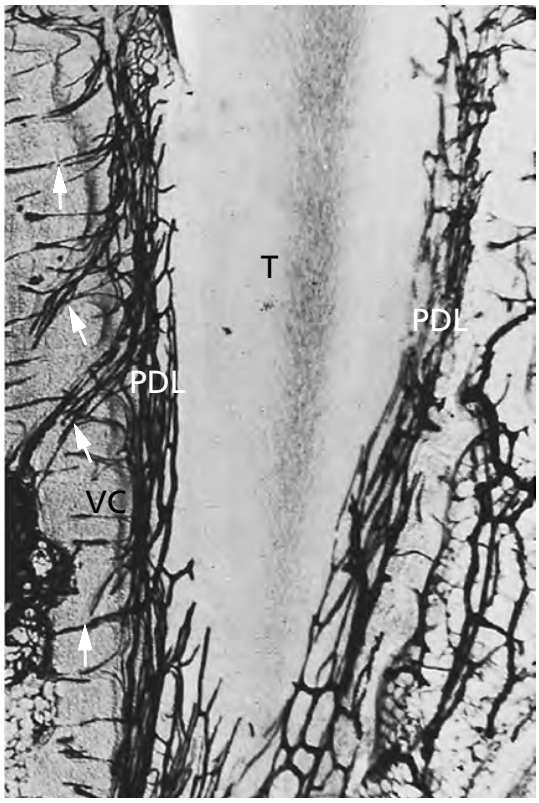

Fig. 1-103 Cleared specimen through a tooth (T) with its periodontium. Blood vessels (perforating rami; arrows) arising from the intraseptal artery in the alveolar bone run through canals in the socket wall, called Volkmann's canals (VC), into the periodontal ligament (PDL), where they anastomose.

Fig. 1-104 Cleared specimen illustrating the blood vessels in the periodontal ligament in a tissue section cut parallel to the root surface. After entering the periodontal ligament, the blood vessels (perforating rami; arrows) anastomose and form a polyhedral network which surrounds the root like a stocking.

vessels in the periodontal ligament form a polyhedral network surrounding the root. The free gingiva receives its blood supply from supraperiosteal blood vessels, the blood vessels of the periodontal ligament, and the blood vessels of the alveolar bone.

The circulatory system (blood vessels and lymphatic vessels) is key to the transport of cells and vital biomolecules and nutrients throughout the body. Beside transport inside vessels, there is the so-called *extravascular* circulation through which nutrients and other substances are carried to the individual cells and metabolic waste products are removed from the tissue (Fig. 1-106). In the arterial end of the capillary a hydraulic pressure of approximately 35 mmHg is maintained as a result of the pumping function of the heart. Since the hydraulic pressure is higher than the osmotic pressure in the tissue (approximately 30 mmHg), transportation of substances will occur from the blood vessels to the extravascular space. In the venous end of the capillary system, the hydraulic pressure has decreased to approximately 25 mmHg (i.e. 5 mmHg lower than the osmotic pressure in the tissue). This allows transportation of substances from the extravascular space to the blood vessels. Thus, the difference between the hydraulic pressure and the osmotic pressure results in transportation of substances from the blood vessels to the extravascular space in the arterial part of the capillary, while in the venous part, transportation of substances occurs from the extravascular space to the blood vessels. An extravascular circulation is hereby established.

Lymphatic system of the periodontium

The smallest lymph vessels, the *lymph capillaries*, form an extensive network in the connective tissue. The wall of the lymph capillary consists of a single layer of endothelial cells. For this reason, such capillaries are difficult to identify in an ordinary histologic section. The lymph is absorbed from the tissue fluid through the thin walls into the lymph capillaries. From the capillaries, the lymph passes into larger lymph vessels which are often in the vicinity of corresponding blood vessels. Before the lymph enters the blood stream, it passes through one or more *lymph nodes* in which the lymph is filtered and supplied with lymphocytes. The lymph vessels are like veins in that they have valves. The lymphatic system of the periodontium is illustrated in Fig. 1-107. The lymph from the periodontal tissues drains to the lymph nodes of the head and neck. The labial and lingual gingiva of the mandibular incisor region is drained to the *submental lymph nodes*. The palatal gingiva of the maxilla is drained to the *deep cervical lymph nodes*. The buccal

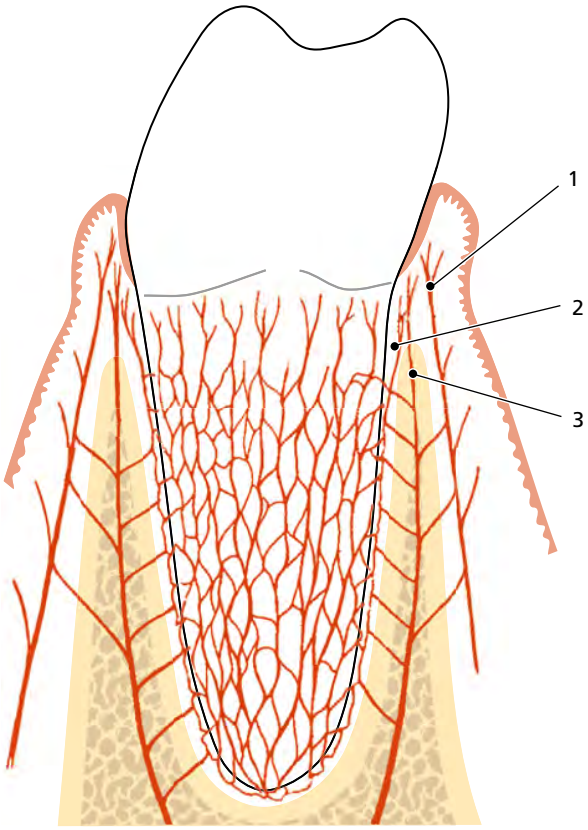

Fig. 1-105 The blood supply of the periodontium. The blood vessels in the periodontal ligament form a polyhedral network surrounding the root. Note that the free gingiva receives its blood supply from (1) supraperiosteal blood vessels, (2) the blood vessels of the periodontal ligament, and (3) the blood vessels of the alveolar bone.

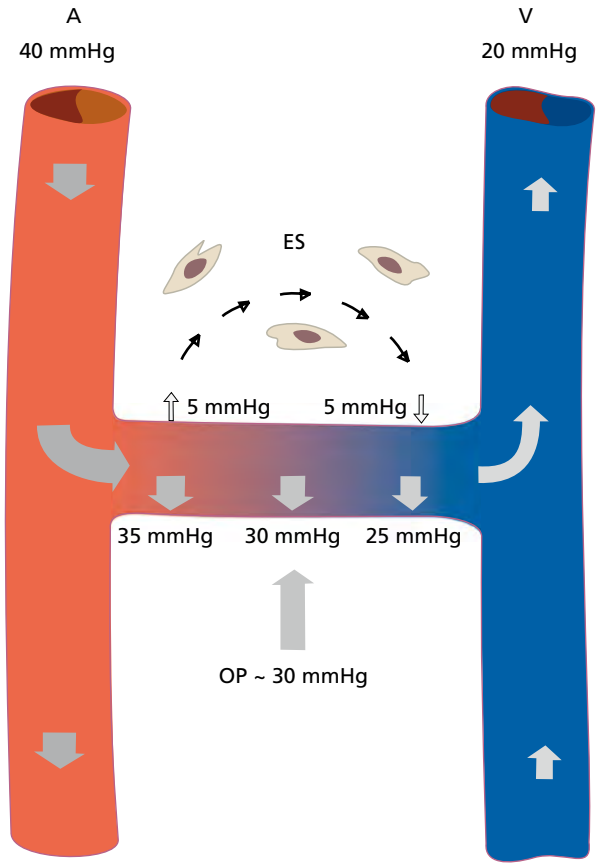

Fig. 1-106 The so-called extravascular circulation (small arrows) through which nutrients and other substances are carried to the individual cells and metabolic waste products are removed from the tissue. gingiva of the maxilla and the buccal and lingual gingiva in the mandibular premolar–molar region are drained to *submandibular lymph nodes*. Except for the third molars and mandibular incisors, all teeth with their adjacent periodontal tissues are drained to the submandibular lymph nodes. The third molars are drained to the *jugulodigastric lymph node* and the mandibular incisors to the *submental lymph nodes*.

Nerves of the periodontium

Like other tissues in the body, the periodontium contains receptors which record pain, touch, and pressure (*nociceptors* and *mechanoreceptors*). In addition to the different types of sensory receptors, nerve components are found innervating the blood vessels of the periodontium. Nerves recording pain, touch, and pressure have their trophic center in the *semilunar ganglion* and are brought to the periodontium via the *trigeminal nerve* and its end branches. Owing to the presence of receptors in the periodontal ligament, small forces applied on the teeth may be identified. For example, the presence of a very thin (10–30 µm) metal foil strip placed between the teeth during occlusion can readily be identified. It is also well known that a movement which brings the teeth of the mandible in contact with the occlusal surfaces of the maxillary teeth is arrested reflexively and altered into

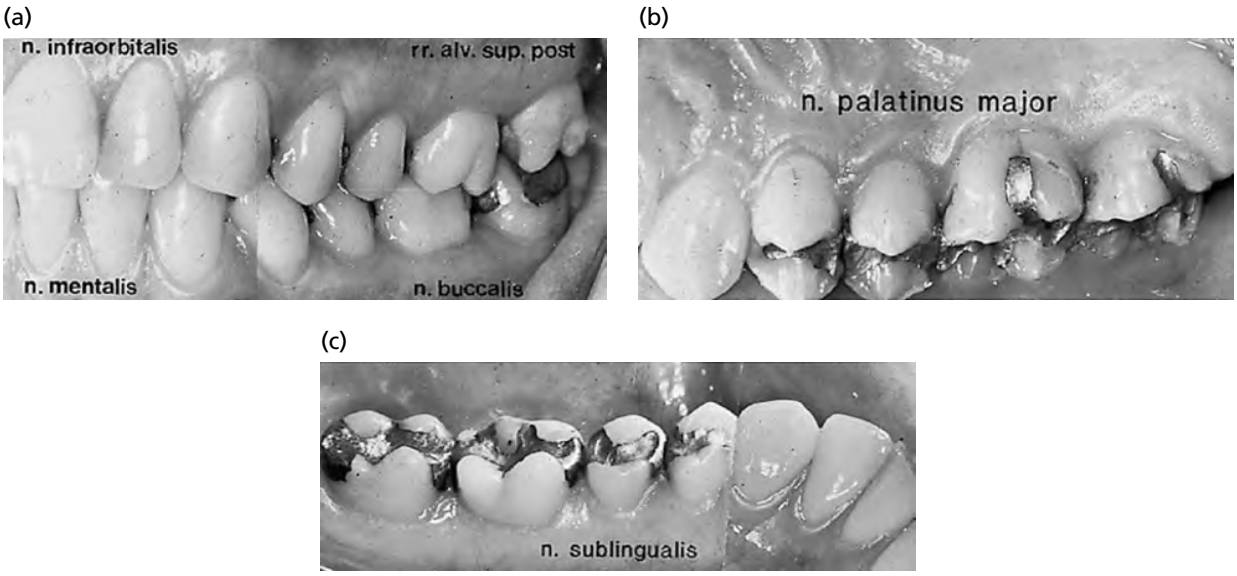

Fig. 1-108 The various regions of the gingiva that are innervated by end branches of the trigeminal nerve. (a) Innervation of the gingiva on the labial aspect of maxillary incisors, canines, and premolars by superior labial branches from the infraorbital nerve (n. infraorbitalis), innervation of the buccal gingiva in the maxillary molar region by branches from the posterior superior dental nerve (rr. alv. sup. post), innervation of the gingiva at the labial aspect of mandibular incisors and canines by the mental nerve (n. mentalis), and innervation of the gingiva at the buccal aspect of the molars by the buccal nerve (n. buccalis). (b) Innervation of the palatal gingiva by the greater palatal nerve (n. palatinus major), except for the area of the incisors, which is innervated by the long sphenopalatine nerve (n. pterygopalatini). (c) Innervation of the lingual gingiva in the mandible by the sublingual nerve (n. sublingualis), which is an end branch of the lingual nerve.

an opening movement if a hard object is detected in the chew. Thus, the receptors in the periodontal ligament, together with the proprioceptors in muscles and tendons, play an essential role in the regulation of chewing movements and chewing forces.

The various regions of the gingiva that are innervated by end branches of the trigeminal nerve are illustrated in Fig. 1-108. The gingiva on the labial aspect of maxillary incisors, canines, and premolars is innervated by *superior labial branches* from the *infraorbital nerve* (Fig. 1-108a). The buccal gingiva in the maxillary molar region is innervated by branches from the *posterior superior dental nerve* (Fig. 1-108a). The palatal gingiva is innervated by the *greater palatal nerve* (Fig. 1-108b), except for the area of the incisors, which is innervated by the *long sphenopalatine nerve*. The lingual gingiva in the mandible is innervated by the *sublingual nerve* (Fig. 1-108c), which is an end branch of the *lingual nerve*. The gingiva at the labial aspect of mandibular incisors and canines is innervated by the *mental nerve*, and the gingiva at the buccal aspect of the molars by the *buccal nerve* (Fig. 1-108a). The innervation areas of these two nerves frequently overlap in the premolar region. The teeth in the mandible, including their periodontal ligaments, are innervated by the *inferior alveolar nerve*, while the teeth in the maxilla are innervated by the *superior alveolar plexus*.

The small nerves of the periodontium follow almost the same course as the blood vessels. The nerves to the gingiva run in the tissue superficial to the periosteum and put out several branches to the oral gingival epithelium on their way towards the free gingiva. The nerves enter the periodontal ligament apically through branches of the dental nerve and laterally through the perforations in the socket wall (Volkmann's canals) (see Fig. 1-103). In the periodontal ligament, the nerves join larger bundles that take a course parallel to the long axis of the tooth. Figure 1-109 shows small nerves

Fig. 1-109 Photomicrograph showing small nerves (arrows) that have emerged from larger bundles of ascending nerves in order to supply certain parts of the periodontal ligament tissue.

that have emerged from larger bundles of ascending nerves in order to supply certain parts of the periodontal ligament tissue. Various types of neural terminations, such as free nerve endings and Ruffini's corpuscles, have been identified in the periodontal ligament.

Chapter 2

Bone as a Living Organ

Darnell Kaigler[1] and William V. Giannobile[2]

[1] Department of Periodontics and Oral Medicine, University of Michigan School of Dentistry and Department of Biomedical Engineering, College of Engineering, Ann Arbor, MI, USA
[2] Harvard School of Dental Medicine, Boston, MA, USA

Introduction

Bone is a complex organ composed of multiple specialized tissues (osseous, periosteum/endosteum, and bone marrow) that act synergistically and serve multiple functions (Fig. 2-1). Its composition allows the bone tissue to: (1) provide structural and mechanical stability, (2) protect highly sensitive organs from external forces, and (3) participate as a reservoir of cells and minerals that contribute to systemic homeostasis of the body. Therefore, the concept of "bone as a living organ", integrates the structurally dynamic nature of bone with its capacity to orchestrate multiple mechanical and metabolic functions; these characteristics have important local and systemic implications (McCauley & Somerman 2012). The structural and functional properties of bone are modulated by many factors (e.g. biochemical, hormonal, cellular, biomechanical) and ultimately, it is these influences that determine bone quality in a given context (Ammann & Rizzoli 2003; Marotti & Palumbo 2007; Bonewald & Johnson 2008; Ma *et al*. 2008). The purpose of this chapter is to provide foundational knowledge of bone development, structure, function, and homeostasis.

Development

During embryogenesis, the skeleton forms by either a direct or indirect ossification process. In direct ossification, termed *intramembranous osteogenesis*, mesenchymal progenitor cells condensate and undergo direct differentiation into osteoblasts (Nanci & Moffat 2012). This process occurs to form the mandible, maxilla, flat bones of the skull, and clavicles.

In contrast, in indirect ossification, termed *endochondral osteogenesis*, bone formation is initiated through a cartilage template, which serves as an anlage that is gradually replaced by bone. The mandibular condyle, long bones of the skeleton, and vertebrae form through this cartilage-dependent growth process (Ranly 2000) (Fig. 2-2).

Intramembranous bone formation

During intramembranous osteogenesis, an ossification center develops through mesenchymal condensation. As the collagen-rich extracellular matrix (ECM) develops and matures, osteoprogenitor cells undergo further osteoblastic differentiation. On the outer surfaces of the ossification center, a fibrous

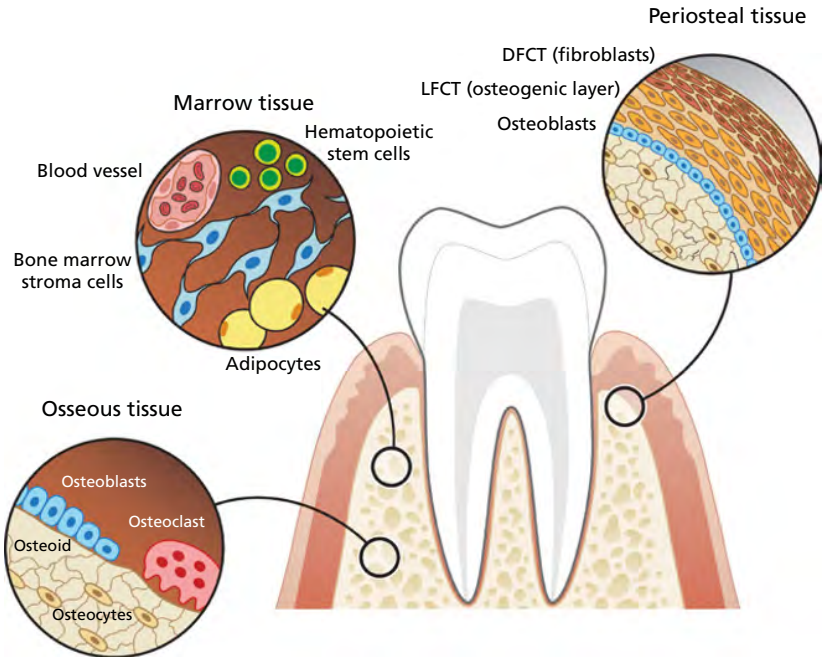

Fig. 2-1 Bone as an organ. The bone organ encompasses a number of complex tissues that synergize during health to execute a number of functions. It serves as a source of stem cells and a reservoir of minerals and other nutrients; it protects a number delicate organs; and it acts as a mechanosensoring unit that adapts to the environment and individual demands. This figure highlights three main tissues and their respective cells that are involved in these roles and the maintenance of the structure and function of bone as an organ. DFCT, dense fibrous connective tissue; LFCT, loose fibrous connective tissue.

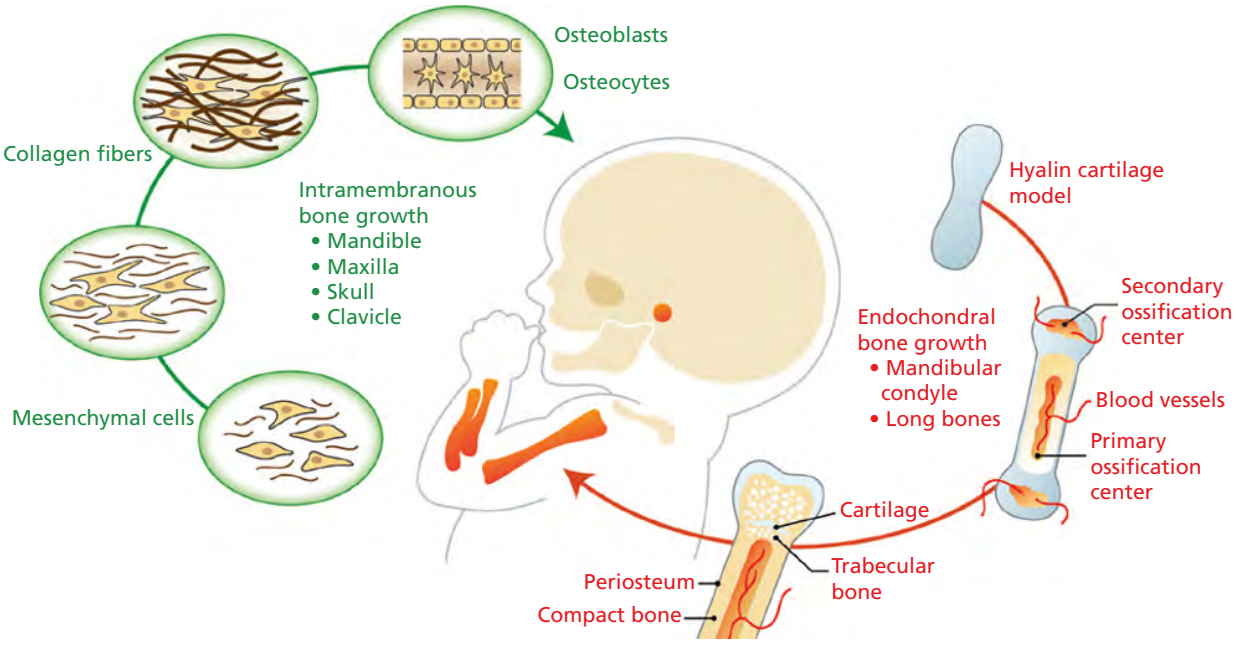

Fig. 2-2 Bone development. There are two types of process involved in bone development: intramembranous ossification (green arrow) and endochondral ossification (orange arrow). They primarily differ in the presence of a cartilaginous template during endochondral bone growth. During intramembranous osteogenesis, an ossification center develops through mesenchymal condensation. As the collagen-rich extracellular matrix develops and matures, osteoprogenitor cells undergo further osteoblastic differentiation. A subpopulation of osteoblasts become embedded in the mineralizing matrix and gives rise to the osteocyte lacuno-canalicular network. Within the craniofacial complex, most bones develop and grow through this mechanism. On the other hand, long bones within the skeleton and the mandibular condyle initially develop through the formation of a cartilaginous template that mineralizes and is later resorbed by osteoclasts and replaced by bone. The endochondral bone growth process leads to the formation of primary and secondary ossification centers that are separated by a cartilaginous structure known as the growth plate. As bone develops and matures through these two processes, structurally distinct areas of compact bone and trabecular bone are formed and maintained through similar bone remodeling mechanisms.

periosteum forms over a layer of osteoblasts. As new osteoblasts form from the underside of the periosteum, appositional growth occurs. A subpopulation of osteoblasts becomes embedded in the mineralizing matrix and gives rise to the osteocyte lacunocanalicular network. Within the craniofacial complex, most bones develop and grow through this mechanism.

Endochondral bone formation

During endochondral osteogenesis, bones develop through the formation of a cartilaginous template (hyaline cartilage model) that mineralizes and is later resorbed by osteoclasts and replaced by bone that is laid down afterwards. This process begins during the third month of gestation. The endochondral bone growth process leads to the formation of primary and secondary ossification centers that are separated by a cartilaginous structure known as the growth plate. Following the formation of the primary ossification center, bone formation extends towards both ends of the bone from the center of the shaft. The cartilage cells on the leading edges of ossification die. Osteoblasts cover the cartilagenous trabeculae with woven, spongy bone. Behind the advancing front of ossification, osteoclasts absorb the spongy bone and enlarge the primary marrow cavity. The periosteal collar thickens and extends toward the epiphyses to compensate for the continued hollowing of the primary cavity.

The processes of osteogenesis and resorption occur in all directions. The spaces between the trabeculae become filled with marrow tissue. As the new bone matrix remodels, osteoclasts assist in the formation of primary medullary cavities which rapidly fill with bone marrow hematopoietic tissue. The fibrous, non-mineralized lining of the medullary cavity is the endosteum. Osteoblasts form in the endosteum and begin the formation of endosteal bone. The appositional growth of endosteal bone is closely regulated to prevent closure of the primary marrow cavities and destruction of bone marrow.

Structure

Osseous tissue

Osseous tissue is a specialized connective tissue composed of organic and inorganic elements that mineralizes and is populated by highly specialized cells that regulate its stability (Fig. 2-3a).

Matrix

The organic matrix of bone makes up approximately 30–35% of the total bone weight and is formed of 90% collagen type I and 10% non-collagenous proteins, proteoglycans, glycoproteins, carbohydrates, and lipids. The organic matrix is synthesized by osteoblasts, and while it is still unmineralized, is known as osteoid. Within the collagen fibers, mineral nucleation occurs as calcium and phosphate ions are laid down and ultimately form hydroxyapatite crystals. Non-collagenous proteins along the surface of the collagen fibers assist in the propagation of the mineral and the complete mineralization of the matrix.

Inorganic components

Hydrated calcium and phosphate in the form of hydroxyapatite crystals [$3Ca_3(PO_4)_2(OH)_2$] are the principal inorganic constituent of the osseous matrix. Mineralization is clearly depicted in backscatter scanning electron microscopy images (Fig. 2-3b). Different degrees of mineralization are noticeable within the mature bone. Specific elements within the mineral can be further identified by energy-dispersive X-ray spectroscopy (EDS). In Fig. 2-3b, characteristic peaks of calcium and phosphorus are significantly pronounced in bone due to their high content within the hydroxyapatite crystals.

Organic components

Bone is initially laid down as a purely organic matrix rich in collagen as well as in other non-collagenous molecules (Fig. 2-3c). Chemical analysis of bone by Raman spectroscopy clearly highlights this organic counterpart in the matrix. The transition from a purely organic matrix to a mineralized matrix is clearly depicted in the transmission electron micrograph in Fig. 2-3a as an osteocyte becomes embedded within the mineralized mature matrix. As the matrix matures, mineral nucleation and propagation is mediated by the organic components in the ECM. Figure 2-3a shows the aggregation of mineral crystals, forming circular structures. As the mineral propagates along the collagen fibrils, a clear mineralization front forms and clearly demarcates the transition between the osteoid area and the mature bone.

Mineralization

The initiation of the mineralization process within the osteoid matrix typically occurs within a few days of secretion. However, maturation of the mineralized matrix through the propagation of the hydroxyapatite crystals occurs over the course of several months (Fig. 2-3a). In addition to providing the bone with its strength and rigidity to resist load and protect highly sensitive organs, the mineralization of the osteoid allows the storage of minerals that contribute to systemic homeostasis.

Cells

Within the bone tissue, different and distinct cellular components can be identified. These specific cell populations include osteogenic precursor cells, osteoblasts, osteoclasts, osteocytes, mesenchymal stem cells, and hematopoietic elements of bone marrow. This chapter will focus on the three main functional

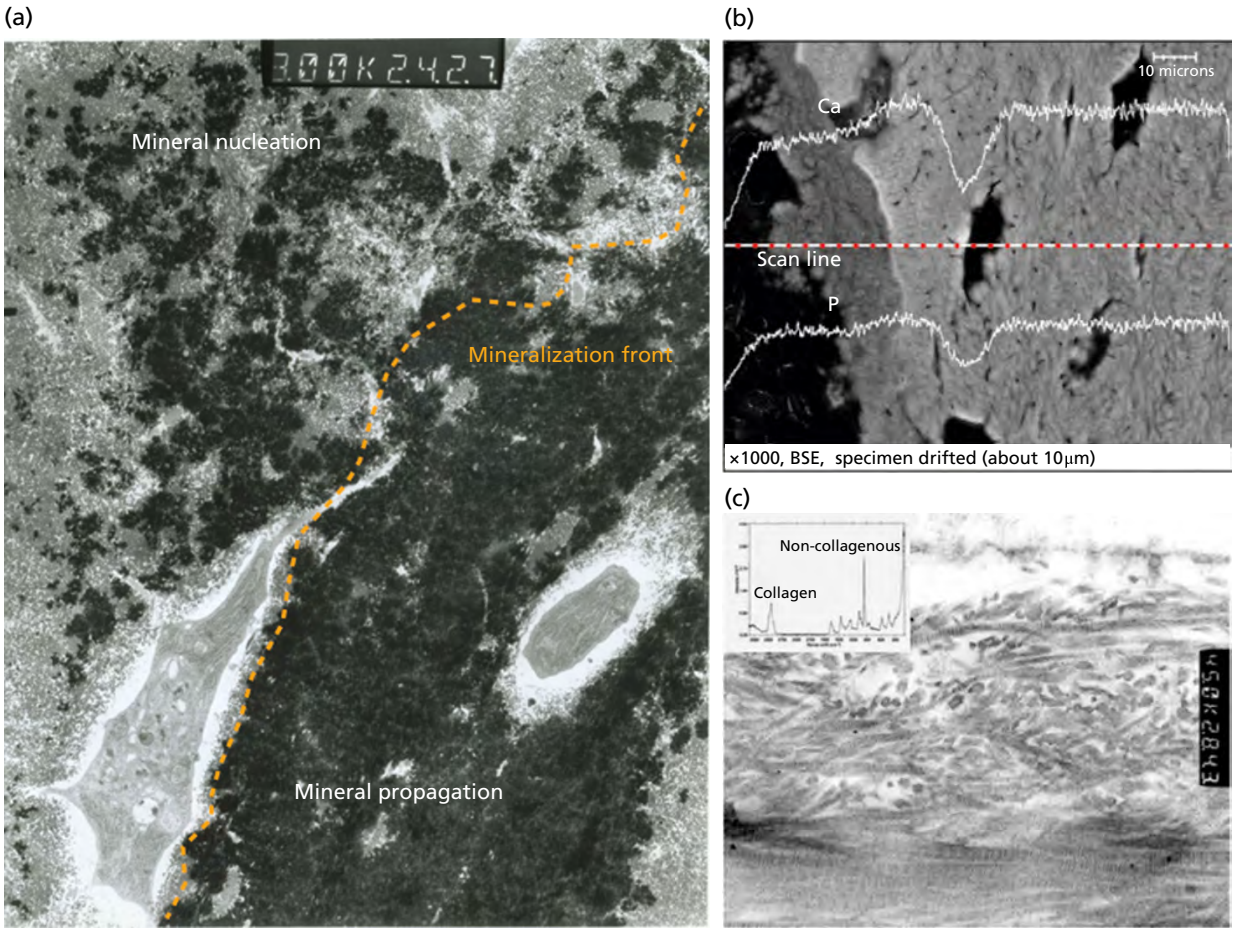

Fig. 2-3 Osseous matrix. The extracellular matrix in bone is particularly abundant compared with its cellular counterpart. (a) The osseous matrix has the unique ability to mineralize: a process that requires the support of organic components and the assistance of highly specialized cells. (b) Calcium and phosphorus are present in the form of hydroxyapatite crystals. These crystals tend to follow the organic scaffold in the bone matrix. The orange dashed line represents a linear scan that emphasizes the high content of calcium and phosphorus in the mature bone, as shown by the energy dispersive X-ray spectroscopy analysis. (c) Collagen fibers as well as non-collagenous proteins are abundant in the matrix and are often found to be arranged in a preferential direction, as shown by the Raman spectroscopy.

cells ultimately responsible for establishing and sustaining skeletal homeostasis.

Osteoblasts (Fig. 2-4)

Osteoblasts are the primary cells responsible for the formation of bone; they synthesize the organic ECM components and control the mineralization of the matrix (Fig. 2-4a, b). Osteoblasts are located on bone surfaces exhibiting active matrix deposition and may eventually differentiate into two different types of cells: bone lining cells and osteocytes. Bone lining cells are elongated cells that cover a surface of bone tissue and exhibit no synthetic activity. The osteoblasts are fully differentiated cells and lack the capacity for migration and proliferation. Thus, for bone formation at a given site, undifferentiated mesenchymal progenitor cells driven by the expression of a gene known as Indian hedgehog (*Ihh*) and later by *RUNX2* (*osteoprogenitor cells*), migrate to the site and proliferate to become osteoblasts (Fig. 2-4c). The determined osteoprogenitor cells are present in the bone marrow, in the endosteum, and in the periosteum that covers the bone surface. Such cells possess an intrinsic capacity to proliferate and differentiate into osteoblasts. The differentiation and development of osteoblasts from osteoprogenitor cells are dependent on the release of osteoinductive or osteopromotive growth factors, such as bone morphogenetic proteins (BMP), and other growth factors, such as insulin-like growth factor (IGF), platelet-derived growth factor (PDGF), and fibroblast growth factor-2 (FGF-2).

Osteocytes (Fig. 2-5)

Osteocytes are stellate-shaped cells and are embedded within the mineralized bone matrix in compartments known as lacunae (Fig. 2-5a, b) with many similarities to cementocytes (also see Chapter 1; Zhao *et al.* 2016). These cells maintain a network of cytoplasmic processes known as dendrites (Fig. 2-5c). These osteocyte cytoplasmic projections extend through cylindrical encased compartments commonly referred to as canaliculi (Robling & Bonewald 2020). They extend to different areas and contact blood vessels and other osteocytes (Fig. 2-5d, e). The osteocyte network is therefore an extracellular and intracellular

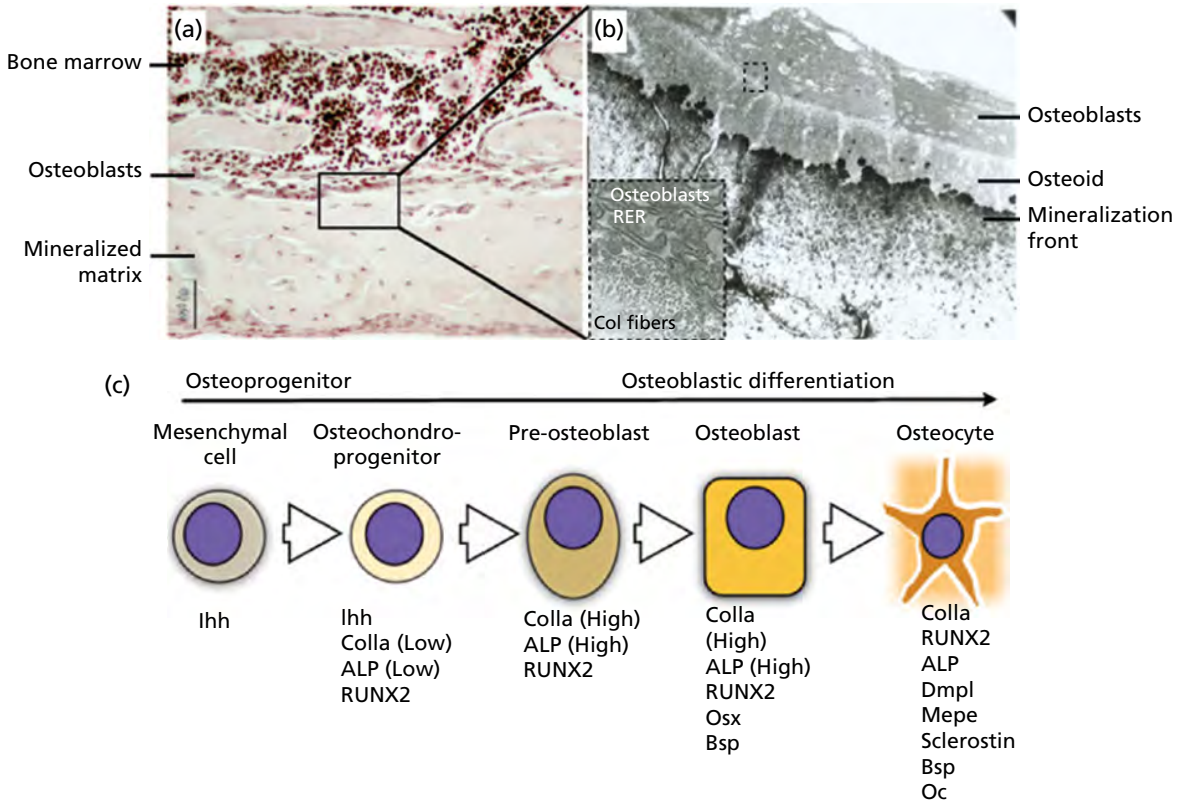

Fig. 2-4 Osteoblast. Osteoblasts are derived from bone marrow osteoprogenitor cells and are responsible for the synthesis of the immature bone matrix known as osteoid. (a) The arrow depicts a group of osteoblasts that line the mature bone that contains cells embedded within the mineralized matrix. (b) Further detail of the osteoblasts lining the mature bone is clearly visualized with transmission electron microscopy (TEM). The abundant rough endoplasmic reticulum (RER) and Golgi apparatus within these cells reflects their high metabolic activity. (c) The key molecules involved in the differentiation of an osteoprogenitor cell through to a mature terminally differentiated osteocyte.

communication channel that is sensitive at the membrane level to shear stress caused by the flow of fluid within the canaliculi space as the result of mechanical stimuli and bone deformation. Osteocytes convert mechanical signals into biochemical mediators that ultimately assist in modulating anabolic and catabolic events within bone. Their organization within the matrix enables them to (1) participate in the regulation of blood calcium homeostasis and (2) sense mechanical loading and transmit this information to other cells within the bone to further orchestrate osteoblast and osteoclast function (Burger *et al*. 1995; Marotti 2000). Different bone diseases and disorders affect the arrangement of the osteocyte lacuno-canalicular system, causing significant disruption of this important cellular organizational network (Fig. 2-6).

Osteoclasts (Fig. 2-7)

Bone formation is closely coupled to bone resorption which is initiated and maintained by osteoclasts (Biosse-Duplan *et al*. 2012). Osteoclasts have the capacity to develop and adhere to bone matrix where they secrete acid and lytic enzymes that degrade and break down the mineral and organic components of bone and cartilage (Fig. 2-7a, b, c). The degradation process of bone matrix results in the formation of a specialized extracellular compartment known as *Howship's lacuna* (Rodan 1992; Vaananen & Laitala-Leinonen 2008). Osteoclasts are specialized multinucleated cells that originate from the monocyte/macrophage hematopoietic lineage. This differentiation process is driven initially by the expression of the transcription factor PU-1. Macrophage colony-stimulating factor (M-CSF) engages osteoclasts in the differentiation pathway and promotes their proliferation and expression of RANKL. At this stage, RANKL-expressing stromal cells interact with pre-osteoclasts and further commit them to differentiation along the osteoclast lineage (Fig. 2-7d, Fig. 2-8).

Periosteal tissue

The periosteum is a fibrous sheath that covers the outer surface of a long bone's shaft (diaphysis), but does not overlay the articulating surfaces. The periosteum consists of dense irregular connective tissue and is divided into a dense, fibrous, vascular layer (the "fibrous layer") and an inner, more loosely arranged, connective tissue inner layer (the "osteogenic layer") (see Fig. 2-1). The fibrous layer is mainly formed of fibroblasts, while the inner layer contains osteoprogenitor cells and mesenchymal stem cells. This layer is also very important in regeneration of osseous tissues (Lin *et al*. 2014).

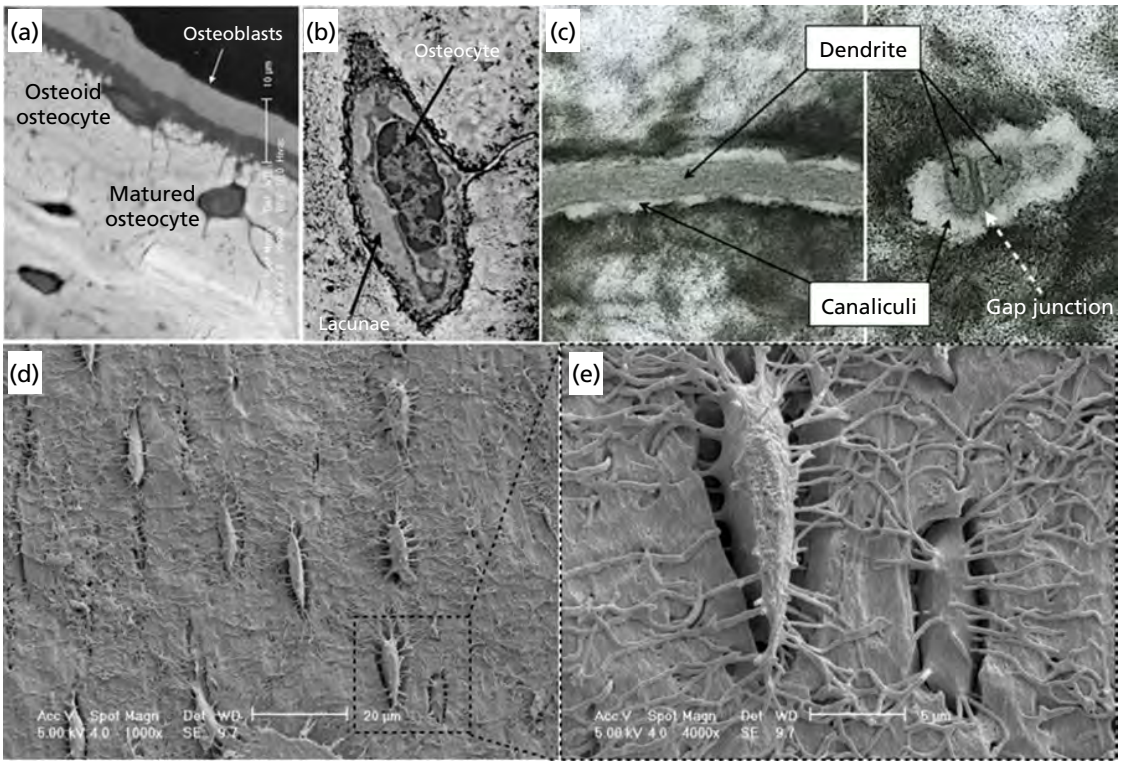

Fig. 2-5 Osteocytes. The osteocyte can be defined as the orchestrator of the remodeling process within bone. (a) As bone matrix is synthesized, a number of osteoblasts become embedded within the osteoid, which later mineralizes and resides in the mature matrix as osteocytes as shown in this backscatter scanning electron micrograph (SEM) treated with osmium to allow the visualization of the cell. (b) The osteocytes reside within a well-defined space in bone known as the osteocyte lacuna. (c) A transmission electron micrograph of a dendrite within a canaliculi, showing the space through which fluid flows; the shear stress from this stimulates the surface of the osteocyte cell membrane. This unique biologic architectural characteristic of the osteocyte and the lacunocanalicular network represent the foundation that allows the conversion of mechanical stimuli into the biochemical signals necessary for bone homeostasis. (d, e) SEM of a casted lacunocanalicular network allow the visualization of the degree of connectivity between osteocytes and the regular diameter of the canalicular structures.

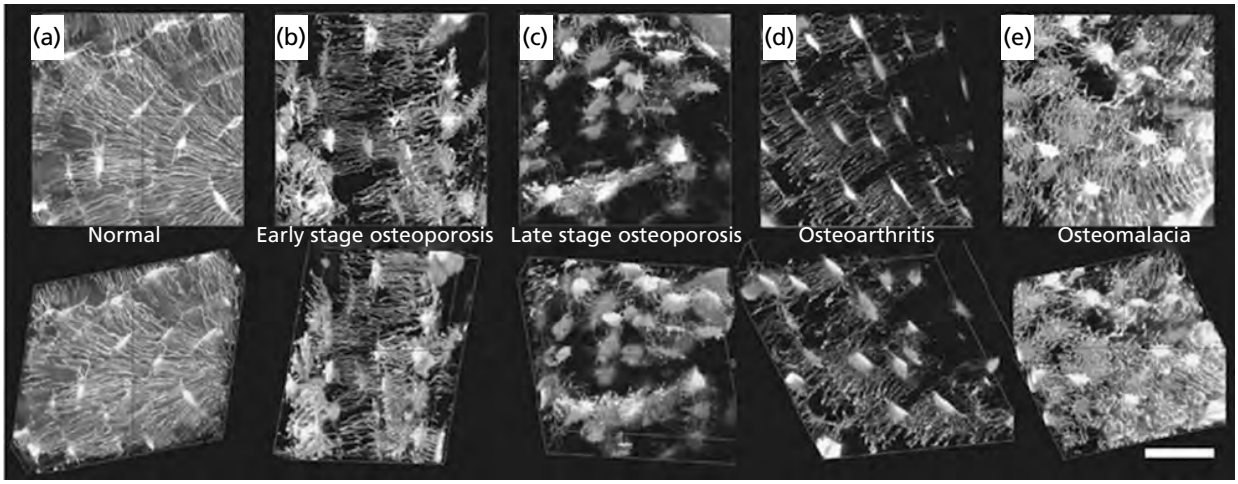

Fig. 2-6 Osteocytes: lacunocanalicular system in disease. (a) In healthy bone, a high density osteocyte system is established throughout the mature matrix and is characterized by high cellular interconnectivity. With disease, the system is significantly disrupted, leading to important functional alterations. (b, c) In osteoporosis, osteocytic density changes and an apparent decrease in cellular interconnectivity is observed. (d) In osteoarthritis, the canalicular system is altered, but with no major lacunar changes. (e) In osteomalacia, the entire osteocyte lacunocanalicular system appears disrupted due to the altered mineralization pattern.

Osteoblasts derived from the "osteogenic layer" are responsible for increasing the width of long bones and the overall size of the other bone types. In the context of a fracture, progenitor and stem cells from the periosteum differentiate into osteoblasts and chondroblasts, which are essential in the process of stabilizing the wound.

In contrast to the osseous tissue, the periosteum has nociceptive nerve endings, making it very sensitive to mechanical stimuli. It also allows the passage

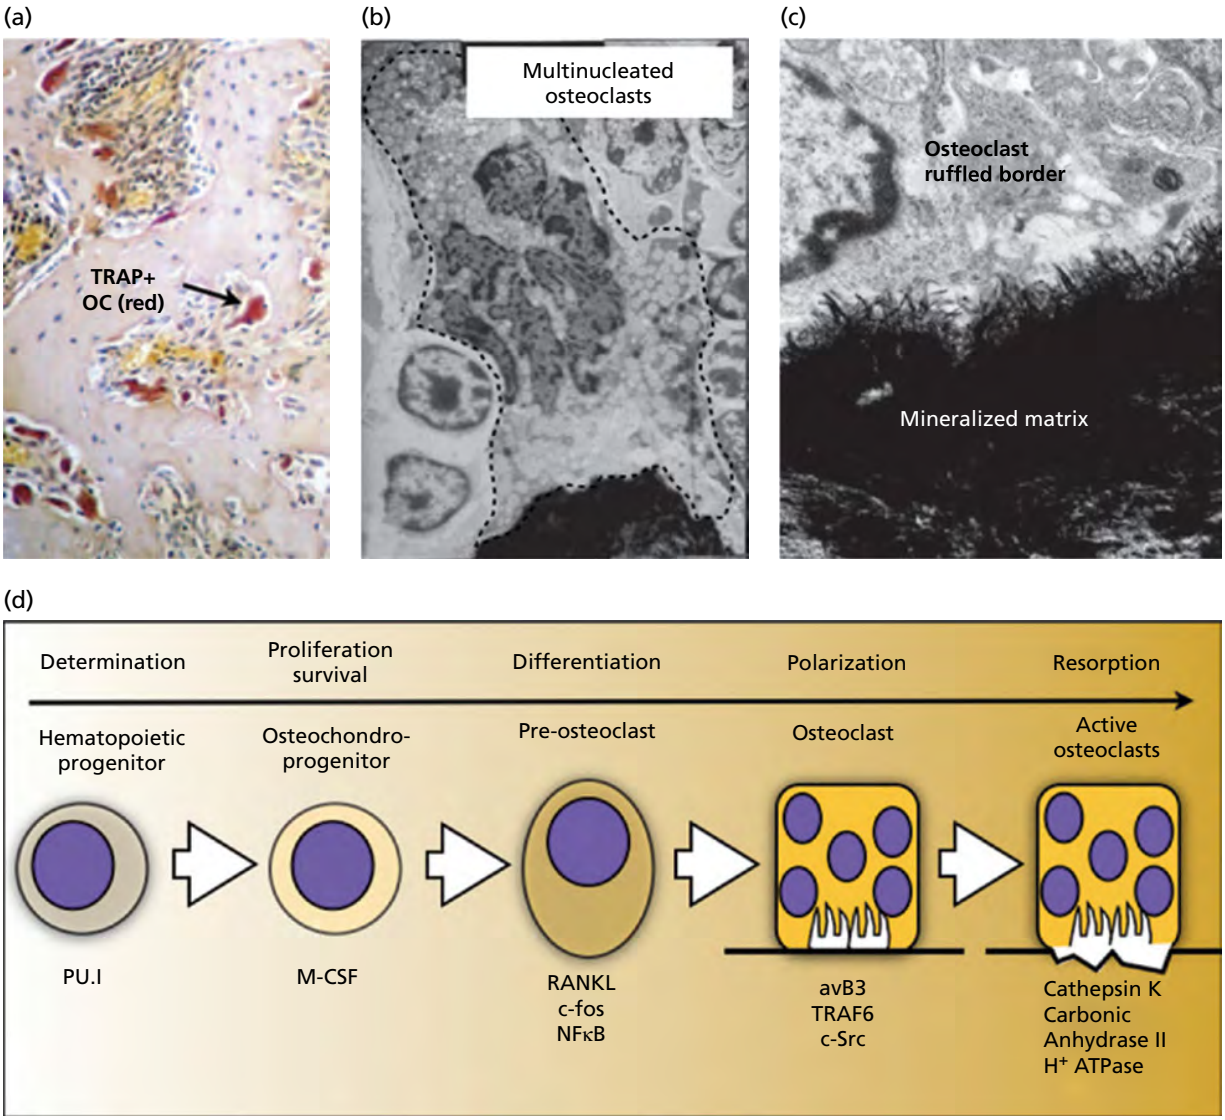

Fig. 2-7 Osteoclasts. (a) Histologically, osteoclasts can be depicted morphologically as multinucleated cells attached to bone matrix using special staining such as the tartrate-resistant acid phosphatase (TRAP) stain (arrow). OC, osteoclast. (b) A transmission electron micrograph of a multinucleated osteoclast attached to the mineralized bone matrix. (c) Ruffled border at the resorbing end of the cells. (d) Osteoclasts are derived from cells of the macrophage/monocyte lineage and represent the bone resorbing units within the skeleton. The key molecules involved in the early events of differentiation of a hematopoietic progenitor through to a mature functional osteoclast are shown.

of lymphatics and blood vessels into and out of bone, providing nourishment. The periosteum anchors tendons and ligaments to bone by strong collagenous fibers in the "osteogenic layer", called Sharpey's fibers, which extend to the outer circumferential and interstitial lamellae. It also provides an attachment for muscles and tendons.

Bone marrow

The bone marrow consists of hematopoietic tissue islands, stromal cells, and adipose cells surrounded by vascular sinuses interspersed within a meshwork of trabecular bone (see Fig. 2-1). The bone marrow is the major hematopoietic organ, a primary lymphoid tissue (responsible for the production of erythrocytes, granulocytes, monocytes, lymphocytes, and platelets) and an important source of mesenchymal stem cells.

Types

There are two types of bone marrow: red marrow, which consists mainly of hematopoietic tissue, and yellow marrow, which is mainly made up of adipocytes. Erythrocytes, leukocytes, and platelets arise in red marrow. Both types of bone marrow contain numerous blood vessels and capillaries. At birth, all bone marrow is red. With age, more and more of it is converted to the yellow type; only around half of adult bone marrow is red. In cases of severe blood loss, the body can convert yellow marrow back to red marrow to increase blood cell production.

Cells

The stroma of the bone marrow is not directly involved in the primary function of hematopoiesis. However, it serves an indirect role by indirectly providing the

ideal hematopoietic microenvironment. For instance, it generates colony stimulating factors, which have a significant effect on hematopoiesis. Cells that constitute the bone marrow stroma are:

- Fibroblasts
- Macrophages
- Adipocytes
- Osteoblasts
- Osteoclasts
- Endothelial cells.

Stem cells

Mesenchymal stem cells (MSC), also called *marrow stromal cells*, were first identified following their isolation and characterization from the bone marrow stroma. MSC are multipotent stem cells that can differentiate into a variety of cell types. They have demonstrated the capacity to differentiate, *in vitro* or *in vivo*, into osteoblasts, chondrocytes, myocytes, adipocytes, vascular cells, and beta-pancreatic islet cells and evidence of their transdifferentiation into neuronal cells has also been reported. In addition, the bone marrow contains hematopoietic stem cells, which give rise to the three classes of blood cells that are found in the circulation: leukocytes, erythrocytes, and platelets (Polymeri *et al*. 2016).

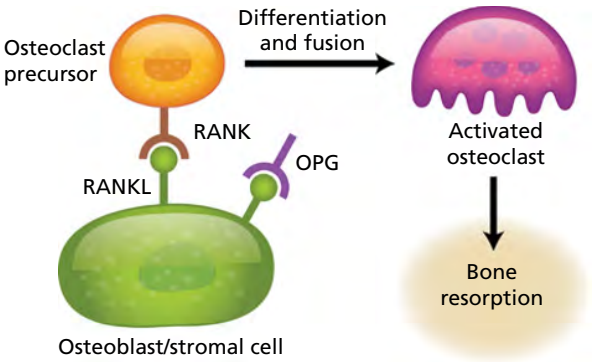

Fig. 2-8 Bone formation/resorption coupling. Bone formation and resorption processes are intimately linked. The osteoblastic/stromal cells provide an osteoclastogenic microenvironment by presenting RANKL to the osteoclast precursor, triggering their further differentiation and fusion, leading to the formation of multinucleated and active osteoclasts. This process is modulated by inhibitors of these interactions such as osteoprotegerin (OPG). In addition, bone formation by osteoblasts depends on the preceding resorption by osteoclasts.

Function

The main functions of bone are to provide locomotion, organ protection, and mineral homeostasis. Mechanical tension, local environment factors, and systemic hormones influence the balance between bone resorption and deposition. The distinct mechanical properties of bone contribute to its strength and ability to allow movement. In addition, an intricate series of interactions between cells, matrix, and signaling molecules maintain calcium and phosphorus homeostasis within the body, which also contributes to mechanical strength.

Mechanical properties

Bone is a highly dynamic tissue that has the capacity to adapt based on physiological needs. Hence, bone adjusts its mechanical properties according to metabolic and mechanical requirements (Burr *et al*. 1985; Lerner 2006). As discussed previously, calcium and phosphorus comprise the main mineral components of bone in the form of calcium hydroxyapatite crystals. Hydroxyapatite regulates both the elastic stiffness and tensile strength of bone. The skeletal adaptation mechanism is regulated primarily by the processes of bone resorption and bone formation, these processes collectively referred to as bone remodeling (Fig. 2-9). Bone is resorbed by osteoclasts,

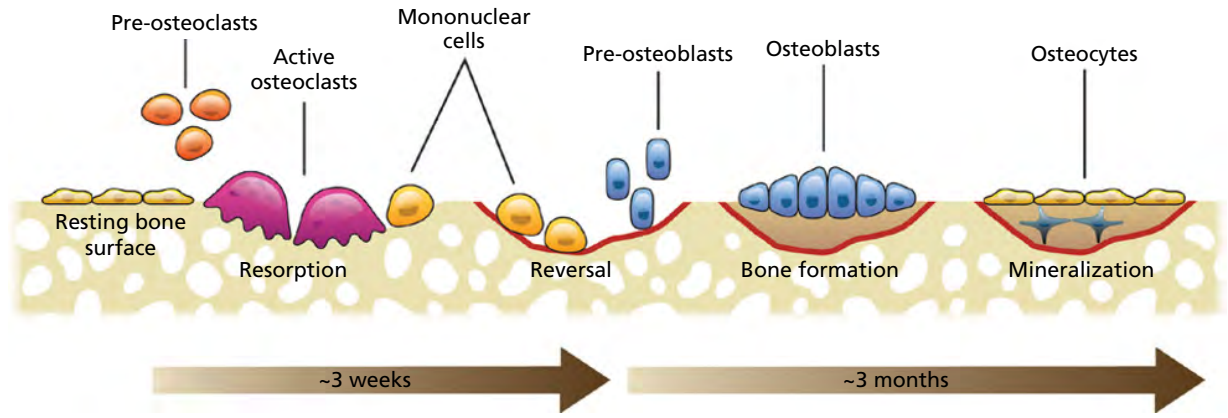

Fig. 2-9 Bone remodeling. The bone remodeling cycle involves a complex series of sequential steps that are highly regulated. The "activation" phase of remodeling is dependent on the effects of local and systemic factors on mesenchymal cells of the osteoblast lineage. These cells interact with hematopoietic precursors to form osteoclasts in the "resorption" phase. Subsequently, there is a "reversal" phase during which mononuclear cells are present on the bone surface. They may complete the resorption process and produce the signals that initiate bone formation. Finally, successive waves of mesenchymal cells differentiate into functional osteoblasts, which lay down matrix in the "formation" phase. (Source: McCauley & Nohutcu (2002). Reproduced from American Academy of Periodontology.)

after which new bone is deposited by osteoblasts (Raisz 2005). From the perspective of bone remodeling, it has been proposed that osteoclasts recognize and 'home' to skeletal sites of compromised mechanical integrity, and once there, initiate bone remodeling inducing new bone formation that is mechanically competent (Parfitt 1995, 2002).

In general, bone tissue responds to patterns of loading by increasing matrix synthesis, and altering composition, organization, and mechanical properties (Hadjidakis & Androulakis 2006). Evidence indicates that the same holds true for bone under repair. When bone experiences mechanical loading, osteoclast mechanoreceptors are directly stimulated, which begins the bone turnover process to regenerate and repair bone in the area. In addition, pressure increases M-CSF expression, increasing osteoclast differentiation in the bone marrow (Schepetkin 1997). Osteoclasts are also indirectly stimulated through osteoblasts and chondrocytes secreting prostaglandins in response to mechanical pressure. The ECM can also promote bone turnover through signaling. Mechanical deformation of the matrix induces electric potentials that stimulate osteoclastic resorption.

Bone strength is determined by a combination of bone quality, quantity, and turnover rate. It is well established that a loss of bone density, or quantity, decreases bone strength and results in increased fracture incidence. However, several pathologic conditions characterized by increased bone density, such as Paget's disease, are also associated with decreased bone strength and increased fracture incidence, so quality of bone is also an important factor in determining bone strength.

Metabolic properties

Calcium homeostasis is of major importance for many physiologic processes that maintain health (Bonewald 2002; Harkness & Bonny 2005). Osteoblasts deposit calcium by mechanisms including phosphate and calcium transport with alkalinization to absorb acid produced by mineral deposition; cartilage calcium mineralization occurs by passive diffusion and phosphate production. Calcium mobilization by osteoclasts is mediated by acid secretion. Both bone-forming and bone-resorbing cells use calcium signals as regulators of differentiation and activity (Sims & Gooi 2008). This has been studied in more detail in osteoclasts: both osteoclast differentiation and motility are regulated by calcium.

Despite calcium being an important mineral acquired exogenously from the diet, bone serves as the major reservoir of calcium and a key regulatory organ for calcium homeostasis. Bone, in major part, responds to calcium-dependent signals from the parathyroid glands and via vitamin D metabolites, although it responds directly to extracellular calcium if parathyroid regulation is lost. Serum calcium homeostasis is achieved through a complex regulatory process whereby a balance between bone resorption, absorption, and secretion in the intestine, and reabsorption and excretion by the kidneys is tightly regulated by osteotropic hormones (Schepetkin 1997). The balance of serum ionized calcium blood concentrations results from a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin. Other osteotropic endocrine hormones that influence bone metabolism include thyroid hormones, sex hormones, and retinoic acids. In addition, fibroblast growth factor aids in phosphate homeostasis. Fig. 2-10 reflects how input from the diet and from the bones and excretion via the gastrointestinal tract and urine maintain homeostasis.

Vitamin D is involved in the absorption of calcium, while PTH stimulates calcium release from the bone, reduces its excretion from the kidney, and assists in the conversion of vitamin D into its biologically active form (1,25-dihydroxycholecalciferol) (Holick 2007). Decreased intake of calcium and vitamin D and estrogen deficiency may also contribute to calcium deficiency (Lips *et al*. 2006). Hormonal factors such as retinoids, thyroid and steroid hormones are capable of passing through biologic membranes and interacting with intracellular receptors to have a major impact on the rate of bone resorption. Lack of estrogen increases bone resorption as well as decreases the formation of new bone (Harkness & Bonny 2005). Osteocyte apoptosis has also been documented in estrogen deficiency. In addition to estrogen, calcium metabolism plays a significant role in bone turnover, and deficiency of calcium and vitamin D leads to impaired bone deposition.

Circulating PTH regulates serum calcium and is released in conditions of hypocalcemia. PTH binds to osteoblast receptors, increasing the expression of RANKL and the binding of RANKL to RANK on osteoclasts (McCauley & Nohutcu 2002). This signaling stimulates bone remodeling by activating osteoclasts with the final goal of promoting calcium release from bone. A secondary function of PTH is to increase calcium reabsorption from the kidney. When administered therapeutically at low, intermittent doses, PTH can act as an anabolic agent to promote bone formation, although the mechanism of this action is not well understood.

T cells produce calcitonin, a 32 amino acid peptide whose main physiologic role is the suppression of bone resorption. Calcitonin receptors are present in high numbers on osteoclasts and their precursors (Schepetkin 1997). Thus, calcitonin is able to act directly on osteoclast cells at all stages of their development to reduce bone resorption through preventing fusion of mononuclear preosteoclasts, inhibiting differentiation, and preventing resorption by mature osteoclasts (McCauley & Nohutcu 2002). The concentration and phosphorylation of calcitonin receptors decreases in the presence of calcitonin. As a result, the effect of calcitonin on osteoclasts is transient and thus is not used for clinical therapeutic applications.

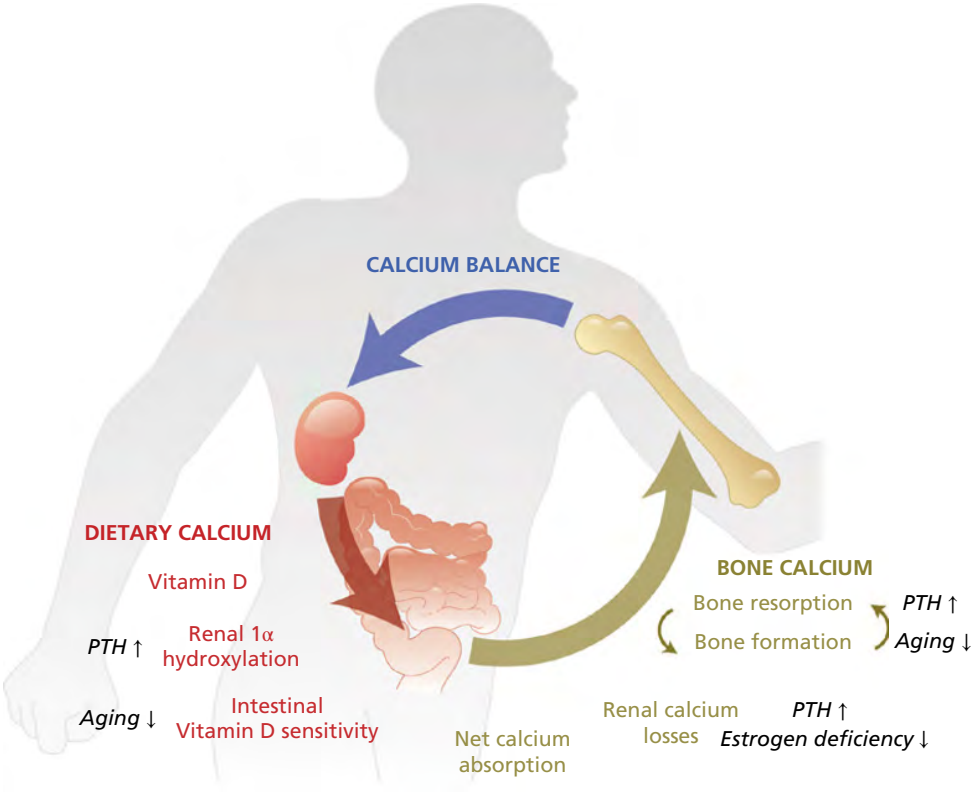

Fig. 2-10 Calcium and bone metabolism. Calcium homeostasis is of major importance for many physiologic processes that maintain health. The balance of serum ionized calcium blood concentrations results from a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin. The figure reflects how input from the diet and from the bones and excretion via the gastrointestinal tract and urine maintain homeostasis. Vitamin D is involved in the absorption of calcium, while PTH stimulates calcium release from the bone, reduces its excretion from the kidney, and assists in the conversion of vitamin D into its biologically active form (1,25-dihydroxycholecalciferol). Decreased intake of calcium and vitamin D and estrogen deficiency may also contribute to calcium deficiency.

Skeletal homeostasis

Healing

In most situations where tissue injury occurs, healing of the injured site leads to the formation of a tissue that differs in morphology, composition, or function of the original tissue. This type of healing is termed *repair*. Tissue *regeneration*, on the other hand, is a term used to describe a healing process that results in complete restoration of morphology, composition, and function. The healing of bone tissue includes both regenerative and repair phenomena, depending on the nature of the injury.

Repair

Trauma to bone tissue, whether repeated stress or a single, traumatic episode, most commonly results in fracture. When bone is damaged, a complex and multistage healing process is immediately initiated in order to facilitate repair. Tissue and cell proliferation are mediated at different stages by carious growth factors, inflammatory cytokines, and signaling molecules. Although it is a continuous process, bone repair can be roughly divided into three phases – inflammation, reparative, and remodeling (Hadjidakis & Androulakis 2006).

The inflammation phase begins immediately after tissue injury and lasts for approximately 2 weeks (Fazzalari 2011). The initial step in the repair process is the formation of a blood clot. Cytokine release from injured cells then recruits inflammatory cells into the area, where macrophages begin phagocytosis of damaged tissue and cells. Osteoclasts begin the process of resorbing damaged bone in the area to recycle mineral components. In addition, cells from myeloid and mesenchymal cell lineages are recruited to the area where they begin to differentiate into osteoblasts and chondroblasts. At this point, the RANKL:osteoprotegerin (OPG) ratio is reduced.

The reparative phase is characterized by the formation of a soft callous where new bone matrix and cartilage scaffolding begins to form. Osteoblasts and chondroblasts produce a protein scaffold to create this callus, which is slowly mineralized to form a hard callus. The hard callus is composed of immature woven bone. The initiation of cartilage and periosteal woven bone formation is primarily mediated through early up-regulation of interleukin 6 (IL-6), OPG, vascular endothelial growth factor (VEGF), and BMPs (Fazzalari 2011). The process of soft to hard callus formation occurs approximately 6–12 weeks from the time of bone fracture.

In the final stage of repair, known as the remodeling phase, the bone matrix and cartilage are remodeled into mature bone. Woven bone is eventually converted into mature lamellar bone through normal bone turnover mediated by osteoblast/osteoclast coupling. Adequate vitamin D and calcium are critical for proper bone repair and their levels may, in part, dictate the rate of repair. The time for the remodeling stage usually requires months from the time of injury; however, it varies depending upon individual variability in bone metabolism.

Regeneration

Optimum bone healing promotes tissue formation in such a way that the original structure and function of bone is preserved. This process is in contrast to tissue repair, which merely replaces lost tissue with immature tissue and does not completely restore form or function.

Over time, bone sustains damage from mechanical strain, overloading, and other forms of tissue injury that results in microfractures and other defects in the bony architecture. In order to prevent greater injury, the bone undergoes a natural remodeling process to regenerate or renew itself. The turnover rates of individual bones is unique, although the average turnover rate is 10% (McCauley & Nohutcu 2002).

Regeneration of bone tissue involves the coupling of bone formation and resorption in a basic multicellular unit (BMU) (Sims & Gooi 2008) (Fig. 2-11). In this process, bone resorption by osteoclasts occurs first over a period of 3–4 weeks, along with cellular signaling to promote osteoblast recruitment to the area. Osteoblasts then form bone for a period of 3–4 months, with a quiescent period between bone resorption and formation, called the reversal phase. Trabecular bone undergoes a significantly higher degree of bone turnover than cortical bone (McCauley & Nohutcu 2002). In a rodent alveolar bone healing model, this process occurs more rapidly, allowing appreciation of the cellular and molecular events that occur during the maturation of the newly regenerated bone (Figs. 2-12, 2-13) (Lin *et al*. 2011).

Bone regeneration is a normal process yet in some scenarios there is a need to regenerate bone at either an accelerated rate or in order to overcome the effects of pathologic bone disorders. Therapeutic strategies to promote bone regeneration include the use of: bone grafts from various sources, epithelial–occlusive barrier membranes, antiresorptive agents, anabolic agents, and growth factors which promote osteoblast differentiation and proliferation (Giannobile *et al*. 2019).

When alterations in bone turnover occur, skeletal homeostasis is disrupted, resulting in conditions of increased or decreased bone mineral density (BMD), or bone necrosis, and often accompanied by a decrease in bone strength. A wide variety of conditions can alter bone homeostasis and these include cancer, menopause, medications, genetic conditions, nutritional deficiencies, or infection. Some of these etiologies, such as vitamin D deficiency, are easily treatable, whereas

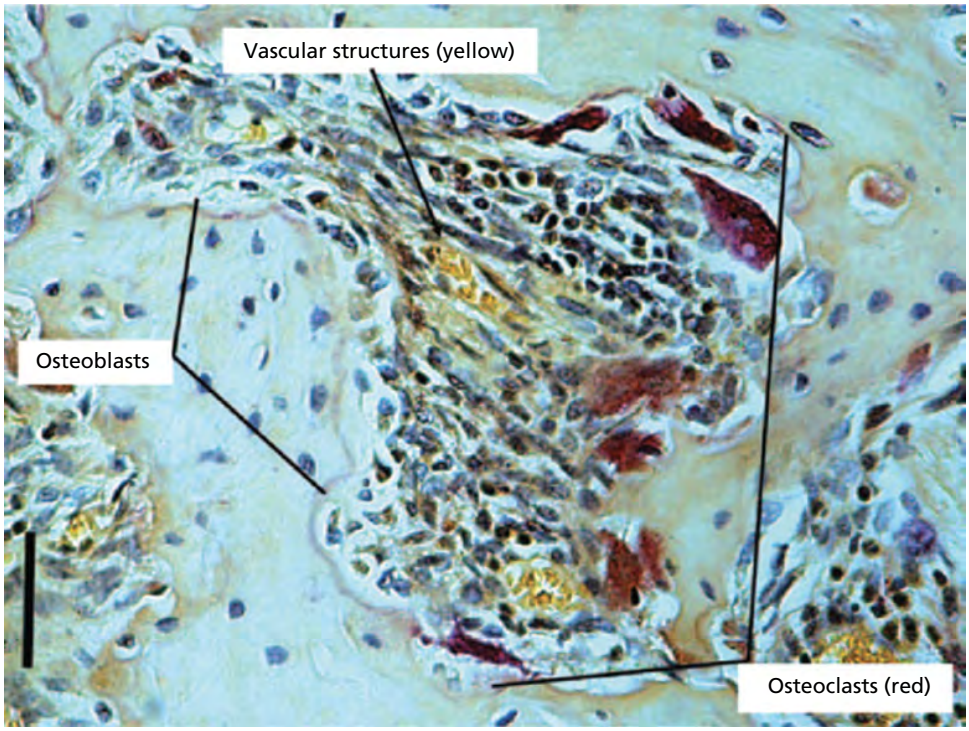

Fig. 2-11 Bone multicellular units (BMU). Bone remodeling occurs in local groups of osteoblasts and osteoclasts called BMU; each unit is organized into an osteoclast reabsorbing front, followed by a trail of osteoblasts reforming the bone to fill the defect left by osteoclasts. The red staining (tartrate acid phosphatase) highlights the resorption front. Note the increased number of multinucleated osteoclasts in this area.

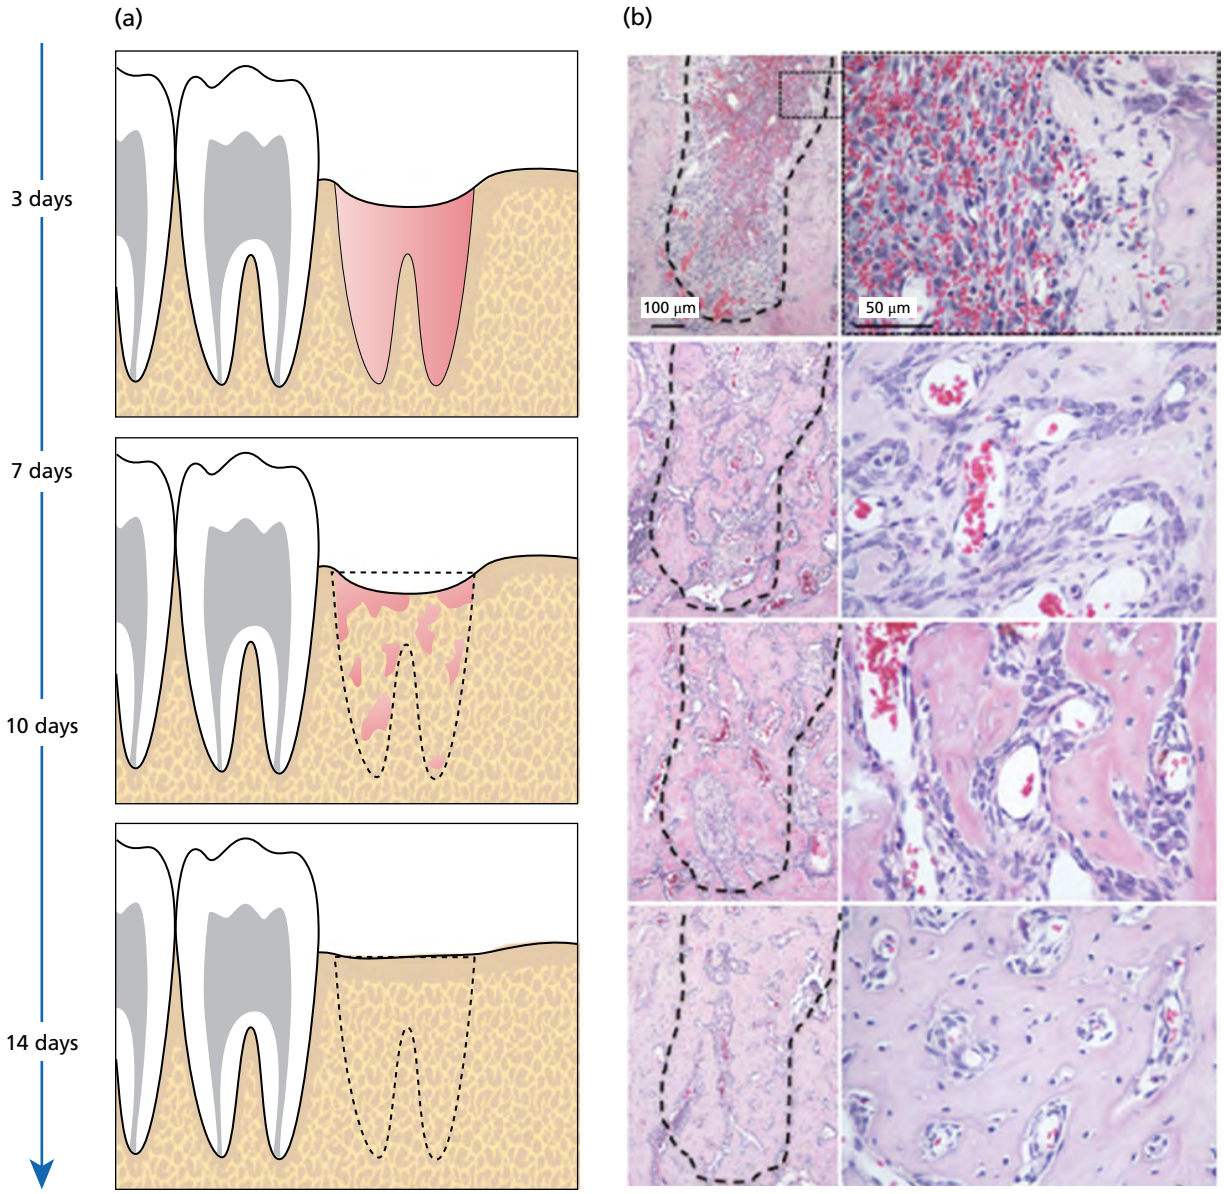

Fig. 2-12 Alveolar socket healing sites over time. (a) Rodent extraction model. Sequence of events that characterize healing during the initial 14 days. (b) Hematoxylin and eosin (H&E) staining for tooth extraction site healing. The histologic images to the right of the healing area (black dashed lines) clearly capture the regeneration of the bone within the alveolar process. Note the clearly visible blood clot at day 3. At day 7, the cell density in the defect area is higher. At day 10, the defect site appears to be filled by a condensed mesenchymal tissue. Finally, by day 14, an integration of the newly formed bone to the original socket walls is noted.

others, such as genetic mutations, are typically treated through managing symptoms. Alterations in bone homeostasis cause a wide array of symptoms, including increased fracture incidence, bone pain, and other skeletal deformities that result in a high degree of morbidity and in some cases mortality. A brief review of the more common conditions is given below.

Disorders

Osteoporosis

Osteoporosis is a common condition characterized by both alterations in the macro- and microarchitecture of the bone (Fig. 2-14). There are multiple etiologies of this systemic disease, including postmenopausal, age-associated, glucocorticoid-induced, secondary to cancer, androgen ablation, and aromatase inhibitors (Kanis 2002). All forms result in reduced bone strength and increased fracture risk, accompanied by a high degree of morbidity and mortality.

Postmenopausal osteoporosis is the most common form of the disease and results from a decline in gonadal hormone secretion following menopause. Rapid loss of trabecular BMD and, to a lesser extent, cortical loss are common in this condition (Kanis 2002).

Diagnosis is made by comparing the BMD of a patient to that of a healthy 20–29-year-old adult of the same gender. Systemic BMD at least 2.5 standard deviations below the average, referred to as a T-score, is used by the World Health Organization (WHO) to define

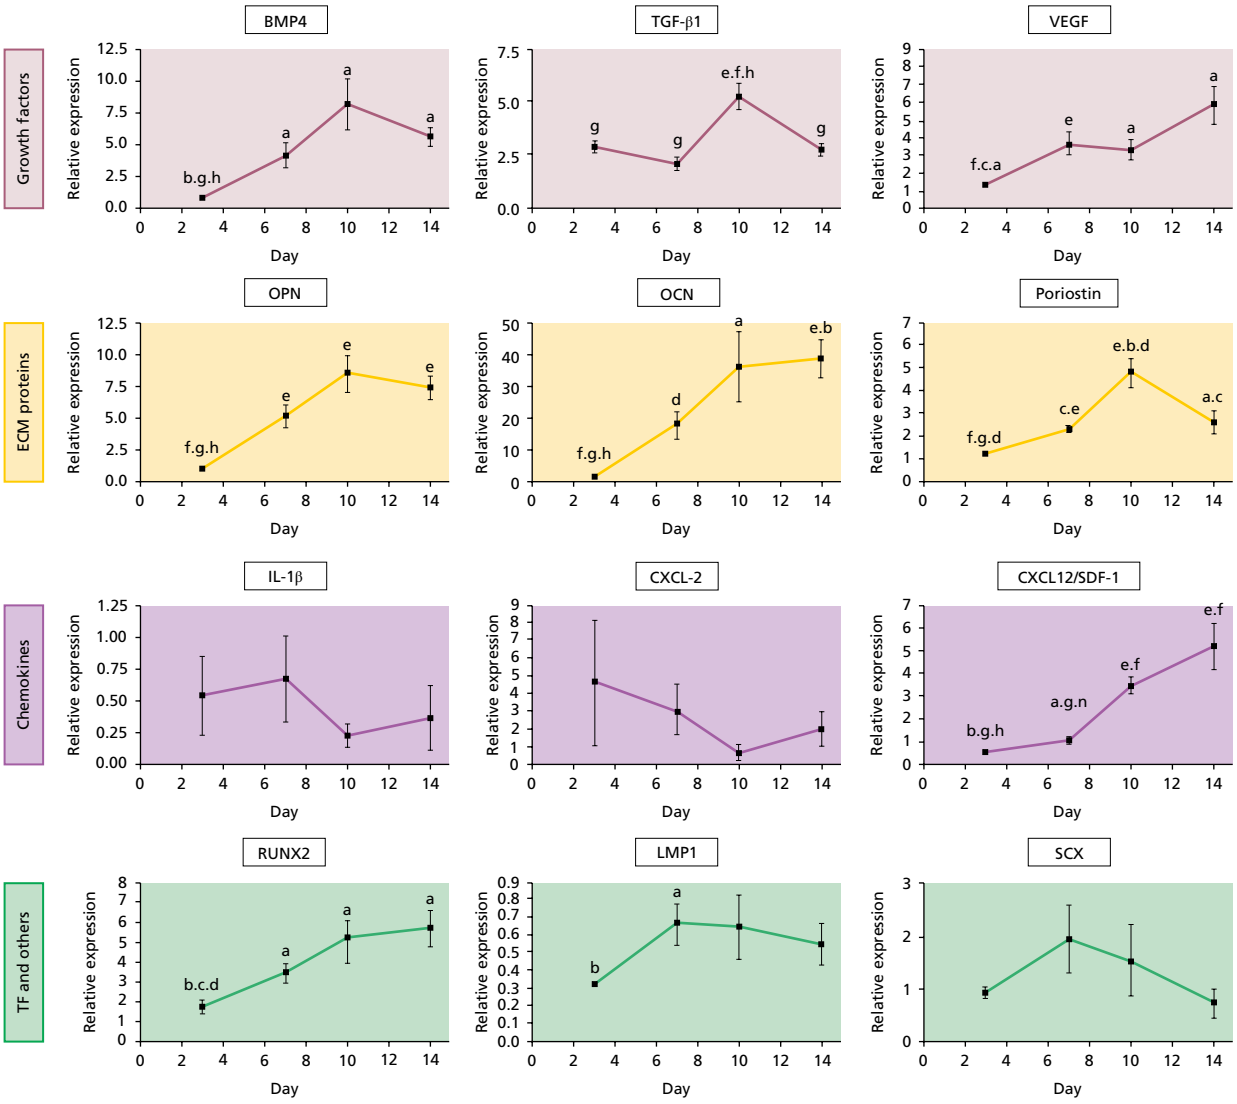

Fig. 2-13 Gene expression pattern of tooth extraction healing sites. Laser capture microdissection (LCM) analysis of genes associated with wound healing categorized them into three different groups: those for growth factors/chemokines, extracellular matrix proteins (ECM), and transcription factors (TF). Three expression patterns were evident. (1) Genes whose expression was slowly increased during the healing process: those for growth factors (*BMP4*, *BMP7*, *Wnt10b*, and *VEGF*), transcription factors (*RUNX2*), and extracellular matrix proteins related to mineralized tissue (*OPN* and *OCN*) were in this group; very interestingly, CXCL12 (SDF-1) gradually increased during extraction socket healing. Transforming growth factor beta 1 (TGF-β1) increased at the midstage of healing (day 10) and then decreased, and periostin (*POSTN*), a target gene of TGF-β1, had the same expression pattern. (2) Genes that were highly expressed at early time points and are downregulated at later stages. Genes for chemokines IL-1β, CXCL2, and CXCL5 belong to this category, although no statistical difference was seen due to the limited number of animals analyzed. Expression of *Wnt5a* and *Wnt4* also seemed to decrease during healing. (3) Genes that were constitutively expressed. LIM domain mineralization protein (LMP-1) and tendon-specific transcription factor SCX were in this group.

osteoporosis (WHO 1994; McCauley 2020). Osteopenia, a less severe form of the disease, is diagnosed when T-scores are between –1.0 and –2.5 (Fig. 2-15).

Osteopetrosis

Osteopetrosis is a group of related diseases in which there is a pronounced increase in BMD due to abnormal bone turnover, and in some ways this is the opposite of osteoporosis. These conditions are inherited and the mode of transmission varies from autosomal dominant to autosomal recessive. Increases in BMD in this patient population are due to a variety of defects in osteoclastic bone resorption. These include higher or lower osteoclast numbers, impaired differentiation, deficiencies in carbonic anhydrase, the ability to form a ruffled border, and alterations in signaling pathways (Stark & Savarirayan 2009). In most cases, it is the ability of the osteoclast to create an acidic environment in the lacunae to resorb bone that is in some way compromised, ultimately resulting in a net increase in bone formation (Fig. 2-16).

Osteomalacia

Vitamin D is essential for the metabolism of calcium and phosphorus in the body, which are the key minerals required for bone formation (Holick 2007).

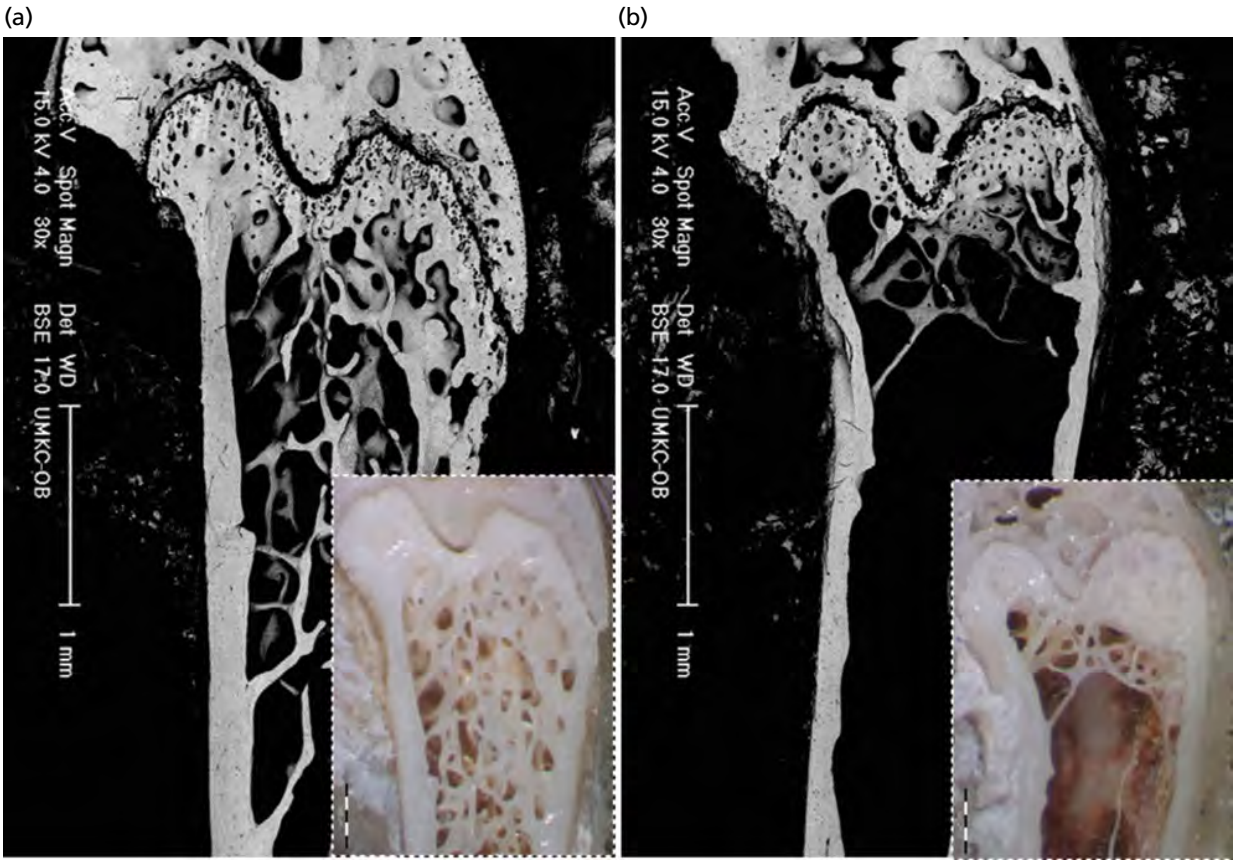

Fig. 2-14 Osteoporosis. In osteoporosis, there is decreased cortical thickness in addition to a marked decrease in trabecular number and connectivity. As this process continues over time, there is further deterioration of the internal architecture with a significant impact on the ability of the bone to sustain compressive forces without failure.

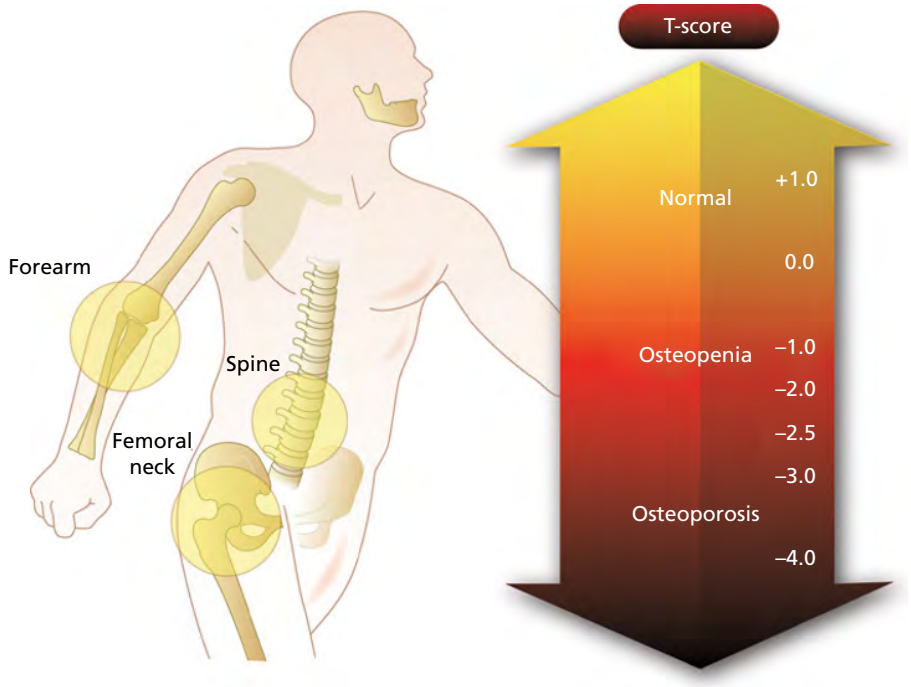

$$\text{T-Score} = \frac{\text{Measured BMD} - \text{young adult mean BMD}}{\text{Young adult standard deviation}}$$

Fig. 2-15 Bone mineral density (BMD). Dual-energy X-ray absorptiometry (DEXA) is considered the preferred technique for measurement of BMD. The sites most often used for DEXA measurement of BMD are the spine, femoral neck, and forearm. The World Health Organization defines osteoporosis based on "T-scores". T-scores refer to the number of standard deviations above or below the mean for a healthy 30-year-old adult of the same sex as the patient.

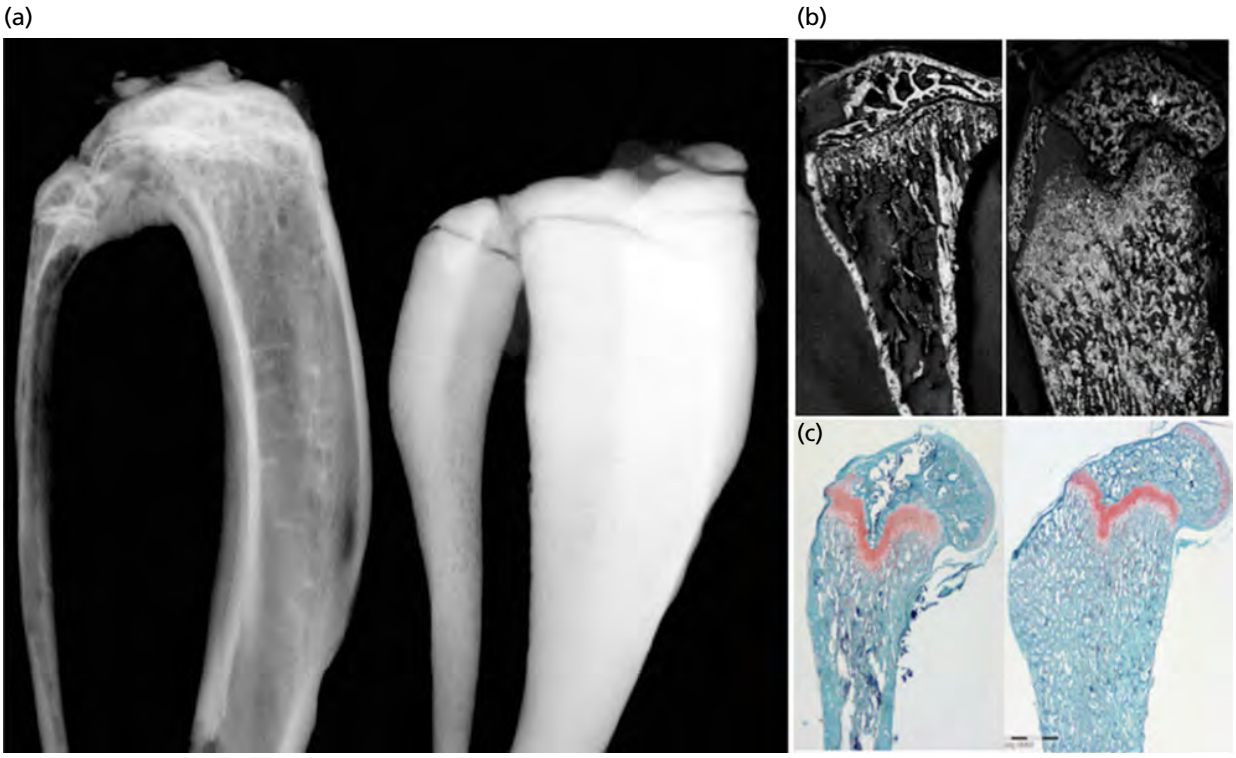

Fig. 2-16 Osteopetrosis. Increased density and deposits of mineralized bone matrix are a common finding in those with osteopetrosis. (a) Obliteration of the bone marrow cavity. (b) Backscatter SEM. (c) Staining with safranin-O.

Vitamin D deficiency, or the inability to absorb the vitamin, is a common condition, especially in Northern climates since vitamin D is obtained primarily through sunlight exposure and diet. Other conditions may also predispose to vitamin D deficiency, such as oncogenic or benign tumors and liver disease.

When inadequate vitamin D is available, mineralization of the bones is impaired, resulting in a condition referred to as osteomalacia. When the disease occurs in children, it is referred to as rickets. The key features of osteomalacia are bones that contain a normal collagen matrix and osteoid structure, but lack proper mineralization, resulting in the softening of bones (Russell 2010). Osteomalacia differs from osteoporosis in that osteomalacia alters bone as it is developing, whereas osteoporosis weakens bones that have already formed (Fig. 2-17).

Severity ranges widely from an asymptomatic presentation to death in early childhood. Despite the increase in bone density, the newly formed bone is of poor quality and symptoms include increased fracture incidence, neuropathy, and short stature. Treatment of osteomalacia involves reversing the vitamin D deficiency status, usually through dietary supplementation combined with removing the cause of the deficiency. In severe cases, early management of this condition may involve a bone marrow transplant. Vitamin D deficiency is also associated with poor regenerative outcomes following periodontal surgical procedures (Bashutski *et al*. 2011).

Osteonecrosis

When ischemia occurs in bone for an extended period of time, often due to an interruption in blood supply, cell death occurs. Cells from a hematopoietic lineage are most prone to the negative effects of ischemia and cannot survive longer than 12 hours without an adequate blood supply (Steinberg 1991). Cells directly responsible for bone mineralization and turnover – osteoblasts, osteoclasts, and osteocytes – are less prone to anoxia, although cell death occurs in these cells after 48 hours of anoxia. If the blood supply resumes quickly, healing may occur and the bone may recover. However, after this critical time period passes, the bone in question will necrose, requiring partial or total resection, followed by reconstruction.

Osteonecrosis has multiple etiologies including radiation, bisphosphonate use, steroid use, hypertension, and in some cases arthritis or lupus. Bisphosphonate-related osteonecrosis of the jaw (ONJ) is of growing concern in the dental field. ONJ is defined as an area of exposed bone that does not heal within 8 weeks after identification by a healthcare provider (Khosla *et al*. 2008). Patients diagnosed with bisphosphonate-related ONJ include only those who have not had prior radiation to the craniofacial regions. Oral bisphosphonate use is associated with lower risk and has an incidence of 0.01–0.04%; this is in contrast to patients taking intravenous bisphosphonates who have a higher incidence of ONJ at 0.8–12% (Vescovi & Nammour 2011). This higher incidence is likely due to the higher dosing regimen given intravenously

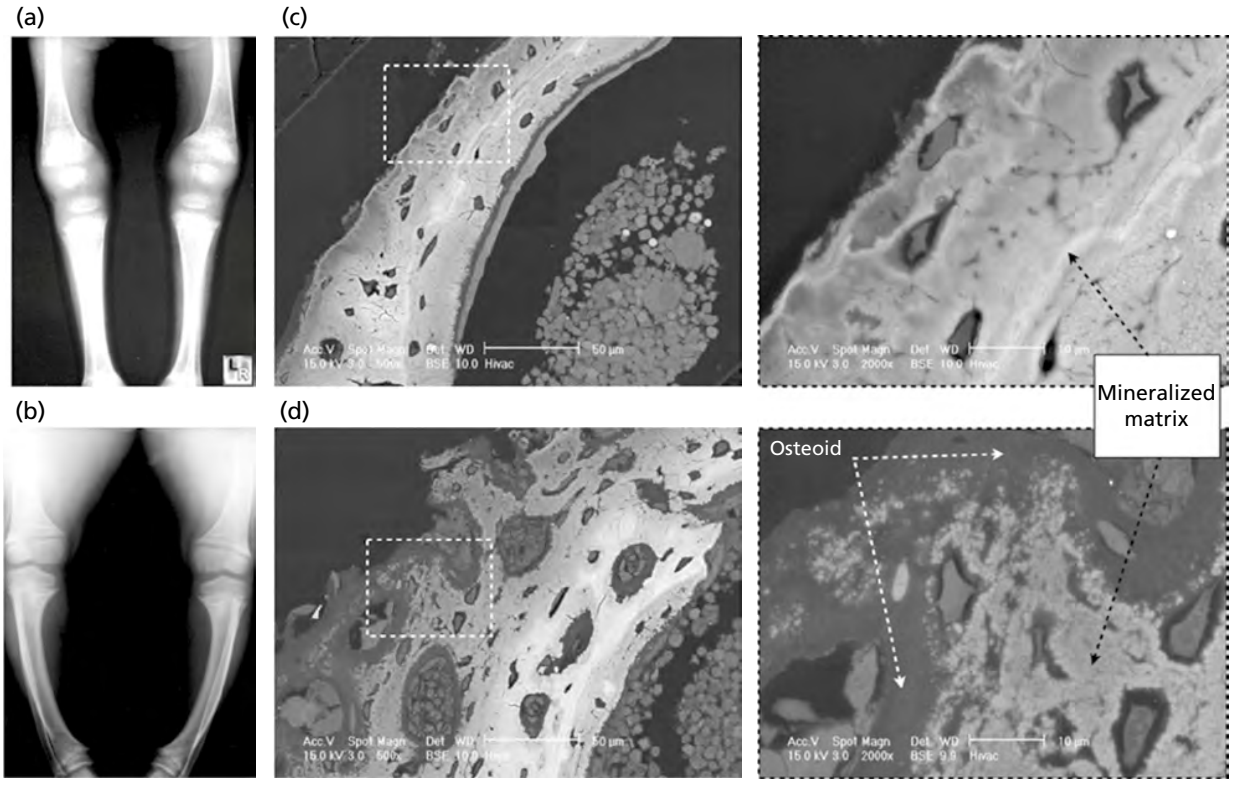

Fig. 2-17 Osteomalacia. (a, c) Normal matrix mineralization and maturation. (b, d) In osteomalacia, large hypomineralized zones accompanied by an increase in osteoid/immature matrix deposits are present.

and the severity and extent of the disease entity being treated. Oral bisphosphonates are typically used to treat osteoporosis, whereas intravenous bisphosphonates are given for the treatment of Paget's disease, multiple myeloma, and other conditions.

Osteomyelitis

Osteomyelitis is an infection of the bone and can be classified according to the source of infection, prognosis, bone anatomy, host factors, and clinical presentation (Calhoun & Manring 2005). Open fractures, surgery, and conditions such as diabetes mellitus and peripheral vascular disease increase the risk of developing osteomyelitis. Osteomyelitis from a hematogenous source is much more common in the pediatric population.

A definitive diagnosis of osteomyelitis is made by isolation of the bacteria in conjunction with diagnostic imaging, but can be challenging. Treatment involves antibiotic therapy in conjunction with drainage, debridement, and other appropriate surgical management, including bone stabilization and skin grafting (Conterno & da Silva Filho 2009).

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is a group of genetic disorders of impaired collagen formation leading to decreased bone quality. Fractures, bone fragility, and osteopenia are common features of the disease. OI is relatively rare, with an incidence of 1 in 10 000 births. Autosomal dominant and recessive forms exist, although the autosomal dominant form is more common (Michou & Brown 2011).

The clinical presentation of OI has features in common with other diseases of bone metabolism, including fractures, bone deformities, and joint laxity. In addition, distinct features of OI include hearing loss, vascular fragility, blue sclerae, and dentinogenesis imperfecta. Type I collagen defects, including interruptions in interactions between collagen and noncollagenous proteins, weakened matrix, defective cell–cell and cell–matrix relationships, and defective tissue mineralization contribute to the etiology of the autosomal dominant form (Forlino *et al*. 2011). In the recessive form, deficiency of any of the three components of the collagen prolyl 3-hydroxylation complex results in a reduced ability of type I procollagen to undergo post-translational modification or folding. The severity of the disease, as well as the presence of defining features, varies widely.

Multiple therapeutic options are employed to treat the symptoms of OI, including surgery, collaboration with hearing, dental, and pulmonary specialists, and medication such as bisphosphonates and recombinant human growth hormone.

Other disorders

Several other conditions can affect bone homeostasis, including primary and secondary hyperparathyroidism, Paget's disease, and fibrous dysplasia.

Hyperparathyroidism is an overproduction of PTH, which promotes resorption of calcium and phosphorus from bone to increase serum calcium to normal levels (Unnanuntana *et al*. 2011). Primary hyperparathyroidism is most commonly caused by a parathyroid gland adenoma, whereas secondary hyperparathyroidism occurs when PTH production is overstimulated in response to low serum calcium. Hyperparathyroidism often presents with no symptoms and is discovered at routine screenings. The clinical presentation is very similar to that of rickets. Treatment includes identifying and eliminating the initiating cause.

Paget's disease is a condition where bone metabolism is significantly higher than normal, with bone formation exceeding that of resorption (Noor & Shoback 2000). This results in excessive bone formation and may affect one or multiple bones. The pelvic bone is most commonly affected. The affected bones, despite having increased bone formation, are weak and deformed. This is due to irregular collagen fiber formation within the bones. Bisphosphonate therapy is effective at decreasing bone turnover in this patient population, although this carries with it an increased risk of developing ONJ. Approximately 0.01–0.04% of patients taking bisphosphonates for the treatment of Paget's disease develop ONJ (Vescovi & Nammour 2011).

Fibrous dysplasia may affect multiple bones, but in 60% of cases, only one bone is affected (Michou & Brown 2011). It most commonly presents in childhood. Fibrous dysplasia lesions form in the medullary cavity extending to the cortical bone and are comprised of hyaline cartilage, immature woven bone, and osteoblast progenitor cells. Symptoms of this condition include fractures and bone pain. Notably, this condition has other craniofacial symptoms, including craniofacial bone deformities, exophthalmos, and dental abnormalities.

Conclusion

It can be appreciated that the dynamic nature of bone and its associated structures serves as an important organ system that supports form and function of the skeleton including the bones of the jaws. This chapter provides the overview of the highly complex and coordinated developmental processes of bone formation and homeostasis during health and disease.

Acknowledgments

The authors appreciate the assistance of Drs. Hector Rios and Jill Bashutski on the previous edition of this chapter. We thank Mr. Chris Jung for his assistance with the figures.

Chapter 3

The Edentulous Ridge

Maurício Araújo[1] and Jan Lindhe[2]

[1] Department of Dentistry, State University of Maringá, Maringá, Paraná, Brazil

Clinical considerations

The alveolar process extends from the basal bone of the maxilla or the mandible and forms a boundary between the outer portion of the maxilla and the inner portion of the mandible (Pietrokovski *et al*. 2007). The alveolar process forms in harmony with the development and eruption of the teeth, and gradually regresses when the teeth are lost. In other words, the formation as well as the preservation of the alveolar process is dependent on the continued presence of teeth. Furthermore, the morphologic characteristics of the alveolar process are related to the size and shape of the teeth, events occurring during tooth eruption, as well as the inclination of the erupted teeth. Thus, subjects with long and narrow teeth, compared with subjects who have short and wide teeth, appear to have a more delicate alveolar process and, in particular in the front tooth regions, a thin, sometimes fenestrated, buccal bone plate (Fig. 3-1).

The tooth and its surrounding attachment tissues – the root cementum, the periodontal ligament, and the bundle bone – establish a functional unit (Fig. 3-2). Hence, forces elicited, for example during mastication, are transmitted from the crown of the tooth via the root and the attachment tissues to the load-carrying hard tissue structures in the alveolar process, where they are dispersed.

The loss of teeth and the loss or change of function within and around the socket will result in a series of adaptive alterations of the now edentulous portion of the ridge. Thus, it is well documented that following *multiple tooth* extractions and the subsequent restoration with removable dentures, the size of the ridge will become markedly reduced, not only in the horizontal but also in the vertical dimension (Figs. 3-3, 3-4). An important long-term study of dimensional ridge alterations in 42 complete denture wearers was presented by Bergman and Carlsson (1985). Cephalometric radiographic examinations were performed in a cephalostat and profiles of the edentulous mandible and maxilla were depicted 2 days after tooth extraction, and subsequently after 5 years and 21 years (Fig. 3-5). The authors concluded that during the observation interval most of the hard tissue component of the ridge was lost. However, there was wide variation in the degree of bone resorption and amount of remaining bone among the patients (Tallgren 1957, 1966; Atwood 1962, 1963; Johnson 1963, 1969; Carlsson *et al*. 1967).

Also, following the removal of *single* teeth, the ridge at the site will be markedly diminished (Fig. 3-6). The magnitude of this change was studied and reported by Pietrokovski and Massler (1967). The authors had access to 149 dental cast models (72 maxillary and 77 mandibular) in which one tooth was missing on one side of the jaw. The outer contours of the buccal and lingual (palatal) portions of the ridge at a tooth site and at the contralateral edentulous site were determined by the use of a profile stylus and

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

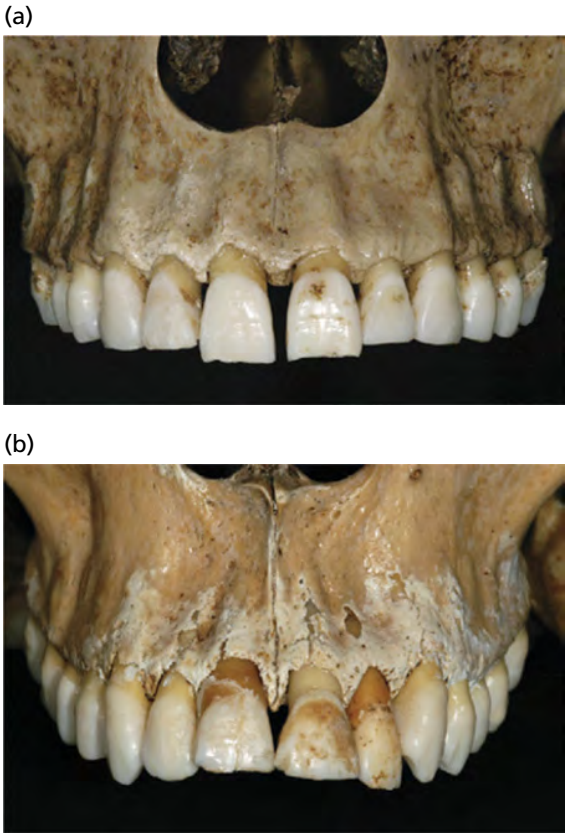

Fig. 3-1 Buccal aspect of adult skull preparations illustrating a dentate maxilla of one subject with a relatively thick (a) and another subject with a relatively thin (b) phenotype.

an imaging technique. Their findings are reported in Table 3-1.

It was concluded that the amount of tissue resorption (hard and soft tissues combined) following the loss of a single tooth was substantial and that the reduction of the ridge was twice as large at the buccal aspect as along the lingual and palatal aspect in all teeth groups examined. The absolute amounts of tissue loss varied from one group of teeth to the next. As a result of this tissue modeling, the center of the edentulous site shifted toward the lingual or palatal aspect of the ridge. The observations made by Pietrokovski and Massler (1967) were supported by findings presented by Schropp *et al*. (2003). They studied bone and soft tissue volume changes that took place during a 12-month period following the extraction of single premolars and molars. Clinical as well as cast model measurements were made immediately after tooth extraction and subsequently after 3, 6, and 12 months of healing. It was observed that the buccolingual/-palatal dimension during the first 3 months was reduced by about 30%, and after 12 months the edentulous site had lost at least 50% of its original width. Furthermore, the height of the buccal bone plate was reduced and after 12 months of healing the buccal prominence was located 1.2 mm apical of its lingual/palatal counterpart.

Misawa *et al*. (2016) evaluated the hard tissue changes that occurred in the alveolar process of

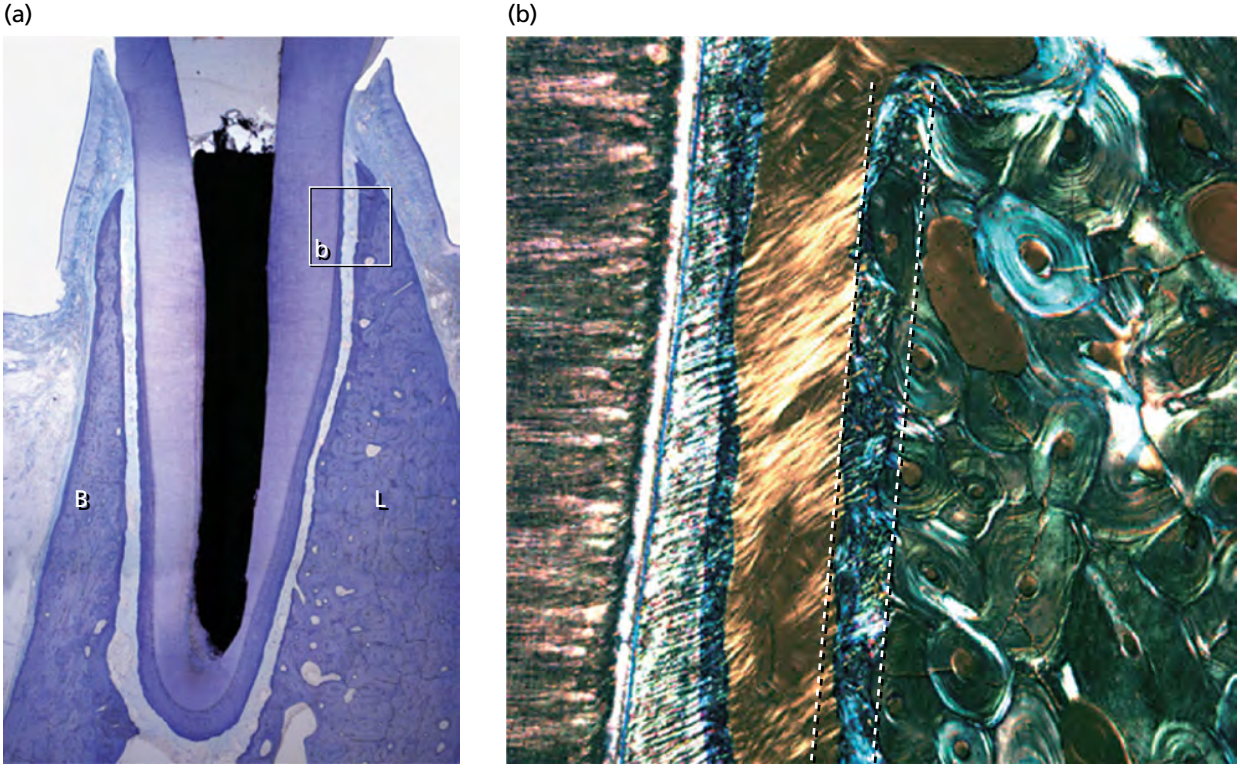

Fig. 3-2 Buccolingual histologic section of the alveolar process. (a) Tooth is surrounded by its attachment tissues (cementum, periodontal ligament, alveolar bone proper). B, buccal aspect; L, lateral aspect. (b) Higher magnification of the attachment tissues. Note that the dentin is connected to the alveolar bone via the root cementum, and the periodontal ligament. The alveolar bone is characterized by its content of circumferential lamellae. The portion of the bone that is facing the periodontal ligament (between the dotted lines) is called the alveolar bone proper or the bundle bone.

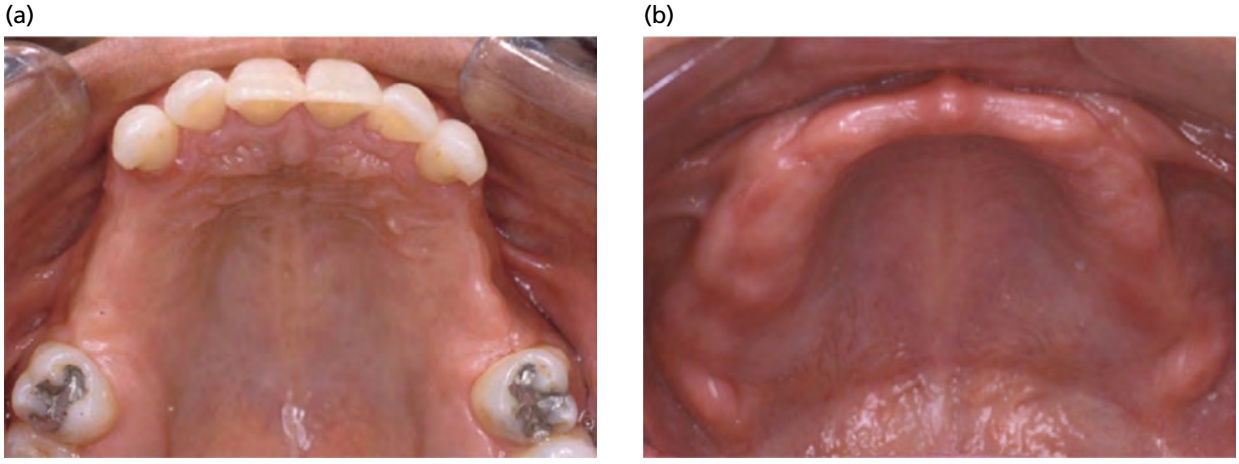

Fig. 3-3 (a) Clinical view of a partially edentulous maxilla. Note that the crest of the edentulous portions of the ridge is narrow in the buccopalatal direction. (b) Clinical view of a fully edentulous and markedly resorbed maxilla. Note that *papilla incisiva* is located in the center of the ridge. This indicates that the entire buccal and also a substantial portion of the palatal ridge are missing.

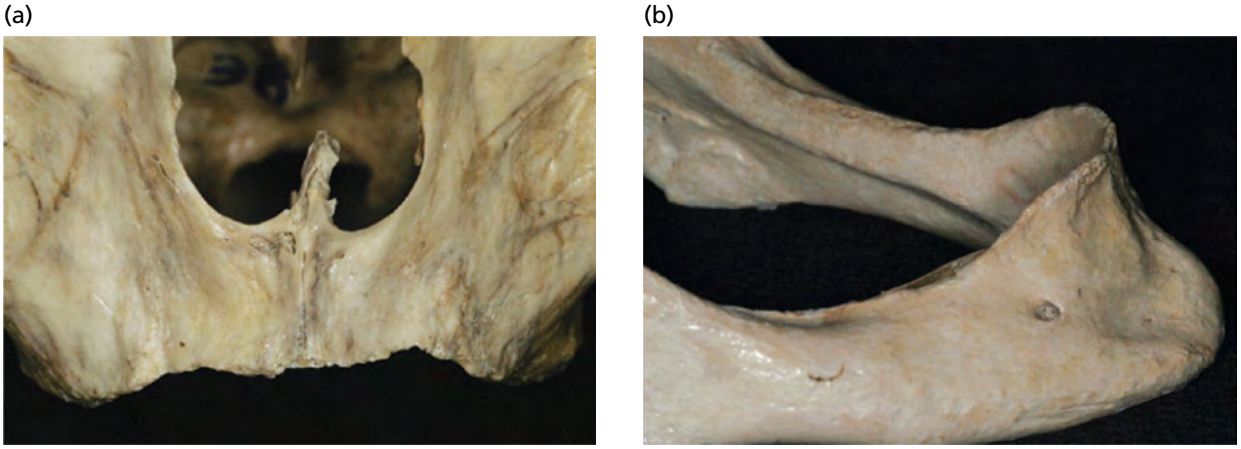

Fig. 3-4 Buccal aspect of a skull preparation illustrating a fully edentulous maxilla (a) and mandible (b). The small segments of the alveolar ridge that still remain are extremely thin in the buccopalatal/-lingual direction.

incisor and premolar sites of the maxilla following tooth removal. The authors obtained cone-beam computed tomograms from fully healed extraction sites (>1 year) and compared such scans with the contralateral pristine tooth sites. The study disclosed that all parameters had been significantly reduced following tooth removal. Thus, the overall (1) cross-sectional area was reduced from 99 to 65 mm^2, (2) the height from 11.5 to 9.5 mm, and (3) the width from about 9 to 3 mm (marginal third), 9 to 5 mm (middle portion), and 9 to 6 mm (apical portion).

The information provided by Pietrokovski and Massler (1967), Schropp *et al*. (2003) and Misawa *et al*. (2016) suggest that if an alveolar process includes a tooth that has a horizontal width of, for example, 12 mm, the edentulous site will be only 6 mm wide 12 months after healing following tooth extraction. During this 12-month interval, 4 mm of tissue will be lost from the buccal and 2 mm from the lingual aspect of the site.

In a clinical study (Sanz *et al*. 2010; Tomasi *et al*. 2010) it was observed that the degree of early (4 months) resorption of the buccal bone plate following tooth extraction was dependent on its original dimension. Thus, bone plates that were <1 mm wide lost substantially more dimension (width and height) than plates that were >1 mm wide.

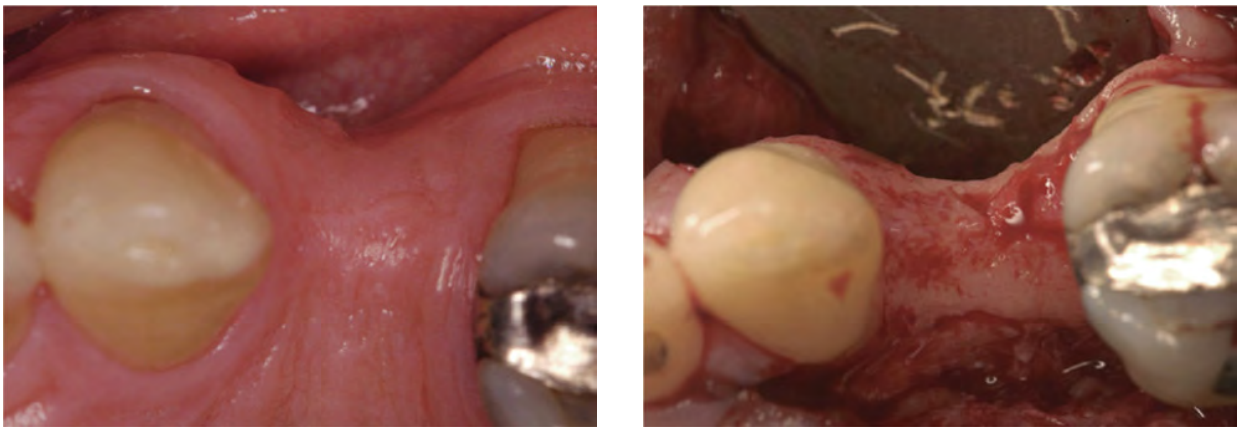

Fig. 3-6 Clinical view of an edentulous ridge in the maxillary premolar region. The premolar was extracted several years before the clinical documentation was made. (a) Note the presence of a buccal invagination of the ridge. (b) Following flap elevation, the crest region of the severely resorbed buccal portion of the alveolar process is disclosed.

Table. 3-1 Average amount of resorption of tooth extraction in different tooth areas.[a]

Tooth	Average amount of resorption (mm)		Difference
	Buccal surface	Lingual/ palatal surface	
Mandibular teeth			
Central incisor	2.08	0.91	1.17
Lateral incisor	3.54	1.41	2.13
Canine	3.25	1.59	1.66
First premolar	3.45	1.40	2.05
Second premolar	3.28	0.75	2.53
First molar	4.69	2.79	1.90
Second molar	4.30	3.00	1.30
Maxillary teeth			
Central incisor	3.03	1.46	1.57
Lateral incisor	3.47	0.86	2.61
Canine	3.33	1.91	1.42
First premolar	3.33	2.04	1.29
Second premolar	2.58	1.62	0.96
First molar	5.25	3.12	2.13

[a] "The amount of resorption was greater along the buccal surface than along the lingual or palatal surface in every specimen examined, although the absolute amounts and differences varied very widely. This caused a shift in the center of the edentulous ridge toward the lingual or palatal side of the ridge with a concomitant *decrease* in arch length in the mandible as well as the maxillae" (Pietrokovski & Massler 1967).

In this context it is important to acknowledge that the buccal bone plate in the frontal tooth region in humans is frequently (>80% of sites) <1 mm wide (Braut *et al*. 2011; Januário *et al*. 2011; Nowzari *et al*. 2012). Hence, it can be anticipated that tooth loss in this part of the dentition may result in marked dimension alterations (horizontal as well as vertical) of the ridge and that this in turn may cause esthetic concerns.

Conclusion: The extraction of single as well as multiple teeth induces a series of adaptive changes in the soft and hard tissues that result in an overall regression of the edentulous site(s). Resorption appears to be more pronounced at the buccal than at the lingual/palatal aspects of the ridge.

It should be realized that the alveolar process might also undergo change as the result of tooth-related disease processes, such as forms of marginal periodontitis, as well as periapical periodontitis. Furthermore, traumatic injuries (including from improper tooth removal techniques) may cause marked damage to the alveolar process of the maxilla and mandible.

Remaining bone in the edentulous ridge

In the publication by Schropp *et al*. (2003), bone tissue formation in single extraction sockets was studied by means of subtraction radiography. Thus, radiographs of the study sites were obtained using a standardized technique immediately after tooth extraction and then after 3, 6, and 12 months of healing (Fig. 3-7). It was observed that in the first few months, some bone loss (height) took place in the alveolar crest region. Most of the bone gain in the socket occurred in the first 3 months. There was additional gain of bone in the socket between 3 and 6 months. In the interval between 6 and 12 months, the newly formed bone obviously remodeled and the amount of mineralized tissue was reduced. In other words, in the later phases of socket healing, small amounts of mineralized tissue may have remained in the center of the edentulous site.

The bony part of the edentulous ridge in humans was examined in biopsies sampled from the posterior portions of the jaw by Lindhe *et al*. (2012). The peripheral borders of the ridge were consistently lined with dense cortical bone. More central parts harbored cancellous bone and included trabeculae made up mainly of lamellar bone (Fig. 3-8a). The trabeculae

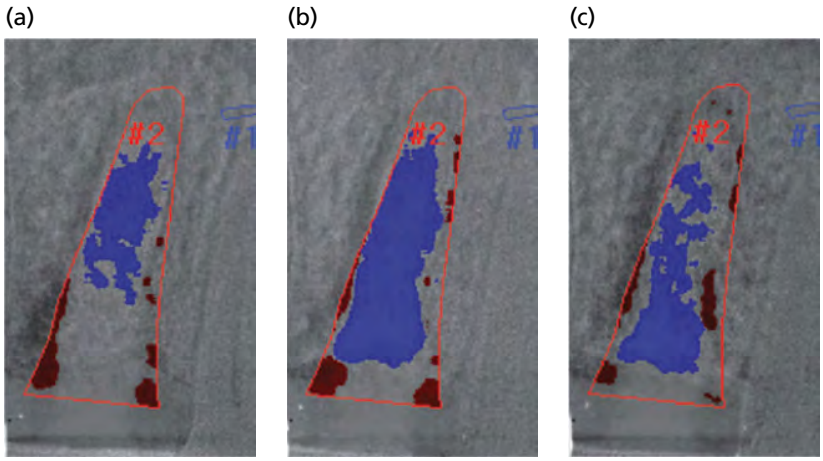

Fig. 3-7 Radiographic (subtraction radiography) images of an extraction site obtained after (a) 3 months, (b) 6 months, and (c) 12 months of healing. The blue color represents areas of new bone formation. During the first 6 months, the deposition of new bone was intense. Between 6 and 12 months, some of the newly formed bone was remodeled. Fig. 3-8 Histologic sections of an edentulous site obtained from the maxillary premolar region in man. (a) The marginal portion of the ridge (BC) is protected by a cortical cap made up of lamellar bone, while more central regions house the cancellous bone (CB). (b) The cancellous bone is characterized by the trabeculae of mineralized bone (T) within the bone marrow (BM) compartment.

that were embedded in bone marrow varied in shape, and frequently had a haphazard orientation. The bone marrow was dominated by adipocytes, vascular structures, and scattered inflammatory cells. The hard tissue component of the ridge was comprised of a mixture of mineralized bone (about 60%), bone marrow (about 20%), and fibrous tissue (about 15%) (Fig. 3-8b).

Classification of remaining bone

Based on the volume of remaining mineralized bone, the edentulous sites may, according to Lekholm and Zarb (1985), be classified into five different groups (Fig. 3-9). In groups A and B, substantial amounts

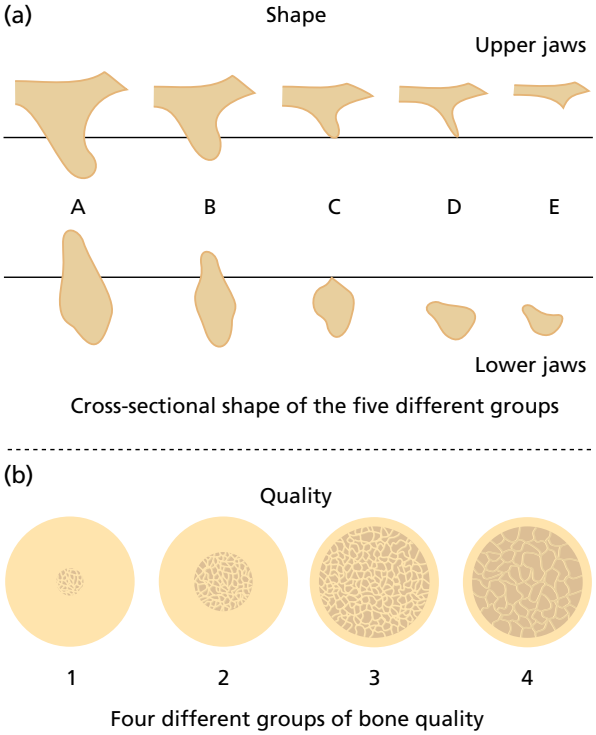

Fig. 3-9 (a) A classification of residual jaw shape and (b) jaw bone quality. (Source: Lekholm & Zarb 1985. Reproduced from Quintessence.)

of the ridge still remain, whereas in groups C, D, and E, only minute amounts of hard tissue remain. Lekholm and Zarb (1985) also classified the "quality" of the bone in the edentulous site. Class 1 and class 2 characterized a location in which the walls – the cortical plates – of the site are thick and the volume of bone marrow is small. Relatively thin walls of cortical bone, however, will border sites that belong to class 3 and class 4, while the amount of cancellous bone (spongiosa), including trabeculae of lamellar bone and marrow, is large.

Topography of the alveolar process

The alveolar process that houses the roots of the teeth extends from the basal bone (Fig. 3-10a) of the maxilla and the mandible. The shape and dimensions (height and width) of the basal bone vary considerably from subject to subject (Figs. 3-10a, b) and from site to site in the same individual. There is no distinct boundary between the alveolar process and the basal bone of the jaws.

At sites of the jaws where the teeth erupt in "normal" orientation in the developing alveolar process, hard tissue will be present on the facial (buccal) as well as on the lingual (palatal) aspect of the roots (Fig. 3-10c). However, at sites where the teeth erupt with a facial orientation, the facial (buccal) bone of the alveolar process will become thin and at times even disappear (dehiscence, fenestration) (Fig. 3-10d).

The outer walls of the alveolar process – facial (buccal), marginal, and lingual (palatal) aspects – are continuous with the outer walls of the basal bone. The walls are comprised of dense cortical bone, while more central portions harbor trabecular bone (radiographic term; spongy bone, anatomic term; cancellous bone, histologic term) that contains bone trabeculae within the bone marrow.

The cortical walls (plates) of the alveolar process are continuous with the bone that lines the sockets, that is the alveolar bone proper or the bundle bone (see Fig. 3-2b). The cortical plates (the outer walls) of the alveolar process meet the alveolar bone proper at

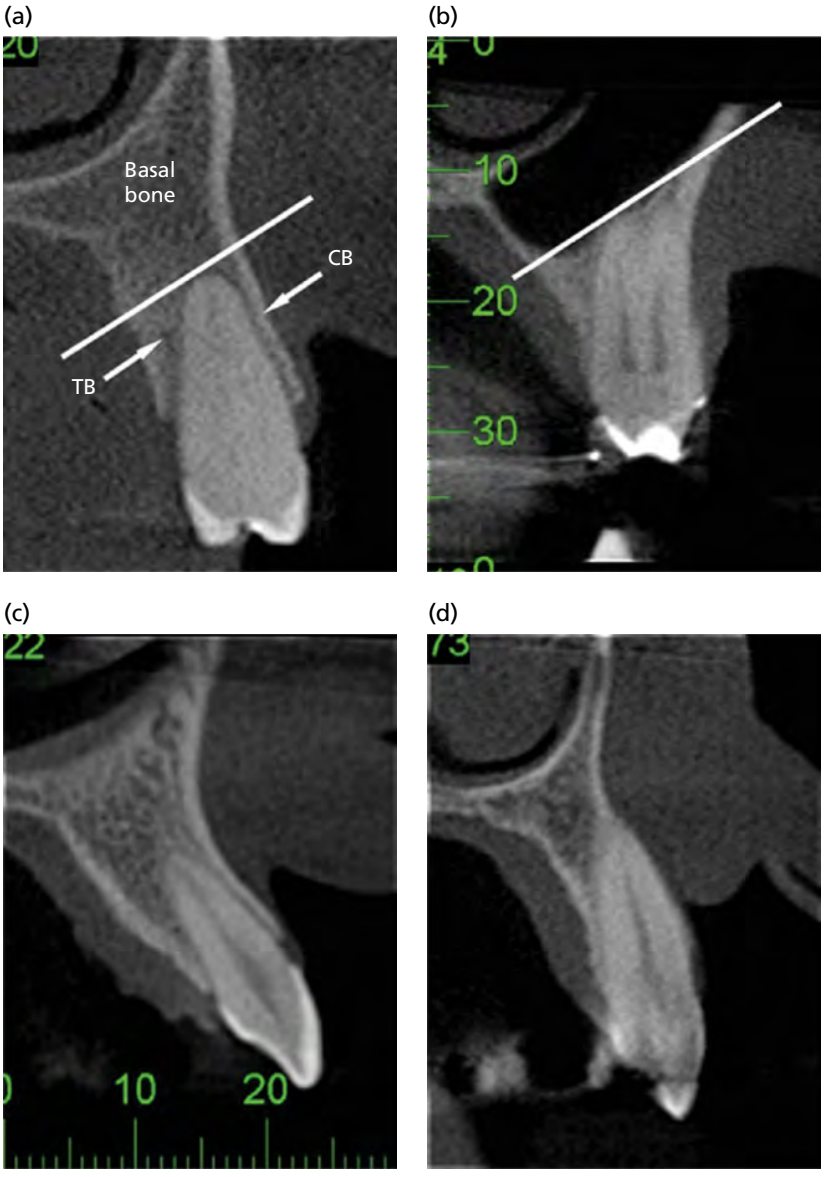

Fig. 3-10 (a) Cone-beam tomogram of the premolar region of the maxilla. The alveolar process is continuous with the voluminous basal bone of the maxilla. CB, cortical bone plate; TB, trabecular bone. (b) Cone-beam tomogram of the premolar region of the maxilla. Note that at this site the dimension of the basal bone is very small. (c) Tomogram of an anterior maxillary tooth with a "normal" direction of eruption. The incisor resides within the bony compartment of the alveolar process. (d) Tomogram of a canine tooth that erupted in a facial orientation. The facial (buccal) bone of the alveolar process is thin or even absent.

the crest of the interdental septum. In subjects (sites) with healthy periodontium, the crest of the septum is located 1–2 mm apical of the cementoenamel junction.

In some portions of the dentition (such as in the symphysis region of the mandible), the trabecular bone component of the alveolar process may be absent.

From an alveolar process to an edentulous ridge

The alterations that occur in the alveolar process following the extraction of a single tooth can, for didactic reasons, be divided in two interrelated series of events, namely *intra-alveolar processes* and *extra-alveolar processes*.

Intra-alveolar processes

The healing of extraction sockets in human volunteers was studied by, for example, Amler (1969) and Evian *et al*. (1982). Although the biopsy technique used by Amler only allowed the study of healing in the marginal portions of the empty socket, his findings are often referred to.

Amler stated that following tooth extraction, the first 24 hours are characterized by the formation of a *blood clot* in the socket. Within 2–3 days the blood clot is gradually replaced with *granulation tissue*. After 4–5 days, the *epithelium* from the margins of the soft tissue starts to proliferate to cover the granulation tissue in the socket. One week after extraction, the socket contains granulation tissue and *young connective tissue*, and *osteoid* formation is ongoing in the apical portion of the socket. After 3 weeks, the socket contains connective tissue and there are signs of mineralization of the osteoid. The *epithelium* covers the wound. After 6 weeks of healing, bone formation in the socket is pronounced and trabeculae of newly formed bone can be seen.

Amler's study was of short duration, so it could only evaluate events that took place in the marginal portion of the healing socket. His experimental data did not include the important later phase of socket healing that involves the processes of modeling and remodeling of the newly formed tissue in various parts of the alveolus. Thus, the tissue composition of the fully healed extraction site was not documented in the study.

In a later and longer-term study, Trombelli *et al*. (2008) examined socket healing in biopsies sampled during a 6-month period from human volunteers. They confirmed most of Amler's findings and reported that in the early healing phase (tissue modeling), the socket was filled with granulation tissue that was subsequently replaced with provisional connective tissue and woven bone. In biopsies sampled in later phases of healing, it was observed that the process by which woven bone was replaced by lamellar bone and marrow, that is remodeling, was slow and exhibited great individual variation. In only a limited number of specimens representing 6 months of healing had woven bone been replaced with bone marrow and trabeculae of lamellar bone. It can be assumed therefore that tissue modeling following tooth extraction in humans is a rather rapid process, while the subsequent remodeling is slow and may take years to be completed.

The results from experiments using the dog model (Cardaropoli *et al*. 2003; Araújo & Lindhe 2005) will be used in this chapter to describe details of the various phases of socket healing, including processes of both modeling and remodeling. It should be remembered that healing of the postextraction sites in these animal studies, including phases of modeling and remodeling, was a rapid process compared to socket healing in humans. Thus, the extraction socket was in most instances completely healed (filled with cancellous bone) after 2–3 months.

The model

Buccal and lingual full-thickness flaps are elevated and the distal roots of mandibular premolars extracted (Fig. 3-11a). The mucosal flaps are subsequently replaced to provide soft tissue coverage of the fresh extraction wound (Fig. 3-11b). Healing of the experimental sites is monitored in biopsy specimens obtained at time intervals varying from 1 day to 6 months (Fig. 3-11c).

Overall pattern of socket healing

Figure 3-12 shows a mesiodistal section of a fresh extraction socket bordered by adjacent roots. The socket walls are continuous with the alveolar bone proper of the neighboring teeth. The tissue inside the interdental (inter-radicular) septa is made up of cancellous bone and includes trabeculae of lamellar bone within bone marrow.

The empty socket is first filled with blood and a *coagulum* (clot) forms (Fig. 3-13a). Inflammatory cells (polymorphonuclear leukocytes and monocytes/macrophages) migrate into the coagulum and start to phagocytose elements of necrotic tissue. The process of wound cleansing is initiated (Fig. 3-13b). Sprouts of newly formed vessels and mesenchymal cells (from the severed periodontal ligament) enter the coagulum and *granulation tissue* is formed. The granulation tissue is gradually replaced with *provisional connective tissue* (Fig. 3-13c) and subsequently immature bone (*woven bone*) is laid down (Fig. 3-13d). The hard tissue walls of the socket – the alveolar bone proper or the bundle bone – are gradually resorbed and the socket becomes filled with immature woven bone (Fig. 3-13e). The initial phase of the healing process (tissue modeling) is now complete. In subsequent phases, the woven

(b) Mucosal, full-thickness flaps were replaced and sutured to close the entrance of the socket. (c) Site after 6 months of healing. Note the saddle-shaped outline (loss of tissue) of the alveolar crest region.

Fig. 3-12 Histologic section showing the mesiodistal aspect of a fresh extraction socket bordered by two neighboring roots. Note that the alveolar bone from the tooth sites is continuous with the walls of the empty socket. The interdental septum contains cancellous bone including trabeculae of lamellar bone and marrow.

bone in the socket will be gradually remodeled into lamellar bone and marrow (Fig. 3-13f–h).

Important events in socket healing

Blood clotting

Immediately after tooth extraction, blood from the severed vessels will fill the socket. Proteins derived from vessels and damaged cells initiate a series of events that lead to the formation of a fibrin network (Fig. 3-14). *Platelets* form aggregates and interact with the fibrin network to produce a *coagulum* (a blood clot) that effectively plugs the severed blood vessels and stops the bleeding. The blood clot acts as a physical matrix that directs cellular movements and it contains substances that are of importance for the forthcoming healing process. Thus, the clot contains substances (i.e. *growth factors*) that (1) influence mesenchymal cells and (2) enhance the activity of inflammatory cells. Such substances will thus induce and amplify the migration of various types of cells into the socket wound, as well as their proliferation, differentiation, and synthetic activity within the coagulum.

Although the blood clot is crucial in the initial phase of wound healing, its removal is mandatory

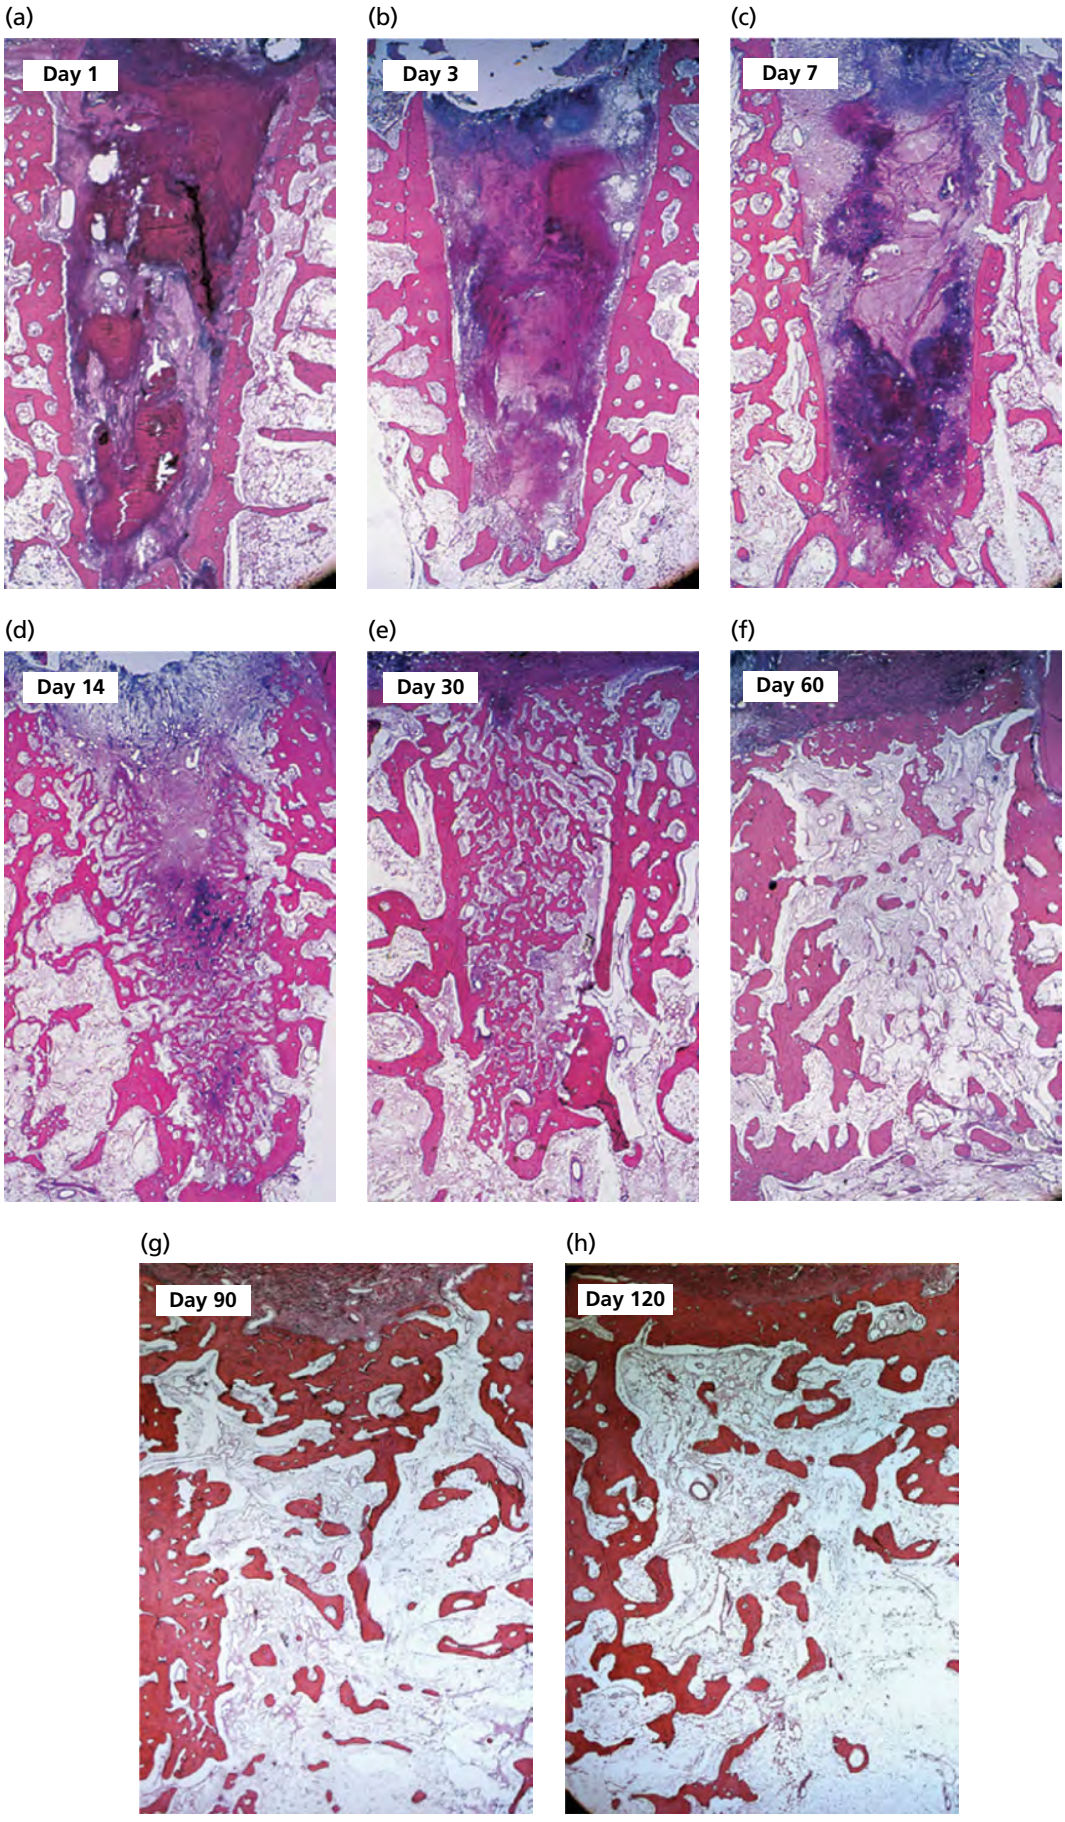

Fig. 3-13 (a–h) Overall pattern of bone formation in an extraction socket. For details see text.

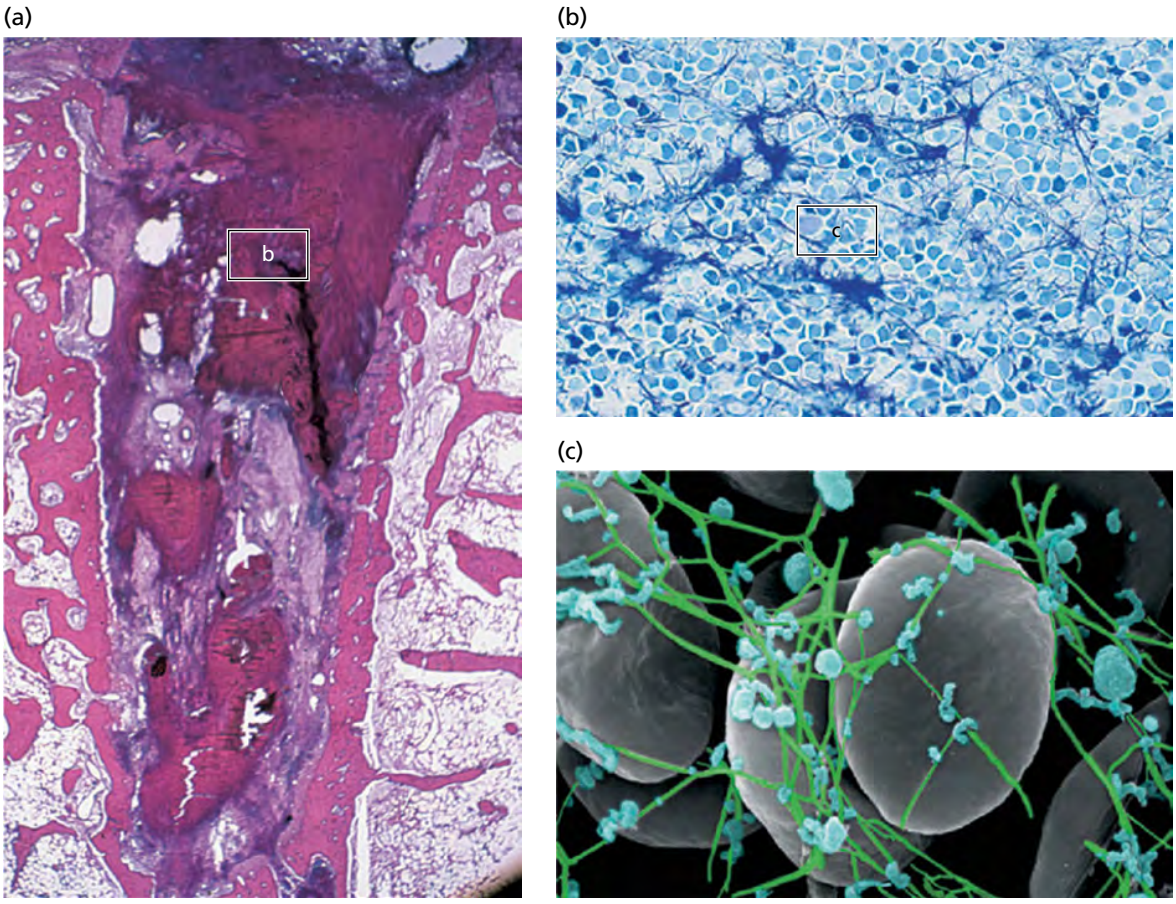

Fig. 3-14 Histologic section (mesiodistal aspect) representing 1 day of healing (a). The socket is occupied with a blood clot that contains large numbers of erythrocytes (b) entrapped in a fibrin network, as well as platelets [blue in (c)].

to allow the formation of new tissue. Thus, within a few days after the tooth extraction, the blood clot will start to break down, that is, the process of "fibrinolysis" is initiated (Fig. 3-15).

Wound cleansing

Neutrophils and macrophages migrate into the wound, engulf bacteria and damaged tissue, and clean the site before the formation of new tissue can start. The neutrophils enter the wound early, while macrophages appear somewhat later. The macrophages are not only involved in the cleaning of the wound but they also release growth factors and cytokines that further promote the migration, proliferation, and differentiation of mesenchymal cells. Once the debris has been removed and the wound has been "sterilized", the neutrophils undergo a programmed cell death (*apoptosis*) and are removed from the site through the action of macrophages. The macrophages subsequently withdraw from the wound.

Tissue formation

Sprouts of vascular structures (from the severed periodontal ligament) as well as mesenchymal, fibroblast-like cells (from the periodontal ligament and from adjacent bone marrow regions) enter the socket. The mesenchymal cells start to proliferate and deposit matrix components in an extracellular location (Fig. 3-16); *granulation tissue* will gradually replace the blood clot. This granulation tissue eventually contains macrophages and a large number of fibroblast-like cells, as well as numerous newly formed blood vessels. The fibroblast-like cells continue to (1) release growth factors, (2) proliferate, and (3) deposit a new extracellular matrix that guides the ingrowth of additional cells and allows the further differentiation of the tissue. The newly formed vessels provide the oxygen and nutrients that are needed for the increasing number of cells that occur in the new tissue. The intense synthesis of matrix components exhibited by the mesenchymal cells is called *fibroplasia*, while the formation of new vessels is called *angiogenesis*. A *provisional connective tissue* is established through the combination of fibroplasia and angiogenesis (Fig. 3-17).

The transition of the provisional connective tissue into bone tissue occurs along the vascular structures. Thus, osteoprogenitor cells (e.g. pericytes) migrate and gather in the vicinity of the vessels. They differentiate into osteoblasts that produce a matrix of collagen fibers, which takes on a woven pattern. The *osteoid* is formed. The process of mineralization is initiated within the osteoid. The osteoblasts continue to lay down osteoid and occasionally such cells are trapped in the matrix and become osteocytes. This newly formed bone is called *woven bone* (Figs. 3-17, 3-18).

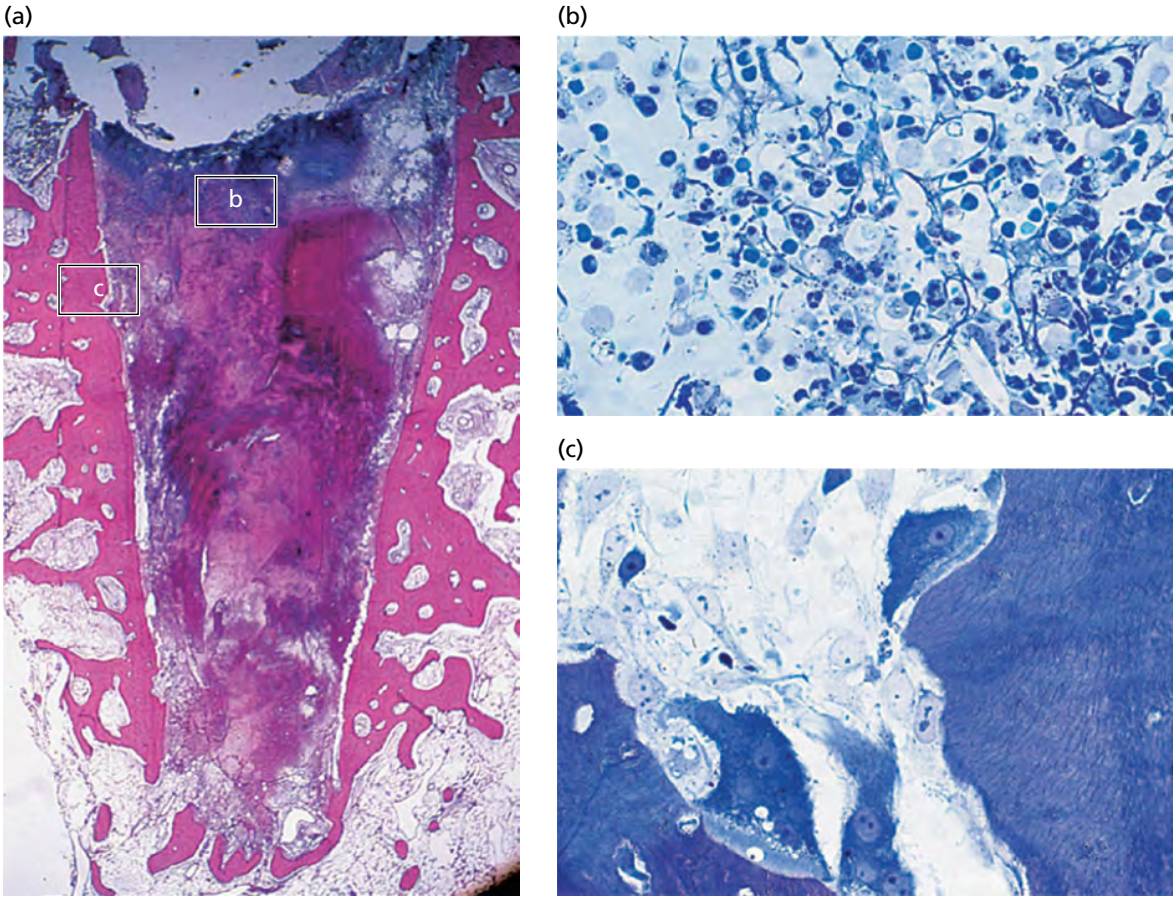

Fig. 3-15 (a) Histologic section (mesiodistal aspect) representing 3 days of healing. (b) Note the presence of neutrophils and macrophages that are engaged in wound cleansing and the breakdown of the blood clot. (c) Osteoclastic activity occurs on the surface of the old bone in the socket walls.

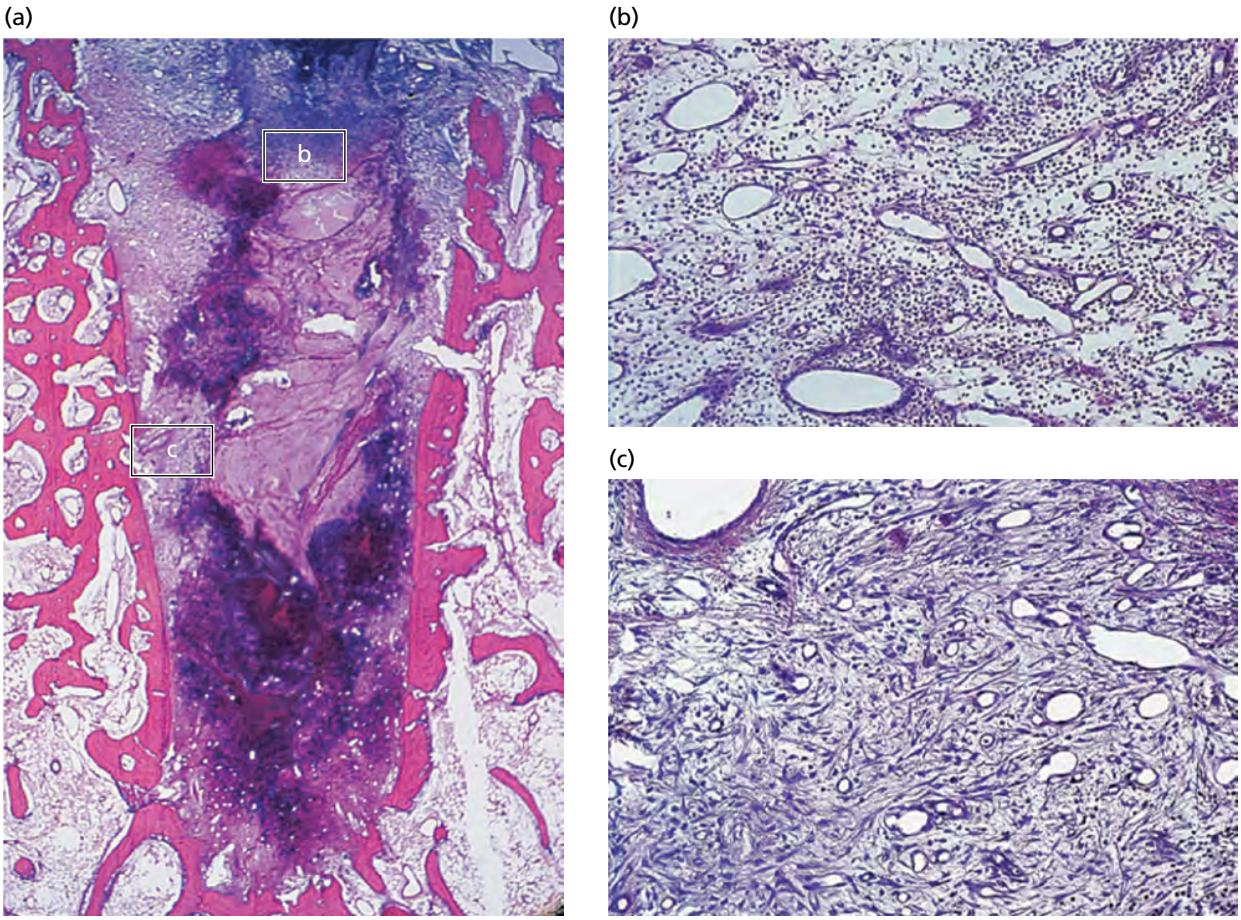

Fig. 3-16 (a) Histologic section (mesiodistal aspect) representing 7 days of healing. (b) Note the presence of a richly vascularized early granulation tissue with large numbers of inflammatory cells in the upper portion of the socket. (c) In more apical areas, a tissue including large numbers of fibroblast-like cells is present (late granulation tissue).

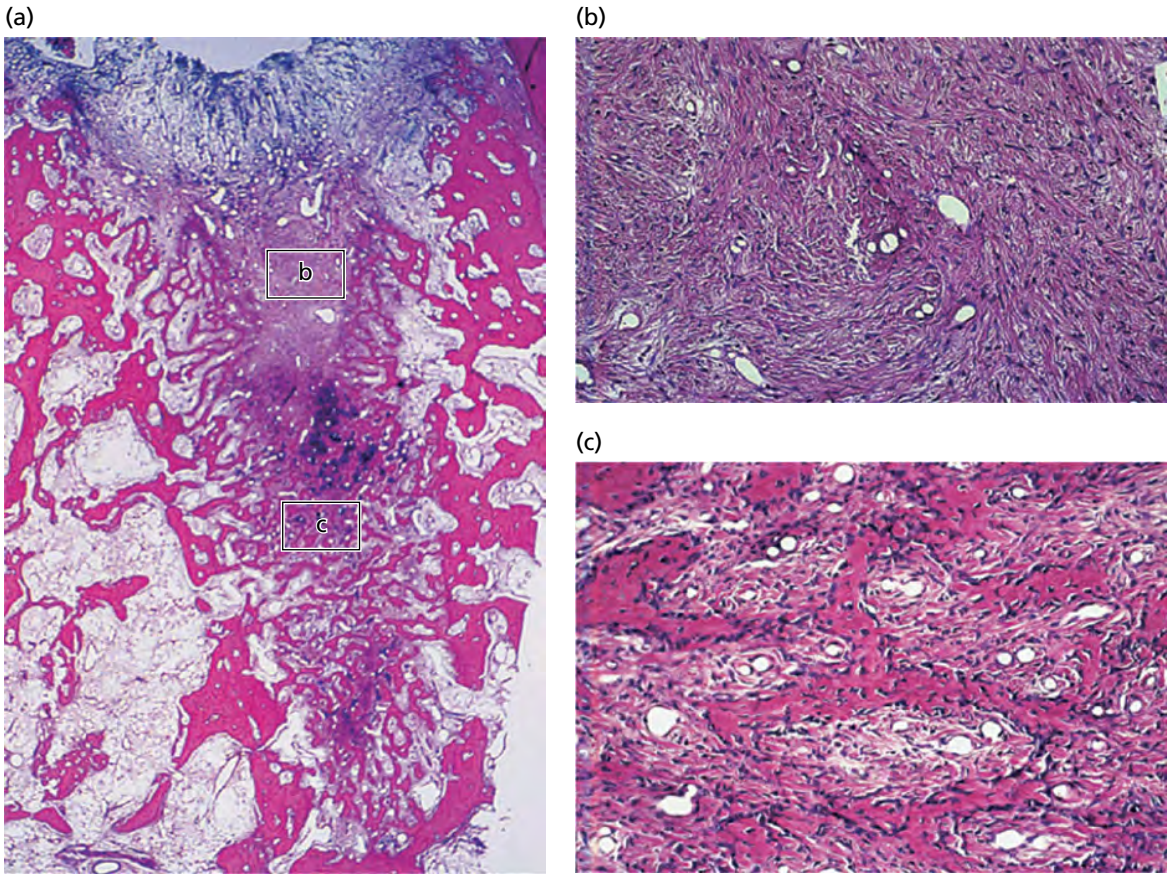

Fig. 3-17 (a) Histologic section (mesiodistal aspect) representing 14 days of healing. (b) In the marginal portion of the wound, a provisional connective tissue rich in fibroblast-like cells is present. (c) The formation of woven bone has at this time interval already begun in the apical and lateral regions of the socket.

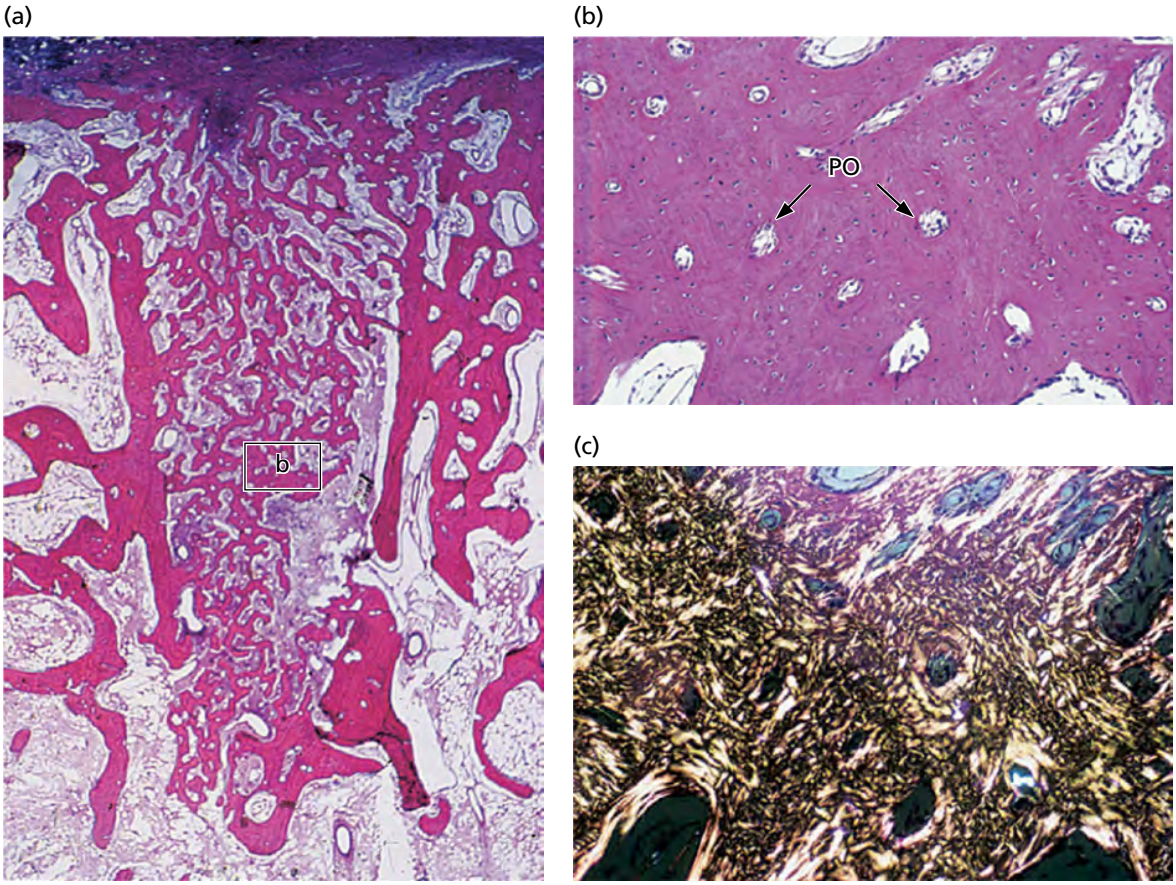

Fig. 3-18 (a) Histologic section (mesiodistal aspect) representing 30 days of healing. The socket is filled with woven bone. (b) Woven bone contains a large number of cells and primary osteons (PO). (c) The woven pattern of the collagen fibers of this type of bone is illustrated (polarized light).

The woven bone is the first type of bone to be formed and is characterized by (1) its rapid deposition as finger-like projections along the route of vessels, (2) the poorly organized collagen matrix, (3) the large number of osteoblasts that are trapped in its mineralized matrix, and (4) its low load-bearing capacity. Trabeculae of woven bone are shaped around and encircle the vessel. The trabeculae become thicker through the deposition of additional woven bone. Cells (osteocytes) become entrapped in the bone tissue and the first set of osteons, the *primary osteons*, are organized. The woven bone is occasionally reinforced by the deposition of so-called *parallel-fibered bone* (collagen fibers organized not in a woven but in a concentric pattern).

It is important to realize that during this early phase of healing most of the bone tissue in the walls of the socket (the bundle bone) is removed.

Tissue modeling and remodeling

The initial bone formation in this dog model is a fast process. Within a few weeks, the entire extraction socket is filled with woven bone or, as this tissue is also called, *primary bone spongiosa*. The woven bone offers (1) a stable scaffold, (2) a solid surface, (3) a source of osteoprogenitor cells, and (4) an ample blood supply for cell function and matrix mineralization.

The woven bone with its primary osteons is gradually replaced with lamellar bone and bone marrow (Fig. 3-19). In this process, the primary osteons are replaced with *secondary osteons*. The woven bone is first resorbed to a certain level. The level of the resorption front will establish a so-called *reversal line*, which is also the level from which new bone with secondary osteons will form (Fig. 3-20). Although this remodeling may start early during socket healing, it will take several months until all woven bone in the extraction socket has been replaced with lamellar bone and marrow.

An important part of socket healing involves the formation of a *hard tissue cap* that will close the marginal entrance to the socket. This cap is initially comprised of woven bone (Fig. 3-21a), but is subsequently remodeled and replaced with lamellar bone that becomes continuous with the cortical plate at the periphery of the edentulous site (Fig. 3-21b). This process is called corticalization.

The wound is now healed, but the tissues in the site will continue to adapt to functional demands.

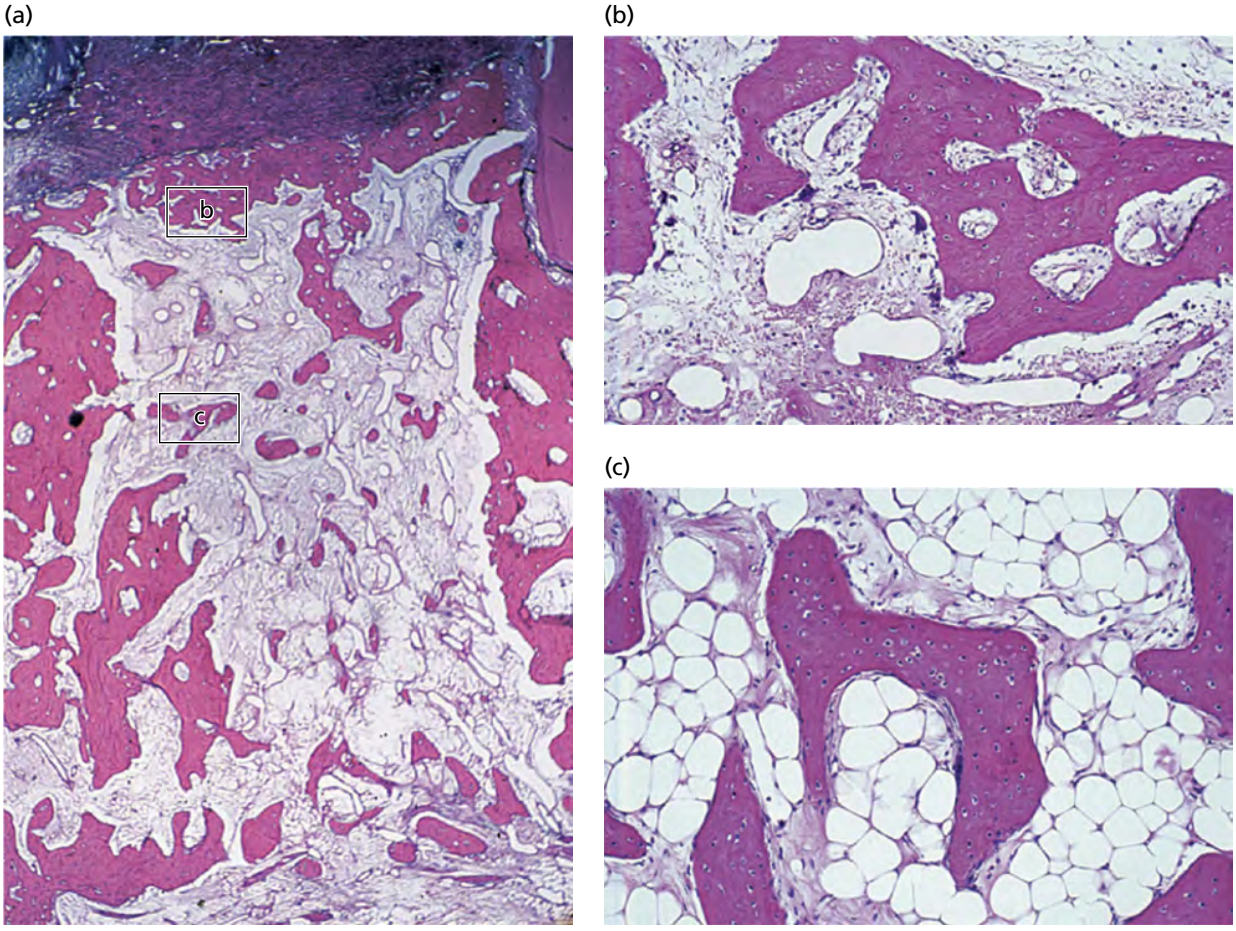

Fig. 3-19 (a) Histologic section (mesiodistal aspect) representing 60 days of healing. (b) A large portion of the woven bone has been replaced with bone marrow. (c) Note the presence of a large number of adipocytes residing in a tissue that still contains woven bone.

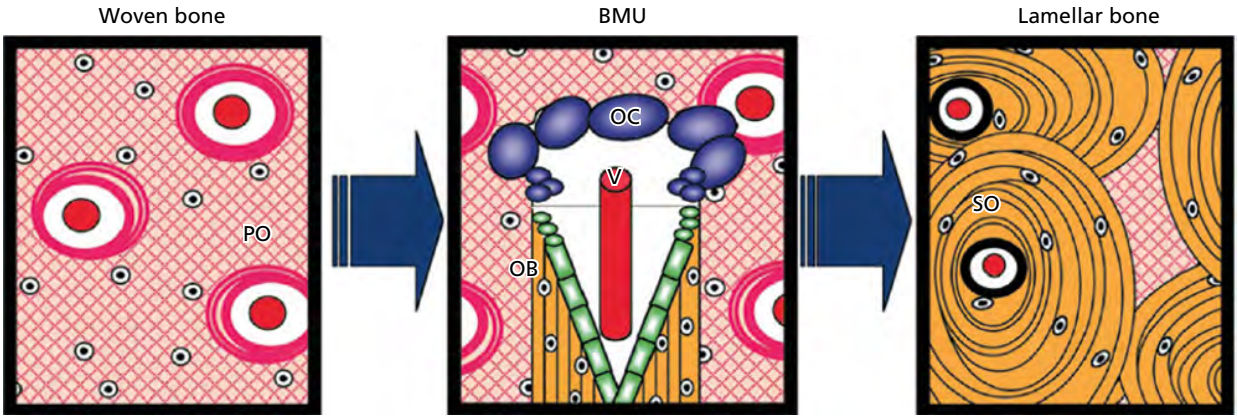

Fig. 3-20 Woven bone is replaced by lamellar bone. Woven bone with primary osteons (PO) is substituted by lamellar bone in a process that involves the presence of bone multicellular units (BMU). The BMU contains osteoclasts (OC), as well as vascular structures (V) and osteoblasts (OB). Thus, the osteoblasts in the BMU produce bone tissue in a concentric fashion around the vessel, and lamellar bone with secondary osteons (SO) is formed.

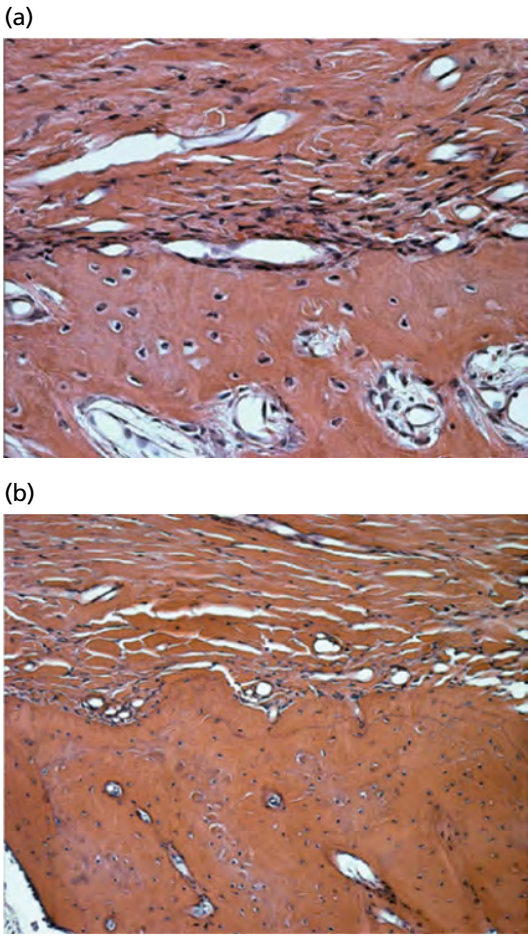

Fig. 3-21 Histologic sections (mesiodistal aspect) describing the hard tissue that has formed at the entrance of a healing extraction socket and the process of corticalization. (a) Woven bone with primary osteons occupies the socket entrance after 60 days of healing. (b) After 180 days, the woven bone has mainly been replaced with lamellar bone.

Since there is no stress from forces elicited during mastication and other occlusal contacts, there is no demand on the mineralized bone in the areas previously occupied by the tooth. Thus, in this model the socket apical of the hard tissue cap will remodel mainly into marrow.

Extra-alveolar processes

In an experiment using the dog model (Araújo & Lindhe 2005), alterations in the profile of the edentulous ridge that occurred following tooth extraction were carefully examined. In this study the third and fourth mandibular premolars were hemisected. Buccal and lingual full-thickness flaps were raised; the distal roots were carefully removed. The flaps were replaced and sutured to cover the fresh extraction socket. Biopsy specimens, including an individual extraction socket and adjacent roots, were obtained after 1, 2, 4, and 8 weeks of healing. The blocks were sectioned in the *buccolingual* plane.

- *1 week after tooth extraction* (Fig. 3-22). At this interval the socket is occupied by a coagulum. Furthermore, a large number of osteoclasts can be seen on the outside as well as on the inside of the buccal and lingual bone walls. The presence of osteoclasts on the inner surface of the socket walls indicates that the bundle bone is being resorbed.
- *2 weeks after tooth extraction* (Fig. 3-23). Newly formed immature bone (woven bone) resides in the apical and lateral parts of the socket, while more central and marginal portions are occupied by a provisional connective tissue. In the marginal and outer portions of the socket walls, numerous osteoclasts can be seen. In several parts of the socket walls the bundle bone has been replaced with woven bone.
- *4 weeks after tooth extraction* (Fig. 3-24). The entire socket is occupied with woven bone at this stage of healing. Large numbers of osteoclasts are present in the outer and marginal portions of the hard tissue walls. Osteoclasts also line the trabeculae of woven bone present in the central and lateral aspects of the socket. In other words, the newly formed woven bone is being replaced with a more mature type of bone.
- *8 weeks after tooth extraction* (Fig. 3-25). A layer of cortical bone covers the entrance to the extraction site. Corticalization has occurred. The woven bone that was present in the socket at the 4-week

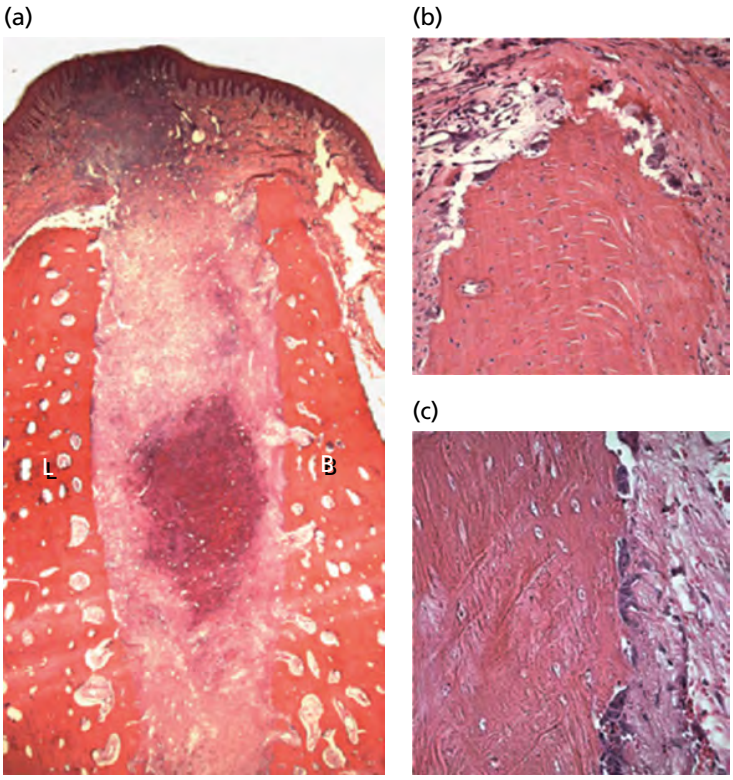

Fig. 3-22 (a) Histologic section (buccolingual aspect) of the socket after 1 week of healing. Note the presence of a large number of osteoclasts on the crestal portion (b) and inner portion (c) of the buccal wall. B, buccal bone; L, lingual bone.

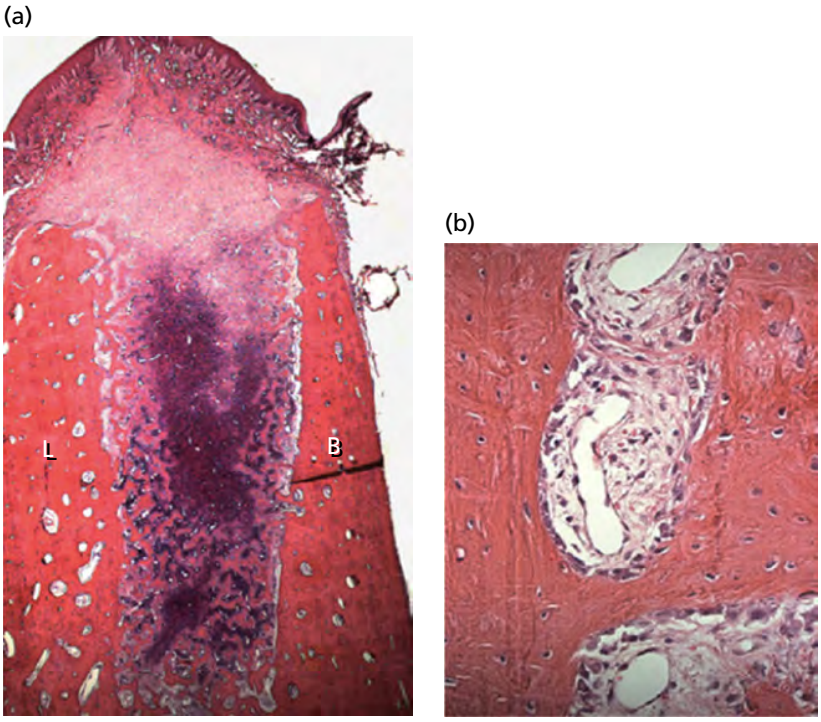

Fig. 3-23 (a) Histologic section (buccolingual aspect) of the socket after 2 weeks of healing. (b) Note that the bundle bone in the lingual aspect of the socket is being replaced with woven bone. B, buccal bone; L, lingual bone.

interval is replaced with bone marrow and some trabeculae of lamellar bone in the 8-week specimens. On the outside and on the top of the buccal and lingual bone wall there are signs of ongoing hard tissue resorption. The crest of the buccal bone wall is located apical of its lingual counterpart.

The relative change in the location of the crest of the buccal and lingual bone walls that took place during the 8 weeks of healing is illustrated in Fig. 3-26. While the level of the margin of the lingual wall remained reasonably unchanged, the margin of the buccal wall shifted several millimeters in an apical direction. The reason why more bone loss occurred in the buccal than in the lingual wall during socket healing in this animal model is not completely understood.

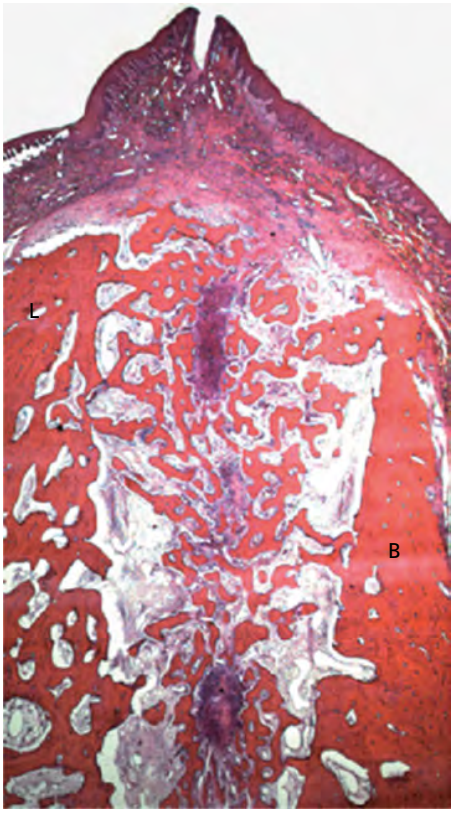

Fig. 3-24 Histologic section (buccolingual aspect) of the socket after 4 weeks of healing. The extraction socket is filled with woven bone. On the top of the buccal wall, the old bone in the crest region is being resorbed and replaced with either connective tissue or woven bone. B, buccal bone; L, lingual bone.

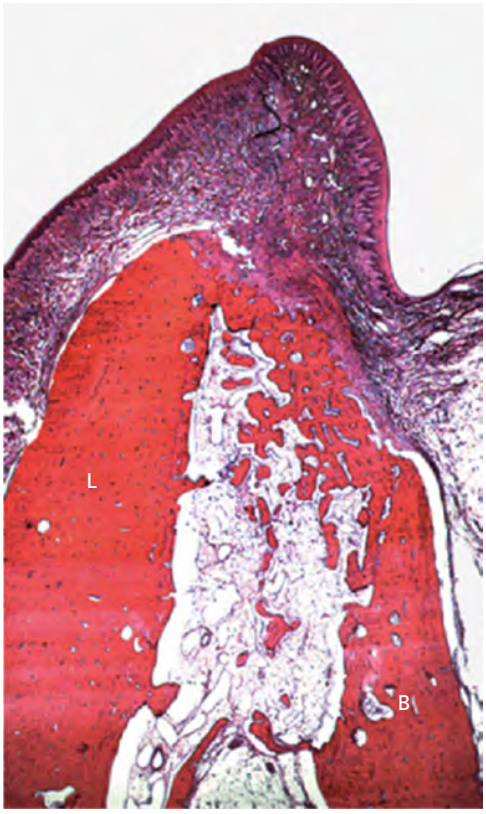

Fig. 3-25 Histologic section (buccolingual aspect) of the socket after 8 weeks of healing. The entrance of the socket is sealed with a cap of newly formed mineralized bone. Note that the crest of the buccal wall is located apical of the crest of the lingual wall. B, buccal bone; L, lingual bone.

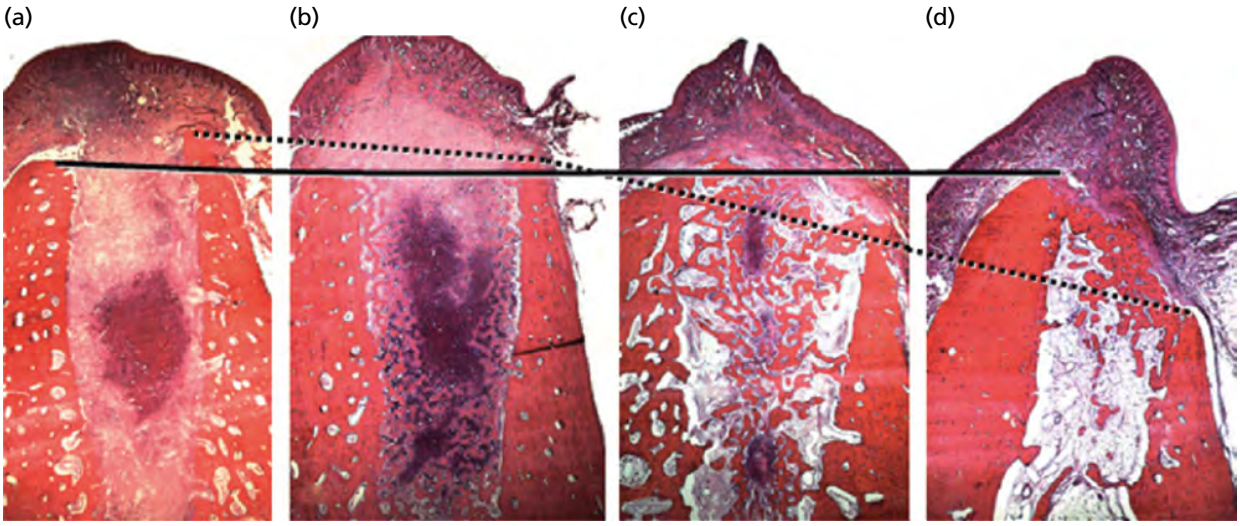

Fig. 3-26 Histologic sections (buccolingual aspects) showing the profile of the edentulous region in the dog after (a) 1, (b) 2, (c) 4, and (d) 8 weeks of healing following tooth extraction. While the marginal level of the lingual wall was maintained during the process of healing (solid line), the crest of the buccal wall was displaced >2 mm in the apical direction (dotted line).

Prior to tooth extraction, the marginal 1–2 mm of the crest of the thin buccal bone wall was occupied by bundle bone. Only a minor fraction of the crest of the wider lingual wall contained bundle bone. Bundle bone, as stated above, is a tooth-dependent tissue and will gradually disappear after tooth extraction. Thus, because there is relatively more bundle bone in the crest region of the buccal than of the lingual wall, hard tissue loss may become most pronounced in the buccal wall.

Topography of the edentulous ridge: summary

As described previously in this chapter, the processes of modeling and remodeling that occur following tooth extraction (loss) result in resorption of the various components of the previous alveolar process. The amount of tissue loss that occurs in these processes varies considerably from subject to subject and from site to site in the same individual (Figs. 3-27, 3-28).

As a rule, the resorption of the buccal bone wall is more pronounced than the resorption of the lingual/palatal wall and hence the center of the ridge will move in a lingual/palatal direction. In the extreme case, the entire alveolar process may be lost following tooth removal and then only the basal bone of the mandible and the maxilla may remain to constitute the ridge.

The outer (cortical) walls of the remaining portion of the alveolar ridge (basal bone and residues of the alveolar process) are comprised of lamellar bone. The cortical plates of the ridge often enclose the cancellous bone that harbors trabeculae of lamellar bone and marrow (Fig. 3-29). The bone marrow contains numerous vascular structures as well as adipocytes and pluripotent mesenchymal cells.

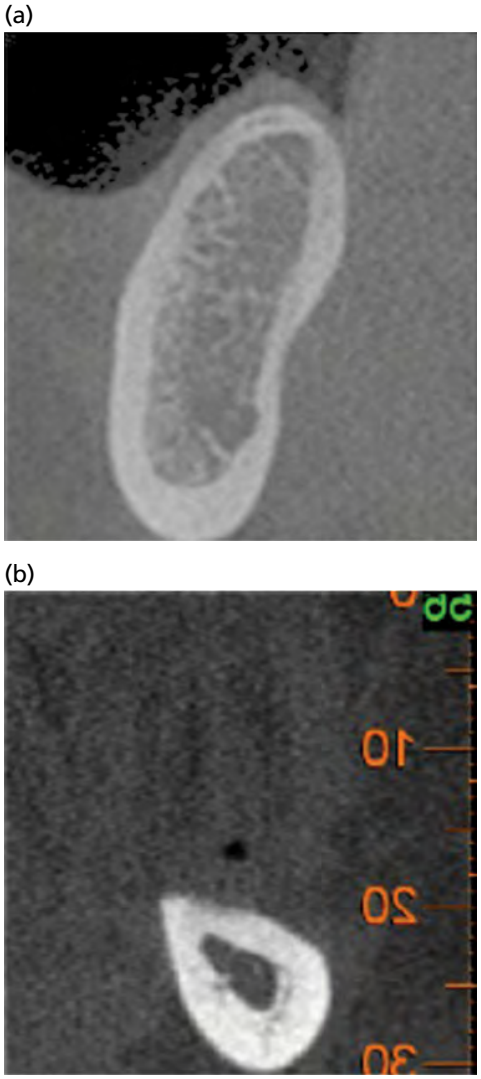

Fig. 3-28 Cone-beam computed tomograms illustrating edentulous regions of the first molar region of the mandible. (a) Remaining bone of the ridge is voluminous, is lined by dense cortical bone, and harbors large amounts of trabecular bone. (b) In this edentulous site, the entire alveolar process is lost and only the tissue of the corpus mandibulae remains.

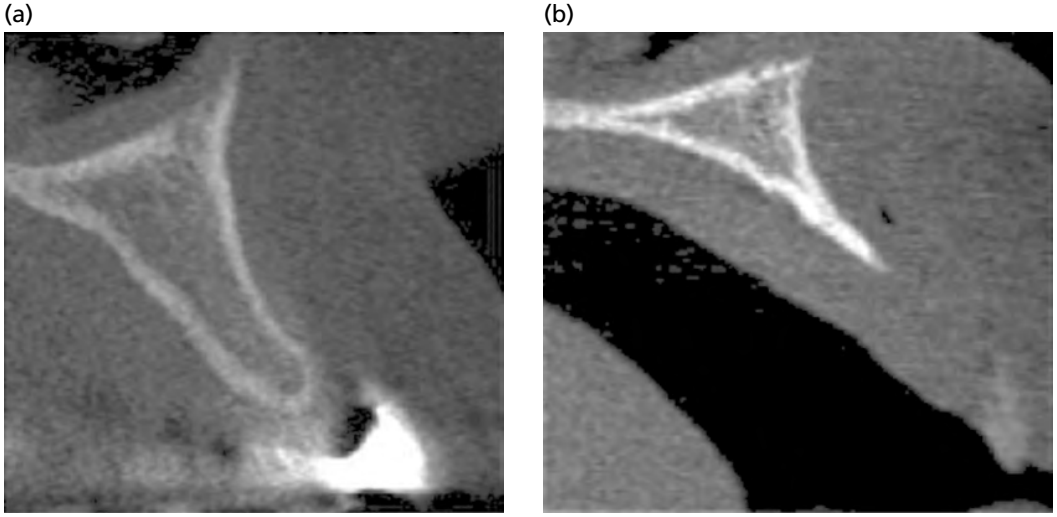

Fig. 3-27 Cone-beam computed tomograms that illustrate edentulous incisor sites of the maxilla with (a) large amounts of remaining hard tissue (cortical bone as well as trabecular bone) and (b) minute remnants of ridge tissue (only cortical bone).

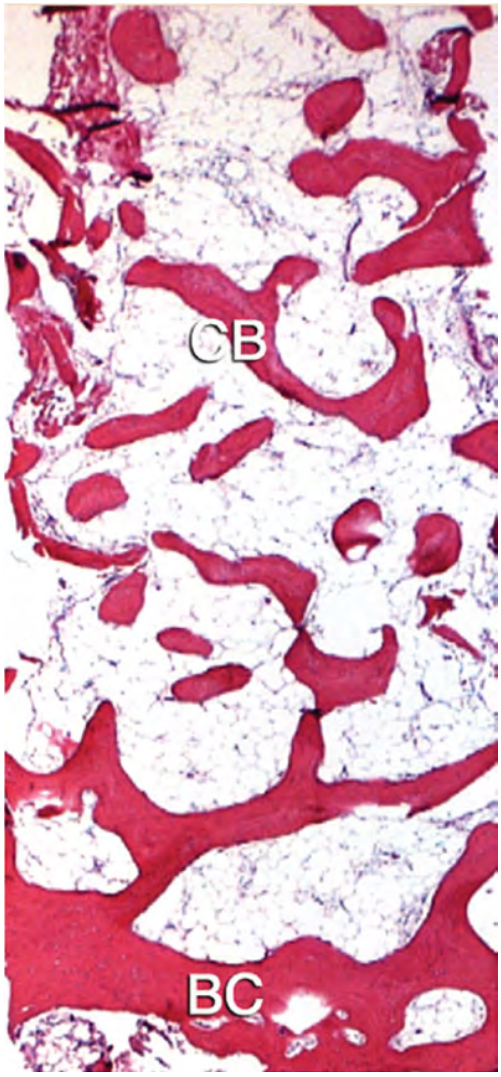

Fig. 3-29 Histologic section representing an edentulous maxilla. The biopsy was obtained >6 months postextraction. The marginal portion of the tissue (the bone crest [BC]) is comprised of dense lamellar bone, while more central portions harbor the cancellous bone (CB).

Depending on factors such as the type of jaw (maxilla or mandible), location (anterior, posterior) in the jaw, depth of the buccal and lingual vestibule, and amount of hard tissue resorption, the edentulous ridge may be lined with either masticatory, keratinized mucosa, or lining, non-keratinized mucosa.

Gingiva

Dimensions of the supracrestal attachment

A term traditionally used to describe the dimensions of the soft tissues that face the teeth was the *biologic width of the soft tissue attachment*. In a consensus report from the World Workshop on Periodontology (Jepsen *et al*. 2018), this term was replaced with the *supracrestal attachment*.

The development of the *biologic width/supracrestal attachment concept* was based on studies and analyses by, among others, Gottlieb (1921), Orban and Köhler (1924), and Sicher (1959), who documented that the soft tissue attached to the teeth was comprised of two parts, one of fibrous tissue and one of epithelium. In a publication by Gargiulo *et al*. (1961) called "Dimensions and relations of the dentogingival junction in humans", sections from autopsy block specimens that exhibited different degrees of "passive tooth eruption" (i.e. periodontal tissue breakdown) were examined. Histometric assessments were made to describe the length of the sulcus (not part of the attachment), the epithelial attachment (today called the junctional epithelium), and the connective tissue attachment (Fig. 4-1). It was observed that the length of the connective tissue attachment varied within narrow limits (1.06–1.08 mm), while the length of the attached epithelium was about 1.4 mm at sites with normal periodontium, 0.8 mm at sites with moderate, and 0.7 mm at sites with advanced periodontal tissue breakdown. In other words, (1) the dimension of the attachment varied between about 2.5 mm in the normal case and 1.8 mm in the advanced disease case, and (2) the most variable part of the attachment was the length of the epithelial attachment (junctional epithelium).

Dimensions of the buccal tissue

The morphologic characteristics of the gingiva are related to the dimension of the alveolar process, the form (anatomy) of the teeth, events that occur during tooth eruption, and the eventual inclination and position of the fully erupted teeth (Wheeler 1961; O'Connor & Biggs 1964; Weisgold 1977). Oschenbein and Ross (1969) and Becker *et al*. (1997) proposed (1) that the anatomy of the gingiva is related to the contour of the osseous crest and (2) that two basic types of gingival architecture may exist, namely the "*pronounced scalloped*" and the "*flat*" phenotype.

Subjects who belong to the "*pronounced scalloped*" phenotype have long and slender teeth with tapered crown form, delicate cervical convexity, and minute

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

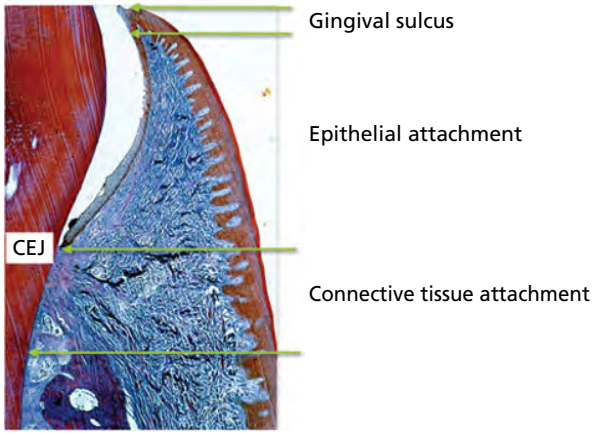

Fig. 4-1 Histological section describing the dimensions of the various components of the soft tissue attachment at the buccal surface of a tooth with healthy periodontium. The combined length of the junctional epithelium (epithelial attachment) and the connective tissue attachment is considered to represent the "supracrestal attachment/biologic width" of the soft tissue. Note the gingival sulcus is *not* part of the attachment. CEJ, cementoenamel junction.

Fig. 4-2 A subject who belongs to the "pronounced scalloped" gingival phenotype. The crowns of the teeth are comparatively long and slender. The papillae are comparatively long, the gingival margin is thin, and the zone of attached gingiva is short.

interdental contact areas that are located close to the incisal edge (Fig. 4-2). The maxillary front teeth of such individuals are surrounded by a thin free gingiva, the buccal margin of which is located at or apical of the cementoenamel junction. The zone of gingiva is narrow, and the outline of the gingival margin is highly scalloped (Olsson *et al*. 1993). On the other hand, subjects who belong to the "*flat*" gingival phenotype have incisors with squared crown form with pronounced cervical convexity (Fig. 4-3). The gingiva of such individuals is wider and more voluminous, the contact areas between the teeth are large and more apically located, and the interdental papillae are short. It was reported that subjects with a pronounced scalloped gingiva often exhibited more advanced soft tissue recession in the anterior maxilla than subjects with a flat gingiva (Olsson & Lindhe 1991).

Kan *et al*. (2003) measured the dimension of the gingiva – as determined by bone sounding – at the buccomesial and buccodistal aspects of maxillary anterior teeth. Bone sounding determines the distance between the soft tissue margin and the crest of the bone and, hence, provides an estimate that is about 1 mm greater than that obtained in a regular probing pocket depth measurement. The authors reported that the thickness of the gingiva varied between subjects of different gingival phenotypes. Thus, the height of the gingiva at the buccal-approximal surfaces in subjects who belonged to the flat phenotype was, on average, 4.5 mm, while in subjects belonging to the pronounced scalloped phenotype the corresponding dimension (3.8 mm) was significantly smaller.

Fig. 4-3 A subject who belongs to the "flat" gingival phenotype. The crowns of the teeth are comparatively short but wide. The papillae are comparatively short but voluminous and the zone of attached gingiva is wide.

Pontoriero and Carnevale (2001) evaluated the reformation of the gingival unit at the buccal aspect of teeth exposed to crown lengthening procedures using a denudation technique. At the 1-year follow-up examination after surgery, the regain of soft tissue – measured from the level of the denuded osseous crest – was greater in patients with a thick (flat) phenotype than in those with a thin (pronounced scalloped) phenotype (3.1 mm versus 2.5 mm). No assessment was made of the bone level change that had occurred between the baseline and the follow-up examination. It must, however, be anticipated that some bone resorption had taken place during healing and that the height of the new connective tissue attachment had been re-established coronal to the level of the resected osseous crest.

The dimensions of the buccal gingiva may also be affected by the buccolingual position of the tooth within the alveolar process. A change of the tooth position in the buccal direction results in reduced dimensions of the buccal gingiva, while an increase is observed following a lingual tooth movement (Coatoam *et al*. 1981; Andlin-Sobocki & Brodin 1993). In fact, Müller and Könönen (2005) demonstrated in a study of the variability of the thickness of the buccal gingiva of young adults that most of the variation in gingival thickness was due to the tooth position and that the contribution of subject variability (i.e. flat and pronounced scalloped phenotypes) was minimal.

Dimensions of the interdental papilla

The interdental papilla in a normal, healthy dentition has one buccal and one lingual/palatal component that are joined in the col region (see Chapter 1). Experiments performed in the 1960s (Kohl & Zander 1961; Matherson & Zander 1963) revealed that the shape of the papilla in the col region was not determined by the outline of the bone crest, but by the shape of the contact relationship that existed between adjacent teeth.

Tarnow *et al*. (1992) studied whether the distance between the contact point (area) between teeth and the crest of the corresponding interproximal bone could influence the degree of papilla fill that occurred at the site. Presence or absence of a papilla was determined visually in periodontally healthy subjects. If there was no space visible apical of the contact point, the papilla was considered complete. If a "black space" was visible at the site, the papilla was considered incomplete. The distance between the facial level of the contact point and the bone crest (Fig. 4-4) was measured by sounding. The measurement thus included not only the epithelium and connective tissue of the papilla, but in addition the entire supra-alveolar connective tissue in the interproximal area (Fig. 4-5). The authors reported that the papilla was complete when the distance from the contact point to the crest of the bone was ≤5 mm. When this distance was 6 mm, papilla fill occurred in about 50% of cases and when ≥7 mm, it was incomplete in about 75% of cases. Considering that the supracrestal connective tissue attachment is about 1 mm high, these data indicate that the papilla height may be limited to about 4 mm in most cases. Interestingly, papillae of similar height (3.2–4.3 mm) were found to reform following surgical denudation procedures (van der Velden 1982; Pontoriero & Carnevale 2001), but to a greater height in patients with a thick (flat) phenotype than in those with a thin (pronounced scalloped) phenotype.

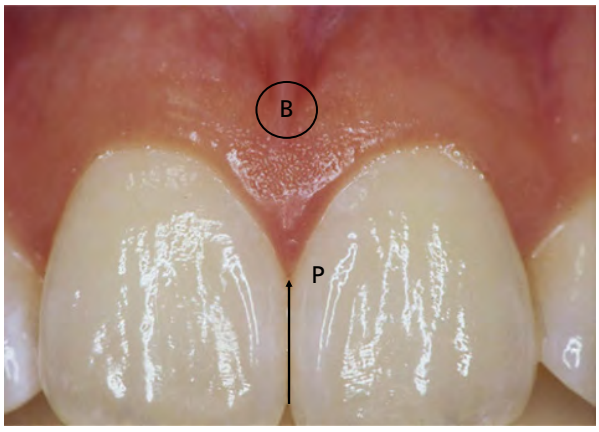

Fig. 4-4 Tarnow *et al*. (1992) measured the distance between the contact point (P) between the crowns of the teeth and the bone crest (B) using sounding (transgingival probing).

Fig. 4-5 Mesiodistal section of the interproximal area between the two central incisors. Arrows indicate the location of the cementoenamel junction. Dotted line indicates the outline of the marginal bone crest. The distance between the contact point (P) between the crowns of the teeth and the bone crest (B) indicates the height of the papilla.

Summary:

- *Flat gingival (periodontal)* phenotype: the buccal marginal gingiva is comparatively thick, the papillae are often short, the bone of the buccal cortical wall is thick, and the vertical distance between the interdental bone crest and the buccal bone is short (about 2 mm).
- *Pronounced scalloped gingival (periodontal)* phenotype: the buccal marginal gingiva is delicate and may often be located apical of the cementoenamel junction (receded), the papillae are high and slender, the buccal bone wall is often thin, and the vertical distance between the interdental bone crest and the buccal bone is long (>4 mm).

Peri-implant mucosa

The soft tissue that surrounds dental implants is termed *peri-implant mucosa*. Features of the peri-implant mucosa are established during the process of wound healing that occurs subsequent to the closure of mucoperiosteal flaps following implant installation (one-stage procedure) or following abutment connection (two-stage procedure) surgery. Healing of the mucosa results in the establishment of a soft tissue attachment (transmucosal attachment) to the implant. This attachment serves as a seal that prevents products from the oral cavity reaching the bone tissue, and thus ensures osseointegration and the rigid fixation of the implant.

The peri-implant mucosa and the gingiva have several clinical and histologic characteristics in common. Some important differences, however, also exist between the gingiva and the peri-implant mucosa.

Dimensions of the supracrestal attachment

The structure of the mucosa that surrounds implants made of titanium has been examined in humans and several animal models. In a study in the dog, Berglundh *et al*. (1991) compared some anatomic features of the gingiva at teeth and the mucosa at implants. Details of the research model used in this study are briefly outlined here, as this model was used in subsequent experiments that will be described in this chapter.

The mandibular premolars on one side of the mandible were extracted, leaving the corresponding teeth in the contralateral jaw quadrant. After 3 months of healing following tooth extraction, implants were installed (Fig. 4-6) and submerged. Another 3 months later, abutment connection was performed and the animals were placed in a plaque-control program. Four months later biopsies of tooth and implant sites were harvested.

The clinically healthy gingiva and peri-implant mucosa had a pink color and a firm consistency (Fig. 4-7). On radiographs obtained from the tooth sites, it was observed that the alveolar bone crest was located about 1 mm apical of a line connecting the cementoenamel junction of neighboring teeth (Fig. 4-8). In the implant sites the bone crest was located close to the junction between the abutment and the implant (Fig. 4-9).

Histologic examination revealed that the two soft tissue units, the gingiva and the peri-implant mucosa, had several features in common. The oral epithelium of the gingiva was well keratinized and continuous with the thin junctional epithelium that faced the enamel and that ended at the cementoenamel junction (Fig. 4-10). The supra-alveolar connective tissue was about 1 mm high and the periodontal ligament about 0.2–0.3 mm wide. The principal fibers extended from the root cementum in a fan-shaped pattern into the soft and hard tissues of the marginal periodontium (Fig. 4-11).

The outer surface of the peri-implant mucosa was also covered by a keratinized oral epithelium, which in the marginal border connected with a thin barrier epithelium (similar to the junctional epithelium at the teeth) that faced the abutment part of the implant (Fig. 4-12). The barrier epithelium was a few cell layers thick (Fig. 4-13) and terminated about 2 mm apical of the soft tissue margin (Fig. 4-12) and 1–1.5 mm from the bone crest. The connective tissue in the

The junctional epithelium is about 2 mm long and the supracrestal connective tissue portion about 1 mm high.

compartment above the bone appeared to be in direct contact with the surface of the implant (Figs. 4-12, 4-13). The collagen fibers in this connective tissue originated from the periosteum of the bone crest and extended towards the margin of the soft tissue in directions parallel to the surface of the abutment.

The observation that the barrier epithelium of the healthy mucosa consistently ended at a certain distance (1–1.5 mm) from the bone is important. During healing, fibroblasts of the connective tissue of the mucosa apparently formed a biologic attachment to the titanium surface of the abutment portion of the implant. This attachment zone was evidently not recognized as a wound and was therefore not covered with an epithelial lining.

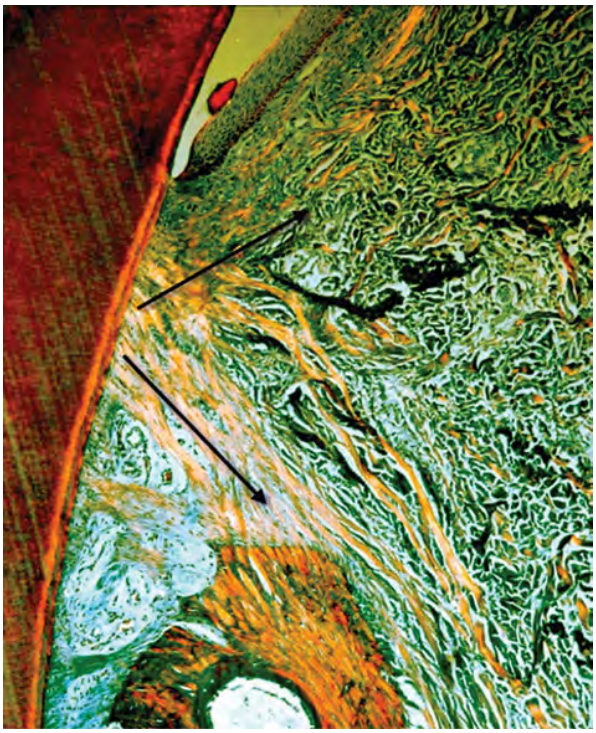

Fig. 4-11 Higher magnification of the supracrestal connective tissue portion seen in Fig. 4-10. Note the direction of the principal fibers.

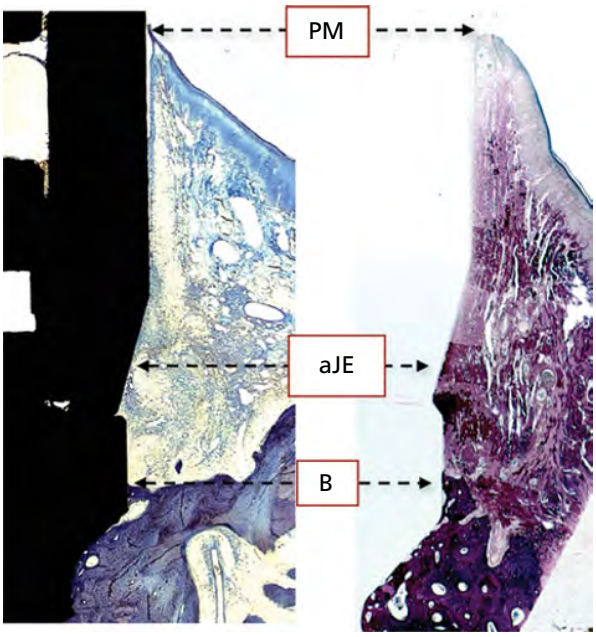

Fig. 4-12 Microphotographs of buccolingual sections of the peri-implant mucosa. Note the position of the soft tissue margin (PM; top arrow), the apical cells of the junctional epithelium (aJE; center arrow), and the crest of the marginal bone (B; bottom arrow). The junctional epithelium is about 2 mm long and the implant–connective tissue interface about 1.5 mm high.

In further preclinical *in vivo* experiments (Abrahamsson *et al*. 1996, 2002), it was observed that a similar mucosal attachment formed when different types of implant systems were used. In addition, the formation of the attachment appeared to be

independent of whether the implants were initially submerged or not.

Studies by Abrahamsson *et al*. (1998) and Welander *et al*. (2008) demonstrated that the material used in the abutment part of the implant was of decisive importance for the location of the connective tissue portion of the transmucosal attachment. Abutments made of aluminum-based sintered ceramic (Al_2O_3) and zirconium dioxide (ZrO_2) allowed for the establishment of a mucosal attachment similar to that which occurred at titanium abutments. Abutments made of a gold alloy or dental porcelain, however, provided conditions for inferior mucosal healing. When such materials were used, the connective tissue attachment failed to develop at the abutment level. Instead, the connective tissue attachment occurred in a more apical location. Thus, during healing following the abutment connection surgery, some resorption of the marginal peri-implant bone took place to expose the titanium portion of the implant to which the connective tissue attachment eventually formed. The histological analysis made by Welander *et al*. (2008) further revealed that the connective tissue interface at gold (Au/Pt)-alloy abutments contained lower amounts of collagen and fibroblasts and larger fractions of leukocytes than that at abutments made of titanium and zirconium dioxide (ZrO_2) (Figs. 4-14, 4-15).

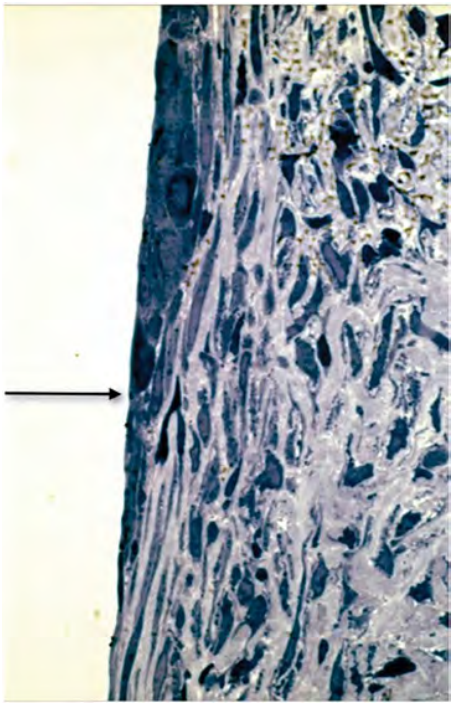

Fig. 4-13 Higher magnification of the apical portion of the junctional epithelium (arrow) in Fig. 4-12.

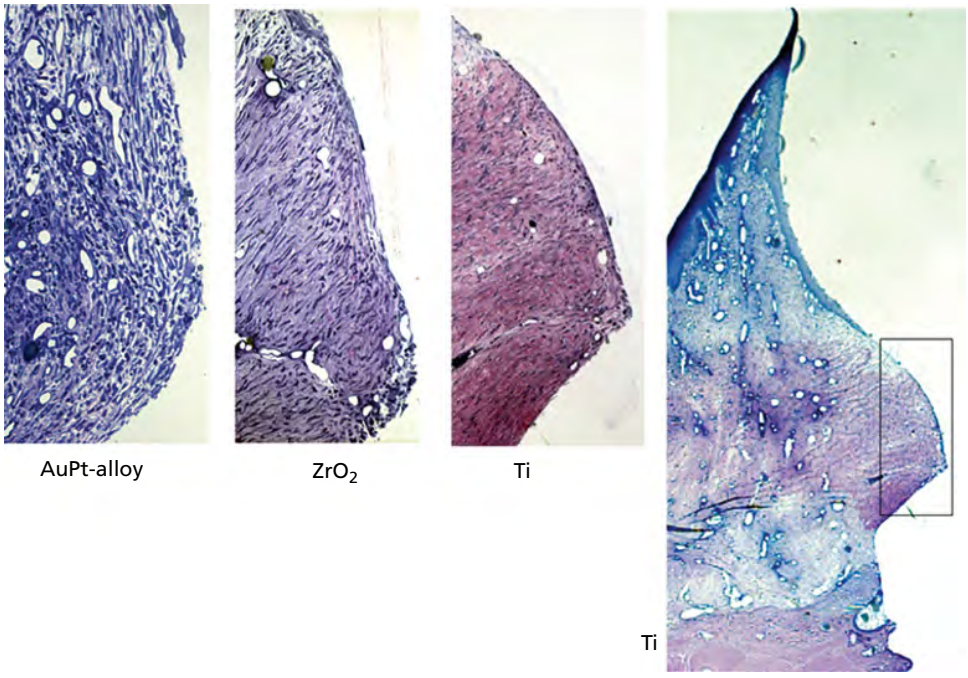

Fig. 4-15 Microphotographs illustrating bucco-lingual sections of the peri-implant mucosa adjacent abutments made of titanium (Ti), zirconium dioxide (ZrO_2) and gold (Au-Pt) alloy. (Source: Welander *et al*. 2008. Reproduced with permission from John Wiley & Sons.)

The location and dimensions of the transmucosal attachment were examined in a preclinical study by Berglundh and Lindhe (1996). Implants were installed and submerged. After 3 months of healing, abutment connection was performed. On the left side of the mandible, the volume of the ridge mucosa was maintained, while on the right side the vertical dimension of the mucosa was reduced to 2 mm or less (Fig. 4-16) before the flaps were replaced and sutured. In biopsy specimens obtained after another 6 months, it was observed that the transmucosal attachment at all implants included a barrier epithelium component that was about 2 mm long and a zone of connective tissue that was about 1.3–1.8 mm high.

Further examination disclosed that at sites with a thin mucosa, wound healing had consistently included marginal bone resorption to establish space for a mucosa that eventually could harbor both the epithelial and the connective tissue components of the transmucosal attachment (Figs. 4-17).

Thus, the dimensions of the epithelial and connective tissue components of the transmucosal attachment at implants are established during wound healing following implant surgery. As is the case for bone healing after implant placement (see Chapter 5), the wound healing in the mucosa around implants is a delicate process that requires several weeks of tissue remodeling.

In a preclinical *in vivo* experiment, Berglundh *et al*. (2007) described the morphogenesis of the peri-implant mucosa. A non-submerged implant installation technique was used and the mucosal tissues were secured to the marginal portion of the implants. A plaque-control program was initiated. Biopsies were harvested at various intervals to provide healing periods extending from day 0 (2 hours) to 12 weeks.

Large numbers of neutrophils infiltrated and degraded the coagulum that occupied the compartment between the mucosa and the implant during the initial phase of healing. The first signs of epithelial proliferation were observed after 1–2 weeks of healing and a mature barrier epithelium was seen after 6–8 weeks (Fig. 4-18). The collagen fibers

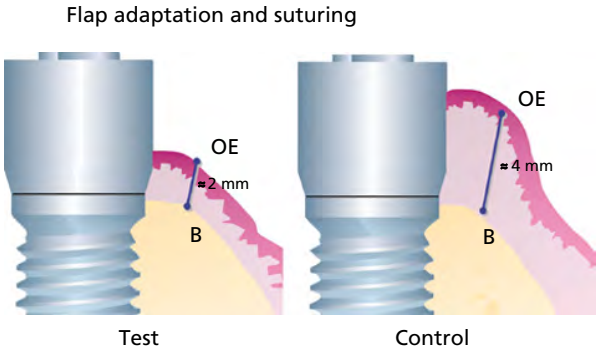

Fig. 4-16 The mucosa at the test site was reduced to about 2 mm. (Source: Berglundh & Lindhe 1996. Reproduced with permission from John Wiley & Sons.)

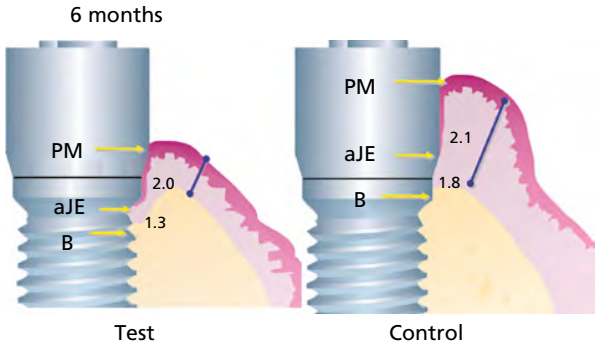

Fig. 4-17 The peri-implant mucosa at both control and test sites contained a 2-mm long barrier epithelium and a zone of connective tissue that was about 1.3–1.8 mm high. Bone resorption occurred in order to accommodate the soft tissue attachment at sites with a thin mucosa. (Source: Berglundh & Lindhe 1996. Reproduced with permission from John Wiley & Sons.)

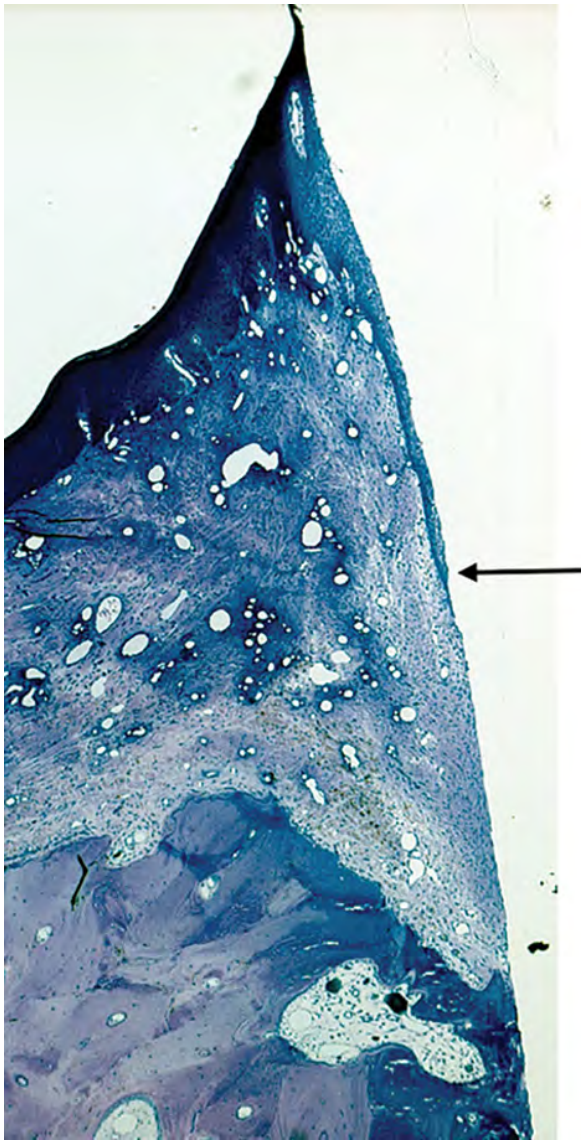

Fig. 4-18 Microphotograph illustrating a buccolingual section of the peri-implant mucosa after 6 weeks of healing. Arrow indicates apical cells of the junctional epithelium. (Source: Berglundh *et al*. 2007. Reproduced with permission from John Wiley & Sons.)

of the mucosa were organized after 4–6 weeks of healing (Fig 4-19).

Tomasi *et al*. (2013, 2016) used a novel human biopsy model to study the early healing of peri-implant mucosa. Biopsies of peri-implant soft tissues were retrieved in 21 patients after 2, 4, 6, 8, and 12 weeks of healing. The histological analysis revealed that dimensional and qualitative changes in the mucosa over time were consistent with those reported in previous preclinical *in vivo* studies. Further analysis disclosed that densities of inflammatory cells and vascular structures in the peri-implant mucosa decreased over time and that the formation of the junctional epithelium was completed at 8 weeks of healing (Fig. 4-20).

Summary: The junctional and barrier epithelia are about 2 mm long and the zones of supra-alveolar connective tissue are between 1 and 1.5 mm high. Both epithelia are attached via hemidesmosomes to the tooth/implant surface (Gould *et al*. 1984). The main attachment fibers (the principal fibers) invest in the root cementum of the tooth, but at the implant site the equivalent fibers run in a direction parallel to the implant and fail to attach to the metal body. The soft tissue attachment to implants is properly established first after several weeks of healing.

Structure and composition

The connective tissue in the supra-alveolar compartments at teeth and implants was examined by Berglundh *et al*. (1991). The main difference between the mesenchymal tissue at a tooth and at an implant site was the occurrence of cementum on the root of the tooth. From this cementum (Fig. 4-11), coarse dentogingival and dentoalveolar collagen fiber bundles projected in lateral, coronal, and apical directions. At the implant site, the collagen fiber bundles were orientated in an entirely different manner. Thus, the fibers invested in the periosteum at the bone crest and projected in directions parallel to the implant surface (Figs. 4-19, 4-20).

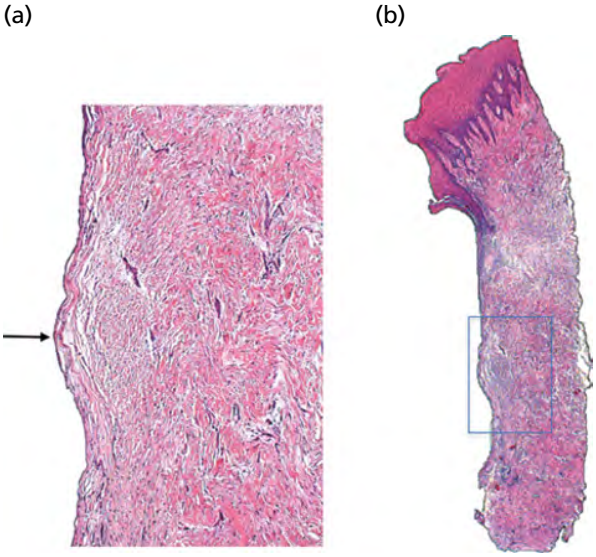

Fig. 4-20 Microphotograph illustrating a section of a human peri-implant mucosa after 8 weeks of healing (a). Higher magnification (b). Arrow indicates apical cells of the junctional epithelium. Note the direction of collagen fibers, which is parallel to the surface of the abutment device. (Source: Tomasi *et al*. 2013. Reproduced with permission from John Wiley & Sons.)

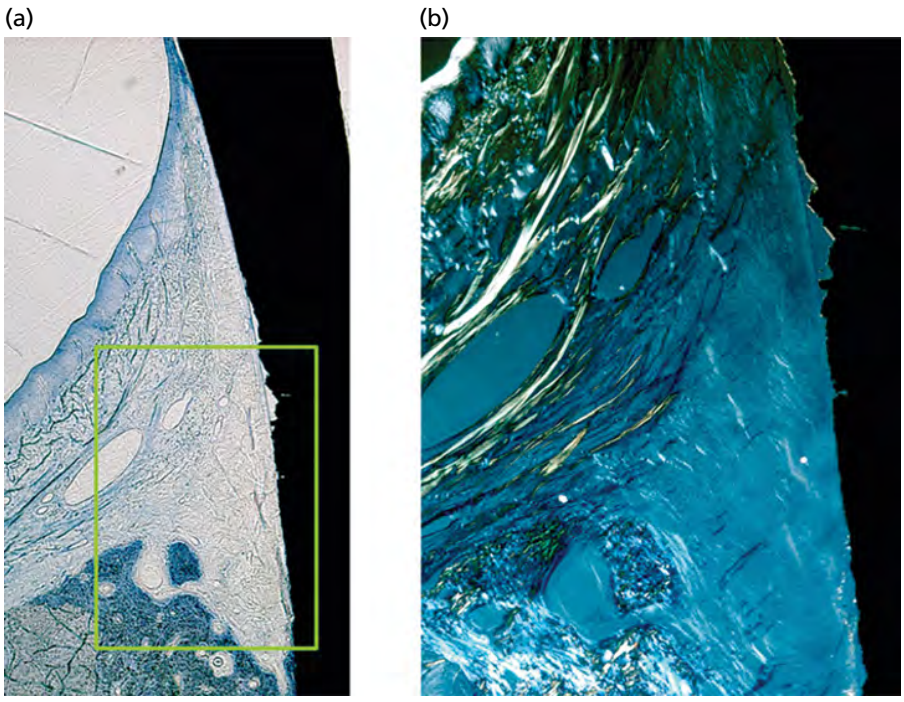

Fig. 4-19 Microphotograph illustrating a buccolingual ground section of the peri-implant tissues after 6 weeks of healing (a). Higher magnification (b) demonstrating collagen fibers running from the periosteum of the bone crest and extending in directions parallel to the surface of the implant. (Source: Berglundh *et al*. 2007. Reproduced with permission from John Wiley & Sons.)

The connective tissue in the supracrestal area at implants contained more collagen fibers, but fewer fibroblasts and vascular structures than the corresponding tissue at teeth. Moon *et al*. (1999), in a preclinical *in vivo* study, reported that the attachment tissue close to the implant (Fig. 4-21) contained few blood vessels and a large number of fibroblasts that were orientated with their long axes parallel to the implant surface (Fig. 4-22). In more lateral compartments, there were fewer fibroblasts, but more collagen fibers and more vascular structures. It was concluded that the connective tissue attachment between the titanium surface and the connective tissue is established and maintained by fibroblasts.

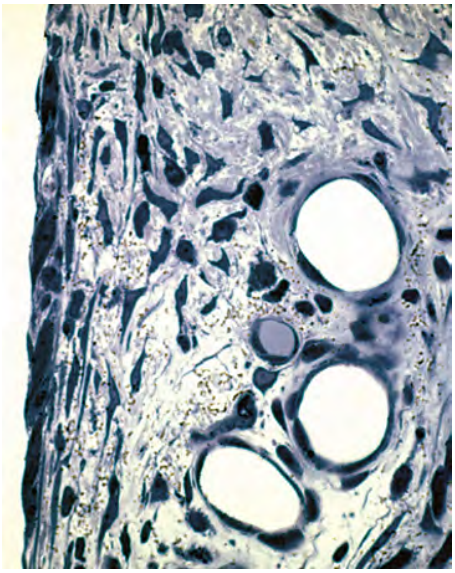

Fig. 4-21 Microphotograph of the implant–connective tissue interface of the peri-implant mucosa. A large number of fibroblasts reside in the tissue next to the implant.

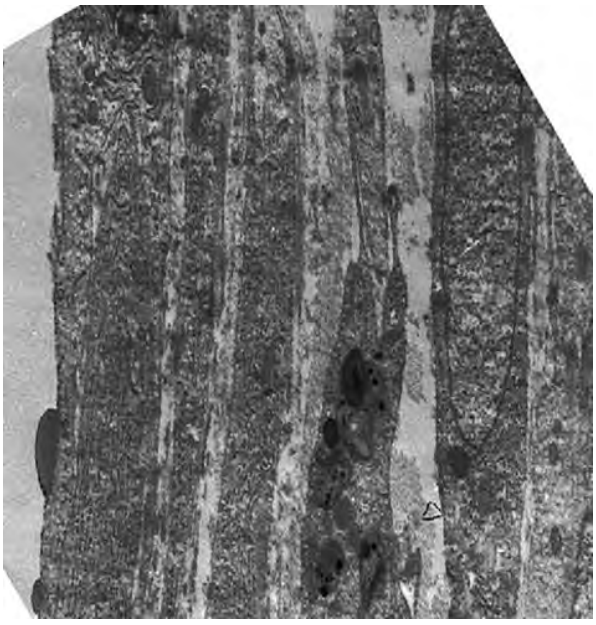

Fig. 4-22 Electron micrograph of the implant–connective tissue interface. Elongated fibroblasts are interposed between thin collagen fibrils (magnification ×24 000).

Vascular supply

The vascular supply to the gingiva comes from two different sources (Fig. 4-23). The first source is represented by the large *supraperiosteal blood vessels* that put forth branches to form (1) the capillaries of the connective tissue papillae under the oral epithelium and (2) the vascular plexus lateral to the junctional epithelium. The second source is the *vascular plexus of the periodontal ligament*, from which branches run in a coronal direction and terminate in the supra-alveolar portion of the free gingiva. Thus, the blood supply to the zone of supra-alveolar connective tissue attachment in the periodontium is derived from two apparently independent sources (see Chapter 1).

Berglundh *et al*. (1994) observed that the vascular system of the peri-implant mucosa (Fig. 4-24) originated *solely* from the large *supraperiosteal blood vessels* on the outside of the alveolar ridge. These vessels gave off branches to the supra-alveolar mucosa and formed (1) the capillaries beneath the oral epithelium and (2) the vascular plexus located immediately lateral to the barrier epithelium. The connective tissue part of the transmucosal attachment to titanium implants contained only a few vessels, all of which could be identified as terminal branches of the *supraperiosteal blood vessels*.

Fig. 4-23 Buccolingual cleared section of the marginal portion of a tooth. The vessels were filled with carbon (arrows). Note the presence of supraperiosteal vessels on the outside of the alveolar bone, the presence of a plexus of vessels within the periodontal ligament, as well as vascular structures in the very marginal portion of the gingiva.

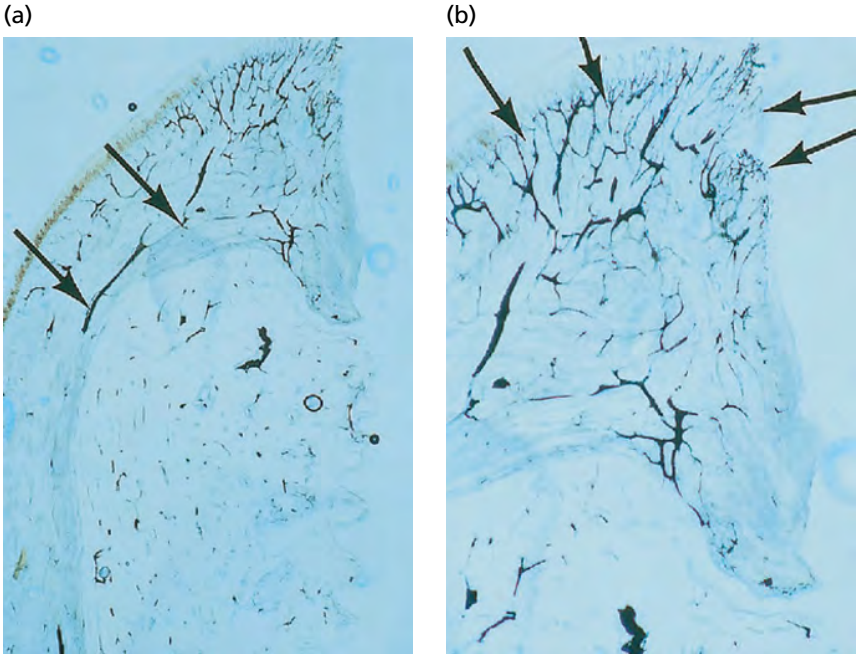

Fig. 4-24 (a) Buccolingual cleared section of the marginal portion of peri-implant tissues (the implant was positioned to the right). Note the presence of a supraperiosteal vessel on the outside of the alveolar bone (arrows), but also that there is no vasculature that corresponds to the periodontal ligament plexus. (b) Higher magnification (of a) of the peri-implant soft tissue and the bone implant interface. Note the presence of a vascular plexus lateral to the junctional epithelium (arrows), but the absence of vessels in the more apical portions of the soft tissue facing the implant and the bone.

Summary: The gingiva and the peri-implant mucosa share some characteristics, but differ in the composition of the connective tissue, the alignment of the collagen fiber bundles, and the distribution of vascular structures.

Probing gingiva and peri-implant mucosa

It was assumed for many years that the tip of the probe in a pocket depth measurement identified the most apical cells of the junctional (pocket) epithelium or the marginal level of the connective tissue attachment. This assumption was based on findings by, for example, Waerhaug (1952), who reported that the "epithelial attachment" (e.g. Gottlieb 1921; Orban & Köhler 1924) offered no resistance to probing. Waerhaug (1952) inserted thin blades of steel or acrylic into the gingival pocket of various teeth of young subjects without signs of periodontal pathology. He concluded that the insertion of the blades could be performed without resulting in bleeding and that the device consistently reached the cementoenamel junction (Fig. 4-25).

Subsequent studies observed, however, that the tip of a periodontal probe in a pocket depth measurement seldom identified the base of the dentogingival epithelium. Thus, in the absence of an inflammatory lesion, the probe frequently failed to reach the apical part of the junctional epithelium (e.g. Armitage *et al*. 1977). If an inflammatory lesion was present in the gingival connective tissue, however, the probe penetrated beyond the epithelium to reach the apicolateral border of the infiltrate.

Lang *et al*. (1994) in a preclinical *in vivo* study prepared the implant sites in such a way that at probing some were healthy, a few exhibited signs of mucositis, and some exhibited peri-implantitis. Probes with different geometry were inserted into the pockets using a standardized probing procedure and a force of 0.2 N. The probe locations were studied in histologic ground sections. The mean "histologic" probing depth at healthy and peri-implant mucositis sites was about 1.8 mm, while at sites with peri-implantitis the corresponding values were about 3.8 mm. Lang *et al*. (1994) further stated that at healthy and mucositis sites, the probe tip identified "the connective tissue adhesion level" (i.e. the base of the barrier epithelium), while at peri-implantitis sites, the probe exceeded the base of the ulcerated pocket epithelium by a mean distance of 0.5 mm. At such peri-implantitis sites, the probe reached the base of the inflammatory cell infiltrate.

Schou *et al*. (2002) compared probing measurements at implants and teeth in another preclinical *in vivo* study. Ground sections were produced from tooth and implant sites that were (1) clinically healthy, (2) slightly inflamed (mucositis/gingivitis), and (3) severely inflamed (peri-implantitis/periodontitis) and in which probes had been inserted. An electronic probe (Peri-Probe®) with a tip diameter 0.5 mm and a standardized probing force of 0.3–0.4 N was used. It was demonstrated that the probe tip was located at a similar distance from the bone in healthy tooth sites and implant sites. On the other hand, at implants exhibiting mucositis and peri-implantitis, the probe tip was consistently identified at a more apical position than at corresponding tooth sites (gingivitis and periodontitis).

Abrahamsson and Soldini (2006) in a preclinical *in vivo* study evaluated the location of the probe tip in healthy periodontal and peri-implant tissues. They reported that probing with a force of 0.2 N resulted in a probe penetration that was similar at implants and teeth. Furthermore, the tip of the probe was often at or close to the apical cells of the junctional/barrier epithelium. The distance between the

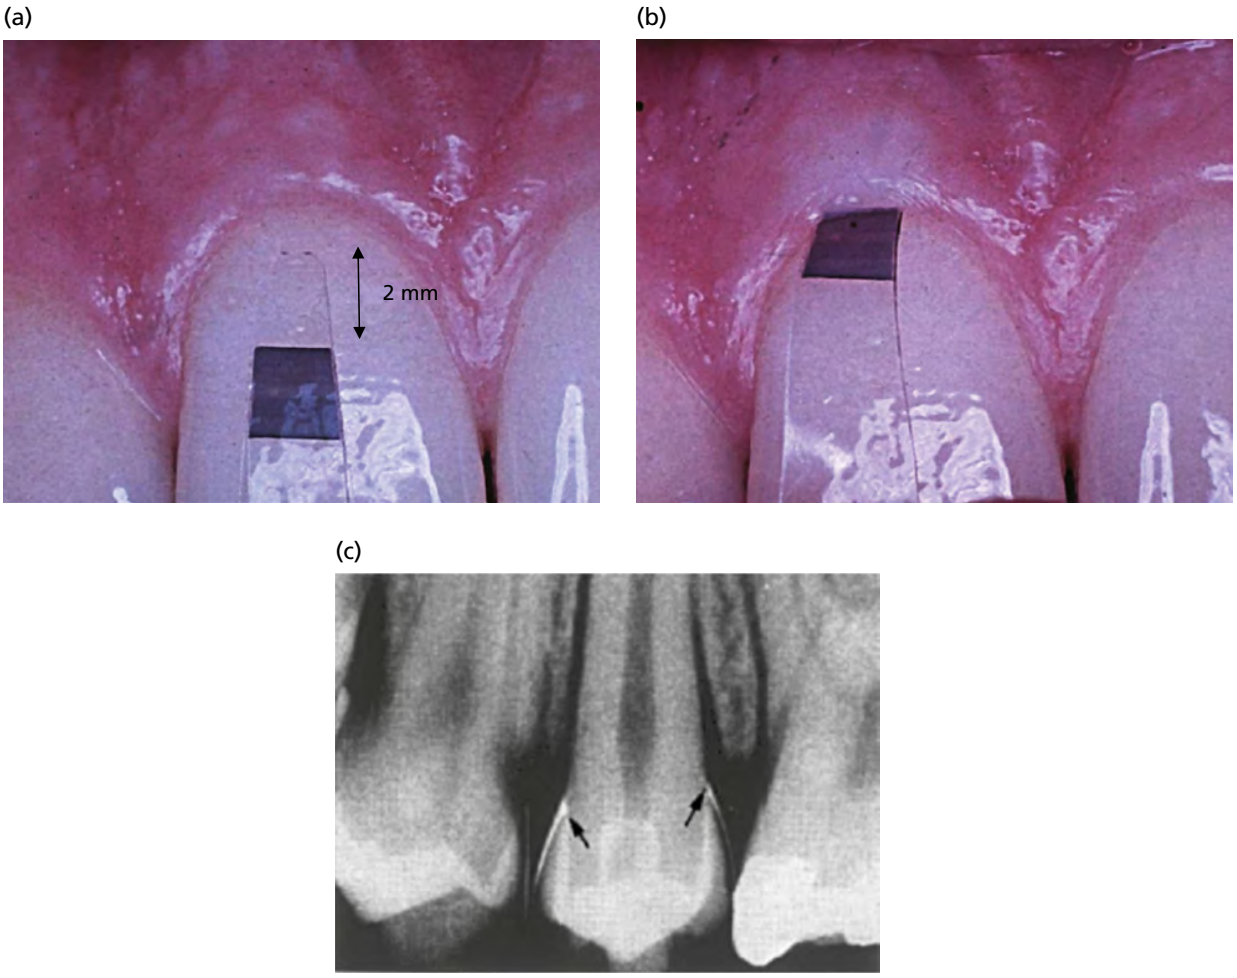

Fig. 4-25 Acrylic strip with a blue zone located 2 mm from the strip margin (a) prior to and (b) after its insertion into a buccal "pocket". With a light force the strip could be inserted 2 mm into the "pocket". (c) Thin blades of steel were inserted into pockets at approximal sites of teeth with healthy periodontal tissue. On radiographs, Waerhaug (1952) could observe that the blades consistently reached the cementoenamel junction.

tip of the probe and the bone crest was about 1 mm at both teeth and implants (Figs. 4-26, 4-27). Similar observations were reported from clinical studies in which different implant systems were used (Buser *et al*. 1990; Quirynen *et al*. 1991; Mombelli *et al*. 1997). In these studies, the distance between the probe tip and the bone was assessed in radiographs and varied between 0.75 and 1.4 mm when a probing force of 0.25–0.45 N was used.

By comparing the findings from the studies reported above, it becomes apparent that probing depth and probing attachment level measurements are meaningful at implant sites.

Dimensions of the buccal soft tissue at implants

Chang *et al*. (1999) compared the dimensions of the periodontal and peri-implant soft tissues of subjects who had been treated with an implant-supported single-tooth restoration in the esthetic zone of the maxilla and who had a non-restored natural tooth in the contralateral position (Fig. 4-28). In comparison to the natural tooth, the implant-supported crown was bordered by a thicker buccal mucosa (2.0 mm versus 1.1 mm), as assessed at a level corresponding to the bottom of the probeable pocket and had a greater probing pocket depth (2.9 mm versus 2.5 mm) (Fig. 4-29). It was further observed that the soft tissue margin at the implant was more apically located (about 1 mm) than the gingival margin at the contralateral tooth.

Kan *et al*. (2003) studied the dimensions of the peri-implant mucosa at single implants that had been placed in the anterior maxilla for about 3 years. Bone sounding measurements performed at the buccal aspect of the implants showed that the height of the mucosa was 3–4 mm in the majority of the cases. Less than 3 mm of mucosa height was found at only 9% of the implants. It was suggested that implants in this category (1) were found in subjects who belonged to a *thin periodontal phenotype*, (2) had been placed too labially, and/or (3) had the emergence of an over-contoured facial prosthetic. A peri-implant soft tissue dimension of >4 mm was usually associated with a *thick periodontal phenotype*.

Dimensions of the papilla between teeth and implants

Schropp *et al*. (2003) demonstrated that following single-tooth extraction the height of the papilla at the adjacent teeth was reduced by about 1 mm. Concomitant with this reduction (recession) of the papilla height, the pocket depth was reduced and some loss of clinical attachment occurred.

Following single-tooth extraction and subsequent implant installation, the height of the papilla in the tooth implant site will be dependent on the attachment level of the tooth. Choquet *et al*. (2001) studied the papilla level adjacent to single-tooth dental implants. The distance between the apical extension of the contact point between the crowns and the bone crest, as well as the distance between the soft tissue level and the bone crest, was measured on radiographs. The examinations were made 6–75 months after the insertion of the crown restoration. The authors observed that the papilla height consistently was about 4 mm and, depending on the location of the contact point between adjacent crown papilla, fill was either complete or incomplete (Fig. 4-30). The closer the contact point was to the incisal edge of the crowns (restorations), the less complete was the papilla fill.

Chang *et al*. (1999) studied the dimensions of the papillae at implant-supported single-tooth restorations in the anterior region of the maxilla and at non-restored contralateral natural teeth. They found that the papilla height at the implant-supported crown was significantly shorter and showed less fill of the embrasure space than the papilla at the natural tooth (Fig. 4-31). It is evident that the anatomy of the adjacent natural teeth (e.g. the diameter of the root, the proximal outline/curvature of the cementoenamel junction/connective tissue attachment level) has a profound influence on the dimension of the papilla lateral to an implant.

Kan *et al*. (2003) assessed the dimensions of the peri-implant mucosa lateral to single implants placed in the anterior maxilla and the adjacent teeth using bone sounding measurements. The bone sounding measurements were performed at the proximal aspects of the implants and at the teeth. The authors reported that the thickness of the mucosa at the mesial/distal surfaces of the implant sites was on average 6 mm, while the corresponding dimension at the adjacent tooth sites was about 4 mm. It was further observed that the dimensions of the peri-implant mucosa of subjects who belonged to the *thick periodontal phenotype* were significantly greater than those of subjects with a *thin phenotype*.

The level of the connective tissue attachment on the adjacent tooth surface and the position of the contact point between the crowns are obviously key factors that determine whether or not a complete papilla fill will be obtained at the single-tooth implant-supported restoration (Fig. 4-32). Although there are indications that the dimensions of the approximal soft tissue may vary between individuals having thin and thick periodontal phenotypes, the height of the papilla at single-implant restorations seems to have a biologic limit of about 4 mm (compare this with the dimension of the interdental papilla). Hence, to achieve a complete papilla fill of the embrasure space, a correct location of the contact area between the

implant crown and the tooth crown is mandatory. In this respect it must also be recognized that the papilla fill at single-tooth implant restorations is unrelated to whether the implant is inserted according to a one- or two-stage protocol and whether a crown restoration is inserted immediately following surgery or delayed until the soft tissues have healed (Jemt 1999; Ryser *et al*. 2005).

Dimensions of the "papilla" between adjacent implants

When two neighboring teeth are extracted, the papilla at the site will be lost (Fig. 4-33). Hence, at replacement of the extracted teeth with implant-supported restorations, the topography of the bone crest and the thickness of the supracrestal soft tissue

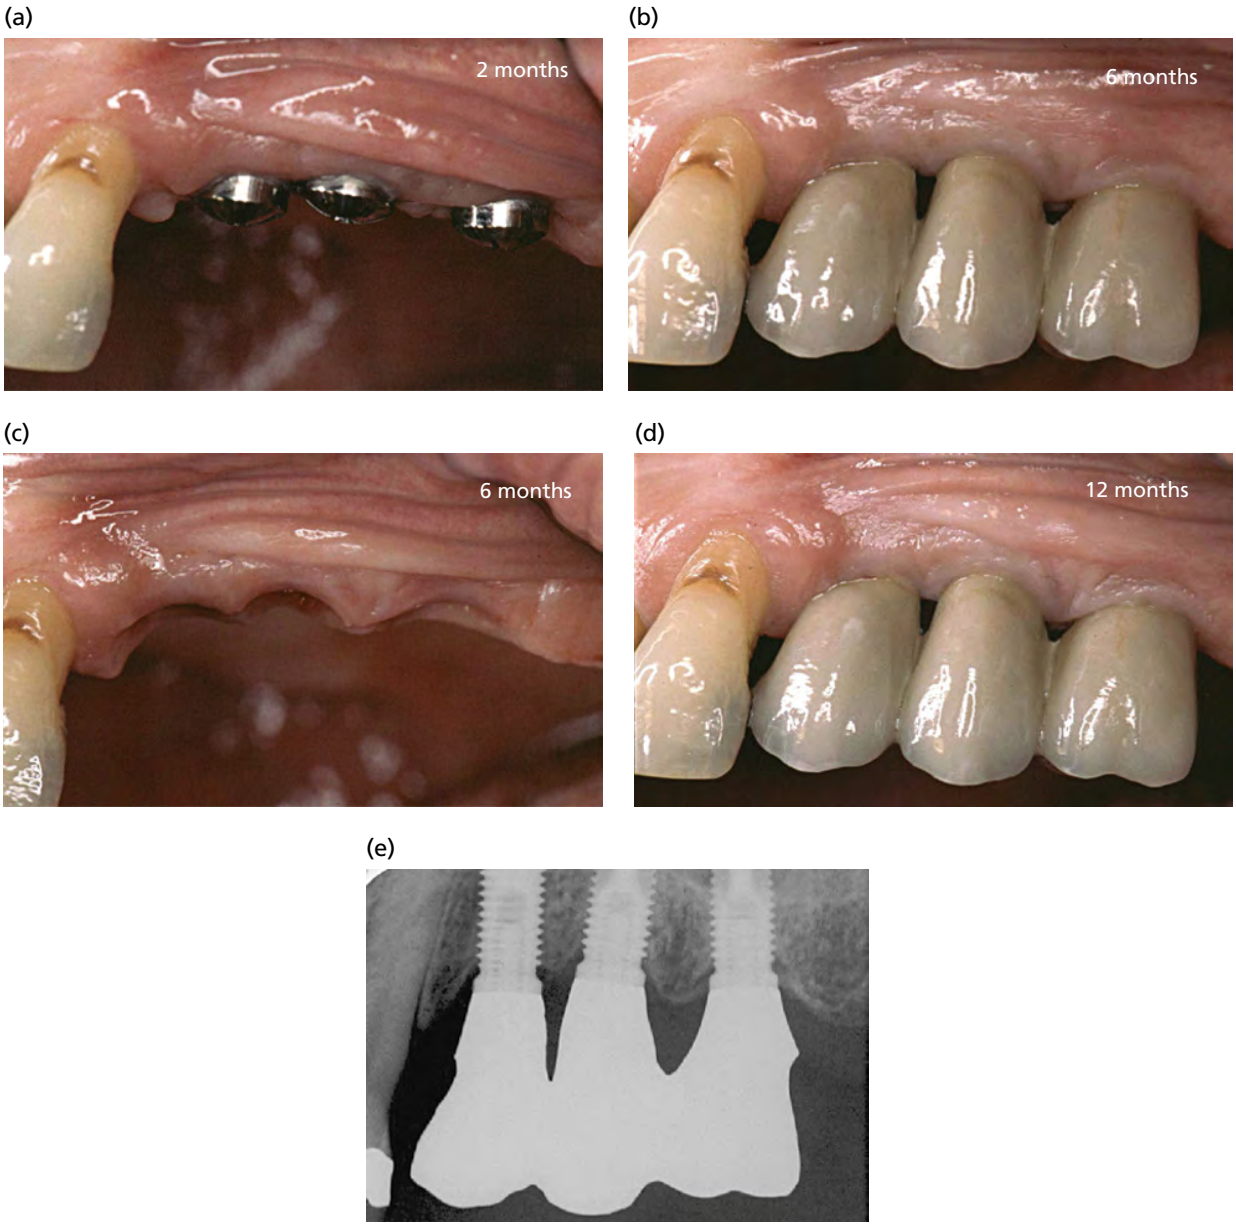

Fig. 4-34 See text for details.

portion are the factors that determine the position of the soft tissue margin in the interimplant area ("implant papilla"). Tarnow *et al*. (2003) assessed the height above the bone crest of the interimplant soft tissue ("implant papilla") by transmucosal probing. It was found that the mean height of the "papillae" was 3.4 mm, with 90% of the measurements in the range of 2–4 mm.

The dimension of the soft tissues between adjacent implants seems to be independent of the implant design. Lee *et al*. (2006) examined the soft tissue height between implants of two different systems, as well as the potential influence of the horizontal distance between implants. The height of the interimplant "papilla", that is the height of soft tissue coronal to the bone crest measured on radiographs, was about 3.1 mm for both implant systems. No difference was found regarding the "papilla" height for either of the implant systems at sites with a horizontal distance between the implants of <3 mm and those with a distance of 3 mm or greater. Gastaldo *et al*. (2004) evaluated the presence or absence of "papilla" between two adjacent implants. They found that complete "papilla" fill occurred only at sites where the distance from the bone crest to the contact point between the crown restorations was <4 mm. Thus, these observations show that the soft tissue between two implants will have a maximum height of 3–4 mm, and that the distance from the contact point between the crown restorations to the bone crest determines whether a complete papilla fill will occur or not (Fig. 4-34).

Chapter 5

Osseointegration

Niklaus P. Lang[1], Tord Berglundh[2], and Dieter D. Bosshardt[1]

[1]Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland
[2]Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

The fully healed site of the edentulous ridge (see Chapter 3) is most often covered by a masticatory mucosa that is about 2–3 mm thick. The masticatory mucosa is covered by a keratinized oral epithelium and includes a connective tissue rich in fibroblasts and collagen fibers that are firmly attached to the bone via the periosteum. The outer walls of the edentulous ridge, the cortical plates, are comprised of lamellar bone and enclose the cancellous bone that contains trabeculae of lamellar bone that are embedded in bone marrow. The bone marrow contains numerous vascular structures as well as adipocytes and pluripotent progenitor cells.

Different implant systems have been used to replace missing teeth, including subperiosteal implants, endosseous implants with fibrous encapsulation, and endosseous implants with direct bone contact (*osseointegrated*).

One definition of *osseointegration* (a term originally proposed by Brånemark *et al*. [1969]) was provided by Albrektsson *et al*. (1981) who suggested that this was "a direct functional and structural connection between living bone and the surface of a load carrying implant". Another definition was provided by Zarb and Albrektsson (1991) who proposed that *osseointegration* was "a process whereby clinically asymptomatic rigid fixation of alloplastic materials is achieved and maintained in bone during functional loading". Schroeder *et al*. (1976, 1981, 1995) used the term *"functional ankylosis"* to describe the rigid fixation of the implant to the jaw bone, and stated that "new bone is laid down directly upon the implant surface, provided that the rules for atraumatic implant placement are followed and the implant exhibits primary stability".

Thus, in order to acquire proper conditions for osseointegration (or functional ankylosis), the implant must exhibit proper initial fixation (primary stability) following installation in the recipient site. This initial or primary stability is the result of the contact relationship or friction that is established between mineralized bone (often the cortical bone) at the recipient site and the implant device.

Implant installation

Tissue injury

Basic rule: The less traumatic the surgical procedure and the smaller the tissue injury (the damage) in the recipient site during implant installation, the more expeditious is the process through which new bone is formed and laid down on the implant surface.

The various steps used at implant installation, such as (1) *incision* of the mucosa, often but not always followed by (2) the elevation of *mucosal flaps* and the

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

separation of the periosteum from the cortical plates, (3) the preparation of the *canal* in the cortical and spongy (cancellous) bone of the recipient site, and (4) the insertion of the implant device into this canal, bring to bear a series of mechanical insults and injury to both the mucosa and the bone tissue. The host responds to this injury with an inflammatory reaction, the main objective of which is to eliminate the damaged portions of the tissues and prepare the site for regeneration or repair. To the above-described injury to the hard tissues must be added the effect of the so-called "press fit", that is when the inserted implant is slightly wider than the canal prepared in the host bone. In such situations, (1) the mineralized bone tissue around the implant is compressed and exhibits a series of microfractures, (2) the blood vessels, particularly in the cortical portion, of the canal will collapse, (3) the nutrition to the bone in this portion is compromised, and (4) the affected tissues most often become non-vital.

The injury to the soft and hard tissues of the recipient site, however, also initiates the process of wound healing that ultimately ensures that (1) the implant becomes "ankylotic" with the bone, that is osseointegrated, and (2) a delicate mucosal attachment (see Chapter 4) is established and a soft tissue seal forms that protects the bone tissue from substances in the oral cavity.

Wound healing

The healing of the severed bone following implant installation is a complex process that apparently involves different events in different compartments of the surgical site.

In the *cortical bone compartment*, the non-vital mineralized tissue must first be removed (resorbed) before new bone can form. In the *spongy (cancellous) compartment* of the recipient site, on the other hand, the surgically inflicted damage (preparation of the canal and the installation of the implant) results mainly in soft tissue (marrow) injury that initially involves localized bleeding and clot (coagulum) formation. The coagulum is gradually resorbed and becomes replaced with granulation tissue. This is associated with an in-growth of blood vessels, leukocytes, and mesenchymal cells from the walls of the prepared canal. As a result of the continuous migration of mesenchymal cells from the surrounding marrow, the granulation tissue, in turn, is replaced with provisional soft connective tissue (provisional matrix) and eventually with osteoid. In the osteoid, deposition of hydroxyapatite crystals will occur in the collagen network around the newly formed vascular structures. Hereby, immature woven bone is formed (for detail see Chapter 3) and sequentially osseointegration occurs.

Cutting and non-cutting implants

Although today, various implant materials such as titanium alloys and zirconia are available on the market, this chapter only discusses screw-shaped implants made of c.p. titanium. The design of the metal device and the installation protocol followed may influence the speed of the process that leads to osseointegration.

"*Non-cutting*" implants (Fig. 5-1) require meticulous handling of the recipient site, including the preparation of a standardized track (thread) on the inside of the hard tissue canal. This track (thread) is prepared (precutting) using a thread-tap that is fitted with cutting edges (Fig. 5-2).

"Non-cutting" implants are usually designed as a cylinder with a rounded "apical" base. Pilot and twist drills of gradually increasing dimensions are used to prepare the hard tissue canal of the recipient site to a final diameter corresponding to the diameter of the implant body. On the surface of the cylinder,

Fig. 5-1 Ground section of a "non-cutting" implant and surrounding tissues obtained from a biopsy performed 24 hours after implant installation.

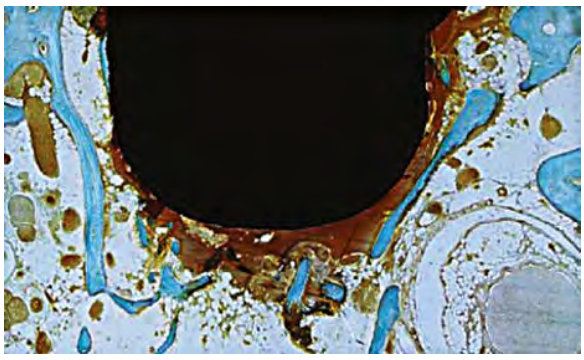

Fig. 5-2 Detail from the apical region of the implant described in Fig. 5-1. Note the presence of a coagulum in the bone marrow.

the implant is designed with a helix-shaped pitch, which results in an increase of the total diameter of the implant. The implant and the cavity prepared in the hard tissues of the recipient site become congruent. When the implant is installed, the pitch on the device will capture and follow the helix-shaped track on the wall of the hard tissue canal and thereby guide the implant with a minimum of force into the preprepared position (Fig. 5-1).

Proper initial fixation (stability) of the implant was obtained by the large contact area that was achieved between the metal screw and the bone wall in the cortical compartment of the recipient site (Fig. 5-1). During site preparation and placement of the implant, bone trabeculae in the spongy compartment of the site were obviously dislocated into the bone marrow. Blood vessels in the marrow compartment were severed, bleeding was provoked, and a coagulum had formed (Fig. 5-2).

After 16 weeks of healing (Fig. 5-3) the marginal portions of the "non-cutting" implant are surrounded by dense lamellar bone that is in direct contact with the rough surface of the metal device. Also, in the apical portion of the implant, a thin coat of mature bone can be seen to contact the implant surface and to separate the titanium screw from the bone marrow.

Cutting or self-tapping implants are designed with cutting edges placed in the "apical" portion of the screw-shaped device. The threads of the screw are prepared during manufacturing by cutting a continuous groove into the body of the titanium cylinder. When a self-tapping implant is to be placed, the recipient site is first prepared with pilot and twist drills to establish a hard tissue canal that may have a final diameter of slightly less than that of the twist drill. During insertion, the cutting edges in the "apical" portion of the implant create a narrow track in the walls of the canal and thereby establish the final implant dimension. When the implant has reached its insertion depth, contact has been established between the outer portions of the threads and the mineralized bone in the cortical compartment (initial or primary fixation is thereby secured) and with the severed bone marrow tissue in the spongy (cancellous) bone compartment.

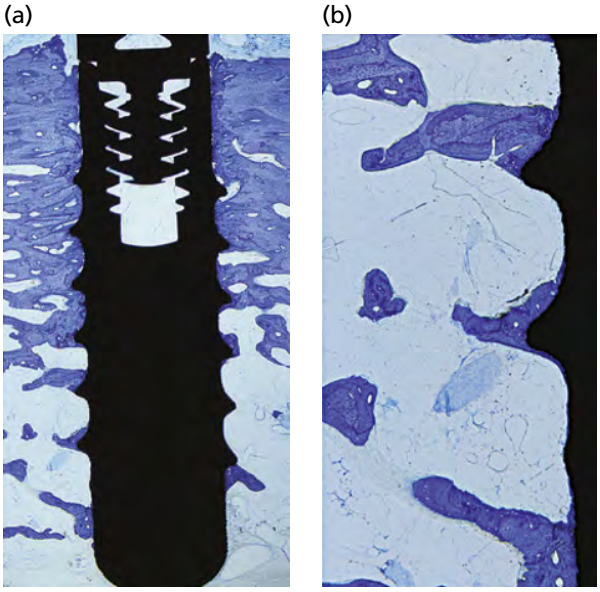

Fig. 5-3 (a) Ground section showing a "non-cutting" implant and surrounding bone after 16 weeks of healing. In the cortical portion of the recipient site, the bone density is high. (b) Detail of (a). In more apical areas, a thin coat of bone is present on the implant surface. Note also the presence of trabeculae of lamellar bone that extend from the implant into the bone marrow.

Figure 5-4 illustrates a recipient site with a self-tapping implant possessing a rough surface

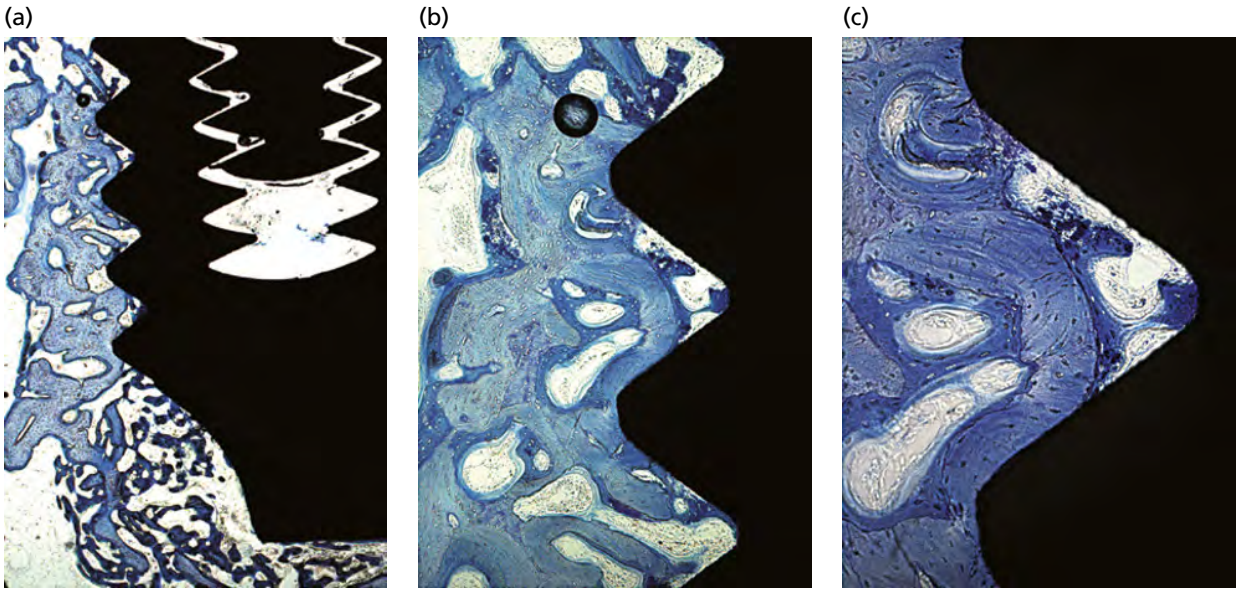

Fig. 5-4 (a) Ground section of a self-tapping implant site from a biopsy sampled after 2 weeks of healing. In the apical area, large amounts of woven bone have formed. (b) Detail of (a). In the threaded region, newly formed bone can be seen to reach contact with the implant surface. (c) Higher magnification of (b). Newly formed bone extends from the old bone and reaches the titanium surface in the invagination between two consecutive "threads".

modification. The biopsy was harvested 2 weeks after installation surgery. The outer portion of the thread is in contact with the "old" bone, while new bone formation is the dominant feature in the invaginations between the threads and in areas lateral to the "apical" portions of the implant. Thus, discrete areas of newly formed bone can be seen also in direct contact with the implant surface. In sections representing 6 weeks of healing (Fig. 5-5), it was observed that a continuous layer of newly formed bone covers most of the rough implant surface. This newly formed bone is also in contact with the old, mature bone that is present in the periphery of the recipient site. After 16 months of healing (Fig. 5-6), the bone tissue in

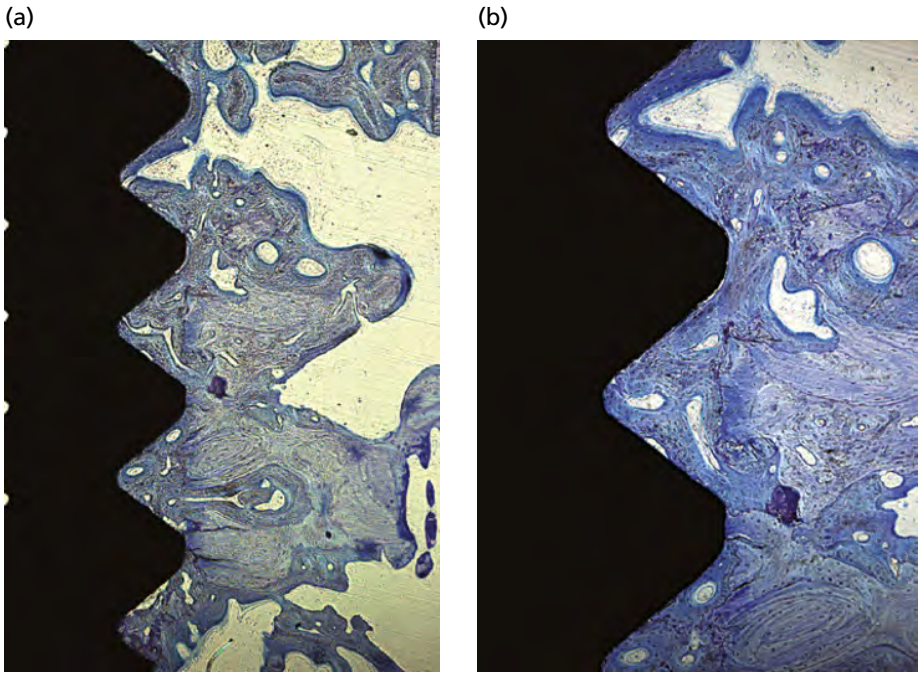

Fig. 5-5 Ground section of an implant site with a self-tapping implant from a biopsy specimen obtained after 6 weeks of healing. (a) In the marginal area, a continuous layer of bone covers most of the implant surface. (b) Higher magnification. Note the zone of newly formed (darker stained) bone that is in direct contact with the implant surface.

the zone of osseointegration has remodeled and the entire hard tissue bed for the implant is comprised of lamellar bone including both concentric and interstitial lamellae.

Process of osseointegration

De novo bone formation in the severed alveolar ridge following implant placement was studied in experiments in various experimental animal models. As an example, Berglundh *et al*. (2003) and Abrahamsson *et al*. (2004) described various steps involved in bone formation and osseointegration to implants placed in the mandible of dogs.

The device: Custom-made implants made of c.p. titanium and in the shape of a solid screw and configured with a rough surface topography were utilized (Fig. 5-7). In the implant device, the distance between two consecutive profiles of the pitch (i.e. the threads in a vertical cross-section) was 1.25 mm. A 0.4-mm deep U-shaped circumferential trough had been prepared within the thread region during manufacturing (Fig. 5-8). The tip of the pitch was left untouched. Following the installation of the non-cutting device (Fig. 5-9), the pitch was engaged in the hard tissue walls prepared by the cutting/tapping device. This provided initial or primary fixation of the device. The void between the pitch and the body of the implant established a geometrically well-defined wound chamber (Fig. 5-10). Biopsies were performed to provide healing periods extending from 2 hours following implant insertion to 12 weeks of healing. The biopsy specimens were prepared for ground sectioning as well as for decalcified sections.

Fig. 5-7 Device used in the dog experiment. The implant is a modification of a solid screw. The distance between two consecutive threads is 1.25 mm. The depth of the trough is 0.4 mm.

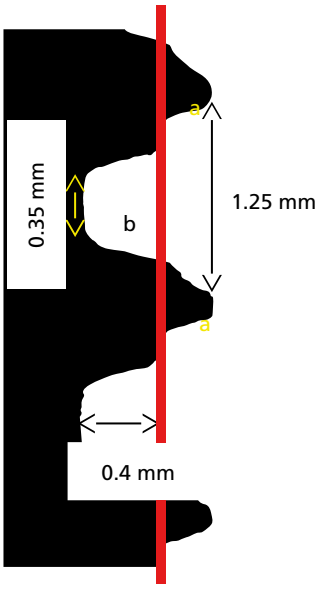

Fig. 5-8 The dimensions of the "wound chamber" in the implant device.

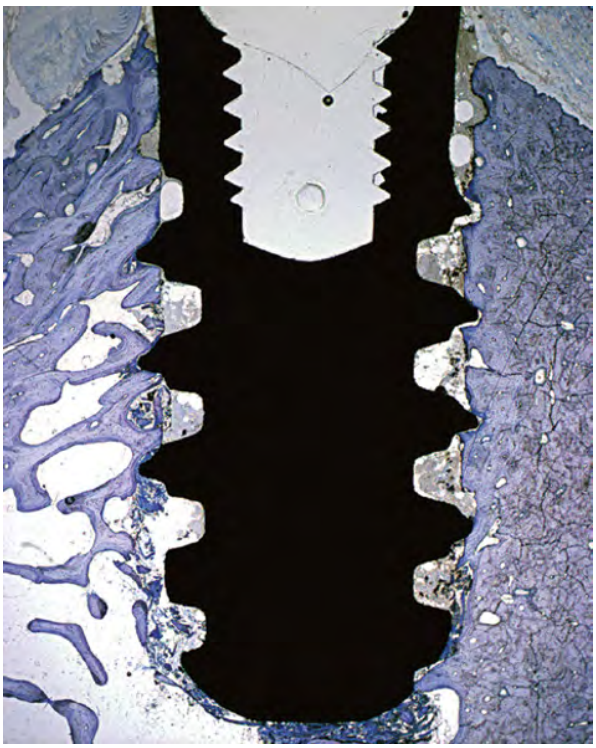

Fig. 5-9 Ground section showing the implant and adjacent tissues immediately after implant installation. The pitch region is engaged in the hard tissue wall. The void between two consecutive pitch profiles includes the wound chamber.

The wound chamber: Figure 5.10 illustrates two wound chambers in a cross-section (ground section) of an implant with surrounding soft and hard tissues from a biopsy specimen sampled 2 hours after installation of the metal device. The peripheral portions of the pitch were in contact with the invaginations of the track prepared by the tap in the cortical bone. The wound chambers (Fig. 5-11a) were occupied with a blood clot in which erythrocytes, neutrophils, and

monocytes/macrophages were trapped in a network of fibrin (Fig. 5-11b). The leukocytes were apparently engaged in the wound cleansing process.

Fibroplasia: Figure 5-12a illustrates a device with surrounding tissues after 4 days of healing. The coagulum had in part been replaced with granulation tissue that contained numerous mesenchymal cells, extracellular matrix components, and newly formed vascular structures (angiogenesis) (Fig. 5-12b). A *provisional connective tissue (matrix)* had been established.

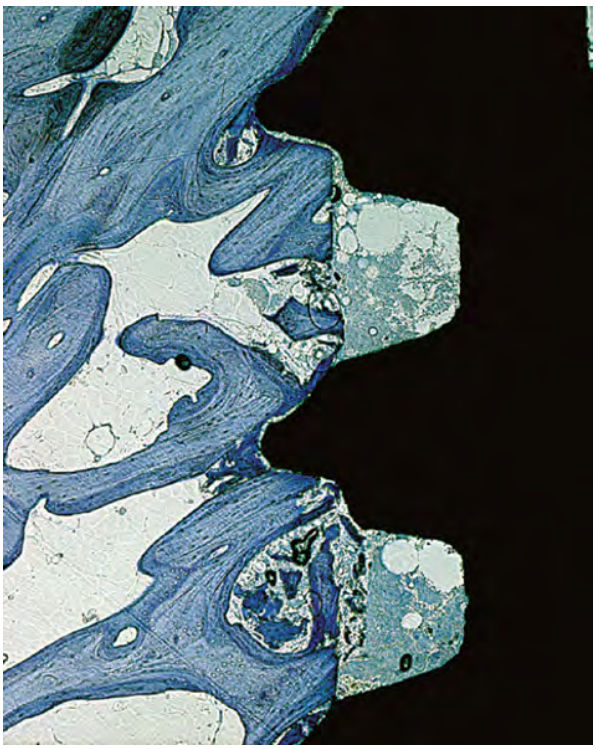

Fig. 5-10 Detail of Fig. 5-9. The wound chamber was filled with blood and a coagulum has formed.

Bone modeling: After 1 week of healing, the provisional connective tissue in the wound chambers was rich in vascular structures and contained numerous mesenchymal cells (Fig 5-13a). The number of remaining inflammatory cells was small. In several compartments of the chamber, a cell-rich immature bone (woven bone) was seen in the provisional soft connective tissue that surrounded the blood vessels. Woven bone formation occurred in the center of the chamber as well as in discrete locations that apparently were in direct contact with the surface of the titanium device (Fig. 5-13b). This was considered to represent the very first phase of osseointegration; contact between the implant surface and newly formed woven bone.

After 2 weeks of healing, woven bone formation appeared to be pronounced in all compartments, apical as well as lateral, surrounding the implant (Fig. 5-14a). Large areas of woven bone were found in the bone marrow regions "apical" of the implant. In the wound chamber, portions of the newly formed woven bone apparently extended from the old bone into the provisional connective tissue (Fig. 5-14b) and had in many regions reached the surface of the titanium device. At this interval, most of the implant surface was occupied by newly formed bone and a more comprehensive and mature osseointegration had been established (Fig. 5-14c). In the pitch regions, there were signs of ongoing new bone formation (Fig. 5-14d). Thus, areas of the recipient site located lateral to the device, that were in direct contact with the host bone immediately following installation

surgery and provided initial fixation for the implant, had undergone resorption and were also involved in new bone formation after 2 weeks of healing.

At 4 weeks (Fig. 5-15a), the newly formed mineralized bone extended from the cut bone surface into the chamber and a continuous layer of cell-rich, woven bone covered most of the titanium wall of the chamber. The central portion of the chamber was filled with a primary spongiosa (Fig. 5-15b), rich in vascular structures and a multitude of mesenchymal cells.

Remodeling: After 6–12 weeks of healing, most of the wound chambers were filled with mineralized bone (Fig. 5-16). Bone tissue, including primary and secondary osteons, could be seen in the newly formed tissue and in the mineralized bone that made contact with the implant surface. Bone marrow that contained blood vessels, adipocytes, and mesenchymal cells was observed to surround the trabeculae of mineralized bone.

Summary: The wound chambers were first occupied with a coagulum. With the in-growth of vessels and migration of leukocytes and mesenchymal cells, the coagulum was replaced with granulation tissue. The migration of mesenchymal cells continued and the granulation tissue was replaced with a provisional matrix, rich in vessels, mesenchymal cells, and

fibers. The process of *fibroplasia* and angiogenesis had started. Formations of newly formed bone could be recognized already during the first week of healing; the newly formed woven bone projected from the lateral wall of the cut bony bed (appositional bone formation; distance osteogenesis) (Davies 1998), but *de novo* formation of new bone could also be seen on the implant surface, that is at a distance from the parent bone (contact osteogenesis) (Davies 1998). During subsequent weeks, the trabeculae of woven bone were replaced with mature bone, that is lamellar bone and marrow (bone remodeling).

Morphogenesis of osseointegration

A series of publications have described the process of osseointegration of titanium implants placed in human volunteers (Bosshardt *et al*. 2011; Donos *et al*. 2011; Ivanovski *et al*. 2011; Lang *et al*. 2011). In these studies, solid screw devices with a moderately rough surface were placed in the retromolar region of the mandible and submerged healing conditions were established. Biopsies including the implant with surrounding tissues were retrieved with the use of a trephine drill after 1, 2, 4, and 6 weeks. The examination of the samples included histologic and morphometric measurements and particular attention was paid to tissue elements that were in direct contact with or close to the implant surface (the tissue–implant interface), for example old bone, osteoid, newly formed bone, and non-mineralized mesenchymal soft tissue. In addition, at all examination intervals bone debris and solid bone particles were present in the wound lateral to the implant. Such constituents were obviously remnants of the drilling procedure used to prepare the hard tissue canal into which the implant was subsequently introduced.

Overall pattern of implant integration

Figure 5-17 describes the changes in the morphometric measurements in the tissue–implant interface region during the course of the study. After 1 week of healing, about 40% of the interface region was made up of soft tissue (granulation tissue, provisional connective tissue) and an additional 50% of bone debris and old bone. After 2 weeks, the amount of newly formed bone was still small, but the amount of soft tissue was markedly reduced. In the interval between 2 and 4 weeks, new bone formation was apparently pronounced in the interface zone. Thus, in this interval, newly formed bone increased from about 10% to about 30%, while the amount of hard tissue debris was markedly reduced. Also, in the period between 4 and 6 weeks, new bone formation was pronounced (from 30% to about 60%) and the diminution of old bone and bone debris markedly decreased. In other words, in humans the process of osseointegration appears to be most active in the interval between 2 and 6 weeks.

Summary: During the 6 weeks of healing that was monitored in this particular study in humans, it was observed that while the amount of old bone, bone debris,

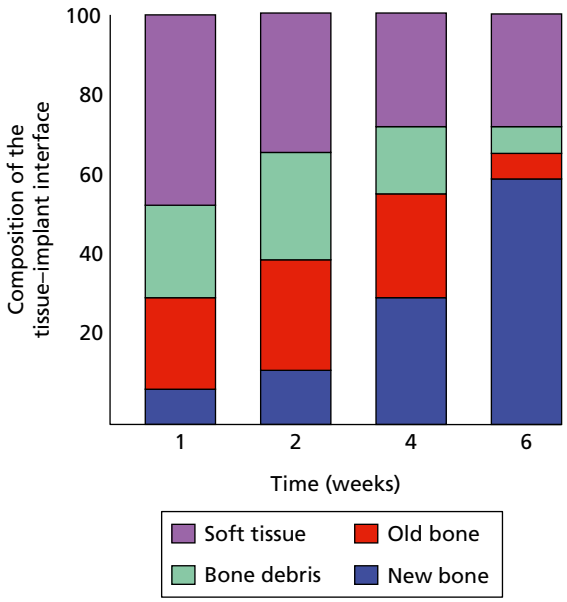

Fig. 5-17 The percentages of new bone, old bone, bone debris, and soft tissue in the "tissue–implant interface" after 1, 2, 4, and 6 weeks of healing. Note that the percentage of old bone, soft tissue, and bone debris that was present in the zone next to the implant surface decreased over time and that the amount of newly formed bone increased. There are reasons to suggest that (1) the contact between old bone and the implant established the initial "mechanical" stability of the titanium device, while (2) the newly formed bone subsequently achieved osseointegration.

and soft tissue that initially occurred in close proximity to the implant gradually decreased, the amount of newly formed bone increased (Fig. 5-17). This pattern of healing that eventually resulted in osseointegration is in close agreement with the results obtained from the animal experiments reported earlier in this chapter.

Biopsy sample observations

Early wound

An implant with surrounding tissues sampled in the early phase after the surgical installation of the device is shown in Fig. 5-18. Note the presence of old bone, particularly in the cortical (marginal) region of the site. This old compact bone appeared to be in direct contact with the implant and obviously facilitated the initial mechanical stability of the device. Note also that more apical portions of the implant were surrounded by non-mineralized tissue, bone debris, and bone particles.

Healing process

After *1 week of healing*, substantial amounts of old bone occupied the marginal portion of the surgically prepared site. This bone tissue appeared to be in close contact with the implant device (Fig. 5-19). As stated above, this close fit between the remaining old bone and the titanium device was most likely a prerequisite for initial implant stability and of importance in establishing optimal healing conditions in the hard tissue wound. At this early interval, newly formed bone occurred on the surface of old bone tissue (Fig. 5-20), while areas of bone resorption could be identified in adjacent regions of the tissue wound.

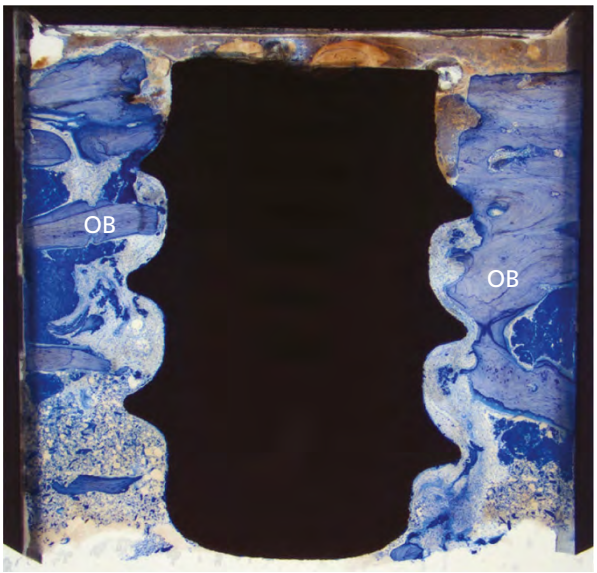

Fig. 5-18 Longitudinal ground section through a biopsy including a solid screw implant device. While compact old bone (OB) is found in contact with the coronal portion of the implant, the apical portion is comprised of less dense tissues and debris.

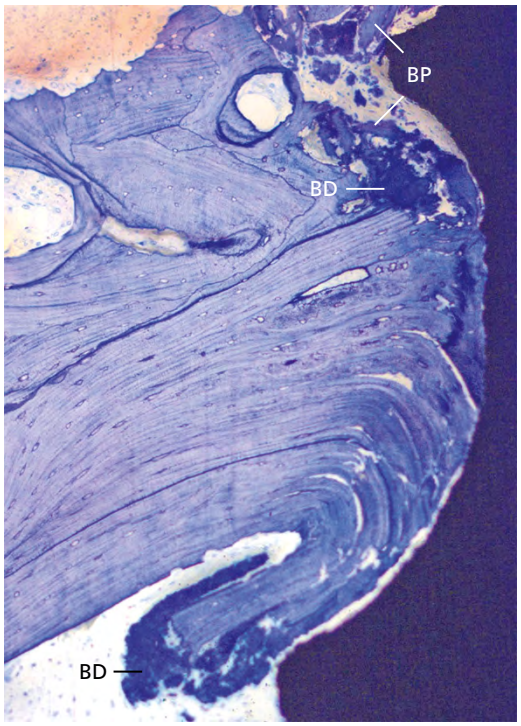

Fig. 5-19 Compact bone in direct contact with the implant surface in the coronal portion after 1 week of healing. Note the presence of bone particles (BP) and bone debris (BD) of varying size close to the implant surface.

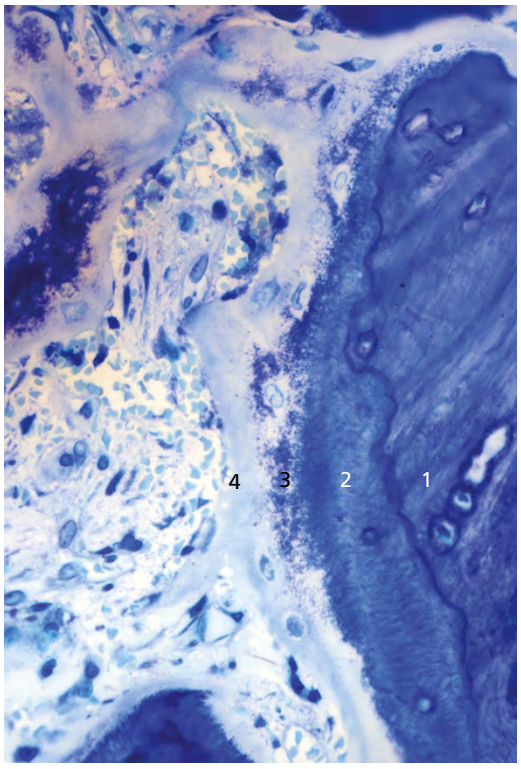

Fig. 5-20 Initial stage of bone apposition onto the surface of old bone occurring at a distance from the implant surface after 1 week of healing. 1, old bone; 2, new mineralized bone matrix; 3, mineralization foci at the mineralization front; 4, osteoid lined by osteoblasts.

In other words, phenomena such as hard tissue apposition and resorption characterized the healing process in this early phase.

Bone debris, bone particles, soft mesenchymal tissue as well as thin layers of osteoid tissue were also frequently found on or close to the implant surface (Figs. 5-21, 5-22).

At the *2-week interval*, remnants of old bone apparently still remained in the marginal portion of the implant site. Areas of hard tissue resorption (Howship´s lacunae; Fig. 5-23) could be found immediately adjacent to as well as at a distance from the implant. In addition, minute areas of newly formed bone occurred on or immediately lateral to the surface of the implant device. This formation of woven bone was the first sign of what may be called osseointegration (Figs. 5-24, 5-25). Furthermore, at this interval, tiny ledges of newly formed woven bone apparently connected old bone to the titanium screw device (Fig. 5-25).

At the *4-week interval*, the healing process features of modeling and remodeling were pronounced. Thus, in some areas close to the implant surface resorptive processes were discernible, while in adjacent areas woven bone had formed (Fig. 5-26).

At the *6-week interval*, large amounts of newly formed woven bone (Fig. 5-27), but also lamellar bone and marrow, were present in close proximity to the implant device. This kind of newly formed hard tissue was apparently part of a more stable "bone–implant contact", in other words osseointegration.

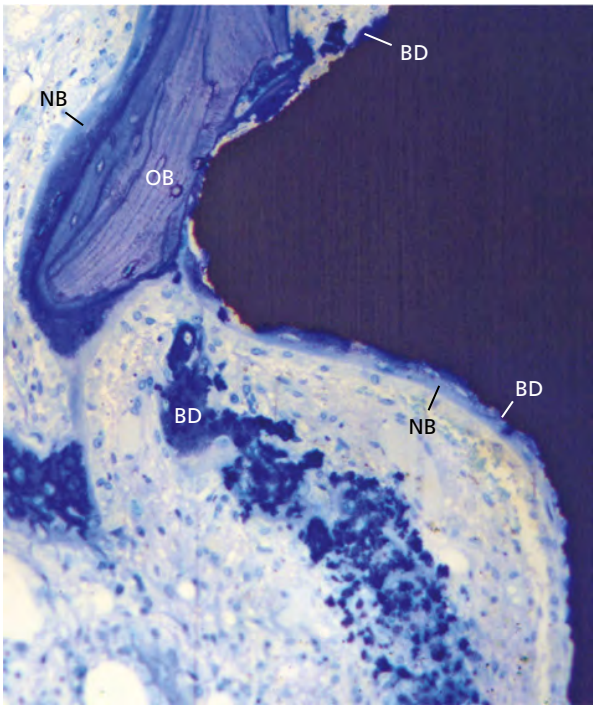

Fig. 5-22 After a healing period of 1 week, old bone (OB) is still in contact with the pitch of the implant thread. Newly formed bone (NB) is present (1) on the ledges of old bone and (2) on the implant surface. Bone debris (BD) is found adhering to the implant surface, but is also embedded in the adjacent mesenchymal soft tissue. The newly formed bone mainly consists of a partly mineralized osteoid lined by osteoblasts.

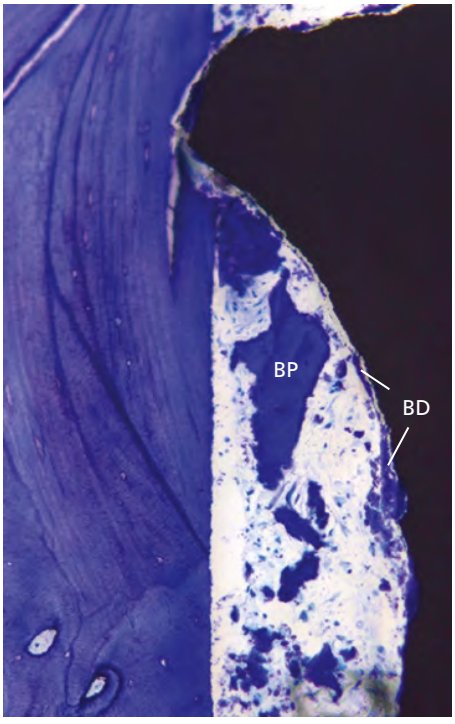

Fig. 5-21 After 1 week of healing, a considerable amount of bone debris (BD) and larger bone particles (BP) are present in the gap between the implant surface and the cut bone bed.

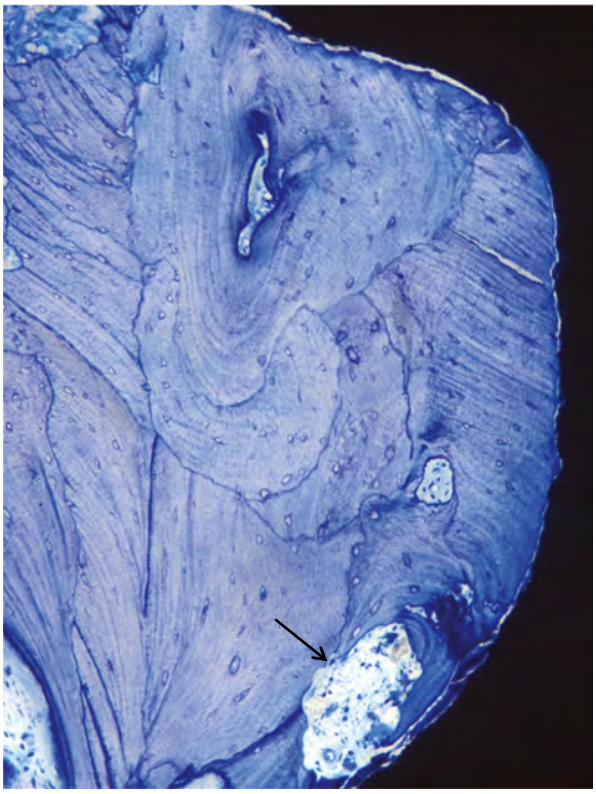

Fig. 5-23 Area of compact old bone in contact with the most coronal portion of the implant after a healing period of 2 weeks. Note the presence of bone resorption at the bottom of the micrograph (arrow).

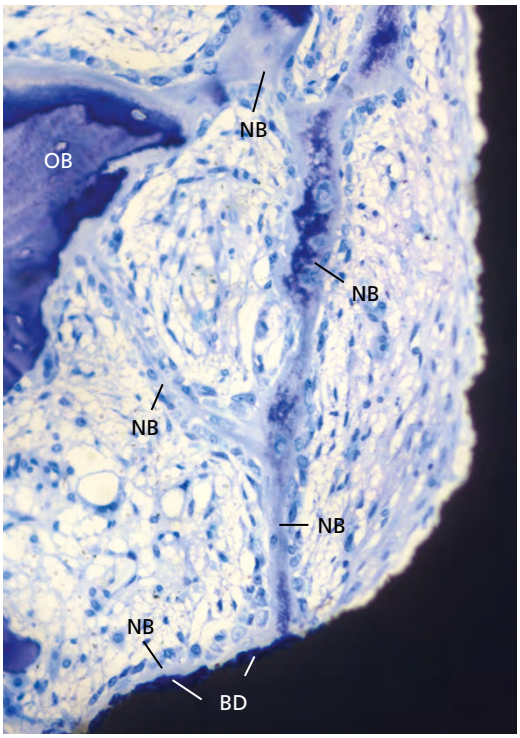

Fig. 5-24 Site characterized by active tissue modeling, in other words woven bone formation. The newly formed trabeculae of woven bone extend from old bone into the provisional connective tissue. OB, old bone; NB, new bone; BD, bone debris.

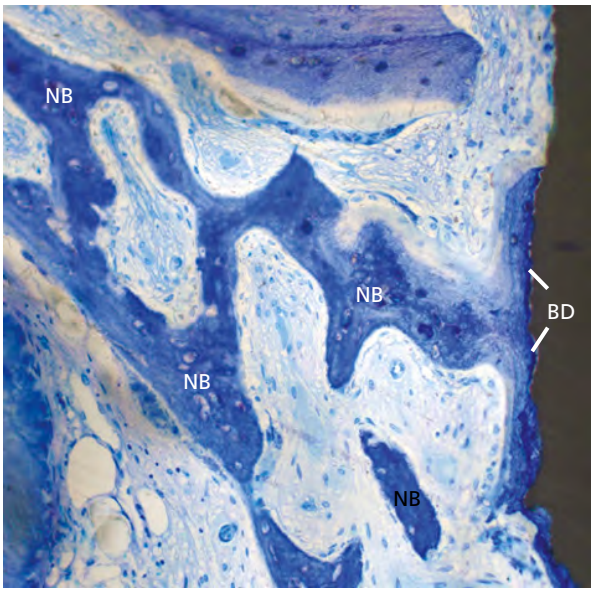

Fig. 5-26 Micrograph showing the implant–tissue interface and the peri-implant tissues of an implant after 4 weeks of healing. The newly formed bone (NB) forms a tiny trabecular network connecting the surface of the old bone with the implant surface. Deposition of new bone on the implant surface was associated with the presence of bone debris (BD).

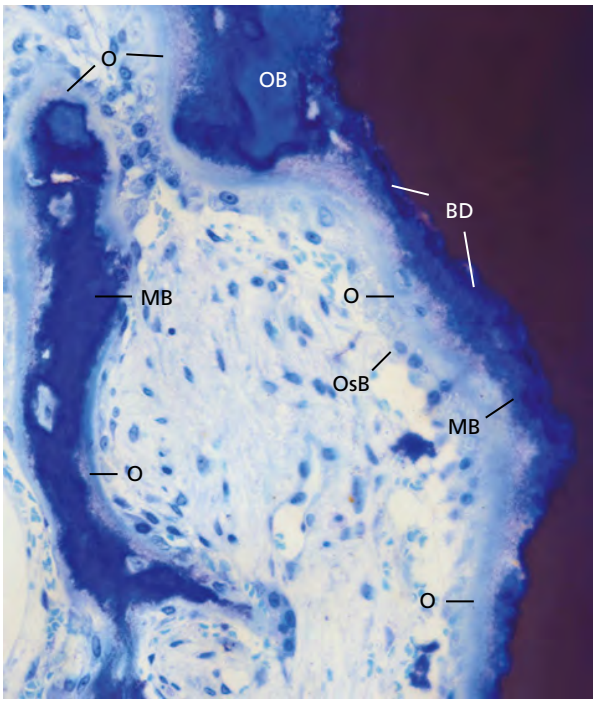

Fig. 5-25 Micrograph showing the implant–tissue interface of an implant site after 2 weeks of healing. The area is filled with a provisional connective tissue matrix and zones of new bone are discernible as well as osteoid tissue on the implant surface. Note the presence of bone debris (BD) on the surface of the implant. Tissue elements, including mineralized matrix of immature bone (MB) as well as osteoid tissue (O) and old bone (OB), are in contact with the implant surface. OsB, osteoblasts between osteoid and connective tissue.

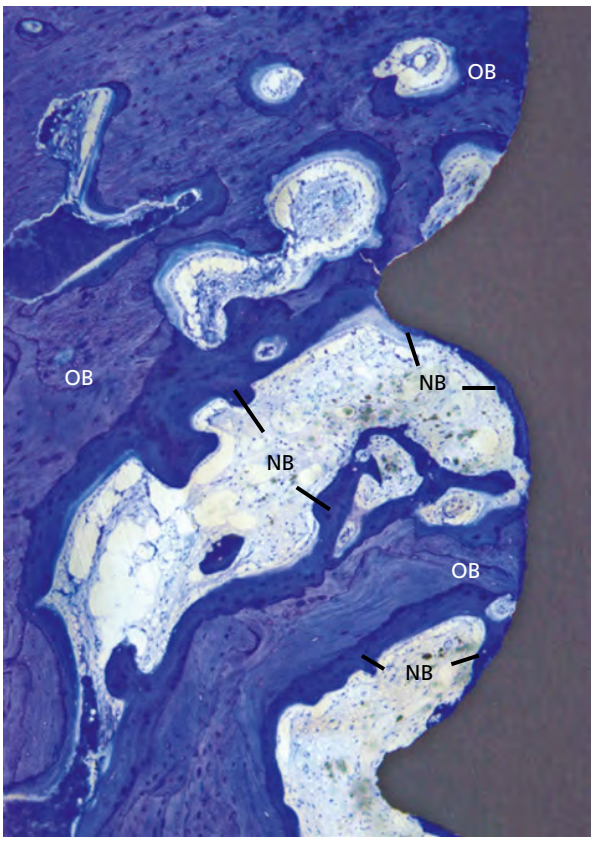

Fig. 5-27 Micrograph showing the implant–tissue interface after 6 weeks of healing. New bone (NB) is found on the surface of old bone (OB) and on the implant surface.

Part 2: Epidemiology

Chapter 6

Epidemiology of Periodontitis

Panos N. Papapanou[1] and Ryan T. Demmer[2]

[1] Division of Periodontics, Section of Oral, Diagnostic, and Rehabilitation Sciences, Columbia University College of Dental Medicine, New York, NY, USA
[2] Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, MN, USA

Introduction

The term epidemiology is of Hellenic origin; it consists of the preposition "epi", which means "among" or "against", and the noun "demos", which means "people". As denoted by its etymology, epidemiology is defined as "the study of the distribution of disease or a physiological condition in human populations and of the factors that influence this distribution" (Lilienfeld 1978). An older but more inclusive description by Frost (1941) emphasizes that "epidemiology is essentially an inductive science, concerned not merely with describing the distribution of disease, but equally or more with fitting it into a consistent philosophy". Thus, inferences drawn from epidemiologic investigations extend beyond the description of the distribution of diseases in different populations (*descriptive* epidemiology) but also: (1) elucidate their etiology by integrating information derived from other disciplines such as genetics, biochemistry, microbiology, sociology and others to evaluate the consistency of epidemiologic data with hypotheses developed clinically or experimentally (*analytical* epidemiology); and (2) provide the basis for developing and evaluating preventive procedures and public health practices (*interventional* epidemiology).

Based on the above, epidemiologic research in periodontology must: (1) fulfill the task of providing data on the *prevalence* of periodontal diseases in different populations, that is, the frequency of their occurrence, as well as on the *severity* of such conditions (i.e. the amount of pathologic changes); (2) elucidate aspects related to the *determinants* and the *etiology* of these diseases (*risk* and *causative* factors); and (3) provide documentation concerning the effectiveness of preventive and therapeutic measures on a population basis.

Methodological issues

Examination methods: index systems

Examination of the periodontal status of a given individual includes clinical assessments of inflammation in the gingiva, recordings of probing depths and clinical attachment levels, as well as radiographic assessments of the amount of loss of supporting alveolar bone. A variety of index systems for the scoring of

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

these parameters have been developed, some of which were designed exclusively for examination of patients in a dental practice set-up, while others were developed for use in epidemiologic research. The design of the index systems and the definition of the various scores inevitably reflect the knowledge of the etiology and pathogenesis of periodontal diseases at the time these systems were introduced, as well as concepts related to therapeutic approaches and strategies accepted at the time. This section will not provide a complete list of all available scoring systems, but rather give a brief description of a limited number of indices that are either currently used or are likely to be encountered in the recent literature. For a detailed description of earlier scoring systems and a historical perspective of their development, the reader is referred to Ainamo (1989).

Assessment of inflammation of the periodontal tissues

Presence of inflammation in the gingiva is usually recorded by the use of a probe, and often according to the principles of the Gingival Index System outlined by Löe (1967). According to this system, absence of visual signs of inflammation in the gingival unit is scored as 0, while a slight change in color and texture is scored as 1. Visual inflammation and bleeding tendency from the gingival margin right after a periodontal probe is run along the gingival margin is scored as 2, while overt inflammation with tendency for spontaneous bleeding is scored as 3. Plaque deposits are scored in a parallel index (Plaque Index System) on a scale from 0 to 3 (Silness & Löe 1964): the absence of plaque is scored as 0, plaque disclosed after running the periodontal probe along the gingival margin as 1, visible plaque as 2, and abundant plaque as 3. Simplified variants of both the gingival and the plaque indices have been used extensively (Ainamo & Bay 1975), assessing presence/absence of inflammation or plaque, respectively, in a binomial fashion (*dichotomous scoring*). In such systems, bleeding from the gingival margin and visible plaque correspond to a score of 1, while absence of bleeding and no visible plaque correspond to a score of 0.

Bleeding after probing to the base of the probeable pocket (Gingival Sulcus Bleeding Index) has been a common way of establishing the occurrence of subgingival inflammation (i.e. the presence of an inflammatory infiltrate adjacent to the ulcerated pocket epithelium) (Mühlemann & Son 1971). In this dichotomous registration, bleeding emerging within 15 seconds after probing is scored as 1.

Assessment of loss of periodontal tissue support

One of the early indices providing indirect information on the loss of periodontal tissue support was the Periodontal Index (PI) developed in the 1950s by Russell (1956), and was the most widely used index in epidemiologic studies of periodontal disease until the 1980s. Its criteria are applied to each tooth and the scoring is as follows: a tooth with healthy periodontium scores 0, a tooth with gingivitis around only part of the tooth circumference scores 1, a tooth with gingivitis encircling the tooth scores 2, pocket formation scores 6, and loss of function due to excessive tooth mobility scores 8. Due to the nature of the criteria used, the PI is a reversible scoring system, and a tooth or an individual can have the score lowered or reduced to 0 after treatment.

In contrast to the PI system, the Periodontal Disease Index (PDI), developed by Sigurd Ramfjord in 1959 (Ramfjord 1959), is a system designed to assess *destructive* disease; it measures *loss of attachment* instead of *pocket depth* and is, therefore, an irreversible index. The scores, ranging from 0 to 6, denote periodontal health or gingivitis (scores 0–3) and various levels of attachment loss (scores 4–6).

In contemporary epidemiologic studies, loss of periodontal tissue support is assessed by measurements of probing pocket depth (PPD) and probing attachment level (PAL). PPD is defined as the distance from the gingival margin to the apical location of the tip of a periodontal probe that is inserted into the pocket using a moderate probing force. Likewise, PAL or clinical attachment level (CAL) is defined as the distance from the cemento-enamel junction (CEJ) to the location of the probe tip. Probing assessments are usually carried out at several locations along the tooth circumference (buccal, lingual, mesial, and distal). The number of probing assessments per tooth has varied in epidemiologic studies from two to six, while the examination may include either all teeth present (*full-mouth*) or a subset of *index* teeth (*partial-mouth* examination).

Carlos *et al*. (1986) proposed an index system which records loss of periodontal tissue support. The index was denoted the Extent and Severity Index (ESI) and consists of two components (*bivariate* index): (1) the *Extent*, describing the proportion of tooth sites of a subject showing signs of destructive periodontitis; and (2) the *Severity*, describing the amount of probing attachment loss at the diseased sites, expressed as a mean value. An attachment loss threshold of >1 mm was set as the criterion that qualified a tooth site as affected by the disease. The introduction of a threshold value serves a dual purpose: (1) it readily distinguishes the fraction of the dentition affected by disease at levels exceeding the error inherent in the clinical measurement of attachment loss; and (2) it prevents unaffected tooth sites from contributing to the individual subject's mean attachment loss value. In order to limit the number of measurements to be performed, a partial examination comprising the mid-buccal and mesiobuccal aspects of the upper right and lower left quadrants was recommended. It has to be emphasized that the

system was designed to assess the cumulative effect of destructive periodontal disease rather than the presence of the disease itself. The bivariate nature of the index facilitates a rather detailed description of attachment loss patterns: for example, an ESI of (90, 2.5) suggests a generalized but rather mild form of destructive disease, in which 90% of the tooth sites are affected by an average attachment loss of 2.5 mm. In contrast, an ESI of (20, 7.0) describes a severe, localized form of disease.

Radiographic assessment of alveolar bone loss

The potential and the limitations of intraoral radiography to describe loss of supporting periodontal tissues were reviewed in classic publications (Lang & Hill 1977; Benn 1990) and more recent reports (Vandenberghe *et al*. 2010). Radiographs have been commonly employed in older cross-sectional epidemiologic studies to quantify the amount of alveolar bone loss due to periodontitis rather than the presence of the disease itself, and provide valid estimates of the extent and severity of destructive periodontitis affecting interproximal surfaces (Pitiphat *et al*. 2004). Assessments of bone loss in intraoral radiographs are usually performed by evaluating a multitude of qualitative and quantitative features of the visualized interproximal bone, including (1) the presence of an intact lamina dura, (2) the width of the periodontal ligament space, (3) the morphology of the bone crest ("even" or "angular" appearance), and (4) the distance between the CEJ and the most coronal level at which the periodontal ligament space is considered to exhibit normal width. The threshold for bone loss, that is, the CEJ–bone crest distance considered to indicate that bone loss has occurred, varies between 1 and 3 mm in different studies. Radiographic data are usually presented as (1) mean bone loss scores per subject (or group of subjects) and (2) number or percentage of tooth surfaces per subject (or group of subjects) exhibiting bone loss exceeding certain thresholds. In early studies, bone loss was frequently recorded using "ruler" devices, describing the amount of lost or remaining bone as a percentage of the length of the root or the tooth (Schei *et al*. 1959; Lavstedt *et al*. 1975). An increased awareness of the adverse effects of ionizing radiation no longer allows the use of intraoral radiography as a screening tool to survey periodontal conditions in epidemiologic studies.

Assessment of periodontal treatment needs

An index system aimed at assessing the need for periodontal treatment in large population groups was developed, on the initiative of the World Health Organization (WHO), by Ainamo *et al*. (1982). The principles of the Community Periodontal Index for Treatment Needs (CPITN) can be summarized as follows:

1. The dentition is divided into six *sextants* (one anterior and two posterior tooth regions in each dental arch). The treatment need in a sextant is recorded when two or more teeth not intended for extraction are present. If only one tooth remains in the sextant, the tooth is included in the adjoining sextant.
2. Probing assessments are performed either around all teeth in a sextant or around certain index teeth (the latter approach has been recommended for epidemiologic studies). Only the most severe measure in the sextant is chosen to represent the sextant.
3. The periodontal conditions are scored as follows:
   - *Code 0* is given to a sextant with no pockets, calculus, or overhangs of fillings and no bleeding on probing.
   - *Code 1* is given to a sextant with no pockets, calculus, or overhangs of fillings, but in which bleeding occurs after gentle probing in one or several gingival units.
   - *Code 2* is assigned to a sextant if there are no teeth with pockets exceeding 3 mm, but in which dental calculus and plaque-retaining factors are identified subgingivally.
   - *Code 3* is given to a sextant that harbors teeth with 4–5-mm deep pockets.
   - *Code 4* is given to a sextant that harbors teeth with pockets that are 6 mm deep or deeper.
4. The treatment needs (TN) scores range from 0 to 4 and are based on the most severe periodontal condition code in the entire dentition, recorded as above. Thus, TN 0 indicates no need for periodontal therapy in the presence of gingival health (*Code 0*), TN 1 need for improved oral hygiene (*Code 1*); TN 2 need for scaling, removal of overhangs, and improved oral hygiene (*Codes 2 + 3*); and TN 3 more advanced treatment needs (*Code 4*).

Although not designed for epidemiologic purposes, this index system has been extensively used, and CPITN-based studies have often been the sole source of epidemiologic information on periodontal conditions, particularly those from developing countries. A later modification of the index, termed Community Periodontal Index (CPI) (WHO 1997), places more emphasis on the assessment of periodontal conditions rather than the assessment of periodontal treatment needs. A substantial amount of data generated by the use of CPITN/CPI have been accumulated in the WHO Global Oral Data Bank (Miyazaki *et al*. 1992; Pilot & Miyazaki 1994; Petersen & Ogawa 2005, 2018; Petersen *et al*. 2010) and are accessible electronically through servers maintained at the WHO Collaborating Centers at the Niigata University, Japan and the University of Malmö, Sweden.

Periodontitis "case definition" in epidemiologic studies

A fundamental prerequisite for any meaningful comparative assessment of prevalence is a valid and accurate definition of the disease under investigation. Unfortunately, no uniform criteria have been established in periodontal research for this purpose. Epidemiologic studies have employed, in an inconsistent manner, a wide array of symptoms, including gingivitis, PPD, clinical (or probing) attachment level, and radiographically assessed alveolar bone loss. Considerable variation characterizes the threshold values employed for defining periodontal pockets as "deep" or "pathologic", or the CAL and alveolar bone scores required for assuming that loss of periodontal tissue support has, in fact, occurred. In addition, the number of "affected" tooth surfaces required for assigning an individual subject as a "case", that is, as suffering from periodontal disease, has varied. These inconsistencies in the definitions inevitably affect the data describing the distribution of the disease (Papapanou 1996; Kingman & Albandar 2002; Demmer & Papapanou 2010; Catunda *et al*. 2019) and, consequently, the identification of risk factors (Borrell & Papapanou 2005). Any review of the literature charged with the task of comparing disease prevalence or incidence in different populations or at different time periods must first confront the interpretation of the published data and literally "decode" them in order to extract relevant information that is amenable to inter-study comparisons. These problems have been addressed in the literature and three specific aspects have attracted special attention, namely (1) the ability of partial recordings to reflect full-mouth conditions, (2) the use of the CPITN system in studies of periodontal disease, and (3) the definition of a "periodontitis case" in epidemiologic studies.

It is clear that an optimal examination of periodontal conditions should include circumferential probing assessments around all teeth. Nevertheless, the majority of epidemiologic studies have, for practical reasons, employed partial recording methodologies. The rationale for the use of partial examinations has been based on: (1) the fact that the time required for carrying out a partial recoding is significantly decreased, resulting in lower costs and better patient acceptance; and (2) the assumption that the amount of information lost is kept to a minimum (i.e. that the examined segments adequately reflect the periodontal condition of the entire dentition). However, attempts to quantify accurately the amount of information lost through the different partial recording systems made by several investigators (Diamanti-Kipioti *et al*. 1993; Eaton *et al*. 2001; Susin *et al*. 2005; Kingman *et al*. 2008) have revealed that the discrepancy between the findings obtained by means of partial- and full-mouth surveys may be substantial. These studies have typically employed full-mouth data for a series of periodontal parameters and compared them with the values obtained by assessments of a subset of teeth or tooth surfaces. Their results suggest that:

1. Reasonably high correlations between full-mouth and half-mouth clinical attachment loss scores should be expected in adult populations, due to the apparent symmetry of periodontal conditions around the midline.
2. The performance of a partial recording system is directly dependent on the actual prevalence and extent of periodontal disease in the population in question and, consequently, on the age of the subjects examined; the less frequent the disease in the population and the lower the proportion of affected sites affected in each individual, the more difficult it becomes for the partial examination to portray accurately the full-mouth periodontal status.
3. A full-mouth examination provides the best means of accurately assessing the prevalence and severity of periodontal disease in a population.

The use of the CPITN system in epidemiologic studies of periodontal disease was critically evaluated in a number of publications (Schürch *et al*. 1990; Butterworth & Sheiham 1991; Baelum *et al*. 1993a, b; Baelum & Papapanou 1996; Benigeri *et al*. 2000). At the time the system was designed, the conversion from periodontal health to periodontitis was thought to follow a continuum of conditions of increasing severity, ranging from health to gingivitis, calculus deposition, formation of deep pockets, and destructive, progressive disease. Consequently, treatment approaches were primarily focused on probing depths to determine the choice between non-surgical and more complex, surgical periodontal therapy. As mentioned earlier, the CPITN system was originally intended for population screening in order to determine treatment needs and to facilitate preventive and therapeutic strategies; it was not meant to describe the prevalence, extent, and severity of periodontal disease and several studies have questioned the suitability of the CPITN for such purposes. For example, Butterworth and Sheiham (1991) examined the ability of CPITN to reflect changes in periodontal conditions in patients of a general dental practice before and after periodontal therapy. Despite a substantial improvement in periodontal status, that is, a reduction in gingivitis, calculus scores, and deep pockets, the CPITN scores were only marginally improved. Furthermore, in a rural Kenyan subject sample, Baelum *et al*. (1993b) refuted the validity of the *hierarchical principle* of the CPITN, that is, the assumption that a tooth with calculus is assumed to be also positive for bleeding on probing, or that a tooth with deep pockets is assumed to be positive for both calculus and bleeding. In a companion paper, results from a full-mouth examination were compared with those generated by the use of the 10 index teeth recommended by the WHO for surveys of adults (Baelum *et al*. 1993a). The study revealed that the partial CPITN methodology

seriously underestimated the more severe periodontal conditions both in terms of prevalence and severity, by failing to detect a substantial proportion of subjects with periodontal pockets. Finally, an examination of the relationship between CPITN findings and the prevalence and severity of clinical attachment loss demonstrated that the CPITN scores do not correlate consistently with clinical attachment loss measures, but tend to overestimate prevalence and severity among younger subjects and underestimate such parameters in elderly populations (Baelum *et al*. 1993a). Collectively, the above data call for caution in the interpretation of epidemiologic studies based on the CPITN/CPI systems.

In 1999, an International Workshop for a Classification of Periodontal Diseases and Conditions (Armitage 1999), introduced eight categories of periodontal disease, but defined two principal forms of periodontitis, *chronic* and *aggressive periodontitis*. *Chronic periodontitis* was described as the more "common" form that occurs primarily in adults, and progresses at a relatively slow rate, resulting in an extent and severity of periodontal tissue loss that is largely commensurate with the presence of local etiologic factors. In contrast, *aggressive periodontitis* was defined as a more infrequently occurring form that affects primarily, but not exclusively, young, systemically healthy individuals, progresses rapidly, and results in substantial loss of periodontal tissue support that may be disproportionate to the occurrence of local etiology. Importantly, a primary feature of *aggressive periodontitis* was considered to be *familial aggregation,* that is, a propensity to affect several members of the same family (parents and siblings), indicating that genetic predispositions and common environmental exposures may be important determinants of the disease. However, none of the three primary features of *aggressive periodontitis* (a systemically healthy patient; rapid attachment loss and bone loss; familial aggregation) (Lang *et al*. 1999) can facilitate the differential diagnosis between *chronic* and *aggressive periodontitis* in the setting of an epidemiologic study: the first because it is entirely non-specific; the second because it requires at least two examinations over time to determine how "rapidly" the periodontal destruction has occurred; and the third because it is subject to *reporting bias*, and requires extensive interviewing and verification to ascertain reliably. As a result, very sparse epidemiologic data have been generated to date by strictly adhering to the primary criteria of these principal forms of periodontitis.

Instead, several studies have reported periodontitis prevalence data using the periodontitis case definition introduced by a working group from the Centers for Disease Control (CDC) and the American Academy of Periodontology (AAP) that is based on a combination of probing depth and CAL assessments (Page & Eke 2007; Eke *et al*. 2012). The CDC/AAP case definitions do not distinguish between chronic and aggressive forms of periodontitis, but define: (1) *severe periodontitis* as the presence of at least two interproximal sites with ≥6 mm of clinical attachment loss, not on the same tooth, *and* the presence of at least one interproximal site with a ≥5-mm probing depth; (2) *moderate periodontitis* as the presence of two or more interproximal sites with ≥4 mm of clinical attachment loss occurring at two or more different teeth *or* two or more interproximal sites with a ≥5-mm probing depth, not on the same tooth; and (3) *mild periodontitis* as the presence of two or more interproximal sites with ≥3 mm of clinical attachment loss and two or more interproximal sites with ≥ 4 mm probing depth or one site with probing depth ≥ 5 mm.

An alternative, two-level periodontitis case definition for use in epidemiologic studies was developed by a working group of the 5th European Workshop in Periodontology (Tonetti & Claffey 2005), and consisted of a *sensitive* definition (proximal attachment loss of ≥3 mm in two or more non-adjacent teeth) and a *specific* definition (proximal attachment loss of ≥5 mm in ≥30% of the teeth present). The former definition aimed at capturing incipient forms of the disease, while the latter was meant to reflect periodontitis of substantial extent and severity.

To the best of our knowledge, no epidemiologic studies have been published at the time of authorship of this chapter that have employed the latest classification system of periodontal diseases and conditions that was introduced at the 2017 World Workshop, which is described in detail in Chapter 16. According to this system, patients formerly classified as having either chronic or aggressive periodontitis are now grouped in a single category that is further subdivided on the basis of two-vector system by *Stage* and *Grade* (Papapanou *et al*. 2018; Tonetti *et al*. 2018). *Stage* reflects the severity of the disease (expressed through attachment loss and bone loss), but also factors in *tooth loss* that has occurred as a result of periodontitis. In addition, it reflects the anticipated complexity of the treatment that is required to eradicate/reduce the current level of infection and inflammation, and to restore patient masticatory function. *Grade* describes additional biological dimensions of the disease including the observed or inferred progression rate, the risk for further deterioration, the presence of risk factors and co-morbidities, and the risk that the disease or its treatment may adversely affect the particular patient's general health status.

As mentioned above, a concise "case definition" is essential for assessing disease prevalence and incidence and to generate comparable data across populations. Given the lack of universal consensus on the definitions of periodontitis and the continuously evolving epidemiologic approaches, in the following text we have opted to summarize the available data on the prevalence and progression of periodontal disease according to the age range of the examined cohorts. We thus first present findings from epidemiologic studies in adults, including studies exclusively targeting elderly populations, followed by corresponding findings derived from children, adolescents, and young adults.

Prevalence of periodontitis

Periodontitis in adults

To acquire some historical perspective and appreciate how the concepts of both the descriptive and the analytical epidemiology of periodontitis have evolved over the years, some older epidemiologic investigations are worth mentioning.

Starting with a study performed during the 1950s in India, Marshall-Day *et al*. (1955) used assessments of alveolar bone height to distinguish gingivitis and destructive periodontal disease in 1187 dentate subjects. The authors reported: (1) a decrease in the percentage of subjects with "gingival disease without any bone involvement" with increasing age concomitant with an increase in the percentage of subjects with "chronic, destructive periodontal disease"; and (2) a 100% occurrence of destructive periodontitis after the age of 40 years. Findings from other epidemiologic studies from the same period verified a high prevalence of destructive periodontal disease in the adult population in general, and a clear increase in disease prevalence with age. In the 1960s, Scherp (1964) reviewed the available literature on the epidemiology of periodontal disease and concluded that: (1) periodontal disease appears to be a major, global public health problem affecting the majority of the adult population after the age of 35–40 years; (2) the disease starts as gingivitis in youth, which, if left untreated, leads to progressive destructive periodontitis; and (3) >90% of the variance of the periodontal disease severity in the population can be explained by age and oral hygiene. These notions, based on established concepts of the pathogenesis of periodontal disease of that time, dominated the periodontal literature until the late 1970s.

Studies performed during the 1980s provided a more thorough description of the site-specific features of periodontal disease and the high variation in periodontal conditions between and within different populations. Contrary to previous custom, the prevalence issue was no longer addressed through assigning individuals simply to a "periodontitis-affected" or a "disease-free" group, based on presence or absence of attachment or alveolar bone loss. Instead, studies began to unravel details concerning the *extent* to which the dentition was affected by destructive disease (i.e. the percentage of tooth sites involved) and the *severity* of the defects (expressed as the magnitude of the tissue support lost due to the disease). The traditional description of pocket depth and attachment loss scores in terms of *subject mean values* was soon complemented by *frequency distributions*, revealing percentages of tooth sites exhibiting probing depth or attachment level of varying severity. Such an additional analysis appeared necessary after it became clear that mean values offer a crude description of periodontal conditions and fail to reflect the variability in the severity of periodontal disease within and between individuals. In an article presenting different methods of evaluating periodontal disease data in epidemiologic research, Okamoto *et al*. (1988) proposed the use of *percentile plots* in the graphic illustration of attachment loss data. As exemplified by Fig. 6-1, such plots make it possible to illustrate simultaneously both the proportion of subjects exhibiting attachment loss of different levels and the severity of the loss within the subjects. Similar plots may be produced for other parameters, such as gingivitis, probing depths, and gingival recession, and may provide a comprehensive description of both the prevalence and the severity of periodontal disease in a given sample.

In the mid-1980s, a group of Danish investigators (Baelum *et al*. 1986) described cross-sectional findings for dental plaque, calculus, gingivitis, loss of attachment, periodontal pockets, and tooth loss in a sample of adult Tanzanians aged 30–69 years. Despite the fact that the subjects examined exhibited large amounts of plaque and calculus, pockets deeper than 3 mm and attachment loss of >6 mm occurred at <10% of the tooth surfaces. Edentulism was virtually non-existent, and a very small percentage of subjects had experienced major tooth loss. Of particular interest was the analysis of the distribution of sites within

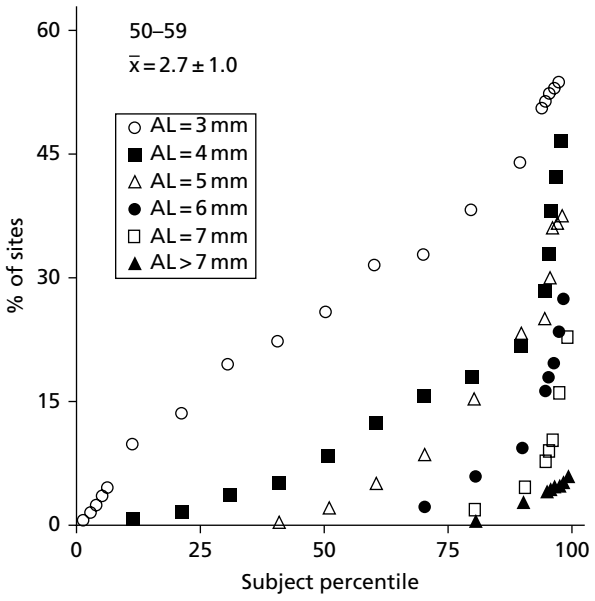

Fig. 6-1 Attachment loss in a group of Japanese subjects aged 50–59 years. The mean value of attachment level and the standard deviation are shown in the top of the figure. The x-axis represents the subject percentile and the y-axis represents the percentage of sites in the subjects showing attachment loss of 3, 4, 5, 6, 7, and >7 mm (represented by 8). Subjects with no or only minor signs of attachment loss are reported to the left and subjects with increasing amounts of periodontal destruction are reported to the right of the graph. For example, the median subject (50th percentile), exhibited 5-mm attachment loss at 2%, 4-mm loss at 8%, and 3-mm loss at 25% of its sites. (Source: Okamoto *et al*. 1988. Reproduced with permission from John Wiley & Sons.)

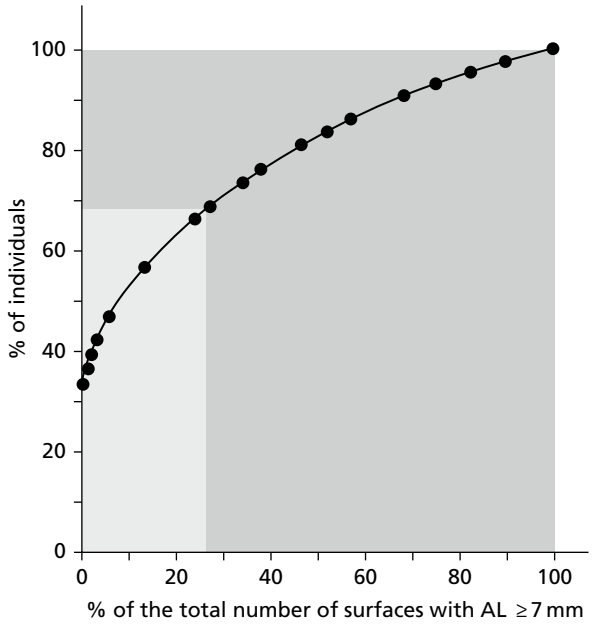

Fig. 6-2 Cumulative distribution of individuals aged ≥50 years according to the cumulated proportion of surfaces with attachment loss (AL) of ≥7 mm. All individuals are arranged according to increasing number of surfaces with AL of ≥7 mm present in each individual. Thus, individuals with few such surfaces are represented on the left side of the diagram and those with many such surfaces on the right side. It is seen that 31% (69–100%) of the individuals account for 75% (25–100%) of the total number of surfaces with AL of ≥7 mm present (shaded area). (Source: Baelum *et al*. 1986. Reproduced with permission from John Wiley & Sons.)

subjects (Fig. 6-2). This analysis revealed that 75% of the tooth sites with attachment loss of >6 mm were found in 31% of the subjects, indicating that a subset of the sample was responsible for the majority of the observed periodontal breakdown. In other words, advanced periodontal disease was not evenly distributed in the population and not readily correlated to supragingival plaque levels; instead, the majority of the subjects examined exhibited negligible periodontal problems, while a limited group was affected by advanced disease.

In a study of similar design performed in Kenya, the same investigators analyzed data from 1131 subjects aged 15–65 years and confirmed their earlier observations (Baelum *et al*. 1988). Poor oral hygiene in the sample was reflected by high plaque, calculus, and gingivitis scores. However, pockets ≥4 mm deep were found in <20% of the surfaces and the proportion of sites per individual with deep pockets and advanced loss of attachment revealed a pronounced skewed distribution. The authors suggested that "destructive periodontal disease should not be perceived as an inevitable consequence of gingivitis which ultimately leads to considerable tooth loss" and called for a more specific characterization of the features of periodontal breakdown in those individuals who seem particularly susceptible.

At approximately the same time, Löe *et al*. (1986) published data from a longitudinal study that showed distinct patterns for the *progression* of untreated periodontitis. In a population never exposed to any preventive or therapeutic intervention related to oral diseases in Sri Lanka, a cohort of 480 14–31-year-old male tea-plantation laborers was recruited in 1970 and underwent subsequent follow-up examinations. A total of 161 individuals among those originally enrolled were re-examined in 1985, essentially generating data on the natural history of periodontal disease between the ages of 14 and 46 years. Despite poor plaque control and virtually ubiquitous gingival inflammation in the entire sample, three distinct patterns of progression of periodontitis were observed over the follow-up period, based on interproximal longitudinal attachment loss and tooth mortality rates: one group, comprising approximately 8% of the total, exhibited rapid progression of periodontal disease (RP); another group (approximately 11%) exhibited no progression (NP) of periodontal disease beyond gingivitis; and a third group between these two extremes (approximately 81%) exhibited moderate progression (MP). The mean loss of attachment in the RP group was 9 mm and 13 mm at the age of 35 and 45 years, respectively, as opposed to 1 mm and 1.5 mm in the NP group, and 4 mm and 7 mm in the MP group. As a result, the annual rate of longitudinal attachment loss in the RP group varied between 0.1 and 1.0 mm, in the MP group between 0.05 and 0.5 mm, and in the NP group between 0.05 and 0.09 mm. Thus, this study clearly demonstrated huge variability in progression of periodontitis in a seemingly homogeneous population, and suggested that variables other than age, plaque, and gingival inflammatory status are important determinants of periodontal deterioration over time.

The common theme that emerged in the above studies, that is, that a relative limited proportion of the population suffers from severe periodontitis, has been corroborated by more recent studies from various parts of the world, a number of which are summarized in Table 6-1. Although what constitutes "severe periodontitis" is far from identical across reports in the literature, a review that consolidated data from 72 epidemiologic studies originating from 37 countries that collectively included data from approximately 300 000 participants estimated this fraction to range between 10 and 12%, to vary considerably between regions and countries, and to show a steep increase between the third and fourth decade in life (Kassebaum *et al*. 2014). The increased rates of tooth loss of periodontally affected teeth occurring after this age appears to account for the subsequent decline in prevalence. It is worth pointing out that studies employing full-mouth examination protocols generally generate higher prevalence estimates, underscoring the decisive impact of the examination methodology employed (Kingman & Albandar 2002;

Table 6-1 Selected population-representative studies of periodontitis prevalence published after 2000. (Sources: NHANES, National Health and Nutrition Examinations Surveys; CDC/AAP, Centers for Disease Control/American Academy of Periodontology.)

Authors/country	Sample/methodology	Findings
Baelum *et al*. (1988a) Kenya	A stratified random sample of 1131 subjects, 15–65 years; full-mouth assessments of tooth mobility, plaque, calculus, BoP, PD, and AL	Plaque in 75–95% and calculus in 10–85% of all surfaces PD ≥4 mm in <20% of sites AL of ≥1 mm in 10–85% of sites Percentage of sites/subject with PD or AL of ≥4 mm or ≥7 mm conspicuously skewed
Brown *et al*. (1990) USA	A sample of 15 132 subjects, stratified by geographic region, representing 100 million employed adults aged 18–64 years; probing assessments at mesial and buccal sites in one upper and one lower quadrant; mesial assessments performed from the buccal aspect of the teeth; assessments of gingivitis, PD, AL, and gingival recession	44% of all subjects had gingivitis at an average of 2.7 sites/subject and at <6% of all sites assessed Pockets 4–6 mm were observed in 13.4% of subjects at an average of 0.6 sites/person and at 1.3% of all sites assessed; corresponding figures for pockets ≥7 mm were 0.6%, 0.01, and 0.03% AL ≥3 mm was prevalent in 44% of subjects (increasing with age from 16% to 80%) affecting an average of 3.4 sites/subject; corresponding figures for AL ≥5 mm were 13% (2–35%) and 0.7 sites/subject
Salonen *et al*. (1991) Sweden	A random sample of 732 subjects, 20–80+ years, representing 0.8% of the population of a southern geographic region; full-mouth radiographic examination; alveolar bone level expressed as a percentage of the root length (B : R ratio); B : R of ≥80% represents intact periodontal bone support	Age group of 20–29 years: 38% of subjects had no sites with a B : R of <80% and 8% of subjects had ≥5 sites below this threshold Corresponding figures for the age group 50–59 years: 5% and 75%; after the age of 40, women displayed more favorable B : R ratios than men
Hugoson *et al*. (1998a) Sweden	Three random samples of 600, 597, and 584 subjects aged 20–70 years, examined in 1973, 1983, and 1993, respectively; full-mouth clinical and radiographic examination; based on clinical and radiographic findings, the subjects were classified according to severity of periodontal disease in five groups, where group 1 (G1) included subjects with close to faultless periodontal tissues and group 5 (G5) subjects with severe disease	Edentulism decreased over the 20-year period from 11% to 8% to 5%; percentage distribution of the subjects in the five groups in 1973, 1983, and 1993 respectively was: G1 8%, 23%, 22%; G2 41%, 22%, 38%; G3 47%, 41%, 27%; G4 2%, 11%, 10%; G5 1%, 2%, 3%; the increase in the prevalence of subjects with severe disease was apparently due to the increased number of dentate subjects at the older ages
Schürch & Lang (2004) Switzerland	A total of 1318 subjects, randomly selected based on community rosters in seven regions, aged 20–89 years; probing assessments of PD and AL for all teeth present; assessments of plaque and gingivitis for index teeth	7.1% of subjects were edentulous; mean number of teeth present in dentate subjects was 21.6 Mean values of PD reached a plateau of 3 mm by the age of 49 years AL increased dramatically after the age of 50 years and paralleled a marked loss of teeth
Susin *et al*. (2004a) Brazil	A sample of 853 dentate individuals, selected by multistage probability sampling, aged 30–103 years; full-mouth examination of AL at six sites/tooth	Moderate AL (≥5 mm) and advanced AL (≥7 mm) occurred in 70% and 52% of the subjects, affecting an average of 36% and 16% of their teeth, respectively; in comparison to 30-39-year-olds, 40-49-year-olds had 3× increased risk for moderate and 7.4× increased risk for advanced AL; corresponding figures for ≥ 50-year-olds were 5.9× and 25.4×, respectively
Dye *et al*. (2007) USA	NHANES 1999–2004 study, nationally representative sample comprising 10 312 individuals in four age cohorts (35–49, 50–64, 65–74, and 75+ years; partial-mouth examination in two randomly selected quadrants (one maxillary and one mandibular) at the mesiofacial and mid-facial sites of all fully erupted teeth excluding third molars	Prevalence of AL ≥3 mm in the four age cohorts was 36.1%, 53.4%, 67.2%, and 75.5%, respectively Corresponding figures for PD ≥4 mm were 11.9%, 13.2%, 11.3%, and 12.1%, respectively
Wang *et al*. (2007) China	A sample of 1590 dentate subjects with ≥14 teeth present, aged >25 years, from four geographic regions, equally farmers and urban professionals; partial-mouth examination at six sites in each of six index teeth	Average of 40% of sites bled on probing in the rural group as compared with 35% in the urban group Prevalence of AL ≥4 mm was approximately 10% in ages 25–34 years, increasing to 31%, 53%, and 70% in ages 35–44, 45–59, and >60 years, respectively, in the rural group; corresponding figures were 18%, 38%, and 57% in the urban group

Table 6-1 (*Continued*)

Authors/country	Sample/methodology	Findings
Holtfreter *et al*. (2010) Germany	The fourth German Dental Health Survey examined a total of 1965 individuals aged 35–44 years (adult sample) and 65–74 years (senior sample); partial-mouth examination of PD and AL at three sites in each of 12 index teeth	AL ≥3 mm was prevalent in 95% of the adults and 99.2% of the seniors (68.7% and 91.4% of teeth affected, respectively) PD ≥4 mm was prevalent in 70.9% and 87.4% of the adult and senior cohorts, respectively
Eke *et al*. (2018) USA	NHANES 2009–2014 study, nationally representative sample comprising 10 683 individuals in three age cohorts (30–44, 45–64, 65+ years); full-mouth examination at six sites per tooth at all fully erupted teeth excluding third molars	Prevalence of AL ≥3 mm in the three age cohorts was 81.3%, 92.1%, 96.5% Prevalence of AL ≥5 mm was 22.7%, 43.1%, 55.1%, respectively Corresponding figures for PD ≥4 mm were 33.3%, 39.9%, and 40.6%, and for PD ≥ 6 mm 6.4%, 10.1%, and 9.4%, respectively Prevalence of severe periodontitis, according to the CDC/AAP definition (Page & Eke 2007) was 4.1% in ages 30–44 years, 10.4% in ages 45–64 years, and 9.0% in ages 65+ years; corresponding figures for total periodontitis (mild + moderate + severe) were 29.5%, 46.0%, and 59.8%, respectively.
Sun *et al*. (2018) China	A multistage stratified sample comprising 4410 individuals in ages 35–44 years from 31 provinces in mainland of China; full-mouth examination at six sites per tooth at all fully erupted teeth excluding third molar	Prevalence of PD 4–5 mm was 45.8%, and PD ≥ 6 mm 6.9% Prevalence of CAL 4–5 mm was 25.5%, CAL 6–8 mm 6.4%, and CAL ≥9 mm 1.3%

AL, attachment level; BoP, bleeding on probing; CDC/AAP, Centers for Disease Control/American Academy of Periodontology; CEJ, cemento-enamel junction; NHANES, National Health and Nutrition Examinations Surveys; PD, probing depth.

Natto *et al*. 2018). A recent study (Billings *et al*. 2018) compared two large, population-based representative samples, one from the National Health and Nutrition Examination Survey for years 2009–2014 (NHANES) in the USA (Dye *et al*. 2014; Dye *et al*. 2019), and another from the Study of Health in Pomerania, Germany (SHIP-Trend) for years 2008–2012 (Völzke *et al*. 2011), to examine the effect of age in the distribution of periodontitis in the general population, and to define age-dependent thresholds for severe periodontitis. The data showed that the mean clinical attachment loss increased linearly with age in both samples and was higher in SHIP-Trend than NHANES across the age spectrum. Although mean pocket depth was relatively constant across age groups in both populations, the upper quintiles of mean clinical attachment loss were consistently lower in NHANES than in SHIP-Trend, underscoring substantial differences in the overall severity of attachment loss between the two population samples.

Table 6-2 summarizes a number of prevalence studies of periodontal disease in elderly subjects. It is evident that attachment loss of moderate magnitude was more frequent and widespread in these cohorts; however, severe disease was again found to affect relatively limited proportions of the samples and usually only a few teeth per person. It must be realized, however, that (1) edentulism increases with age, and (2) "surviving" teeth in elderly individuals are likely those less affected by periodontitis. As discussed later, tooth loss results in an underestimation of the "true" extent and severity of periodontitis in elderly individuals.

Periodontitis in children and adolescents

The form of periodontal disease that affects the *primary* dentition, the condition formerly termed *prepubertal periodontitis*, has been reported to appear in both a generalized and a localized form (Page *et al*. 1983). Information about this disease has mainly been provided by clinical case reports and no data on the prevalence and the distribution of the disease in the general population are available. However, a small number of studies involving samples of children have provided limited data on the frequency with which deciduous teeth may be affected by attachment loss. The criteria used in these studies are by no means uniform, hence the prevalence data vary significantly. In an early study, Jamison (1963) examined the "prevalence of destructive periodontal disease" (indicated by PDI scores >3) in a sample of 159 children in Michigan, USA and reported prevalences of 27% for 5–7-year-old children, 25% for 8–10-year olds, and 21% for 11–14-year olds. Shlossman *et al*. (1986) used an attachment level value of ≥2 mm as a cut-off point and reported prevalences of 7.7% in 5–9-year olds and 6.1% in 10–14-year olds in a sample of native Americans on the Gila River Indian Reservation. Sweeney *et al*. (1987) examined radiographs obtained from 2264 children, aged 5–11 years, who were referred to a University Clinic in Philadelphia, USA for routine dental treatment, and reported that distinct radiographic bone loss was evident at one or more primary molars in 19 children (0.8%), 16 of whom were black, two were Caucasian, and one was Asian.

Table 6-2 Selected prevalence studies of periodontitis in elderly subjects. (Sources: NHANES, National Health and Nutrition Examinations Surveys; CDC/AAP, Centers for Disease Control/American Academy of Periodontology.)

Authors/country	Sample /methodology	Findings
Baelum *et al*. (1988b) China	544 persons, in ages 60+ years, from two urban and one rural area of the Beijing area; assessments of plaque, calculus, gingivitis, loss of attachment, pocket depth, and tooth mobility	0–29% edentulous; mean number of teeth 6.9–23.9, depending on age and sex ≈50% of all surfaces with plaque and calculus 50% of all sites with AL of ≥4 mm <15% with PD ≥4 mm Conspicuously skewed percentage of sites/persons with AL of ≥7 mm and PD ≥4 mm
Beck *et al*. (1990) USA	690 community dwelling adults, in ages 65+ years; probing assessments at mesiobuccal and mid-buccal surfaces, all teeth; "advanced disease": ≥4 sites with AL of ≥5 mm and PD ≥4 mm at ≥1 of those sites; calculation of ESI with AL threshold set at ≥2 mm	Mean ESI in Blacks: 78, 4; in Caucasians: 65, 3.1 Advanced disease in 46% of Blacks and 16% of Caucasians
Gilbert & Heft (1992) USA	671 dentate subjects, in ages 65–97 years, attending senior activity centers; probing assessments at mesial and buccal surfaces of one upper and one lower quadrant; questionnaire data; calculation of ESI with AL threshold set at ≥2 mm	Average of 17.0 teeth/subject 50.7% of subjects with most severe mesial PD of 4–6 mm and 3.4% with PD of ≥7 mm 61.6% with most severe AL of 4.6 mm and 24.2% with AL of ≥7 mm ESI increased with age: 84.8, 3.6 (65–69 years); 88.7, 3.8 (75–79 years); 91.2, 3.9 (85+ years)
Locker & Leake, (1993) Canada	907 subjects, in ages 50–75+ years, living independently in four communities; probing assessments at mesiobuccal and mid-buccal aspects of all teeth; mid-palatal and mesiopalatal probing assessments in upper molars; 23% of subjects edentulous; calculation of ESI with AL threshold set at ≥2 mm; "severe disease": >4 sites with AL ≥5 mm and PD ≥4 mm at ≥1 of those sites	59% of subjects with PD of ≥4 mm, 16% with ≥6 mm, and 3% with ≥8 mm 86% of subjects with AL of ≥4 mm, 42% with ≥6 mm, and 16% with ≥8 mm; 20% of the subjects with a mean PAL of ≥4 mm Severe disease in 22% of subjects; mean ESI: 77, 2.44
Douglass *et al*. (1993) USA	1151 community-dwelling elders, 70+ years old; probing assessments at ≥3 sites/tooth, all teeth; 57% of the sample female, predominantly Caucasian (95%); 37.6% edentulous; mean number of teeth present between 21.5 and 17.9, depending on age	85% of subjects with BoP 66% with 4–6- mm deep pockets affecting an average of 5.3 teeth/subject; 21% with pockets of >6 mm affecting an average of 2.2 teeth 39% with AL of 4–6 mm at 6.7 sites/subject and 56% with AL of >6 mm at 2.7 teeth/subject
Bourgeois *et al*. (1999) France	603 non-institutionalized elderly, in ages 65–74 years; stratified sample with respect to gender, place of residence and socioeconomic group; periodontal conditions assessed by CPITN	16.3% were edentulous 31.5% of subjects had pockets ≥4 mm; 2.3% had pockets ≥6 mm
Hirotomi *et al*. (2002) Japan	761 community dwelling individuals either 70 or 80 years old, in the city of Niigata; full-mouth examination at six sites/ tooth at all functioning, fully erupted teeth	7.5% of those 70 years old and 35.8% of those 80 years old were edentulous; the prevalence of PD ≥6 mm was 10.2%, of CAL ≥5 mm 12.9%, and of severe periodontitis, according to the CDC/AAP definitions, 2%
Levy *et al*. (2003) USA	From a sample of 449 community dwelling elders, mean age 85 years, 342 (76%) were dentate and 236 were examined with respect to PD and AL at four sites/tooth in all teeth present	91% of participants had ≥1 site with ≥4 mm AL, 45% ≥1 site with ≥6 mm AL, and 15% ≥1 site with ≥8 mm AL
Mack *et al*. (2004) Germany	1446 randomly selected subjects in ages 60–79 years, participants in the Study of Health in Pomerania (SHIP); half-mouth examination of PD and AL at four sites/ tooth; plaque calculus and BoP were assessed at index teeth	16% of the 60–65-year-olds and 30% of the 75–79-year-olds were edentulous Among the 70–79-year-olds, median BoP was 37.5% in men and 50% in women Prevalence of PD ≥6 mm was 31.8% and 28.5% in men and women, respectively Prevalence of AL ≥5 mm was 71.9% and 66.9% in men and women, respectively
Syrjälä *et al*. (2010) Finland	1460 individuals, ≥65 years old, participants in the nationally representative Health 2000 Survey; full-mouth examination at four sites/tooth at all erupted teeth except third molars	44.3% were edentulous; 31% of dentate participants had no pockets >3 mm; 28% had 1–3 teeth with ≥4mm pockets, 15% had 4–6 and 26% ≥7 affected teeth; 73% showed BoP at ≥1 sextant

Table 6-2 (*Continued*)

Authors/country	Sample /methodology	Findings
Eke *et al*. (2016b) USA	1983 participants, ≥65 years of age, participants in NHANES 2009–2012; full-mouth examination at six sites per tooth at all fully erupted teeth excluding third molars	19% were edentulous; in ages 65-74 years, 59.7% had mild/moderate periodontitis and 11.8% severe periodontitis, according to the CDC/AAP definitions; corresponding prevalence values were 71.4% and 9.6%, respectively, in ages ≥75 years; the prevalence of PD ≥ 6 mm was 11.9% and of CAL ≥ 5 mm 62.3%
Shariff *et al*. (2018) USA	A tri-ethnic cohort of 1130 participants of the Washington-Heights Inwood Community Aging Project (WHICAP) ≥65 years old; full-mouth examination including assessments of bleeding BoP, PD and CAL at six sites/tooth	14.7% were edentulous; moderate/severe periodontitis according to the CDC/AAP definitions affected 77.5% of the sample Pockets ≥6 mm affected 50.2% of the sample and an average of 5.7% of teeth/person; corresponding figures for CAL ≥5 mm were 71.4% and 23.6%, respectively

AL, attachment level; BoP, bleeding on probing; CDC/AAP, Centers for Disease Control/American Academy of Periodontology; CEJ, cemento-enamel junction; CPITN, Community Periodontal Index of Treatment Needs; ESI, Extent and Severity Index; PD, probing depth.

In contrast, relatively uniform criteria have been used in epidemiologic studies of periodontitis in teenagers and young adults, using the diagnostic criteria of the condition that was earlier termed *localized juvenile periodontitis* (LJP), and was characterized by severe destruction affecting incisors and first molars. Typically, a two-stage approach has been adopted in these studies: first, bite-wing radiographs were used to screen for bone loss adjacent to molars and incisors, and then a clinical examination was performed to verify the diagnosis. As shown by the studies included in Table 6-3 as well as in a recent systematic review (Catunda *et al*. 2019), the prevalence of this form of early-onset disease varied in geographically and/or racially different populations. In Caucasians, the disease appears to affect females more frequently than males and the prevalence is low (approximately 0.1%). In other races, and in particular in Blacks, the disease is more prevalent, probably at levels over 1%, and the gender ratio appears to be reversed, since males are affected more frequently than females. Smoking and low socioeconomic status have been confirmed to be associated with destructive forms of periodontitis in teenage populations (Lopez *et al*. 2001; Susin & Albandar 2005; Levin *et al*. 2006).

Epidemiologic studies of periodontal conditions in adolescents have been also carried out using the CPITN system. Miyazaki *et al*. (1991) presented an overview of 103 CPITN surveys of subjects aged 15–19 years from over 60 countries. The most frequent finding in these groups was the presence of calculus, which was much more prevalent in subjects from non-industrialized than industrialized countries. Probing pocket depths of 4–5 mm were present in about two-thirds of the populations examined. However, the occurrence of deep pockets (≥6 mm) was relatively infrequent: score 4 quadrants were reported to occur in only 10 of the examined populations (in four of the nine examined American samples, one of 16 African samples, one of 10 eastern Mediterranean samples, two of 35 European samples, two of 15 South-East Asian samples, and none of 18 western Pacific samples).

The progression pattern of periodontitis in a sample of 167 adolescents in the UK was studied in a 5-year longitudinal study by Clerehugh *et al*. (1990). In this study, 3% of the initially 14-year-olds had attachment loss of ≥1 mm affecting >1% of sites. However, at age 19 years, 77% showed a similar level of attachment loss and 31% of sites were affected. Presence of subgingival calculus at baseline was significantly associated with disease progression. In a study involving a larger sample size in the USA, Brown *et al*. (1996) studied a nationally representative sample comprising 14 013 adolescents with respect to the pattern of progression of the disease entity formerly termed *early-onset periodontitis*, that is, the type of periodontitis that occurs in individuals of a young age. Subjects were diagnosed at baseline as free from periodontitis, or suffering from LJP, *generalized juvenile periodontitis* (GJP), or incidental attachment loss (IAL). Of the individuals diagnosed with LJP at baseline, 62% continued to display localized periodontitis lesions 6 years later, but 35% developed a generalized disease pattern. Among the group initially diagnosed as suffering from IAL, 28% developed LJP or GJP, while 30% were reclassified in the no attachment loss group. Molars and incisors were the teeth most often affected in all three affected groups. Thus, the study indicated that these three forms of periodontitis may progress in a similar fashion, and that certain cases of LJP may develop into a more generalized form.

The possibility that LJP and *prepubertal periodontitis* are associated conditions, that is, that the former is a development of the latter, has also attracted attention. In an early study, Sjödin *et al*. (1989) retrospectively examined radiographs of the primary dentition of 17 subjects with LJP and reported that 16 of these subjects showed a CEJ–bone crest distance of ≥3 mm in at least one tooth site in their deciduous dentition. The same research group (Sjödin & Matsson 1992) examined the CEJ–bone crest distance in radiographs from

Table 6-3 Selected prevalence studies of periodontitis in adolescents and young adults. (Sources: CDC/AAP, Centers for Disease Control/American Academy of Periodontology.)

Authors/country	Sample/methodology	Findings
Saxén (1980) Finland	A random sample of 8096 16-year-olds; radiographic and clinical criteria (bone loss adjacent to first molars without any obvious iatrogenic factors and presence of pathologic pockets)	Prevalence of LJP 0.1% (8 subjects, 5 of whom were females)
Kronauer *et al*. (1986) Switzerland	A representative sample of 7604 16-year-olds; two step examination (radiographic detection of bone lesion on bitewing radiographs, clinical verification of presence of pathologic pockets)	Prevalence of LJP of 0.1%; 1 : 1 gender ratio
Saxby (1987) UK	A sample of 7266 schoolchildren; initial screening by probing assessments around incisors and first molars; LJP cases diagnosed definitively by full-mouth clinical and radiographic examination	Overall prevalence of LJP of 0.1%, 1 : 1 gender ratio; however, prevalence varied in different ethnic groups (0.02% in Caucasians, 0.2% in Asians, and 0.8% in Afro-Caribbeans)
Neely (1992) USA	1038 schoolchildren 10–12 years old, volunteers in a dentifrice trial; three-stage examination including radiographic and clinical assessments; bitewing radiographs screened for possible cases; bone loss measurements of the CEJ–bone crest distance of ≥2 mm used to identify probable cases; LJP diagnosed clinically as PD of ≥3 mm at ≥1 first permanent molars in the absence of local irritants	117 possible and 103 probable cases identified in steps 1 and 2, respectively; of 99 probable cases contacted, 43 were examined clinically; 2 cases of LJP confirmed in stage 3, yielding a prevalence rate of 0.46%
Cogen *et al*. (1992) USA	4757 children, aged <15 years, from the pool of a children's hospital; retrospective radiographic examination of two sets of bitewings; LJP diagnosed in case of arc-shaped alveolar bone loss in molars and/or incisors	Caucasians: LJP prevalence 0.3%, female : male ratio 4 : 1 Blacks: LJP prevalence 1.5%, female : male ratio ≈1 : 1 Among Black LJP cases with available radiographs from earlier examinations, 85.7% showed evidence of bone loss in the mixed dentition and 71.4% in the deciduous dentition
Löe & Brown (1991) USA	National Survey of US children, multistage probability sampling representing 45 million schoolchildren; 40 694 subjects, 14–17 years old examined; probing assessments at mesial and buccal sites, all teeth; LJP: ≥1 first molar and ≥1 incisor or second molar and ≤2 cuspids or premolars with ≥3 mm AL; GJP: if LJP criteria not met and ≥4 teeth (of which ≥2 were second molars, cuspids or premolars) with ≥3 mm AL; ILA: if neither LJP nor GJP criteria met but ≥1 teeth with ≥3 mm AL; bivariate and multivariate analysis	Population estimates: LJP 0.53%; GJP 0.13%; ILA 1.61%; all 2.27% representing almost 300 000 adolescents; Blacks at much higher risk for all forms of early-onset disease than Caucasians Males more likely (4.3:1) to have GJP than females, after adjusting for other variables; Black males 2.9 times as likely to have LJP than Black females; Caucasian females more likely to have LJP than Caucasian males by the same odds
Bhat (1991) USA	A sample of 11 111 schoolchildren, 14–17 years old; probing assessments at mesial and buccal surfaces of all teeth; multistage cluster sampling stratified by age, sex, seven geographic regions, and rural or urban residence; not stratified by race or ethnicity	22% of children with ≥1 site with AL of ≥2 mm, 0.72% of ≥4 mm, and 0.04% of ≥6 mm Supra- and subgingival calculus in 34% and 23% of children, respectively
van der Velden *et al*. (1989) The Netherlands	4565 subjects, 14–17 years old examined; randomization among high school students; probing assessments at the mesio- and distofacial surfaces of first molars and incisors; one bacterial sample from the dorsum of the tongue and one subgingival plaque sample from the site with maximal attachment loss obtained from 103 of the 230 subjects with AL and cultured for identification of *Aggregatibacter actinomycetemcomitans*	Overall, AL occurred in 5% of the sample and was more frequent in males; 16 subjects (0.3%) had ≥1 site with AL of 5–8 mm; female : male ratio in this group 1.3 : 1 *A. actinomycetemcomitans* identified in 17% of the sampled subjects with AL
Lopez *et al*. (1991) Chile	2500 schoolchildren in Santiago (1318 male, 1182 female), aged 15–19 years; clinical and radiographic assessments; three-stage screening: (1) clinical assessments of PD at incisors and molars, (2) children with ≥2 teeth with PD of ≥5.5 mm subjected to a limited radiographic examination, and (3) children with alveolar bone loss of ≥2 mm invited for a full-mouth clinical and radiographic examination	After screening, 27 subjects had a tentative diagnosis of LJP, of which 8 were confirmed (7 female, 1 male); overall prevalence of LJP 0.32%, 95% CI 0.22– 0.42%; LJP significantly more frequent in the low socioeconomic group

Table 6-3 (*Continued*)

Authors/country	Sample/methodology	Findings
Ben Yehouda *et al*. (1991) Israel	1160 male Israeli army recruits, aged 18–19 years; panoramic radiography; JP diagnosed on the basis of bone loss involving ≥30% of the root length adjacent to first molars or incisors	10 recruits (0.86%, 95% CI 0.84–0.88%) had a bone loss pattern consistent with localized juvenile periodontitis
Melvin *et al*. (1991) USA	5013 military recruits, aged 17–26 years; panoramic radiography followed by full-mouth clinical examination; diagnosis of JP if bone loss and attachment loss was greater at first molars and/or incisors than at other teeth	Overall prevalence of JP 0.76%, female : male ratio 1.1 : 1 Prevalence in Blacks: 2.1%, female : male ratio 0.52 : 1 Prevalence in Whites: 0.09%, female : male ratio 4.3 : 1
Tinoco *et al*. (1997) Brazil	7843 schoolchildren, aged 12–19 years; two-stage screening: (1) clinical assessment of PD at first molars, (2) children with ≥1 tooth with PD ≥5 mm examined further; LJP diagnosed if a person with no systemic disease presented with AL >2 mm at ≥1 sites with radiographic evidence of bone loss and ≥1 infrabony defects at molars/incisors	119 subjects identified at initial screening; 25 confirmed cases of LJP; overall prevalence 0.3% Ethnic origins and gender ratios not reported
Lopez *et al*. (2001) Chile	A random sample of 9162 high school students, aged 12–21 years; probing assessments of AL at six sites/tooth at all incisors and molars	Prevalence of AL of ≥1 mm was 69.2%, of ≥2 mm was 16%, and of ≥3 mm was 4.5%. AL was associated with older age, female gender, poor oral hygiene, and lower socioeconomic status
Levin *et al*. (2006) Israel	642 army recruits (87.5% men), aged 18–30 years (mean 19.6 years); radiographic and clinical examination of first molars and incisors	Prevalence of *aggressive periodontitis* was 5.9% (4.3% LAP, 1.6% GAP); current smoking and north African origin were significantly related to AP
Holtfreter *et al*. (2009) Germany	587 young adults, aged 20–29 years, participants in the Study of Health in Pomerania (SHIP); half-mouth examination of an upper and lower quadrant at four sites/tooth with respect to PD and AL	12% and 1% of sample were found to suffer from "moderate" or "severe" periodontitis, respectively, according to the CDC/AAP criteria; 5% of sample exhibited AL ≥4 mm, 2% ≥5 mm and 1% ≥6 mm
Eres *et al*. (2009) Turkey	3056 students (1563 female and 1493 male) in ages 13–19 years, recruited in public schools in an urban area; clinical periodontal examination using CPTIN; 170 students with code 3 or code 4 sextants were examined radiographically and received a full mouth examination	The prevalence of LAP was 0.6% with a female : male ratio of 1.25 : 1
Elamin *et al*. (2010) Sudan	1200 students, 13–19 years old, selected through multistage, stratified sampling form 38 public and private high schools in Sudan; full-mouth exam at 6 sites per tooth	3.4% of the sample was diagnosed with aggressive periodontitis that was found to be more prevalent in male (4.9%) than female students (2.0%); 16.3% of the students had ≥1 tooth with CAL ≥ 4 mm, and 8.2% had ≥1 tooth with CAL ≥ 5 mm, with no difference in prevalence between male and female students

AL, attachment level; CEJ, cemento-enamel junction; CDC/AAP, Centers for Disease Control/American Academy of Periodontology; CI, confidence interval; CPITN, Community Periodontal Index of Treatment Needs; GAP, generalized aggressive periodontitis; GJP, generalized juvenile periodontitis; ILA, incidental loss of attachment; JP, juvenile periodontitis; LAP, localized aggressive periodontitis; LJP, localized juvenile periodontitis; PD, probing depth.

128 periodontally healthy children aged 7–9 years, in order to define a threshold value that, if exceeded, would indicate a high probability of periodontal pathology around the deciduous teeth. Having set this threshold value at 2 mm, Sjödin *et al*. (1993) retrospectively examined radiographs of the deciduous dentition from 118 patients with *juvenile periodontitis* and 168 age- and gender-matched periodontally healthy controls. The patients were divided in two groups, one comprising those with only one affected site (45 subjects) and another (73 subjects) including those with 2–15 sites with bone loss in their permanent dentition. It was found that 52% of the patients in the latter group, 20% of those in the former group, and only 5% of the controls exhibited at least one site with bone loss in their primary dentition. The authors concluded that, at least in some young subjects with destructive disease, the onset of the disease may manifest in the primary dentition. Similar results were reported by Cogen *et al*. (1992) from a study in the USA. Among systemically healthy young Black subjects with *aggressive periodontitis* and available radiographs of the primary dentition, 71% showed alveolar bone loss adjacent to one or several primary teeth. Finally, an interesting radiographic study of the mixed dentition in Australian children aged 5–12 years by (Darby *et al*. 2005) investigated the prevalence of alveolar bone loss around first

permanent molars, and first and second deciduous molars. Based on radiographs of 542 children, 13% were found to display definite bone loss, that is, bone levels >3.0 mm from the CEJ. Half of all sites with definite bone loss were on the second deciduous molars and, in the vast majority, on distal tooth surfaces. In other words, this study showed that the tooth surface of the deciduous dentition most frequently affected by bone loss was the one in close proximity to the most frequent localization of destructive periodontitis in young age groups, namely the mesial surface of the first permanent molar.

Periodontitis and tooth loss

Tooth loss may be the ultimate consequence of destructive periodontal disease. Teeth lost due to the sequelae of the disease are obviously not amenable to registration in epidemiologic surveys and may, hence, lead to an underestimation of the prevalence and the severity of the disease. The well-established epidemiologic concept of *selection bias* (also referred to as the *healthy survivor effect*, indicating that the comparatively healthier subjects will present for an examination while the more severely affected may refuse participation or fail to present because of the morbidity itself) is in this context applicable at the individual tooth level, since the severely affected teeth may have already been extracted/lost. Aspects related to tooth loss on a population basis have been addressed in numerous publications. Important questions that were analyzed included the relative contribution of periodontitis to edentulism (Eklund & Burt 1994; Takala *et al*. 1994) or to tooth extractions in subjects retaining a natural dentition (Reich & Hiller 1993; McCaul *et al*. 2001; Susin *et al*. 2005; Thorstensson & Johansson 2010; Hirotomi *et al*. 2011).

Typically, surveys addressing the first topic have utilized questionnaire data obtained from general practitioners instructed to document the reasons why teeth were extracted over a certain time period. The results indicate that the reason underlying the vast majority of extractions in ages up to 40–45 years is dental caries. However, in older age cohorts, periodontal disease is about equally responsible for tooth loss. Overall, periodontitis is thought to account for 30–35% of all tooth extractions, while caries and its sequelae for up to 50%. In addition, caries appears to be the principal reason for extractions in cases of total tooth clearance. Finally, identified risk factors for tooth loss include smoking, poor dental health, poverty and other socio-behavioral traits, and poor periodontal status.

Obviously, it is not feasible to "translate" tooth loss data into prevalence figures of periodontal disease. An evaluation, however, of the periodontal status at the population level, and in particular in older age cohorts, must weigh the information provided by tooth loss data, otherwise underestimation of the occurrence and the sequelae of the disease is inevitable (Gilbert *et al*. 2005).

Risk factors for periodontitis

Introduction: definitions

The discipline of epidemiology has been central to causal inquiry for health outcomes in humans since the beginning of the nineteenth century. However, despite numerous historical examples of causal discovery in the health sciences using core epidemiologic methods, a number of surprising and/or inconsistent findings, particularly in regard to complex chronic disease etiology, have weakened confidence in the causal models that helped to vanquish infectious diseases during the early twentieth century. For a more thorough overview of this debate see Demmer and Papapanou (2020).

A careful review of the definition of a "cause" is necessary to understand the underlying logic and models used to identify causal relationships in the health sciences. The following is a popular definition of a cause: "any factor without which the disease event would not have occurred, at least not when it did, given that all other conditions are fixed" (Rothman *et al*. 2008). To test causal hypotheses and identify causes, epidemiologists utilize a conceptual approach referred to as a "potential outcomes" or – synonymously – a "counterfactual framework". A counterfactual framework observes the disease experience in a group of individuals exposed to a hypothesized cause and then inquires what the disease experience in that same group would have been, had they – counter to fact – *not* been exposed to the hypothesized cause during the same time-period, with all other factors held constant. The observations from this theoretical experiment would then yield a causal effect, which is defined as the ratio (or difference) between: (1) the proportion of exposed individuals who develop disease during a given time period; and (2) the proportion of the same exposed individuals that would have developed disease, had they been unexposed during the same observation period. Unfortunately, this thought experiment is untenable in reality. Therefore, a cornerstone of etiologic epidemiological designs is the use of group comparisons. All etiologic epidemiological study designs, including observational designs and randomized interventions, have been developed precisely to enable valid group comparisons that can approximate the counterfactual ideal, and estimate causal effects.

Measures of disease occurrence

As implicitly alluded to above, the use of group comparison to estimate causal effects requires scientists to use measures of disease occurrence. In its simplest form, disease frequency can be captured via counts of diseased individuals (ideally in a clearly defined population during a precise time period). While absolute disease counts are suitable in some instances, they are often inappropriate in the context of group comparison because the groups being compared are almost

always of unequal size. In the setting of unequal group size, the observations at the group level might not enable logical inference at the individual level. For example, if group 1 has 1000 members and 100 cases of disease while group 2 has 100 members and 50 cases of disease the conclusion that group 1 has greater counts of disease is in conflict with the fact that individuals in group 2 have greater probability of disease.

To address this, the concept of risk has served as a fundamental tool for causal inquiry in epidemiology. In the context of a counterfactual (or potential outcomes) framework, risk is a proportion that is numerically equivalent to the probability of disease occurrence defined as follows: the number of people who develop a condition over a specified time period divided by the number of at-risk individuals in the source population under study. In more precise epidemiological terms, risk is often referred to as cumulative incidence (CI); a visual representation of CI and the explicit formula is presented in Fig. 6-3a. It is worth noting that this definition of risk explicitly requires the passage of time such that disease develops during a follow-up period among a subset of initially disease-free individuals. In contrast to cumulative incidence, prevalence reflects the probability of current disease. Prevalence is defined as a ratio of the number of existing cases at a point in time (or during a specific time period) over the total number of individuals in the population under study. For example, if the prevalence of periodontitis is 50% in a particular country, this tells us that the probability of any randomly selected inhabitant having periodontitis is 0.50 (or approximately one in two people). Alternatively, if the cumulative incidence (or risk) of periodontitis in 2020 is 5%, this tells us that during the 2020 calendar year, the probability of developing periodontitis among the initially periodontitis-free population is approximately one in 20. Another commonly used measure of disease occurrence is odds, which is defined as the probability of having the disease over the probability of being disease-free (i.e., 1 - probability of disease). Finally, the concept of incidence rate (or incidence density) is also of central importance to epidemiological inquiry and is closely related to the concept of risk. The incidence rate simply incorporates time explicitly into the denominator as follows: the number of people who develop a condition divided by the person time contributed by initially disease-free individuals during the study period. Person time is calculated for each individual as the amount of time that passes between entry into the study and either: (1) the development of disease; (2) the end of the observation period; or (3) death or loss-to-follow-up.

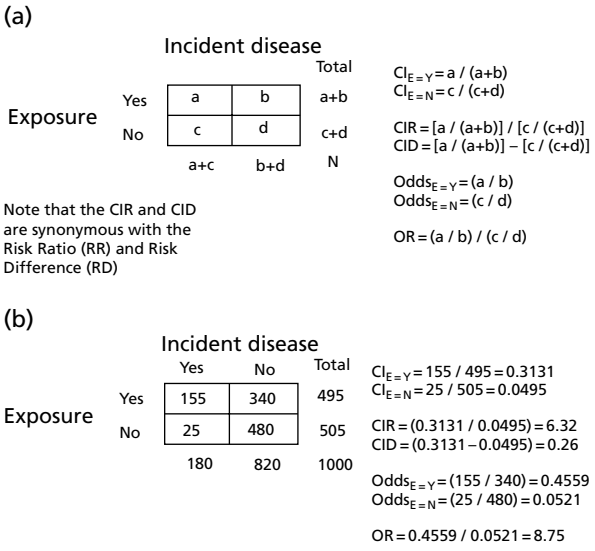

Fig. 6-3 Contingency tables describing the association between a particular exposure and incident disease and the definitions of cumulative incidence (CI), cumulative incidence ratio (CIR), cumulative incidence difference (CID), and odds ratio (OR). (a) describes the definitions and (b) provides a numerical example.

Measures of association

While measures of disease frequency, such as risk (i.e. cumulative incidence), are valuable for a number of reasons, risk is frequently used to assess the evidence for causal associations. This is usually done by comparing risk of disease between two different groups of individuals defined by variation in an "exposure" (i.e. a hypothesized cause of disease). For example, consider a hypothetical situation where exposure to a potential cause, "Z" is studied in a longitudinal cohort study of 1000 subjects (Fig. 6-3b). In this example, the association between exposure and disease can be expressed by the *cumulative incidence ratio* (CIR), also known as the *risk ratio* (RR), which is defined by the ratio of the probability of disease occurrence in the exposed to the probability of disease occurrence in the unexposed. For the data in Fig. 6-3b, the RR is calculated as [(155/495)/(25/505)] = 6.32. This indicates that the probability of disease among individuals exposed to Z was 6.32 times higher than the probability of disease among individuals unexposed to Z. If several important assumptions hold (beyond the scope of this chapter), this risk ratio is an estimate of the causal effect of Z on disease occurrence. Similarly, many investigators often choose to calculate the cumulative incidence difference, also known as the risk difference (RD), which is simply the difference in disease probabilities between exposed and unexposed, or [(155/495) - (25/505)] = 0.26. This concept described for RRs and RDs can be applied to other measures of disease frequency such as odds or incidence density (for examples, please see Demmer & Papapanou 2020). A note of caution is in order with regard to the interpretation of odds ratios (OR). Specifically, the OR is frequently misinterpreted to be synonymous with the RR, although this assumption only holds when the disease is rare (<10% is commonly used as a guide for designating a disease as

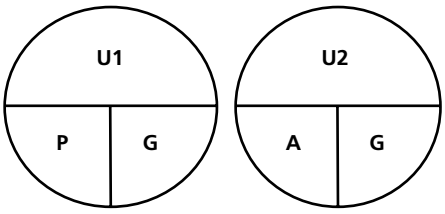
rare). As shown in Fig. 6-3b, since the overall cumulative incidence of disease is 18%, the OR of 8.75 substantially overestimates the RR of 6.32.

Causal inference and causal models

The use of group comparisons to approximate the ideal counterfactual knowledge under investigation is of critical importance but still fails to provide an explicit causal model linking exposures to disease outcomes. For epidemiological designs to yield meaningful causal inferences, coherent causal models of disease etiology are necessary.

A now classic model for causal inference was proposed by Rothman *et al*. (2008) using a "*sufficient cause*" model of causation. A sufficient cause (SC) is defined as "a complete causal mechanism that inevitably produces disease". The SC model visually represents causal hypotheses using causal "pies" as shown in Figs. 6-4 and 6-5. Causal pies are represented as full circles (i.e. sufficient causes) comprised of individual slices termed "*component causes*", each of which is required to complete a sufficient cause and, thus, for disease to occur. According to the main premise of the conceptual model, once all component causes of a sufficient causal pie are in place, disease will inevitably occur. The example in Fig. 6-4 provides a hypothetical sufficient component causal model for the development of human periodontitis in which there are two sufficient causes. In this example, sufficient cause 1 involves the presence of microbial dysbiosis triggered by a particular microorganism (*Porphyromonas gingivalis*) (P), a set of genetic polymorphisms (G) and the additional presence of a number of unknown factors (U1). Sufficient cause 2 is comprised of a different dysbiotic microbial profile, namely dysbiosis triggered by *Aggregatibacter actinomycetemcomitans* (A), the same set of genetic polymorphisms as in SC 1 (G), and another set of unknown factors (U2) which are distinct from U1. In the example visualized in Fig. 6-4, G represents a *necessary cause* – that is, G is a component cause that is present in all sufficient causes of disease and is therefore necessary to be present for periodontitis to occur. However, while G is necessary for the development of periodontitis, G alone is not sufficient to produce periodontitis without the presence of G's causal complements (i.e. P + U1, or A + U2). In contrast, P, A, U1 and U2 represent component causes that are neither sufficient nor necessary to cause periodontitis. If any individual in a hypothetical population completes either SC 1 or SC 2, they will develop periodontitis. A second example (Fig. 6-5) provides a hypothetical set of sufficient causes positing translocation of *Fusobacterium nucleatum* (F) from the oral cavity to the pancreas as a cause of type 2 diabetes mellitus development. In this example, there are three distinct sufficient causes comprised of six different component causes. This example demonstrates a scenario in which there are no necessary causes.

Two points should be emphasized from the SC model approach presented in Figs. 6-4 and 6-5. First, in modern epidemiology, the term "component cause" is synonymous with the more commonly used term, "risk factor". In other words, risk factors, are causes of disease that generally work in tandem with other risk factors (i.e. component causes) to produce disease. Note that the term "risk predictor" is generally



Sufficient Cause 1 Sufficient Cause 2

Prevalence of U1 and U2 is 100% in population 1 and 2.

Table B.
Joint distribution of *P. gingivalis* and periodontitis in population 1

	Periodontitis	No Periodontitis	Total
P. gingivalis present	900	900	1800
P. gingivalis absent	50	150	200

Table C.
Joint distribution of *P. gingivalis* and periodontitis in population 2

	Periodontitis	No Periodontitis	Total
P. gingivalis present	600	600	1200
P. gingivalis absent	350	450	800

Table A. Linking risk factor combinations to periodontitis risk according to Sufficient Causes 1 and 2

U1	U2	A	P	G	SC	Risk	Population 1	Population 2
1	1	1	1	1	1,2	1	500	500
1	1	1	1	0	None	0	500	500
1	1	1	0	1	2	1	50	350
1	1	1	0	0	None	0	50	350
1	1	0	1	1	1	1	400	100
1	1	0	1	0	None	0	400	100
1	1	0	0	1	None	0	50	50
1	1	0	0	0	None	0	50	50

Estimates of the causal effect of *P. gingivalis* on periodontitis in two separate populations

CIR = (900/1800) / (50/200) = 2.0

CID = (900/1800) – (50/200) = 0.25

CIR = (600/1200) / (350/800) = 1.14

CID = (600/1200) – (350/800) = 0.06

Fig. 6-4 Hypothetical sufficient component causal model for the development of human periodontitis in which there are two sufficient causes. Sufficient cause (SC) 1 involves the presence of microbial dysbiosis triggered by a particular microorganism (*Porphyromonas gingivalis*) (P), a set of genetic polymorphisms (G) and the additional presence of a number of unknown factors (U1). Sufficient cause 2 is comprised by dysbiosis triggered by *Aggregatibacter actinomycetemcomitans* (A), the same set of genetic polymorphisms as in SC 1 (G), and another set of unknown factors (U2) which are distinct from U1. CID, Cumulative Incidence Difference; CIR, Cumulative Incidence Ratio.

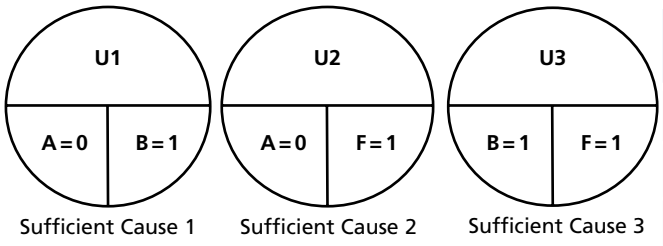


Table A. Linking risk factor combinations to diabetes risk according to Sufficient Causes 1 and 2

A	B	F	SC	Risk	Population 1	Population 2
1	1	1	3	1	900	100
1	1	0	None	0	900	100
1	0	1	None	0	100	900
1	0	0	None	0	100	900
0	1	1	1,2,3	1	100	900
0	1	0	1	1	100	900
0	0	1	2	1	900	100
0	0	0	None	0	900	100

Table B. Joint distribution of *F. nucleatum* and diabetes in population 1

Population 1	Diabetes present	Diabetes absent	Total
F. nucleatum present	1900	100	2000
F. nucleatum absent	100	1900	2000

CIR = (1900/2000) / (100/2000) = 19
CID = (1900/2000) – (100/2000) = 0.9

Table C. Joint distribution of *F. nucleatum* and diabetes in in population 2

Population 2	Diabetes present	Diabetes absent	Total
F. nucleatum present	1100	900	2000
F. nucleatum absent	900	1000	2000

CIR = (1100/2000) / (900/2000) = 1.22
CID = (1100/2000) / (900/2000) = 0.1

Fig. 6-5 Hypothetical sufficient component causal model for the development of type 2 diabetes mellitus involving translocation of *Fusobacterium nucleatum* (F) from the oral cavity to the pancreas. Three distinct sufficient causes are depicted, comprising a total of six different component causes (U1, U2, U3, A, B, and F). Note the absence of any necessary causes. CID, Cumulative Incidence Difference; CIR, Cumulative Incidence Ratio.

used to refer to a variable that predicts risk but for which causality is not assumed (e.g. grey hair is a risk predictor of mortality but not a causal risk factor). Second, and building on the first point, a somewhat obvious conclusion from the SC model is that there are multiple pathways that lead to the development of a given disease and each pathway involves multiple component causes that work together synergistically. This synergy precisely represents the concept of interaction (or effect measure modification) in statistics and epidemiology. In the specific context of SC models, when causal factors interact, any one component cause can only cause disease in the presence (or possibly in the absence) of the other component cause(s) in the same SC.

A careful review of the examples in Figs. 6-4 and 6-5 demonstrates another important concept that helps us understand why an exposure can cause disease even if the strength of association is weak or varies greatly across different studies (for example, as often observed in a meta-analysis). It is apparent that the CIR, that is, the ratio of the proportion of individuals with a certain risk factor that have completed a sufficient cause (i.e. have developed the disease) over the proportion of individuals without the risk factor that have completed a sufficient cause, and the cumulative incidence difference (CID), that is, the difference between the above two proportions, vary across populations in which the distribution of component causes are not equal. This raises a profoundly important point about causal inquiry that is often not appreciated in the health sciences: specifically, the strength of association (using absolute measures) is dependent upon the prevalence of causal complements in the population. The causal complement of a risk factor is defined as the set of all other component causes in all sufficient causes in which a risk factor participates. In the case of Fig. 6-5, the causal complements of F are A=0 and U2, or B=1 and U3. As the prevalence of these causal complements increases, the strength of association between F and diabetes becomes stronger.

What are then the implications of the above causal models for epidemiological research and the ability to identify causes of disease in humans? When we explore risk factors in isolation using reductionist approaches, there can be great variation in the strength of association between a causal factor and a disease outcome across populations. In populations with a low prevalence of causal complements, the strength of association for the main component cause (i.e. risk factor) under investigation will be weak when compared with that in a population with a higher prevalence of causal complements.

In contrast, in disease models where there are multiple sufficient causes in the population, and there is a high prevalence of component causes in sufficient causes where the risk factor of interest does not participate, the observed effect for this particular risk factor will be relatively weak or undetectable. In Fig. 6-5, note that an increase in the prevalence of individuals with both A=0 and B=1 would lead to an increase in the prevalence of individuals susceptible to SC 1, yielding weaker associations between F and diabetes because F cannot cause disease in individuals with SC 1 already complete (i.e. in individuals that are already "doomed"). This concept, known as causal redundancy, has been elegantly discussed in a review by Gatto and Campbell (2010).

Another often cited approach to establishing causality is to apply the Bradford Hill (Hill 1971) criteria below that include:

1. *Strength of the association*. The stronger the association between the potential (*putative*) risk factor and disease presence, the more likely it is that the anticipated causal relation is valid.
2. *Dose–response effect*. An observation that the frequency of the disease increases with the dose or level of exposure to a certain factor supports a causal interpretation.
3. *Temporal consistency*. It is important to establish that the exposure to the anticipated causative factor occurred prior to the onset of the disease. This may be difficult in cases of diseases with long latent periods or factors that change over time.
4. *Consistency of the findings*. If several studies investigating a given relationship generate similar results, the causal interpretation is strengthened.
5. *Biologic plausibility*. It is advantageous if the anticipated relationship makes sense in the context of current biologic knowledge. However, it must be realized that the less that is known about the etiology of a given disease, the more difficult it becomes to satisfy this particular criterion.
6. *Specificity of the association*. If the factor under investigation is found to be associated with only one disease, or if the disease is found to be associated with only one factor among a multitude of factors tested, the causal relation is strengthened. However, this criterion can by no means be used to reject a causal relation, since many factors have multiple effects and most diseases have multiple causes.

It is important to realize that the criteria described above are meant as guidelines for the establishment of a causal inference. None of them, however, is either necessary or sufficient for a causal interpretation. Strict adherence to any of them without concomitant consideration of the others may result in incorrect conclusions. We need only heed the explicit advice of Bradford Hill himself (Hill 1971): "None of my viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a sine qua non [an absolute necessity]."

Interestingly, high variability in measures of association across studies conducted in different populations is often taken to suggest lack of evidence for causality. While consistently strong associations do increase confidence in a causal hypothesis, lack thereof does not necessarily imply no causality. The examples provided above clearly demonstrate that under specific causal hypotheses, not dissimilar to the underlying hypotheses of modern chronic disease etiology, causal effects are *expected* to be inconsistent and at times weak, across different populations, as long as the prevalence of other risk factors varies.

Lastly, in the context of causal inference, some useful applied principles of the *risk assessment process* were discussed by Beck (1994) and consist of the following four steps:

1. The *identification* of one or several individual factors that appear to be associated with the disease.
2. In case of multiple factors, a *multivariate risk assessment model* must be developed that discloses which combination of factors most effectively discriminates between health and disease.
3. The *assessment* step, in which new populations are screened for this particular combination of factors, with a subsequent comparison of the level of the disease assessed with the one predicted by the model.
4. The *targeting* step, in which exposure to the identified factors is reduced by prevention or intervention and the effectiveness of the approach in suppressing the *incidence* of the disease is evaluated.

Thus, according to this process, *potential* or *putative risk factors* (often also referred to as *risk indicators*) are first identified and thereafter tested until their significance as *true risk factors* is proven or rejected.

There are various ways to assess simultaneously the effect of the several putative risk factors identified in step 1 and to generate the *multivariate model* required for step 2. For example, the association between exposure and disease may, for reasons of simplicity, have the form of the following linear equation:

$$y = a + b_1x_1 + b_2x_2 + b_3x_3 + \ldots b_nx_n$$

where y represents occurrence or severity of the disease, a is the intercept (a constant value), x_1, x_2, . . . x_n describe the different exposures (putative risk factors), and b_1, b_2, . . . b_n are *estimates* defining the relative importance of each individual exposure as a determinant of disease, after taking all other factors into account. Such an approach will help to identify factors with statistically and biologically significant effects and may minimize the effect of confounders.

In the third step (*assessment step*), a new population sample that is independent of the one used in the construction of the multivariate model is screened for occurrence of disease and presence of the relevant factors included in the multivariate model of step 2. Alternatively, in the case of a prospective cohort study, exposure to the relevant factors is assessed among the subjects of the new sample, and disease incidence, that is the number of new cases of disease, is determined over a time period after a longitudinal follow-up of the subjects. Subsequently, disease occurrence predicted from the model is compared with the actual disease occurrence, and the *external validity* of the model (i.e. the "behavior" or "fitness" of the model in the new population) is evaluated.

Lastly, during the fourth step (*targeting*), aspects of causality or risk are verified if disease occurrence is suppressed when exposure is impeded. Ideally, such studies should be designed as randomized clinical trials, in which treatment is randomly assigned to one of two groups and the effectiveness of the intervention is assessed in direct comparison to outcomes in an untreated, control group. Additionally, an evaluation of the particular preventive/therapeutic strategy from a "cost–benefit" point of view is also facilitated in such studies. Note that successful fulfillment of the targeting step requires that (1) the factor is amenable to intervention and (2) the intervention is delivered at the appropriate time point. Genetic traits are examples of risk factors not amenable to intervention. Likewise, in cases where a single exposure to a factor results in detrimental and/or irreversible biologic damage (e.g. exposure to a high dose of radiation), interventions protecting against subsequent exposure to the factor (radiation) may not lower the incidence of disease (e.g. cancer).

In the context of periodontitis, it should be realized that few of the putative risk factors for disease development have been subjected to the scrutiny of all four steps. In fact, risk assessment studies in dental research in general have been frequently confined to the first two steps. Numerous cross-sectional studies identifying potential risk factors are available, but a relatively limited number of longitudinal studies involve a multivariate approach to the identification of exposures of interest while simultaneously controlling for the effect of possible confounders. Intervention studies in the form of randomized clinical trials are sparse. In the following text, the issue of risk factors is addressed according to the principles described previously. Results from cross-sectional studies are considered to provide evidence for putative risk factors that may be further enhanced if corroborated by longitudinal studies involving multivariate techniques, or prospective intervention studies. As reviewed by Borrell and Papapanou (2005), distinction is also made between putative factors that are not amenable to intervention (non-modifiable background factors) and modifiable factors (environmental, acquired, and behavioral).

Non-modifiable background factors

Age

The relationship between age and periodontitis is complex. Although it is clear that both the prevalence and the severity of periodontitis increase with age (Albandar & Kingman 1999; Burt 1994; Dye *et al*. 2007; Eke *et al*. 2018), the concept of periodontitis as an inevitable consequence of aging has been challenged over the years (Papapanou *et al*. 1991; Papapanou & Lindhe 1992) and the alleged "age effect" largely represents the cumulative effect of prolonged exposure to true risk factors. Notably, the association between age and periodontitis appears to be different for pocket depth and amount of clinical attachment loss. While there is a pronounced effect of increasing attachment loss with age, the effect on pocket depth appears to be minimal (Albandar 2002; Albandar & Tinoco 2002; Billings *et al*. 2018). Interestingly, the effect of age on attachment loss was found to be attenuated after adjustment for co-variates, such as oral hygiene levels or access to dental care services (Albandar & Tinoco 2002). In addition, epidemiologic studies have often failed to adjust for important co-variates such as presence of systemic diseases, consumption of multiple medications, and co-morbidities related to nutritional disturbances in the older population, all of which could partly account for the increased prevalence and severity of periodontitis in the elderly. On the other hand, age-associated molecular alterations in key phagocytic cells involved in both the protective and destructive immune responses have been shown to affect their ability to carry out efficient antimicrobial functions and to result in a dysregulation of the inflammatory response (Hajishengallis 2010). Since periodontitis is a microbially-associated inflammatory disorder, these alterations in innate immunity likely contribute to more pronounced periodontal pathology in elderly individuals. An age-related, rather than an age-dependent, increased susceptibility to periodontitis in older people is therefore biologically plausible.

Sex

There is no established, inherent difference between men and women in their susceptibility to periodontal disease, although men have been shown to exhibit worse periodontal conditions than women in multiple studies from different populations (Brown *et al*. 1990; Susin *et al*. 2004a; Holtfreter *et al*. 2009; Dye 2012; Eke *et al*. 2016b). This difference has been traditionally considered to reflect the documented better oral hygiene practices (Hugoson *et al*. 1998b; Christensen *et al*. 2003) and/or increased utilization of oral health care services among women (Yu *et al*. 2001; Dunlop *et al*. 2002; Roberts-Thomson & Stewart 2003). On the other hand, there is evidence for sexual dimorphism in elements of both the innate and the acquired immunity that may lead to enhanced pro-inflammatory responses in men (Shiau & Reynolds 2010), which are in line with the epidemiologic evidence of gender-associated disparities in prevalence, extent, and severity of periodontitis.

Race/ethnicity

Differences in the prevalence of periodontitis between countries and across continents have been demonstrated (Dye 2012; Kassebaum *et al*. 2014; Papapanou & Susin 2017), but no consistent patterns across racial/ethnic groups have been documented when co-variates such as age and oral hygiene were

accounted for (Burt & Eklund 1999). National, population representative studies in the USA consistently show a racial/ethnic differential pattern in the prevalence of periodontitis, with Mexican–Americans and African–Americans exhibiting higher prevalence than non-Hispanic Caucasians (Eke *et al*. 2018). However, race/ethnicity is usually a social construct that determines an array of opportunities related to access, status, and resources (Williams 1997, 1999; Hasslanger 2008). As a result, race/ethnicity and socioeconomic status (SES) are strongly intertwined, suggesting that the observed racial/ethnic effect may be partially attributed to confounding by SES due to the unequal meaning of SES indicators across racial/ethnic groups (Williams 1996; Kaufman *et al*. 1997; Krieger *et al*. 1997; Lynch & Kaplan 2000). Corroborating this point, a study reported that African–Americans demonstrated a lower benefit from education and income in terms of periodontal health status than their Mexican–American and Caucasian peers (Borrell *et al*. 2004). These findings confirm that socioeconomic indicators across racial/ethnic groups are not commensurable but, probably, reflect the broad implications of historic unequal opportunities among certain racial groups (Borrell & Crawford 2012; Borrell 2017).

Gene polymorphisms

Evidence that genetic predispositions are significant determinants of periodontitis phenotype was first documented in a number of classic twin (Michalowicz *et al*. 1991) and family studies (Boughman *et al*. 1992; Marazita *et al*. 1994). Aggregate data from genetic studies carried out since then have led to heritability estimates of periodontitis of up to 50% (Michalowicz *et al*. 2000), although a recent systematic review (Nibali *et al*. 2019) reported substantially lower heritability estimates: 38% in twin studies, 15% in other family studies, and only 7% in *genome-wide association studies* (GWAS).

The association of *single nucleotide polymorphisms* (SNPs), that is, of specific variations at defined locations of the genome that occur in least 1% of the population, with different forms of periodontitis has been studied extensively in the literature. Following the study by Kornman *et al*. (1997), who were the first to report an association between a composite genotype based on specific polymorphisms in the interleukin-1 gene cluster and severe periodontitis in non-smokers, there has been an exponential increase in publications examining a plethora of gene polymorphisms as severity markers of periodontitis. These include additional investigations of the particular composite IL-1 gene polymorphism in cross-sectional and case-control studies (e.g. Diehl *et al*. 1999; Armitage *et al*. 2000; Papapanou *et al*. 2001; Li *et al*. 2004; Meisel *et al*. 2004), prospective studies (Ehmke *et al*. 1999; De Sanctis & Zucchelli, 2000; Lang *et al*. 2000; Cullinan *et al*. 2001; Christgau *et al*. 2003; Jepsen *et al*. 2003) as well as studies in which polymorphisms in particular loci of the *IL1A* gene (Ferreira *et al*. 2008; Fiebig *et al*. 2008; Mazurek-Mochol *et al*. 2019), the *IL1B* gene (Lopez *et al*. 2005; Struch *et al*. 2008), and the interleukin-1 receptor antagonist (Berdeli *et al*. 2006; Fiebig *et al*. 2008; Tai *et al*. 2002) were investigated.

In parallel, polymorphisms in additional inflammatory genes have been investigated, including the tumor necrosis factor-alpha gene (Endo *et al*. 2001; Shapira *et al*. 2001; Craandijk *et al*. 2002; Fassmann *et al*. 2003; Shimada *et al*. 2004; Wei *et al*. 2016), the interleukin-6 gene (Holla *et al*. 2004; Nibali *et al*. 2008, 2009; Zhao & Li 2018), the interleukin-4 gene (Kang *et al*. 2003; Holla *et al*. 2008; Jia *et al*. 2017), and the interleukin-10 gene (Kinane *et al*. 1999; Yamazaki *et al*. 2001; Scarel-Caminaga *et al*. 2004; Wang *et al*. 2019). A substantial body of data has accumulated on polymorphisms in genes coding for various receptors, including the leukocyte receptors for the constant part (Fc) of immunoglobulin G (Kobayashi *et al*. 1997; Sugita *et al*. 1999; Meisel *et al*. 2000; Loos *et al*. 2003; Wolf *et al*. 2006; Lavu *et al*. 2016), pattern recognition receptors such as CD14 (Holla *et al*. 2002; Tervonen *et al*. 2007; Zheng *et al*. 2013) and Toll-like receptors (TLRs) 2 and 4 (Folwaczny *et al*. 2004; Fukusaki *et al*. 2007; Noack *et al*. 2008; Zhu *et al*. 2008; Leite *et al*. 2019), and the vitamin D receptor (Nibali *et al*. 2008; Wang *et al*. 2009; Park *et al*. 2019). Additional polymorphisms studied in single studies or a few cohorts have been discussed in a comprehensive review by Laine *et al*. (2012) and a meta-analysis of 53 studies collectively including 4178 cases and 4590 controls (Nikolopoulos *et al*. 2008).

Until fairly recently, the most common study design used for the identification of periodontitis susceptibility genes has been that of a *candidate-gene* association study, and most of the publications listed above fall into that category. However, this approach has several limitations, notably the fact that the hypotheses for the selection of the particular candidate genes are based on current, imperfect knowledge of the molecular mechanisms that govern processes considered to be involved in the disease pathogenesis, while other genes, members of pathways not yet implicated in processes relevant to the disease or of unknown function, are obviously not studied. In addition, (1) most studies have had relatively limited sample size, (2) the frequency of occurrence of the investigated polymorphisms has varied extensively between ethnic groups, (3) the definitions of the outcome variable (periodontitis) has varied considerably across studies, and (4) adequate adjustments for other important co-variates and risk factors have frequently not been carried out (Citterio *et al*. 2019). Notably, a recent comprehensive case-control validation study that involved a fairly large population sample in northern Europe (755 cases of aggressive periodontitis and 3042 periodontitis-free individuals, as well 1437 cases of chronic periodontitis and 1125 controls) attempted to replicate the association of 23 genes that

were repeatedly proposed in the literature to confer risk for severe periodontitis in Caucasian populations (Schaefer *et al*. 2013). However, with the exception of an SNP in the *IL10* gene that was associated with aggressive periodontitis, all other previously proposed associations could not be validated, suggesting the possibility that earlier positive reports were due to type 1 error.

In contrast, GWAS studies adopt a "hypothesis-free" approach to identify genetic loci associated with periodontitis susceptibility by examining polymorphic regions in the entire genome, and are therefore not burdened by the key shortcoming of the candidate gene association approach. However, given the large number of statistical tests required to test the association of every reported polymorphic region with the phenotype under investigation, the obtained *P* values need to be adjusted accordingly and very sample sizes are required to produce reliable findings. To date, only 12 GWAS studies of clinical periodontal status have been published: Five studies involved populations from Europe (Schaefer *et al*. 2010; Teumer *et al*. 2013; Freitag-Wolf *et al*. 2014; Munz *et al*. 2017; Bevilacqua *et al*. 2018), three from Asia (Hong *et al*. 2015; Shimizu *et al*. 2015; Tong *et al*. 2019), and four from the Americas (Divaris *et al*. 2013; Feng *et al*. 2014; Shaffer *et al*. 2014; Sanders *et al*. 2017). However, a meta-analysis of the available GWAS findings (Shungin *et al*. 2019) suggests that there is limited concordance among studies, which can partly be attributable to inherent genetic differences between the populations, but also to inconsistencies in the precise definition of periodontitis "cases" and "controls" across studies. Table 6-4 presents an overview of identified genes associated with poor clinical periodontal status in the available GWAS studies that met a nominal statistical significance level ($P \leq 5 \times 10^{-6}$).

In addition, three publications (Divaris *et al*. 2012; Rhodin *et al*. 2014; Offenbacher *et al*. 2016), all stemming from a single GWAS study in the USA involving participants in the Atherosclerosis Risk in Communities (ARIC) study have investigated whether there is evidence that distinct subgingival colonization patterns, or so-called "periodontal microbial traits", are associated with specific genetic loci. These studies have analyzed subgingival plaque samples using the "checkerboard" DNA-DNA hybridization technique

Table 6-4 Genes mapping to single nucleotide polymorphisms reported to have a suggestive association ($P \leq 5 \times 10^{-6}$) with various periodontitis-associated clinical phenotypes in genome-wide association studies. Genes listed in boldface font have been identified in at least two independent population samples.

Tong *et al*. (2019) China	Chronic periodontitis	***SIGLEC5***

CDC/AAP, Centers for Disease Control/American Academy of Periodontology.

Table 6-5 Genes mapping to single nucleotide polymorphisms reported to have a suggestive association ($P \leq 5 \times 10^{-6}$) with various microbial or biologically informed complex traits in genome-wide association studies. All three publications listed below originate from the same population sample (the Atherosclerosis Risk in Communities study; ARIC). Genes listed in boldface font were associated with more than one trait.

Authors/country	Periodontitis-associated microbial/biologically informed traits	Associated genes
Divaris *et al*. (2012) USA	High colonization by *Aggregatibacter actinomycetemcomitans*; "high *A.a*. trait"	***KCNK1***; ***KIAA1804***; *FOS*; *DP2*; *ODZ2*; *WWC1*; *GRID1*; *M1346/WAPAL*; *KIAA1715*; *EVX2*; *EXTLP2*
Divaris *et al*. (2012) USA	High colonization by *Porphyromonas gingivalis*; "high *P.g*. trait"	*OTOF*; *C2Orf70*; *CIB4*; *TTLL11*; *ANKRD30A*; *DAB2IP*
Divaris *et al*. (2012) USA	High colonization by "red complex" bacteria (*P. gingivalis, Tanerella forsythia, Treponema denticola*); high "red complex" trait	*PKN2*; *HTR4*; *GLDC*; *TBC1D1*; *PTTG2*; ***KIAA1804***; *FBXO38*; *UHRF2*; ***KCNK1***
Divaris *et al*. (2012) Rhodin *et al*. (2014) USA	High colonization by selected "*orange complex*" bacteria (*Prevotella intermedia, Fusobacterium nucleatum, Parvimonas micra* and *Campylobacter rectus*); high "orange complex" trait	*RUNX2*; *CLIC5*; *TRPS1*; *CSMD3*; *CAMTA1*; *VAMP3*; *WDR59*
Offenbacher *et al*. (2016) USA	Biologically informed complex traits (combinations of bacterial colonization by selected microbial species and gingival crevicular fluid interleukin-1 beta levels)	*RBMS3*; *CLEC19A*; *TRA*; *GGTA2P*; *TM9SF2*; *IFI16*; *C1QTNF7*; *TSNARE*; *HPVC1*; *SLC15A4*; *PKP2*; *SNRPN*

(Socransky *et al*. 1994). Findings from these studies, that is, identified genes associated with these microbial traits that met a nominal statistical significance level ($P \leq 5 \times 10^{-6}$), are summarized in Table 6-5.

The available GWAS studies have involved participants across the age spectrum. Given that periodontitis is more pronounced in older ages, there is significant concern that younger individuals involved in these studies who, at the time of examination, presented with no periodontitis or showed signs of mild disease, may have been misclassified, as they might develop more pronounced disease at later stages of their life. To mitigate this concern, Papapanou *et al*. (2021) carried out an external validation of the findings of the available GWAS studies in a sample of 1130 elderly participants (65–98 years old). In these analyses carried out in a sample with fully developed periodontitis-associated phenotypes, they examined the association of the loci listed in Tables 6-4 and 6-5 with respect to multiple clinical, periodontitis-associated phenotypes, including edentulism, as well as a number of microbial traits. In general, genes previously reported in available GWAS studies to be associated with periodontitis-related clinical phenotypes or periodontal microbial traits replicated rather poorly: out of a total of 92 genes tested, 22 genes met the statistical significance threshold after multiple comparisons, and only two genes were found to be associated with more than one of the phenotypes examined. Notably, no genes were associated with the CDC/AAP classification of periodontitis, and the single gene (*SIGLEC5*) identified by the recent meta-analysis as associated with a composite phenotype of "severe periodontitis/loose teeth" (Shungin *et al*. 2019) did not replicate.

In conclusion, there is insufficient epidemiologic evidence that unequivocally establishes any of the above polymorphisms as true risk factors for periodontitis. Studies employing larger cohorts, strict and biologically informed criteria for periodontitis, and refined analytical methods will enhance our understanding of the role of genetic influences in the pathobiology of periodontitis.

Environmental, acquired, and behavioral factors

Microbial factors

In a classic experiment carried out in the mid-1960s, Harald Löe *et al*. demonstrated the causal association between dental plaque accumulation and gingival inflammation (Löe *et al*. 1965; Theilade *et al*. 1966). A 3-week accumulation of plaque in young, periodontally healthy individuals was paralleled by the development of inflammatory changes in the gingival tissues that were fully reversible after prophylaxis and re-institution of oral hygiene measures. A few years later, Lindhe *et al*. (1973) extended these observations and demonstrated in an experimental model in the Beagle dog that long-standing plaque accumulation, facilitated by the placement of cotton ligatures at the level of the gingival margin, induced an irreversible breakdown of the periodontal apparatus, that is, in loss of connective tissue attachment and alveolar bone. These two landmark studies provided the first experimental evidence of the etiological role of bacteria in the development of periodontal diseases and formed the conceptual foundation for the development of antiplaque strategies in their prevention and treatment.

Until fairly recently, the identities of the organisms associated with periodontal lesions or with periodontal health were limited to those that could be cultured in the laboratory. Several cross-sectional and longitudinal epidemiologic studies published in the 1990s and the first decade of the new millennium (e.g. Grossi *et al*. 1994; Beck *et al*. 1990, 1997; Machtei *et al*. 1997;

Papapanou *et al*. 1997, 2002; Timmerman *et al*. 1998; Van der Velden *et al*. 2006) established the association of certain so called "periodontal pathogens" including *Porphyromonas gingivalis, Tannerella forsythia* and *Aggregatibacter actinomycetemcomitans* with deep pocketing, and progressive periodontal lesions. A pivotal publication from the Forsyth group (Socransky *et al*. 1998), collected subgingival plaque samples from 185 subjects, 160 of whom suffered from periodontitis and 25 were periodontally healthy, and determined the presence and levels of 40 subgingival taxa in a total of 13261 plaque samples using whole genomic DNA probes and checkerboard DNA-DNA hybridization. Using various analytical methods to assess community ordination, the investigators identified five major bacterial complexes that were consistently observed using any of the analytical methods, one of which, the so called "red complex" that included *Tanerella forsythia*, *Porphyromonas gingivalis*, and *Treponema denticola*, related strikingly to clinical measures of periodontal disease, and particularly with pocket depth and bleeding on probing. Notably, the consensus report of the 1996 World Workshop in Periodontics (Consensus Report on Periodontal Diseases: Pathogenesis and Microbial Factors, 1996) had identified three species, *Aggregatibacter actinomycetemcomitans* (termed *Actinobacillus actinomycetemcomitans* at the time), *Porphyromonas gingivalis,* and *Tanerella forsythia* (formerly termed *Bacteroides forsythus*), as *causative agents* for periodontitis.

However, with the advent of culture-independent, molecular methods of bacterial identification and enumeration such as 16S rRNA gene amplification and high-throughput sequencing, our understanding of the bacterial composition of the periodontal region evolved significantly (Chen *et al*. 2010). The study of thousands of plaque samples derived from a variety of clinical periodontal conditions demonstrated that approximately 700 prokaryote species can colonize the oral cavity and approximately 150 species can simultaneously colonize oral sites of an individual host (Dewhirst 2016). In addition to the traditional pathogens mentioned above, newly recognized non-cultivable or poorly cultivable organisms that increase in abundance at diseased sites include the Gram-positive bacteria *Filifactor alocis* and *Peptostreptococcus stomatis*; Gram stain-negative members of the phylum *Firmicutes* including the genera *Dialister*, *Megasphaera*, *and Selenomonas*; and species in the genera *Prevotella*, *Desulfobulbus*, and *Synergistes*.

In recognition of the fact that periodontal pathogens do not fulfill the classic Koch's postulates defining the causal relationship between an infectious agent and a disease, Haffajee and Socransky (1994) introduced a list of revised criteria to be used in the identification of bacterial periodontal pathogens, including: (1) *association*, expressed through high odds ratios in disease; (2) *elimination*, according to which suppression of the pathogens beyond detection results in a conversion of the state of periodontal disease to health; (3) *development of a host response*, in other words the expectation that a true pathogen that gains access to the host tissues and is actively involved in the disease process will elicit a systemic antibody response while a mere colonizer will not; (4) *presence of virulence factors* that can account for the microbe's ability to inflict tissue damage; and (5) *evidence from animal studies* that corroborate the observations in humans and demonstrate development of periodontal pathology after infection by the microorganism. Admittedly, what constitutes a microbial pathogen in the context of periodontal diseases has been a subject of considerable debate in the periodontal literature. The debate has been further fueled by the recognition that presumed "causal pathogens" can be encountered in biofilms of periodontally healthy individuals, casting serious doubt on the earlier proposed postulate that these microorganisms may behave as exogenous pathogens. For example, studies performed in children (Tanner *et al*. 2002; Yang *et al*. 2002) that analyzed plaque from the gingival crevice, tooth surface, and dorsum of the tongue revealed that sizeable proportions of subjects harbored *P. gingivalis*, *T. forsythia*, and *A. actinomycetemcomitans* despite absence of overt gingival inflammation. Likewise, a high carrier state was documented in studies that sampled infants, children, adolescents, and adults with apparently healthy periodontal conditions (Könönen 1993; Lamell *et al*. 2000; Rotimi *et al*. 2010).

Today, it is increasingly recognized that periodontal diseases are not bacterial infections in the classic sense, that is, caused by a single or a limited number of pathogens that are not regular constituents of the resident periodontal microbiota, but are rather driven by dysbiotic bacterial communities that induce a perturbation of the host homeostasis in susceptible individuals. Bacterial constituents of these dysbiotic communities that have disproportionate effects relative to their abundance, the so-called *keystone species* (Hajishengallis *et al*. 2012), exhibit synergistic interactions that enhance colonization, persistence, or virulence of the entire bacterial community. Nevertheless, the association between high levels of colonization by specific bacteria and periodontitis progression has been corroborated by longitudinal data in untreated populations. For example, in the study by Papapanou *et al*. (1997), a discriminant analysis based on quantitative assessments of subgingival bacterial load classified correctly the substantial majority of the subjects with progression of periodontitis over a preceding 10-year period. Indeed, bacterial profiles classified correctly 75% of the subjects with 10 or more sites with longitudinal attachment loss of ≥3 mm, and 85% of those that remained stable over the observation period. In a 7-year follow-up study of Indonesian adolescents (Timmerman *et al*. 2000; Timmerman *et al*. 2001), and in a subsequent 15-year follow-up of the same cohort (Van der Velden *et al*. 2006), it was

shown that the subgingival presence of *A. actinomycetemcomitans* was associated with disease progression, defined as presence of longitudinal attachment loss of ≥2 mm.

Important observations have also been reported with respect to the role of specific bacteria on the onset of periodontitis in young individuals. In a group of 96 primarily African–American and Hispanic schoolchildren followed for at least 2 years and 6 months, Fine *et al*. (2007) reported that eight of 38 *A. actinomycetemcomitans*-positive but none of 38 *A. actinomycetemcomitans*-negative adolescents, all of whom were periodontally intact at the baseline examination, developed bone loss over the observation period. In a 2-year prospective study of clinical periodontal status in adolescents in Morocco, Haubek *et al*. (2008) reported that colonization by a specific clone of *A. actinomycetemcomitans*, namely the highly-leukotoxic JP2 clone, conferred a much higher risk for the onset of aggressive periodontitis in periodontally healthy schoolchildren than concomitant colonization by a variety of clones of the same species, or the total absence of colonization by *A. actinomycetemcomitans*. Indeed, in comparison with schoolchildren who were not colonized by *A. actinomycetemcomitans*, the relative risk for incident disease in those colonized exclusively by JP2 clones was 18.0 (95% CI 7.8–41.2), as compared with 12.4 (95% CI 5.2–29.9) in those colonized by both JP2 and non-JP2 clones, and 3.0 (95% CI 1.3–7.1) in those colonized exclusively by non-JP2 clones of *A. actinomycetemcomitans*. This study underscored the important role of this particular periodontal pathogen in the etiology of early-onset forms of periodontitis, but also demonstrated that within-species variation in virulence is associated with differences in the clinical presentation of the disease. A more recent longitudinal study reported that concomitant detection of *A. actinomycetemcomitans*, *Streptococcus parasanguinis*, and *F. alosis* may signify risk for bone loss in African–American adolescents (Fine *et al*. 2013).

Collectively, data generated in the past 30 years have enhanced our knowledge of the role of periodontal bacteria as risk factors for periodontitis and underscore the fact that, although abundance by specific microbiota in the subgingival plaque has been shown to confer risk for periodontitis, it is the collective decrease of the subgingival plaque burden that consistently results in substantial improvement in clinical periodontal status. Thus, it is primarily the fulfillment of the "targeting" step of the risk assessment process described above that validates the role of the plaque microbiota as risk factors for periodontitis. As demonstrated in systematic reviews, removal of subgingival plaque with or without adjunctive antiseptics or antibiotics followed by adequate maintenance care, is the single most successful and consistent approach in the treatment of periodontitis (Herrera *et al*. 2002; Tonetti & Chapple 2011; Suvan *et al*. 2019).

Cigarette smoking

The biologic plausibility of an association between tobacco smoking and periodontitis has been founded on the broad effects of multiple tobacco-related substances on cellular structure and function. Smoking has been shown to affect the vasculature, the humoral and cellular immune responses, cell signaling processes, and tissue homeostasis (for reviews see Kinane & Chestnutt, 2000; Palmer *et al*. 2005; Zhang *et al*. 2019). Furthermore, while older, culture-based studies that examined only a limited number of species suggested that the composition of the subgingival microbiota in smokers is rather similar to that of non-smokers (Stoltenberg *et al*. 1993), more recent studies that utilized robust, culture-independent methodologies demonstrated that smoking contributes significantly to enhanced subgingival dysbiosis (Camelo-Castillo *et al*. 2015; Coretti *et al*. 2017; Hanioka *et al*. 2019).

Early epidemiologic data provided the first evidence that cigarette smoking is associated with poor periodontal status (Bergström 1989; Locker *et al*. 1991; Jette *et al*. 1993). Data derived from the NHANES III study (Tomar & Asma 2000) suggested that as many as 42% of periodontitis cases in the USA can be attributed to current smoking, and another 11% to former smoking. Similarly, in a study from Brazil, Susin *et al*. (2004) reported that the attributable fraction of clinical attachment loss due to cigarette smoking was 37.7% and 15.6% among heavy and moderate smokers, respectively. An abundance of data from different parts of the world has documented that tobacco smoking is associated with a higher extent and severity of periodontitis after adjustment for multiple covariates (Roberts-Thomson *et al*. 2014; Zhan *et al*. 2014; Eke *et al*. 2015; Lee *et al*. 2016; Eke *et al*. 2018; Zhao *et al*. 2019). Likewise, data from longitudinal studies indicate that smoking confers a statistically significant increased risk for periodontitis progression in multivariate models (Beck *et al*. 1995, 1997; Machtei *et al*. 1999; Norderyd *et al*. 1999; Chen *et al*. 2001; Ogawa 2002; Paulander *et al*. 2004; Mdala *et al*. 2014; Leite *et al*. 2018).

Studies examining the effects of smoking on the outcome of periodontal therapy have demonstrated that treatment responses are impaired by smoking, with current or heavy smokers exhibiting poorer responses than former or never smokers (e.g. Ah *et al*. 1994; Kaldahl *et al*. 1996; Grossi *et al*. 1997; Trombelli *et al*. 2003; Rieder *et al*. 2004; Stavropoulos *et al*. 2004; Angst *et al*. 2019). Notably, these studies have confirmed the negative effect of smoking on the outcome of multiple periodontal treatment modalities, including non-surgical, surgical, and regenerative periodontal therapy. Published meta-analyses of the effects of smoking on the outcome of periodontal therapy support the above conclusions (Garcia 2005; Labriola *et al*. 2005; Patel *et al*. 2012; Kotsakis *et al*. 2015).

Importantly, smoking cessation was shown to have beneficial effects on periodontal status. In a longitudinal study (Bolin *et al*. 1993), 349 subjects with ≥20 remaining teeth were examined on two occasions 10 years apart. Progression of alveolar bone loss was assessed on radiographs at all interproximal tooth surfaces and was shown to be significantly attenuated in individuals who gave up smoking during the observation period. Extending these observations, Krall *et al*. (1997) reported that, over a mean follow-up period of 6 years, subjects who continued to smoke had a 2.4–3.5-fold higher risk of tooth loss when compared with individuals who quit smoking. In a 10-year follow-up study, Bergström *et al*. (2000) observed an increase of periodontally diseased sites concomitant with loss of periodontal bone height in current smokers, as compared with non-smokers; the periodontal condition of the latter group remained unaltered throughout the period of investigation. The periodontal condition in former smokers was similarly stable to that of non-smokers, underscoring the beneficial effects of smoking cessation. In a shorter (12-month) follow-up study evaluating the adjunctive effect of smoking cessation on the outcome of non-surgical periodontal therapy, Rosa *et al*. (2011) showed enhanced gain in clinical attachment in chronic periodontitis patients who quit smoking when compared with their smoker counterparts. Importantly, smoking cessation alone or in conjunction with non-surgical periodontal therapy appears to result in a composition of subgingival microbiota that comprises higher levels of health-associated species and lower levels of periodontal pathogens (Fullmer *et al*. 2009; Delima *et al*. 2010). Lastly, a recent systematic review of the impact of the promotion of healthy lifestyles in patients with periodontitis identified smoking cessation as a key strategy to achieve improvements in periodontal health (Ramseier *et al*. 2020).

In conclusion, cigarette smoking clearly fulfills the risk assessment process criteria stipulated by Beck (1994) and is considered a major risk factor for periodontitis.

Diabetes mellitus

An association between diabetes mellitus (DM) and periodontitis has been reported in the literature since the 1960s (Belting *et al*. 1964). Several biologically plausible mechanisms by which the disease may contribute to impaired periodontal conditions have been identified over the past two decades (for comprehensive reviews see Lalla *et al*. 2000; Mealey & Oates 2006; Lalla & Papapanou 2011; Graves *et al*. 2020).

Early epidemiologic studies in the 1980s and the 1990s provided the first solid evidence that patients with DM show higher extent and severity of periodontitis than individuals free of diabetes. In a limited-sized study from Sweden involving participants with long- or short-duration diabetes and diabetes-free controls, Hugoson *et al*. (1989) were the first to document that diabetes duration was positively associated with the extent of periodontal pocketing. Larger studies involving individuals at the Gila River Indian community in Arizona, USA (Shlossman, Knowler *et al*. 1990; Emrich *et al*. 1991) expanded these observations and confirmed that individuals with diabetes have consistently poorer periodontal status than those without the disease. This accumulating evidence resulted in an influential publication by Löe (1993), who coined periodontal disease as "the sixth complication of diabetes mellitus". Approximately a decade ago, Chávarry *et al*. (2009) examined in a systematic review whether diabetes remains associated with periodontitis of higher severity after adjustment for potential confounders, as well as whether it influences the response to periodontal therapy. Out of 49 cross-sectional studies that fulfilled the inclusion criteria, 27 documented a higher extent and severity of periodontitis in diabetes, and a meta-analysis indicated a statistically significant average estimated difference in clinical attachment loss of 1 mm (95% CI 0.15–1.84 mm) between diabetic and diabetes-free individuals. The difference was primarily documented in patients with type 2 diabetes, while the estimated difference in attachment level between patients with type 1 diabetes and diabetes-free controls was not statistically significant.

The adverse effects of DM on periodontal status appear to be particularly pronounced in subjects with long duration of DM and poor metabolic control (Taylor *et al*. 1996; Grossi & Genco 1998; Taylor *et al*. 1998; Lalla *et al*. 2004). Indeed, studies have provided evidence of a dose–response relationship between poor metabolic control and the severity as well as the progression of periodontitis (Seppälä *et al*.1993; Tervonen & Oliver 1993; Tervonen & Karjalainen 1997; Guzman *et al*. 2003; Bandyopadhyay *et al*. 2010; Demmer *et al*. 2012; Morita *et al*. 2012). Expanding this observed dose–response relationship to include the pre-diabetic state as well, several studies (Saito *et al*. 2004; Lim *et al*. 2014; Song *et al*. 2016; Perez *et al*. 2017) reported that the level of glucose intolerance in non-diabetic individuals correlates positively with the severity of periodontal disease. Indeed, in a recent systematic review, Kocher *et al*. (2018) emphasized that the level of hyperglycemia in a continuous scale, rather than specific cut-off definitions of diabetes, are more meaningful in the quantification of the risk conferred by DM for periodontal pathology.

Interestingly, and in line with the above concepts of a continuous level of risk associated with the level of hyperglycemia, the outcome of periodontal treatment in patients with diabetes and good metabolic control is similar to that of non-diabetic periodontitis patients (Westfelt *et al*. 1996; Christgau *et al*. 1998; Faria-Almeida *et al*. 2006; Navarro-Sanchez *et al*. 2007), while patients with poorly controlled DM

display an inferior treatment outcome (Tervonen & Karjalainen 1997; Santos *et al*. 2009; Kaur *et al*. 2015).

The age of onset of DM manifestations in the periodontal tissues has been addressed in studies examining children and adolescents with type 1 DM (de Pommereau, Dargent-Paré *et al*. 1992; Pinson *et al*. 1995) and both type 1 and type 2 DM (Lalla *et al*. 2006). All three studies documented more pronounced gingival inflammation in subjects with diabetes aged between 6 and 18 years. The case-control study by Lalla *et al*. (2006) further reported that clinical attachment loss was more pronounced in young patients with diabetes after adjustment for age, gender, ethnicity, gingival bleeding, and frequency of dental visits. In a subsequent publication, Lalla *et al*. (2007a) reported data on 350 children with either type 1 or type 2 DM and found a strong positive association between mean HbA1c levels over the 2 years preceding the dental examination and periodontitis. In a report including a total of 700 children, 350 with diabetes and 350 non-diabetic controls, Lalla *et al*. (2007b) documented a statistically increased periodontal destruction in children with diabetes across all disease definitions tested and in both age subgroups of 6–11 and 12–18 years.

Several studies suggest a two-way relationship between DM and periodontitis. Beyond the observed increased severity of periodontal tissue destruction in subjects with DM, studies indicate a higher incidence of DM complications and poorer metabolic control of diabetes in periodontitis patients (for review see Lalla & Papapanou 2011). These findings are discussed in more detail in Chapter 11.

Obesity

The biologic plausibility of a potential link between obesity and periodontitis has been suggested to involve an hyperinflammatory state involving adipose-tissue derived cytokines, an aberrant lipid metabolism prevalent, as well as the pathway of insulin resistance (Saito *et al*. 1998; Nishimura & Murayama 2001; Akram *et al*. 2016), all of which may collectively result in an accelerated breakdown of the periodontal tissues. Indeed, a number of studies have indicated a positive association between obesity, defined as body mass index (BMI) ≥30 kg/m^2, and periodontitis. Four publications have documented such an association in the NHANES III database. Wood *et al*. (2003), using a subset including Caucasian subjects aged 18 years and older, reported that BMI, waist-to-hip ratio, visceral fat, and fat-free mass were associated with periodontitis after adjusting for age, gender, history of diabetes, current smoking, and socioeconomic status. Al-Zahrani *et al*. (2003) reported a significant association between both BMI and waist-to-hip ratio and periodontitis in younger adults, but no association in middle-aged or older adults. Genco *et al*. (2005) reported that overweight subjects in the upper quartile of the insulin resistance index were 1.5 times more likely to have periodontitis compared with their counterparts with a high BMI but a low insulin resistance index. Lastly, Andriankaja *et al*. (2010) demonstrated an association between *metabolic syndrome* (i.e. a combination of hypertension, impaired fasting glucose, large waist circumference, and dyslipidemia) and periodontitis in women, and between abdominal obesity and periodontitis in both genders.

In a longitudinal study of 1038 healthy, Caucasian US male veterans, obesity conferred a 41–72% increased risk for progression of periodontitis, after adjustment for several co-variates (Gorman *et al*. 2012).

Corroborating data have been reported also from countries other than the USA. In a sample of 643 apparently healthy Japanese adults, Saito *et al*. (2001) reported that waist-to-hip ratio, BMI, and body fat were significant risk indicators for periodontitis after adjustments for known risk factors. In a longitudinal study from Japan involving a sample of 3590 individuals, the 5-year incidence of periodontitis was statistically higher for both those with a BMI between 25 and 30 kg/m^2 and those with a BMI of ≥30 kg/m^2, when compared with individuals with a BMI of ≤22 kg/m^2 (Morita *et al*. 2011), establishing a dose–response relationship between overweight/obesity and risk for periodontitis. Finally, in a study involving a nationally representative sample of 7188 subjects in Korea, *metabolic syndrome* was associated with periodontitis (Kwon *et al*. 2011). In contrast, an inverse association between obesity and clinical attachment loss was observed in a study involving 1579 men and women in Denmark (Kongstad *et al*. 2009).

The three most recent systematic reviews that compiled the available evidence linking obesity to periodontitis have all demonstrated a positive association between the two conditions. This appears to be the case both in adolescents and young adults (Khan *et al*. 2018) as well as across the age spectrum (Martinez-Herrera *et al*. 2017; Arboleda *et al*. 2019). However, there is inconclusive evidence on the effects of obesity on the outcomes of periodontal therapy, as evidence from longitudinal studies is sparse (Arboleda *et al*. 2019).

Osteopenia/osteoporosis

Several early cross-sectional studies, of limited sample size and largely confined to postmenopausal women, have suggested that women with low bone mineral density are more likely to have gingival recession and/or pronounced gingival inflammation and clinical attachment loss (von Wowern *et al*. 1994; Mohammad *et al*. 1996, 1997; Tezal *et al*. 2000).

In a radiographic study of 1084 subjects aged 60–75 years, Persson *et al*. (2002) reported a positive association between osteoporosis and periodontitis with an OR of 1.8 (95% CI 1.2–2.5). However, studies that have failed to report such an association have also been published (Weyant *et al*. 1999; Lundström *et al*. 2001).

Based on these observations, it has been hypothesized that the systemic loss of bone density in osteoporosis may, in combination with hormone action, heredity, and other host factors, result in an increased susceptibility to inflammation-associated destruction of the periodontal tissues (Wactawski-Wende 2001). Suggested mechanisms underlying the association also include disruption of the homeostasis concerning bone remodeling, hormonal balance, and inflammation resolution (Wang & McCauley 2016).

In a cross-sectional study of 1329 postmenopausal women in the USA, systemic bone density was positively associated with clinical attachment loss in women with subgingival calculus, but negatively associated in women without calculus (Brennan *et al*. 2007). The data from longitudinal studies are apparently conflicting. Payne *et al*. (1999, 2000) reported an enhanced longitudinal alveolar bone loss in osteoporotic women versus women with normal mineral bone density. Yoshihara *et al*. (2004) reported a significant association between bone mineral density and 3-year longitudinal attachment loss in Japanese subjects aged ≥70 years after adjustment for covariates. In contrast, Reinhardt *et al*. (1999) reported no significant impact of serum estradiol levels on longitudinal attachment loss over a 2-year period. Nevertheless, the most recent systematic reviews available concluded that osteoporosis is indeed a risk factor for periodontitis (Wang & McCauley 2016; Goyal *et al*. 2017) but also emphasize that well-controlled longitudinal and interventional studies are necessary to inform evidence-based clinical guidelines.

Human immunodeficiency virus infection

Early studies published in the late 1980s seemed to indicate that both the prevalence and the severity of periodontitis were exceptionally high in patients with acquired immunodeficiency syndrome (AIDS) (Winkler & Murray 1987), but a more tempered picture emerged in subsequent publications. While it cannot be ruled out that the initial reports included biased samples, it is also possible that the successful control of immunosuppression in human immunodeficiency virus (HIV)-positive subjects by means of high activity antiretroviral therapy (HAART) and other continuously evolving pharmacotherapies has influenced the incidence of periodontal disease progression in HIV-seropositive subjects and has resulted in less severe periodontal manifestations of HIV infection (Chapple & Hamburger 2000). For example, a cross-sectional study of 326 HIV-infected adults (McKaig *et al*. 1998) revealed that, after adjustments for CD4 counts, persons taking HIV antiretroviral medication were five times less likely to suffer from periodontitis than those not taking such medication, underscoring the importance of the host's immunologic competency in this context.

Nevertheless, subsequent publications continued to generate conflicting results. Thus, although a number of studies (Smith *et al*. 1995; Robinson *et al*. 1996; Ndiaye *et al*. 1997; McKaig *et al*. 1998; Nittayananta *et al*. 2010; Stojkovic *et al*. 2011; Groenewegen *et al*. 2019) indicated higher prevalence and severity of periodontitis in HIV-positive subjects when compared with controls, other studies are either not supportive of this notion or indicate that the differences in periodontal status between HIV-seropositive and -seronegative subjects are limited (Cross & Smith 1995; Lamster *et al*. 1997; Scheutz *et al*. 1997; Vastardis *et al*. 2003; Ryder *et al*. 2017; Williams-Wiles & Vieira 2019). Studies investigating the pathobiology of periodontitis in HIV-infected subjects suggested that specific IgG subclass responses to periodontopathic bacteria were similar in HIV-positive and HIV-negative subjects (Yeung *et al*. 1993), while CD4 count levels were not found to correlate with the severity of periodontitis (Martinez Canut *et al*. 1996; Vastardis *et al*. 2003).

The few available longitudinal studies are equally conflicting. Two companion publications, from a short-term follow-up study (Cross & Smith 1995; Smith *et al*. 1995) involving a group of 29 HIV-seropositive subjects who were examined at baseline and at 3 months, reported a low prevalence and incidence of clinical attachment loss. The subgingival microbial profiles of the seropositive subjects resembled those of non-systemically affected subjects, and did not correlate with their CD4 and CD8 lymphocyte counts. Similarly, in a small follow-up study of 12 months' duration, Robinson *et al*. (2000) found no difference in the progression of periodontitis between HIV-positive and HIV-negative subjects. Hofer *et al*. (2002) demonstrated that compliant HIV-positive subjects can be successfully maintained in a manner similar to non-infected controls. However, a 20-month follow-up study of 114 homosexual or bisexual men (Barr *et al*. 1992) revealed a clear relationship between incidence of clinical attachment loss and immunosuppression, expressed through CD4 cell counts. The authors suggested that HIV-infection in combination with older age confers an increased risk for attachment loss. Similar observations were reported by Lamster *et al*. (1997), who concluded that periodontitis in the presence of HIV infection is dependent upon the immunologic competency of the host as well as the local inflammatory response to the subgingival microbiota. A large longitudinal investigation conducted between 1995 and 2002 involving 584 HIV-seropositive and 151 HIV-seronegative women, examined every 6 months, demonstrated no differences in baseline clinical attachment loss or in periodontitis progression between the two groups (Alves *et al*. 2006). Lastly, a 24-month follow-up of 73 HIV-positive individuals who received comprehensive care, the observed resolution of periodontitis was deemed similar to that expected in HIV-uninfected periodontitis patients, and was associated

with improved CD4 counts among those who were initially immunosuppressed (Valentine *et al*. 2016).

As emphasized in a very recent comprehensive review of current trends and developments in HIV research as it pertains to periodontal diseases (Ryder *et al*. 2020), the antiretroviral therapies administered over the last 20 years have had a profound impact on the sequelae of HIV infection, and the almost certain mortality historically associated with them has evolved into a chronic condition compatible with an extended lifespan. However, existing disparities in access to state-of-the art care globally (Geter *et al*. 2018; Ottria *et al*. 2018), combined with emerging comorbidities in ageing HIV-positive individuals (Erlandson & Karris, 2019), necessitate keen awareness of the association between HIV-infection and oral pathologies and additional research.

Psychosocial factors

The mechanisms by which psychosocial stress may affect periodontal status are complex. It has been suggested that one of the plausible pathways may involve behavioral changes leading to smoking and poor oral hygiene that, in turn, may affect periodontal health (Genco *et al*. 1998). In the absence of an unequivocal biologic measure of stress, a limited number of studies have used proxy measures of stress to study its association with periodontitis. In a study of 1426 subjects in Erie County, NY, USA, Genco *et al*. (1999) reported that adults who were under financial strain and exhibited poor coping behaviors were at increased risk of severe periodontitis when compared with subjects who demonstrated good coping behavior patterns under similar financial strain, or with controls under no financial strain. In a sample of 1089 adults in rural Japan, job- and health-related stress was positively associated with clinical attachment loss after adjustments for common risk factors (Akhter *et al*. 2005). War-related stress was found to be associated with poor periodontal conditions in Croatia (Spalj *et al*. 2008). Similar observations were made in a study of an immigrant population from Ethiopia, in which psychological distress was positively associated with deep periodontal pockets (Vered *et al*. 2011). In contrast, a study of 681 subjects carried out in Lithuania (Aleksejuniene *et al*. 2002) could not document an association between psychosocial stress and periodontitis, although the disease was found to correlate with lifestyle factors. In a small prospective study, Linden *et al*. (1996) reported that longitudinal attachment loss was significantly predicted by increasing age, lower socioeconomic status, lower job satisfaction, and type A personality, characterized by aggressive, impatient, and irritable behavior.

Clearly, the role of stress in periodontitis has not been fully explored and multiple gaps in our knowledge exist. Nevertheless, given the established role of the sympathetic, parasympathetic, and peptidergic/sensory nervous systems, as well as that of the hypothalamic–pituitary–adrenal axis on brain-to-immune regulatory pathways, such a role is clearly biologically plausible. Experimental animal studies have begun to shed light on basic mechanisms that may explain the link between psychosocial factors and periodontitis. For example, a study by Breivik *et al*. (2006) demonstrated that experimentally induced depression accelerated tissue breakdown in a ligature-induced periodontitis rat model and that pharmacologic treatment of depression attenuated this breakdown. In a study in humans, salivary cortisol levels (indicative of psychological stress) were positively associated with the extent and severity of periodontitis (Hilgert *et al*. 2006). In a case-control study of 56 patients with periodontitis and 44 periodontally healthy controls (Haririan *et al*. 2018), salivary levels of neuropeptides VIP (vasoactive intestinal peptide) and NPY (neuropeptide Y) were associated with bleeding on probing and the extent and severity of periodontitis. Lastly, a meta-analysis collectively analyzing 573 individuals, including 258 participants with chronic and 72 with aggressive periodontitis demonstrated on average a 53% higher level of salivary cortisol in aggressive periodontitis patients than in periodontally healthy controls (Botelho *et al*. 2018) but emphasized that well-designed longitudinal studies are required to fully elucidate the role of psychological factors on periodontitis and account for possible confounders.

Concluding remarks

The analytical epidemiologic studies described in this chapter are obviously diverse with respect to important elements of design and methodology, such as definitions of disease, sample size, use of full-mouth or partial-mouth recording protocols, length of follow-up in longitudinal studies, adjustment for potential confounders, etc. Nevertheless, despite these apparent shortcomings, a number of conclusions can be made with reasonable certainty:

1. Subgingival bacterial dysbiosis, cigarette smoking, and diabetes mellitus are the major established risk factors for periodontitis. The clinical significance of additional emerging, biologically plausible factors needs to be further investigated in future studies.
2. There is a need to introduce uniform definitions of periodontitis to be used in analytical epidemiologic studies. This will facilitate valid comparisons, establish whether seemingly conflicting data reflect true biologic variation or are exclusively owed to methodologic inconsistencies, and contribute to the correct identification of risk factors. Consistent implementation of the standards for reporting periodontitis prevalence and severity in epidemiologic studies introduced by the joint EU/USA periodontal epidemiology working group (Holtfreter *et al*. 2015) may allow for

meaningful comparisons across populations and better insights into the determinants of global variation. Furthermore, adoption of the definitions introduced by the recent World Workshop for the Classification of Periodontal Diseases and Conditions (Papapanou *et al*. 2018; Tonetti *et al*. 2018) can provide a unifying basis and facilitate collection of comparable data across the globe. Obviously, no definition is devoid of shortcomings and the above proposals are no exception.

3. Studies need to distinguish between risk factors and disease markers and predictors. Although the use of the latter as explanatory variables in multivariate models may increase the coefficient of determination (i.e. the proportion of the variance explained by means of the models), it may also obscure the significance of true etiologic factors. For example, as shown by Ismail *et al*. (1990), factors with biologically plausible etiologic potential (such as dental plaque) may not retain their significance in multivariate models that include alternative expressions of disease such as tooth mobility. It has been demonstrated that baseline levels of disease and morphologic features such as angular bony defects are powerful predictors of future disease progression (Papapanou *et al*. 1989; Papapanou & Wennström 1991). Haffajee *et al*. (1991) demonstrated that age, plaque, and bleeding on probing are related to baseline disease levels as well as to incident disease. In the search of true exposures of significance for disease onset or progression, inclusion of a factor in a model may thus erroneously discredit a co-varying, biologically significant other factor. Likewise, factors associated with the initiation of the periodontitis may be different from the ones involved in its progression (Beck *et al*. 1995), and this distinction between them may have implications for assessment strategies and may improve the accuracy of the risk/prediction models.

One of the issues related to the descriptive epidemiology of periodontitis that is still under debate is whether their worldwide prevalence has been decreasing over the past couple of decades. Unfortunately, the data do not allow a clear answer for a number of reasons. First, no universal conclusion is possible, since the prevalence of periodontal disease appears to vary with race and geographic region. Second, the quality of the data available is not consistent across the globe. While several well-conducted, population-representative epidemiologic studies have been carried out in a number of industrialized countries, the majority of studies in the developing world have used the CPITN system, which produced data of inadequate detail. Moreover, studies using the exact same methodology to evaluate representative samples drawn from the same population over time are sparse. Among the few exceptions where such data are available derive from the USA and the National Health and Nutrition Examination Survey. Indeed, data obtained through a partial recording methodology were interpreted to suggest a trend for decreasing prevalence of periodontitis (Dye *et al*. 2007), although more recent data obtained through a full mouth examination protocol do not seem to corroborate this trend (Eke *et al*. 2018). A series of studies from Sweden (Hugoson *et al*. 1992,1998a, 2005, 2008; Wahlin *et al*. 2018) documented, by clinical and radiographic means, the frequency distribution of various levels of severity of periodontitis in five cross-sectional studies over a 40-year period (in 1973, 1983, 1993, 2003, and 2013). In these studies, subjects were grouped according to the severity of their periodontal conditions into five groups: groups 1 and 2 included subjects who were periodontally healthy or only had gingivitis; group 3 included subjects with moderate periodontitis, that is, whose loss of periodontal tissues support did not extend beyond one-third of the root length; and groups 4 and 5 included subjects with more severe destructive disease. As shown in Fig. 6-6 (Wahlin *et al*. 2018) a clear increase in the frequency of subjects in groups 1 and 2 was noted over the observation period, from 43% in 1983 to 60% in 2013. This increase occurred primarily at the expense of group 3, which declined from 41% in 1983 to 33% in 2013. Nevertheless, the frequency of subjects with severe periodontitis did not decrease statistically significantly over time from 16% in 1983, to 11% in 2013. However, tooth retention increased dramatically in the severe periodontitis group from an average of 14 teeth per person in 1983 to 21 teeth in 2013 (Fig. 6-7). Based on these data derived from a population with access to, arguably, one of the best oral health care systems in the world, we may conclude that (1) the fraction of the population which is apparently most susceptible to severe periodontitis remains substantial, although (2) there is a clear benefit from improved oral health awareness, access to care, and increased utilization of therapeutic resources, as expressed by higher tooth retention in all groups.

It has also been well documented in these and other studies that the rate of edentulism has decreased substantially over the past 30 years, with elderly groups retaining their natural dentition and higher mean numbers of teeth than their counterparts a generation ago (Kassebaum *et al*. 2014). This fact *per se* should contribute to an increased prevalence of periodontal disease in older age cohorts, since retained teeth in the elderly are more likely to experience substantial cumulative attachment loss which forms the basis of the assessment of prevalence (Douglass & Fox 1993; Eke*et al*. 2016). Additional research is clearly required to further elucidate these issues, and an adequate and consistent epidemiologic methodology is essential for generating valid comparative data. Arguably, one

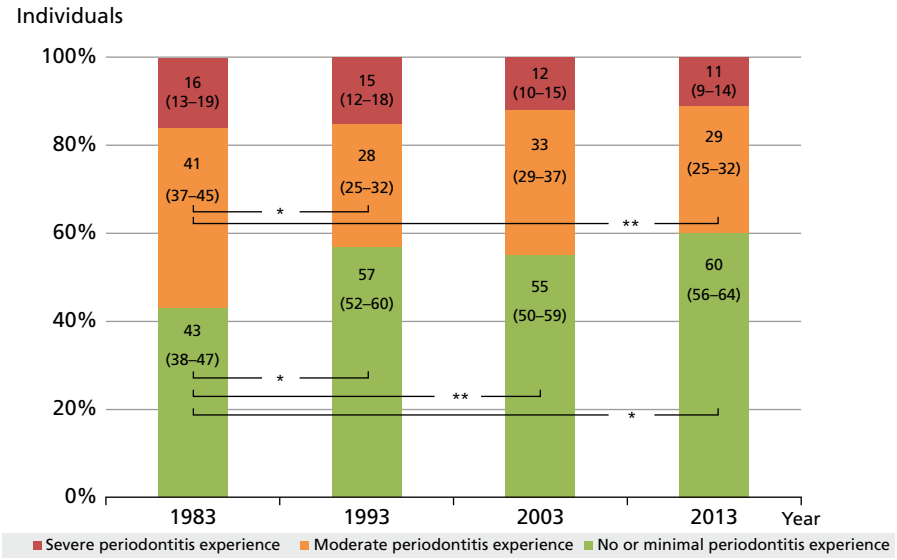

Fig. 6-6 Frequency distribution of subjects with healthy periodontal conditions or gingivitis (no/minimal; groups 1+2), moderate (group 3), and severe periodontitis (groups 4+5), in a Swedish cohort in 1983, 1993, and 2003 and 2013. For definitions, see text. (Source: Wahlin *et al*. 2018, reproduced with permission.)

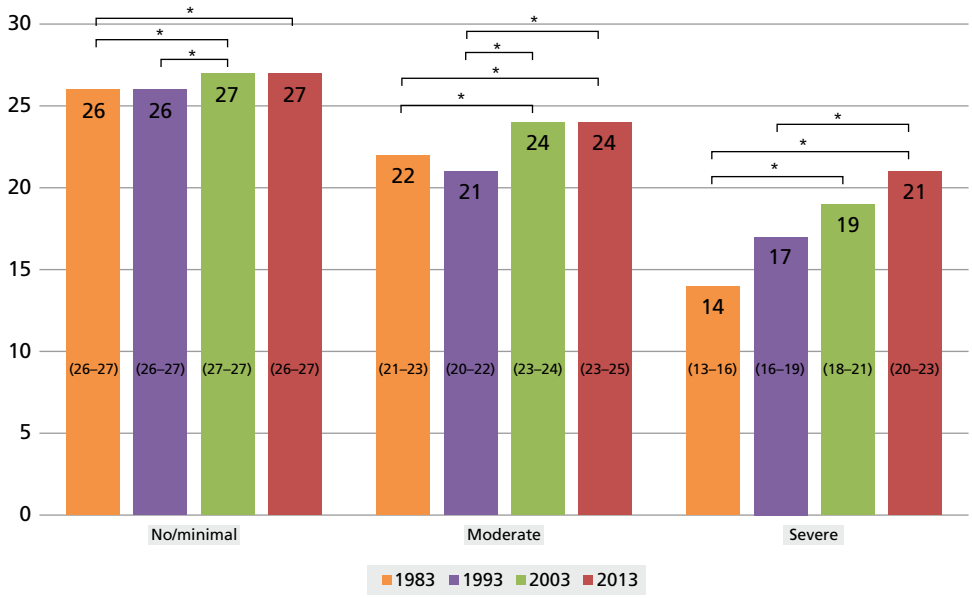

Fig. 6-7 Mean number of teeth present (range in parenthesis) in subjects with healthy periodontal conditions or gingivitis (no/minimal; groups 1+2), moderate (group 3), and severe periodontitis (groups 4+5), in a Swedish cohort in 1983, 1993, and 2003 and 2013. For definitions, see text. (Source: Wahlin *et al*. 2018, reproduced with permission.)

of the important tasks for future epidemiologic research is to identify determinants of susceptibility to severe periodontitis, prior to the development of irreversible tissue damage (Papapanou 2012; Papapanou & Susin 2017). Although several risk factors have been established and a wide array of disease markers has been recognized, the impact of interventions targeting these factors on the state of periodontal health on the population level has yet to be fully appreciated. To assess the magnitude of the clinical benefit achieved by such modulation, prospective, long-term epidemiologic studies must be conducted.

Chapter 7

Epidemiology of Peri-Implant Diseases

Jan Derks, Cristiano Tomasi, and Tord Berglundh

Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

Epidemiology includes evaluation of the prevalence and risk factors of diseases in populations at risk. Epidemiological findings may generate hypotheses regarding etiology and pathogenesis. Ultimately, understanding the dynamics of diseases can assist in creating prophylactic and therapeutic strategies, and influence the allocation of resources in medical care and directions in education.

Because an implant device is involved, epidemiology of peri-implant diseases differs from epidemiology of, for example, periodontal diseases (see Chapter 6); outcomes may be considered as complications of an intervention rather than occurrence of a natural disease. This puts a specific focus on the target population, which, in this context are subjects provided with implant-supported restorative therapy. While epidemiological data on periodontal diseases have a broad applicability, the validity of similar data on peri-implant diseases may be less obvious, because, from a global perspective, populations at risk do not necessarily share the same characteristics. One important aspect is the variation in levels of implant therapy in different countries. Registry data from Sweden suggest that about 8% of subjects aged ≥70 years currently have at least one dental implant (SKaPa 2018). Given the widespread use of dental implants in many parts of the world, an epidemiological approach towards peri-implant diseases is justified.

Disease definition

Peri-implant diseases include two entities: peri-implant mucositis and peri-implantitis, and their typical characteristics were summarized at the 2017 World Workshop on Classification of Periodontal and Peri-implant Diseases and Conditions (Berglundh *et al*. 2018a). Thus, peri-implant mucositis constitutes an inflammatory lesion in the peri-implant mucosa surrounding an endosseous implant without loss of supporting peri-implant bone. Further, peri-implantitis is a pathological condition occurring in tissues around dental implants, characterized by inflammation in the peri-implant mucosa and progressive loss of supporting bone. Marginal bone loss is a distinctive feature of peri-implantitis.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Case definition

A disease definition provides descriptive information on the characteristics of a condition, and detailed information on etiology and pathogenesis of peri-implant mucositis and peri-implantitis is presented in Chapter 20. Case definitions, on the other hand, offer specific points of measurement, which are prerequisites for the diagnosis of a disease and studies of its prevalence, incidence, and risk factors. In addition to case definitions, guidelines for the description of severity of the disease are also important. To facilitate interpretation and comparison of data, researchers should adhere to accepted case definitions, which should ideally be clinically relevant and evidence based.

Tomasi and Derks (2012) reviewed the methodology of clinical research on the incidence, prevalence, and risk factors of peri-implant diseases. The authors found a significant heterogeneity between relevant studies in terms of case definitions. Thus, six publications on peri-implant mucositis presented six different case definitions, which varied in terms of thresholds of probing pocket depth and the detection of "absence of bone loss" in radiographs. Case definitions for peri-implantitis were reported in 12 studies. While the clinical criteria for soft tissue inflammation were largely consistent, the thresholds for the assessment of bone loss in radiographs varied extensively. In all, seven different levels of bone loss were used, and the thresholds ranged from 0.4 mm to 5 mm. It is obvious that the inconsistency in terms of case definitions contributed to the variation in prevalence of peri-implant diseases observed in the current literature (Derks & Tomasi 2015).

In a consensus report from the 2017 World Workshop on Classification of Periodontal and Peri-implant Diseases and Conditions, case definitions were proposed for peri-implant health, peri-implant mucositis, and peri-implantitis. These were adapted for use in day-to-day clinical practice and in epidemiological studies (Berglundh *et al*. 2018a). The most important clinical tool to distinguish between peri-implant health and disease is bleeding/suppuration on probing (BoP), while the distinction between peri-implant mucositis and peri-implantitis is made by assessment of bone loss in radiographs. The consensus report emphasized that bone loss in this context should exceed possible crestal bone level changes resulting from initial bone remodeling after implant placement. A summary of the case definitions for peri-implant health, peri-implant mucositis, and peri-implantitis established at the 2017 World Workshop is presented in Table 7-1.

Peri-implant health

Clinical and histological features of the healthy peri-implant mucosa were reviewed by Araujo and Lindhe (2018) and details are also described in Chapter 4. Distinctive for peri-implant health is the absence of BoP and visual signs of inflammation, such as swelling and redness. As peri-implant mucosal dimensions may vary between, for example, posterior and anterior locations, it is not possible to define a range of probing depths compatible with health. The consensus report (Berglundh *et al*. 2018a) also underlined that peri-implant health can exist around implants with reduced bone support, as peri-implant health can be achieved at sites successfully treated for peri-implantitis. In addition, implant placement in sites presenting with ridge deficiencies may also result in a "reduced" bone level located apical of the implant margin.

Table 7-1 Case definitions of peri-implant diseases suggested by the 2017 World Workshop on Classification of Periodontal and Peri-implant diseases and Conditions (Source: Data from Berglundh *et al*. 2018a.)

	Peri-implant health	Peri-implant mucositis	Peri-implantitis	
Visual signs of inflammation (e.g. swelling and redness)	No	Yes	Yes	
Bleeding/suppuration on probing	No	Yes	Yes	
Increase in probing pocket depth	No	Possible	Yes (≥6 mm if no previous reference)	
Progressive bone loss (beyond initial bone remodeling)	No	No	**Epidemiological studies**	**Day-to-day clinical practice**
			Yes	Yes
			Baseline documentation available Bone loss exceeding measurement error	*Baseline documentation available* Bone loss (no threshold)
			Baseline documentation not available Bone level ≥3 mm	*Baseline documentation not available* Bone level ≥3 mm

In summary, the case definition of peri-implant health to be used in day-to-day clinical practice and epidemiological studies presented in the consensus report (Berglundh *et al*. 2018a) includes: (1) absence of visual signs of inflammation and bleeding/suppuration on gentle probing; (2) no increase in probing depth compared to previous examinations; and (3) no bone loss (Table 7-1).

Peri-implant mucositis

Clinical and histopathological characteristics, and risk indicators of peri-implant mucositis, were described in a review by Heitz-Mayfield and Salvi (2018). The presence of an inflammatory lesion in the peri-implant mucosa and the absence of loss of supporting bone are the two fundamental features of peri-implant mucositis. The lesion occupies a connective tissue zone lateral, but not apical, of the pocket epithelium (for details see Chapter 20). The main clinical characteristic of peri-implant mucositis is BoP, while visual signs of inflammation, such as swelling and redness, may also occur. Similar to gingivitis around teeth, peri-implant mucositis often presents with an increase in probing pocket depth as a result from swelling or decrease in probing resistance. The consensus report stated that there is strong evidence that plaque is the etiological factor for peri-implant mucositis and that the lesion can resolve after reinstitution of plaque control procedures.

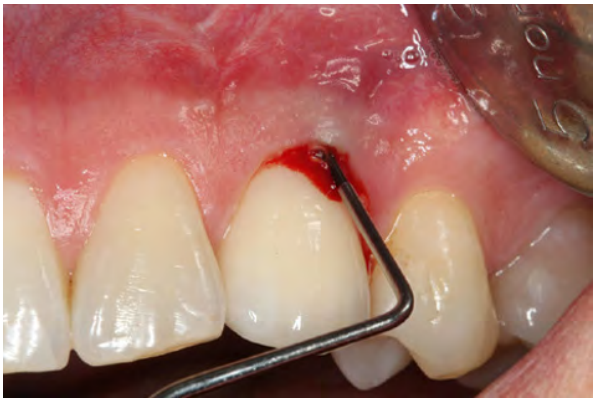
In summary, the case definition of peri-implant mucositis to be used in day-to-day clinical practice and epidemiological studies presented in the consensus report (Berglundh *et al*. 2018a) includes (1) bleeding and/or suppuration on gentle probing and (2) no bone loss (Table 7-1).

Peri-implantitis

Schwarz *et al*. (2018) reviewed the clinical and histopathological characteristics and risk indicators of peri-implantitis. The two main features of peri-implantitis are inflammation in the peri-implant mucosa and loss of supporting bone. Peri-implantitis lesions extend apical of the pocket epithelium into the supracrestal connective tissue (for details see Chapter 20) and are larger than those at peri-implant mucositis and periodontitis sites. Clinical signs of inflammation including BoP, increased probing pocket depths, and/or recession of the mucosal margin are key findings together with radiographic bone loss (Fig. 7-1).

In summary, the case definition of peri-implantitis to be used in day-to-day clinical practice and epidemiological studies presented in the consensus report (Berglundh *et al*. 2018a) includes (1) bleeding and/or suppuration on gentle probing and (2) increased probing pocket depth compared to previous examinations and (3) bone loss. The case definition of peri-implantitis when previous examination data or radiographs are lacking includes (1) bleeding and/or suppuration on gentle probing, (2) probing pocket depths of ≥6 mm and (3) bone levels ≥3 mm apical of the most coronal portion of the intra-osseous part of the implant.

(a)



(b)

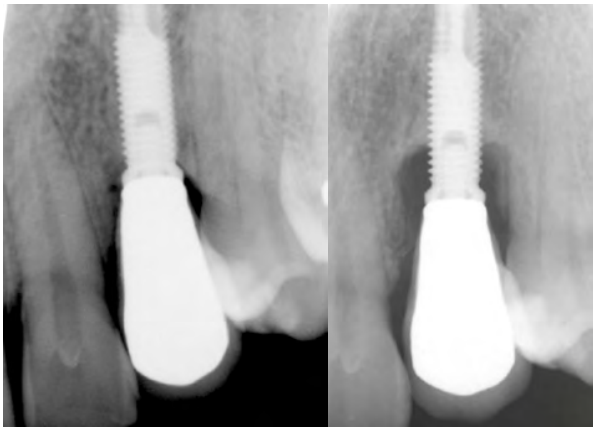


Fig. 7-1 **(a)** Bleeding on probing at an implant installed 11 years earlier. (b) The 11-year follow-up radiograph indicates bone loss relative to baseline, confirming the diagnosis of peri-implantitis.

Examination methods

The case definitions of peri-implant health and diseases highlight the importance of baseline or reference assessments to allow for evaluations of changes in probing pocket depths and marginal bone levels over time. An increase of probing pocket depth may serve as an indicator of disease progression. The clinical assessment of soft tissue inflammation in sites with peri-implant disease relies on visual signs of inflammation and the presence of bleeding/suppuration on probing (Heitz-Mayfield & Salvi 2018). As studies on periodontal disease have shown the consistency between BoP and a histologically detected inflammatory lesion in gingival tissues, there are reasons to suggest a similar association for assessments of peri-implant diseases. This assumption is justified by findings from experimental studies on gingivitis and peri-implant

mucositis demonstrating a similar pattern of the development of an inflammatory lesion following periods of plaque accumulation (Berglundh *et al*. 1992; Ericsson *et al*. 1992; Leonhardt *et al*. 1992) and data from clinical studies showing that plaque accumulation was directly related to the rate of BoP (Pontoriero *et al*. 1994; Salvi *et al*. 2012). In the study on experimental peri-implant mucositis by Salvi *et al*. (2012) the plaque formation phase was followed by an additional period of infection control and the findings on reduction in BoP towards the end of the study underlined the reversibility of the condition.

The importance of BoP in regard to assessment of peri-implant disease was addressed in clinical studies. In an evaluation including 112 implant-carrying patients, Farina *et al*. (2017) showed that the probability of BoP at implant sites was similar to that of corresponding tooth sites. It is important to note that the authors adjusted the comparisons for probing pocket depth. In two longitudinal studies, the predictive value of BoP at implants was evaluated (Carcuac *et al*. 2017; Karlsson *et al*. 2019). Results indicated that, while BoP was a poor predictor for future bone loss, the absence of BoP was a strong predictor for the preservation of marginal bone levels. These observations are in line with data evaluating the value of BoP at teeth and underline its clinical relevance.

The recommendation in the consensus report from the 2017 World Workshop (Berglundh *et al*. 2018a) to obtain baseline or reference measurements is critical for assessments of bone level changes in radiographs during follow-up. Thus, a radiographic evaluation following the completion of the implant-supported prosthesis is indicated. An additional radiograph obtained after an initial (one-year) function period may then serve as an ideal baseline as physiological remodeling will be completed.

In cases where previous examination data or radiographs are lacking, the diagnosis of peri-implantitis is based on the combination of the clinical findings of BoP and a probing pocket depth ≥6 mm together with the assessment of a bone level located ≥3 mm apical of the most coronal portion of the intraosseous part of the implant. This case definition is important for diagnosis in day-to-day clinical practice, as patients may present for the first time and previous records are not available. Epidemiological research on peri-implant diseases, however, should ideally be designed to include data from previous examinations performed after the first year in function of the implant. Another concern regarding epidemiological research on peri-implant diseases is the importance of a valid and relevant threshold for bone loss. Thus, the measurement error of the assessment of bone levels around implants within each study should be considered. Previous studies have reported on mean values of measurement errors of 0.5 mm and below.

Prevalence of peri-implant diseases

The occurrence of peri-implant diseases has predominantly been evaluated in studies using a cross-sectional design. Such analyses provide information on the prevalence of the condition. Thus, little is known about the incidence of the disease, that is, the number of new cases occurring during a given time period. Selected studies on the prevalence of peri-implant mucositis and peri-implantitis are summarized in Table 7-2. Data originating from different countries and patient cohorts are largely in agreement, when taking the specific case definitions or thresholds of measurements into consideration. In general, peri-implant mucositis was found consistently to be more frequent than peri-implantitis. In a meta-analysis, Derks and Tomasi (2015) found a weighted mean prevalence of 43% and 22% for peri-implant mucositis and peri-implantitis, respectively. The confidence intervals of the estimates, however, were large, mostly due to the heterogeneity of case definitions used in the included studies. The majority of reports relied on convenience samples, that is, groups of patients attending a single clinical center, commonly in a university/hospital setting. In the two studies that adopted an epidemiological approach and enrolled random population samples, the reported prevalence of peri-implantitis was 15% (Derks *et al*. 2016) and 34% (Kordbacheh *et al*. 2019), respectively.

In contrast to epidemiological studies on periodontitis, where age of the patient is directly related to the time of exposure (time at risk), the time at risk in studies on peri-implant diseases is determined by the time point of implant installation. Function times for implants vary considerably within and between study samples and need to be considered when evaluating prevalence data. Table 7-2 illustrates the variation in time of function of implants between the studies. As the occurrence of peri-implant diseases accumulates with time, it is reasonable to expect studies with longer follow-up periods to report on higher proportions of disease (Derks & Tomasi 2015).

Extent and severity of peri-implantitis

To describe the burden of a disease, the severity and extent of the condition should be considered in addition to its prevalence. For peri-implant diseases, the interpretation of these characteristics is challenging. Severity of periodontitis at teeth is assessed by the amount of clinical attachment loss or radiographic bone loss relative to the length of the root and the age of the patient (Papapanou *et al*. 2018). A corresponding approach at implants is less feasible as implant length may vary considerably. Different cut-off points in radiographic bone loss expressed in millimeters have therefore been proposed. Thus, Derks *et al*. (2016) used different thresholds of bone loss ranging from 0.5 mm to 4 mm within the same study sample to describe severity of peri-implantitis. While 45% of

Table 7-2 Selection of studies on the prevalence of peri-implant diseases and their respective case definitions.

Study	Function time	Sample	Case definitions	Prevalence of peri-implant diseases (patient level)

Wada *et al*. (2019), Japan	≥3 years mean: 5.8 years	Convenience sample 543 subjects	*Mucositis* BoP and absence of bone loss *Peri-implantitis* BoP/SUP and bone loss >1 mm from year 1 after loading	*Mucositis* 24% *Peri-implantitis* 16%

BoP, bleeding on probing; PD, probing pocket depth; SUP, suppuration.

all subjects presented with an overall occurrence of peri-implantitis (≥1 implant with BoP and bone loss >0.5 mm) after 9 years, a smaller group of 15% demonstrated moderate/severe forms (≥1 implant with BoP and bone loss >2 mm) of the disease. The corresponding proportions using similar case definitions reported by Koldsland *et al*. (2010) were 47% and 20%.

The evaluation of the extent of peri-implant diseases is hampered by a pronounced variation in the number of implants within single patients. While the average number of implants per individual in the cross-sectional analysis by Derks *et al*. (2016) was 4.0, a range of one to 12 implants was observed. These numbers should be viewed in regard to the average number of >20 teeth per patient that is commonly reported in surveys on periodontal disease. In two separate reports, an extent of peri-implantitis of 40% was observed (Mir-Mari *et al*. 2012; Derks *et al*. 2016). It should be noted, however, that patients with single implants were excluded from these analyses.

Peri-implantitis and implant loss

Untreated peri-implantitis may lead to implant loss with obvious consequences in terms of discomfort, loss of function, and cost. Implant loss has been evaluated as the primary outcome measure in the majority of studies on implant therapy (Needleman *et al*. 2012). While early implant loss may be related to the failure to achieve osseointegration, late implant loss constitutes a failure to maintain integration and may therefore be a consequence of progressive bone loss. Karlsson *et al*. (2020) observed that 42% of patients diagnosed with moderate/severe peri-implantitis after 9 years of function also had experienced implant loss. This clustering suggests that peri-implantitis represents a major cause of implant loss. This assumption is further supported by data from other evaluations, in which either all implant loss (Rosenberg *et al*. 2004; Roccuzzo *et al*. 2010, 2014; Dvorak *et al*. 2011; Malò *et al*. 2014) or the majority of implant loss (Romeo *et al*. 2004; Daubert *et al*. 2015; Jemt *et al*. 2017) was attributed to peri-implantitis. Longitudinal data on patients with peri-implantitis also indicate that progression of the disease leads to implant loss. Thus, Karlsson *et al*. (2019) in a 3.3-year follow-up study on patients previously diagnosed with moderate/severe peri-implantitis reported that 12 out of initially 133 implants in nine patients (out of 70) were lost during the observation time, all due to progression of the disease. These observations underline the importance of early diagnosis, prevention, and treatment of peri-implant diseases.

Etiology of peri-implant diseases

The term etiology implies a causal association between an exposure and an outcome. Hence, the etiological factor needs to be present and precede the occurrence of the event of interest. A risk factor, on the other hand, modifies the probability of the occurrence of the outcome but is not an absolute prerequisite. Criteria for scientific evidence supporting causation have been suggested and critically discussed (Hill 1965; Rothman & Greenland 2005). Causal associations have to be confirmed in prospective and interventional studies.

In analogy with periodontal diseases, bacterial plaque has been identified as the etiological factor of peri-implant diseases. In the consensus report from the 2017 World Workshop on Classification of Periodontal and Peri-implant Diseases and Conditions, it was stated that strong evidence is available identifying plaque as the etiological factor for peri-implant mucositis (Berglundh *et al*. 2018a). Data from human studies support the cause-and-effect relationship between plaque and the development of the disease. Thus, in a series of studies emulating the experimental gingivitis model (Löe *et al*. 1965), accumulation of plaque at implants in humans was allowed to occur over 21 days (Pontoriero *et al*. 1994; Zitzmann *et al*. 2001; Salvi *et al*. 2012; Meyer *et al*. 2017). During this period, peri-implant sites consistently developed visual and other clinical signs of peri-implant mucositis, that is, swelling, redness, and BoP (Heitz-Mayfield & Salvi 2018). Further, the inflammatory condition could be reversed or reduced after reinstating plaque control measures over an additional 3-week period (Salvi *et al*. 2012; Meyer *et al*. 2017).

Because peri-implant mucositis is the precursor of peri-implantitis (Jepsen *et al*. 2015), it is reasonable to evaluate the evidence supporting plaque as the cause of peri-implantitis. Experimental studies in humans evaluating plaque as the etiological factor for peri-implantitis are, for ethical reasons, not feasible. Preclinical models, however, have shown that the disruption of the supracrestal soft tissue barrier by means of a ligature together with plaque formation results in (1) downgrowth of the bacterial biofilm, (2) soft tissue inflammation, and (3) loss of marginal bone support (Zitzmann *et al*. 2004; Albouy *et al*. 2008; Carcuac *et al*. 2020) (for details, see Chapter 20). Epidemiological evidence on etiological factors for peri-implantitis may be obtained from retrospective evaluations. Thus, Schwarz *et al*. (2018) analyzed data from observational studies and found that patients exhibiting poor plaque control and not attending regular maintenance therapy were at higher risk of developing peri-implantitis (see Table 7-4 for more details). Further evidence on plaque as the etiological factor stems from studies evaluating long-term outcomes of therapy of peri-implantitis. Thus, using treatment strategies targeted at removal of bacterial deposits on implant surfaces and patient-performed plaque control, levels of soft tissue inflammation, and continued marginal bone loss were suppressed (Carcuac *et al*. 2017; Roccuzzo *et al*. 2017; Schwarz *et al*. 2017b; Berglundh *et al*. 2018b).

Risk factors for peri-implant diseases

The use of the terms "risk factor" or "risk indicator" depends on data quality and study design. For simplicity, the term "risk factor" will be used in this chapter. Risk factors for peri-implantitis can be grouped according to the patient or the implant. While potential etiological factors are ideally studied in prospective and longitudinal research, risk factors may be evaluated through a variety of study designs, such as cross-sectional analyses or retrospective cohort studies.

Peri-implant mucositis

Selected studies on potential risk factors for peri-implant mucositis are presented in Table 7-3. In general, the available evidence on risk factors in this context is limited. In line with the description on the etiological factor, analysis of data from cross-sectional studies consistently revealed associations between poor plaque control and lack of compliance to supportive therapy and the condition peri-implant mucositis. As an example, Wada *et al*. (2019) reported on a significantly elevated risk for patients with plaque scores >20% to present with an implant with peri-implant mucositis. The design of the implant-supported supraconstruction was also found to be a factor consistently associated with peri-implant mucositis, as illustrated in the interventional study by de Tapia *et al*. (2019). The authors evaluated the effect of treatment of mucositis and observed a greater improvement at sites, at which supraconstructions had been adjusted in order to facilitate access for oral hygiene. The ability of patients to perform plaque control measures has been demonstrated to be associated with the dimensions of the keratinized mucosa. Thus, Souza *et al*. (2016) reported that in patients with a reduced dimension of keratinized mucosa (<2 mm) plaque scores were higher and patients reported more frequently on pain during brushing. The evidence on the potential association between the width of keratinized mucosa and peri-implant mucositis, however, is conflicting. This fact may be explained by the variation in terms of patient groups, perception of discomfort, and case definitions.

Table 7-3 Selection of studies on potential risk factors for peri-implant mucositis.

Independent variable	Studies	Comment
Poor plaque control/lack of compliance to supportive therapy	Ferreira *et al*. (2006) Roos-Jansåker *et al*. (2006) Konstantinidis *et al*. (2015) Wada *et al*. (2019)	Consistent evidence of association
Design/extent of the implant-supported prostheses	Heitz-Mayfield *et al*. (2011) Konstantinidis *et al*. (2015) Tapia *et al*. (2019) Wada *et al*. (2019)	Consistent evidence of association
Dimensions of keratinized peri-implant mucosa	Adibrad *et al*. (2009) Bouri *et al*. (2008) Boynueğri *et al*. (2013) Crespi *et al*. (2010) Frisch *et al*. (2013) Konstantinidis *et al*. (2015) Lim *et al*. (2019) Roos-Jansåker *et al*. (2006) Schrott *et al*. (2009) Wada *et al*. (2019) Zigdon & Machtei (2008)	Inconsistent evidence of association
Smoking	Karbach *et al*. (2009) Konstantinidis *et al*. (2015) Rinke *et al*. (2011) Roos-Jansåker *et al*. (2006) Wada *et al*. (2019)	Inconsistent evidence of weak association
Systemic diseases	Ferreira *et al*. (2006) Karbach *et al*. (2009) Konstantinidis *et al*. (2015) Roos-Jansåker *et al*. (2006) Wada *et al*. (2019)	Inconsistent evidence of weak association

Peri-implantitis: risk factors related to the patient

Selected studies on potential risk factors for peri-implantitis related to the patient are presented in Table 7-4. Information on risk factors on peri-implantitis is more extensive when compared with peri-implant mucositis. There is convincing evidence that subjects who are susceptible to periodontitis, as assessed by current or history of periodontitis, are at high risk for peri-implantitis. This is illustrated by findings from two cross-sectional studies originating from Scandinavia. Thus, in a study on 109 patients with a mean follow-up period of 8.4 years, Koldsland *et al*. (2010, 2011) noted an elevated risk for peri-implantitis in periodontitis-susceptible subjects (odds ratio 6). Likewise, Derks *et al*. (2016) examined 596 individuals after a similar follow-up period and reported on the same strength of association between periodontitis and peri-implantitis.

In line with findings related to peri-implant mucositis, poor plaque control and lack of compliance to supportive therapy were also consistently identified as risk factors for peri-implantitis. In a 5-year follow-up evaluation on patients initially diagnosed with mucositis, Costa *et al*. (2012) found

Table 7-4 Selection of studies on potential risk factors for peri-implantitis related to the patient.

Independent variable	Studies	Comment
History/presence of periodontitis	Canullo *et al*. (2016) Casado *et al*. (2013) Costa *et al*. (2012) Dalago *et al*. (2017) Daubert *et al*. (2015) de Araújo Nobre *et al*. (2015) Derks *et al*. (2017)	There is evidence that poor plaque control and lack of regular maintenance therapy constitute risk factors for peri-implantitis (Schwarz *et al*., 2018)
Age	Aguirre-Zorzano *et al*. (2015) Daubert *et al*. (2015) Derks *et al*. (2016) Ferreira *et al*. (2006) Marrone *et al*. (2013) Renvert *et al*. (2014) Roos-Jansåker *et al*. (2006)	Inconsistent evidence of weak association

Table 7-4 (*Continued*)

Independent variable	Studies	Comment
Gender	Casado *et al*. (2013) Derks *et al*. (2016) Ferreira *et al*. (2006) Koldsland *et al*. (2011) Konstantinidis *et al*. (2015) Kordbacheh Changi *et al*. (2019) Renvert *et al*. (2014) Rodrigo *et al*. (2018) Roos-Jansåker *et al*. (2006)	Inconsistent evidence of weak association
Systemic diseases	Casado *et al*. (2013) Canullo *et al*. (2016) Dalago *et al*. (2017) Daubert *et al*. (2015) de Araújo Nobre *et al*. (2015) Derks *et al*. (2016) Dvorak *et al*. (2011) Ferreira *et al*. (2006) Koldsland *et al*. (2011) Konstantinidis *et al*. (2015) Marrone *et al*. (2013) Renvert *et al*. (2014) Rodrigo *et al*. (2018) Rokn *et al*. (2017) Roos-Jansåker *et al*. (2006) Wada *et al*. (2019)	Available evidence is inconclusive as to whether diabetes is a risk factor for peri-implantitis. Evidence suggesting systemic conditions (other than diabetes) to be risk factors for peri-implantitis is limited (Schwarz *et al*., 2018)
Smoking	Aguirre-Zorzano *et al*. (2015) Canullo *et al*. (2016) Casado *et al*. (2013) Daubert *et al*. (2015) Dalago *et al*. (2017) de Araújo Nobre *et al*. (2015) Derks *et al*. (2016) Dvorak *et al*. (2011) Koldsland *et al*. (2011) Konstantinidis *et al*. (2015) Marrone *et al*. (2013) Renvert *et al*. (2014) Rinke *et al*. (2011) Rokn *et al*. (2017) Roos-Jansåker *et al*. (2006) Schwarz *et al*. (2017) Wada *et al*. (2019)	There is no conclusive evidence that smoking constitutes a risk factor for peri-implantitis (Schwarz *et al*., 2018)

that supportive therapy had a significant impact in preventing the progression of mucositis into peri-implantitis. Thus, while 18% of patients with regular maintenance care developed peri-implantitis, the corresponding proportion among subjects without regular supportive care was more than twice as high.

While associations between periodontitis and systemic disorders have been identified (see Chapter 6), similar links between peri-implantitis and systemic conditions have not been demonstrated. This lack of association also applies to cigarette smoking. In this context, however, it should be noted that smoking as an independent factor may not easily be identified in a statistical analysis due to the strong effect of other parameters such as periodontitis (Derks *et al*. 2016; Dalago *et al*. 2017).

Peri-implantitis: risk factors related to the implant

The only implant-related factor that has been consistently associated with the risk for peri-implantitis is the design and extent of the prosthetic reconstruction (Table 7-5). This observation is in line with findings previously discussed for peri-implant mucositis. As an example, Serino and Ström (2009) evaluated the accessibility of implant-supported restorations for oral hygiene measures in patients diagnosed with peri-implantitis. The authors noted that only few sites with access for oral hygiene were affected (18%), while 65% of the non-cleansable sites showed peri-implantitis. In addition, Rodrigo *et al*. (2018) observed an elevated risk for peri-implantitis at

Table 7-5 Selection of studies on potential risk factors for peri-implantitis related to the treatment, site, or implant.

Augmentation	Canullo *et al*. (2016) Daubert *et al*. (2015) Derks *et al*. (2016) Dvorak *et al*. (2011) Konstantinidis *et al*. (2015) Rokn *et al*. (2017) Wada *et al*. (2019)	No evidence of association

implants that were not accessible for cleaning (odds ratio 4.9). In addition to the design, the extent of therapy, expressed by the number of implants, has been implicated as a risk factor. Individual studies have shown an association between the risk for peri-implantitis and other factors such as type of retention (screw-retained or cemented) of the prosthetic reconstruction or the dimension of the keratinized mucosa. A comprehensive analysis of the literature, however, failed to identify a consistency in these relationships (Schwarz *et al*. 2018), as the results from a number of reports are in conflict. The reasons for this discrepancy are unclear.

Concluding remarks

Epidemiology in the field of peri-implant diseases is an emerging area of research with obvious shortcomings and limitations. Nevertheless, some conclusions can be made based on the available data:

- Sound and commonly accepted case definitions of peri-implant diseases are essential for diagnosis in day-to-day clinical practice and to support a reliable epidemiological evaluation.
- The 2017 World Workshop on Classification of Periodontal and Peri-implant Diseases and

Conditions suggested clear case definitions for peri-implant health, peri-implant mucositis, and peri-implantitis that may be applied in epidemiological research as well as in day-to-day clinical practice.

- Peri-implant probing assessments and subsequent radiographic examinations are essential tools for diagnosis.
- Peri-implant mucositis and peri-implantitis are common conditions in patients provided with dental implants.
- There is evidence to support bacterial plaque as the etiological factor of peri-implant diseases.
- Peri-implantitis is preceded by peri-implant mucositis, which highlights the importance of preventive measures aiming at resolution of soft tissue inflammation.
- The main risk factors for peri-implant mucositis are poor plaque control and lack of compliance to supportive therapy as well as the design of the implant-supported prostheses.
- The main risk factors for peri-implantitis are history of periodontitis, poor plaque control, and lack of compliance to supportive therapy as well as the design and extent of the implant-supported prostheses.

Introduction

Dental biofilms develop on the hard surfaces of the mouth, such as teeth, dentures, and implants. These dental biofilms form part of the oral microbiome, which in turn is part of the human microbiome. Contemporary studies show that the human microbiome plays an essential role in the health and well-being of their host. Humans have evolved to have an intimate and largely beneficial relationship with these microorganisms; however, this relationship is dynamic and fragile, and a number of intrinsic and extrinsic factors can damage this exquisite balance, and such events can lead to disease.

The human microbiome

The human body is estimated to be composed of approximately 10^{14} cells, of which only half are mammalian (Sender *et al*. 2016). The other 50% are the microorganisms that form the human microbiome, which has been defined as the microbes and their collective genomes that are living in or on our body (Cho & Blaser 2012). The human microbiome plays a fundamental role in the normal development of the body and confers significant benefits to the host. For example, the human microbiome contributes to the differentiation and maturation of the host mucosa and its immune system, to the breakdown of dietary components and the generation of energy, and to the exclusion of exogenous microbes, many of which could be pathogenic (Cho & Blaser 2012; Kilian *et al*. 2016). In general, this relationship is mutually beneficial (i.e. *symbiotic*) in that the microorganisms gain a warm and nutritious environment in which to grow while delivering the benefits described above to the host. On occasions, the balance of the microbiome at a site can be disrupted which can result in this synergistic relationship breaking down, and disease can be a consequence (a process termed *dysbiosis*).

The composition of the microbiome varies at distinct surfaces on the body (e.g. the skin, mouth, digestive and reproductive tracts) despite the frequent

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

transfer of organisms between these sites; their characteristic composition reflects the significant differences in the biological and physical properties of each habitat (Wilson 2005). These properties determine which microorganisms are able to colonize successfully, and which will predominate or be only a minor component of the established microbiome. These resident microorganisms function as an interactive *microbial community* resulting in the properties of the microbiome being greater than the sum of those of the constituent species (see later). The largest and most diverse microbiomes in the human body are found in the gut, followed by the mouth. Features of the oral microbiome will now be described.

The oral microbiome

The mouth is similar to other habitats within the body in having a characteristic microbial community that provides benefits for the host. The mouth is warm and moist, and is able to support the growth of a wide range of microorganisms, including viruses, mycoplasma, bacteria, *Archaea*, fungi, and protozoa, but in which bacteria are the most numerous (Dewhirst *et al*. 2010; Marsh *et al*. 2016b). These microorganisms colonize mucosal and dental surfaces in the mouth to form three-dimensional, structurally organized multispecies communities that are termed *biofilms* (Marsh *et al*. 2011). The biofilms that form on teeth are referred to as dental plaque; dental plaque that becomes calcified is termed *calculus* (see later). The cultivable portion of the microbiome is also referred to as the *oral microbiota*. In general, desquamation ensures that the microbial load on mucosal surfaces is kept relatively low. In contrast, the mouth is a unique site in the body in that it provides non-shedding surfaces (teeth, dentures, implants) for microbial colonization. This can result in the accumulation of large numbers of microorganisms, particularly at stagnant and hard-to-clean sites, unless patients practice effective oral hygiene. Over 770 different types of microorganism (taxa or phylotypes) have been detected in samples from the mouth; of these, 57% are officially named, 13% unnamed but cultivable, and 30% are known only as currently "uncultivable" phylotypes. A single individual may harbour between 100 and 300 species. It is beyond the scope of this chapter to describe the properties of members of the resident oral microbiome, and the reader is recommended to refer to specialist texts for more detail (for example, Marsh *et al*. 2016b) or to the two curated oral 16S rRNA databases: the Human Oral Microbiome Database (HOMD; http://www.homd.org) or the Core Oral Microbiome Database (CORE; http://microbiome.osu.edu).

An appreciation of the relationship between the host and oral microbiome is critical to understand the factors that can lead to dental diseases, and for the effective clinical management of dental patients.

The mouth as a microbial habitat

The mouth supports the growth of a diverse oral microbiome; however, the composition and metabolic activity of the biofilm found on distinct surfaces in the mouth varies substantially due to differences in the biological and physical properties of each site (Fig. 8-1a). The primary source of nutrients for the oral microbiome is provided by the host, and include the proteins and glycoproteins present in saliva and gingival crevicular fluid (GCF). The metabolism of these complex host molecules requires the concerted action of consortia of bacteria (see later), in which their metabolic capabilities are combined in order to achieve complete breakdown (Marsh & Zaura 2017; Miller *et al*. 2019). The mouth is maintained at a temperature of around 35–37 °C, which is suitable for the growth of a broad range of microbes, though temperature does increase at subgingival sites during inflammation, which can favor the growth and metabolism of some putative periodontal pathogens. Although the mouth is overtly aerobic, the majority of oral bacteria are facultatively or obligately anaerobic (Marsh *et al*. 2016b). As oral bacteria exist as members of microbial communities, some anaerobic species survive in more aerobic habitats by existing in close partnership with oxygen-consuming species.

pH is a major determinant of bacterial distribution and metabolism in the mouth. The buffering activity of saliva plays a major role in maintaining the intraoral pH at around neutrality, which favors the growth of the resident oral microbiome. The pH in dental biofilms falls rapidly to below pH 5.0 following the intake of dietary sugars due to the production of acidic fermentation products (Marsh *et al*. 2016b). Many health-associated bacteria can tolerate brief conditions of low pH but are inhibited or killed by more frequent or prolonged exposures to acidic conditions (Svensater *et al*. 1997). This can result in the enrichment of acid-tolerant species, especially mutans streptococci, bifidobacteria, and lactobacilli, which are normally only minor components of dental biofilms at healthy sites, and increases the risk of dental caries. Inflammation raises the flow of GCF in the subgingival habitat; GCF introduces not only components of the host defenses, but if these fail to clear the microbial challenge, then host proteins in GCF can be exploited as a potential novel nutrient supply by some fastidious and proteolytic bacteria, giving them a competitive advantage, and this can drive deleterious shifts in the balance of the subgingival biofilm. The pH of the healthy gingival crevice is approximately 6.9, but this rises to pH 7.4 or higher during inflammation (Eggert *et al*. 1991) because of the catabolism of host proteins. Bacterial metabolism in mature oral biofilms results in sharp gradients of oxygen and pH, thereby generating a mosaic of microenvironments suitable for the growth of a variety of bacteria, enabling the coexistence of species that would otherwise be incompatible with one another.

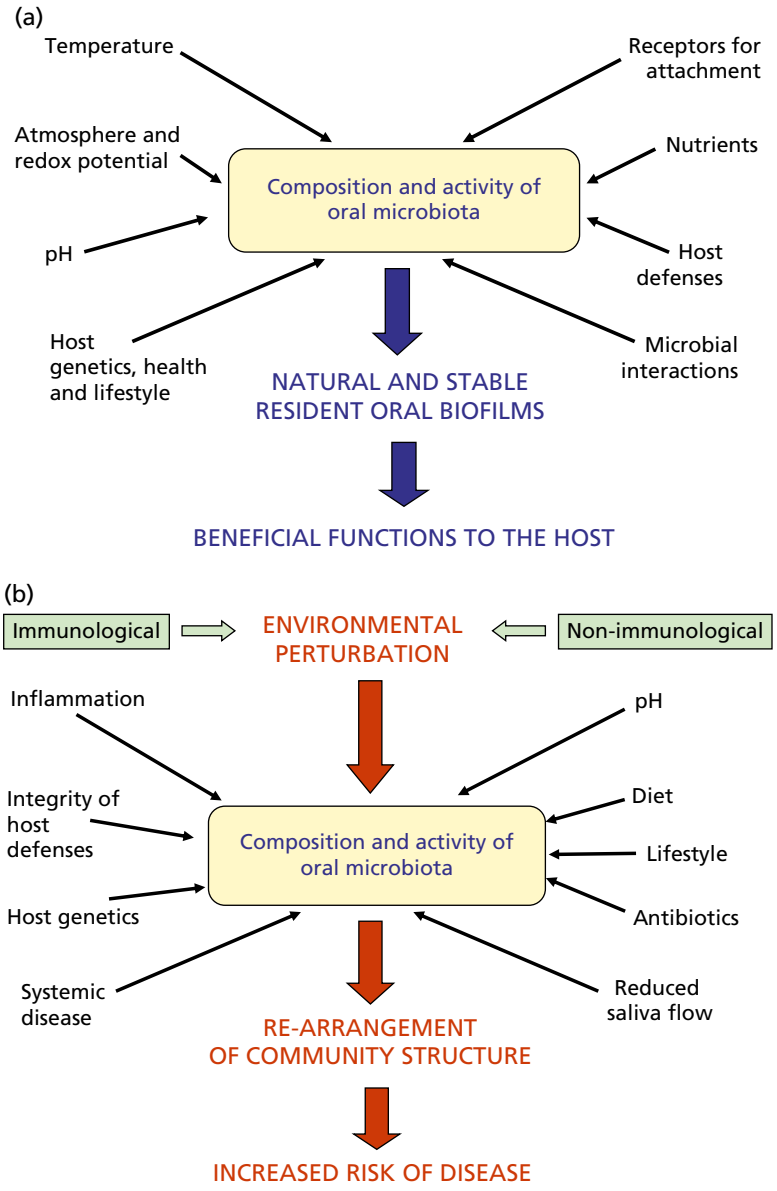

Fig. 8-1 Host factors that influence the microbial composition, activity and stability of the resident oral microbiota. (a) A number of host factors help to determine the composition and activity of the natural and beneficial oral microbiota. (b). A perturbation in a key environmental factor can disrupt the natural stability (microbial homeostasis) of the resident microbiota at a site and result in a re-arrangement of the composition and activity of the resident microbial community; such a change might predispose the site to disease. (Source: Adapted from Marsh et al. 2011.)

The mouth is richly endowed with components of both the innate (e.g. lysozyme, lactoferrin, sialoperoxidase, host defence peptides, etc.) and adaptive (secretory IgA, IgG, complement, neutrophils, etc.) immune response (Marsh *et al*. 2016a, b). The persistence of these microbial communities involves some members of the resident oral microbiota engaging in active cross-talk with the host to downregulate potential damaging proinflammatory responses (Hasegawa *et al*. 2007; Cosseau *et al*. 2008).

The lifestyle of an individual can affect the distribution and metabolism of the oral microbiota. The impact of a diet with a high frequency of intake of fermentable carbohydrates has been discussed above. Smoking may select for potential periodontal pathogens in dental biofilms, and diabetics have a higher frequency of some Gram-negative periodontal pathogens. The composition of the oral microbiome can also change with age. This can be as a consequence of a number of host-related events, including tooth eruption in early life, hormonal changes in puberty, or the waning of the immune response in old age (Marsh *et al*. 2016).

In general, once established, the microbial composition of the biofilm at a site remains stable over time (Hall *et al*. 2017), but this is a dynamic relationship. A major perturbation to the host environment, such as a substantial change in diet or an alteration to the immune status of the host, can drive deleterious shifts in the balance of the oral microbiota, and increase the risk of disease (Fig. 8-1b). Importantly, this stability, termed *microbial homeostasis*, stems

not from any biological indifference by the resident microbiota, but reflects a highly dynamic state in which the relative proportions of individual species are held in balance due to the numerous interactions, both synergistic and antagonistic (see later) (Marsh & Zaura 2017). This natural balance is maintained despite continual surveillance by the host defenses and the regular exposure of the mouth to a variety of modest environmental stresses, such as the diet, changes in saliva flow, oral hygiene, and lifestyle practices such as smoking (Fig. 8-1a). However, microbial homeostasis can breakdown on occasions if one of the key parameters affecting growth is perturbed and is sufficiently robust or regular to result in the reorganization of the composition of the biofilm, with the outgrowth of previously minor components (Fig. 8-1b). Such perturbations can be due to immunological (e.g. neutrophil dysfunction, immune suppression, etc.) or non-immunological (e.g. xerostomia, diet change, etc.) factors, and can predispose a site to disease (Marsh *et al*. 2011), and forms the basis of the "ecological plaque hypothesis" that describes the dynamic relationship between the oral microbiota and the host in health and disease (Marsh 2003).

Methods to determine the composition and function of the oral microbiome

The traditional way to determine the composition of the oral microbiome has been to use conventional culture techniques, in which samples are collected, dispersed, and then inoculated onto a range of agar plates. These agar plates can be formulated to grow the majority of bacterial or fungal species present or designed to be selective to support only specific groups of microbes. The agar plates have to be incubated at a relevant temperature (usually 37 °C), for an appropriate length of time, before the resultant microbial colonies are examined, and further tests are conducted to determine the identity of the isolate (Marsh *et al*. 2016b). This process is time consuming and relatively expensive, and it is now appreciated that <50% of the organisms present in a sample are cultivable.

Contemporary approaches use molecular (i.e. culture-independent) methods to detect and identify microorganisms (Wade & Prosdocimi 2020). These rely on detecting the nucleic acid signatures that are specific to each species, and range from targeted approaches such as PCR, DNA-DNA checkerboard systems, or microarrays, to more open-ended approaches in which all of the microbial DNA in a sample is digested, amplified, sequenced, re-assembled, and finally mapped against a reference database of relevant genomes, so that the whole diversity of the microbiota is revealed. These approaches are not without their own bias, as it can be more difficult to lyse and extract DNA from some organisms, while the primers used for amplification are not optimized for all species (Wade & Prosdocimi 2020). However, the introduction of these culture-independent approaches has changed our awareness of the richness and diversity of the oral microbiome in health and disease (Marsh *et al*. 2016b; Wade *et al*. 2016), and will lead to chairside kits and services to help diagnose oral diseases and monitor the outcome of treatment (Belibasakis *et al*. 2019).

Rather than just cataloguing the types of microorganism that are present at a site, complementary molecular approaches are also being used to monitor gene expression so as to determine the metabolic and functional activity in a sample (e.g. transcriptomics, proteomics, metabolomics). In the future, more emphasis may be placed on what microorganisms are "doing" (i.e. their function and activity) rather than providing a list of "who" is present (Takahashi 2015; Espinoza *et al*. 2018). It is likely that different combinations of species within a microbial community will perform similar tasks, and this might explain why there is not always a clear consensus when comparing the composition of dental biofilms in health and disease from different studies.

The development and composition of the oral microbiome

The mother is the main source of the oral microbiome in the newborn baby. It was originally thought that the fetus was sterile, but evidence has been emerging that some microbes (and microbial DNA) can be detected in the placenta and amniotic fluid (see Tuominen *et al*. 2019). The mode of delivery, and whether the baby is breast or formula fed, can influence the initial oral microbiome. Over time, the properties of the mouth dictate which bacteria predominate, and so a characteristic oral microbiome develops and, once teeth erupt, dental biofilms form and the microbiota becomes more diverse with increased numbers of obligate anaerobes (Mason *et al*. 2018).

Analysis of large numbers of subjects has identified a "core oral microbiome", which includes Gram-positive genera such as *Actinomyces*, *Corynebacterium*, *Gemella*, *Granulicatella*, *Rothia*, and *Streptococcus*, and Gram-negative genera including *Capnocytophaga*, *Fusobacterium*, *Haemophilus*, *Neisseria*, *Porphyromonas*, *Prevotella*, and *Veillonella* (Zaura *et al*. 2009; Chen & Jiang 2014; Diaz *et al*. 2016; Hall *et al*. 2017).

The microbial composition of dental biofilms varies at distinct sites on a tooth (fissures, approximal surfaces, gingival crevice) due to inherent differences in their anatomy and biology (Papaioannou *et al*. 2009; Marsh *et al*. 2016b) (Fig. 8-2). Fissures are influenced by saliva and the diet, and support a relatively sparse microbiota consisting of mainly saccharolytic Gram-positive bacteria, such as streptococci, while obligately anaerobic, and especially Gram-negative species, are rarely recovered (Espinoza *et al*. 2018). In contrast, the microbiota found in the healthy gingival crevice is heavily

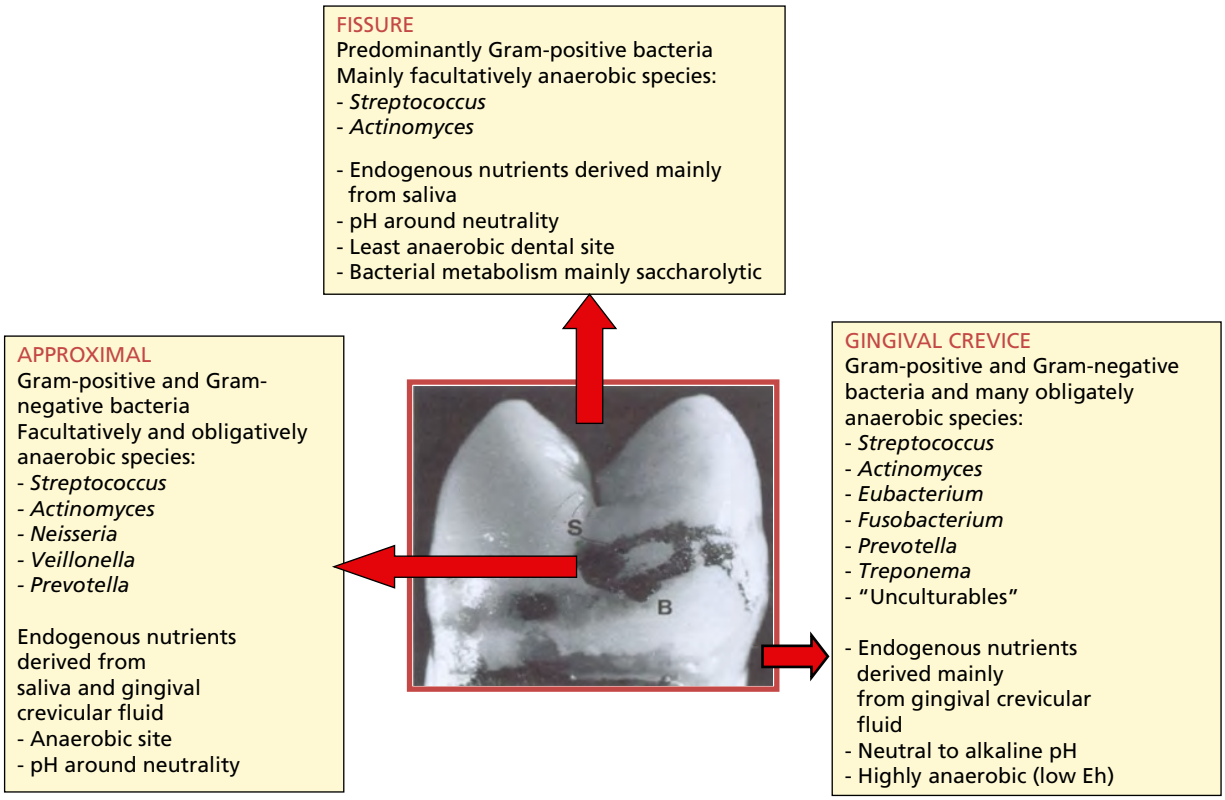

Fig. 8-2 Predominant groups of bacteria found at, and the key features of, distinct sites on the tooth surface.

influenced by GCF and has greater proportions of proteolytic and obligately anaerobic species, many of which are Gram-negative, although *Actinomyces* and *Streptococcus* spp. are also present (Abusleme *et al*. 2013). Highly nutritionally fastidious bacteria are found, including spirochetes, and many novel species are present, some of which cannot currently be grown in pure culture, and are referred to as being "unculturable". These latter bacteria have evolved to coexist with other species, and some can now be grown in co-culture with a partner organism that provides essential co-factors (Wade *et al*. 2016). Black pigmented anaerobes (e.g. *Prevotella* and *Porphyromonas* species) have an absolute requirement for hemin for growth, and these organisms can obtain this co-factor from the degradation of heme-containing host molecules present in GCF. Approximal surfaces have a microbiota that is intermediate in composition between that of fissures and the gingival crevice, and this site also harbors many obligately anaerobic species.

Dental biofilm formation

The most diverse collections of oral microorganisms are found in the biofilms on teeth (previously referred to as dental plaque) (Aas *et al*. 2005; Papaioannou *et al*. 2009; Dewhirst *et al*. 2010; Abusleme *et al*. 2013; Marsh *et al*. 2016b). Dental biofilms form via an ordered sequence of events, resulting in a structurally and functionally organized, species-rich microbial biofilm (Socransky & Haffajee 2002; Kolenbrander *et al*. 2006) (Fig. 8-3). Distinct stages in dental biofilm formation can be discerned and will now be described in more detail. It should be noted that these stages are arbitrary, as the attachment, growth, removal, and reattachment of microorganisms are continuous processes, and biofilms can undergo continual reorganization over time.

Conditioning film formation

Microorganisms rarely colonize clean enamel. Within seconds of eruption, or following cleaning, tooth surfaces become coated with a conditioning film of molecules (biologically active proteins, phosphoproteins, and glycoproteins) derived mainly from saliva (but also from GCF and bacteria) (Hannig *et al*. 2005). The properties of this conditioning film (also referred to as the "acquired pellicle") dictate which species are able to colonize.

Reversible and more permanent attachment

Initially, bacteria can be held reversibly near to the surface by weak, long-range, physicochemical forces between the electrical charge on the molecules on the pellicle-coated surface and those on the microbial cell. This reversible adhesion creates the opportunity for stronger and more permanent attachment. Molecules (adhesins) on these early bacterial colonizers (mainly streptococci such as *Streptococcus mitis*, *Streptococcus oralis*) can bind to complementary receptors in the acquired pellicle to make the

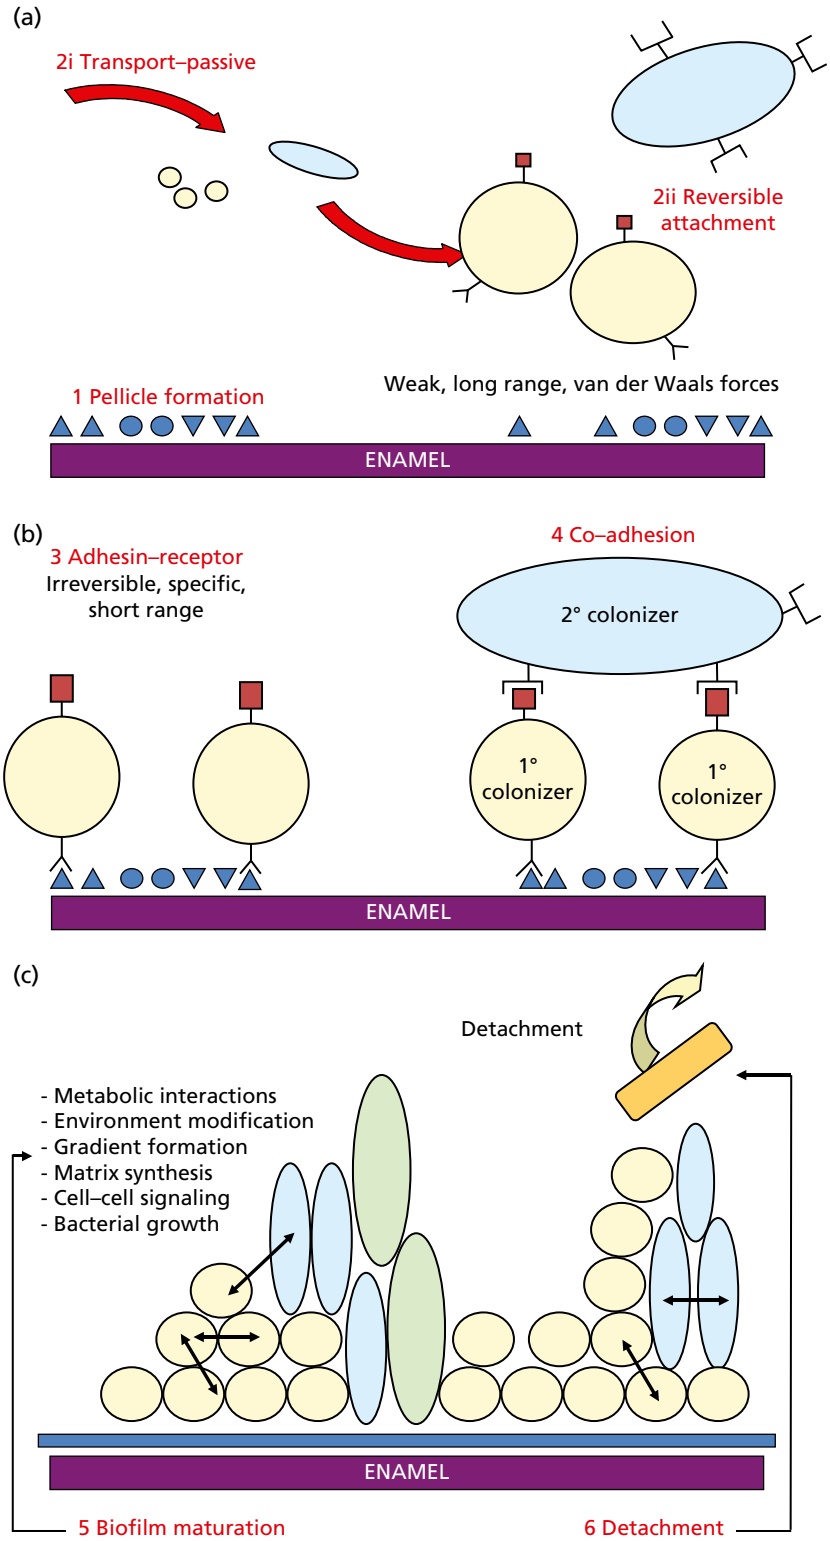

Fig. 8-3 The different stages in the formation of dental biofilms. (a) A conditioning film (the acquired pellicle) forms on a clean tooth surface (1). Bacteria are transported passively to the tooth surface (2i), where they may be held reversibly by weak, long-range forces of attraction (2ii). (b) Attachment becomes more permanent by specific stereo-chemical molecular interactions between adhesins on the bacterium and complementary receptors in the pellicle (3), and secondary colonizers attach to the already attached primary colonizers by molecular interactions (co-adhesion) (4). (c) Growth results in biofilm maturation, facilitating a wide range of intermicrobial interactions (synergistic and antagonistic) (5). On occasions, cells detach to colonize elsewhere (6). (Source: Marsh *et al*. 2016b. Reproduced with permission from Elsevier.)

attachment stronger (Busscher *et al*. 2008; Nobbs *et al*. 2011). Individual species can use multiple adhesins. In Gram-positive bacteria, several families of surface proteins can act as adhesins, including serine-rich repeat, antigen I/II, and pilus families, while in Gram-negative bacteria, autotransporters, extracellular matrix-binding proteins, and pili function as adhesins (Nobbs *et al*. 2011).

Co-adhesion

Once attached, the pioneer colonizers start to multiply. The metabolism of these early attached bacteria modifies the local environment, for example, by making it more anaerobic following their consumption of oxygen and the production of "reduced" end products of metabolism. Molecules on the surface of the attached pioneer species can act as receptors for the more fastidious secondary (and even later) colonizers, by a process termed co-adhesion or co-aggregation. Over time, waves of co-adhesion results in the composition of the biofilm becoming more diverse (microbial succession) (Kolenbrander *et al*. 2006) (Fig. 8-4). A key organism in dental biofilm development is *Fusobacterium nucleatum*. This species can co-adhere to most oral bacteria, and acts as an important bridging organism between early and later colonizing species. Co-adhesion may also ensure that bacteria are co-located with other organisms with complementary metabolic functions.

Plaque maturation

Some attached bacteria synthesize extracellular polymers (the biofilm matrix) that can consolidate the attachment of cells to the dental surface and to each other. These polymers include soluble and insoluble glucans, fructans, proteins, and extracellular DNA. This matrix is more than a mere scaffold for the biofilm; the matrix can bind and retain molecules, including enzymes, and also retard the penetration of charged molecules into the biofilm (Allison 2003; Vu *et al*. 2009; Marsh *et al*. 2011). The close proximity of different species provides the opportunity for numerous interactions (Marsh & Zaura 2017) that can be synergistic or antagonistic; some examples of these include:

- *Nutritional interactions*. Food chains develop between different species (in which the end product of metabolism of one organism is used as a primary nutrient by secondary feeders), and these interactions can increase in complexity to form "food webs" among numerous species (Marsh & Zaura 2017). The catabolism of structurally complex host macromolecules such as glycoproteins found in saliva and GCF requires metabolic cooperation by several species. These interactions increase the metabolic efficiency of the microbial community, and also create numerous interdependencies (Periasamy & Kolenbrander 2010; Marsh *et al*. 2011) which promote stability and resilience in the composition of the biofilm (Rosier *et al*. 2018).
- *Cell–cell signaling and gene transfer*. Bacteria in biofilms communicate with one another using a variety of systems including by quorum sensing in a cell density-dependent manner via small diffusible molecules (Miller & Lamont 2019). For example, Gram-positive bacteria secrete small peptides to coordinate gene expression among cells of a similar species (Suntharalingam & Cvitkovitch 2005), while other bacterial species communicate using autoinducer-2 (AI-2) (Kolenbrander *et al*. 2002), which may function across both Gram-positive and Gram-negative bacteria. Several putative periodontal pathogens (*F. nucleatum*, *Prevotella intermedia*, *Porphyromonas gingivalis*, *Aggregatibacter actinomycetemcomitans*) secrete a signal related to AI-2 (Fong *et al*. 2001; Frias *et al*. 2001). In *Streptococcus mutans*, quorum sensing is mediated by a competence stimulating peptide (CSP) (Li *et al*. 2002), which also increases the transformation frequency of recipient cells. Lysed cells in biofilms could act as donors of DNA, thereby increasing the opportunity for horizontal gene transfer in dental plaque. The recovery of resident and pathogenic bacteria from the nasopharynx with penicillin resistance genes showing a common mosaic structure confirms that gene transfer occurs among streptococci and between *Neisseria* species.
- *Antagonism*. Bacteria produce molecules that can be inhibitory to neighboring cells, thereby providing an organism with a competitive advantage when competing for space and nutrients. The molecules include hydrogen peroxide, bacteriocins organic acids, and enzymes (Marsh *et al*. 2016b).

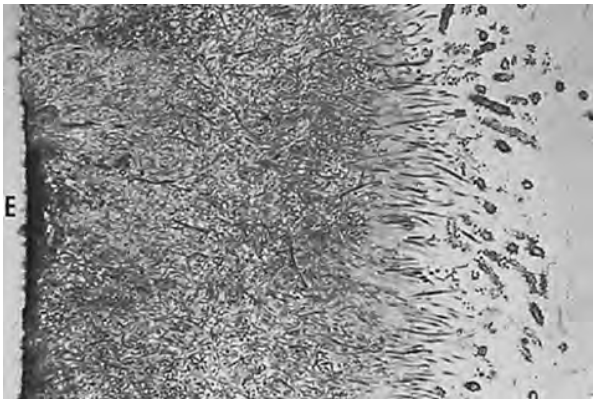

Fig. 8-4 Semi-thin section of a supragingival biofilm on enamel (E) which has been dissolved prior to sectioning. Magnification ×750. (Source: Listgarten 1976.)

As the dental biofilm grows and matures, it becomes spatially and functionally organized (Zijnge *et al*. 2010; Mark Welch *et al*. 2016, 2019). The metabolism of bacteria creates gradients in factors that are critical to microbial growth resulting in a mosaic of microenvironments. Such vertical and horizontal stratification can explain how organisms with apparently contradictory growth requirements can coexist at the same site. Oxygen-consuming species may be located in the outer regions of the biofilm with obligate anaerobes persisting in deeper layers, and consumers and producers of certain metabolites, such as lactate, tend to be near each other (Mark Welch *et al*. 2016, 2019). Clear structural features can be observed microscopically as the biofilm develops.

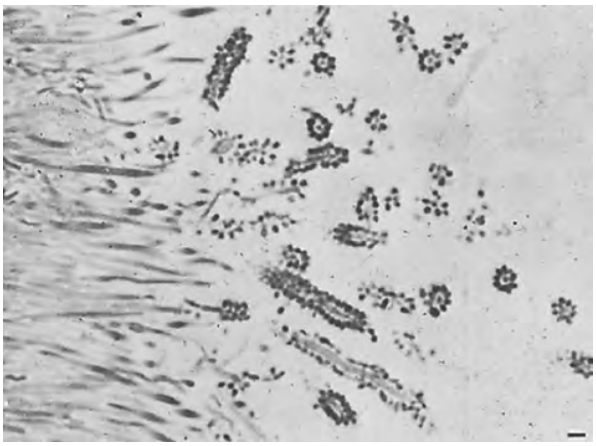

Fig. 8-5 "Corn-cob" formations seen at the biofilm surface in Fig. 8-4. Magnification ×1300. Bar 1 µm. (Source: Listgarten 1976.)

Initially, microcolonies of probably single species develop, and these merge with other species. These structures can grow to form "stacks" and "palisades" of cells, and channels have been observed that penetrate from the outer surface into the depths of the biofilm, which may aid movement of molecules in and out of the biofilm. These channels are often filled with extracellular polymers. Subgingival biofilms have a complex architecture, with distinct tooth-associated and epithelial cell-associated biofilms, with a less dense zone of organisms between the two (Socransky & Haffajee 2002). Characteristic cell associations can be seen in mature dental biofilms, such as "corn-cob" (in which coccal-shaped cells attach along the tip of filamentous organisms; Fig. 8-5) and "test-tube brush" (rod-shaped bacteria protruding perpendicularly from bacterial filaments) formations (Zijnge *et al*. 2010). Corn-cobs can form between diverse groups of microorganisms, including streptococci adhering to a central axis of yeast cells or hyphae, and of streptococci attached to *Corynebacterium matruchotii*, and between *Veillonella* spp. and *Eubacterium* spp. Lactobacilli formed the central axis of some of the "test-tube brushes", with organisms such as *Tannerella*, *F. nucleatum*, and *Synergistes* spp. radiating from this central cell.

Detachment

Bacteria can detect adverse changes in environmental conditions and detach from biofilms so as to be able to colonize more favorable environments elsewhere. Some species produce proteases that degrade the adhesin that is retaining them within the biofilm.

The significance of a biofilm and community lifestyle for microorganisms

The vast majority of microorganisms in nature, including in the mouth, are found attached to surfaces as biofilms. The ability to attach to, and be retained at a surface, is a fundamental survival strategy for most microorganisms, as otherwise they would be lost from habitats such as the mouth by the flow of saliva and swallowing. There would be little scientific or clinical interest if the properties of (1) biofilms were similar to those of conventional planktonic (liquid culture) cells, and (2) if the capabilities of microbial communities were merely the sum of those of the constituent species. However, bacterial gene expression alters markedly when cells form a biofilm, resulting in a radically different phenotype, while the binding of bacteria to specific host receptors can trigger significant changes in host cell gene expression (Marsh 2005).

Furthermore, several potential benefits arise when species interact to function as a microbial community (Caldwell *et al*. 1997; Shapiro 1998; Marsh & Bowden 2000) including:

- a broader habitat range for growth. For example, the metabolism of early colonizers alter the local environment, making conditions suitable for attachment and growth of later (and more anaerobic) species;
- an increased metabolic diversity and efficiency, so that complex host molecules that are recalcitrant to catabolism by individual organisms can be broken down by microbial consortia;
- an enhanced tolerance of environmental stress, antimicrobial agents, and the host defenses. Neighboring cells of a different species can produce neutralizing enzymes (β-lactamase, IgA protease, catalase, etc.) that protect inherently susceptible organisms from inhibitors (Brook 1989). As mentioned earlier, horizontal gene transfer is also more efficient in multispecies biofilms (Molin & Tolker-Nielsen 2003; Wilson & Salyers 2003). Microbial communities can also afford physical protection from phagocytosis for cells deep within a spatially organized consortium (Costerton *et al*. 1987; Fux *et al*, 2005);
- an enhanced ability to cause disease. Abscesses are examples of polymicrobial infections whereby organisms that individually cannot cause disease are able to do so when they are present as a consortium (pathogenic synergism) (van Steenbergen *et al*. 1984); this property is pertinent to periodontal diseases where individual species may play particular roles in overcoming the host defenses and driving inflammation.

In this way, microbial communities display emergent properties, i.e. the properties of the community are more than the sum of its component populations.

An important clinical consequence of both the structural and functional organization of multispecies biofilms is their reduced susceptibility to antimicrobial agents (Gilbert *et al*. 1997, 2002; Ceri *et al*. 1999; Stewart & Costerton 2001). An organism

growing on a surface can be many times more tolerant of an antimicrobial agent than the same cells grown planktonically (Stewart & Costerton 2001), with older biofilms being most recalcitrant. Several mechanisms contribute to the reduced susceptibility of biofilms to antimicrobial agents (Stewart & Costerton 2001; Gilbert *et al*. 2002). Microorganisms conventionally become resistant due to mutations affecting the drug target, to the presence of efflux pumps that prevent accumulation of the agent, or to the production of neutralizing enzymes, etc., but, significantly, even sensitive bacteria become less susceptible to antimicrobials when growing on a surface. The structure of a biofilm may restrict the penetration of the antimicrobial agent; charged inhibitors can bind to oppositely charged polymers that make up the biofilm matrix (diffusion-reaction theory), and so only inhibit organisms at the surface, leaving cells relatively unaffected in deeper layers. The biofilm matrix can also bind and retain neutralizing enzymes (e.g. β-lactamase) at concentrations that could inactivate an antibiotic or inhibitor (Allison 2003). Bacteria growing as a biofilm display a novel phenotype, and this could reduce their sensitivity to inhibitors because the drug target may be modified or not expressed, or the organism may use alternative metabolic strategies for growth. Bacteria grow only slowly under nutrient-depleted conditions in an established biofilm and, as a consequence, are much less susceptible than faster dividing cells. In addition, it has also been proposed that the environment in the depths of a biofilm may be unfavorable for the optimal action of some drugs (Gilbert *et al*. 2002). The increased tolerance of some biofilms to antibiotics may also be due to a subpopulation of "persister" organisms that are specialized survivor cells (Keren *et al*. 2004).

Benefits to the host of a resident oral microbiota.

The host has a sophisticated array of host defenses provided by both the innate and adaptive arms of the immune system, the primary function of which is to protect tissues against microbial colonization and invasion. Despite these host defenses, the host has evolved over millennia to support a complex resident microbiome and, at first sight, this might appear paradoxical (the "commensal paradox") (Henderson & Wilson 1998). It is now apparent that the resident microbiome confers considerable benefit to the host, and that these natural microbial residents are essential for the normal development of the physiology, nutrition, and defenses of the host (Marsh 2000; Wilks 2007) (Fig. 8-6).

Complex biological mechanisms permit a synergistic coexistence between the host and the resident microbiota, while enabling the host to retain the capacity to respond to exogenous microbial challenges. The host is not indifferent to the presence of the diverse microbial communities that reside on its surfaces. There is active cross-talk between the resident microbiome and host in order to effectively maintain this constructive relationship. The host has evolved to tolerate resident microorganisms without initiating a damaging inflammatory response, while also being able to mount an efficient defense against pathogens (Devine *et al*. 2015). Pathogenic and non-pathogenic bacteria may initiate different intracellular signaling pathways and innate immune responses in epithelial cells (Canny & McCormick 2008; Hooper 2009; Neish 2009). Certain oral streptococci have been shown to suppress epithelial cell cytokine expression (Hasegawa *et al*. 2007; Peyret-Lacombe *et al*. 2009). *Streptococcus salivarius*

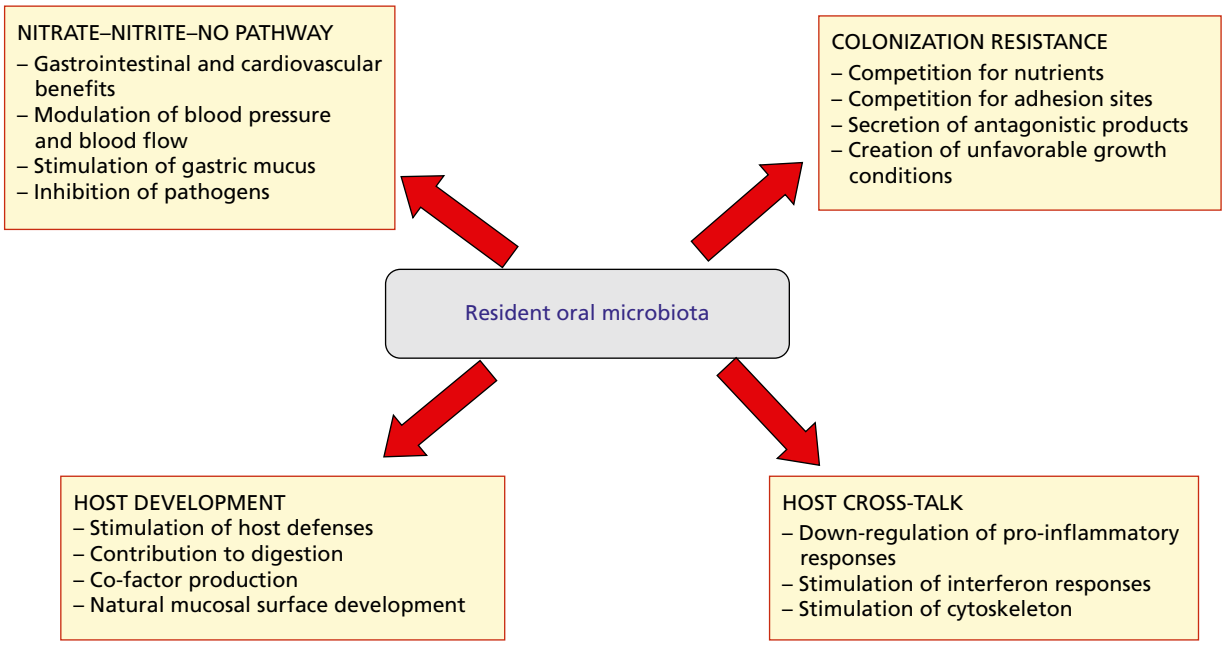

Fig. 8-6 Beneficial functions of the resident oral microbiota. (Sources: Marsh & Bowden 2000; Wilks 2007.)

K12 not only downregulated epithelial cell inflammatory responses by inhibiting the NF-κB pathway, but also actively stimulated beneficial pathways, including type I and II interferon responses, and exerted significant effects on the cytoskeleton and adhesive properties of the host cell (Cosseau *et al*. 2008). The "commensal communism" paradigm proposes that our oral microbiome and mucosa form a unified "tissue" in which host-microbe "cross-talk" is finely balanced to ensure microbial survival and prevent the induction of damaging inflammation (Henderson & Wilson 1998).

One of the principal benefits of the existence of a resident and beneficial microbiota at a site is the ability to prevent colonization by exogenous (and often pathogenic) microorganisms. This property, termed "colonization resistance" (Van der Waaij *et al*. 1971) or "pathogen exclusion", is due to various properties of resident microbes including their: (1) more effective attachment to host receptors; (2) greater efficacy to catabolize and grow on endogenous nutrients; (3) creation of unfavorable growth conditions to discourage attachment and multiplication of invading organisms; and (4) production of antagonistic substances (hydrogen peroxide, bacteriocins, etc.) that are inhibitory to exogeneous species. Colonization resistance can be impaired by factors that compromise the integrity of the host defenses or perturb the stability of the resident microbiota, such as the side-effects of cytotoxic therapy, lifestyle issues, or the long-term use of broad spectrum antibiotics (Johnston & Bodley 1972). For example, the latter can suppress the resident bacterial oral microbiota permitting overgrowth by previously minor populations of oral yeasts. Attempts to boost colonization resistance using replacement therapy (in which resident organisms are deliberately re-implanted), for example, after periodontal therapy (Teughels *et al*. 2007), or by the use of probiotics (Devine & Marsh 2009) or prebiotics (molecules that improve the growth of members of the beneficial resident microbiome) (Slomka *et al*. 2017), are being explored.

Resident oral bacteria play an important role in maintaining many important aspects of the gastrointestinal and cardiovascular systems, via the metabolism of dietary nitrate. Approximately 25% of ingested nitrate (present in beets and green vegetables) is secreted in saliva where facultatively anaerobic oral resident bacteria (such as *Rothia* and *Neisseria* species) reduce nitrate to nitrite. Nitrite affects a number of key physiological processes including the regulation of blood flow, blood pressure, gastric integrity, and tissue protection against ischemic injury. Nitrite can be further converted to nitric oxide in the acidified stomach, and this has antimicrobial properties, and contributes to defenses against enteropathogens and in the regulation of gastric mucosal blood flow and mucus formation (Hezel & Weitzberg 2015; Vanhatalo *et al*. 2018).

Biofilms on implant surfaces

In the oral cavity, biofilms with a distinct composition may be encountered attached to different solid oral surfaces, including teeth, prosthetic devices, and dental implants (Belibasakis *et al*. 2015). The formation and maturation of biofilms on dental implant surfaces can trigger inflammation of the peri-implant tissues and lead to peri-implant diseases, such as mucositis and peri-implantitis, in a similar manner as the subgingival biofilm is associated with gingivitis and periodontitis (Lang *et al*. 2011). The use of experimental multispecies *in vitro* and *in vivo* biofilm models has shown that biofilm formation on implant titanium surfaces follows similar kinetics as on tooth surfaces, with an initial formation of an acquired pellicle due to adsorption of salivary components, mainly proteins, followed by specific adherence by *Streptococcus*, *Veillonella*, and *Actinomyces* species, and then by progressive colonization of secondary and tertiary colonizers, such as *F. nucleatum* and *P. gingivalis*, respectively (Schmidlin *et al*. 2013; Sanchez *et al*. 2014).

Despite the similarities between biofilms on tooth and implant surfaces, some specific features might be attributed to the specific implant surface characteristics. The current knowledge on biofilms on implant surfaces is mainly based on experiments under controlled conditions, where bacterial populations are known. These conditions, however, are very different from those found in the oral cavity, where the microbial communities may vary according to the different specific microenvironments and hence, the effect of implant surfaces on biofilm development *in vivo* still needs to be elucidated.

With the aim of improving the dynamics of osseointegration, different modifications in the implant surface microtopography increased its predictability and reduced the time to achieve implant stability and clinical success. These modifications have involved changes in their surface physicochemical characteristics, mainly its roughness, hydrophobicity, surface free energy and wettability, resulting in most of the currently commercialized implant systems with titanium or titanium alloys having a moderately rough microsurface topography (Albrektsson & Wennerberg 2004).

These complex surface topographies, which clearly enhance implant osseointegration, may also facilitate the development of complex biofilms and impair their cleanability. Recent *in vivo* (Xing *et al*. 2015; Al-Ahmad *et al*. 2016; Ribeiro *et al*. 2016; de Melo *et al*. 2017) and *in vitro* biofilm models (Schmidlin *et al*. 2013; Sanchez *et al*. 2014; Violant *et al*. 2014) have studied the impact of implant surface characteristics on biofilm formation, demonstrating that the physicochemical properties of the surface, and mainly its roughness, significantly affected early bacterial colonization, biofilm formation, and maturation. Studies evaluating biofilms on implants and abutments,

with different surface composition and topography, have shown that there is a correlation between surface roughness and viable biomass within the biofilm (Hahnel *et al*. 2015) as well as increased bacterial colonization and diversity (Teughels *et al*. 2006; Xing *et al*. 2015). Other studies, however, have reported that surface free energy or the biomaterial manufacturing, rather than roughness, may be the key factor determining initial bacterial adhesion (Mabboux *et al*. 2004; Violant *et al*. 2014). Using an *in vitro* multibacterial species biofilm (Fig. 8-7), significant differences in biofilm thickness and three-dimensional structure, were reported when comparing titanium and zirconium surfaces (Sanchez *et al*. 2014). In most of these experimental studies, however, although the early bacterial colonization is significantly influenced by different implant surface characteristics, once developed on the implant surface, mature biofilms are quite similar, in terms of the number of bacteria and thickness or three-dimensional structures when comparing different surface microtopographies (Schmidlin *et al*. 2013; Zhao *et al*. 2014; Sanz *et al*. 2017) (Fig. 8-8).

Most of these experimental models did not use dental implants but rather specimens, such as discs or slabs reproducing the implant surface microtopography, but lacking the macroscopic and topographic characteristics such as the threads that may also influence bacterial colonization. Recent studies (Bermejo *et al*. 2019a) have demonstrated different patterns of bacterial colonization and biofilm deposition depending on whether the biofilm is in the peak of the thread or the valley between threads (Fig. 8-8).

The use of scanning electron microscopy (SEM) has shown the presence of mature biofilms in moderate-roughness titanium implant surfaces with bacterial communities forming large stacks or towers distributed between broad channels, all surrounded with a

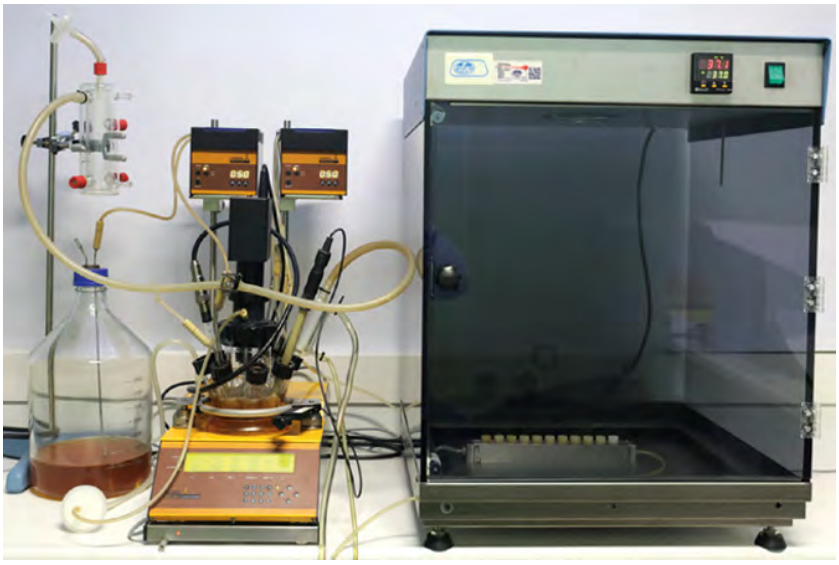

Fig. 8-7 *In vitro* biofilm system consisting of a bio-generator, gas pumps, and the Robbins-device where implants are tested.

thick extracellular matrix covering the whole implant surface. When compared with smooth titanium surfaces or zirconia surfaces, the main difference is the presence of higher numbers of bacteria within their characteristic pores, which may have implications, not only for the accumulation of larger numbers of bacteria, but also with the likely greater difficulty for their removal (Schmidlin *et al*. 2013; Ferreira Ribeiro *et al*. 2016; Bermejo *et al*. 2019b) (Fig. 8-9).

Dental calculus

Dental calculus or tartar represents mineralized bacterial biofilm, although calculus formation can be induced in germ-free animals as a result of precipitation of mineral salts originating from saliva (Theilade 1964). Supragingival calculus is located coronal to the gingival margin (Fig. 8-10a), whereas subgingival calculus is found apical to the gingival

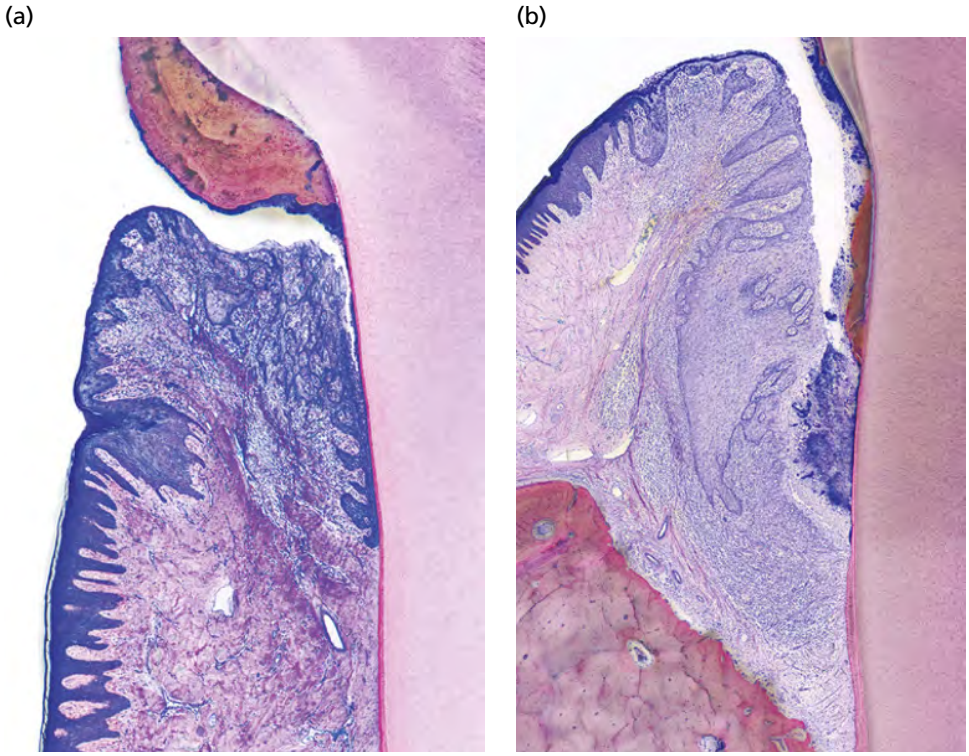

Fig. 8-10 (a) Supragingival calculus adhering to enamel and the root surface of a tooth from a dog. An initial gingival pocket and a slight gingival inflammation has developed. (b) Subgingival calculus on the root of a tooth from a dog with a periodontal pocket. Note the inflamed gingival tissue and bone loss. For both supra- and subgingival calculus, uncalcified dental biofilm extends apically and forms a calculus-free zone between the apical termination of calculus and the apical extension of the pockets. Undecalcified ground sections.

margin (Fig. 8-10b). Supra- and subgingival calculus both have characteristic features. It should be noted that calculus continually harbors a viable bacterial biofilm (Zander *et al*. 1960; Theilade 1964; Schroeder 1969).

Clinical appearance and distribution

Supragingival calculus appears as a creamy-whitish to dark yellow or even brownish mass of moderate hardness (Fig. 8-11). The degree of calculus formation is not only dependent on the amount of bacterial biofilm present, but also on the secretion of the salivary glands. Hence, supragingival calculus is predominantly found adjacent to the excretion ducts of the major salivary glands, such as the lingual aspect of the mandibular anterior teeth for the submandibular glands and the buccal aspect of the maxillary first molars, whereas the parotid gland ducts open into the oral vestibule.

Subgingivally, calculus may be found by tactile exploration only, since it is usually not visible to the naked eye. Occasionally, subgingival calculus may be visible on dental radiographs provided that the deposits are of sufficient mass (Fig. 8-12). Small deposits or residual deposits following root instrumentation may barely be visualized radiographically. If the gingival margin is pushed open by a blast of air or retracted by a dental instrument, a brownish-to-black calcified hard mass with a rough

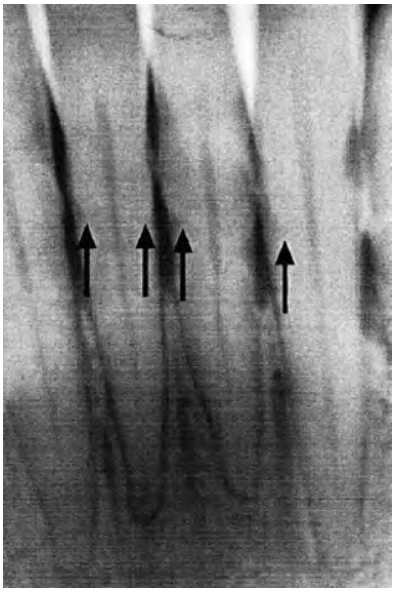

Fig. 8-12 Subgingival calculus may be visible (arrows) on radiographs if abundant deposits are present.

Fig. 8-11 Abundance of supragingival calculus deposits. (a) Gross deposits as a result of long-term neglect of oral hygiene. Two mandibular incisors have been exfoliated. (b) Supragingival biofilm usually covering the lingual aspect of mandibular incisors. Note the intense inflammatory reaction adjacent to the deposits. (c) Same patient and region as in (b) following removal of the calculus. The gingival tissues demonstrate healing.

surface may become visible (Fig. 8-13). Again, this mineralized mass reflects predominantly bacterial accumulations mixed with products from GCF and blood. Consequently, subgingival calculus is found in most periodontal pockets, usually extending from the cementoenamel junction to close to the bottom of the pocket. However, a band of approximately 0.5 mm is usually found coronal to the apical extension of the periodontal pocket (Fig. 8-14). This zone appears to be free of mineralized deposits owing to the fact that GCF is exuding from the periodontal soft tissues and acting as a gradient against microbial accumulation. This calculus-free zone can also be seen in histological sections (see Fig. 8-10a, b). Like supragingival calculus, subgingival calculus also provides an ideal substrate for bacterial adhesion (Zander *et al*. 1960; Schroeder 1969).

Biofilm mineralization varies greatly between and within individuals and also within the different regions of the oral cavity. There is great variability in the formation rate of both bacterial biofilm and in dental calculus. In some subjects, the time required for the formation of supragingival calculus is 2 weeks, at which time the deposit may already contain approximately 80% of the inorganic material found in mature calculus (Fig. 8-15) (Mühlemann & Schneider 1959; Mandel 1963; Mühlemann & Schroeder 1964). In fact, evidence of mineralization may already be present after a few days (Theilade 1964). Nevertheless, the formation of dental calculus with the mature crystalline composition of old calculus may require months to years (Schroeder & Baumbauer 1966).

Calculus formation and structure

In humans, the formation of calculus is always preceded by the development of a bacterial biofilm. The intermicrobial biofilm matrix and the bacteria themselves provide the matrix for calcification, which is driven by the precipitation of mineral salts. Supragingival biofilm becomes mineralized due to the precipitation of mineral salts present in saliva, whereas subgingival biofilm mineralizes due to the presence of mineral salts in the inflammatory exudate passing through the pocket. It is, therefore, evident that subgingival calculus represents a secondary product of infection and not a primary cause of periodontitis.

Mineralization starts at crystallization foci in the intermicrobial (intercellular) matrix and on the bacterial walls (Fig. 8-16), and eventually proceeds inside the bacteria (Fig. 8-17) (Zander *et al*. 1960). The detection of lactate dehydrogenase, alkaline and acid phosphatase activities, and various extracellular matrix proteins in the biofilm suggests that

Fig. 8-15 Seven-day-old calcified biofilm. Observe the isolated calcification centers indicated by the black areas (von Kossa stain).

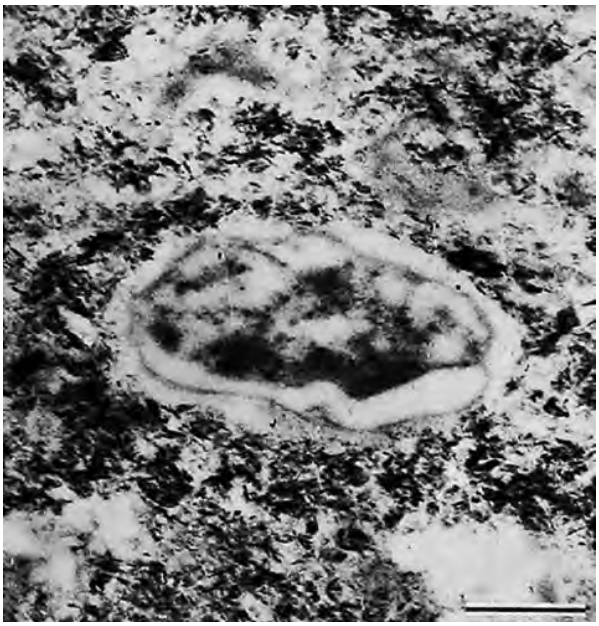

Fig. 8-16 Thin section of old biofilm. A degenerating organism is surrounded by intermicrobial matrix in which initial mineralization has begun with the deposition of small needle-shaped electron-dense apatite crystals. Fig. 8-17 Thin section of old mineralizing biofilm. The intermicrobial matrix is totally calcified, and many microorganisms show intracellular crystal deposition. Magnification ×9500. Bar: 1 µm. (Source: Theilade 1964.)

calculus formation is not merely a passive mineralization process. Bacterial enzymes (Friskopp & Hammarström 1982), calcium phosphate supersaturation, cell membrane-associated constituents, and inactivation of nucleation inhibitors (Jin & Yip 2002) may all be involved in the initiation and regulation of biofilm calcification. Osteopontin and bone sialoprotein (Fig. 8-18), two non-collagenous extracellular matrix proteins involved in the mineralization of bone and cementum, have been immunodetected in human calculus, but not in the unmineralized dental biofilm. Osteopontin and bone sialoprotein are present in blood plasma, and osteopontin has been identified in GCF and saliva (Ogbureke & Fisher 2004; Sharma & Pradeep 2007). Their presence in the biofilm matrix and at the surface of bacteria suggests an involvement in the regulation of mineralization.

The progression of mineralization in an incremental pattern from the inner zones of the bacterial biofilm outward may produce concentric rings, called Liesegang rings, that reflect successive phases of mineralization. Furthermore, the presence of numerous mineralization foci, from which mineralization spreads and which partially coalesce, may leave some unmineralized areas and thus account for the porous nature of calculus, whose cavities and channels are filled with uncalcified biofilm (see Fig. 8-15).

Attachment to tooth surfaces and implants

Dental calculus generally adheres tenaciously to tooth surfaces; consequently, the removal of subgingival calculus may be difficult. The reason for this firm attachment to the tooth surface is the fact that the pellicle beneath the bacterial biofilm also calcifies. This, in turn, results in an intimate contact with enamel (Fig. 8-19), cementum (Fig. 8-20), or dentin crystals (Fig. 8-21) (Kopczyk & Conroy 1968; Selvig 1970). In addition, the surface irregularities are also penetrated by calculus crystals and, hence, calculus is virtually locked onto the tooth. This is particularly the case on exposed cementum, where small pits and irregularities occur at the sites of the previous insertion of Sharpey's fibers (Bercy & Frank 1980). Uneven root surfaces may be the result of carious lesions and small areas of cementum may have been lost due to resorption, when the periodontal ligament was still invested into the root surface (Moskow 1969). Under such conditions, it may become extremely difficult to remove all calculus deposits without sacrificing some hard tissues of the root.

Although some irregularities may also be encountered on dental implant surfaces, the attachment to commercially pure titanium is generally less intimate than to root surface structures. This in turn means that calculus may be chipped from dental implants (Fig. 8-22) without detriment to the implant surface (Matarasso *et al*. 1996). Excess cement at the crown–abutment interface has been associated with peri-implant disease (Pauletto *et al*. 1999; Gabski *et al*. 2008; Wilson 2009). The rough surface of the cement may provide a biofilm/calculus retention site, which can lead to peri-implant disease (Lang *et al*. 2004). Overhang at such sites (Fig. 8-23) may impede calculus removal. After removal of excess cement, clinical and endoscopic signs of peri-implant disease disappear in the majority of cases (Wilson 2009).

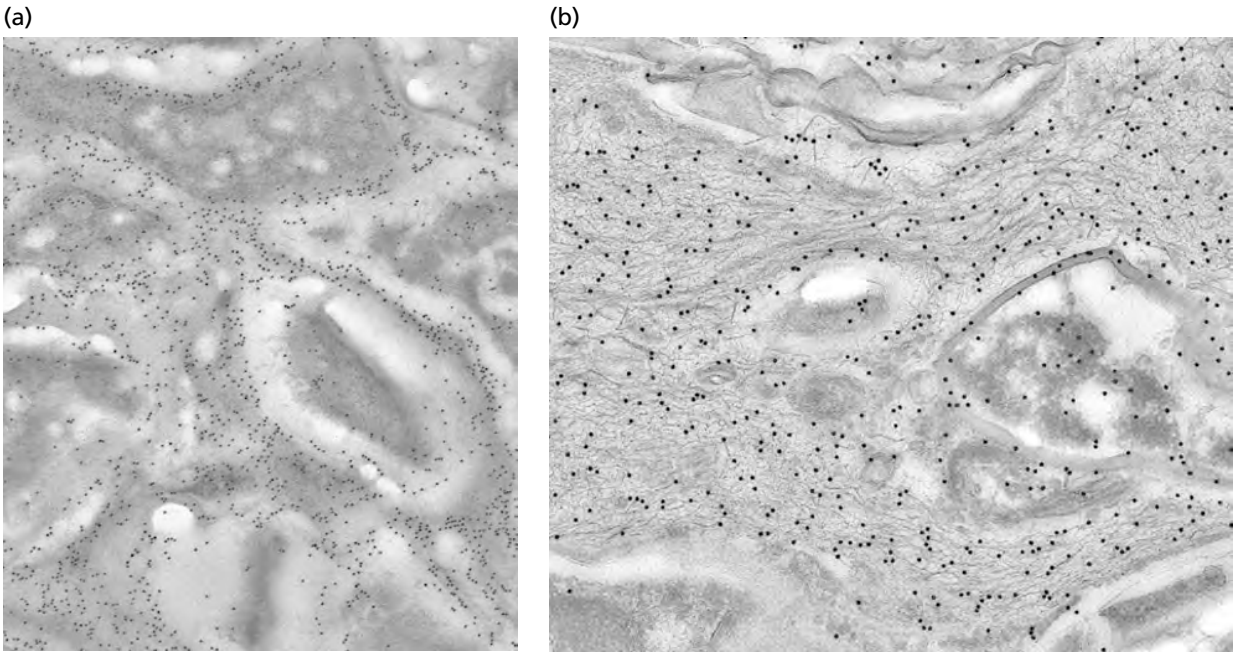

Fig. 8-18 Immunolabeling of calculus on a human tooth root with an antibody against bone sialoprotein. (a) Predominant gold particle labeling of the bacterial cell walls in the inner portion of calculus. (b) Labeling over extensive intermicrobial filamentous matrix. Ultrathin sections viewed under the transmission electron microscope.

Magnification × 37 500. Bar: 0.1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

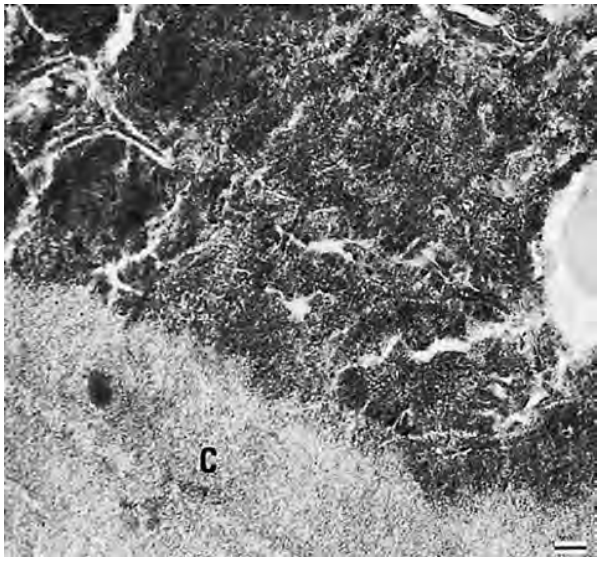

Fig. 8-20 Thin section of cementum surface (C) with overlying calculus. The calculus is closely adapted to the irregular cementum and is more electron dense and therefore harder than the adjacent cementum. To the right, part of an uncalcified microorganism. Magnification ×32 000. Bar: 0.1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

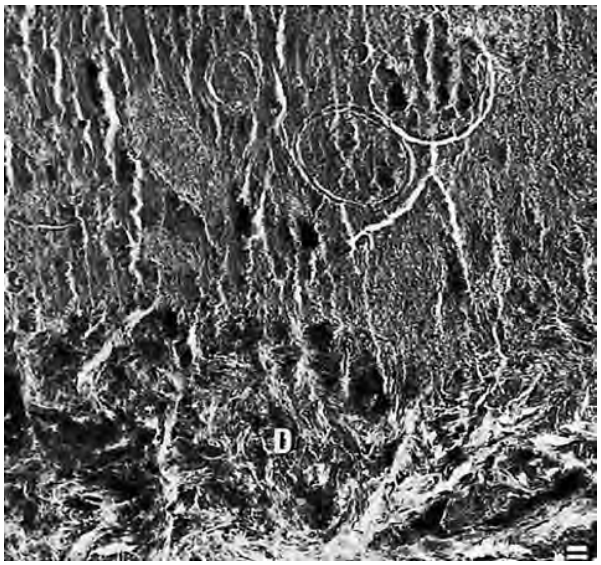

Fig. 8-21 Thin section of dentin (D) surface with overlying calculus. The interface between the calculus and dentin cannot be precisely determined because the calculus crystals fill the irregularities of the dentin surface, which is devoid of cementum as a result of a previous scaling of the root surface. The circular profiles in the calculus completely surround calcified bacteria. Magnification ×19 000. Bar: 1 µm. (Source: Selvig 1970. Reproduced with permission from John Wiley & Sons.)

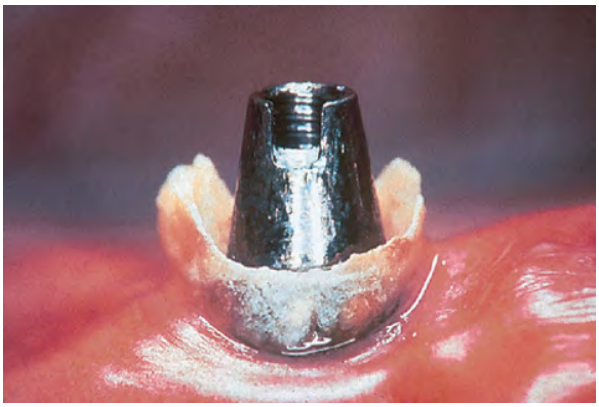

Fig. 8-22 Calculus deposit on an oral implant in a patient without regular maintenance care.

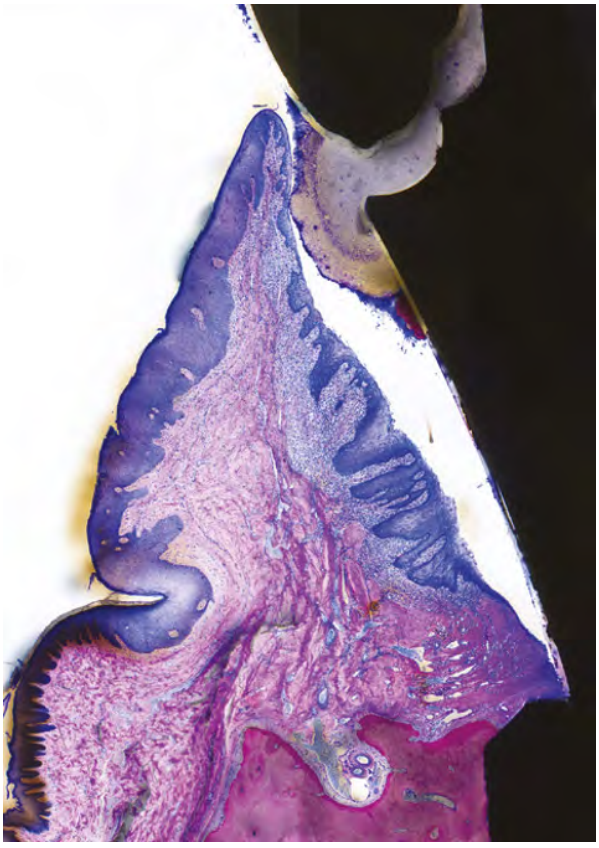

Fig. 8-23 Excess cement at the abutment–crown interface provides an ideal substrate for biofilm and calculus deposition and retention. Bacterial biofilm covers the entire surface of the cement, whereas calculus is present apical to the cement overhang. Detachment of the epithelium indicates pocket formation. The detachment of the apical-most portion of the epithelium, however, may represent an artifact due to histologic processing. Undecalcified ground section.

Calculus composition

Recent and old calculus consists of four different crystals of calcium phosphate (for reviews, see Schroeder 1969; Jepsen *et al*. 2011):

1. $CaH(PO_4) \times 2H_2O$ = brushite (B)
2. $Ca_4H(PO_4)_3 \times 2H_2O$ = octa calcium phosphate (OCP)
3. $Ca_5(PO_4)_3 \times OH$ = hydroxyapatite (HA)
4. $\beta\text{-}Ca_3(PO_4)_2$ = whitlockite (W).

X-ray diffraction studies suggest that mineralization begins with the deposition of OCP and dicalcium phosphate dehydrate (DCPD), followed by less soluble HA and W (Rowles 1964; White 1997). Supragingival calculus is clearly built up in layers and shows a great heterogeneity from one layer to another with regard to mineral content (37% on average, range of 16%–51%) (Kani *et al*. 1983; Friskopp & Isacsson 1984; Sundberg & Friskopp 1985). Subgingival calculus appears somewhat more homogeneous, since it is built up in layers of equally high mineral density (58% on average, range of 32%–78%) (Kani *et al*. 1983; Friskopp & Isacsson 1984).

Clinical implications

Although strong associations between calculus deposits and periodontitis have been demonstrated in experimental (Wærhaug 1952, 1955) and epidemiological studies (Lövdal *et al*. 1958), it has to be realized that calculus is always covered by an unmineralized layer of a viable bacterial biofilm. It has been debated whether or not calculus may exert a detrimental effect on the soft tissues owing to its rough surface. However, it has clearly been established that surface roughness alone does not initiate gingivitis (Wærhaug 1956). It could even be observed that a normal epithelial attachment with hemidesmosomes and a basal lamina forms on calculus if its surface was disinfected using chlorhexidine (Fig. 8-24) (Listgarten & Ellegaard 1973). Furthermore, it has been demonstrated that autoclaved calculus may be encapsulated in connective tissue without inducing marked inflammation or abscess formation (Allen & Kerr 1965).

These studies clearly exclude the possibility of dental calculus being a primary cause of periodontal diseases. Calculus seems to have a secondary effect by providing a surface configuration conducive to further biofilm accumulation. Nevertheless, calculus deposits may develop in areas that are difficult to access for oral hygiene or may, depending on their size, jeopardize proper oral hygiene practices. Calculus may also amplify the effects of bacterial biofilm by keeping the bacterial deposits in close contact with the tissue surface, thereby influencing both bacterial ecology and tissue response (Friskopp & Hammarström 1980).

Well-controlled animal (Nyman *et al*. 1986) and clinical (Nyman *et al*. 1988; Mombelli *et al*. 1995) studies have shown that the removal of subgingival biofilm on top of subgingival calculus results in healing of periodontal lesions and the maintenance of healthy gingival and periodontal tissues, provided that the removal is meticulous and performed on a regular basis. One of these studies (Mombelli *et al*. 1995) clearly demonstrated that microbiota composition and clinical parameters following the diligent and complete removal of subgingival biofilm on top of mineralized deposits after chipping off gross

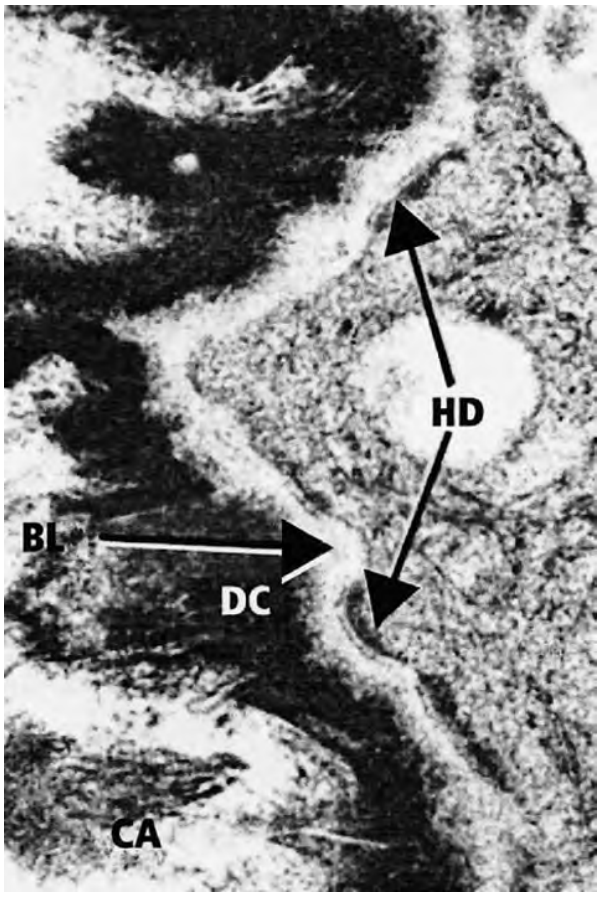

Fig. 8-24 Hemidesmosomal attachment of junctional epithelium on dental calculus in the absence of bacteria following application of chlorhexidine. BL, basement lamina; CA, calculus; DC, dental cuticle; HD, hemidesmosomes. Magnification ×32 000. (Source: Data from Listgarten & Ellegaard 1973.)

amounts of calculus were almost identical to those obtained with routine removal of subgingival calculus by root surface instrumentation. Again, it has to be realized that meticulous supragingival biofilm control guarantees the depletion of the supragingival bacterial reservoir for subgingival recolonization. These studies have clearly elucidated the role of subgingival calculus as a biofilm-retaining factor. Likewise, calculus formation on implant surfaces resulted in the development of peri-implant diseases. Anti-infective surgical peri-implantitis treatment, which included calculus removal, followed by supportive therapy was effective in the long-term in the majority of patients and implants (Berglundh *et al*. 2018; Heitz-Mayfield *et al*. 2018).

The presently available techniques used to remove deposits on the root surface cannot completely eliminate all calculus from diseased root surfaces. Factors such as anatomy, probing depth, instruments, and experience influence the efficacy (Jepsen *et al*. 2011). Some agents have been proven to reduce calculus formation (Jepsen *et al*. 2011). However, their effects appear to be limited to supragingival calculus and complete prevention cannot be achieved with them.

Conclusions

The mouth supports the establishment of diverse communities of microorganisms. These communities, and those present at other habitats in the body, play an active and critical role in the normal development of the host and in the maintenance of health. Clinicians need to be aware of the beneficial functions of the resident oral microbiome, so that treatment strategies are focused on the control rather than the elimination of these natural biofilms. Oral care practices should attempt to maintain plaque at levels compatible with health in order to retain the beneficial properties of the resident oral microbiota while preventing microbial excesses that increase the risk of dental diseases. Dental calculus represents mineralized bacterial biofilm. It is always covered by unmineralized viable bacterial biofilm, and hence, does not directly come into contact with the gingival tissues. Calculus, therefore, is a secondary etiologic factor for periodontitis. Its presence, however, makes adequate biofilm removal impossible and prevents patients from performing proper biofilm control. It is the most prominent biofilm-retentive factor that has to be removed as a basis for adequate periodontal and peri-implant therapies and prophylactic activities.

Periodontal infections

Introduction

Our mucosal surfaces are colonized by complex communities of microorganisms, or microbiota, which are uniquely adapted to the different environmental niches in the human body. This microbiota is composed of distinct and specialized microorganisms which are characteristic of the respective niche, for example, the mouth, the gastrointestinal, or the genitourinary tract (Fig. 9-1). Collectively, the microbiota on our mucosal surfaces and other anatomical locations in the body comprise the human microbiome which has become an area of intensive investigation in recent years because of the recognition that the balance between these organisms and the human host plays a fundamentally important role in our biology, the maintenance of our health, and the development of disease.

Of all the environmental niches in the human body, the oral cavity provides an optimal habitat for the growth of bacteria: a stable temperature, constant moisture, an abundant supply of nutrients and, uniquely, the hard surfaces of the teeth which provide a stable site for microbial attachment and accumulation. It is recognized that the different communities of organisms that colonize the distinct anatomical regions of the mouth (the tongue, the buccal and lingual mucosae, the supra- and subgingival surfaces of the teeth and so on) perform an important function in resisting colonization by other, potentially harmful organisms. In addition, recent evidence demonstrates that the oral microbiome may have other, unexpected benefits to the human host.

For example, dietary nitrate, concentrated in saliva to ten-fold the levels in the circulation, is reduced by members of the oral commensal microbiota (e.g. *Neisseriae* and *Rothia* spp.). The resulting microbially produced nitrite is swallowed and either absorbed through the gastrointestinal tract as nitrite or reduced to nitric oxide in the stomach where it contributes to gastric mucosa integrity and provides protection against colonization of the stomach by infectious agents (Kemmerly & Kaunitz 2013). Moreover, the absorbed nitrite in the circulation acts as a substrate for

the production of the potent vasodilator, nitric oxide, which in turn promotes vascular smooth muscle relaxation, lowering of blood pressure, and inhibition of platelet function (Koch *et al*. 2017). As higher-order animals including humans are not capable of reducing nitrate to nitrite, this enzymatic reduction step by the oral microbiome provides a good example of how the bacteria in the human mouth are important contributors to overall health. Indeed, it is suggested that interventionist approaches to positively manipulate this so-called "entero-salivary nitrate system" may provide a convenient means to counteract cardiovascular disease at a population level (Gee & Ahluwalia 2016).

Although there are clear health benefits from a harmoniously balanced oral microbiome and the human host, it is also clear that an imbalance in this relationship occurs in disease (Frank *et al*. 2011) and this is particularly evident in diseases of the periodontium. The evolutionary forces which shaped the development of a calcified dentition of animals have introduced a developmental weak spot from the perspective of infectious disease: nowhere else in the human body is the normally contiguous epithelial barrier of our mucosal surfaces breached by a solid structure which permits the development of a microbial biofilm in direct contact with the adjacent soft tissues. The defense to this challenge, which has co-evolved with the development of teeth, is a sophisticated set of specialized anatomical features supplemented by innate immune and inflammatory responses. The tooth surface at the gingival margin actively develops a dental plaque biofilm which is normally tolerated by the adjacent tissue. However, in disease there are significant alterations to this community of organisms likely driven by and contributing to the enhanced inflammatory conditions. The study of these communities, their transformation from health to disease, so called dysbiosis, and the role of this microbiota in the etiopathogenesis of periodontal pathology are described in the following sections.

Microbiological techniques to study the periodontal microbiota

Our understanding of the periodontal microbiota has undergone sequential stepwise changes over time following the introduction and application of increasingly more sophisticated and higher throughput methods for bacterial characterization and identification (Fig. 9-2). Analysis of the human oral microbiome extends back through history to the very first microscopic observations of bacteria over three centuries ago and continues apace to this day through the application of high throughput DNA sequencing techniques. The more recent techniques provide a description of this microbiota in extraordinary detail which was hitherto impossible. This century old tradition of oral microbiological analysis has placed our knowledge of the bacterial communities of the mouth at the very leading edge of our understanding of the human microbiome. From these investigations, it is now recognized that the oral microbiome is highly complex: approximately 1000 different microorganisms are able to stably colonize the human mouth. Any one individual may harbor 200–300 microbial species and the composition of this community is a personalized signature which differentiates them from other individuals. However, in the case of diseases involving a complex microbial etiology, where the fundamental basis is one of dysbiosis, or perturbation of a normal commensal microbiota, the description of the infectious challenge is more demanding. Here, the accuracy of the description is intimately linked to the effectiveness of the technology available to quantitatively and qualitatively determine the composition of a complex microbial mixture.

The initial description of bacterial cells in the oral cavity was performed by Antonie van Leeuwenhoek, who in 1676 used the newly invented microscope, to describe the "animacules" in the biofilms from human teeth. In the intervening period our understanding of the complexity, site specificity, and environmentally driven nature of these microbial communities has expanded with each technological advance in microbial identification and classification. Advances accompanied the introduction of standardized cultural techniques on solid media, the development of anaerobic culture systems, the introduction of non-cultural techniques for bacterial identification and the use of molecular phylogeny through nucleic acid analyses using DNA:DNA hybridization, the polymerase chain reaction (PCR), Sanger DNA sequencing, and the more recent developments in high throughput pyro-sequencing and metagenomics (Wade 2011). These cultural and non-cultural investigations have now culminated in the development of the Human Oral Microbiome Database (http://www.homd.org) which lists all bacterial species found in the human mouth (Dewhirst *et al*. 2010).

The progress made in describing the etiological agents of infectious diseases in the late nineteenth and early twentieth century naturally led to a search for the causative organisms involved in periodontal infections. However, these investigations were restricted by the techniques available for either visual inspection of subgingival samples or by the relatively primitive cultural techniques that had been developed at this early phase of the discipline of microbiology. As a result of the inability to accurately define the etiological agent(s) of the disease, in contrast to the great strides being made elsewhere in describing the causative organisms in the major, mono-specific infectious diseases, there was a loss of impetus in microbiological research into periodontal infections in the early decades of the 20th century. A summary of these early descriptions was summarized by Socransky and Haffajee (1994).

Introduction of anaerobic techniques

A major breakthrough in our understanding of the complexity of the periodontal microbiota was achieved through the introduction of methods which allowed the laboratory culture of anaerobic microorganisms. The low oxygen levels in the subgingival biofilm are highly permissive for the growth of obligately anaerobic bacteria and hence a significant fraction of the total periodontal microbiota had been largely undetected in previous microbiological investigations conducted under aerobic conditions. This technological advance included the use of anaerobic roll tubes and anaerobic jars which could be flushed with oxygen-free gases and then sealed to prevent the access of air. More latterly, anaerobic chambers were developed which enabled the culture of anaerobic bacteria on both solid and liquid media in a relatively spacious, low oxygen environment periodically flushed with a mixture of nitrogen, carbon dioxide, and hydrogen.

These studies were pioneered by several oral microbiology laboratories throughout the 1970s and 1980s (Socransky 1970; Slots 1976, 1977; Tanner *et al*. 1979; Slots & Rosling 1983; Haffajee *et al*. 1984; Christersson *et al*. 1985; Dzink *et al*. 1985; Loesche *et al*. 1985; Dzink *et al*. 1988; Haffajee *et al*. 1988; van Winkelhoff *et al*. 1988; Zambon *et al*. 1988; Tanner & Bouldin 1989) but, because of the highly labor intensive nature of the methodology, were usually limited to the analysis of relatively few periodontal subjects. Importantly, however, these investigations began to put clear definition to the very significant qualitative differences in the overall microbiota present at periodontally diseased sites compared with control healthy sites and to identify some of the key, characteristic organisms which were frequently associated with disease. The exhaustive investigations conducted in the Virginia Polytechnic Institute laboratories of Holdeman and Moore (Moore 1987) were typical of these investigations and are among the most influential studies of the total, cultivatable, anaerobic microbiota. Studies of this kind began

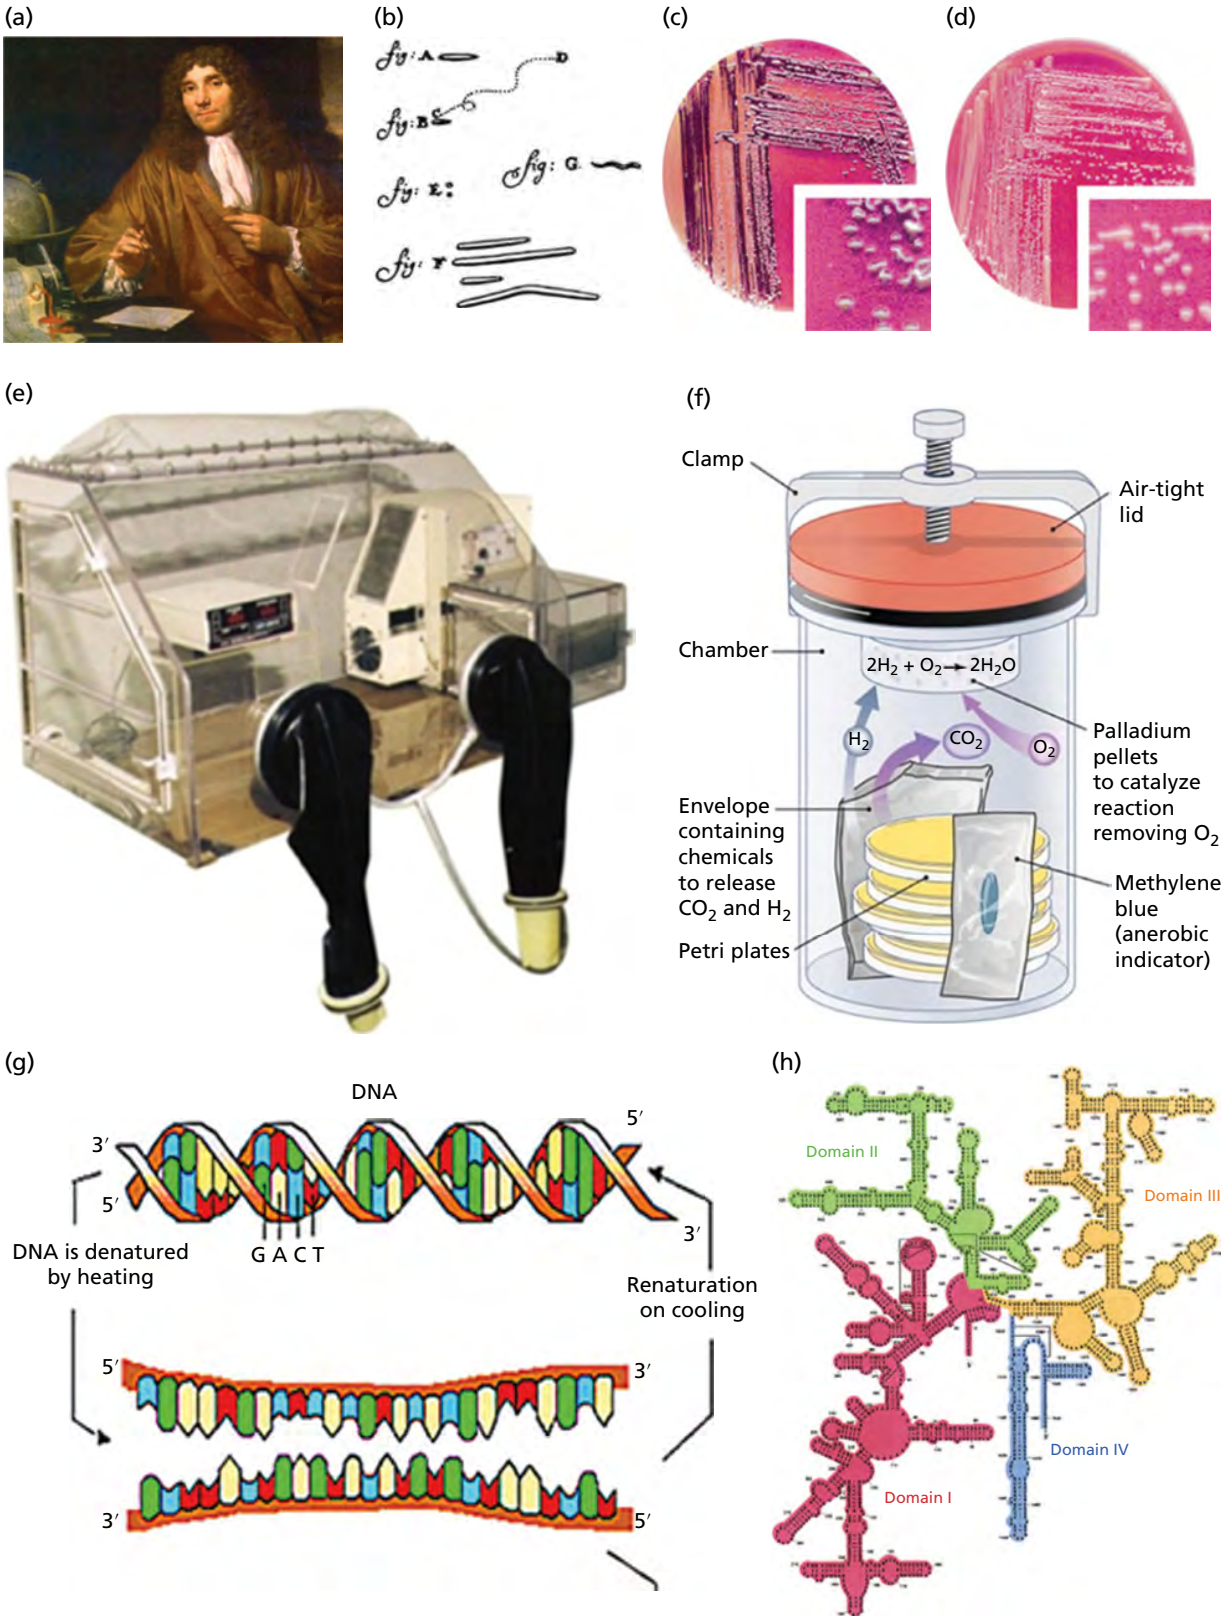

Fig. 9-2 Technological advances linked to increased understanding of the oral microbiota. Appreciation of the complexity of the oral microbiota has increased with the development of technology. Microscopy: (a) Antonie van Leeuwenhoek who used the first microscopes to characterize dental plaque bacteria (b). to convincingly reveal the sheer complexity of the microbiota in periodontal disease to a level that had hitherto been unseen and began to develop a reference catalogue of bacterial taxa which would prove invaluable for later investigations. Furthermore, those bacteria which were significant components of the subgingival plaque from diseased sites were also frequently present, albeit at reduced levels in supragingival samples, and vice versa. Indeed, several studies demonstrated that many of the bacteria positively associated with the microbiota at a diseased subgingival site were also present in healthy subgingival sites. These investigations indicated that a specific etiology for the periodontal disease process could only be explained on the basis of a quantitative rather than solely qualitative perspective. To gain sufficient power to address the nature of the etiology it would be necessary to perform studies involving significantly more samples/subjects than was feasible by this total microbiological analysis approach which was typically restricted to investigations on relatively small numbers of individuals. However, these large scale anaerobic microbiological analyses on a relatively few samples had provided several valuable, potential "specific periodontal pathogens" for future studies.

Targeted analysis of periodontal microbiota

Having developed a candidate list of putative periodontal pathogens, it became possible to perform rather more targeted investigations which aimed to focus on detection of this group of bacteria in larger numbers of clinical samples than it was feasible to process when the entire cultivatable microbiota was examined. These investigations relied upon the application of a combination of identification approaches: novel selective media for the enrichment or selective culture of specific bacteria; immunological techniques using newly developed monoclonal antibodies or polyvalent sera to individual species; or microscopy for the identification of spirochaetes. For example, Bragd *et al*. (1987) used a selective media approach to evaluate the association of *Actinobacillus* (now *Aggregatibacter*) *actinomycetemcomitans, Bacteroides* (now *Porphyromonas*) *gingivalis*, and *Bacteroides (Prevotella) intermedia* in over 200 samples from progressing and non-progressing periodontal sites. Similarly Slots *et al*. (1990) employed a cultural approach to examine the influence of subject age on the prevalence and recovery of *A. actinomycetemcomitans* and *B. intermedius* in 1624 patients aged between 15 and 89 years. Grossi *et al*. (1995) used an immunochemical approach to assess the presence of eight candidate periodontal pathogens in a study involving 1361 subjects to identify risk markers for periodontal bone loss. Suda *et al*. (2002) used an indirect immunofluorescence approach to enumerate the levels of *Eikenella corrodens* in samples from over 250 periodontal and control samples and Riviere *et al*. (1997) used a similar antibody and microscopy-based investigation to determine the levels of different spirochaetes in an analysis of the development of periodontal disease using over 1000 samples from 65 subjects.

By focusing on a small group of candidate organisms using relatively high throughput approaches it became possible to design appropriately statistically powered investigations to address a number of key issues relevant to the etiology and treatment of periodontal disease. These included the presence of these candidate periodontal pathogens in different global populations (van Winkelhoff *et al*. 1999) studies of the association between different organisms such as *Bacteroides forsythus* and *Bacteroides gingivalis* (Gmur *et al*. 1989), their spatial distribution in plaque (Kigure *et al*. 1995), the association with disease of different morphotypes of the same species, such as the smooth and rough colony types *Peptostreptococcus micros* (van Dalen *et al*. 1998; Kremer *et al*. 2000) and the effect of treatment on persistence/eradication of these key organisms (Mandell *et al*. 1986; Rodenburg *et al*. 1990; Mombelli *et al*. 2000). Furthermore, when isolation and identification of a specific organism was coupled to more detailed characterization of the individual strain (by for example restriction digestion of the isolates' DNA followed by separation by agarose electrophoresis) it became feasible to perform transmission studies. Notably, Petit *et al*. (1993a, b) and Van Steenbergen *et al*. (1993) used this approach to demonstrate that *P. gingivalis* was transmitted between spouses and that intrafamilial transmission of individual strains of *P. intermedia* and *P. nigrescens* also occurred.

Other investigations utilized these selective methodologies to examine the association of alternative bacterial species with periodontal disease in addition to the, by now well-established periodontal bacteria mentioned above. In so doing the list of bacterial species positively associated with periodontal disease, in particular adult disease, was extended to include for example, *Wolinella* (now *Campylobacter*) *recta* (Lai *et al*. 1992; Rams *et al*. 1993), Enterococci (Rams *et al*. 1992), *P. micros* (van Dalen *et al*. 1998), eubacterial species (Grossi *et al*. 1995), *E. corrodens* (Suda *et al*. 2002), *Fusobacterium nucleatum* (van Winkelhoff *et al*. 2002), and other species. Hence, although a specific microbial etiology for periodontal disease was still considered by many to be the most reasonable interpretation of the accumulated data, there was an acceptance that the nature of the microbial challenge, particularly in the case of chronic adult periodontitis, was highly complex and likely to vary significantly between individuals and potentially within an individual at different sites and at different times (Maiden *et al*. 1990).

In contrast to adult-type chronic periodontitis, in one particular instance of aggressive periodontitis affecting adolescents of African descent, there is evidence to suggest that a single specific

microbial etiology may be responsible for the development of disease. *A. actinomycetemcomitans* is a Gram-negative rod that produces a leucotoxin that specifically lyses human neutrophils. The organism displays significant genetic diversity, but one particular clone, referred to as JP2, has a number of genetic variations that distinguish it from other clonal types, including a 530 base pair deletion in the promoter region of the leucotoxin gene operon. As a result, the JP2 clone produces significantly enhanced levels of leucotoxin compared to the other lineages of this bacterium which could theoretically lead to an enhanced potential to disrupt the immune defenses of the periodontium. Population genetic analysis by multilocus sequencing of *A. actinomycetemcomitans* strains from geographically dispersed individuals suggest that the JP2 clone originally emerged as a distinct genotype in the Mediterranean part of Africa over 2000 years ago and subsequently spread to West Africa, from where it was transferred to North and South America by the trans-Atlantic slave trade in the sixteenth to eighteenth centuries. Remarkably, despite its now global dissemination, the JP2 clone still remains exclusively associated with individuals of West African descent, indicating a strong host tropism effect (Haubek *et al*. 2008). Although the prevalence of aggressive periodontitis in adolescents is normally <1%, it is far higher in individuals of North and West African descent. In a longitudinal study of the disease in Moroccan adolescents, 61 of 428 (14.3%) individuals who were periodontally healthy at baseline had developed disease after 2 years. Moreover, in this population, individuals who carried the JP2 clone at baseline were far more at risk of developing disease than those who carried non-JP2 clones of this bacterium (relative risk 18.0 versus 3.0) (Haubek *et al*. 2008). Hence, the JP2 clone of *A. actinomycetemcomitans* has the characteristics of a traditional bacterial pathogen, albeit in a host-restricted background.

Introduction of nucleic acid-based techniques for bacterial identification

With the development of a catalogue of the major cultivatable species in the periodontal microbiota came the need to develop more rapid, less time-consuming and laborious methods for larger scale epidemiological analyses of the association of these organisms with health and disease. This was accomplished through the introduction of techniques that were not reliant on culture immediately following sample collection. The most commonly used of these were analyses based on nucleic acid approaches – PCR amplification of specific regions of the chromosome of the target organism, usually the *16S rRNA* gene, followed by quantitation of the product and DNA:DNA hybridization techniques.

Use of the DNA:DNA checkerboard methodology

A step change in the potential throughput of microbiological analyses of periodontal plaque samples arrived with the introduction and application of DNA:DNA hybridization technology. The development of the checkerboard assay allowed the simultaneous hybridization of 45 individual DNA samples extracted from periodontal plaque against 30 different DNA probes on a single membrane. The DNA probes can either be prepared from whole genomic DNA extracted from the relevant target bacterium or alternatively PCR amplicons of bacterial species-specific regions of the *16S rRNA* gene. Hybridization of the sample DNA with the probe DNA is then visualized via a chemifluorescent signal, the intensity of which is proportionate to the amount of the target organism DNA present in each sample.

Although there are some limitations to the accuracy of identification of individual bacterial species because of potential cross-hybridization of DNA from closely related bacterial species in the same clinical samples, application of this technology revolutionized the analysis of clinical samples and the ability to make definitive bacterial associations with periodontal health and disease. Now it was possible to perform qualitative and quantitative analysis of the bacterial composition of far, far greater numbers of clinical samples than the previous culture-based methodologies. For example, in a landmark investigation, Socransky *et al*. (1998) analyzed approximately 13 000 plaque samples from 185 subjects using whole genomic DNA probes to 40 bacterial species (Fig. 9-3). Associations were sought among species using cluster analysis and community ordination techniques. One of the key and fundamentally important findings of this study, which has shaped our understanding of periodontal infections, was the definition of bacterial complexes, as opposed to individual bacterial species, which were associated with either periodontal health or periodontal disease (Fig. 9-4).

This finding led to the concept that there may be a co-dependency or synergy between different bacterial species acting in concert as a specific complex. The complex most strongly associated with periodontal disease, the "red complex", was composed of three bacterial species which subsequently became the focus of intense investigation: *P. gingivalis*, *Treponema denticola*, and *Tannerella forsythia*. Other complexes, for example the yellow complex which comprised predominantly different streptococcal species, and the green complex which contained a preponderance of *capnocytophaga* species, represented early colonizers of dental plaque which were more closely associated with health. The orange complex contained those organisms generally considered to colonize dental plaque later: fusobacteria species, members

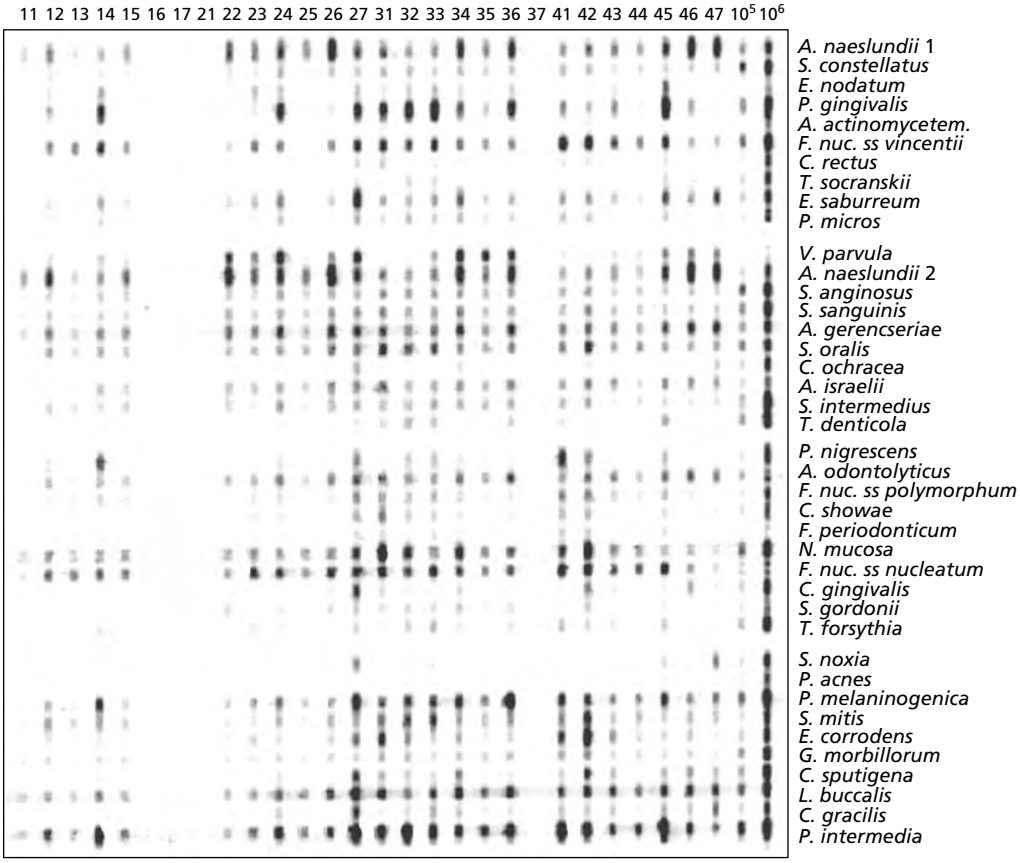

Fig. 9-3 The vertical lanes are the plaque samples numbered 11–47 and two lanes of standards on the far right contain either 105 or 106 cells of each test bacterial species. The horizontal lanes contain whole genomic DNA probes labelled with digoxygenin to each represented bacterium. A signal at the intersection of the vertical and horizontal lanes indicates the presence of a bacterial species and the intensity of the signal is related to the number of bacterial cells present. The methodology enables the simultaneous and rapid analysis of 40 different bacterial species in 28 different plaque samples. (Source: Reprinted from Socransky & Haffajee 2008, with permission of Wiley-Blackwell.)

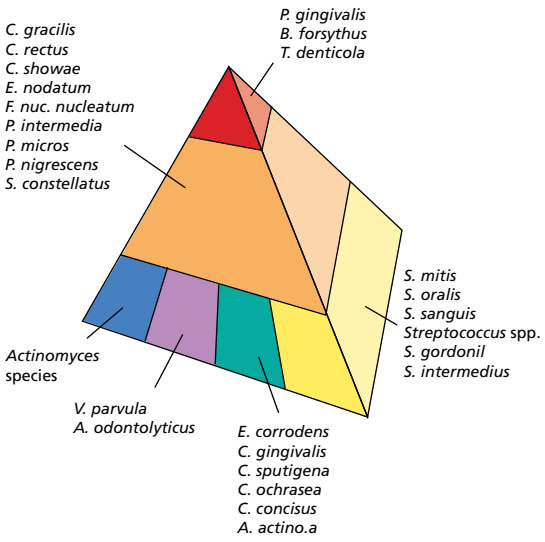

Fig. 9-4 The association among subgingival species. The different colors in the pyramid represent different bacterial complexes which are frequently detected in association with one another. The base of the pyramid represents the early stage of plaque development whereas the apex contains those organisms thought to be the last species to become established in the microbiota. The red complex of bacteria are those organisms frequently associated with sites of periodontal disease. (Source: Reprinted from Socransky & Haffajee 2002, with permission.)

of the *Prevotella* and the *Campylobacter* genera. The presence of these organisms is now thought to facilitate colonization of mature dental plaque by the red complex organisms either through the presentation of appropriate binding sites or by the creation of a suitable environment for the growth of these more fastidious species.

It is noteworthy that *A. actinomycetemcomitans*, the bacterium associated with rapidly progressive disease in individuals of West African descent, does not cluster with the most disease-associated red complex organisms. This probably reflects the very large effect of the host genetic background on the disease associated with this bacterium as described previously. Use of the checkerboard technology enabled a range of questions to be addressed concerning, for example, the sequential changes that occur in the composition of supragingival and subgingival plaque during development and the qualitative and quantitative influence of tooth cleaning on the microbiology of supra- and subgingival plaque. An example of this kind of study is shown in Fig. 9-5 which demonstrates the significant qualitative and quantitative differences associated with disease not only in subgingival but also supragingival plaque.

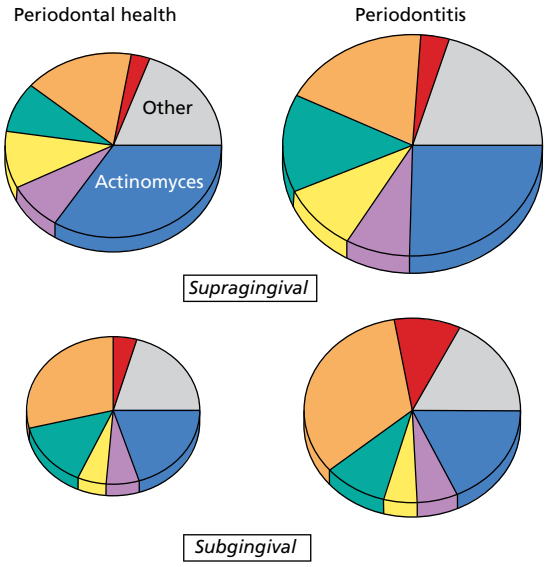

Fig. 9-5 The mean percentage DNA probe count of microbial groups in supragingival and subgingival plaque. Plaque samples from periodontally healthy (58) and periodontitis (136) subjects and subgingival plaque samples from periodontally healthy (189) and periodontitis subjects (635). The species were grouped into seven microbial groups based on the description of Socransky *et al.* (1998) and described in more detail in Fig. 9.4. The "other" category represents probes to species that did fall into a complex as well as probes to new species whose relationships with other species has not yet been ascertained. The areas of the pies were adjusted to reflect the mean total DNA probe counts at each of the sample locations. The significance of differences in mean percentages of the supra- and subgingival complexes in health and disease was tested using the Kruskal Wallis test. All complexes differed significantly among groups at $P < 0.001$ after adjusting for seven comparisons. (Source: Reprinted from Socransky & Haffajee, 2008, with permission of Wiley-Blackwell.)

PCR amplification of *16S rRNA* gene of periodontal bacteria

16S ribosomal RNA (or *16S rRNA*) is a component of the 30S small subunit of all bacterial ribosomes. The genes coding for it are referred to as 16S rDNA. Although the sequences of 16S rDNA are highly conserved between different bacteria, they also contain hypervariable regions that can provide species-specific signature sequences useful for bacterial identification. Therefore, once the sequence of a 16S rDNA gene from a bacterium has been determined, it is possible to design a PCR, using primers which will anneal to sequences within the hyper-variable regions, which will specifically amplify only the 16S rDNA from the target bacterium. The great advantages of the application of this methodology to the detection of periodontal bacteria in clinical samples is the high sensitivity of detection, the high throughput which can be attained, the speed of assay, and that multiple bacterial species can be detected in the same reaction – multiplex PCR. As a result, this technology has been used extensively for the detection of putative periodontal pathogens. Typically, these studies focused on the detection of only a few bacterial species including the well-established periodontal bacteria *P. gingivalis*, *Tannerella forsythia*, *Treponema denticola*, and *A. actinomycetemcomitans* (Leys *et al*. 2002; de Lillo *et al*. 2004; Sanz *et al*. 2004; Tanner *et al*. 2006). However, studies involving PCR amplification of the 16S rDNA gene have also been used to confirm the presence of novel and, in some instances non-culturable, bacterial species whose presence was originally identified by cloning and sequence analysis of the 16S rDNA in periodontal samples. These investigations confirmed that several additional species, including those that have not yet been grown *in vitro*, were associated with oral health or periodontitis. These molecular studies have significantly extended the number of potential periodontal pathogens. For example, based on their 16S rDNA analysis of subgingival plaque samples from healthy subjects and subjects with refractory periodontitis, adult periodontitis, human immunodeficiency virus periodontitis, and acute necrotizing ulcerative gingivitis, Paster *et al*. (2001) described several new candidates. Species or phylotypes commonly detected in disease but rarely in health included *Eubacterium saphenum*, *Filifactor alocis* (previously *Fusobacterium alocis*), *Catonella morbi*, *Megasphaera* sp., *Dialister* sp., and *Selenomonas sputigena*, and several of these organisms, in particular *Filifactor alocis* have subsequently been confirmed to be positively associated with disease in other studies.

The initial studies in this area were largely qualitative in nature in that they only determined whether an organism was present or absent (or more correctly below the limits of detection of the assay – typically 100 bacterial cells). Subsequently, real-time PCR, also referred to as qPCR or qRT-PCR, has been introduced which quantifies the numbers of copies of the gene of interest in a given sample. Real-time PCR has been used to detect and quantify several periodontal pathogens including *A. actinomycetemcomitans*, *P. gingivalis*, *P. intermedia*, and total bacteria, in clinical samples (Lyons *et al*. 2000; Maeda *et al*. 2003; Boutaga *et al*. 2007; Atieh 2008). Studies of this nature are now being superseded by the application of high throughput, next generation sequencing methodologies described in a following section.

The human oral microbe identification microarray

Recognition of the increased and substantial microbial diversity of dental plaque led to the development of new diagnostic methodologies capable of the rapid identification of greater numbers of bacterial phylotypes in periodontal infections (Paster & Dewhirst 2009). The Human Oral Microbe Identification Microarray (HOMIM) was developed in order to examine the complex oral microbial diversity in a single hybridization on glass slides (Paster *et al*. 2006; Preza *et al*. 2008, 2009b). This high sample-throughput, *16S rRNA*-based technology allows the simultaneous detection of approximately 300 key and predominant bacterial species,

including species that have not yet been cultivated *16S rRNA*-based, oligonucleotide probes are printed onto glass slides. The *16S rRNA* genes in clinical samples are PCR amplified using *16S rRNA* universal forward and reverse primers, fluorescently labeled and then hybridized to the probes on the slides. In order to analyze the large datasets from HOMIM arrays, individual signals are translated into a "bar code" format in which the bands correspond to the presence or absence of a particular organism and band intensities reflect the organism's abundance. The bar code format of HOMIMs comparing the microbial profiles of approximately 300 bacterial species from subjects with periodontal health and periodontitis is illustrated in Fig. 9-6. These data can be analyzed further to determine specific bacterial associations (Colombo *et al*. 2009; Preza *et al*. 2009a, b) or the relationships of *entire* microbial populations with respect to health and disease using correspondence analysis, as shown in Fig. 9-7. The dramatic difference in the overall bacterial population structure of these two sets of data vividly reinforces the findings of the total cultural microbiology studies performed some 30 years ago and is consistent with dysbiosis of the microbiota as a defining characteristic of periodontal disease.

Use of this array-type technology for relatively rapid semiquantitative analysis of the microbial community composition in periodontal research investigations is still widely used (Paes Batista da Silva A *et al*. 2016; Cui *et al*. 2019). However, there is now a growing consensus that next generation sequencing technologies, based on *16S rRNA*, provide significantly expanded oral bacterial species identification and hence a more comprehensive representation of oral bacterial community structure (Mougeot *et al*. 2016).

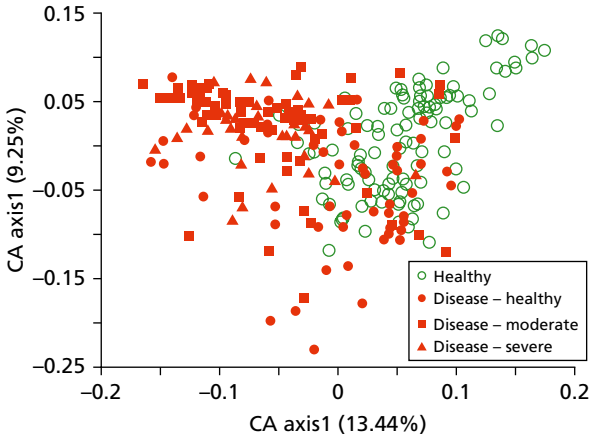

Fig. 9-7 Correspondence analysis of subgingival plaque bacterial communities in health and disease. Each symbol represents one community from one site. Communities that are closer together have more similar HOMIM profiles. In this plot, the healthy sites from healthy subjects (green circles) are distinct from healthy and diseased sites in diseased subjects (red symbols). (Source: Courtesy of Dr. Vanja Klepac-Ceraj: Forsyth Dental.)

Unculturable bacteria in the periodontal microbiome

The introduction of non-culture-based methods for description of the total microbial population of oral samples led to a recognition that a significant proportion of oral bacteria are unculturable and can only be detected using molecular techniques. This phenomenon is also recognized in other sites of the human body and environmental samples such as the soil and the river water. Particular interest in the periodontal research field has focused recently on the TM7 phylum (now renamed Saccharibacteri*a*) (Bor *et al*. 2019).

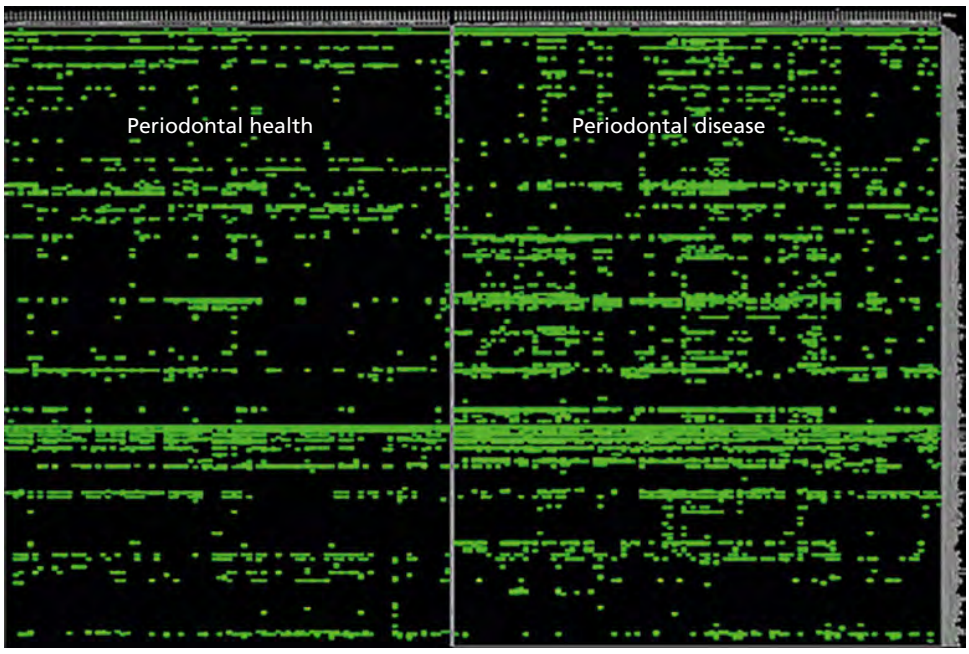

Fig. 9-6 Bacterial profiles of 461 bacterial taxa (representing approximately 300 species) comparing subgingival plaque from 105 healthy sites in periodontally healthy subjects ($n = 20$) with 154 diseased sites from periodontally diseased subjects (n = 47). (Source: Reprinted from Paster & Dewhirst 2009, with permission, figure courtesy of A.P. Colombo.)

This phylum belongs to a newly described bacterial major lineage or superphylum called Candidate Phylum Radiation (CPR) potentially containing over 70 phyla. Remarkably, the CPR may account for more than 25% of all bacterial diversity. TM7 bacteria are present in the microbiome at a variety of sites in the human body including the gastrointestinal tract, skin, and female genital tract (Brinig *et al*. 2003; Eckburg *et al*. 2005; Fredricks *et al*. 2005; Gao *et al*. 2007). Furthermore, the detection of TM7 using *16S rRNA* gene sequencing of the calcified dental plaque (calculus) from Neanderthal specimens suggests that these organisms have been constituents of the oral microbiome throughout human evolution (Brinig *et al*. 2003; Weyrich *et al*. 2017).

Until recently, there was little information on the biology of this group of organisms. However, insights into the TM7 lifestyle and genomics have begun to emerge following the first successful cultivation of a member of this phylum – TM7x (HMT_952) from the oral cavity (He *et al*. 2015) (Fig. 9-8). The isolation procedure involved targeted antibiotic enrichment with a culture medium that supports the growth of TM7 bacteria in an *in vitro* multispecies oral microbial community (Tian *et al*. 2010; Edlund *et al*. 2013). These studies have demonstrated that the TM7 are very small bacteria of approximately 200–300 nm, with a reduced genome size of 20–25% of most other oral bacteria. Furthermore, they are highly specialized obligate parasites of other bacteria. Although, there are many examples of parasitism of eukaryotic organisms by prokaryotes, the *in vitro* co-culture studies of the oral TM7x (HMT 952) with its host bacterium, *Actinomyces odontolyticus*, was the first ever demonstration of one bacterium able to parasitize another. As obligate parasites, TM7 organisms will represent a burden to their host bacteria and a number of negative consequences have been reported including reduced cellular growth rate and division, increased stress responses (Bor *et al*. 2019), and cell lysis under certain circumstances (He *et al*. 2015). Paradoxically, however, there may also be positive outcomes for the host bacterium including an increased tendency to form biofilms in the presence of TM7 and a subversion of the usual host response to the parasitized bacterium (Bedree *et al*. 2018).

Emerging evidence indicates that these obligately parasitic bacteria may have a role to play in the development of disease based on an increase abundance of TM7 in the microbiota associated

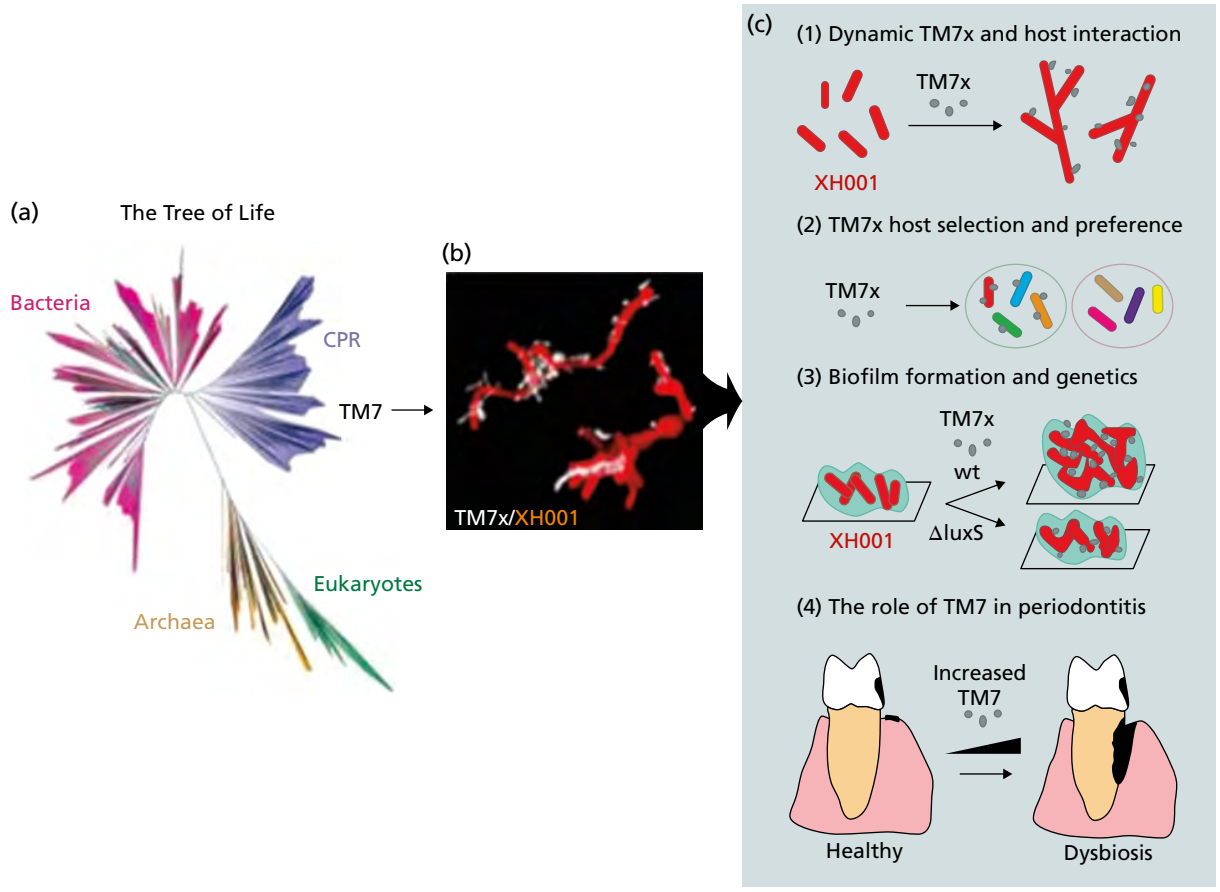

Fig. 9-8 TM7x represents the first Candidate Phylum Radiation (CPR) bacteria co-cultivated with its host. (a) Current view of the tree of life highlights TM7 and CPR. (b) Fluorescence *in situ* hybridization image shows the parasitic relationship between TM7x and its bacterial host XH001. (c) TM7x/XH001 provides a better understanding of bacterial epiparasitic interaction: (1) a detailed mechanistic understanding of the dynamic parasitic interaction between TM7x and its host bacterium XH001; (2) the host selection and host range of TM7x; (3) the impact of interaction on bacterial physiology; and (4) pathogenic potential. with inflammatory disease including gingivitis and periodontitis (Brinig *et al*. 2003; Fredricks *et al*. 2005; Kuehbacher *et al*. 2008). In health, TM7 is normally present in low amounts of the order of 1% of the total microbiota (Brinig *et al*. 2003; Podar *et al*. 2007). However, significantly greater levels of TM7 were associated with gingivitis severity and periodontal disease (Paster *et al*. 2002; Brinig *et al*. 2003; Rylev *et al*. 2011; Liu *et al*. 2012; Kistler *et al*. 2013; Camelo-Castillo *et al*. 2015). Furthermore, the elevated levels in gingivitis appear to reduce after successful treatment (Huang *et al*. 2016). As a result of these studies, TM7 bacteria are now considered to be members of the core microbiota associated with periodontal disease (Abusleme *et al*. 2013).

The mechanism through which members of the TM7 may actively contribute to the pathogenesis of disease has not been established. However, given that these parasitic organisms interact with key members of the overall microbial community – *Actinomyces* spp. are now well-established hosts but it is likely that there will be many other examples – TM7 bacteria may play a significant role in modeling the composition of the periodontal microbial community structure, its activity, and its interaction with the immune and inflammatory response.

The next generation sequencing revolution

Sequence analysis of *16S rRNA* has become the method of choice for detection of culturable and non-culturable bacteria because of its universal presence in all organisms and because, through PCR primer design, it is possible to describe either all the species present in a given sample or target specific genera. Application of this approach led to the description of 13 phyla in the domain Bacteria in the human oral microbiome: Actinobacteria, Bacteroidetes, Chlamydiae, Chloroflexi, Euryarchaeota, Firmicutes, Fusobacteria, Proteobacteria, Spirochaetes, SR1, Synergistetes, Tenericutes, and TM7 in addition to methanogenic species of the *Methanobrevibacter* genus from the domain Archaea. Several hundred distinct species are contained within these divisions, representing the highly diverse microbial communities of the mouth (Dewhirst *et al*. 2010).

Application of next generation DNA sequencing (NGS) of 16s rRNA to the oral and periodontal microbiota is the newest technological advance in our study of the complex communities of bacteria which colonize the subgingival area in health and disease. The procedures build upon advances in both high throughput DNA sequencing technologies and bioinformatic tools to aid data analysis. Following extraction, the total DNA in a clinical sample is subjected to PCR amplification using a PCR primer set that targets a taxonomically informative region of the 16s rRNA: small fragments usually covering one or two hypervariable regions (such as V1–V3, V4, or V4–V5 regions) of the *16S rRNA* gene. After amplification, the resultant amplicons are sequenced and then mapped to a reference 16S sequence database for taxonomic identification and abundance estimation. Advances in NGS technology including extensive multiplexing of samples, now permits rapid analysis of hundreds of samples and the analysis of millions of PCR amplicons in a single NGS run.

Although the high-throughput sequencing of *16S rRNA* genes can usually profile taxonomic composition at the genus or species level, whole genome sequencing (metagenomics) can potentially provide species- or even strain-level taxonomic resolution in microbial population analysis. This may be particularly important where genetic variability within a given bacterial species leads to the appearance of potentially more virulent strains or clonal types which would not be detected by the analysis of *16S rRNA* sequencing. Furthermore, metagenomics provides more information regarding metabolic characteristics and enables an understanding of the functional capacities of microbial communities. Metagenomics based on NGS identifies the sequence of entire genomes by producing random fragments of DNA (25–500 bp) and comparing these to reference genome databases.

Over the last decade these approaches have been applied to the community composition of the periodontal microbiome in health and disease (Griffen *et al*. 2012; Abusleme *et al*. 2013; Kirst *et al*. 2015; Hong *et al*. 2015). The results have largely agreed with earlier cultivation-based and low throughput molecular analyses but at a far greater taxonomic resolution of the overall community. It is now broadly recognized that the diversity of the microbiota and hence its complexity increases in periodontitis compared with health. The increased diversity appears to be a consequence of the outgrowth of organisms present at only low abundance in health, rather than the exogenous acquisition of new organisms. Shifts in the microbiota which accompany gingivitis are different to those observed in periodontitis, with gingivitis potentially representing a transitional stage from health to disease. Similar to earlier studies, the community biomass increases significantly from health to gingivitis and then to periodontitis (Diaz *et al*. 2016).

An additional finding from these subgingival microbiome characterizations via *16S rRNA* gene sequencing is the identification of species whose proportions do not change from health to disease. These species are referred to as core species, as they are present in similar proportions regardless of health status. Core species represent bacteria capable of interacting with health-associated and periodontitis-associated community members. Two of the most consistently detected species in this group are *Campylobacter gracilis* and *F. nucleatum* ss. *vincentii*. The latter is also a very abundant component of both healthy and periodontitis-associated plaque and has been suggested as an important component of plaque structure because of its ability of coaggregation with many other species (Kolenbrander *et al*. 2010).

A summary of the key species most strongly associated with health or periodontitis, based on their repeated appearance in NGS analyses conducted by different groups in distinct patient cohorts is shown in Fig. 9-9 (Curtis *et al*. 2020). *Actinomyces* spp., *Rothia* spp., and *Streptococcus sanguinis* are the main health-associated taxa which are reduced in periodontitis and a diverse group of mostly Gram-negative species are enriched in periodontitis. The greater number of species associated with periodontitis than species associated with health is consistent with the higher diversity of periodontitis communities, in which species are more evenly distributed and therefore more species can be detected with a similar sequencing effort than in the less diverse healthy communities, which tend to be dominated by a few taxa. In summary, periodontitis is accompanied by profound shifts in the composition of subgingival communities, with the emergence of, for the most part, different Gram-negative species to those enriched during gingivitis, that outgrow health-associated taxa. Among enriched species are the previously described red complex triad composed of *Treponema denticola*, *P. gingivalis*, and *Tannerella forsythia* (Fig. 9-9). However, several other *Treponema* spp. also appear as abundant components of periodontitis communities, again in agreement with the early microscopy studies, which indicated the abundance of spirochaetes was associated with the severity of periodontal destruction (Armitage *et al*. 1982). *P. intermedia*, *Filifactor alocis*, *Desulfobulbus* sp. HOT 041 and *Fretibacterium* sp. HOT 360, among others, are also abundant components of periodontitis communities (Curtis *et al*. 2020). The shift in the microbial community structure of the periodontal microbiome is referred to as dysbiosis, meaning a deleterious change to a microbiota which is no longer in balance with the host, as opposed to symbiosis, the situation in health, where the host and its resident microbiota are in homeostatic equilibrium (Curtis *et al*. 2011).

Periodontal bacteria and virulence

In addition to dysbiosis, several other characteristics of this microbiota need to be considered to appreciate properly the role of bacteria in periodontal disease. First, the growth of these organisms in a subgingival biofilm leads to a number of characteristics which define the biology of these organisms and can present a unique challenge to the adjacent tissues. These include: interbacterial nutritional dependencies and communication; the development of specific

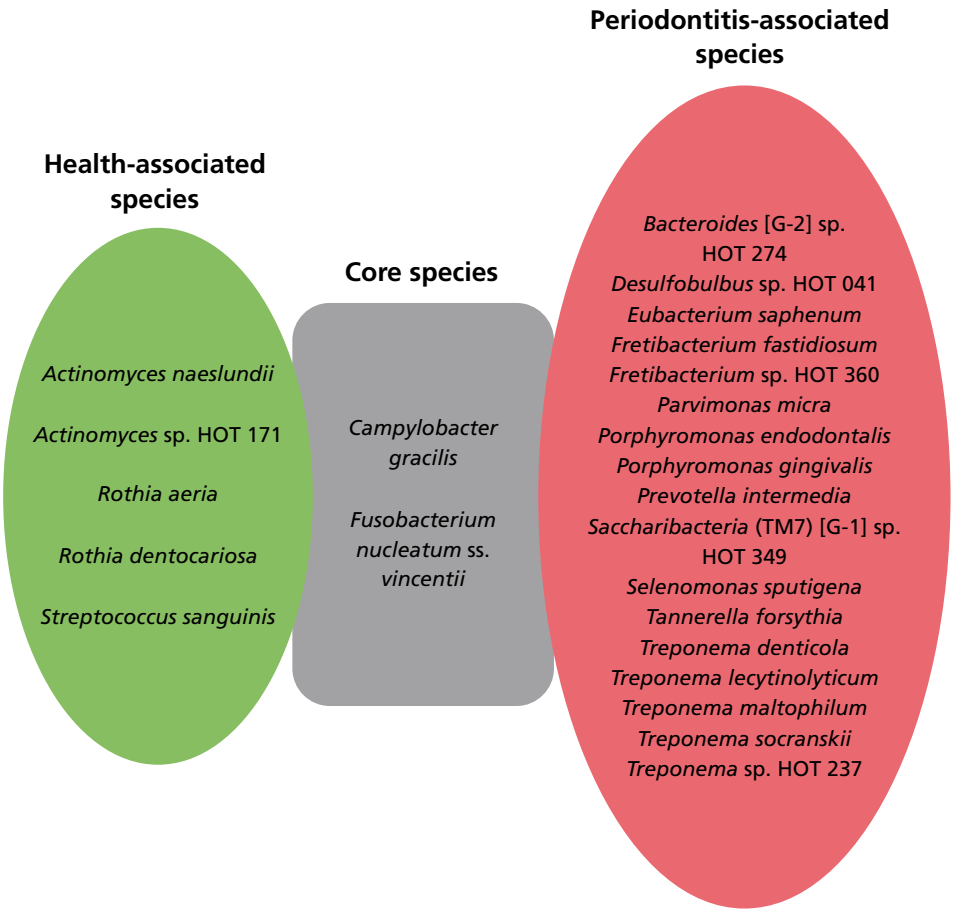

Fig. 9-9 Health-associated, periodontitis-associated, and core species of the subgingival microbiome. The green and red circles show species with significantly increased proportions in either health or periodontitis and therefore strongly associated with health or disease. The gray circle indicates core species, which are those with unchanged proportions in health and periodontitis. (Source: Adapted from Curtis *et al*. 2020.)

consortia of different bacterial species which may act cooperatively in the presentation of a microbial challenge; an optimal environment for genetic exchange between different species and, finally, resistance to the immune and inflammatory clearance mechanisms of the host and to chemical antimicrobial agents. A more detailed description of the consequences of the biofilm lifestyle adopted by dental plaque bacteria is given in Chapter 8. Secondly, analysis of the population structure of some of the bacterial species associated with periodontal disease reveals significant genetic differences which, in some instances, has a defining role in the pathogenic variation within an individual species. Third, analysis of the properties of bacterial species frequently present in a dysbiotic periodontal microbiota has demonstrated that the ability to successfully manipulate elements of the innate and inflammatory response is a common characteristic of these microorganisms and may indeed represent an overriding principle of periodontal virulence.

The virulence of a microbial pathogen is generally defined as the degree of pathogenicity or ability of the organism to cause disease measured by an experimental procedure. It represents a combination of highly complex parameters and depends upon both the relative infectivity of the organism and the severity of the disease produced. However, in all cases these two parameters of infectivity and disease severity are profoundly influenced by the nature and status of the host organism or the site of colonization in that host. Thus, a breach in the normal defensive barriers of the host, for example, trauma, immunosuppression/dysfunction, or coinfection by another organism, can dramatically increase the virulence of a given organism. Hence, any description of microbial virulence is fundamentally reliant on an understanding of the relative susceptibility of the colonized host.

The requisite stages in the life cycle and spread of one organism which parasitizes another are presented in Fig. 9-10. The key steps are: initial colonization and attachment; multiplication and nutrition; evasion of the host defenses; (in some cases) invasion and, lastly, exit in order to disseminate to a new host. Specific gene products (presumptive virulence factors) are required to facilitate each of these processes, and these products will vary from organism to organism dependent upon the particular strategy employed to satisfy each element of the life cycle. The

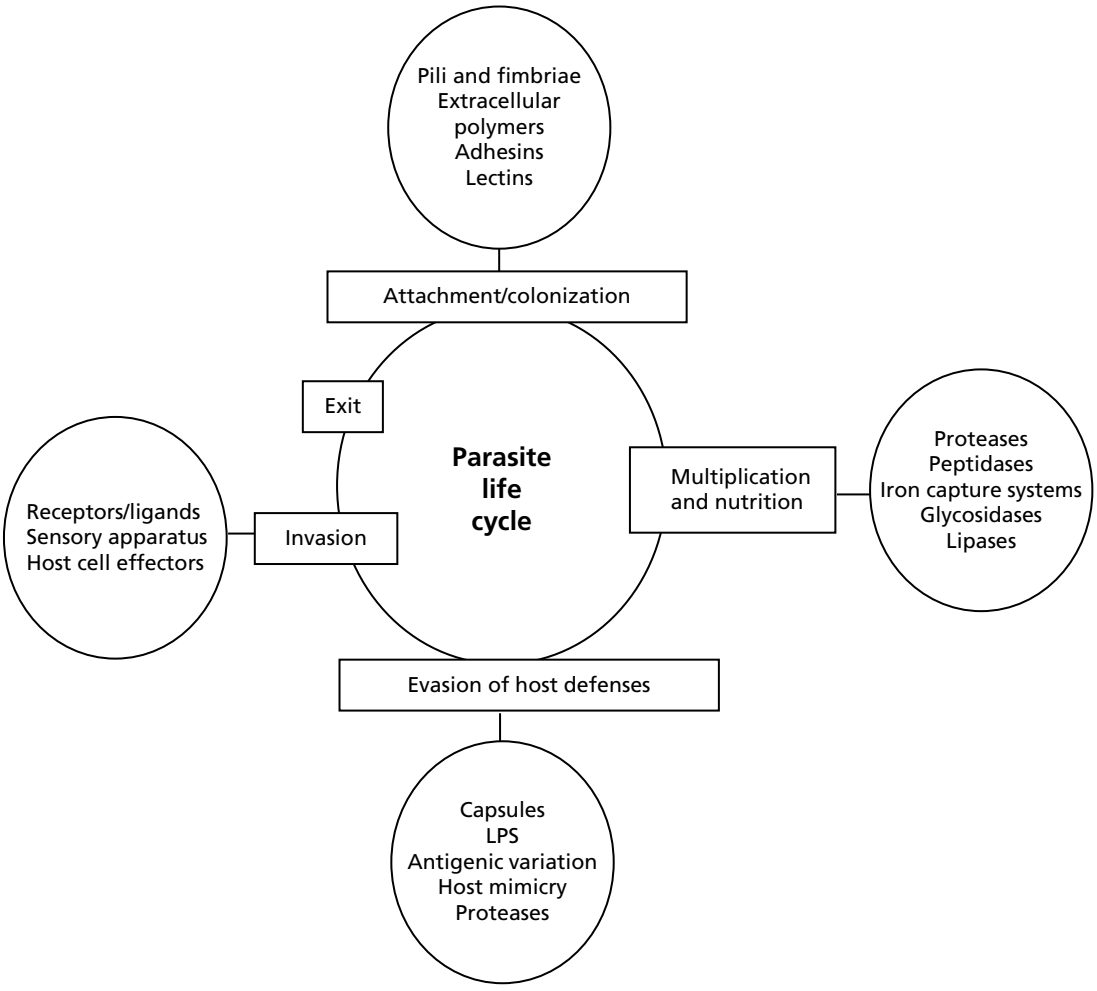

Fig. 9-10 Essential components of the parasite life cycle. Successful colonization and transmission of a parasite is dependent upon the ability to attach, multiply, evade host defenses, invade, and exit the host. These processes each require specialized gene products and processes. (Source: Adapted from Curtis *et al*. 2005.)

gene products or traits associated with each step in the life cycle presented in Fig. 9-10 represent examples drawn from multiple organisms. Disease can be defined as the unfavorable outcome to the host by the application of these life cycle stages of the pathogen *in a susceptible host background*.

The virulence determinants of a pathogen can simply be defined as those gene products which facilitate colonization, growth and survival within the diseased host organism, and spread to a new host In most cases, the rationale for considering these determinants to be important determinants of the virulence of these organisms is derived from a wealth of *in vitro* investigations and/or animal models employing isogenic mutants of the gene of interest. Further details of the properties of these organisms in relation to the pathogenesis of disease can be found in reviews on this subject (Hajishengalis 2009; Henderson *et al*. 2010; Sharma 2010; Dashper *et al*. 2011; Bostanci & Belibasakis 2012; Dahlen *et al*. 2019). However, an emerging key property of several of these organisms concerns the strategies they appear to employ in order to evade the host defenses operative in the periodontium.

It is becoming increasingly evident that microbial organisms, having co-evolved with the innate defense systems of their respective hosts, have developed strategies not only to overcome protective host barriers but also to manipulate these systems to their own advantage. One example of this phenomenon is the ability of cell surface proteins of both Gram-negative and Gram-positive bacteria, including *A. Actinomycetemcomitans* and *P. gingivalis*, to influence the pattern of cytokine expression by host cells (Darveau *et al*. 1998). The term "bacterial modulins" was introduced by Henderson, Poole, and Wilson to describe these bacterial cytokine-inducing molecules because of their ability to modulate eukaryotic cell behavior (Henderson *et al*. 1996). More recently, a sophisticated manipulation of the host response by *P. gingivalis* has been described as a consequence of the biological properties of different molecular species of the lipid A portion of the lipopolysaccharide of this bacterium (Darveau *et al*. 2004). Some of these lipid A species are able to act as agonists of the host response through Toll-like receptor signaling, and thus have similar biological properties to the hexa-acylated lipid A species of enteric organisms. Conversely, other lipid A moieties produced by *P. gingivalis* act as antagonists of this signaling pathway and are able to block the activity of the proinflammatory lipid A forms (Reife *et al*. 2006). This has led to the suggestion that by altering the proportions of the different lipid A components, *P. gingivalis* may be able to manipulate the innate response in order, for example, to downregulate the inflammatory response as a defensive measure.

An additional evasive measure practised by some of the more well characterized periodontal bacteria, a component of the so-called "stealth technology", involves entry into other host cells, primarily epithelial cells, to gain access to an immune privileged site (Lamont & Jenkinson 1998; Fives-Taylor *et al*. 1999; Meyer *et al*. 1999). Verification of this process *in vivo* is now emerging by the detection of these and other species using fluorescent labelling within buccal epithelial cells taken directly from the mouth (Fig. 9-11) (Rudney *et al*. 2005). In the case of *P. gingivalis*, the organism has been shown to rapidly invade epithelial cells derived from the human gingiva and accumulate and persist in high numbers with a perinuclear localization (Lamont & Jenkinson 2000). This positioning is similar to the localization observed for purified preparations of RgpA which is able to translocate the plasma membrane of epithelial cells (Scragg *et al*. 2002). Although the precise mechanism is still under investigation, FimA, a major fimbria, and the gingipain proteinases are required for the attachment and internalization of the bacterial cells. In the case of *A. actinomycetemcomitans*, although the precise details of the mechanism are unknown, there is a suggestion that the invasion process may be augmented by soluble CD14 derived from saliva (Takayama *et al*. 2003).

The recognition that the virulence properties of some of the key organisms involved in periodontal disease may be more directed towards an anti-inflammatory or subversive phenotype is leading to a new appreciation of the etiopathogenesis of the disease process and this is presented in the next section of this chapter.

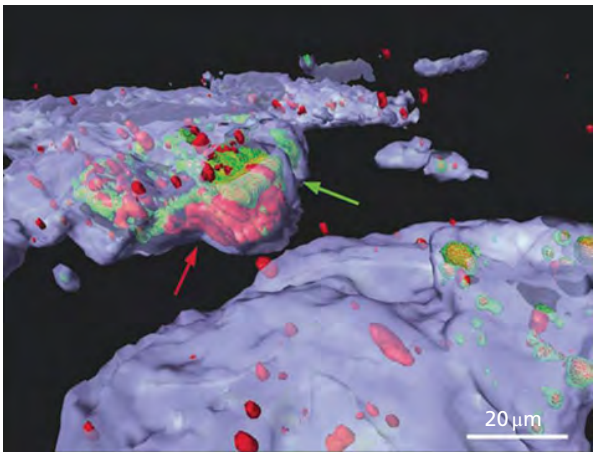

Fig. 9-11 Intracellular bacteria in buccal epithelial cells. A three-dimensional reconstruction of buccal epithelial cells stained using a specific probe for *A. actinomycetemcomitans* (green) and a universal probe for all bacteria (red). Bacteria recognized only by the universal probe are shown in solid red, whereas co-localization of the *A. actinomycetemcomitans* and universal probes is depicted by a green wireframe over a red interior. Reconstructed buccal epithelial cell surfaces are presented in blue. The red and green colors are muted when bacterial masses are intracellular, and brighter when bacteria appear to project out of the surface. The large mass which appeared to have a lobular structure was seen to be a cohesive unit containing *A. actinomycetemcomitans* in direct proximity to other species (red and green arrows). (Source: Adapted from Rudney *et al*. 2005.)

Microbial pathogenesis of periodontal disease

The underlying principles of infectious disease first enunciated by Louis Pasteur and subsequently proven by Robert Koch provided the essential framework for the identification of microorganisms responsible for diseases of a monospecific etiology. Koch's postulates provide four criteria which should be met in order to identify an infectious agent as a disease-causing agent: the microorganism must be found in abundance in all organisms suffering from the disease, but should not be found in healthy organisms; the microorganism must be isolated from a diseased organism and grown in pure culture; the cultured microorganism should cause disease when introduced into a healthy organism; finally the microorganism must be re-isolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent. Although these principles have undergone significant revisions since their introduction and have been updated into a molecular interpretation by Falkow (1988), they underpinned the discovery of the causative agents of very many medically important infections throughout the mid-nineteenth and early twentieth centuries. Koch himself applied these criteria to the discovery of *Mycobacterium tuberculosis* and *Bacillus anthracis* – the causative agents of tuberculosis and anthrax respectively.

The extensive microbiological analyses of periodontal infections which have been undertaken over the last 100 years have led to the formulation of a number of hypotheses on the fundamental nature of the pathogenesis of the disease. In each case, bacteria in dental plaque are acknowledged to be the critically important agent in driving an inflammatory response in the periodontal tissues which can ultimately lead to destructive disease. Hence, although the processes of irreversible destruction of the soft tissues of the periodontium and the bony support structures of the teeth occur through host-mediated mechanisms, these are dependent upon stimulation by a bacterial challenge. However, the underlying principles of each of these hypotheses differ significantly. From the initial stages of the last century it was believed that periodontal disease was the cumulative effect of all the bacterial species found in dental plaque. This non-specific plaque hypothesis held that the precise microbial composition of dental plaque was not the critical determinant of disease, rather it was the magnitude of the total bacterial challenge, or the amount of dental plaque, in juxtaposition to the periodontal tissues, that was the overriding factor which determined the balance between health and disease. The origins of this hypothesis extend as far back as the end of the nineteenth century when bacterial isolation and identification techniques were still in their infancy. Gradually, this non-specific view of the etiology came under increasing scrutiny. First, it was clear that the presence of large accumulations of dental plaque in some individuals did not lead to destructive disease or, in some instances, even mild symptoms of inflammation. Furthermore, the increased sophistication of clinical microbiology was beginning to demonstrate that there were very marked differences in the microbial composition of dental plaque taken from sites in patients with disease in comparison to healthy sites in the same patient or indeed from healthy individuals. Hence, the prevailing view altered to one in which the presence and potential overgrowth of specific bacteria, or periodontal pathogens, was decisive.

The specific plaque hypothesis (Loesche 1979) has provided the conceptual framework for much of the investigation of the microbial etiology of periodontal disease for the last 40 years. More detailed investigations of the microbiota have led to the identification of increasing numbers of bacterial species which appear to be more associated with disease than health. Patterns in the association between different bacterial species in different clinical conditions were observed which encouraged the view that there may be specific combinations or complexes of species which were the most critical in the development of disease. Importantly, laboratory investigations of the pathogenic potential of some of these candidate species, either singly or in combination, came under investigation in both animal models and using *in vitro* systems. This led to the development of plausible biological mechanisms by which these specific organisms could contribute to the promotion or deregulation of an inflammatory response and/or impaired immune defense of the periodontal tissues.

The diagnostic and treatment implications of the specific plaque hypothesis are self-evident. If specific bacterial species are the driving force of the disease, then identification of the presence of these organisms in an individual ought to be helpful in predicting clinical outcome. Furthermore, targeted treatment strategies which aim to eliminate or at least control these particular organisms rather than necessarily attempting to eliminate the entire microbial population should be clinically beneficial. The specific plaque hypothesis also raises the issue of where and how these organisms are acquired. If they are acquired exogenously, that is transmitted from another individual rather than being component members of the oral microbiota acquired early in life, then strategies which prevent or limit transmission in the human population could be considered beneficial in the same way as prevention of transmission of more well known medically important human pathogens is an accepted and successful public health measure. This latter issue has been subsequently addressed by an alternative hypothesis – the ecological plaque hypothesis (Marsh 2003). In this thesis, the contribution of the environment in which the bacteria of dental plaque reside is paramount. The varying abilities of different bacteria to grow and proliferate

under different environmental conditions will dictate the balance of microbial communities at any given site on the tooth surface. For example, in a periodontal pocket where the pH can rise to well over pH 7, those bacteria most well suited to grow at alkaline pH will be able to out compete those bacteria most suited to more acid conditions. Similarly, organisms able to withstand the antimicrobial properties of the host's inflammatory response will be more predominant at inflamed sites in the periodontium than those bacteria ill equipped for this injurious environment. Hence, the composition of microbial communities in disease will be intimately linked to the environmental conditions prevalent at a diseased site.

Shifts in the environmental conditions caused by, for example, the introduction of different nutrients because of the arrival of a plasma exudate in the form of gingival crevicular fluid, will lead to concomitant shifts in the microbial community. Organisms previously limited in their growth because of, for example, only very low concentrations of the iron source, hemin, will have the nutritional capacity to increase in number and potentially out compete those bacteria most frequently found in health where low or no gingival crevicular fluid is present. Those bacteria able to withstand the killing effects of migratory phagocytic cells will be able to increase in number at the expense of those organisms susceptible to these killing mechanisms. In so doing the newly selected microbial community will present a different and potentially more injurious challenge to the periodontal tissues and hence the escalation of increasing inflammation coupled to frustrated bacterial clearance will continue. Importantly, the ecological plaque hypothesis allows for the fact that potential periodontal pathogens may be present in health, albeit in relatively low numbers, but with the capacity to become more dominant members of the community when the environmental conditions favor their competitiveness over the other, more health-associated, members of the microbiota. In so doing, this hypothesis can explain the microbial specificity of the disease without the requirement for the acquisition of these periodontal pathogens via an exogenous route of transmission in order to initiate the disease. This evolving view of the pathogenesis of periodontal disease now has a further modification which incorporates elements of all the preceding views, both specific and non-specific, and acknowledges the fundamental importance of dysbiosis of the normally benign microbial populations of the tooth surface in the development of disease (Darveau *et al*. 2012). The essence of this more recent concept of pathogenesis comes primarily from the recognition of the global population changes that occur to the microbiota in periodontal disease. As described above, there is now a broad consensus that during the progression of periodontal disease, the oral microbiota undergoes a major transition wherein the microbial community structure is shifted to an increase in total bacterial diversity accompanied by an outgrowth in the total number of disease-associated bacteria which start to predominate in the population, while otherwise being present in low numbers in a state of health (Diaz *et al*. 2016). This transition to dysbiosis of the oral microbiota during disease is completely contrary to the changes observed in microbially mediated diseases in other environments of the body such as the gut. During inflammatory disease conditions at this site, dysbiosis is accompanied by a decreased level of microbial diversity, particularly by a reduction in the anaerobic microbes, otherwise associated with conditions of health.

The drivers of the shift in microbial populations during periodontal disease are complex and multifactorial. They will include the composition of the microbial challenge and the efficacy of the immune and inflammatory systems of the host which themselves will be governed by both environmental and genetic factors. Two particular characteristics of the periodontal microbiota have acquired some significance. First, certain groups of organisms that subvert the inflammatory response are known to be responsible for influencing a community wide change on the overall bacterial population. For example, *P. gingivalis*, an organism long associated with the development of periodontal disease, has been suggested to exert a "keystone" effect in the oral microbial population during periodontal disease, by triggering a state of dysbiosis and inflammation (Hajishengallis *et al*. 2012). *P. gingivalis* is involved in both immune subversion and maintaining inflammation in the host tissues by facilitating communication between the C5aR arm of the complement system and toll-like receptor 2 molecules (TLR2) (Maekawa *et al*. 2014). Studies in mice have also shown that *P. gingivalis* is not just the sole orchestrator of this shift but is also greatly assisted by the involved activity of the commensal bacterial population (. This was particularly demonstrated in germ-free mice where the absence of the commensal microbiota failed to initiate periodontal disease and alveolar bone loss (Hajishengallis *et al*. 2011). More recently, the dysbiotic state induced by *P. gingivalis* has been shown to be a highly stable system in experimental animal models and, moreover, can be transmitted and cause periodontal bone loss in healthy recipient animals (Payne *et al*. 2019).

Further evidence to support a role for the normally benign, commensal microbiota in periodontal disease has come from a combination of metagenomic and metatranscriptomic approaches in human oral samples. For example, in a comparison of baseline versus progressing periodontal sites (Duran-Pinedo *et al*. 2014), those organisms with the largest number of upregulated putative virulence determinants were health-associated streptococcal species. Similar results were obtained when comparing baseline non-progressing with baseline progressing sites. These findings further emphasize that focusing solely on those organisms which become dominant in disease as the drivers of periodontitis may be an oversimplification: although the contribution of the disease-associated species, many of which have been shown

to have properties consistent with deregulation of the immune and inflammatory response, cannot be ignored, the overall virulence challenge in periodontitis may actually be a product of the entire microbial community (Siqueira & Rôças 2009; Berezow & Darveau 2012).

Another potential driver for the conversion to dysbiosis is the largely inflammophilic nature of the oral microbial population (Hajishengallis 2014). Disease-associated bacteria are present in subgingival plaque even in states of health at very low abundances, and these may be responsible for triggering persistent baseline levels of inflammation, albeit low, even during healthy conditions. It can be argued that provoking the inflammatory response has two benefits to an inflammophilic organism: first, through the initiation of tissue destruction, a protected site for colonization is produced which may allow the organism to out compete other less inflammophilic organisms; secondly, the accumulation of nutrients such as hemin-containing compounds and proteins from tissue exudates/plasma will facilitate the survival of specific types of anaerobic bacteria, thus generating a competitive survival advantage in the ecosystem. Thus, the inflammophilic nature of the oral microbiome drives a "self-feeding" cycle of tissue damage and bacterial survival and growth (Hajishengallis *et al.*, 2012) (Fig. 9-12). Hence the inflammatory response and the microbiome are in a bi-directional balance in oral health (homeostasis) and a bi-directional imbalance in periodontitis.

In summary, our understanding of the microbial pathogenesis of periodontal disease has undergone significant changes over the last century and continues to be refined to this day through more detailed analyses of clinical samples, improved understanding of the biology of the component organisms of this microbiota, and application of experimental model systems. The central role of a dysbiotic microbiota has been highlighted, similar to our understanding of the etiology of diseases with a complex microbial etiology at other sites of the human body. In all of these cases, disease is a consequence of a breakdown in the normally homeostatic balance between the commensal microbiota and the immune and inflammatory systems of the tissues. In this regard, periodontal infections and the response to them represent an excellent, accessible, and tractable system to understand the underlying principles of a wide range of inflammatory diseases of humans characterized by a dysbiotic commensal microbiome.

Peri-implant infections

Introduction

With a large and increasing number of dental implants being placed worldwide, it is expected that there will be an increase in the number of patients diagnosed with peri-implant diseases. Peri-implant diseases are plaque-associated inflammatory conditions of the tissues surrounding an implant and are defined as either (1) peri-implant mucositis, where there are clinical signs of inflammation (bleeding on probing, BoP) of the peri-implant mucosa without loss of supporting bone, or (2) peri-implantitis, where there is progressive bone loss in addition to

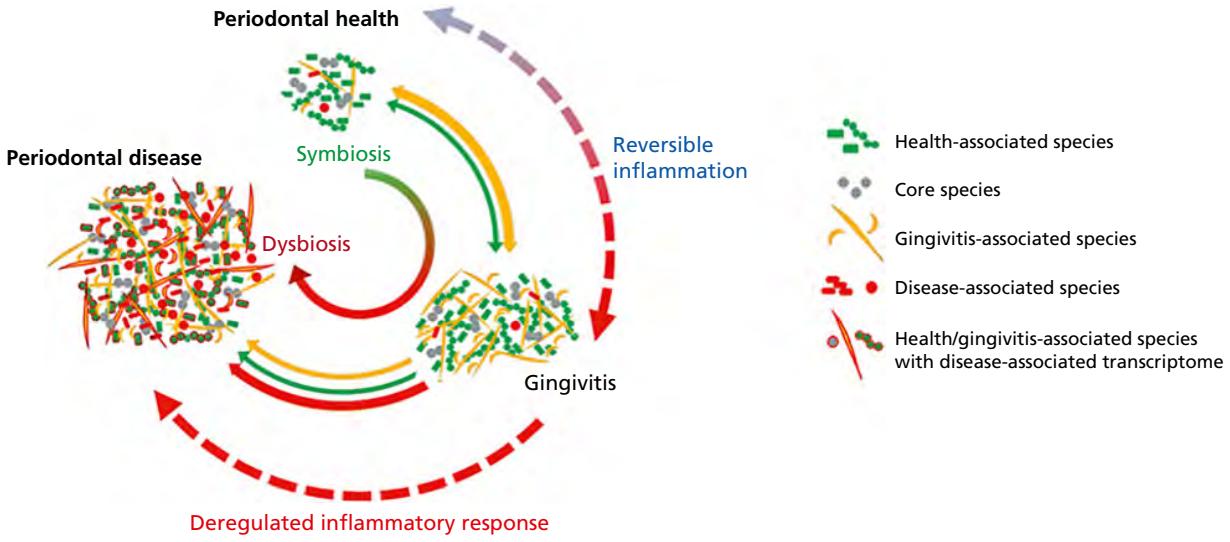

Fig. 9-12 The bidirectional relationship between the subgingival microbiome and the inflammatory and immune response. The symbiotic microbiota in health is dominated by health-associated species (green) and low abundances of species associated with gingivitis (orange) and periodontitis (red). Gingivitis is characterized by an increased biomass (green and orange arrows) comprising both green and particularly orange species and an associated increase in inflammation. In periodontitis, biomass increases further (green, orange, and red arrows) and the red species become increasingly dominant in the dysbiotic microbiota. Furthermore, the repertoire of gene expression in the green and orange species is altered with increased expression of virulence determinants. This is accompanied by the development of a deregulated inflammatory response and tissue destruction. Interventions which are able to resolve the inflammatory response may also be important in the reversal of the dysbiotic microbiota. (Source: Adapted from Curtis *et al*. 2020.)

inflammation (BoP) of the surrounding soft tissues (Berglundh *et al*. 2018). In peri-implantitis, probing depths ≥6 mm and suppuration are frequently present (Fig. 9-13).

These infections represent an imbalance between the peri-implant biofilm and the host response to the biofilm, resulting in dysbiosis and tissue destruction. Recent advances in molecular techniques, already described in this chapter, have generated a significant body of data enabling characterization of the microbial diversity of peri-implant biofilms in health and disease.

This section addresses the etiology of peri-implant diseases, describing the nature of supra- and submucosal biofilms associated with healthy and diseased peri-implant tissues in both partially dentate and edentulous subjects. Factors influencing peri-implant biofilm formation including material surface characteristics, local environment, and implant-supported-prosthesis design are discussed. Similarities and differences in the microbiota associated with periodontal and peri-implant infections are outlined, and the clinical implications discussed.

Peri-implant biofilm formation

When a dental implant is placed, the endosseous part of the implant should ideally be surrounded by bone and is, therefore, usually not exposed to biofilm formation. In contrast, the transmucosal part of the implant/abutment, once exposed to the oral cavity, becomes rapidly colonized by microorganisms (Fürst *et al*. 2007), which attach to salivary proteins and peptides constituting the pellicle. The pellicle provides receptors for adhesins present on the cell surface of all oral bacterial species. Enamel pellicles and titanium pellicles are not identical. Salivary pellicles formed on titanium surfaces *in vitro* have been found to include molecules such as high molecular weight mucins, α- amylase, secretory IgA, and proline-rich proteins, whereas molecules commonly found on tooth enamel (cystatins and low molecular weight mucins) were not detected (Edgerton *et al*. 1996). Although the salivary pellicle that forms on titanium surfaces might differ from that forming on enamel surfaces, the differences do not seem to influence the bacterial composition of the biofilm formation (Leonhardt *et al*. 1995).

Because of a common ecologic environment, the principles and sequence of biofilm formation at teeth and implants are similar (Lang & Berglundh 2011). Biofilm formation is initiated by adhesion of early colonizers such as *Streptococcus sanguinis* and *Actinomyces naeslundii*, through interactions with the salivary pellicle. The early colonizers grow, modify the environment, and promote the adhesion of secondary colonizers via co-aggregation (Fig. 9-14).

The biofilm with its diverse community of interacting organisms, glycocalyx matrix, and complex structure becomes stable over time, affording a protective environment from host defenses and antimicrobial agents (Marsh 2005; Socransky & Haffajee 2005; Kolenbrander *et al*. 2006). Figure 9-15 shows a scanning electron micrograph illustrating the characteristic biofilm formation on a titanium implant surface. Factors which may influence microbial colonization include the surface characteristics of the implant/abutment, local environment, resident oral microbiota, and implant prosthesis design and its accessibility for oral hygiene.

Surface characteristics of the implant/abutment

Surface characteristics of the implant/abutment and restorative components, including chemical composition, surface free energy (SFE; wettability), and surface roughness, may impact biofilm formation. Both *in vitro* and *in vivo* studies have indicated that increasing the surface roughness of titanium results in greater bacterial adhesion and biofilm accumulation (Teughels *et al*. 2007, 2006; Subramani *et al*. 2009; Burgers *et al*. 2010; Fröjd *et al*. 2011). An *in vitro* scanning electron microscope study investigating attachment of oral species to titanium disks with various surface characteristics, demonstrated an increased bacterial attachment to rough surfaces (Wu-Yuan *et al*. 1995). In a series of split-mouth studies, it was demonstrated that an increase in the surface

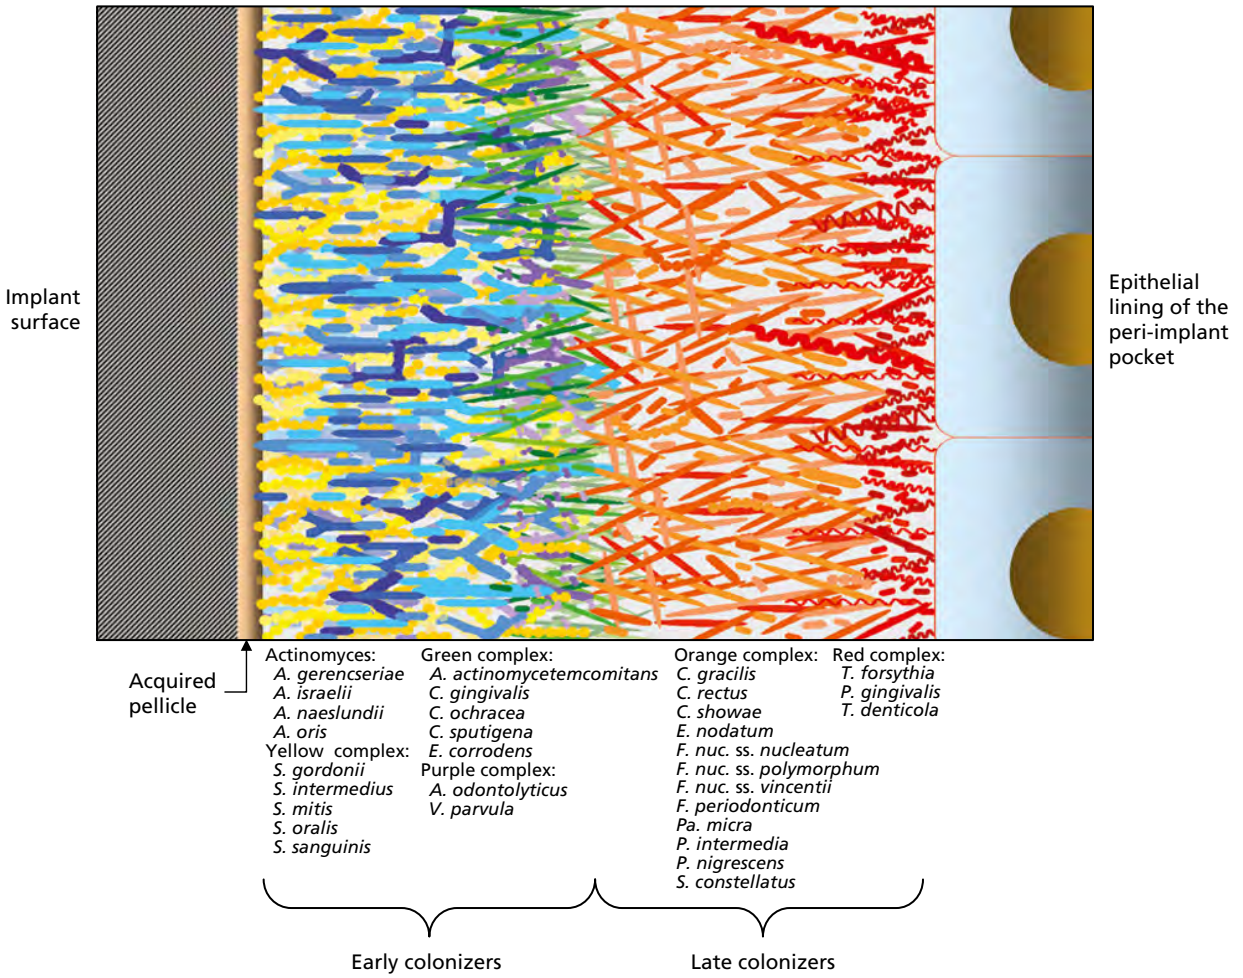

Fig. 9-14 Simplified schematic representation of the microbial succession that may take place on an implant surface exposed to the oral environment. Microbial species are colored according to the microbial complexes described by Socransky *et al*. (1998).

The bacterial cell mass within the extracellular matrix covers the surface of the implant with the typical morphology of stacks containing bacterial communities interspersed among broad circulation channels.

roughness (Ra) above a threshold of 0.2 µm and/or an increase in the SFE facilitated biofilm formation on restorative materials (Teughels *et al*. 2006). The effect of SFE on supra- and submucosal plaque maturation around implants was investigated by comparing plaque from abutments with either a high (titanium) or a low (teflon coating) SFE (Quirynen *et al*. 1993). The teflon-coated titanium abutments harbored a less mature biofilm characterized by a higher proportion of cocci and a lower proportion of motile organisms and spirochetes than the uncoated titanium abutments (Quirynen *et al*. 1993). When both surface characteristics interact with each other, surface roughness was found to be predominant (Teughels *et al*. 2006). The impact of surface roughness on biofilm formation can be explained by several factors, including the protection from shear forces, increased area for adhesion, and difficulty in cleaning rough surfaces which enables rapid regrowth of the biofilm by multiplication of resident bacterial species (Quirynen & Bollen 1995). Quantitative analysis of 14-day supra- and submucosal biofilm formation on titanium healing abutments in 10 subjects, showed that biofilm formation was significantly increased by higher surface roughness in supramucosal areas, with no influence of increased surface roughness in the submucosal environment (Elter *et al*. 2008).

The recent development of *in vitro* multispecies biofilm models and the use of microscopic techniques such as scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM) has enabled investigators to study the dynamics and

structure of biofilms forming on implant surfaces. When comparing the biofilm formation between hydroxyapatite, titanium, and zirconia surfaces, the dynamics were similar irrespective of the surface. However, significant differences were reported on the three-dimensional organization of the biofilms and on the number of bacteria within the biofilms. Although hydroxyapatite and titanium surfaces showed similar biofilm dynamics and structure, biofilms on zirconium surfaces were significantly thinner than on titanium and hydroxyapatite surfaces and with the percentage of area coverage by biofilm on zirconium material significantly lower than over titanium surfaces (Sanchez *et al*. 2014). In a subsequent study, using the same *in vitro* biofilm model but on whole implant surfaces, studying implants with different micro surface topography CLSM demonstrated a significantly greater biomass in moderate-roughness surface implants when compared with minimal-roughness surface implants. SEM showed a higher number of bacteria within the characteristic surface micropores in the moderate-roughness surface implants and qPCR analysis also reported significantly higher number of total bacteria and concentrations in the moderate-roughness surface implant (Bermejo *et al*. 2019b) (Fig. 9-16).

Biofilm formation on implant surfaces may not only be influenced by the micro surface topography but also by the implant macro design. Analysis of biofilm formation on implant surfaces has shown that the

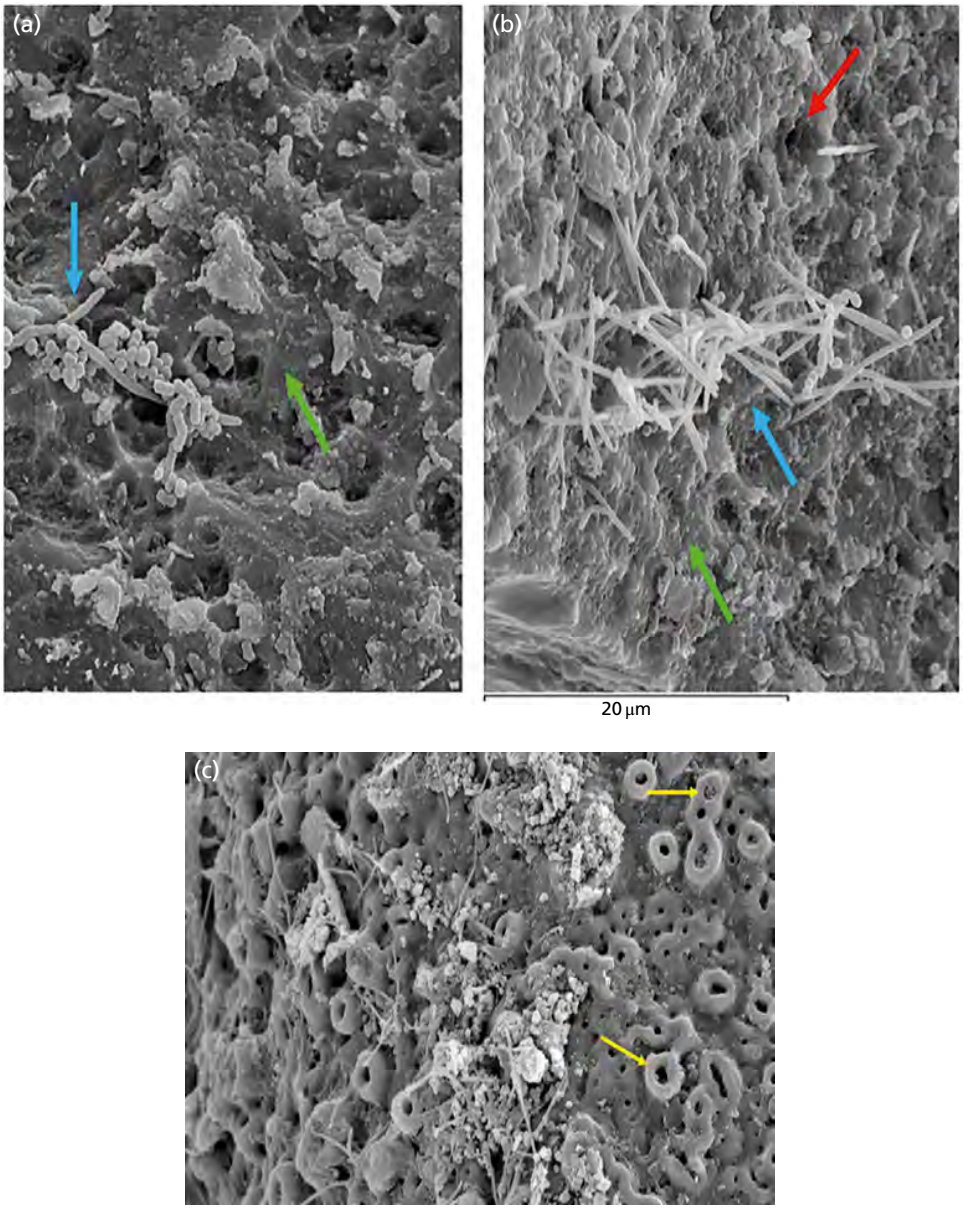

Fig. 9-16 (a, b) Biofilms on a minimal-roughness implant surface. Spindle-shaped rods forming 3-D structures and adherent short streptococcal chains (*Fusobacterium nucleatum* and *Streptococcus oralis*) (blue arrows). See titanium surface covered by a thick extracellular matrix covering the implant surface (green and red arrows). (c) Biofilms on a moderate-roughness implant surface with similar structural characteristics to those found on minimal-roughness surfaces. Bacteria are disposed in larger masses of bacterial communities covering the implant surface and within the larger pores of the moderate-roughness surface (yellow arrows).

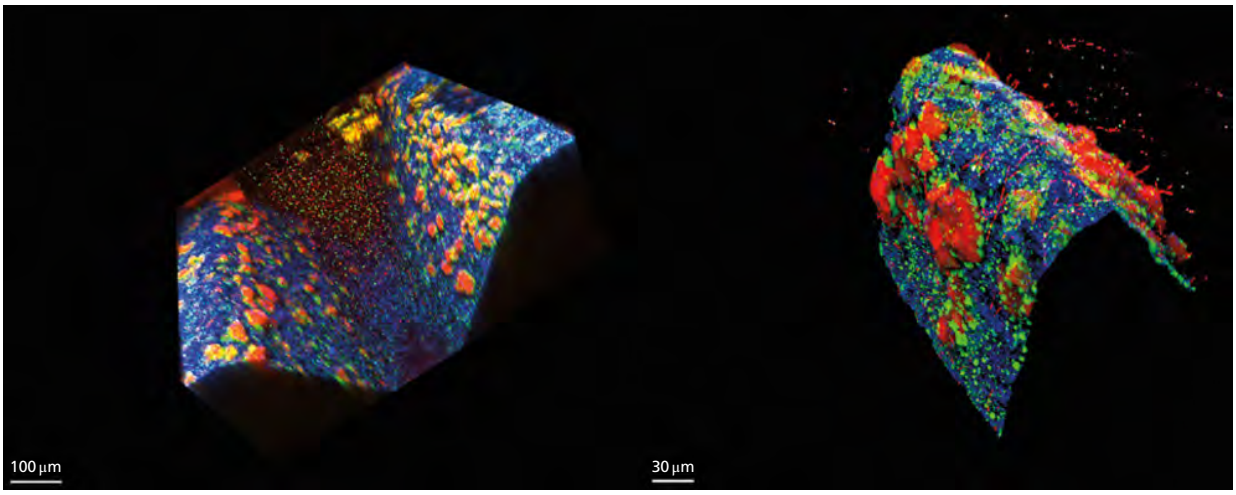

Fig. 9-17 Confocal laser scanning microscopy images depicting biofilm formation at both the peaks and the valleys of dental implants. BacLight Live/Dead stain assessing the vitality of cells within the biofilm clearly shows a higher proportion of dead cells in the valleys between the cells. Blue, implant material; green, live cells; red, dead cells.

entire implant surface will be colonized by bacteria in a short period of time evolving to a mature, well-structured biofilm. However, depending on the location, the biofilm will exhibit different ratios of cell viability, with the peaks of the threads harboring more live bacteria and the valleys between the threads accumulating greater amounts of dead bacteria, which possibly reflects the reduced availability of nutrients in the least accessible areas (Bermejo et al. 2019a) (Fig. 9-17).

Similar results have also been reported using *in vitro* two and three-species biofilm models, 16S ribosomal RNA (rRNA) fluorescence, and confocal scanning laser microscopy (CSLM) (Fröjd *et al*. 2011). After 2 hours, surfaces with increased surface roughness had higher bacterial adhesion, most likely the result of protection of bacteria from shear forces. However, after 14 hours the volume of biofilm was similar on all surfaces, indicating that the influence of surface characteristics on adhesion was surpassed by biofilm development (Fröjd *et al*. 2011).

A range of restorative materials is available for fabrication of implant components, including titanium, gold, ceramics, and zirconia. Because of an increased demand for tooth-colored restorations, zirconium oxide ceramics (zirconia) have become more widely used as materials for implant abutments and transmucosal components of implant prostheses. In an *in vivo* study using CSLM to investigate the formation of oral biofilm on various dental ceramics, zirconia was shown to exhibit low biofilm accumulation when used intraorally (Bremer *et al*. 2011). Several randomized controlled studies have compared the early bacterial colonization of periodontal pathogens at zirconium oxide abutments to titanium alloy abutments. Although zirconium oxide abutments showed lower SFE than titanium abutments, there was no difference in the adhesion of *A. actinomycetemcomitans* and *P. gingivalis*, 5 weeks after abutment connection (Salihoglu *et al*. 2011). This lack of difference between zirconia and titanium was confirmed in a similar study evaluating bacterial counts of seven bacterial species 2 weeks and 3 months following abutment connection (van Brakel *et al*. 2011).

Recent studies employing molecular methods of detection have found that titanium and zirconia abutment surfaces are rapidly colonized by a bacterial community similar to those found in adjacent teeth (de Freitas *et al*. 2018; Raffaini *et al*. 2018). De Freitas *et al*. (2018) examined the biofilm at implant sites after 1, 3, and 6 months of loading in 20 participants and found titanium or zirconia abutments as well as teeth showed similar total numbers of operational taxonomic units (OTUs) colonizing surfaces over time. The most prevalent phyla identified were Firmicutes, Proteobacteria, Fusobacteria, Bacteroidetes, and Actinobacteria with significant differences between abutment surfaces and time point. The results suggested that there may be a selective adhesion of different bacterial genotypes for either titanium or zirconia surfaces (de Freitas *et al*. 2018).

A study using DNA-checkerboard and 16S-rDNA-pyrosequencing identified 161 bacterial taxa representing 12 different phylotypes associated with either titanium or zirconia implant-abutments in 20 healthy participants (Nascimento *et al*. 2016). Species belonging to the genera *Fusobacterium*, *Prevotella*, *Actinomyces*, *Porphyromonas*, *Veillonella*, and *Streptococcus* were common in all sites. Some differences were observed at sites with titanium abutments compared with zirconia abutments and titanium abutments presented the highest total microbial count and higher counts of pathogenic species (Nascimento *et al*. 2016).

A cross-sectional study evaluated early biofilm formation, using checkerboard DNA-DNA hybridization, at titanium and zirconia implant abutments in 20 individuals over a period of 30 days. Genome counts were found to be low at the time of implant loading for both abutment materials and increased over time with similar microbial counts and diversity over time (Raffaini *et al*. 2018).

Based on the surface roughness value Sa (average 3D height deviation), a proposal to categorize the surfaces of titanium implants as smooth (Sa <0.5 µm), minimally rough (Sa 0.5–1.0 µm), moderately rough (Sa 1.1–2.0 µm), and rough (Sa >2.0 µm) was made (Albrektsson & Wennerberg 2004). The original Brånemark turned machined surface was a minimally rough surface. More recently, the surfaces of commercially available titanium implants have been modified to promote osseointegration and are moderately rough or rough. If these implant surfaces become exposed to the oral environment, because of loss of supporting peri-implant marginal bone, the roughened surface may enhance biofilm formation and contamination of the implant surface. Although there is no evidence that surface roughness of a properly placed and integrated implant influences the development of peri-implant infection, it has been documented that rough surface implants (titanium plasma sprayed [TPS]) are more likely to develop peri-implantitis than minimally rough implant surfaces if the implant surface becomes exposed to the oral environment (Lang & Berglundh 2011).

Local oral environment

Peri-implant colonization has been studied in both edentulous and partially dentate patients. A cause-and-effect relationship between biofilm formation on implants and peri-implant mucositis has been demonstrated in humans (Pontoriero *et al*. 1994; Zitzmann *et al*. 2001; Heitz-Mayfield *et al*. 2012; Salvi *et al*. 2012). In these studies, when oral hygiene was discontinued in order to allow undisturbed plaque accumulation, clinical signs of peri-implant inflammation appeared after a few days and resolved when oral hygiene was reinstated. Not surprisingly, the composition of peri-implant biofilms associated with this inflammation, which may lead to further peri-implant infection in a susceptible host, is influenced by the local environment and the microbiota on the remaining teeth in partially dentate subjects. Cross-sectional studies have shown that the microbiota identified in the peri-implant sulci are nearly identical to those found at neighboring teeth (Quirynen & Listgarten 1990; Leonhardt *et al*. 1993; Mombelli *et al*. 1995a; Lee *et al*. 1999b; Hultin *et al*. 2000, Agerbaek *et al*. 2006). It has been shown that deeper periodontal pockets harbor a greater number and proportion of periodontal pathogens (Socransky *et al*. 1991), serving as a potential reservoir for recolonization.

Transmission of bacteria from periodontal pockets to the peri-implant region of newly placed implants has been suggested in longitudinal studies (Mombelli *et al*. 1995a). A number of studies have used techniques to identify individual strains of bacteria in order to determine if transmission from a periodontal site to an implant site can occur in a patient (Sumida *et al*. 2002; Takanashi *et al*. 2004). Using pulsed field gel electrophoresis (PFGE), chromosomal DNA segmentation patterns of isolates of *P. gingivalis* and *P. intermedia* obtained from implants and natural teeth in the same subjects were found to be identical, whereas PFGE patterns differed among samples from different subjects (Sumida *et al*. 2002). Similarly, it was found that 75% of the *P. gingivalis* isolates in samples from teeth and implants were the same in one subject, whereas 100% of the *P. intermedia* strains within a subject were a perfect match, clearly demonstrating transmission from the natural teeth to the implant sites (Takanashi *et al*. 2004). Although the remaining dentition seems to be the primary source of bacteria for the colonization of implant surfaces in partially dentate subjects, the potential role of soft tissue surfaces, crypts of the tongue or tonsils, and saliva as reservoirs for implant colonization should also be considered. A comprehensive assessment of the microbiota associated with oral mucosal surfaces in edentulous subjects wearing complete dentures outlined the numerous habitats colonized by biofilms of differing complexities, unique to each individual (Sachdeo *et al*. 2008). Biofilm samples were taken from the dentures, the dorsal, lateral, and ventral surfaces of the tongue, the floor of the mouth, buccal mucosa, hard palate, vestibule/lip, and saliva. Checkerboard DNA–DNA hybridization was used to analyse the levels and proportions of 41 different species. Distinct patterns of microbial colonization were seen on different soft tissue surfaces and in saliva. One of the more important findings of this investigation was the detection of the periodontal pathogens *A. actinomycetemcomitans* and *P. gingivalis* in these edentulous subjects, as it was previously thought that these species would not be present following removal of all teeth (Sachdeo *et al*. 2008). Other studies have also reported the presence of periodontal pathogens in edentulous subjects (Danser *et al*. 1998; Cortelli *et al*. 2008) and in edentulous subjects in an elderly population who had never worn dentures but had a history of periodontitis (Fernandes *et al*. 2010).

In contrast, a recent study in 26 edentulous patients evaluated the levels of *P. gingivalis*, *T. forsythia*, and *S. aureus* prior to and 6 months after placement of one-piece zirconia and titanium implants (Siddiqi *et al*. 2016). A qRT-PCR assay using SYBR green/ROX chemistry was used for the detection and quantification of the three bacteria. Samples were collected from both the tongue and from around the implants once placed. The results showed that prior to implant placement all three bacterial species were below the limit of quantification and that they were not identified at either zirconia or titanium implants 6 months after placement (Siddiqi *et al*. 2016).

Taken together, the above findings have clinical implications for the prevention of peri-implant infections. Pathologic conditions in the oral environment, such as the persistence of untreated periodontal disease, could induce changes in the ecosystem that may favor the colonization of pathogenic microorganisms at implant sites (Lang & Berglundh 2011). Treatment

of periodontal disease prior to implant placement, and provision of adequate supportive periodontal/peri-implant maintenance care in order to reduce the reservoir of potential periodontal pathogens, may reduce the risk of peri-implant infections.

Oral hygiene and accessibility

The importance of maintenance care in the prevention of peri-implant infections has been demonstrated in several studies where subjects who did not follow a structured maintenance care program had a greater incidence of peri-implant infections than those who followed a maintenance care program (Roccuzzo *et al*. 2010, Costa *et al*. 2012). The importance of good compliance following treatment [adhering to the recommended prophylaxis/supportive periodontal therapy (SPT) interval, and maintaining a full-mouth plaque score of <20% (O'Leary *et al*. 1972)] was also highlighted in a cross-sectional study where the prevalence of peri-implantitis was associated with poor compliance (Rinke *et al*. 2011).

Peri-implant infection has been linked with poor oral hygiene (Lindquist *et al*. 1997; Ferreira *et al*. 2006) (Fig. 9-18). Higher plaque scores, assessed using the modified Plaque Index (mPI) (Mombelli *et al*. 1987), were significantly associated with peri-implant infection in a cross-sectional study evaluating 212 partially dentate subjects with implant-supported prostheses (Ferreira *et al*. 2006). One pertinent study underlined the importance of designing implant prostheses with adequate access for cleaning (Serino and Ström 2009). Subjects who were referred for treatment of peri-implantitis at one or more of their implants were found to have no access for appropriate oral hygiene measures in a high proportion of the implants diagnosed with peri-implantitis, whereas good access for oral hygiene was rarely associated with peri-implantitis (Serino & Ström 2009). Implant reconstructions should be designed to enable access for regular self-performed biofilm removal, and for early detection of clinical signs of peri-implant infection (Fig. 9-19).

Microbiota associated with peri-implant mucosal health

An understanding of the nature and composition of biofilms associated with peri-implant health and disease is important in order to develop targeted and effective preventive and treatment strategies for the management of peri-implant infections.

A peri-implant biofilm is formed within minutes of exposure to the oral cavity, and a multispecies supra- and submucosal complex community develops within weeks to months of exposure to the oral cavity (Quirynen *et al*. 2005; Fürst *et al*. 2007). This is similar to the dynamics of biofilm formation at teeth (Socransky & Haffajee 1997; Li *et al*. 2004; Kolenbrander *et al*. 2006), although it has been suggested that it may take longer for a mature biofilm to develop at implant sites (Papaioannou *et al*. 1995; Sbordone *et al*. 1999). Figures 9-20 and 9-21 illustrate the similarity of the microbiota colonizing tooth and implant sites within the same subject (Quirynen *et al*. 2006). Figure 9-22 illustrates the increase in detection frequency of *P. gingivalis* and *Tannerella forsythia* over time after non-submerged implant placement in 22 partially dentate subjects with a history of treated aggressive periodontitis (De Boever & De Boever 2006).

Early investigations characterized the peri-implant microbiota using darkfield microscopy and culture analyses to examine samples taken from the peri-implant sulci of newly placed implants in edentulous subjects (Mombelli *et al*. 1987, 1988; Mombelli & Mericske-Stern 1990). The microbiota associated with peri-implant health was described as predominantly Gram-positive facultative cocci, with high levels of *Actinomyces* and *Veillonella* spp., low total anaerobic counts, low levels of Gram-negative anaerobic rods, and low proportions of *Fusobacterium* spp., spirochetes, fusiforms, motile and curved rods. Thus, the microbiota appeared similar to that associated with healthy periodontal sites in healthy periodontal subjects (Socransky & Haffajee 2005).

As previously discussed, the lack of detection of species such as *P. gingivalis* in edentulous patients (Mombelli *et al*. 1987; Danser *et al*. 1994, 1995, 1997) and edentulous patients with implants (Mombelli *et al*. 1987; Ong *et al*. 1992) led to the suggestion that periodontal pathogens do not colonize dental implants placed in edentulous individuals. However, subsequent investigations incorporating more sensitive molecular techniques for analyses (including polymerase chain reaction [PCR], DNA– DNA checkerboard hybridization) have shown this not to be the case. Using molecular techniques, the presence of periodontal pathogens (including *P. gingivalis*, *T. forsythia*, *A. actinomycetemcomitans*, *Treponema denticola*, *Parvimonas micra*, *Streptococcus intermedius*) in low proportions and levels was demonstrated in healthy peri-implant sulci in fully edentulous subjects (Lee *et al*. 1999b; Hultin *et al*. 2002; Quirynen *et al*. 2005;

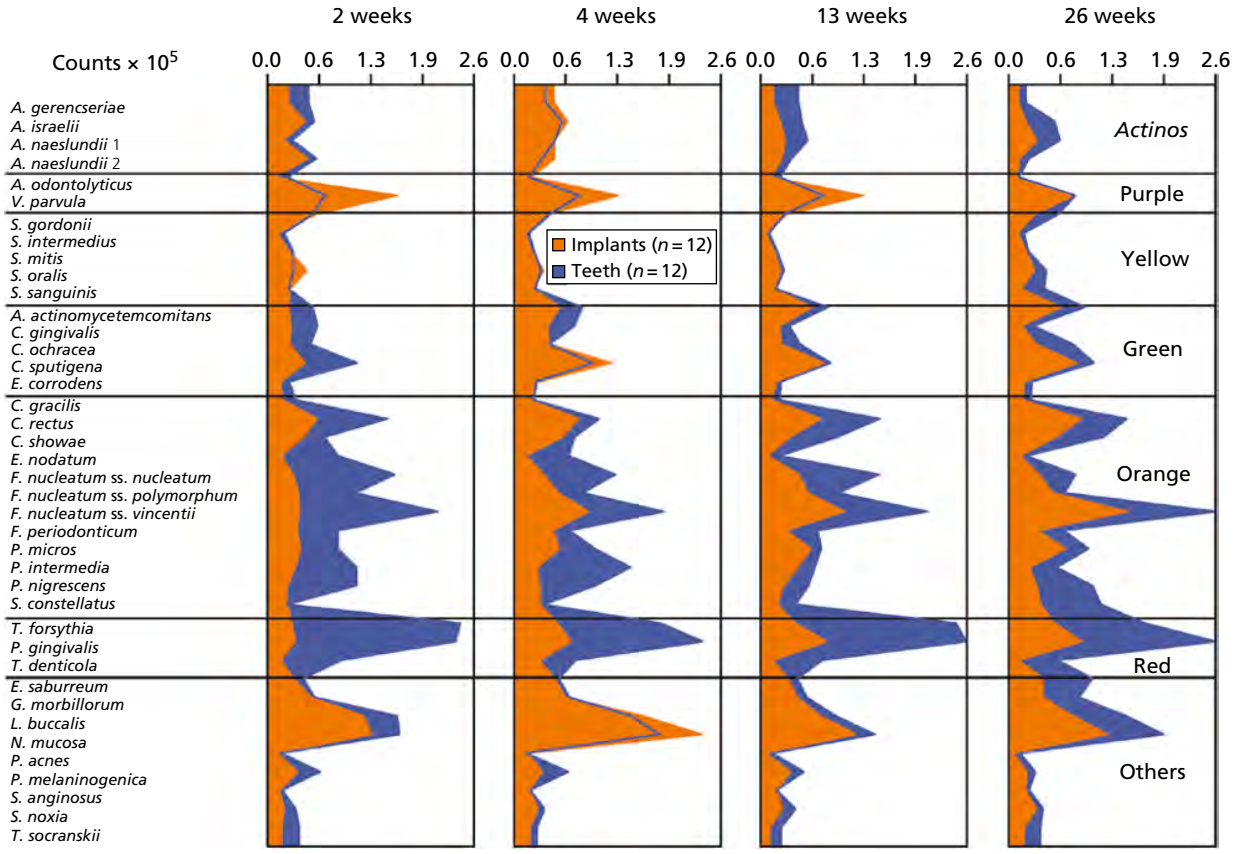

Fig. 9-20 Mean counts (×10^5) of 40 species in samples from 48 implants and 48 teeth in 12 subjects at 2, 4, 13, and 26 weeks after exposure of the implant to the oral environment. Mean counts of each species were computed by averaging the data for each site category separately in each subject, and then averaging across subjects at each time point separately. Significance of differences between site categories was sought using the Mann–Whitney test. No significant differences were found after adjusting for multiple comparisons (Socransky *et al*. 1991). The species were ordered and grouped according to the complexes described by Socransky *et al*. (1998). (Source: Data adapted from Quirynen *et al*. 2006.)

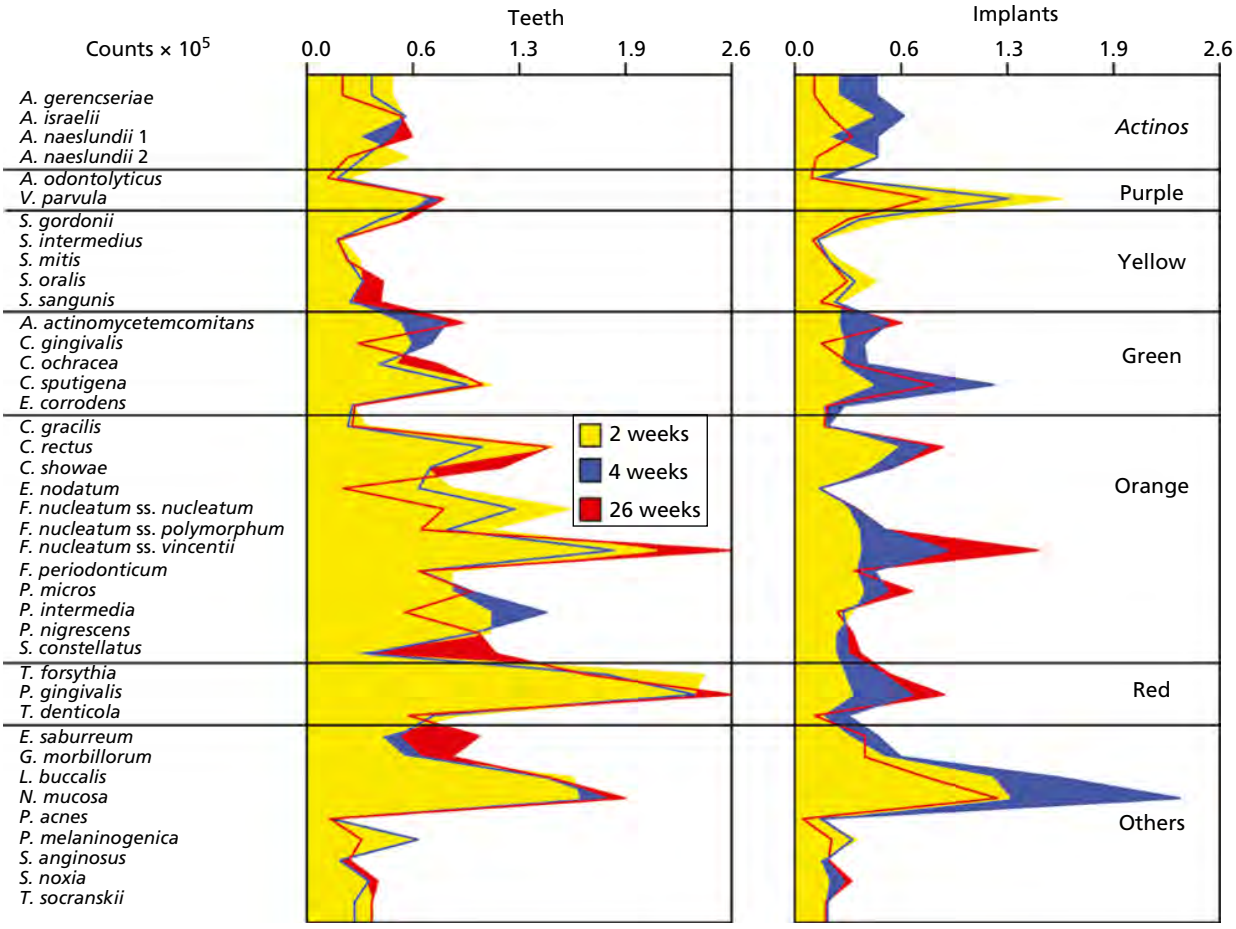

Fig. 9-21 Mean counts (×10^5) of 40 species at 2, 4, and 26 weeks after implant exposure in samples from 48 teeth (left panel) and 48 implants (right panel) from 12 subjects. Mean counts of each species were computed by averaging the data for each site category separately in each subject, and then averaging across subjects at each time point separately. Significance of differences over time was sought using the Friedman test. No significant differences were detected after adjusting for multiple comparisons (Socransky *et al*. 1991). The species were ordered and grouped according to the complexes described by Socransky *et al*. (1998). (Source: Data adapted from Quirynen *et al*. 2006.)

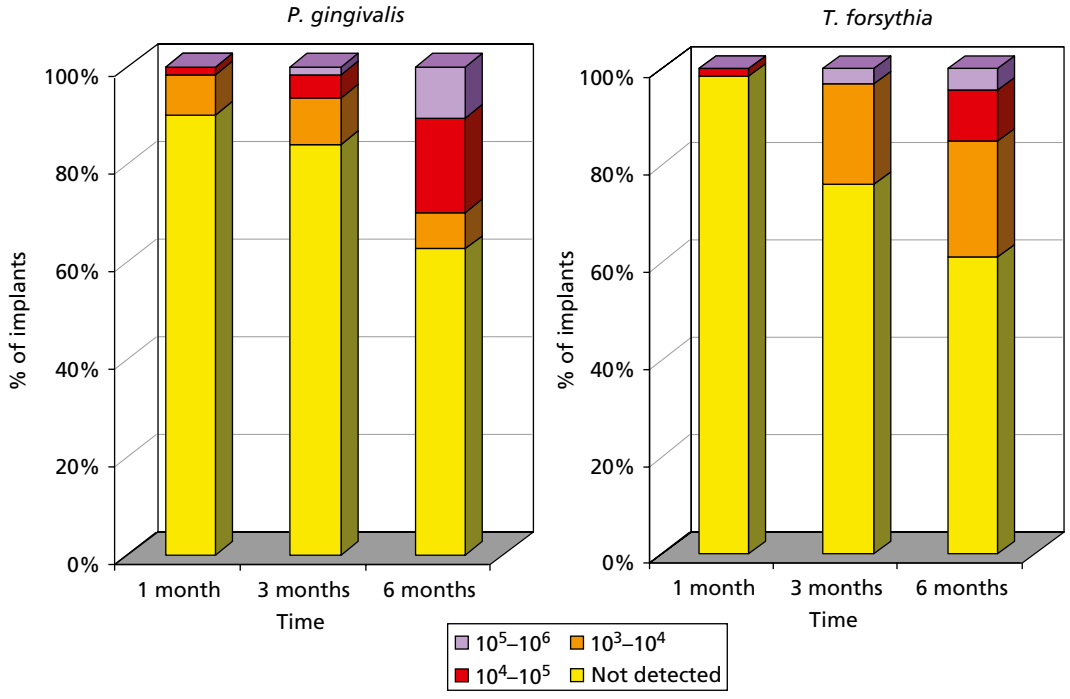

Fig. 9-22 Stacked bar charts of the frequency of detection of *Porphyromonas gingivalis* (left panel) and *Tannerella forsythia* (right panel) at different levels on 68 implants inserted in 22 subjects with a history of treated aggressive periodontitis at different time points. The bar colors indicate the different levels of detection of *P. gingivalis* and *T. forsythia* using DNA probes. (Source: Data adapted from De Boever & De Boever 2006.)

Devides & Franco 2006; Van Assche *et al*. 2009; Fernandes *et al*. 2010; Quirynen & Van Assche 2011) and partially dentate subjects (Lee *et al*. 1999b; Casado *et al*. 2011; Van Assche *et al*. 2011) (Figs. 9-20, 9-21, 9-22). It should be emphasized that in patients with good oral hygiene and a stable periodontal condition, implants can maintain a successful treatment outcome without peri-implant infection despite the presence of periodontal pathogens (Van Assche *et al*. 2011).

Microbiota associated with peri-implant infections

The characteristics of biofilms associated with peri-implant disease (peri-implant mucositis and peri-implantitis) have been studied using various microbiologic techniques and sampling methods, most of which disrupt the three-dimensional structure of the biofilm. Although the majority of studies have found the composition of the submucosal microbiota to be similar to that in periodontitis, with a mixed anaerobic infection dominated by Gram-negative bacteria, some studies have found high numbers of other microorganisms not commonly associated with periodontal diseases, including enteric rods and yeasts, or microorganisms associated with extraoral infections such as staphylococci (i.e. *Staphylococcus aureus* and *Staphylococcus epidermidis*) or peptostreptococci (Leonhardt *et al*. 2003; Fürst *et al*. 2007; Persson *et al*. 2010).

Numerous studies have documented the presence of periodontal pathogens at peri-implantitis sites (Rams and Link, 1983; Rams *et al*. 1984, 1991; Mombelli *et al*. 1987, 1988, 2001; Becker *et al*. 1990; Sanz *et al*. 1990; Alcoforado *et al*. 1991; Rosenberg *et al*. 1991; Mombelli & Lang 1992; Augthun & Conrads 1997; Danser *et al*. 1997; Salcetti *et al*. 1997; Kalykakis *et al*. 1998; Muller *et al*. 1999; Hultin *et al*. 2000; Rutar *et al*. 2001; Leonhardt *et al*. 2003; Botero *et al*. 2005; Covani *et al*. 2006; Persson *et al*. 2006, 2010; Shibli *et al*. 2008; Emrani *et al*. 2009; Maximo *et al*. 2009; Tabanella *et al*. 2009). Figure 9-23 illustrates the microbial complexity of a submucosal biofilm associated with a peri-implantitis lesion. Some studies have examined the microbiota of healthy peri-implant sites, comparing that found in the context of an otherwise healthy mouth versus that found when peri-implantitis was present at some implants, noting an increased level of pathogens even in healthy sites in patients with peri-implantitis (Fig. 9-24). The findings of the mentioned studies outline the similarities in microbiota found at sites with peri-implant infection and periodontitis.

The microbiota associated with peri-implant mucositis appears to be similar to that associated with peri-implantitis (Maximo *et al*. 2009; Casado *et al*. 2011), suggesting that supramucosal plaque formation and development of peri-implant mucositis is the precursor to peri-implantitis. Plaque samples, analyzed using checkerboard DNA–DNA hybridization for 40 bacterial species, from 13 subjects with peri-implantitis and 12 subjects with peri-implant mucositis found similar levels of all species with the exception of three species (*T. forsythia*: higher levels in peri-implantitis; *Actinomyces gerencseriae* and *Campylobacter ochracea*: lower levels in peri-implantitis) (Maximo *et al*. 2009) (Fig. 9-25). In another study evaluating the presence and levels of 36 species by DNA–DNA hybridization, there were no significant differences observed in supra- and submucosal microbial profiles from the same implant site, in 22 subjects with peri-implantitis (Shibli *et al*. 2008) (Fig. 9-26). Deeper peri-implant pockets harbor greater total anaerobic counts and presence of *P. gingivalis* compared to shallower peri-implant pockets (Rutar *et al*. 2001). Human cytomegalovirus (HCMV) and Epstein–Barr virus (EBV) have also been associated with peri-implant infection, suggesting a possible etiologic role via local immune suppression allowing overgrowth of periodontal pathogens (Jankovic *et al*. 2011). HCMV was detected in 65% and EBV in 45% of the 20 peri-implantitis sites evaluated, whereas co-infection was reported in 33% of peri-implantitis sites. In healthy and peri-implant mucositis sites, no co-infection was detected (Jankovic *et al*. 2011).

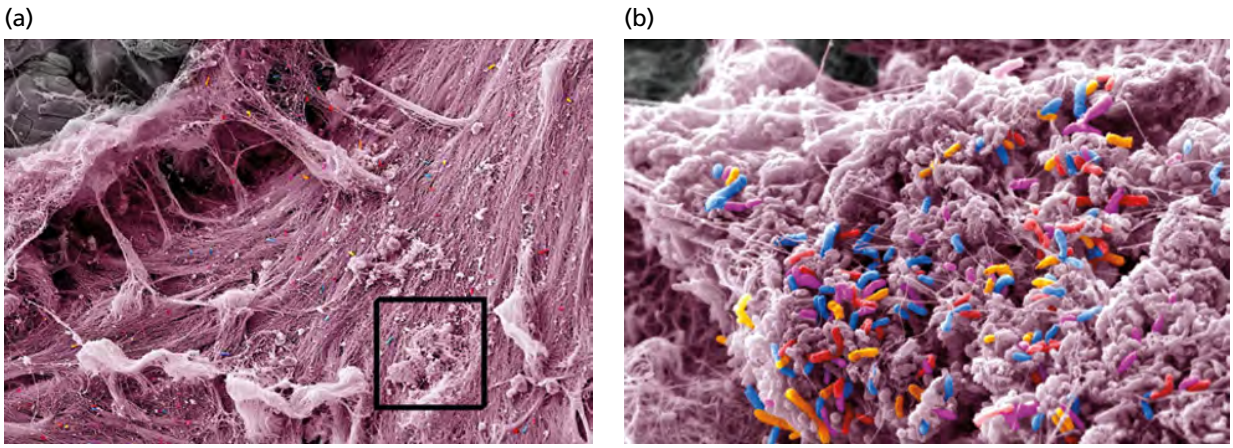

Fig. 9-23 (a) Scanning electron micrograph showing biofilm on an implant surface (black square) from a biopsy specimen retrieved from a peri-implantitis patient. (b) Higher magnification of the biofilm surface demonstrating its microbial complexity (subgingival bacteria marked with different colors).

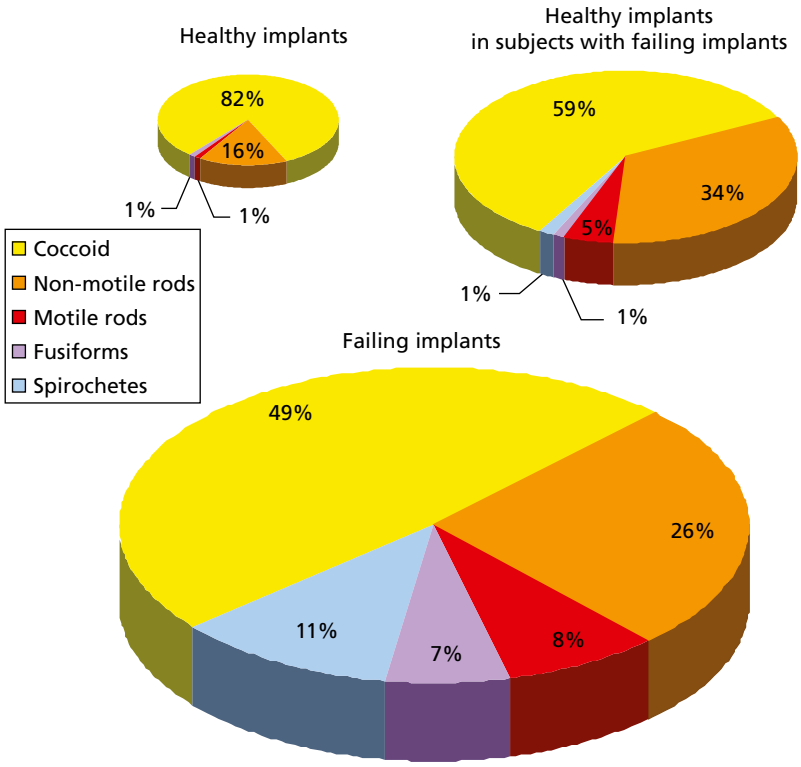

Fig. 9-24 The mean percentage of different morphotypes in the microbiota of samples from 10 healthy implant sites in subjects with only successful implants, samples from six healthy implant sites, and from eight peri-implantitis sites in subjects with peri-implantitis. The numbers correspond to the mean percentage of each morphotype within the microbiota. The areas of the pie charts have been adjusted to reflect mean total counts of each site category. (Source: Data adapted from Mombelli *et al*. 1987.)

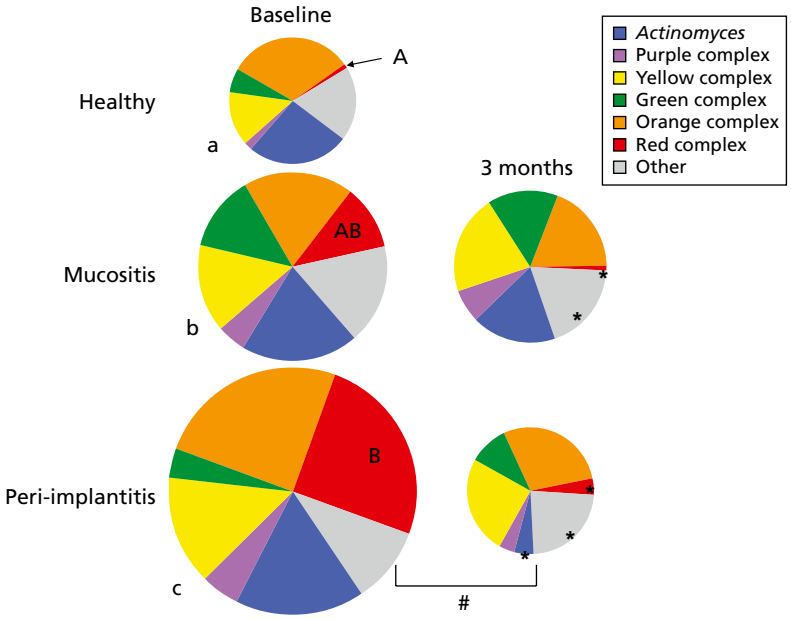

Fig. 9-25 The mean percentage DNA probe count of subgingival microbial complexes (Socransky *et al*. 1998) from samples of submucosal biofilms obtained from healthy implants ($n = 10$), implants with mucositis (n = 12), and implants with peri-implantitis (n = 13) at baseline and 3 months after mechanical therapy (diseased implants only). The areas of the pie charts were adjusted to reflect the mean total counts of each clinical group. Significance of differences between the two time points for the total DNA probe counts ($^{\#}P < 0.05$) and the proportions of each complex ($^{*}P < 0.05$) was tested using the Wilcoxon signed-rank test. Different uppercase letters indicate differences in proportions of microbial complexes among groups at baseline using the Kruskal–Wallis and Dunn *post-hoc* tests. Different lowercase letters indicate differences in the mean total DNA probe counts at baseline using the Kruskal–Wallis and Dunn *post-hoc* tests. (Source: Data adapted from Maximo *et al*. 2009.)

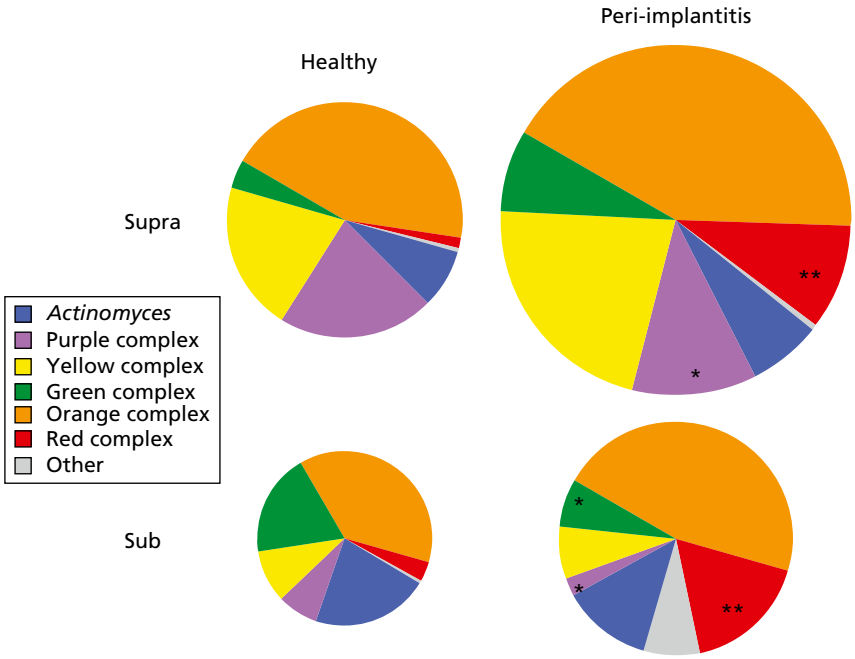

Fig. 9-26 The mean percentage DNA probe count of microbial complexes (Socransky *et al*. 1998) in samples of supra- and submucosal biofilms obtained from healthy implants (n = 22) and implants with peri-implantitis (n = 22). Areas of the pie charts were adjusted to reflect the mean total DNA probe counts of each sample type. Significance of differences between the two clinical groups for the proportions of each complex was tested for supra-and submucosal samples separately using the Mann–Whitney U-test ($^{*}P$ <0.05; $^{**}P$ <0.01). (Source: Data adapted from Shibli *et al*. 2008.)

There is no histologic documentation of bacterial invasion of the peri-implant tissues, although it has been suggested that this may occur because of the epithelial ulceration and disruption of connective tissue adhesion observed in experimental peri-implantitis studies (Lang & Berglundh 2011).

Molecular techniques, including *16S rRNA* gene sequencing, have led to the identification and discovery of previously unrecognized microorganisms in the oral cavity (Faveri *et al*. 2008; Ahn *et al*. 2011; Wade 2011). Because of these advances, researchers are now recognizing the diversity of both the periodontal and peri-implant microbiota. Phyla including Chloroflexi, Tenericutis, and Synergistes, and species including *P. micra*, *Peptostreptococcus stomatis*, *Pseudoramibacter alactolyticus*, and *Solobacterium moorei*, have been identified from peri-implantitis sites (Koyanagi *et al*. 2010) (Fig. 9-27). Furthermore, Archaea, a distinct group of single-cell microorganisms that produce methane gas and have been associated with periodontal disease severity (Lepp *et al*. 2004) have also been identified using *16S rRNA* clonal analyses at peri-implantitis sites, suggesting a role in the etiology of peri-implant infection (Faveri *et al*. 2011). Subgingival/submucosal samples were obtained from 50 periodontally healthy sites, 50 healthy peri-implant sites, and 25 peri-implantitis sites. The prevalence of Archaea (*Methanobrevibacter oralis*) was significantly higher at peri-implantitis sites compared with healthy sites at implants and teeth (Faveri *et al*. 2011).

The true nature, role, and diversity of the microbiota associated with peri-implant infections may only be realized as future investigations focus on the study of non-cultivable organisms, using techniques which do not disrupt the three-dimensional structure of the biofilm.

Periodontal and peri-implant microbiomes in health and disease

Recent studies using molecular techniques have evaluated patient-specific periodontal and peri-implant microbiomes indicating that peri-implant and periodontal microbiomes are both complex, diverse, and may differ from one another (Heuer *et al*. 2012; Dabdoub *et al*. 2013; Zhuang *et al*. 2016; Yu *et al*. 2019).

Dabdoub *et al*. (2013) used a deep-sequencing approach to analyze subgingival and peri-implant biofilm samples in 81 partially dentate individuals with periodontal and peri-implant health and disease. They found that 60% of individuals shared less than 50% of all species between their periodontal and peri-implant biofilms. The periodontal microbiome demonstrated significantly higher diversity than the peri-implant microbiome, and distinct bacterial lineages were associated with health and disease at teeth and implants (Dabdoub *et al*. 2013). The above study suggests that the concept of simple proximity is likely insufficient to determine colonization of topographically distinct habitats. The peri-implant and periodontal microbiomes appear to represent microbiologically distinct ecosystems.

Zhuang *et al*. (2016) evaluated 22, partially dentate Chinese subjects with periodontal/peri-implant healthy sites and periodontitis/peri-implantitis sites.

Quantitative real-time polymerase chain reaction (q-PCR) was used to quantify six bacterial species including *P. gingivalis*, *T. denticola*, *A. actinomycetemcomitans*, *F. nucleatum*, *P. intermedia*, and *S. aureus*. Within the same subjects the six species evaluated were common to both periodontal and peri-implant sites irrespective of health status. The prevalence and levels of *P. gingivalis* and *F. nucleatum* were significantly associated with periodontitis but not with peri-implantitis. *A. actinomycetemcomitans* was only associated with periodontitis and peri-implantitis (Zhuang *et al*. 2016).

Yu *et al*. (2019) characterized single-site subgingival and submucosal microbiomes of 18 partially dentate Chinese subjects treated with dental implants. Each subject contributed samples from a site with periodontal health, periodontitis, peri-implant health, and peri-implantitis. Microbial analyses using Illumina MiSeq sequencing revealed 26 phyla and 5726 OTUs. Species (OTU) composition of the periodontal and peri-implant microbiota varied widely between subjects. Firmicutes, Proteobacteria, Fusobacteria, Bacteroidetes, Actinobacteria, Synergistetes, TM7, and Spirochaetes comprised 99.6% of the total detection. Bacterial communities shared high levels of taxonomic similarity. Putative "periodonto-pathogens" such as *Prevotella*, *Porphyromonas*, *Tannerella*, *Bacteroidetes* (G-5), and *Treponema* spp. were associated with periodontitis and peri-implantitis sites. However, the variation between subjects in subgingival/submucosal microbiome composition was greater than the differences observed between implant vs. tooth sites, or between diseased vs. healthy peri-implant/periodontal sites (Yu *et al*. 2019).

The diversity of the peri-implantitis microbiome was also highlighted in a cross-sectional study evaluating 45 submucosal samples from peri-implantitis sites with varying degrees of severity assessed by probing depth (Kroger *et al*. 2018). Analyses by 16s sequencing identified 337 different taxa in the submucosal microbiome. There was a significant correlation of 12 taxa with increasing severity of disease indicating an increased level of dysbiosis in deep peri-implant pockets (Kroger *et al*. 2018).

(b) Fluorescent image of the same field stained specifically by fluorescence *in situ* hybridization (FISH) for Synergistes group A2. Bars correspond to 10 µm. (Source: Courtesy of G.N. Belimpasakis and Helga Lüthi-Schaller, University of Zürich, Switzerland.)

Patients at risk for peri-implant infections

There is strong evidence that patients who have a history of treated periodontitis have an increased risk for peri-implant infections (Hardt *et al*. 2002; Karoussis *et al*. 2003, 2004; Heitz-Mayfield 2008; Ong *et al*. 2008; Roccuzzo *et al*. 2010; Schwarz *et al*. 2018a, b). This is perhaps not surprising considering the two diseases share common risk factors, and patients with a host susceptibility to periodontitis will still be susceptible to biofilm infections at implant sites if periodontal pathogens colonize these sites.

This consideration is supported by findings that in patients diagnosed with advanced periodontitis, the persistence of periodontal pathogens was observed following full-mouth extraction and implant placement (Quirynen & Van Assche 2011). Ten patients with advanced periodontitis had all their teeth extracted and 6 months after tooth extraction, implants were placed. Abutment connection was completed 3–6 months later. Plaque samples were collected from the tongue dorsum, saliva, and subgingival/mucosal area (teeth/implants) before extraction and up to 1 year after abutment connection, and analyzed by culture, quantitative PCR, and checkerboard technology. A reduction in the total number of aerobic and anaerobic colony-forming units (CFU)/mL was observed, and there was a reduction in the detection of *P. gingivalis* and *T. forsythia* in the saliva and on the dorsum of the tongue. However, the submucosal areas of the peri-implant sulci were rapidly colonized by these key pathogens, and no changes could be detected for *A. actinomycetemcomitans*. Thus, whereas the extraction of the remaining periodontally involved teeth resulted in a significant reduction of bacteria related to periodontitis and peri-implantitis, they were not eliminated. The pathogens could then colonize the peri-implant regions and detection frequencies remained high (Quirynen & Van Assche 2011). Although it may take many years, peri-implant infections may develop if periodontal pathogens become established in the peri-implant biofilm in a susceptible host.

Furthermore, periodontal patients with residual probing depths of ≥6 mm at remaining teeth were found to have a greater prevalence of peri-implantitis (bone loss and peri-implant probing depth ≥5 mm with BoP) compared with periodontal patients with no residual pockets, or periodontally healthy subjects (Cho-Yan Lee *et al*. 2012). Moreover, a study including patients in maintenance care, with an average follow-up of 8 years, reported that periodontitis-susceptible patients with implants who developed peri-implantitis had significantly more residual periodontal pockets (≥5 mm) at the end of active periodontal therapy than patients who did not develop peri-implantitis (Pjetursson *et al*. 2012). This highlights the maintenance of periodontal health as a critical factor in reducing risk for peri-implant infection. Clinicians should inform patients with a history of periodontitis of their increased risk for peri-implant infections, and of the importance of optimal oral hygiene and regular supportive periodontal/peri-implant care.

Few studies have investigated the presence of specific bacterial species as a risk for the initiation or progression of peri-implantitis. One study found that the addition of a positive DNA test (which determined the presence of *A. actinomycetemcomitans*, *P. gingivalis*, *P. intermedia*, or *T. denticola*) enhanced the diagnostic power of the presence of bleeding on gentle probing (0.25 N) to predict progression of peri-implant disease (Luterbacher *et al*. 2000).

Acknowledgment

The authors would like to acknowledge the significant contribution of the late Professor Ricardo Teles in the previous edition of this chapter.

Introduction

The experimental gingivitis studies of the 1960s (Löe *et al*. 1965) elegantly demonstrated that there is a one-to-one relationship between the development of dental plaque and the development of gingivitis (Figs. 10-1, 10-2). These studies, together with those of more recent times (Trombelli *et al*. 2004, 2008), also show that there is variation in this response, with some individuals manifesting disease to a greater or lesser degree and at different time periods compared with others. So, while it has been known for many years that plaque is the etiologic agent, the factors contributing to individual patient susceptibility are still not fully understood. While all individuals with periodontitis will have had, at some stage, gingivitis, not all patients with gingivitis, nor all gingivitis lesions, will necessarily progress to periodontitis. The difficulty arises in identifying those lesions with gingivitis which will progress to periodontitis.

As with any disease, treatment planning in periodontics should be based on an understanding of the etiology and pathogenesis of the disease. In this context, it is clear that the bacteria in dental plaque are the cause of both gingivitis and periodontitis; however, it is the way in which an individual responds to these bacteria, rather than the bacteria per se, that determines disease expression and subsequent progression (Seymour 1991, Socransky & Haffajee 2005).

Over the past three decades it has become established that periodontitis results from the interaction

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

of the host's defense mechanisms with biofilms containing complexes including *Aggregatibacter actinomycetemcomitans*, *Porphyromonas gingivalis*, *Tannerella forsythia* and *Treponema denticola* (Socransky *et al*. 1998). Notwithstanding these observations, it has also been shown not only that they occur in a large proportion of the normal population (Cullinan *et al*. 2003), but that there is a high degree of volatility with respect to the presence and/or absence of these organisms over time, such that it would appear that they are more widespread in the community than previously thought. Indeed, it is now recognized that many people carry the organisms without manifesting disease progression (Cullinan *et al*. 2003). In this context, it is clear that most people are in balance with their biofilm for most of the time and it is only when this balance is disturbed that disease results. Such disturbances may occur as a result of environmental influences leading to an opportunistic increase in the numbers of organisms, or a depression of the host's defense mechanisms, or both. Indeed, it has been proposed that the development of inflammation in the gingival tissue itself can change the local ecology of the gingival sulcus thus leading to changes in the plaque microbiota with the ensuing dysbiosis or imbalance between the bacteria and host response resulting in disease progression (Bartold & Van Dyke 2019).

Not all individuals with gingivitis will progress to periodontitis, and not all individuals with periodontitis will progress to tooth loss. This individuality of disease expression is a reflection of individual susceptibility and is due to the interaction of the patient's specific individual pathogenic microbiota, the host's immune system and their own innate susceptibility, together with the impact of environmental and systemic factors (Fig. 10-3) (Cullinan *et al*. 2001; Seymour & Taylor 2004). Individuality of disease expression implies individuality of treatment which is the basis of so-called 'precision periodontal care' and which is reflected in the 2017 classification of periodontitis.

The development of gingivitis and periodontitis was loosely classified into the "initial", "early", "established", and "advanced" lesions by Page and

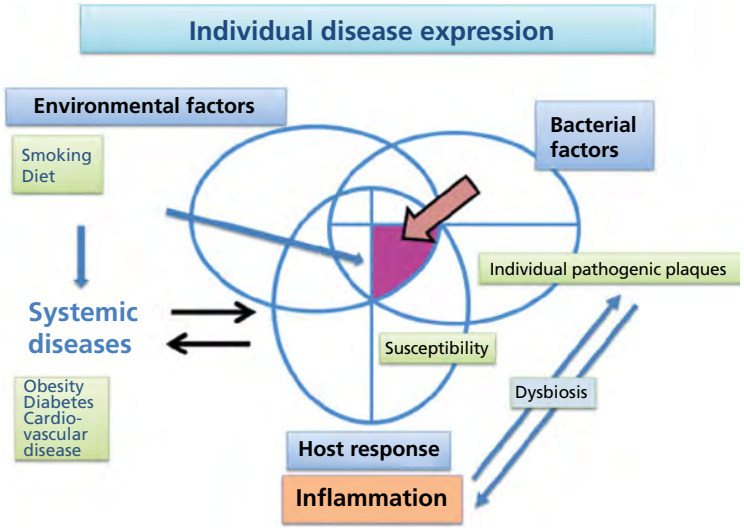

Fig. 10-3 Individuality of disease expression is due to the interaction of the patient's specific individual pathogenic microbiota, the immune system and innate susceptibility, together with the impact of environmental and systemic factors. Schroeder 44 years ago (Page & Schroeder 1976). However, today this is probably better viewed in the first instance as the development of a stable, homeostatic, gingivally confined lesion (gingivitis) in which the plaque microbiota is in balance with the host response. A subsequent dysbiosis or imbalance in this relationship, as a result of environmental, systemic or host factors, including the development of inflammation per se, then leads to the development of a progressive lesion (periodontitis) which is characterized by the loss of connective tissue attachment, destruction of alveolar bone, and apical migration of the junctional epithelium.

Gingivitis

Development of the homeostatic lesion

The development of gingivitis can be studied using the experimental gingivitis model. Two to four days following the beginning of plaque accumulation an "initial" lesion develops. This lesion is subclinical and can only be seen histologically. It is characterized by: (1) the formation of edema, manifesting as an increase in gingival crevicular fluid (GCF) flow; (2) an accumulation of polymorphonuclear neutrophils (PMNs); and (3) loss of connective tissue (Fig. 10-4). Streptococci are among the first organisms to colonize the acquired pellicle as plaque develops. While there is no evidence that these organisms actually invade the tissues they do produce a range of enzymes and metabolic end products which increase the permeability of the sulcular and junctional epithelia, allowing both the ingress of bacterial products and at the same time the outflow of GCF. At this early stage, the GCF is essentially the same as interstitial fluid, but nevertheless contains many serum proteins, including all the components necessary for the activation of complement.

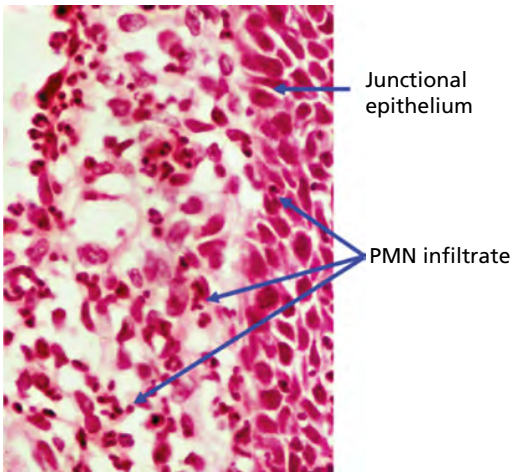

Fig. 10-4 Polymorphonuclear neutrophil (PMN) infiltration with destruction of the infiltrated connective tissue in the initial lesion.

Lipoteichoic acid and peptidoglycans, which are components of the cell wall of these early colonizers, are capable of activating complement via the "alternative pathway". This occurs in the gingival sulcus and results in the production of the "anaphylatoxins" C3a and C5a, which in turn flow back into the tissues, establishing a concentration gradient from the gingival sulcus into the tissues. Once in the tissue, these anaphylatoxins lead to the release of vasoactive amines from resident mast cells. In turn, these vasoactive amines lead to an increase in vascular permeability and the formation of edema, one of the hallmarks of inflammation. Mast cells also release preformed cytokines, including tumor necrosis factor-alpha (TNF-α), which results in the expression of adhesion molecules by endothelial cells and the subsequent sticking and migration of PMNs into the gingival tissues. While activation of the alternative complement pathway is essential for the vascular responses,

bacterially derived chemotactic substances together with C5a are responsible for the migration of PMNs into the gingival sulcus. Once in the gingival sulcus, however, the PMNs are unable to phagocytose the bacteria, which are beginning to form a biofilm and as such are firmly adherent to the tooth surface. In this situation, the PMNs disgorge their lysosomal contents into the gingival sulcus in what has been termed "abortive phagocytosis". These lysosomal enzymes can then return into the tissues and contribute to the local destruction of connective tissues. In addition, PMNs release structures called neutrophil extracellular traps (NETs) which can trap and kill microbial pathogens. These were first described by Brinkman *et al*. (2004) and consist of chromatin structures, nuclear histones, and many granular antimicrobial proteins. NETs are released during a form of pathogen-induced cell death, called NETosis, that differs from apoptosis and necrosis (Steinberg & Grinstein 2007) and represents one of the first lines of defense against pathogens. *In vivo* both dead and viable PMNs can release NETs, which in turn can be associated with severe tissue damage. In addition, a variety of proinflammatory stimuli, all of which can be found in the gingival sulcus, such as lipopolysaccharide (LPS), interleukin-8 (IL-8), TNF, as well as the streptococcal M protein, can all induce NET formation (for review, see Remijsen *et al*. 2011).

While NETs have been described in periodontitis, it is likely that they are also formed in this initial lesion stage of gingivitis and then persist through all stages of gingivitis and periodontitis. Evidence for this, however, is at present lacking.

Other cell types, such as eosinophils and mast cells, are also able to release extracellular traps (von Kockritz-Blickwede *et al*. 2008). These mast cell extracellular traps (MCETs) appear to be released in response to the same factors that lead to NET release from PMNs. MCETs are also composed of nuclear histones together with the antimicrobial cathelicidin LL37, as well as tryptase, a granular mast cell marker, and their formation in the tissues would not only limit the ingress of bacteria but also of bacterial vesicles. They may, however, contribute to localized tissue destruction. Again, while highly likely, evidence for the formation of both NETs and MCETs in the tissues is lacking. Indeed, the role of mast cells in periodontal disease is largely unknown.

Within the gingival sulcus, PMNs also produce and release a variety of cytokines including IL-1, the IL-1 receptor antagonist (IL-1RA), and high levels of IL-17. IL-17 in turn induces the production of IL-8 by sulcus epithelial cells. IL-8 is not only a very strong chemoattractant for PMNs, but as stated earlier, is also a strong stimulus for NET formation, thus establishing a positive feedback loop in an attempt to contain the developing bacterial infection. Indeed, it is highly likely that the role of IL-17 in periodontal disease is a protective one in that it maintains the PMN barrier in the gingival sulcus. It is well established that loss of this barrier, either due to an absence of PMNs (such as agranulocytosis or cyclic neutropenia) or a defect in their function (either chemotactic or phagocytic), leads to severe and rapid progression of periodontal destruction. At this initial stage, however, the lesion occupies no more than 5–10% of the connective tissues and is still not evident clinically.

After approximately 4–7 days of plaque accumulation, the nature of the developing lesion changes from one consisting primarily of PMNs to one with increased numbers of lymphocytes and macrophages (Fig. 10-5). Vascular changes become more pronounced with the opening of previously dormant capillary beds, the formation of postcapillary venules, increased vascular permeability, and the development of perivascular inflammatory infiltrates. As a result, there is a net increase in the flow of fluid into the affected gingival tissues, and a subsequent increase in the flow of GCF. The nature of the GCF at this stage changes from that of interstitial fluid to that of an inflammatory exudate, in other words edema. An increase in the permeability of the sulcular and junctional epithelia, as a result of widening of the intercellular spaces between the epithelial cells, allows increased ingress of bacterial products into the gingival tissues and escalation of the inflammatory response.

This lymphocyte/macrophage lesion develops as small perivascular infiltrates which progressively increase in size and coalesce such that at around day 12–21 following the beginning of plaque accumulation the lesion becomes clinically evident. By day 21, lymphocytes make up 70% of the infiltrate and although there is a four-fold increase in PMN numbers within the junctional epithelium (Lindhe & Rylander 1975),

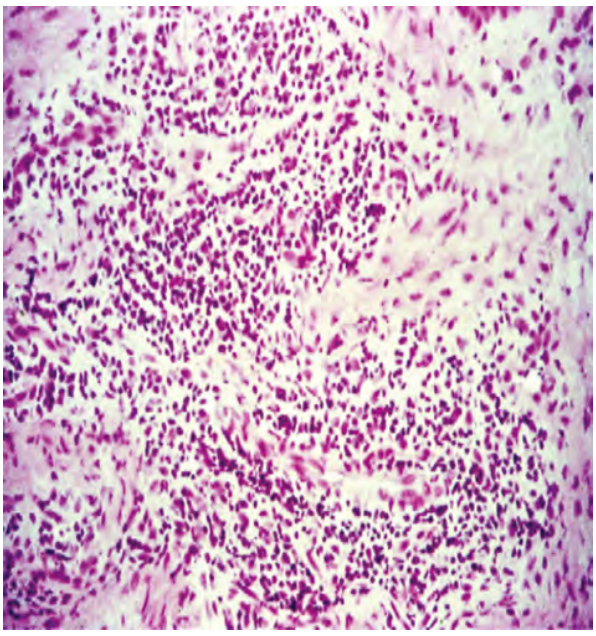

Fig. 10-5 Perivascular lymphocyte/macrophage infiltrate seen in a 21-day experimental gingivitis lesion. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

PMNs and plasma cells make up <10% of the total infiltrate (Seymour *et al*. 1983). As with the initial lesion, the release of cytokines such as TNF-α and IL-17 from mast cells and PMNs undergoing NETosis leads to an increase in cell adhesion molecules, such as endothelial cell leukocyte adhesion molecule-1 (ELAM-1) and intercellular adhesion molecule-1 (ICAM-1), which together with an increase in IL-8 production by the epithelial cells help to establish a fast flow of PMNs through the junctional epithelium and into the gingival sulcus (Moughal *et al*. 1992), where they form a barrier against plaque microorganisms (Attstrom 1971). Although the infiltrated area remains fairly localized at this stage, up to 60–70% of collagen within the infiltrated zone is degraded (Page & Schroeder 1976).

The immunologic events occurring during the development of gingivitis have been described (Seymour *et al*. 1988). These events are identical to the development of delayed-type hypersensitivity (DTH) and involve the formation of perivascular lymphocyte/macrophage infiltrates (Fig. 10-5) which, as they increase in size, coalesce and merge, eventually becoming clinically evident. The infiltrates consist predominantly of T cells (Fig. 10-6), with a CD4:CD8 ratio of around 2:1 (Fig. 10-7), together with both dendritic antigen-presenting cells (APCs) and infiltrating phagocytic macrophages. These activated T cells, along with the sulcular epithelial cells, express high levels of MHC class II antigens (HLA-DR and HLA-DQ) (Fig. 10-8). Langerhans cells are seen in increased numbers in both the oral as well as the oral sulcular epithelium (Fig. 10-9a). Fewer than 5% of the T cells express the IL-2 receptor CD25 (Fig. 10-9b), suggesting that these cells are not proliferating locally. As soluble antigen enters the tissues, it is taken up by the resident Langerhans cells and carried to the regional lymph nodes where antigen-specific T cells are sensitized. In chronic

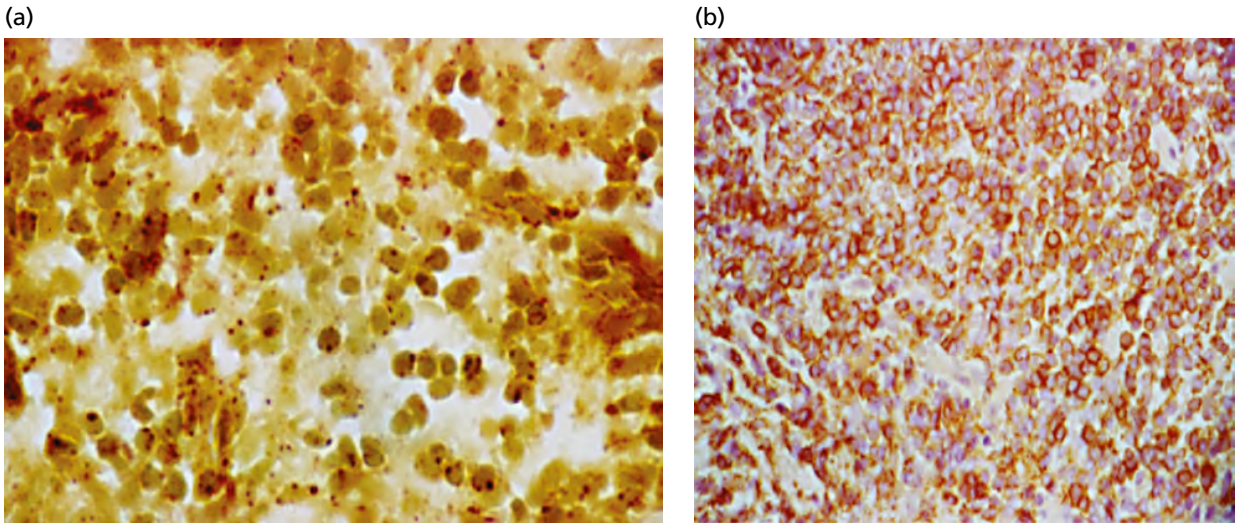

Fig. 10-6 21-Day experimental gingivitis lesion showing the predominance of (a) non-specific esterase-positive and (b) CD3-positive T cells. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

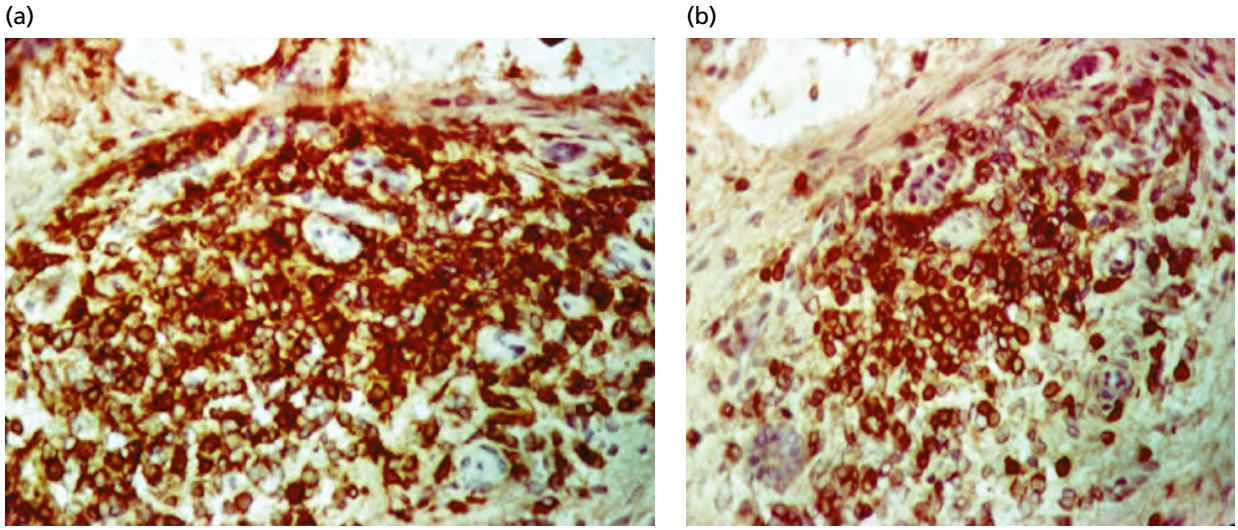

Fig. 10-7 21-Day experimental gingivitis lesion showing a (a) CD4 to (b) CD8 ratio of 2:1. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

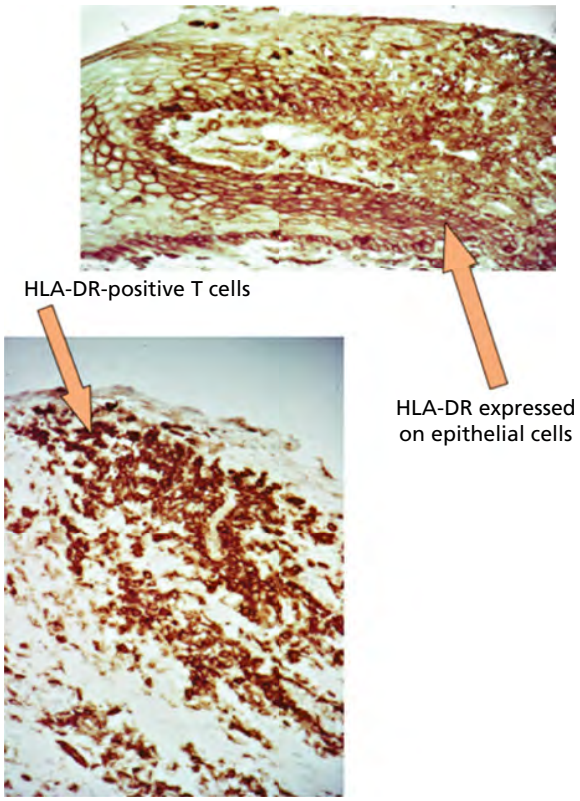

Fig. 10-8 21-Day experimental gingivitis lesion showing HLA-DR-positive activated T cells and HLA-DR-positive epithelial cells. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

gingivitis Langerhans cells can be seen migrating out of the epithelium and through the connective tissue (Fig. 10-10). The sensitized T cells then travel back to the site of original antigen challenge (i.e. the gingival tissues). Once there, following further antigen presentation by dendritic cells, they become activated and together with the infiltrating phagocytic macrophages, they control the ingress of antigen and achieve a balance with the plaque biofilm. While in the developing lesion the majority of macrophages are phagocytic cells, in chronic gingivitis the major APC is the CD14-positive/CD83-positive dendritic cell (Gemmell *et al*. 2002c), with fewer classical pro-inflammatory M1 macrophages compared with the alternative prohealing M2 macrophages (Garaicoa-Pazmino *et al*. 2019). Nevertheless, the production of interferon gamma (IFN-γ) by the activated CD4 T cells further activates the PMNs and macrophages. Although these cannot eliminate the bacterial challenge, they, via the production of NETs in the gingival sulcus and the production of cytokines within the tissues, are able to control the infection. As noted earlier, this sequence of events is identical to that seen in the development of DTH (Poulter *et al*. 1982). The development of DTH is a well-controlled immunologic response which develops in 12–24 hours, peaks within 48 hours, and is gone within a week. In this context, gingivitis can also be considered to be a

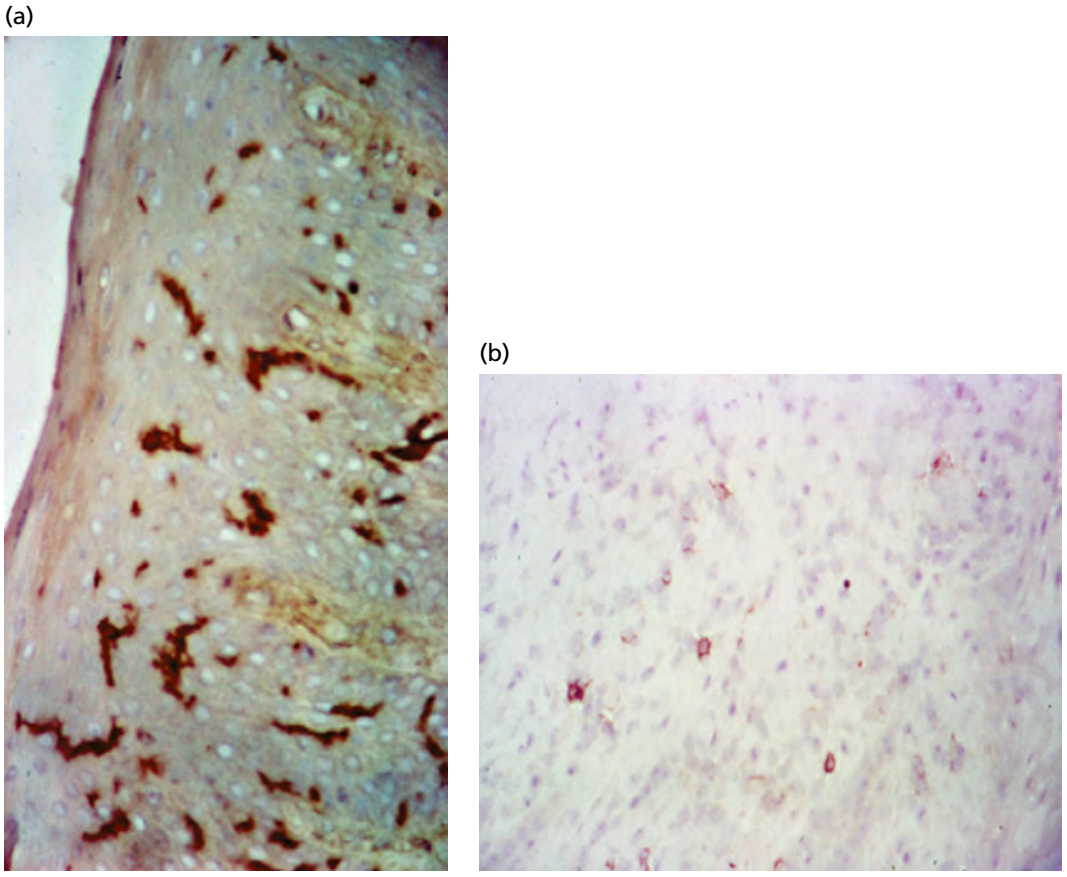

Fig. 10-9 21-Day experimental gingivitis lesion showing (a) increased CD1a-positive Langerhans cells in the oral epithelium and (b) relatively few CD25 (IL-2 receptor)-positive T cells in the infiltrate. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

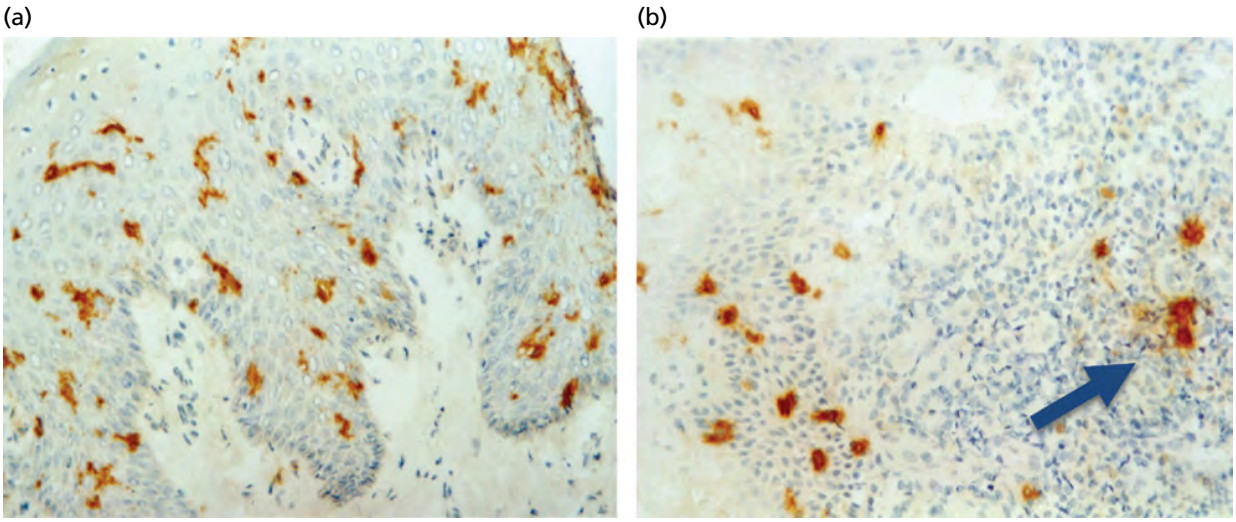

Fig. 10-10 Chronic gingivitis lesion showing (a) increased CD1a-positive Langerhans cells in the oral epithelium and (b) CD1a-positive cells within the inflammatory infiltrate (arrow). (Source: Gemmell *et al*. 2002c. Reproduced with permission from John Wiley & Sons.)

well-controlled immunologic response but, as noted earlier, because of the persistence of the plaque biofilm, the immunologic response persists rather than resolving. The subsequent, prolonged nature of the inflammatory response results in gingivitis becoming chronic in nature. While in most people the immune response is able to contain the microbial challenge, it is only with mechanical cleaning that the microbial challenge can be cleared. Collagen is degraded in the stable lesion but does not result in any loss of attachment. When the plaque is removed, gingival tissues repair and remodel, and there is no permanent damage to or alteration of tissue architecture.

The epithelial barrier

The gingival epithelium is not only a physical barrier to the ingress of microorganisms and their products, but it also plays an important role in in the innate immune system and in maintaining homeostasis. The discovery of pattern recognition receptors (PRRs), such as toll-like receptors (TLRs), has led to a far greater understanding of innate immunity and the induction of adaptive immunity. TLRs are found on a range of cells including gingival epithelial cells which express a number of TLRs including TLR2,3,4,5,6, and 9 (for review see Mahanonda & Pichyangkul 2007). These TLRs recognize structures known as pathogen-associated molecular patterns (PAMPs) that are highly conserved across a wide variety of pathogens. Such PAMPs include LPS, peptidoglycan, bacterial DNA, double-stranded RNA, and lipoprotein.

Activation of gingival epithelium via TLR-2 leads to the production of IL-8 which, as stated earlier, is a very powerful chemoattractant and stimulus for NET formation thus contributing to the formation of the PMN barrier (Attstrom 1971) and maintenance of the stable, homeostatic lesion. Deficiencies in PMN numbers or function result in rapid and advanced periodontal destruction.

TLR signaling also leads to the production of antimicrobial peptides (α- and β-defensins, the cathelicidin LL37, and calprotectin) which further limit bacteria within the gingival sulcus and are thus important in maintaining the symbiotic relationship between the host and the plaque microbiota. α-defensins are not only potent antimicrobial agents; they also activate the classical complement pathway and can upregulate the production of IL-8. The β-defensins hBD1, hBD2, and hBD3 have been demonstrated in both oral and sulcular epithelium (Dale 2002; Dunsche *et al*. 2002; Dommisch & Jepsen 2015). These too are not only antimicrobial but may also be involved in mediating inflammation (Ganz 2003). In a recent study, Dommisch *et al*. (2019) have shown the sequential expression of a number of antimicrobial peptides (including β-defensins, the CC-chemokine 20 ligand CCL20, S100A7/psoriasin, and calgranulin A/B) during the development of gingival inflammation. These authors showed that there was a significant increase in hBD2 and hBD3 mRNA expression by day 3 of an experimental gingivitis, reaching a peak at day 14 and then declining by day 21. In contrast, CCL20 mRNA peaked at day 3 but declined by days 14 and 21. The S100A7/psoriasin and S100A/B calgranulin A and the S100A9 calgranulin B also peaked at day 3 but the levels were maintained through day 14. These mRNA results were largely confirmed by protein analysis of GCF although the authors did note a large degree of interindividual variation. This study is the first to show the sequential and differential expression of these antimicrobial peptides in an experimental gingivitis model and, as the authors point out, again highlights the importance of these molecules in maintaining gingival homeostasis.

Factors influencing the pathogenesis of gingivitis

Predisposing factors are defined as those factors which retain or hinder the removal of plaque and therefore are associated with both the maintenance and severity of gingival inflammation. On the other hand, modifying factors are defined as those factors which alter the nature or course of the inflammatory response. As chronic inflammation involves a vascular response and a cellular response together with the simultaneous presence of destruction and repair, anything which alters the vascular response, the cellular response, or the repair potential of the tissues can be considered a modifying factor.

Vascular response

Sex hormones

Physiologic and pathologic endocrine changes have long been established as significant modifying factors in the expression of gingivitis (Sooriyamoorthy & Gower 1989; Mariotti 1999; Tatakis & Trombelli 2004). The variation in sex hormone levels during puberty (Mombelli *et al*. 1989; Bimstein & Matsson 1999), pregnancy (Hugoson 1971), and menstruation (Koreeda *et al*. 2005) has been shown to alter the plaque–gingivitis relationship, resulting in increased levels of inflammation. Gingival and periodontal tissues contain receptors for sex steroid hormones and their physiology is regulated, at least in part, by serum and salivary hormonal levels (Soory 2000). In particular, estrogen has a stimulatory effect on both the metabolism of collagen and on angiogenesis, and at the same time it leads to a decrease in keratinization of the gingival epithelium. However, it is progesterone which is thought to have the major effect in the gingival tissues, both in terms of its effect on the levels of proinflammatory mediators (Lapp *et al*. 1995; Markou *et al*. 2011) and on the gingival vasculature. It has been known for many years that progesterone not only increases vascularity of the gingival tissues but also increases their permeability, thus resulting in a highly vascular edematous inflammatory response (Hugoson 1970; Lundgren *et al*. 1973).

Pregnancy was one of the first conditions identified as having an impact on the expression of gingivitis (Ziskin *et al*. 1946; Löe & Silness 1963; Silness & Löe 1964). In particular, increases in both the prevalence and severity of gingivitis were reported during the second and third trimester of pregnancy (Löe & Silness 1963; Hugoson 1971; Arafat 1974). The generally accepted mechanisms leading to the exaggerated inflammatory response are related to the increased levels of progesterone, which lead to increased permeability and dilatation of gingival capillary vessels, resulting in increased vascular flow and exudation (Hugoson 1970; Lundgren *et al*. 1973). These effects are partly mediated by an increased synthesis of prostaglandin (Miyagi *et al*. 1993).

Variations in the severity of gingival inflammation have also been described with the onset of puberty in both males and females (Parfitt 1957; Sutcliffe 1972; Hefti *et al*. 1981; Mombelli *et al*. 1989) as well as during the menstrual cycle, particularly during the ovulation period (Koreeda *et al*. 2005). Fluctuation of sex steroid hormones, which may affect blood volume, flow rate, and vascular permeability, are thought to alter the host response, leading to the observed increase in the clinical signs of gingival inflammation (Baser *et al*. 2009; Becerik *et al*. 2010) and the observed increase in gingival exudate (Hugoson 1971). The evidence, however, suggests that hormonal variations do not affect clinically healthy gingiva, but do exacerbate existing chronic gingivitis (Holm-Pedersen & Löe 1967; Kovar *et al*. 1985; Niemi *et al*. 1986; Becerik *et al*. 2010).

Early clinical studies reported a higher incidence of gingival inflammation in women taking hormonal contraceptives compared with women not taking these agents (Lindhe & Bjorn 1967; El-Ashiry *et al*. 1970; Pankhurst *et al*. 1981). However, formulations of oral contraceptives have changed dramatically, resulting in substantially lower concentrations of hormones and more recent studies suggest that the effect of newer contraceptive pills on gingivitis is practically nil (Preshaw *et al*. 2001).

Diabetes

Diabetes is an endocrine condition with a well-characterized effect on gingivitis. Clinically, subjects with diabetes, whether insulin-dependent or non-insulin dependent, have significantly higher gingival inflammation compared with those who do not have diabetes with similar plaque levels (Bernick *et al*. 1975; Cutler *et al*. 1999; Salvi *et al*. 2005, 2010).

At the vascular level, the accumulation of advanced glycation end products (AGEs) alters the function of several intercellular matrix components, including vascular wall collagen, resulting in thickening of the capillary basement membrane and loss of vascular elasticity (Ulrich & Cerami 2001). Results from controlled histologic studies in animals showed that diabetes was associated with changes of the gingival vasculature, such as the formation of new vessels with variable wall thickness, hyperemia, localized moderate-to-severe vasculitis (Tesseromatis *et al*. 2009), increased vascular permeability accompanied by increased leukocyte adhesion molecule expression, and enhanced leukocyte rolling (Sima *et al*. 2010).

Smoking

The effect of smoking on the expression of plaque-induced gingival inflammation is controversial. A number of studies have shown that smokers, when compared with non-smokers, accumulate plaque at the same rate but exhibit significantly less gingival

inflammation in experimental gingivitis studies, albeit with similar plaque levels (Bergstrom & Preber 1986; Danielsen *et al*. 1990; Lie *et al*. 1998; Müller *et al*. 2002). In addition, significantly lower GCF volumes were detected at periodontally healthy or slightly inflamed sites in young regular smokers compared with non-smokers (Persson *et al*. 1999). At the same time, a single episode of smoking has been shown to produce a transient increase in GCF volume (McLaughlin *et al*. 1993).

The biologic mechanisms underlying the suppressive effect of smoking on clinical parameters of gingival inflammation are poorly understood. A structural and/or functional impairment of the gingival and periodontal microcirculatory system, however, has been put forward (Scott & Singer 2004). In one, albeit small, study, the periodontal vascular system in smokers was found to be composed of smaller numbers of large vessels, but larger numbers of small vessels, compared with non-smokers, with no differences in terms of mean vascular density between smokers and non-smokers (Mirbod *et al*. 2001). This, together with the well-established nicotine-induced peripheral vasoconstriction as well as the reduction in GCF, is consistent with the effect of smoking being mediated, at least in part, by modulation of the local vascular response.

Cellular response

Blood dyscrasias

The systemic conditions usually identified as affecting the cellular response in gingivitis are the blood dyscrasias, including neutropenias (Andrews *et al*. 1965; Rylander *et al*. 1975; Reichart & Dornow 1978), leukemias (Levin & Kennedy 1973; Bergmann *et al*. 1992), and human immunodeficiency virus/acquired immune deficiency syndrome (AIDS) (Glick *et al*. 1990). These conditions are characterized either by low numbers of functional PMNs (neutropenias) or large numbers of immature dysfunctional leukocytes (leukemias) infiltrating the gingival tissues or, as in the case of AIDS, by a very low CD4-positive T-cell count and the inability to mount an effective T-cell response. Other conditions which are characterized by defective PMN function, either phagocytic (Chédiak–Higashi syndrome) or chemotactic (Down's syndrome) (Izumi *et al*. 1989), also display severe gingival inflammation. These conditions highlight the fact that abnormalities in cell numbers or function can modify the inflammatory response to plaque and manifest as severe gingival inflammation.

Diabetes

As noted earlier, the development of gingivitis involves an initial innate immune response to the formation of plaque. In the presence of a poor innate response and the relative lack of PMNs in the gingival sulcus, a more severe inflammatory response occurs. In addition to the vascular response noted earlier, hyperglycemia also leads to an impairment of immune cell function (Gugliucci 2000). In this respect, individuals with uncontrolled diabetes show reduced PMN function (Marhoffer *et al*. 1992), defective chemotaxis (Ueta *et al*. 1993), and significantly more severe gingival inflammation compared with those without diabetes with similar plaque levels (Gislen *et al*. 1980; Cianciola *et al*. 1982; Rylander *et al*. 1987; Salvi *et al*. 2005).

Chronic hyperglycemia leads to the accumulation of AGEs, which bind to macrophages and monocytes (Brownlee 1994), resulting in an increased release of proinflammatory mediators (Iacopino 1995) and more severe gingival inflammation with higher levels of IL-1β and matrix metalloproteinase-8 (MMP-8) (Salvi *et al*. 2010).

Smoking

Smoking also has a profound effect on the immune system and the development of inflammation (Barbour *et al*. 1997; Palmer *et al*. 2005). Reduced migration (Eichel & Shahrik 1969) and phagocytic capacity of PMNs (Kenney *et al*. 1977) and increased numbers of circulating T and B lymphocytes (Sopori & Kozak 1998) has been demonstrated in smokers. However, the relevance of these mechanisms in altering the gingival inflammatory response to the dental biofilm needs to be determined.

Longitudinal studies using ante-dependence modeling, such as a Markov chain, enables the results of a sequence of exams to be analysed longitudinally, taking into account serial dependence, allowing for both progression and regression between disease categories. Using this approach Faddy *et al*. (2000), showed that smoking had no effect on disease progression but significantly reduced disease regression. Using a similar approach Shätzle *et al*. (2009) reanalysed the data from the 26-year longitudinal Norwegian academic study on the natural history of periodontitis and showed that smoking led to initiation of disease 3–4 years earlier, compared with that in the non-smokers. These studies were then confirmed by Ramseier *et al*. (2017) who reexamined the Sri Lankan tea laborers originally examined in 1970 (Löe *et al*. 1986) and showed that in this population smoking was associated with disease initiation but not with disease progression (Fig.10-11). While the mechanism underlying this association of smoking with the initiation of periodontitis remains speculative, it is likely that reduction in PMN migration and function, noted above, is involved.

Repair potential

The final feature of a chronic inflammatory response is the ability of the tissue to repair itself, such that anything which affects this ability will modify the gingival response to plaque and will either manifest

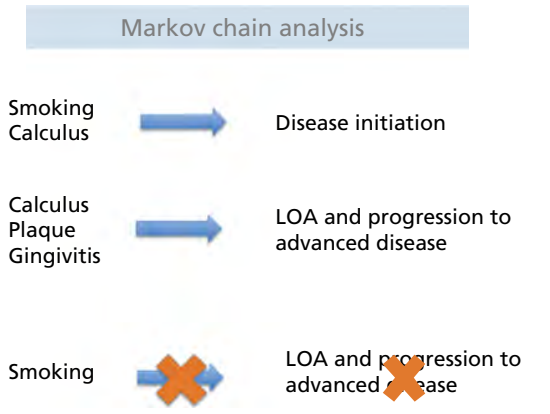

Fig. 10-11 Markov chain analysis of the effect of smoking on the initiation and progression of periodontitis (Ramseier *et al*. 2017) indicating that smoking and calculus are associated with the initiation of periodontitis, calculus plaque and gingivitis are associated with loss of attachment (LOA) and progression to advanced disease, while smoking was not associated with progression of periodontitis.

as an enlargement (over response) or loss of connective tissue (impaired response) and progression to periodontitis.

Over response

Several drugs (Seymour 1993), including anticonvulsants such as phenytoin (Angelopoulos 1975a, b), antihypertensive calcium channel blockers such as nifedipine (Nery *et al*. 1995; O'Valle *et al*. 1995), and the immunosuppressant cyclosporine (Seymour & Jacobs 1992; O'Valle *et al*. 1995) cause severe gingival enlargement, a reaction related to the plaque-induced gingival inflammation (Seymour *et al*. 1996). Although these drugs have different pharmacologic mechanisms, a common denominator appears to be their effect on calcium metabolism which has been hypothesized to result in gingival enlargement (Hassell & Hefti 1991). Consistent with this concept is the fact that the clinical and histologic features of gingival enlargement induced by phenytoin, cyclosporine, or nifedipine are all similar (Hassell & Hefti 1991; Seymour *et al*. 1996). Histologic studies have shown that accumulation of extracellular matrix within the gingival connective tissue is the main feature of the overgrown tissues (Rostock *et al*. 1986; Mariani *et al*. 1993).

It is well established that the severity of the gingival enlargement is related to the level of plaque control and the presence of gingivitis (Steinberg & Steinberg 1982; Addy *et al*. 1983; Hassell *et al*. 1984; Tyldesley & Rotter 1984; Daley *et al*. 1986; McGaw *et al*. 1987; Modeer & Dahllof 1987; Yahia *et al*. 1988; Barclay *et al*. 1992; Lin & Yang 2010), which supports the concept that the enlargement reflects an over response of the repair component of the inflammatory reaction. Further, a high concentration of tissue plasminogen activator (t-PA) (Buduneli *et al*. 2004) and plasminogen activator inhibitor type 2 (PAI-2) has been demonstrated in GCF from enlarged sites, which suggests that the enlargement itself may act as a predisposing factor and lead to the aggravation of gingival inflammation (Kinnby *et al*. 1996). However, whether and to what extent the drugs associated with gingival enlargement may intimately modulate the complex host–bacteria interaction leading to gingival inflammation remains to be determined.

Impaired response

An example of how an impaired repair potential can influence the expression of gingivitis can be seen in vitamin C deficiency where an impairment of collagen metabolism results in highly inflamed, friable gingivae in the presence of plaque. Indeed, in both humans (Leggott *et al*. 1986, 1991) and non-human primates (Alvares *et al*. 1981) a subclinical deficiency of ascorbic acid results in increased gingivitis relative to non-deficient controls with similar plaque levels and the same type of microbiota.

Other studies, although preliminary and limited in number, suggest that other nutritional factors, including vitamin E (Cohen & Meyer 1993; Offenbacher *et al*. 1990; Asman *et al*. 1994), riboflavin, calcium, and frequency of fiber intake (Petti *et al*. 2000) may influence the incidence and severity of plaque-induced gingivitis, but their mechanisms are unknown.

Ante-dependence modeling has shown that smoking significantly inhibits the healing capacity of the periodontal tissues. Indeed, Faddy *et al*. (2000) showed that the healing capacity of smokers was only 28% that of non-smokers and was equivalent to that of non-smokers 36 years older. In other words, the periodontal healing capacity of a 45-year-old smoker is that of an 81-year-old non-smoker. This inhibition of healing together with the earlier initiation of disease progression could account for the increased prevalence of periodontitis seen in smokers.

Periodontitis

Histopathology of periodontitis

In 1965, Brandtzaeg and Kraus (1965) demonstrated the presence of immunoglobulin-producing plasma cells in the gingival tissues of patients with periodontitis. This was the first direct evidence that adaptive immune mechanisms play a role in the pathogenesis of periodontal inflammation. It was not until 1970, however, that Ivanyi and Lehner (1970), using peripheral blood lymphocyte transformation assays, highlighted a role for cell-mediated immunity. It is now well established that the periodontitis lesion itself involves predominantly B cells and plasma cells (Fig. 10-12) (Mackler *et al*. 1977; Seymour *et al*. 1978; Seymour & Greenspan 1979; Berglundh *et al*. 2011). Although the majority of lymphocytes are immunoglobulin-bearing B cells, up to 30% of the lymphocytes may be T cells. Clinically it is not yet possible to

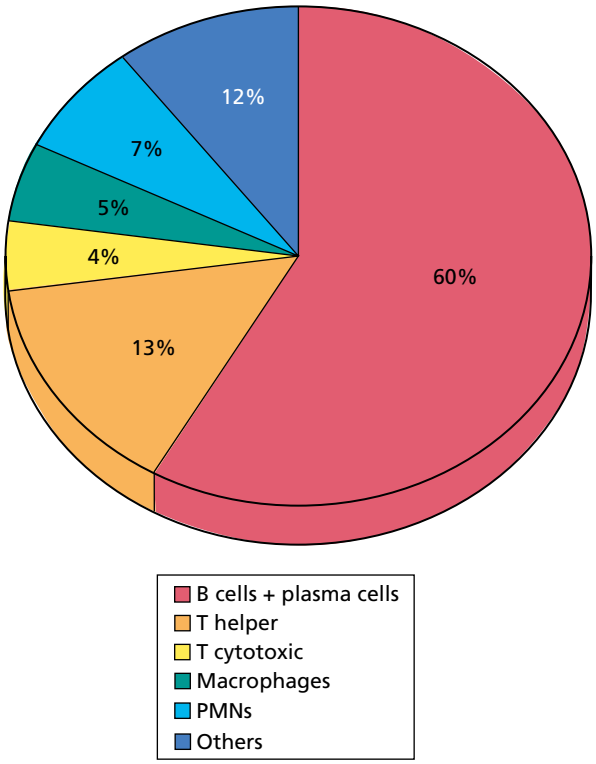

Fig. 10-12 Distribution of cells in periodontitis lesions. (Source: Adapted from Berglundh *et al*. 2011. Reproduced with permission from John Wiley & Sons.)

determine disease activity; hence, it is not possible to say if the increased proportions of B cells and plasma cells seen in some clinical gingivitis lesions represent a stable gingivitis lesion or indeed is the beginning of a progressive periodontitis lesion. In this context, and in terms of the development of periodontal disease (gingivitis and periodontitis), it is probably better to consider this end stage of gingivitis and the increasing numbers of plasma cells as a possible transitional lesion between gingivitis and periodontitis.

While the gingivally confined T-cell lesion remains relatively stable, this B-cell/plasma cell lesion progresses and leads to the development of a periodontal pocket. Connective tissue breakdown leads to loss of the connective tissue attachment to the tooth and as a result the junctional epithelium migrates in an apical direction, thus forming a periodontal pocket (Fig. 10-13). This in turn becomes lined by pocket epithelium with in-growth of rete pegs into the surrounding connective tissue (Fig. 10-14). Polymorphonuclear neutrophils continue to migrate through this pocket lining epithelium and into the periodontal pocket where they form a barrier between the tissues and plaque biofilm. Increased permeability and ulceration of the pocket epithelium allows further ingress of microbial products, leading to the continued production of inflammatory cytokines such as interleukin-1 (IL-1), TNF-α, and prostaglandin E_2 (PGE_2) (for review, see Gemmell *et al*. 2007), and perpetuation of the inflammatory process resulting in destruction of both connective tissue and bone (Reynolds & Meikle 1997).

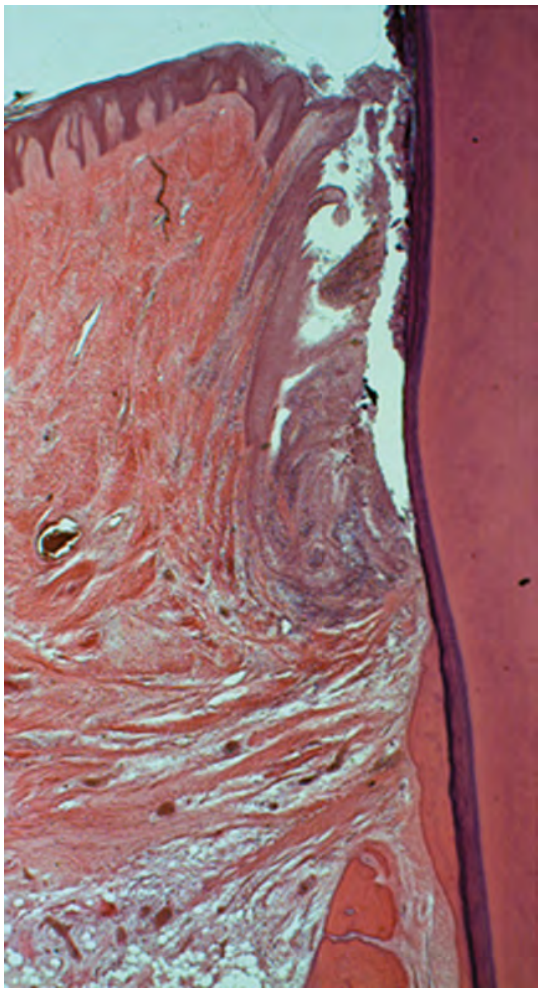

Fig. 10-13 Autopsy specimen showing a human periodontitis lesion. Calculus and biofilm in the pocket. Note the infiltrated connective tissue lateral and apical of the pocket epithelium.

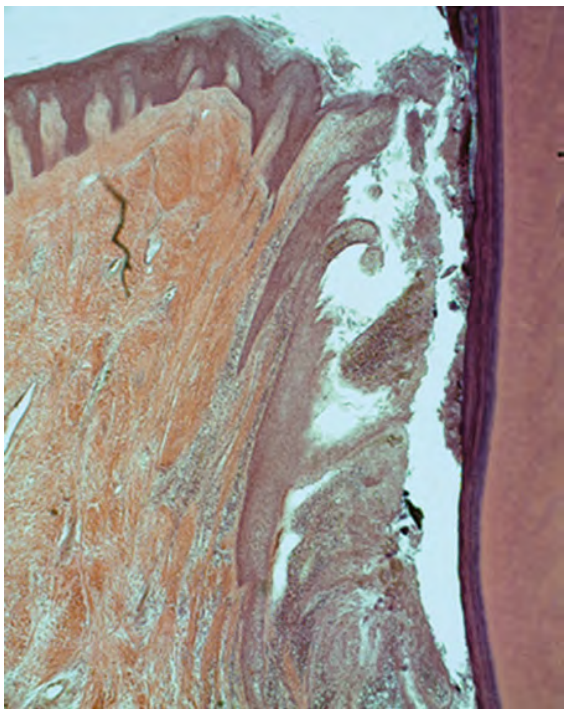

Fig. 10-14 Detail of Fig. 10.13. Note the ulcerated pocket epithelium with rete pegs into the connective tissue.

Surrounding the inflammatory infiltrate is a fibrous tissue band. This is common to all chronic inflammatory lesions and is an attempt by the lesion to wall off from the surrounding tissues. Indeed, in periodontitis, irrespective of the depth of the pocket, the underlying alveolar bone and periodontal ligament do not become inflamed (Fig. 10-15).

As the lesion progresses the same cellular make-up persists with the overt loss of attachment becoming evident clinically and histologically (Figs. 10-16, 10-17). It is now generally accepted that the mechanism of tissue destruction is via the effects of the immune response (Birkedal-Hansen 1993) and is not a direct consequence of the bacteria *per se*. Macrophages are not a dominant feature of the advanced lesion, comprising fewer than 5% of the cells. Fibroblasts, however, when stimulated by the inflammatory cytokines IL-1, IL-6, TNF-α, and PGE_2, produce matrix metalloproteinases (MMPs), which are a family of proteinases whose primary purpose is the degradation of the extracellular matrix. Collagen molecules are cleaved into smaller fragments, which then become denatured in the extracellular environment or are phagocytosed by surrounding fibroblasts. As the lesion advances, alveolar bone loss becomes apparent. However, the non-infiltrated fibrous band remains adjacent to the crestal bone, effectively encapsulating the progressing lesion and walling it off from the surrounding tissues. It should be noted again that the underlying bone and periodontal ligament remain non-inflamed (Fig. 10-18).

B cells in periodontitis

As noted above, the periodontitis lesion is characterized by large numbers of B cells and plasma cells. Immunoglobulin-bearing B cells in a periodontitis lesion are illustrated in Fig. 10-19. B cells can be activated either by specific antigens or by polyclonal activators. Indeed, a number of the putative periodontal pathogens, including *P. gingivalis, A. actinomycetemcomitans,* and *Fusobacterium nucleatum* have been shown to have profound polyclonal B-cell activation properties (Bick *et al*. 1981; Mangan *et al*. 1983; Carpenter *et al*. 1984; Ito *et al*. 1988). However, polyclonal activators do not activate all B cells.

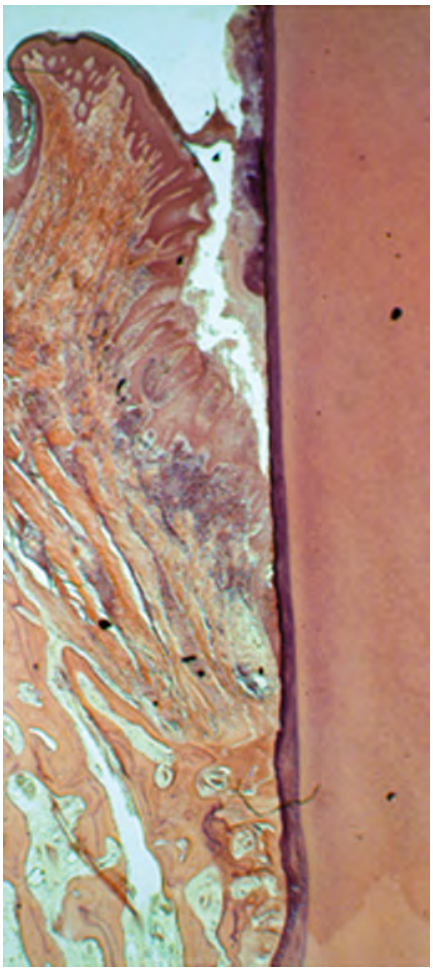

Fig. 10-16 Autopsy specimen showing a human periodontitis lesion. The overt loss of attachment and bone is characteristic for the advanced lesion.

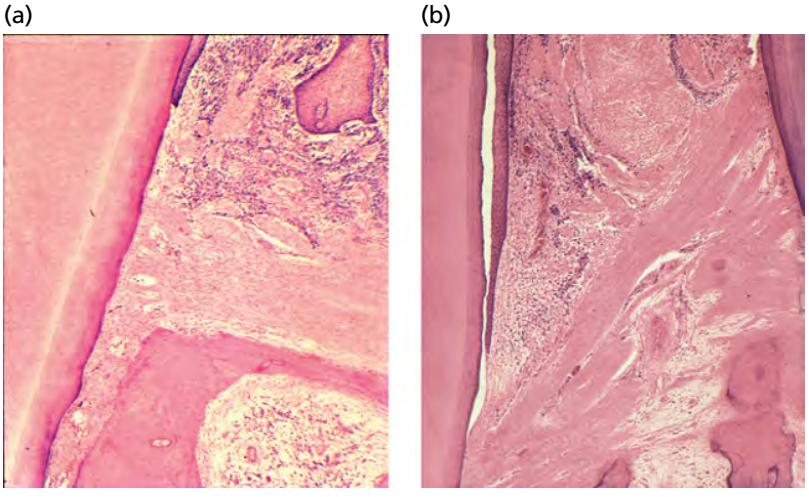

Fig. 10-15 A band of non-infiltrated connective tissue is interposed between the infiltrated connective tissue and the alveolar bone. (a) Suprabony pocket. (b) Infrabony pocket.

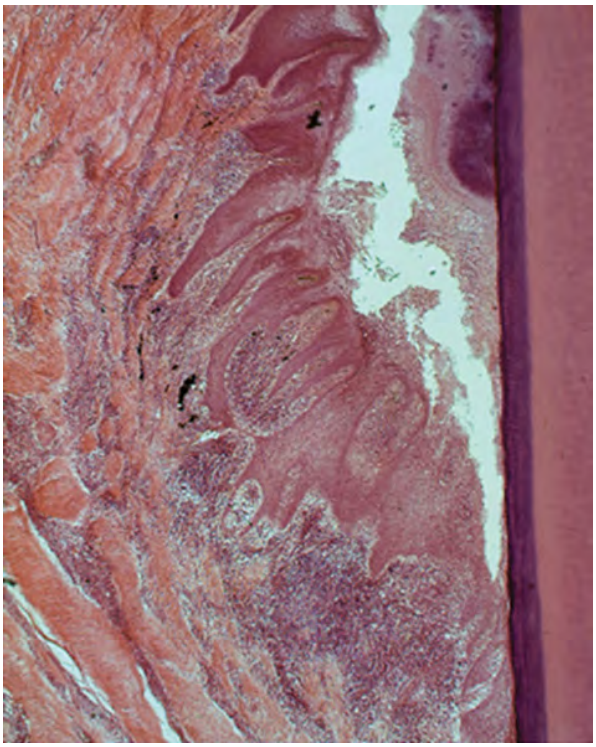

Fig. 10-17 Detail of Fig. 10.16. Pocket epithelium walling off calculus and biofilm in the pocket.

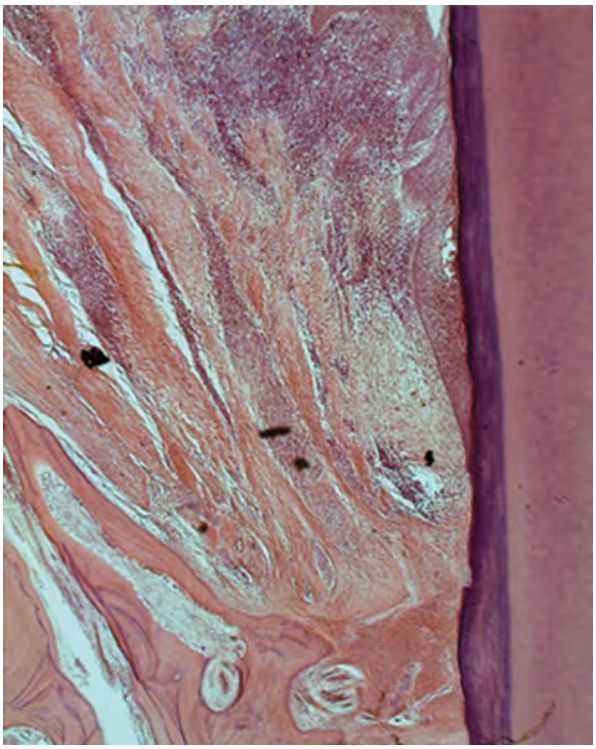

Fig. 10-18 Detail of Fig. 10.16. Note the non-infiltrated fibrous band between the infiltrated connective tissue and the bone.

Approximately 30% of B cells may be stimulated by a single polyclonal activator, with different activators acting on different B-cell subpopulations. Further, the antibodies produced as a result of this polyclonal activation are likely to be of low affinity and the memory component may not be induced (Tew *et al*. 1989). At the same time, a degree of antigen-specific induction of sensitized B cells is also likely to occur. The principal immunoglobulin class produced in the periodontal tissues is IgG, followed by IgM and some IgA.

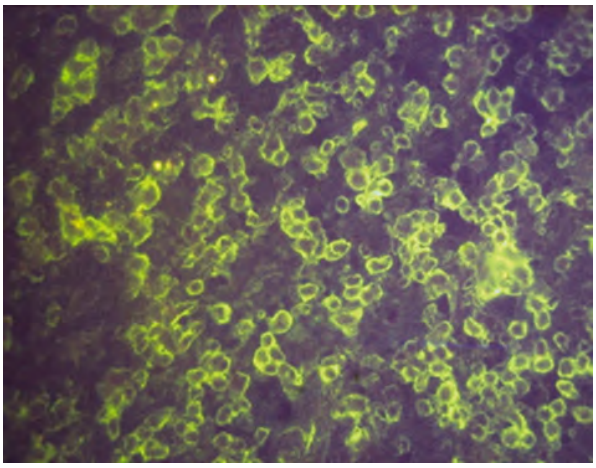

Fig. 10-19 Immunoglobulin-bearing B cells in a periodontitis lesion. (Source: Seymour *et al*. 2009. Reproduced with permission from John Wiley & Sons.)

The role of specific antibodies in the pathogenesis of chronic periodontitis is poorly understood. High titers of specific antibodies to *P. gingivalis* and *A. actinomycetemcomitans* have been demonstrated in the serum and GCF of subjects with periodontal disease; however, the reports are still conflicting with respect to disease activity (Baranowska *et al*. 1989; Nakagawa *et al*. 1994; Ebersole *et al*. 1995). Immunodominant antigens of *P. gingivalis* and *A. actinomycetemcomitans* have also shown different patterns of immunoreactivity, while anti-*P. gingivalis* antibodies with different avidities have been demonstrated in various forms of periodontal disease (Mooney & Kinane 1994). It has been suggested that antibodies with high avidity confer resistance to continued or repeated infection, whereas non-protective low-avidity antibodies may be incapable of effectively mediating a variety of immune responses (Lopatin & Blackburn 1992; Kinane *et al*. 2008).

While a strong antibody response has been suggested to be generally protective, facilitating bacterial clearance and arresting disease progression (Offenbacher 1996; Kinane *et al*. 2008), the mechanism by which this is achieved is unclear. Antibodies, by virtue of their molecular size, are unlikely to penetrate the biofilm and hence their ability to clear the subgingival infection is questionable. Equally, PMNs do not penetrate the biofilm, again limiting their ability to clear the infection. Nevertheless, an increased capacity of serum to opsonize *P. gingivalis* has been shown to be a distinctive feature in patients with past destructive periodontal disease (Wilton *et al*. 1993). However, this high level of opsonizing antibody is more likely to be related to past bacteremias and the ability to clear the serum, than an ability to clear the subgingival infection. On the other hand, repeated infection with *A. actinomycetemcomitans* in an animal

model has been shown to elicit an anti-leukotoxin antibody which protects PMNs from the leukocidal activity of the leukotoxin (Underwood *et al*. 1993). In this context, specific antibodies to bacterial products may be involved in controlling disease expression rather than clearing the organism from the subgingival biofilm. On the other hand, polyclonal B-cell activation by periodontopathic bacteria and the production of non-specific and/or low-avidity antibodies may not be capable of controlling the disease.

As well as producing immunoglobulins/antibodies, continued B-cell activation leads to the production of high levels of cytokines, including IL-1 and IL-10, which may contribute to subsequent tissue destruction. However, while *P. gingivalis* depresses the gene for IL-1β in T cells, it has been shown to induce an increased percentage of peripheral blood B cells from periodontitis patients to produce IL-1β (Gemmell & Seymour 1998). Since macrophages are not a dominant feature of the advanced lesion (Chapple *et al*. 1998) and suppressed cell-mediated immunity is associated with advanced periodontitis, it may be that B cells are the major source of IL-1 in periodontitis.

Macrophages in periodontitis (M1 and M2)

Activated macrophages are now recognized to display a degree of plasticity with at least two different phenotypes being identified. The classical or M1 macrophage produces proinflammatory cytokines such as IL-6 and TNF-α, while the M2 macrophage is reported to play a role in the resolution of inflammation and in the promotion of healing. Such macrophages produce increased amounts of IL-10 and low levels of IL-6 (Das *et al.* 2015). As noted above, macrophages are not a dominant feature of periodontitis (Chapple *et al*. 1998), occurring in fewer than 5% of the infiltrating cells (Berglundh *et al*. 2011). In addition, in a recent study Garaicoa-Pazmino *et al.* (2019) investigated the polarization of M1 and M2 macrophages in both gingivitis and in periodontitis. This study again confirmed the low levels of macrophages in periodontitis lesions but showed that there was no significant difference in the proportion of M1 and M2 macrophages between the two lesions, although the numbers of macrophages were much higher in the gingivitis lesions (Fig. 10-20). These results are not surprising in that both periodontitis and gingivitis are chronic inflammatory lesions and chronic inflammation is defined by the simultaneous presence of destruction and repair. In both lesions this is reflected in the proportions of destructive M1 and the prohealing M2 macrophages with tissue destruction seen in periodontitis probably being due to B cell, rather than macrophage, cytokine production.

Conversion of gingivitis to periodontitis

Why some people develop periodontitis while others do not, remains a fundamental question in periodontology. In a relatively small clinical and radiological study, Thorbert-Mros *et al*. (2017) have shown that those patients with advanced disease between the ages of 30 and 45 years had radiologically detectable bone loss between the ages of 22 and 28 years. This finding is in accord with that of Ramseier *et al*. (2017) who showed, in their 40-year longitudinal study of the natural history of periodontitis, that a mean loss of attachment of less than 1.81 mm in those under 30 years predicted a cohort with at least 20 teeth at age 60 years. The converse of this is that those with a mean loss of attachment of more than 1.81 mm had fewer than 20 teeth at age 60 years. Both these studies highlight the need to treat those under 30 years who show signs of early disease. But the question remains – why do these people develop disease at an early age? As discussed previously, a strong innate immune response in the gingival sulcus together with the epithelial barrier and antimicrobial peptides are essential in maintaining the homeostatic gingival lesion and any defect or deficiency in these mechanisms is likely to lead to the development of periodontitis.

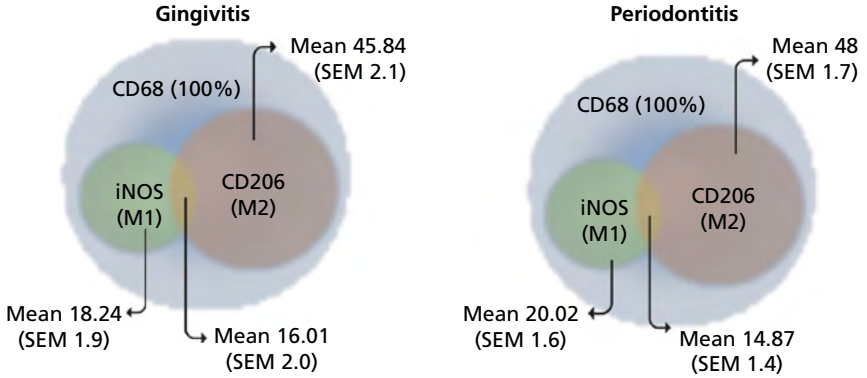

Fig. 10-20 Representation of the CD68-positive macrophage distribution in gingivitis and periodontitis showing no difference between the two lesions. Inducible nitric oxide synthase (iNOS) is expressed predominantly by M1 macrophages while the mannose receptor (CD206) is expressed predominantly by M2 macrophages, (Source: Garaicoa-Pazmino *et al*. (2019). Reproduced with permission from John Wiley & Sons.)

The Th1/Th2 paradigm

Clearly the development of periodontitis involves a switch from a predominantly T cell/macrophage lesion (Brecx *et al*. 1988; Seymour *et al*. 1988) to one involving large numbers of B cell and plasma cells (Seymour *et al*. 1979). The question then arises as to what are the controlling mechanisms of this switch? The fact that the development of gingivitis is identical to the development of DTH and that progressive chronic periodontitis is fundamentally a B-cell lesion, led to the concept that gingivitis and hence the stable periodontal lesion is mediated by Th1 cells, while periodontitis is mediated by Th2 cells (Seymour *et al*. 1993) and the conversion of gingivitis to periodontitis involves a shift from a Th1 to a Th2 mediated response. In this concept it was proposed that a strong innate immune response leads to the production of high levels of IL-12 by both PMNs and macrophages, which in turn leads to a Th1 response, cell-mediated immunity, protective antibody, and a stable periodontal lesion. In contrast, a poor innate immune response with polyclonal B-cell activation leads to a Th2 response, non-protective antibody, and a progressive periodontal lesion. Since being put forward over 25 years ago, this hypothesis has attracted a lot of attention with a number of studies supporting the hypothesis by showing either depressed Th1 responses or increased Th2 responses in periodontitis. In contrast, other studies (primarily in animal models) have implicated increased Th1 responses in periodontitis, while others have highlighted a role for Th0 cells. Nevertheless, it is now generally agreed that periodontitis in humans is mediated by a balance in Th1 and Th2 cells with a shift towards a Th2 profile (Berglundh & Donati 2005; Kinane & Bartold 2007).

Suppression of cell-mediated immunity

The first study to report a possible suppression of cell-mediated immunity in advanced periodontitis subjects was by Ivanyi and Lehner (1970). Subsequently, a number of studies have shown that periodontopathic bacteria, including *P. gingivalis, A. actinomyetemcomitans*, *T. denticola, Capnocytophaga ochracea*, and *F. nucleatum* (Shenker *et al*. 1982; Shenker & Slots 1989; Shenker & Datar 1995) could induce lymphocyte suppression *in vitro*. In addition, T cells extracted from periodontitis lesions not only have a reduced ability to respond in an autologous mixed lymphocyte reaction (AMLR), but also fail to produce IL-2, suggesting that this suppression of cell-mediated responses in periodontitis may also occur *in vivo* (Seymour *et al*. 1985) The fact that the AMLR returns to normal following periodontal therapy (Evans *et al*. 1989) also supports the concept that the suppressive effect of plaque bacteria on cell-mediated immunity (i.e. Th1 responses) may be fundamental in the conversion of a stable to a progressive lesion.

T cells and homeostasis

T cells are involved in nearly all immunoregulatory interactions both *in vivo* and *in vitro*, and a delicate balance between effector and regulatory subsets is required for immune homeostasis. Th1 cells not only mediate DTH but also increase the ability of macrophages to kill intracellular and extracellular pathogens (Romagnani 1992). Further, there is evidence that T cells are involved in the recruitment and activation of PMNs at the site of infection (Campbell 1990), suggesting that in the stable lesion, activation of PMNs may be crucial in keeping the infection under control. Indeed, a strong innate immune response in the gingival tissues and the production of IL-12 could be critical in the establishment of a Th1 response. The presence of natural killer (NK) cells in gingival tissues has also been demonstrated (Wynne *et al*. 1986) and may also be significant in the establishment of a Th1 response. The production of IFN-γ enhances the phagocytic activity of both PMNs and macrophages, and hence containment of the infection.

In contrast, the B-cell nature of the progressive periodontitis lesion suggests either an increase in production of Th2 cytokines or a decline in the production of Th1 cytokines, in other words a shift in the balance towards Th2.

Cytokine profiles

Studies over the past decade have supported the hypothesis that Th1 cells are associated with the stable lesion and Th2 cells with disease progression (for review, see Gemmell *et al*. 2007). However, other studies have reported a predominance of Th1-type cells or reduced Th2 responses in diseased tissues (Ebersole & Taubman 1994; Salvi *et al*. 1998; Takeichi *et al*. 2000). More recently, the involvement of both Th1 and Th2 cells in periodontal disease in humans (for review, see Gemmell *et al*. 2007) has been suggested. However, although cytokine patterns reflecting both subsets can be found in periodontitis tissues (Yamamoto *et al*. 1997), as previously noted, it is now agreed (Berglundh & Donati 2005; Kinane & Bartold 2007) that periodontitis in humans is associated with a shift towards a Th2 response. Further circumstantial evidence for this concept is seen in the fact that *P. gingivalis* cysteine proteases (gingipains) hydrolyze IL-12, thereby having the capacity to reduce IL-12-induced IFN-γ production by CD4 cells and so favor a shift to a Th2 response and subsequent disease progression (Yun *et al*. 2001). Also, peripheral blood cells from periodontitis patients produce significantly lower levels of IL-12 (Fokkema *et al*. 2002) and the numbers of IgG4-positive B cells in the gingival tissues have been shown to increase relative to IgG2-positive cells with increasing inflammation, indicating the influence of IL-4 and Th2 responses and a corresponding decrease in IFN-γ and Th1 responses in large infiltrates in periodontitis.

CD8 T cells

The CD4:CD8 ratio in gingivitis is approximately 2:1 (Seymour *et al*. 1988; Berglundh *et al*. 2002a; Zitzmann *et al*. 2005). This is consistent with the ratio seen in peripheral blood, in secondary lymphoid organs, and in the development of DTH (Poulter *et al*. 1982). In contrast, early studies on cells extracted from periodontitis lesions (Cole *et al*. 1987; Stoufi *et al*. 1987) reported the CD4:CD8 ratio in periodontitis to be around 1:1. Despite this obvious increase in CD8-positive T-cells, their functional activity in the context of periodontitis is poorly understood. While the majority of CD4 clones established from periodontitis tissues have Th2 phenotypes producing high levels of IL-4 and low levels of IFN-γ, the majority of CD8 clones produce equal amounts of IL-4 and IFN-γ, that is they have a Th0 phenotype (Wassenaar *et al*. 1995). Similar to CD4 cells, two subsets of CD8 clones exist. One, whose primary function is to mediate cytolytic activity, produces high levels of IFN-γ, but no IL-4 or IL-5. These are the classic CD8-positive cytotoxic T cells. The secondary function of this subset is to suppress B cells. The other subset of CD8 cells, whose primary function is to suppress the proliferative response of cytotoxic CD8 T-cell clones and to suppress cell-mediated immunity, produce high levels of IL-4 together with IL-5. These are the classic CD8-positive suppressor cells. The secondary effect of these cells is to provide help to B cells. It has been shown that peripheral blood CD8 cells from highly susceptible patients with severe periodontitis produce high levels of intracellular IL-4. If these cells also occur locally within the periodontal tissues of these susceptible patients, they may participate in the local response by suppressing IFN-γ-producing cells and favoring humoral immune responses (Wassenaar *et al*. 1995), and hence a shift towards a type 2 function. Teng (2003), however, has played down a role for CD8 cells in periodontal disease by concluding that this subset does not participate directly in the destruction during disease progression. Although they may not play a direct role in tissue destruction, CD8-positive T cells do produce cytokines which play a role in both innate and adaptive immune responses and are important in the lysis of bacteria-infected or bacteria-damaged tissues and cells. Overall, the role of CD8-positive T cells in the pathogenesis of periodontitis has been largely overlooked. However, determination of the functions of this subset is paramount in fully understanding the pathogenesis of periodontal disease.

Control of the Th1/Th2 balance

While the Th1/Th2 paradigm provides a possible mechanism by which periodontal lesions become progressive or remain stable, an important question that remains is, what causes some lesions to show Th1 characteristics while others show Th2 characteristics? The answers may lie in the nature of the microbial challenge, as well as particular genetic and environmental susceptibility factors. Importantly, some of these factors may be clinically identifiable and modifiable.

It is likely that different T-cell subsets predominate at different phases of disease and the inability to determine disease activity clinically has been a major limitation in all studies. However, it remains clear that the balance of cytokines in inflamed periodontal tissues is what determines whether the disease remains stable or leads to progression and tissue destruction (Seymour & Gemmell 2001). In this context, the control of Th1 and/or Th2 expression is therefore fundamental in understanding the immunoregulatory mechanisms in chronic periodontitis. Factors that control Th1 and Th2 expression include:

- Genetics
- Innate immune response
- Nature of the antigen
- Nature of the antigen-presenting cell
- Hypothalamic–pituitary–adrenal axis and the sympathetic nervous system
- Treg/Th17 axis.

Genetics

Study of identical twins who were raised apart indicates that between 38% and 80% of the variation in periodontal disease is due to genetics (for review, see Michalowicz 1994). Susceptibility to *P. gingivalis* infection in mice is also genetically determined (Gemmell *et al*. 2002b), although the relevance of this to human periodontal disease remains to be ascertained. However, it is interesting to note that the susceptible strains of mice show low Th1 responses, while the resistant strains show moderate-to-high Th1 responses to *P. gingivalis*.

Innate immune response

It is generally stated that there are two distinct arms of the immune response; the non-specific natural or innate response and the specific or adaptive immune response. In recent years, however, the distinction between these has become blurred with the discovery that, in many respects, the innate immune response determines the nature of the subsequent adaptive response and at the same time aspects of the adaptive response control the effectiveness of the innate response.

IL-12

As noted earlier, PMNs are a consistent feature of the periodontal lesion in both gingivitis and periodontitis, and deficiencies in PMN function are associated with severe and rapidly progressive periodontitis. A strong innate immune response will result in high levels of IL-12 and is therefore

associated with a Th1 response, while a poor innate immune response and relatively low levels of IL-12 favor a Th2 response. Support for the concept of a Th1 response in gingivitis came from a study demonstrating significantly higher levels of IL-12 in the GCF from gingivitis sites in both gingivitis and periodontitis patients compared with periodontitis sites from the same periodontitis patients (Orozco *et al*. 2006).

Toll-like receptors

As noted earlier, TLRs occur on a number of cells including dendritic cells, PMNs, and macrophages among others, and have the ability to recognize PAMPs such as LPS, peptidoglycan, bacterial DNA, double-stranded RNA, and lipoprotein.

Given their role in innate immunity, it is likely that TLRs are important in determining the nature of the host response to plaque. TLR-2 and TLR-4, upon stimulation, may induce markedly different immune responses as determined by the resulting cytokine profiles. When stimulated, TLR-4 has been shown to promote expression of IL-12 and INF-γ-inducible protein-10 (IP-10), which is indicative of a Th1 response. Conversely, TLR-2 promotes the inhibitory IL-12p40, which is characteristic of a Th2 response (Re & Strominger 2001). These differences are reflected in differential cytokine expression by *Escherichia coli*-derived LPS and *P. gingivalis*-derived LPS. *E. coli*-derived LPS, which activates TLR-4, induces a strong Th1 response, while *P. gingivalis*-derived LPS, which activates TLR-2 (Hirschfeld *et al*. 2001), induces a strong Th2 response (Pulendran *et al*. 2001). These findings may indicate a further mechanism of susceptibility to periodontitis.

Nature of the antigen

Biofilms containing complexes of bacteria including *P. gingivalis, T. forsythia,* and *T. denticola* have been related to periodontitis, such that it is unlikely that a single antigen or a single organism is responsible for the disease. Further, there is the possibility that different people may have individually specific pathogenic complexes such that any single complex may not be pathogenic in all people. Indeed, little is actually known of the biofilm-specific antigens involved in periodontal disease and of the immune response to them. T-cell clones derived from mice immunized with *P. gingivalis* alone were found to have a Th1 profile, whereas T-cell clones derived from mice immunized with *F. nucleatum* followed by *P. gingivalis* demonstrated a Th2 profile (Choi *et al*. 2000). This may be due to the fact that *F. nucleatum* is a polyclonal B-cell activator such that B cells subsequently present the *P. gingivalis* antigen. Further, mice immunized with *F. nucleatum* were subsequently unable to make antibody to *P. gingivalis* (Gemmell *et al*. 2002a, 2004). This was not the case if bacteria were injected in reverse order. These findings, albeit preliminary, nevertheless show that it is possible for co-infection with multiple organisms to modulate the immune response. The level and relevance of this modulation to human periodontal disease, however, remains to be demonstrated but it is likely to involve the Th1/Th2 balance.

Nature of the antigen-presenting cell

It has been suggested (Kelso 1995) that Th1 and Th2 cells actually represent a spectrum of cells and, depending upon the conditions, can produce either Th1 or Th2 cytokines. In this context, Th0 cells may represent cells midway in the spectrum as well as naïve or non-committed cells.

The predominant APC in gingivitis tissues is a CD14-positive, CD83-positive dendritic cell (Gemmell *et al*. 2002c). In periodontitis tissues, the predominant APC is a CD19-positive, CD83-positive B cell, although a large number of CD83-positive endothelial cells are also present (Fig. 10-21), suggesting that these cells may also be involved in antigen presentation. Bacterial antigen presentation by endothelial cells induce anergy in transmigrating Th1 cells (Kanwai *et al*. 2000) which may also favor a move to a Th2 profile.

The cytokine profile of *P. gingivalis*-specific CD4 T-cell lines can be modified by changing the APC. When autologous peripheral blood mononuclear cells are used as APCs, the cell lines are predominantly IFN-γ producing, with a Th1 profile, but if autologous Epstein–Barr virus-transformed B cells are used, the same cell lines become predominantly IL-4 producing, that is they have a Th2 profile (Gemmell & Seymour 1998). These findings suggest that it is possible to modulate the Th1/Th2 profile by varying the nature of the APC. In gingivitis, the predominant APC is a dendritic cell, whereas in periodontitis it is primarily a B cell.

Hypothalamic–pituitary–adrenal axis and the sympathetic nervous system

It is well accepted that stress, or at least the inability to cope with stressful situations, results in rapid progression of periodontitis. Stimulation of the sympathetic nervous system as well as hypothalamic–pituitary–adrenal axis activation leads to a selective suppression of Th1 responses, a shift towards Th2 dominance, and an increase in periodontitis (Breivik *et al*. 2000; Elenkov 2002).

Treg/Th17 axis

Regulatory T cells

Regulatory T cells (Tregs) are a specialized T cell subset characterized by the forkhead/winged helix transcription factor Foxp3. They primarily control exacerbated immune responses as well as the development of autoimmunity and do so through both contact dependent and contact independent mechanisms. They suppress effector T cells (Th1/Th2 and possibly Th17) and increased numbers have been found in periodontitis lesions where there are increased proportions of B cells compared with gingivitis tissues (Nakajima *et al*. 2005; Parachuru *et al*. 2014). Indeed, the numbers of Foxp3-positive cells significantly correlate with the B- and plasma-cell/T cell ratio in lesions dominated by B cells and plasma cells (Parachuru *et al*. 2014). Double labelling immunofluorescence revealed that CD4 but not CD8 cells were Foxp3-positive (Fig. 10-22) and that there was a significant upregulation of the Treg-related gene, signal transducer and activator of transcription (STAT5A), as well as the genes for TGFβ1 and IL-10 in B- and plasma cell dominated periodontitis lesions compared with T cell dominated gingivitis lesions (Parachuru *et al*. 2018). Protein analysis of the same specimens confirmed the gene expression data and showed higher levels of TGFβ1 and IL-10 in B- and plasma cell dominated lesions compared with T cell dominated lesions (Parachuru *et al*. 2018). Although the role of these cells in periodontal disease in humans is still speculative it may be that they are suppressing Th1 mediated responses while contributing to the proliferation of B cells via the production of IL-10. In contrast, da Motta *et al*. (2019) found slightly more Foxp3-positive cells in stage III grade B periodontitis lesion compared with stage IV grade C lesions.

Th17 cells

Over the past two decades most attention has focused on Th1 and Th2 cells; however, a third lineage of T cells has been described, the so-called Th17 cells which selectively produce IL-17. IL-17 induces the secretion of IL-6, IL-8, and PGE_2; hence, these cells are thought to play a crucial role in regulating inflammation. IL-17 is also thought to affect osteoclast activity and thereby mediate bone resorption.

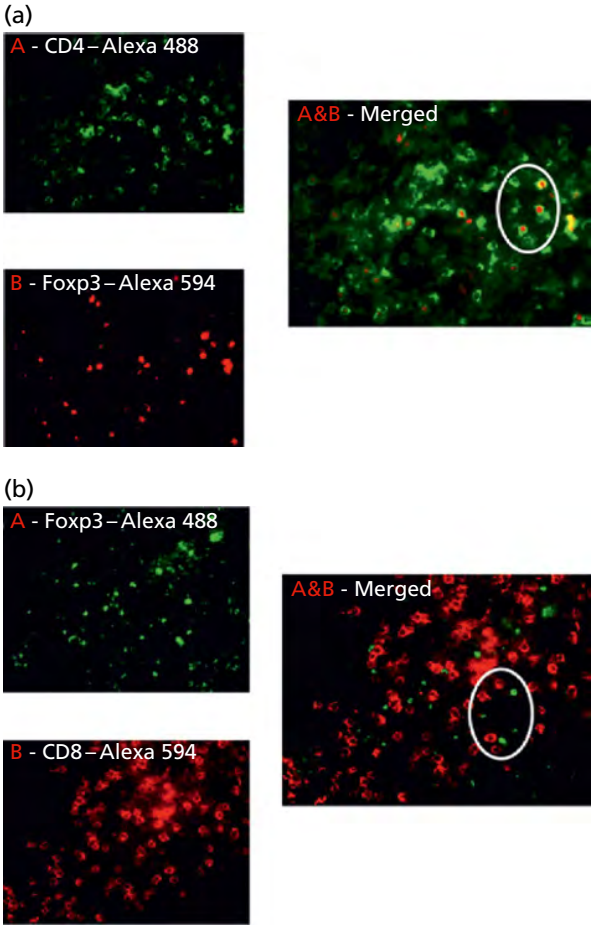

Fig. 10-22 Double labeling immunofluorescence for (a) CD4/Foxp3 and (b) CD8/Foxp3 showing all Foxp3-positive cells are CD4-positive and not CD8-positive. (Source: Parachuru *et al*. 2018. Reproduced with permission from John Wiley & Sons.)

In the mouse, naïve T cells when incubated with transforming growth factor beta (TGF-β) and IL-2 upregulate the transcription factor Foxp3 and develop into the so-called Tregs which have an important function in suppressing autoimmune responses. In contrast, when incubated in the presence of TGF-β and IL-6, CD4-positive T cells express the transcription factor RORγt and become Th17 cells. While these cells are thought to have a protective role against bacterial infections, they may on the other hand contribute to autoimmune disease. There are, however, some important differences between mouse and human Th17 cells. In the human for example, TGF-β is not necessary for Th17 differentiation and there is some doubt over the role of IL-23, with some studies showing that IL-23 is a potent inducer of Th17 cells and others, showing that IL-23 alone is relatively ineffective. Activation of monocytes via TLR-2 is an effective stimulus for Th17 differentiation and, while IL-2 initially inhibits Th17 differentiation, ultimately it leads to Th17 expansion (for review, see Laurence & O'Shea 2007).

P. gingivalis leads to the downregulation of the IL-17 receptor (*IL-17r*) gene in mice (Gemmell *et al*. 2006). *IL-17r*-deficient mice have a defect or

display a significant delay in neutrophil recruitment into infected sites, resulting in susceptibility to infection (Kelly *et al*. 2005). This may account partly for the reported inhibition of entry of PMNs into *P. gingivalis*-induced lesions in mice (Gemmell *et al*. 1997). These studies seem to suggest that IL-17 and its ability to enhance PMN activity would have a protective effect in periodontal disease. In contrast to this mouse study, IL-17 expression in human periodontitis tissue is controversial. In periodontitis patients, 51% of gingival T-cell clones were found to express IL-17 compared with only 11% of peripheral blood T-cell clones (Ito *et al*. 2005). Also, stimulation of peripheral blood mononuclear cells by *P. gingivalis* antigen enhanced not only transcription but also translation of the *IL-17* gene (Oda *et al*. 2003). Thorbert-Mros *et al*. (2019) showed both CD3-positive and CD3-negative CD161-positive cells in gingivitis and periodontitis lesions and claimed that an increase in CD161-positive T cells was a marker of a destructive lesion. On the other hand, immunohistology and gene expression studies on diseased human tissue suggest low levels of IL-17 and low expression of IL-17 pathway genes (Okui *et al*. 2012). These results were confirmed by Parachuru *et al*. (2014, 2018) who demonstrated very few IL-17-positive cells (<1%) in B-cell/plasma cell-dominated periodontitis lesions in humans. They further showed that IL-17-positive cells had an ovoid/plasmacytoid morphology and were larger than the surrounding inflammatory cells (Fig. 10-23). Double immunofluorescence further showed that these IL-17-positive cells are not CD4- nor CD8-positive and hence are not T cells (Figs. 10-24, 10-25). Double labelling with tryptase, however, showed that they are in fact mast cells (Fig. 10-26) (Parachuru *et al*. 2018). This, in fact, is not surprising as it confirms earlier preliminary findings (Culshaw *et al*. 2011) and is consistent with the fact that mast cells appear to be the major source of IL-17 in many lesions including rheumatoid arthritis synovium (Hueber *et al*. 2010; Moran *et al*. 2011), psoriasis (Lin *et al*. 2011; Truchetet *et al*. 2013), renal allograft rejection (Velden *et al*. 2012), atherosclerosis (De Boer *et al*. 2010), and some tumors (Wang *et al*. 2013; Liu *et al*. 2014).

T cells have a high degree of plasticity and while Th17 cells are the major producers of IL-17 in peripheral blood and in culture, within the tissues the nature of the APC together with the cellular microenvironment determines the T cell phenotype. In this context, a Th17 cell entering the periodontal tissues may, under the influence of IL-4, become a Th2 cell and a Th2 cell under the influence of IL-12 and dendritic APCs may become a Th1 cell (Fig.10-27). It is possible therefore that the T cell cytokine profile will change over the course of the disease. It has further been shown that Foxp3 cells can become Th17 cells in autoimmune arthritis (Komatsu *et al*. 2014) and in keeping with this a small number of Foxp3/IL-17 double positive cells have been identified in periodontal disease tissues (Okui *et al*. 2012). Although the role of IL-17 in human periodontal disease remains to be determined it would appear that Th17 cells either do not exist in the tissues or do so in only small numbers and that the source of the low levels of IL-17 may in fact be mast cells.

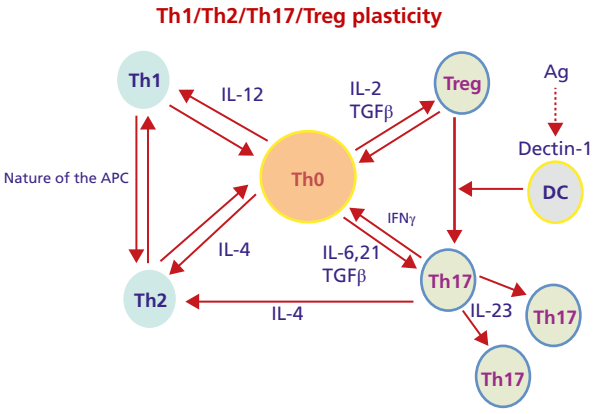

Fig. 10-27 T cell plasticity where the cellular microenvironment and the presence of different cytokines and APCs determine the T cell phenotype. A Th17 cell in the tissues under the influence of IL-4 can become a Th2 cell.

Autoimmunity

Natural killer T cells

Autoimmunity has been suggested to be a feature of periodontal disease. Cross-reactivity of human heat shock protein (HSP) 60 and *P. gingivalis* GroEL, a bacterial homolog, has been observed in periodontal disease (Tabeta *et al*. 2000; Ford *et al*. 2005). HSP60-specific as well as *P. gingivalis* cross-reactive T cells have also been demonstrated to accumulate in periodontitis lesions (Yamazaki *et al*. 2002). Taken together, these data suggest that both a humoral and a cell-mediated specific immune response to HSP60 may be important in the disease process. Additionally, anticollagen type I and III antibodies have been demonstrated in the gingivae of periodontitis patients (Hirsch *et al*. 1988) and collagen type I-specific T-cell clones have been identified in inflamed tissues of periodontitis patients (Wassenaar *et al*. 1995).

A subset of T cells that express NK surface receptors are thought to play an important autoimmune immunoregulatory role. An immunohistologic study found that NK T cells were more numerous in periodontitis lesions compared with gingivitis tissues or peripheral blood. These NK T cells also appeared to associate with CD1d-positive cells and it was suggested that they play a regulatory role in periodontal disease (Yamazaki *et al*. 2001).

The role of autoimmunity in chronic inflammation is still not clear. It is possible that autoimmunity is a feature of all chronic inflammatory processes. In this context, it has been known for many years that gingival fibroblasts are able to phagocytose collagen such that anticollagen antibodies may facilitate this phagocytosis and hence the removal of the broken down collagen. At the same time, an anti-HSP response may enhance the removal of dead and dying cells such that these autoimmune responses may be a natural part of chronic inflammation. Control of these responses would therefore be essential. This concept further illustrates that the role of T cells in periodontal disease may be one of immune homeostasis. Further studies are clearly needed to test this hypothesis and to determine the role of regulatory T cells in periodontal inflammation.

B-cell subsets

There are two major subsets of B cells: B-1 and B-2 cells. B-2 cells are recognized as conventional B cells and represent the traditional group of B cells that take an active part in the adaptive host response. They interact with T cells and develop into memory cells and long-lived plasma cells that produce antibodies with high affinity.

B-1 cells, on the other hand, may either be T-cell independent and responsible for early antibody responses with low affinity, or interact with T cells

and undergo class switching and produce IgG autoantibodies with high affinity. A specific subset of B-1 cells is the B-1a cell, which expresses the surface marker CD5. B-1a cells produce autoantibodies and are found in large proportions in subjects with autoimmune diseases and periodontitis (Afar *et al*. 1992; Berglundh *et al*. 2002b). The proportions of B-1a cells in peripheral blood are reported to be five to six times greater in subjects with periodontitis than in controls, and up to 40–50% of circulating B cells were positive for the B-1a cell marker CD5 in periodontitis (Berglundh *et al*. 2002b). B-1a cells also occur in large proportions in the gingival lesions of periodontitis patients such that the abundance of plasma cells seen in periodontitis lesions may be the result of both B-2 and B-1a proliferation and differentiation (Donati *et al*. 2009a). A study on experimental gingivitis in periodontitis patients has also demonstrated that B-1a cells are involved in the host response to microbial challenge (Donati *et al*. 2009b).

The large proportion of B-1a cells in periodontitis has also been associated with elevated levels of IL-10. B cells are one source of this cytokine and although IL-10 was previously regarded to play mainly anti-inflammatory roles, it also exhibits several proinflammatory functions, including activation of B cells, and serves as an autocrine growth factor for B-1a cells.

Connective tissue matrix destruction

Connective tissue remodeling is regulated by the interplay of cell–cell and cell–matrix interactions involving the production of enzymes, activators and inhibitors, and cytokines and growth factors (Reynolds & Meikle 1997). Proteinases such as the MMPs are key enzymes in tissue degradation. They are produced by resident cells, including fibroblasts, macrophages, and epithelial cells, and are regulated by tissue inhibitors of metalloproteinases (TIMPs).

It has been suggested that tissue destruction in disease processes may be due to an imbalance of MMPs over tissue inhibitors. Greater collagenase activity, which was demonstrated to derive mostly from PMNs, has been found in the GCF of periodontitis patients compared with the GCF of control subjects (Villela *et al*. 1987). MMP-9, which is produced by PMNs, was shown to be prominent not only in the GCF but also in gingival tissue samples from patients with periodontitis. Latent MMP-2 and MMP-9 have been shown to be expressed in the gingival tissues of patients with periodontitis, with the active forms being detected only in tissues associated with clinical disease (Korostoff *et al*. 2000; Seguier *et al*. 2001). Increases in the amounts of MMP-1, -2, -3, and -9, and the active form of MMP-9 have in fact been correlated with the number of CD22-positive B cells. This again suggests a possible mechanism by which B cells contribute to tissue destruction in periodontitis.

Up to 97–99% of the collagen in normal gingiva is made up of collagen types I and III. Collagen type III represents a minor fraction (about 10%). All other types (IV, V, VI, and VII) are related to basement membranes and together do not exceed 1–3%. Transmission electron microscopy of biopsies from periodontitis patients demonstrated the almost complete destruction of collagen types I and III in areas with leukocyte infiltration, while the basement membrane-associated collagen types V and Vl seem to remain and are related to the increased vascularity and epithelial proliferation in the inflamed tissue.

Bone loss

Bone resorption in periodontitis is regulated by the interplay between osteoblasts and the activation of osteoclasts. Osteoclasts share a common origin with cells of the macrophage/monocyte lineage and respond to and produce cytokines that regulate cells of this lineage. Osteoblasts originate from bone marrow stromal stem cells of mesenchymal origin and also have the capacity to produce factors which influence lineage development. Upon stimulation, osteoblasts produce a molecule known as receptor activator of nuclear factor-kappa B (NF-κB) ligand (RANKL), also known as osteoprotegerin-L (OPG-L), which regulates osteoclast differentiation and functions via its receptor (RANK). These activated osteoclasts then produce a number of acids and acid hydrolases which decalcify the mineral content of the bone and break down the organic matrix. The osteoclasts further phagocytose the broken-down organic matrix, thus resorbing the bone. A variety of cells produce a decoy receptor osteoprotegerin (OPG), which when released binds RANKL to prevent activation of RANK and hence osteoclasts (Simonet *et al*. 1997).

While these factors have potent effects on osteoclast development, they also have regulatory effects on immune cell function (Lorenzo 2000), being critical for T-cell maturation and the production of cytokines such as IFN-γ, IL-2, and IL-4 (Kong *et al*. 1999).

Studies have reported increased concentrations of RANKL and decreased concentrations of OPG in the GCF and tissues from periodontitis patients (Mogi *et al*. 2004; Vernal *et al*. 2004). However, the relationship between this observation and the progression of periodontitis is speculative. Interestingly, human gingival fibroblasts stimulated with bacterial LPS have been shown to express OPG and OPG mRNA rather than RANKL. Supernatants of LPS-stimulated fibroblasts reduced the numbers of tartrate-resistant acid phosphatase (TRAP)-positive osteoclasts generated by monocytes cultured in the presence of RANKL and macrophage colony-stimulating factor (M-CSF), suggesting the inhibition of monocyte-derived osteoclasts via the OPG pathway (Nagasawa *et al*. 2002). RANKL and RANKL mRNA are expressed by

inflammatory lymphocytes and macrophages as well as by proliferating epithelium in the vicinity of inflammatory cells. Thus, the high levels of RANKL seen in the GCF of periodontitis patients may be a reflection of the degree of inflammation rather than of bone loss and disease progression *per se*. Although both soluble and membrane-bound RANKL can be produced by activated T cells (Kong *et al*. 1999) and B cells (Taubman *et al*. 2005; Horowitz *et al*. 2010), it is the coupling of osteoblast-produced RANKL with osteoclast-expressed RANK that results in bone loss in periodontitis.

As already stated, IL-1 has a major role in bone resorption in periodontal disease, and both IL-1 and TNF-α have been reported to regulate the balance of RANKL and OPG (Hofbauer *et al*. 1999). Increased IL-1β production by B cells in periodontitis may therefore provide the link between increasing numbers of B cells and alveolar bone destruction in human periodontitis.

Conclusion

While there is no doubt that plaque is the cause of periodontal disease, its expression is the result of the interaction of bacterial, host, environmental, and systemic factors. This interaction leads to individuality of disease expression which in turn leads to individuality of treatment.

Despite over 50 years of research into the immunology of periodontal disease, the precise mechanisms and the role of many cell types remain an enigma. It is clear from the data obtained from a number of human studies that the function of the immune response in periodontal disease is to maintain homeostasis in the presence of the plaque biofilm. In this context, the development of the T-cell response in gingivitis represents the default homeostatic response where the host is in balance with the plaque biofilm. It is when this balance is disturbed, resulting in a dysbiosis between the biofilm and the host, that disease progression occurs. This periodontitis lesion is dominated by B cells and plasma cells and the uncontrolled production of B cell cytokines, including IL-1 and TNF-α, leads ultimately to destruction of the connective tissue attachment, loss of alveolar bone, and apical migration of the junctional epithelium. The B cell nature of this progressive lesion has been clearly demonstrated by Coat *et al*. (2015), who showed that pocket depth and attachment loss were significantly decreased 6 months after treatment with the anti-B cell monoclonal antibody rituximab and that the periodontal status of the subjects followed for up to 48 months after rituximab treatment was improved irrespective of the clinical parameter observed.

The equal proportion of M1 and M2 macrophages reflects the simultaneous presence of destruction and repair that is characteristic of chronic inflammation. Control of this T- to B-cell/plasma cell shift, however, probably involves the balance between Th1 and Th2 cells. While the interplay between a number of mechanisms, including the presence of inflammation in the gingival tissues and its influence on the ecology of the biofilm together with the PMN response in the gingival sulcus, are integral in maintaining homeostasis, control of the Th1/Th2 balance involves genetics, the innate immune response, and the nature of the antigen-presenting cell. The PMN response in the gingival sulcus is critical and any deficiencies in this response either qualitative or quantitative results in advanced disease. The epithelial barrier, IL-17, and the formation of NETs within the gingival sulcus are fundamental. The major source of IL-17 in the gingival sulcus is probably the PMNs themselves while mast cells and not Th17 cells are the major source of the very low levels found in the tissues.

The role of autoimmunity in chronic inflammation is also of major interest. In this context it can by postulated that autoimmunity is a critical and integral part of chronic inflammation in that it enhances the removal of collagen by enhancing fibroblast phagocytosis of protease-digested collagen fragments, as well as the removal of destroyed or dying cells. Control of this process by regulatory T cells (Tregs/NK T) then becomes fundamental and, again, if there is a disturbance in this homeostatic mechanism, enhanced tissue destruction could result.

Chapter 11

Systemic and Environmental Modifying Factors

Evanthia Lalla and Panos N. Papapanou

Division of Periodontics, Section of Oral, Diagnostic, and Rehabilitation Sciences,
Columbia University College of Dental Medicine, New York, NY, USA

Introduction

This chapter discusses systemic and environmental factors that may modify the host's susceptibility to periodontitis and the disease's clinical phenotype, including its extent, severity, progression, and response to therapy. The emphasis is on the two major modifying factors, diabetes mellitus and tobacco smoking. Aspects related to the epidemiologic evidence for the effect of these factors on periodontitis are reviewed in Chapter 6; thus, here we focus on underlying mechanisms, clinical presentation of affected individuals, and treatment considerations. A list of potential modifiers of periodontal health is shown in Table 11-1. Among these, factors such as puberty, menstruation, pregnancy, and medications that affect only the gingival status are discussed in Chapter 15, and the impact of HIV/AIDS on the periodontium is covered in Chapter 19.

Diabetes mellitus

Diabetes mellitus is a common, chronic condition with serious health implications. It comprises a group of metabolic disorders characterized by defects in insulin production, insulin action, or both, leading to abnormal glucose metabolism. The resulting hyperglycemia that characterizes both major types of diabetes (type 1 and type 2) is associated with a range of acute and chronic complications, and may eventually affect all organs of the body, including the periodontal tissues. Indeed, diabetes is established as a major risk factor for periodontitis.

Mechanisms underlying the effect of diabetes on periodontitis

Early studies exploring the mechanisms that may contribute to the increased prevalence and severity of periodontal destruction observed in patients with diabetes suggested the existence of distinct subgingival microbial profiles (Zambon *et al*. 1988). Subsequent reports concluded that the nature of the bacterial challenge in patients with diabetes and periodontitis does not appear to differ from that in those without diabetes (Feitosa *et al*. 1992; Thorstensson *et al*. 1995; Novaes *et al*. 1997; Sbordone *et al*. 1998). Many of these studies included small numbers of individuals, assessed only a handful of bacterial species, and most importantly compared patients with diabetes and periodontitis to controls without diabetes who were periodontally healthy. Taking these limitations into consideration, the subgingival microbial challenge in diabetes was later revisited using a cohort of subjects

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Table 11-1 Potential modifiers of periodontal health.

- Diabetes mellitus
- Tobacco smoking
- Obesity and nutrition
- Osteoporosis
- Stress
- Menstrual cycle
- Pregnancy
- Medications
  - Oral contraceptives
  - Anticonvulsants
  - Immunosuppressants
  - Calcium channel blockers
- HIV/AIDS
- Other systemic diseases and developmental and acquired conditions affecting the periodontal supporting tissues (Jepsen *et al*. 2018)

with type 1 diabetes and a control group of age- and gender-matched individuals without diabetes but with similar levels of periodontitis (Lalla *et al*. 2006b). Bacterial profiles, based on 12 species, as well as the homologous serum antibody responses were found to be comparable between the two groups. Still, this and most other studies of periodontal microbiota changes in diabetes to date were cross-sectional, used traditional microbiological approaches, and were restricted to known biofilm species. Emerging results from molecular microbiome studies have reported alterations in the composition of the oral microbiota in diabetes (Casarin *et al*. 2013; Zhou *et al*. 2013; Matsha *et al*. 2020) and, therefore, larger studies employing global analyses of the periodontal microbiome may be needed to shed light on this issue. For now, it appears that it is mostly the host response to the bacterial challenge that drives the enhanced susceptibility to periodontitis in diabetes.

Indeed, it was proposed early on that impairment of neutrophil function may facilitate bacterial persistence and increase periodontal destruction (Manouchehr-Pour *et al*. 1981a, b; McMullen *et al*. 1981). Subsequently, neutrophil priming in moderately and poorly controlled patients with diabetes, caused by increased levels and activity of protein kinase, was demonstrated (Karima *et al*. 2005). Other studies suggested a hyperinflammatory monocytic phenotype in diabetes characterized by enhanced levels of proinflammatory mediators in gingival crevicular fluid (GCF) or following challenge with lipopolysaccharide (LPS) in culture (Yalda *et al*. 1994; Salvi *et al*. 1997, 1998; Duarte *et al*. 2014).

In a study employing the experimental gingivitis model approach (i.e. 3-week cessation of oral hygiene resulting in gingivitis, followed by 2 weeks of optimal plaque control resulting in resolution of gingival inflammation), individuals with diabetes were found to develop accelerated and exaggerated gingival inflammation compared with controls without diabetes, despite a similar bacterial challenge (Salvi *et al*. 2005). Effects on other relevant cell types have also been reported, such as decreased collagen production and increased collagenolytic activity by gingival and periodontal ligament fibroblasts (Ramamurthy & Golub 1983; Sasaki *et al*. 1992; Yu *et al*. 2012), and hyperinflammatory response by oral epithelial cells (Amir *et al*. 2011).

Consistent with the evidence in humans, a number of animal studies have demonstrated that diabetes may increase the inflammatory response to bacteria. *Porphyromonas gingivalis* injection into the calvariae of diabetic mice was shown to stimulate an exaggerated cytokine expression and inflammatory infiltrate compared with the response observed in non-diabetic mice (Naguib *et al*. 2004; Graves *et al*. 2005; Nishihara *et al*. 2009). Reduction of inflammation and lesion size by specific inhibition of tumor necrosis factor-alpha (TNF-α) in these studies suggested that cytokine dysregulation represents a mechanism through which diabetes alters the host response to the bacterial challenge (Naguib *et al*. 2004; Takano *et al*. 2010).

A number of other reports, including human studies, have focused on osteoclastogenesis-related factors and explored the role of the receptor activator of nuclear factor-kappa B ligand (RANKL) and osteoprotegerin (OPG) in diabetes associated periodontal infections (Mahamed *et al*. 2005; Duarte *et al*. 2007; Lappin *et al*. 2009; Santos *et al*. 2010; Wu *et al*. 2015). These studies have suggested that hyperglycemia in diabetes may modulate the RANKL:OPG ratio in periodontal tissues and thus contribute to alveolar bone destruction. Along this line, the cycle of bone loss and subsequent bone formation was examined in a model of ligature-induced alveolar bone loss in rats (Liu *et al*. 2006b). Osseous repair was significantly limited by diabetes and the level of apoptosis of bone-lining cells was higher. In the calvarial model, diabetic mice also displayed increased fibroblast apoptosis and reduced fibroblast density following *P. gingivalis*-induced injury (Liu *et al*. 2004). Healing was significantly improved by blocking apoptosis with a caspase inhibitor (Al-Mashat *et al*. 2006) or by anti-TNF-α treatment (Liu *et al*. 2006a). These results were confirmed in diabetic mice with intraoral wounds (Desta *et al*. 2010; Siqueira *et al*. 2010). TNF-α inhibition in diabetic rats with ligature-induced periodontitis was also shown to impair expression of growth factors that control proliferation, differentiation, or apoptosis of osteoblasts, to restore the bone coupling process, and to increase the capacity of the animals to form new bone (Pacios *et al*. 2012).

The first attempt to explore more upstream changes induced by diabetes that may explain the observed hyperinflammatory response to infection, focused on the role of the receptor for advanced glycation end products (RAGE), a multiligand signaling receptor and member of the immunoglobulin superfamily of cell-surface molecules. RAGE expression is increased in diabetes and its activation through ligand interaction has an established role in the development and progression of other diabetic complications (Yan *et al*. 2009). First, expression of AGE

ligands and of markers of oxidative stress was demonstrated in gingival tissues of patients with diabetes and periodontitis (Schmidt *et al*. 1996). Subsequently, levels of serum AGEs were shown to be significantly associated with the extent of periodontitis in adults with type 2 diabetes (Takeda *et al*. 2006) and increased AGE and RAGE expression was reported in gingival tissues and saliva of individuals with diabetes and periodontitis (Yoon *et al*. 2004; Katz *et al*. 2005; Abbass *et al*. 2012; Chang *et al*. 2012a; Yu *et al*. 2012; Zizzi *et al*. 2013). More recently, delayed polymorphonuclear apoptosis in individuals with periodontitis and type 2 diabetes was shown to occur through an AGE–RAGE interaction (Manosudprasit *et al*. 2017).

In a model of oral infection and diabetes in mice, *P. gingivalis*-induced alveolar bone loss was increased in diabetic animals compared with non-diabetic controls and was accompanied by enhanced expression of RAGE, inflammatory AGEs, and tissue destructive matrix metalloproteinases (MMPs) in the gingival tissues (Lalla *et al*. 1998). In subsequent studies, treatment with soluble RAGE (sRAGE), the extracellular ligand-binding domain of RAGE which antagonizes interaction of ligands with the whole receptor, decreased levels of TNF-α, interleukin-6 (IL-6), and MMPs in gingival tissues and suppressed alveolar bone loss in a dose-dependent manner in diabetic animals (Lalla *et al*. 2000). Importantly, the beneficial effects of RAGE blockade were paralleled by suppressed expression of the receptor and its ligands in gingival tissues and were independent of the level of glycemia. These findings demonstrated that AGE–RAGE interaction leads to the exaggerated inflammatory response to the bacterial challenge and subsequent tissue destruction seen in diabetes-associated periodontitis. Accumulation of AGEs and their interaction with RAGE have been also shown to contribute to osteoclastogenesis via increased RANKL expression and OPG downregulation in various cell types (Ding *et al*. 2006; Yoshida *et al*. 2009).

Moreover, RAGE may contribute to impaired repair following injury, as shown in studies of excisional dermal wounds in diabetic mice (Goova *et al*. 2001) and of osseous defects following tooth extraction in diabetic rats (Chang *et al*. 2012b). Studies of osteoblast cultures and craniotomy defects in mice in the absence of infection have demonstrated the role of RAGE and its interaction with the AGE ligand carboxymethyl-lysine (CML)–albumin in delayed bone healing (Santana *et al*. 2003). Using the same experimental approach, the apoptotic effect of CML–collagen on osteoblasts was shown to be mediated through RAGE (Alikhani *et al*. 2007).

The basic mechanisms involved in the pathogenesis of diabetes-associated periodontitis are summarized in Fig. 11-1: the hyperglycemia that characterizes diabetes drives the formation of AGEs and leads to increased expression and activation of their chief receptor RAGE. AGEs can impact cellular phenotype directly via receptor-independent pathways but, importantly, the AGE–RAGE interaction negatively affects cellular phenotype and function, leading to enhanced inflammation, production of reactive oxygen species or oxidative stress, and

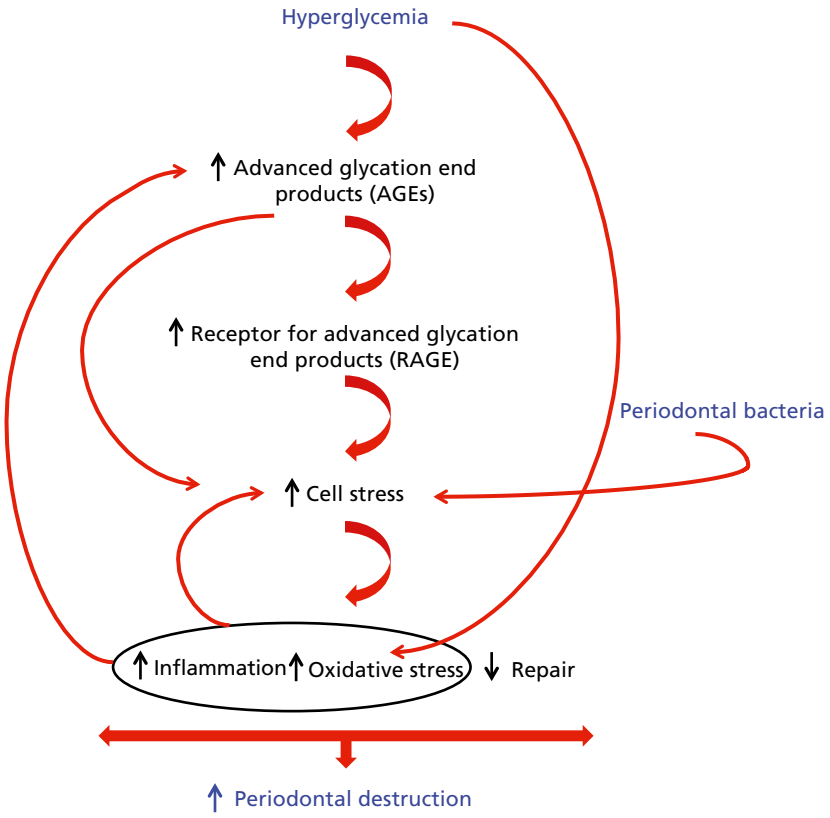

Fig. 11-1 Potential mechanisms in the pathogenesis of diabetes-associated periodontitis (see text).

compromised tissue repair. Hyperglycemia also promotes oxidative stress directly, and both inflammation and oxidative stress can contribute to further AGE formation. These mechanisms coupled with the impact of the periodontal pathogens perpetuate this vicious cycle of inflammatory stress and impaired repair in the diabetic periodontium. Of note, there are several links between the various elements shown in Fig. 11-1, but they cannot all be demonstrated in a single diagram. For example, inflammation and oxidative stress amplify one another and can also promote shifts in the subgingival biofilm. The net result of all these complex pathways is the accelerated periodontal tissue destruction observed in diabetes.

Clinical presentation of the periodontal patient with diabetes

The current consensus is that there are no characteristic phenotypic features unique to periodontitis in patients with diabetes and, on this basis, diabetes-associated periodontitis is not a distinct disease (Jepsen *et al*. 2018). Nevertheless, since diabetes is an important modifying factor of periodontitis, according to the 2018 classification (Papapanou *et al*. 2018), the level of glycemic control is taken into consideration in the assessment of grade of periodontitis.

Patients with diabetes will often present with pronounced clinical and radiographic signs of periodontitis, including gingival inflammation, increased pocketing, and increased attachment, bone, and tooth loss (Figs. 11-2, 11-3, 11-4, 11-5). It is recognized that among those affected by diabetes, patients with poor glycemic control are at a higher risk for presenting with more severe periodontitis (Garcia *et al*. 2015; Genco & Borgnakke 2020). In addition, clinical and radiographic signs of periodontitis progression may be evident (Figs. 11-6, 11-7), especially in periods when glycemic control deteriorates over time (Westfelt *et al*. 1996; Demmer *et al*. 2012; Costa *et al*. 2013b). Beyond the typical appearance of amplified gingival inflammation and bone or attachment loss, poorly controlled or undiagnosed/untreated patients with diabetes may present with or experience multiple recurring periodontal abscesses (Harrison *et al*. 1983; Ueta *et al*. 1993; Herrera *et al*. 2014). Given that many of the effects of hyperglycemia discussed in the section above are irreversible and may have long-lasting effects, poor periodontal status may also be present in patients with adequate current glycemic levels, but past periods of poor metabolic control.

Importantly, even children and adolescents with diabetes may present with significant periodontal changes (Cianciola *et al*. 1982). A series of reports in 6–18-year-old individuals (Lalla *et al*. 2006a, 2007a, b) has demonstrated that increased attachment loss manifests much earlier in life in diabetes than previously recognized and is associated with poor glycemic control. These findings have been supported by subsequent studies and have led to the recommendation that a thorough periodontal evaluation is needed in patients with diabetes across all age groups to allow for early intervention (Jensen *et al*. 2020).

With respect to periodontal therapy outcomes, patients with adequately controlled diabetes can respond well to non-surgical treatment and achieve reduced probing depths and attachment gain (Christgau *et al*. 1998; Hsu *et al*. 2019). In such patients, periodontal status can remain stable over time following therapy (non-surgical and surgical) and appropriate maintenance (Westfelt *et al*. 1996). However, in patients with poor glycemic control, long diabetes duration, and other diabetic complications, response to periodontal therapy appears to be unpredictable as tissue repair and wound healing are often compromised (Tervonen & Karjalainen 1997). There is little available evidence to date on specific responses to different types of surgical therapy in patients with diabetes. Clinicians may use early responses to non-surgical therapy, especially at the more "predictable" sites (e.g. shallow–moderate pockets, accessible sites, single-rooted teeth), in order to identify potential non-responders early, properly inform/advise such patients, and plan further treatment accordingly.

Concepts related to patient management

Studies suggest that oral disease awareness among individuals with diabetes is low (Moore *et al*. 2000; Tomar & Lester 2000; Sandberg *et al*. 2001; Jansson *et al*. 2006; Allen *et al*. 2008; Al Habashneh *et al*. 2010; Poudel *et al*. 2018; Siddiqi *et al*. 2019; Parakh *et al*. 2020). Therefore, dental professionals need to educate their patients with diabetes, young and old, about the link between diabetes and periodontitis, and stress that the two conditions may amplify one another.

Managing the periodontal patient with diabetes who is under good medical care and maintains adequate glycemic control should not generally be difficult. However, as the concepts discussed earlier suggest, patients with poor metabolic control and those who present with other complications and co-morbidities may present a challenge when treated for periodontal conditions. Therefore, special considerations must be taken into account to ensure that the oral care provided is safe and that it leads to predictable outcomes. These considerations include: (1) taking a thorough medical history with a focus on understanding the patient's metabolic profile; (2) establishing communication with the treating physician; (3) performing a careful intraoral evaluation and a comprehensive periodontal examination; (4) addressing other risk factors present, such as smoking or overweight/obesity; and (5) considering co-morbidities and other complications, such as hypertension and vascular or kidney disease.

Initial therapy should focus on the control of acute infections, if present, as these may also have a direct adverse effect on the level of the patient's glycemic control. Good oral and overall health behaviors along

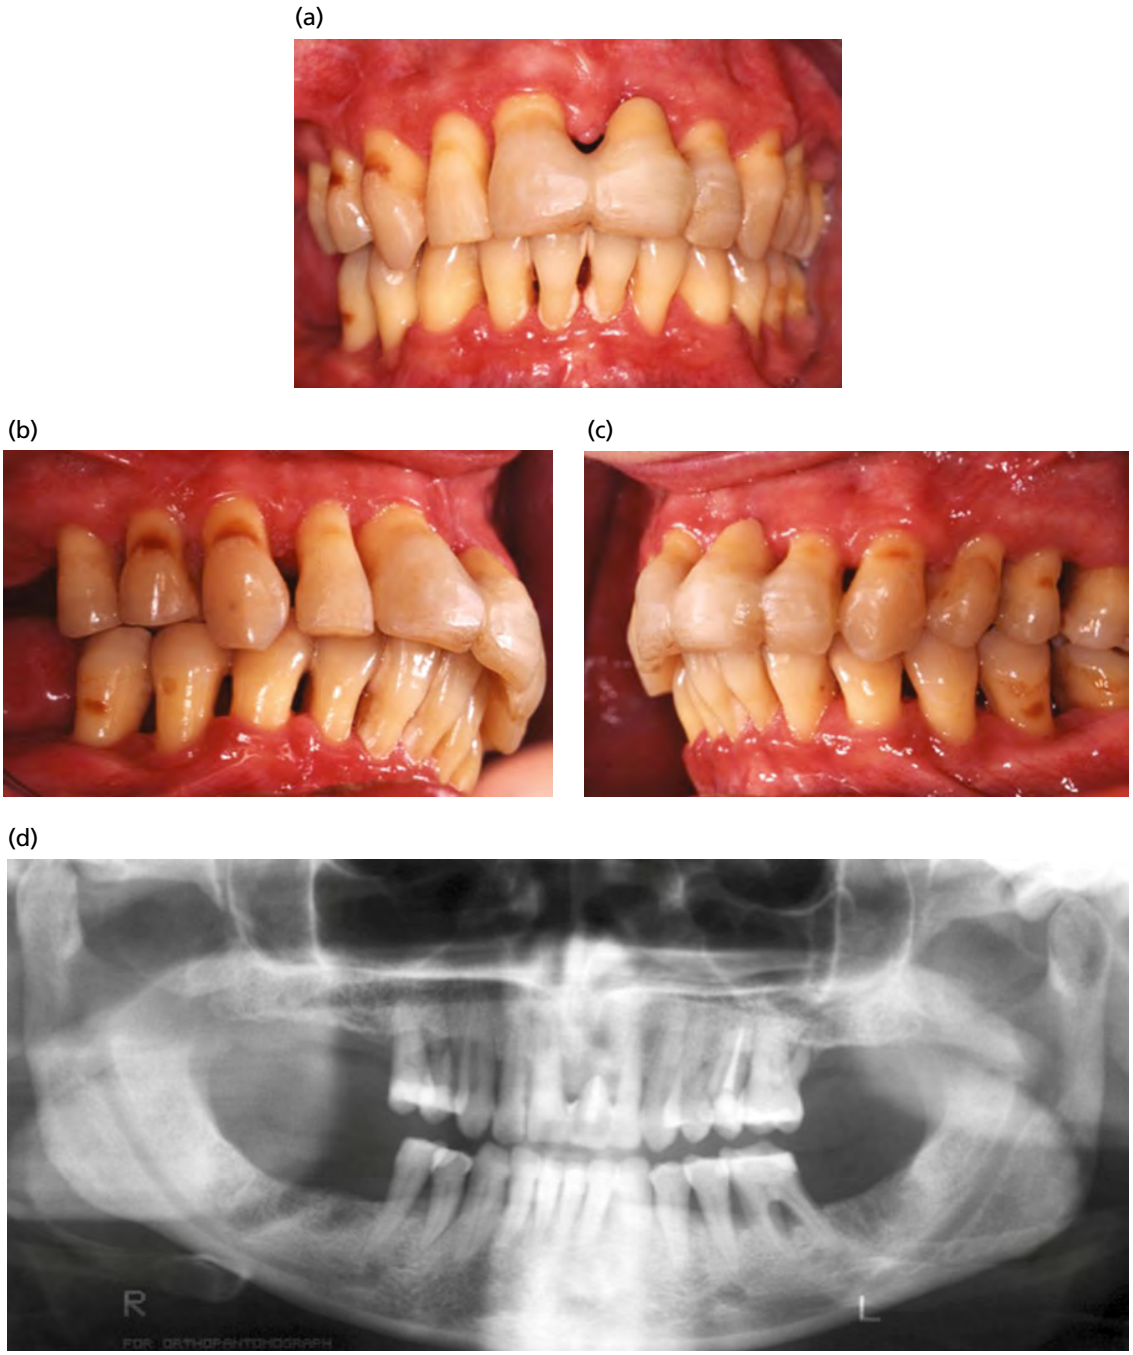

Fig. 11-2 (a–c) Clinical and (d) radiographic presentation of a 38-year-old female patient with type 1 diabetes and generalized Stage IV, Grade C periodontitis. The patient was diagnosed with diabetes at the age of 10 years, has poor glycemic control, and is also a smoker. (Source: Courtesy of Dr. Tellervo Tervonen.)

with lifestyle changes, as needed, must be promoted. Recommendations for proper home care are very important and a less complex, stepwise periodontal therapy plan should be offered whenever possible. Clinical protocols should be in place for determining frequency of maintenance care (to reinforce oral hygiene and prevent, monitor, and treat any disease reactivation), the need for referral to a periodontist, and the need for medical consultation, referral, and follow-up. An interdisciplinary approach and collaboration beyond professional boundaries is essential.

Furthermore, extreme glycemic variability is a relatively common medical emergency in a dental care setting. Prevention, early recognition, and proper management of potential hypo- and hyperglycemic episodes are very important. Dental professionals need to remember that, for all people with type 1 and many with advanced type 2 diabetes, episodes of hypoglycemia are very common and can be precipitated by several factors, including missed or delayed meals, excessive physical activity, stress, or alcohol consumption. Acute hyperglycemic episodes are less common, but also serious. They can be precipitated by pain and stress, that antagonize insulin action, or by under-dosing of diabetic medications prior to the dental appointment. Therefore, consideration must

Comparison reveals progression of bone loss and loss of the upper right second premolar within this short time period, during which glycemic control was poor (HbA1c values of 9–10%). (Source: Courtesy of Dr. Shota Tsuji.)

be given to the appropriate timing and duration of appointments: early mornings are preferable, as patients can tolerate stress better due to higher levels of endogenous corticosteroids. Likewise, procedures should preferably be brief and as atraumatic and pain free as possible, requiring profound anesthesia and adequate post-treatment analgesic coverage. In addition, since the patient's ability to eat may be affected by a periodontal procedure, a change in diabetic regimen may be necessary and should be explored in consultation with the treating physician.

A preoperative determination of glucose levels using the patient's glucometer can be very helpful in prevention and/or early identification of episodes of extreme glycemic variability. Early signs of hypoglycemia (glucose levels <70 mg/dL) include shakiness, weakness, hunger, cold and clammy skin, and nausea, and later symptoms include increasingly bizarre behavior, mental confusion, hypotension, and loss of consciousness. If the patient is conscious, 15–20 g of simple carbohydrates should be given orally (e.g. glucose tablets or gel, 120 mL of fruit juice, 1 tablespoon

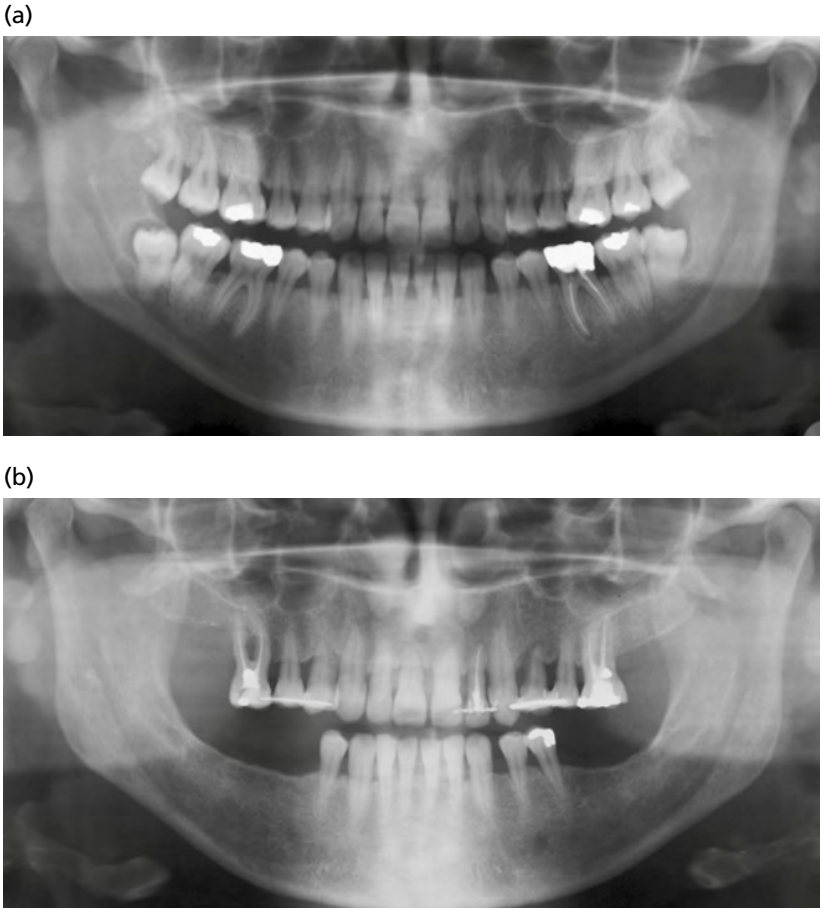

Fig. 11-7 Panoramic radiographs of a female patient with type 1 diabetes (a) at presentation at the age of 29 years and (b) 12 years later. The patient had been diagnosed with diabetes at the age of 12 years, was poorly controlled, and a smoker. She developed nephropathy and was on peritoneal dialysis. Despite comprehensive periodontal therapy, her periodontal status deteriorated significantly. The patient died of a myocardial infarction at age 41. (Source: Courtesy of Dr. Tellervo Tervonen.)

of table sugar). The patient should respond in about 15 minutes and should be then given a snack with complex carbohydrates and protein. If the patient does not respond, treatment can be repeated. If the patient becomes unconscious, glucagon (available as a kit with a 1-mg ampule, diluents, and syringe) can be injected into the upper arm or thigh muscle and medical emergency services must be called. When the patient responds to the glucagon injection and is able to swallow, the oral carbohydrate administration steps described above can be followed until the patient is stabilized. A patient with an acute hyperglycemic emergency (glucose levels >250–300 mg/dL) can present disoriented, thirsty, fatigued, or nauseated, with rapid and deep breathing, hot and dry skin, and fruity breath, and can progress to hypotension and loss of consciousness. Such patients require transfer to an emergency room/hospital setting and immediate medical intervention. Again, having a glucometer at hand is very helpful; glucose levels can be assessed when symptoms arise to confirm whether the episode is because of hypo- or hyperglycemia, and in the case of a hypoglycemic episode, to reassess levels following initial treatment. If a glucometer is not available and the dental professional is unable to differentiate whether the patient is hypo- or hyperglycemic, treatment for hypoglycemia should be initiated. The patient's treating physician should always be informed of extreme glycemic emergencies that occurred in the dental setting and provided with all related information.

Finally, another concern relates to the large number of people worldwide who have diabetes, but remain undiagnosed, and the even larger number of individuals at risk for diabetes who are unaware of it. Since diabetes has early oral effects and many patients visit a dentist annually, often returning for multiple non-emergent visits, dental care settings are ideal healthcare sites that can be used for the early identification of undiagnosed diabetes. Dental professionals can assess risk factors, refer for testing or "formally" screen, and follow up on outcomes.

Early studies aiming to explore the ability of clinical periodontal parameters to identify patients with undiagnosed diabetes were based on national US data and suggested that such an approach is promising (Borrell *et al*. 2007; Strauss *et al*. 2010). The first study to collect data prospectively in a clinical setting in order to discern a simple and efficient protocol to identify people with undiagnosed prediabetes or diabetes revealed that two dental parameters (number of missing teeth and percent of teeth with deep

periodontal pockets) were effective in correctly identifying the majority of cases of unrecognized dysglycemia (Lalla *et al*. 2011, 2013). The addition of a point-of-care HbA1c test result was found to improve significantly the performance of the screening algorithm in the population under investigation. Other approaches to screening in dental settings have since been reported with consistent results (Genco *et al*. 2014; Herman *et al*. 2015; Lalla *et al*. 2015; Holm *et al*. 2016; Acharya *et al*. 2018; Estrich *et al*. 2019). Findings from these studies suggest that incorporating assessment for undiagnosed diabetes into the periodontal evaluation of patients at risk is of value as it can raise patients' awareness and contribute to early diagnosis and treatment of those affected, and highlight a new set of responsibilities for dental professionals.

Tobacco smoking

Tobacco smoking is a prevalent behavior with widespread and severe health consequences. Although tobacco use was once classified as a habit, it is now considered an addiction to nicotine and a chronic relapsing medical condition. Smoking has several effects on the oral cavity, ranging from simple tooth staining to oral cancer.

As reviewed in Chapter 6, tobacco smoking is recognized as an important risk factor for periodontitis, and a multitude of epidemiologic and clinical studies have established its detrimental effect not only on the prevalence and severity of periodontitis, but also on its incidence and progression (Zeng *et al*. 2014; Nociti *et al*. 2015; Leite *et al*. 2018). These effects have been shown to be dose-dependent and can be particularly evident in younger individuals (Kibayashi *et al*. 2007; Stabholz *et al*. 2010; Costa *et al*. 2013a; Zeng *et al*. 2014). There is also evidence for a link between passive, also termed environmental or second-hand, smoking and periodontal disease (Arbes *et al*. 2001; Nishida *et al*. 2008; Akinkugbe *et al*. 2016; Sutton *et al*. 2017). Tobacco smoke contains thousands of different substances (Talhout *et al*. 2011) and most of its harmful effects result through systemic exposure following lung absorption, in addition to the obvious absorption in the oral cavity (Palmer *et al*. 1999).

Electronic nicotine delivery systems (e-cigarettes) are alternative, non-combustible tobacco products that generate an inhalable aerosol. E-cigarette use, or vaping, appeals to current smokers, former smokers, and young people who have never smoked, and e-cigarette use by adolescents is highly prevalent and has been associated with a two- to four-fold increase in cigarette smoking over the following year (Asher *et al*. 2019; Cullen *et al*. 2019). Evidence on the effects of vaping on the oral cavity is currently limited (Yang *et al*. 2020). E-cigarettes have been marketed as useful tools in smoking cessation, but evidence is inadequate to infer that they actually increase quit rates (Lindson-Hawley *et al*. 2016; El Dib *et al*. 2017; Dunbar *et al*. 2019). Importantly, the extent of health risks posed by ingredients that are unique to e-cigarettes but not present in conventional cigarettes must be considered. Also of importance in this context is the changing characteristics of e-cigarettes, the many different contexts in which they are used, and the limited number of studies on their long-term health effects conducted to date (Clapp & Jaspers 2017; Gotts *et al*. 2019).

Mechanisms underlying the effect of smoking on periodontitis

The mechanisms by which cigarette smoking affects periodontal status are not fully understood; however, various potential pathways have been discussed in the literature, including effects on the oral microbiota, the gingival tissues, the inflammatory and immune response, and the healing capacity of the periodontium.

Early reports suggested that the amount of plaque in smokers is higher compared with non-smokers (Preber *et al*. 1980), but studies controlling for confounding factors revealed that smoking does not appear to affect plaque scores, and indeed, in experimental gingivitis models, the rate of plaque formation was similar between smokers and non-smokers (Bergstrom 1981; Preber & Bergstrom 1986; Lie *et al*. 1998). Further, certain studies focused on smoking and qualitative changes in subgingival plaque. Zambon *et al*. (1996) found higher prevalence of *Aggregatibacter actinomycetemcomitans*, *Tannerella forsythia*, and *P. gingivalis* in current and former smokers compared with never-smokers. Similarly, Haffajee and Socransky (2001b) found a higher prevalence of eight bacterial species in current smokers compared with past smokers and non-smokers. Studies employing traditional culture or targeted molecular methods have not always reported consistent findings (Kubota *et al*. 2011; Heikkinen *et al*. 2012; Lanza *et al*. 2016; Joaquim *et al*. 2018), but altered subgingival microbial communities due to smoking are generally revealed using 16S sequencing (Jiang *et al*. 2020). Indeed, tobacco smoking has been shown to affect bacterial acquisition and aggregation, and to promote colonization with key periodontal pathogens (Shchipkova *et al*. 2010; Bagaitkar *et al*. 2011; Brook 2011; Kubota *et al*. 2011; Kumar *et al*. 2011; Bizzarro *et al*. 2013).

Based on the above, it appears that microbiologic differences exist between smokers and non-smokers, but they primarily concern the composition rather than the amount of the subgingival biofilm. No unified conclusion can be drawn currently, however, on how smoking-induced microbial diversity changes contribute to periodontitis.

Importantly, it is well accepted that smoking has the potential to impair several aspects of the innate and immune response and, in the setting of periodontitis, this can tip the balance towards an exaggerated tissue breakdown and impaired repair (Lee *et al*.

2012). To this end, it has been reported that neutrophil migration and chemotaxis in the periodontal tissues are negatively affected in smokers (Pabst *et al*. 1995; Persson *et al*. 2001; Soder *et al*. 2002). Interestingly, neutrophils express functional receptors for many tobacco smoke components and, for example, the numbers of nicotine receptors are increased in smokers and have been shown to decrease following smoking cessation (Ackermann *et al*. 1989; Lebargy *et al*. 1996). Not all data on neutrophil effects are consistent, but overall cigarette smoke appears to shift the balance of neutrophil activities in the more destructive direction (White *et al*. 2018). The effects of tobacco smoking on T- and B-cell numbers and function are more complex and less consistent across studies, as both immunosuppressive and inhibitory processes have been described (Palmer *et al*. 1999; Loos *et al*. 2004). There is also, mostly *in vitro*, evidence suggesting that gingival and periodontal ligament fibroblast recruitment and adhesion may be negatively affected in smokers, and that collagen production is decreased while collagenolytic activity is increased (Tipton & Dabbous 1995; James *et al*. 1999; Gamal & Bayomy 2002; Poggi *et al*. 2002; Karatas *et al*. 2020). Finally, the reported suppressed gingival inflammation in smokers as evidenced by clinical signs of reduced gingival bleeding and bleeding on probing (Preber & Bergstrom 1985, 1986; Bergstrom *et al*. 1988; Bergstrom & Bostrom 2001) appears to be related to fewer gingival vessels (Rezavandi *et al*. 2002; Palmer *et al*. 2005), rather than to vasoconstriction as originally speculated. The above effects of smoking on the inflammatory response, vasculature, and fibroblast function can also explain its well-described negative effects on healing following non-surgical and surgical periodontal therapy (Kinane & Chestnutt 2000).

Much less is known about the mechanisms underlying the effects of passive smoking on the periodontium. However, there is evidence for increased levels of salivary cotinine (a nicotine metabolite), higher levels of a number of inflammatory mediators, and an increased proportion of phagocytic cells in gingival lesions of individuals exposed to second-hand smoking, possibly indicating an altered host response to the bacterial challenge (Walter *et al*. 2012).

Clinical presentation of the periodontal patient who smokes

The current consensus is that there is no unique phenotype of periodontitis in smokers and, on this basis, smoking-associated periodontitis should not be a distinct diagnosis (Jepsen *et al*. 2018). Nevertheless, since smoking is an important modifying factor of periodontitis, according to the 2018 classification (Papapanou *et al*. 2018), the current level of tobacco use is taken into consideration in the assessment of grade of periodontitis.

The periodontal effects of smoking become evident relatively early in the course of tobacco use, and smokers often present clinically and radiographically with signs of increased bone, attachment, and tooth loss (Figs. 11-8, 11-9). Deeper pockets and more attachment loss may often be seen in mandibular anterior and maxillary palatal sites (Haffajee & Socransky 2001a; Adler *et al*. 2008). At the same time, however, smoking may mask some other important clinical signs of gingivitis and periodontitis, complicating the usual approach to recognizing these conditions. Indeed, smokers often present with fibrotic gingiva and limited gingival erythema and edema relative to the amount of plaque and the severity of the underlying bone loss (Scott & Singer 2004). Bleeding on probing is reduced in a dose-dependent manner in smokers compared with non-smokers with similar levels of plaque (Bergstrom & Bostrom 2001; Dietrich *et al*. 2004), and it can re-emerge within weeks in patients who quit, even in the presence of improved plaque control (Nair *et al*. 2003).

Importantly, and as described in detail in Chapter 6, multiple studies examining the effects of smoking have demonstrated that response to periodontal therapy is compromised in smokers, with current smokers exhibiting less probing depth reduction and/or attachment gain compared to former or never smokers (Heasman *et al*. 2006). Meta-analyses of the effects of smoking on the outcomes of periodontal therapy corroborate these conclusions (Garcia 2005; Labriola *et al*. 2005; Patel *et al*. 2012; Kotsakis *et al*. 2015) and suggest that a smoker's post-treatment clinical presentation may not be compatible with the expected profile of a treated patient.

Concepts related to patient management

The evidence reviewed earlier has direct patient management implications. Patients who smoke need to be informed of their enhanced risk for limited or delayed treatment responses and this may actually provide an opportunity to further motivate a patient to consider smoking cessation.

Dental professionals are healthcare providers and, as such, have the responsibility to advocate smoking cessation among their patients. In doing so, they can contribute to improved patient oral health, overall health, and quality of life. A Cochrane review of 14 studies totaling more than 10500 participants (Carr & Ebbert 2012) reported that behavioral interventions conducted by oral health professionals in a dental office or other community setting could significantly increase cessation rates in cigarette smokers and users of smokeless tobacco.

Smoking cessation has been shown in longitudinal studies to have beneficial effects on the periodontal status (Bolin *et al*. 1993; Krall *et al*. 1997; Bergstrom *et al*. 2000; Rosa *et al*. 2014; Leite *et al*. 2018; Ramseier *et al*. 2020) and smoking cessation alone or in conjunction with non-surgical periodontal therapy appears to result in a subgingival environment that comprises higher levels of health-associated

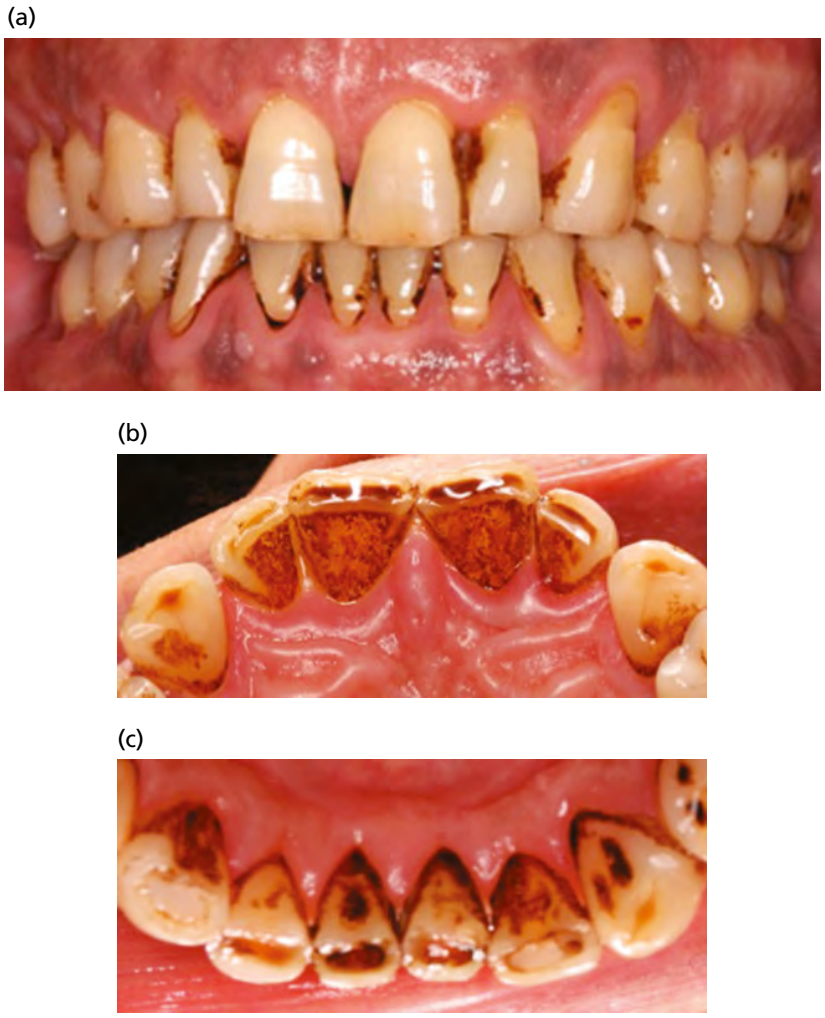

Fig. 11-8 Clinical appearance of a 53-year-old male patient who reports smoking one pack a day for 35 years. (a) Anterior view; (b) palatal view of the maxillary anterior teeth, and (c) lingual view of the mandibular anterior teeth. Note the heavy staining. Periodontal examination revealed probing depths of up to 9 mm, gingival recessions, and furcation involvements at all molars. (Source: Courtesy of Dr. Matthew Hickin.)

species and lower levels of pathogens (Fullmer *et al*. 2009; Delima *et al*. 2010).

There are multiple opportunities to interact with patients and provide tobacco use intervention, especially after initial periodontal evaluation of a new patient and during the long-term maintenance phase of periodontal therapy. Different approaches can be used. Asking every patient about tobacco use, documenting smoking status and motivation to quit, and advising patients to stop are the minimum obligations. A more comprehensive intervention that includes offering smoking cessation counseling with pharmacologic therapy and supportive follow-up is ideal. Complex patients such as those suffering from psychiatric illness or medical co-morbidities should be referred to smoking cessation specialists/clinics where comprehensive treatment can be offered. Inquiry about e-cigarette use and the reasons for it, is also appropriate. Sharing that vaping is not without risks and providing advice to reduce or quit e-cigarette use are also indicated.

Some of the different approaches to smoking cessation that can be considered in the dental setting are briefly discussed below. In general, evidence to date suggests that dental professionals often ask their patients about smoking, but don't always provide help regarding cessation, and several barriers to delivering smoking cessation intervention by dental professionals have been reported (Albert *et al*. 2005; Kunzel *et al*. 2006; Patel *et al*. 2011; Rosseel *et al*. 2011; Jannat-Khah *et al*. 2014; Chaffee *et al*. 2020). For those providers who identify lack of time or expertise/confidence as barriers, a "brief intervention" approach may be a useful model. The dental team can give patients educational brochures to take home and also provide some encouragement and support by relating tobacco use to medical and oral health risks. This strategy is often effective as the advice of a trusted healthcare provider is always valuable.

If the dental team is willing to be more proactive and the patient is motivated, a behavioral program can be introduced. The "five A's", from the United States Department of Health and Human Services

Fig. 11-9 Same patient as in Fig. 11-8. (a, b) Maxillary left buccal and palatal views and (c) corresponding radiograph; (d, e) mandibular left buccal and lingual views and (f) corresponding radiograph. Heavy staining and advanced bone loss are apparent. (Source: Courtesy of Dr. Matthew Hickin.)

(2020), is considered the gold standard approach for delivering a tobacco cessation intervention:

Ask: Ask about smoking behavior directly and document status (current, former, or never smoker; duration and number of cigarettes per day). Tobacco use status indicators on paper charts or electronic records can make screening easier.

Advise: Advise patient to quit. The message should be clear, strong, and tailored. A good time to do this is after the periodontal examination is completed and when findings, etiology, risk factors, and prognosis are discussed. Several health organizations and internet sites that provide valuable information are available.

Assess: Assess the patient's readiness and motivation to quit. If the patient is willing to attempt cessation, provide assistance as described below. If the patient is clearly unwilling to attempt quitting at this time, offer written materials about quitting and re-assess at future appointments. Improving the patient's interest and readiness level is a successful intervention, even if cessation is not immediately contemplated.

Assist: Assist the patient willing to make a quit attempt by providing a structured plan for quitting. Decide on a quit date and encourage the patient to seek support from family and friends. Consider the use of pharmacotherapies that have proven effective and are briefly described below. Anticipate challenges that might threaten smoking cessation and decide in advance on a plan of action if/when those arise.

Arrange: Arrange follow-up, including behavioral support and telephone contact/counseling. The first week of cessation is especially critical.

A variety of other approaches exist to deliver behavioral interventions for smoking cessation, and could also be considered: tobacco quitlines, web-based interventions, smartphone applications. Healthcare providers must remember that the elements that make a particular technology-mediated approach effective for cessation may shift as technologies, and the ways in which people interact with and use technology, evolve.

Based on the strong evidence available for brief tobacco cessation interventions, the US Preventive Services Task Force (Siu 2015) recommends that clinicians deliver such interventions to all adult smokers. Even brief (<3 minutes) advice from a physician significantly improves cessation rates and is highly cost-effective (Stead *et al*. 2013).

Pharmacologic treatment options to smoking cessation include nicotine replacement therapy, sustained-release bupropion, and varenicline (Aubin *et al*. 2011). Nicotine replacement therapy involves the use of products that provide low doses of nicotine, but do not contain the toxins found in smoke. The goal of therapy is to relieve cravings for nicotine and ease the withdrawal symptoms. Nicotine supplements come in different forms: transdermal patch, gum, lozenges, nasal spray, and inhaler. The different forms of replacement therapy can be used alone or in combination, and all work well if they are used correctly. The choice depends on the patient's smoking habits and preferences, and initial treatment lasts for 2–3 months. Side effects include headaches, nausea, and insomnia in the first few days, especially with the patch. Sustained-release bupropion inhibits the neuronal uptake of norepinephrine and dopamine. It can therefore control nicotine withdrawal symptoms and may also help patients manage associated anxiety and depression. Treatment with bupropion should be initiated 1–2 weeks before the quit date, because 1 week is necessary to achieve steady-state blood levels; treatment usually lasts for 2–3 months, but it can continue safely for maintenance for up to 6 months. The use of bupropion is contraindicated for patients with a history of seizures, eating disorders, and those who are on certain antidepressants. Common side effects of bupropion include insomnia and dry mouth, and patients should be monitored closely for unusual changes in behavior, such as agitation, depression, and attempted suicide (Hays & Ebbert 2010). Varenicline is the newest drug for smoking cessation. It has a structure similar to that of nicotine and thus it can antagonize nicotine binding to its receptor sites. As with buproprion, varenicline treatment starts 1 week before the quit date and continues for 3 months; maintenance treatment, if needed, may be for up to 6 months. Common side effects include nausea, trouble sleeping, and abnormal or vivid dreams (Garrison & Dugan 2009; Hays & Ebbert 2010). Patients taking varenicline should be monitored closely for any changes in mood and behavior.

Unfortunately, nicotine dependence is chronic and strong, and therefore the possibility of relapse is high. Smokers often must experience many attempts at cessation before they can remain totally tobacco free. They are certainly more likely to be successful if they have support with quitting. Providing encouragement at every appointment with the dentist and hygienist is key in helping dental patients stay smoke free.

Obesity and nutrition

Obesity, a condition characterized by accumulation of excess body fat, is defined in adults as a Body Mass Index (BMI) of ≥30 kg/m^2, while a BMI between 25 and 29.9 kg/m^2 indicates an overweight individual (WHO 2020). In the past few decades, many countries in both the industrialized and the developing world have experienced a substantial increase in the prevalence of obesity (Fox *et al*. 2019), which is known to be a major contributor to morbidity and mortality (Lenz *et al*. 2009). Concomitant occurrence of obesity, insulin resistance, dyslipidemia, and hypertension constitute the metabolic syndrome, a precursor condition to type 2 diabetes and incident cardiovascular disease (Kumari *et al*. 2019).

As discussed in Chapter 6, several studies have demonstrated a positive association between obesity/metabolic syndrome and periodontitis. Indeed, the three most recent systematic reviews that compiled the available evidence linking obesity to periodontitis have all demonstrated a positive association between the two conditions, both in adolescents and young adults (Khan *et al*. 2018) as well as across the entire age spectrum (Martinez-Herrera *et al*. 2017; Arboleda *et al*. 2019). Although the limited number of longitudinal studies of adequate quality does not facilitate the exact delineation of the temporality of this association at the present time, it is biologically plausible that obesity may contribute to a higher risk for periodontitis. However, it is unclear thus far whether presence of obesity negatively affects the treatment outcomes of non-surgical periodontal therapy; three systematic reviews published almost concurrently failed to convincingly document differences in treatment responses between obese and non-obese patients with periodontitis (Akram *et al*. 2016; Gerber *et al*. 2016; Nascimento *et al*. 2016).

The function of the adipose tissue as essentially an endocrine organ (Scheja & Heeren 2019) is central to the association between obesity and periodontitis. Adipocytes secrete a variety of metabolically and immunologically active molecules, termed adipokines, among which leptin, adiponectin, and resistin have been studied the most. The primary function of leptin is to negatively regulate appetite and weight (Charchour *et al*. 2020), but it also interacts with other hormones including insulin (Margetic *et al*. 2002; Ghadge & Khaire 2019). Interestingly, there is a negative correlation between GCF and serum levels of leptin in periodontitis, and this association was reported to become stronger with increasing levels of attachment loss (Karthikeyan & Pradeep 2007a, b). Serum levels of adiponectin are decreased in obesity, insulin resistance, diabetes, and cardiovascular disease (Matsuzawa *et al*. 2004; Maeda *et al*. 2020). *In vitro*, adiponectin has been shown to be a potent negative regulator of osteoclast formation in response to challenge by *A. actinomycetemcomitans* LPS (Yamaguchi *et al*. 2007). Its levels in GCF have been recently

reported to be significantly elevated in periodontitis (Preshaw *et al*. 2020), but there is no clear association between its serum levels and periodontal status (Furugen *et al*. 2008; Saito *et al*. 2008; Goncalves *et al*. 2015). In contrast, serum levels of resistin were found to be higher in patients with periodontitis than in periodontally healthy individuals, and to correlate with the extent of bleeding on probing (Furugen *et al*. 2008; Saito *et al*. 2008). Collectively, adipokine action and oxidative stress have been proposed to serve as the common link in the pathobiology of obesity and periodontitis (Bullon *et al*. 2009; Suvan *et al*. 2018; Jepsen *et al*. 2020). Indeed, there is evidence of higher serum levels of markers of oxidative stress and of decreased antioxidant capacity in individuals with periodontitis when compared with periodontally healthy controls (Chapple *et al*. 2007; Ling *et al*. 2016).

The role of nutritional exposures in the etiology and therapeutic management of periodontitis has not been adequately studied, but has recently gained increasing attention. Observations documented in the Ebers Papyrus (circa 1550 BC), writings by Hippocrates (460–370 BC), and eighteenth century reports of bleeding gums and tooth loss in sailors that did not have access to fresh fruit and vegetables over prolonged time periods, would later have been attributed to scurvy-associated pathologies (for a comprehensive review see Van der Velden 2020). Ascorbic acid (vitamin C) is a powerful antioxidant radical scavenger (Da Costa *et al*. 2012) that is distributed in multiple cell types including polymorphonuclear leukocytes, platelets, and endothelial cells (Evans *et al*. 1982), and which has been shown to exercise effects on osteoclasts and periodontal ligament fibroblasts (Mimori *et al*. 2007). The effects of vitamin C deficiency on the gingival tissues were demonstrated in early studies of controlled depletion and supplementation (Leggott *et al*. 1986, 1991), as well as in epidemiologic studies (Nishida *et al*. 2000). Likewise, although it has long been known that vitamin D and calcium are important for skeletal development and maintenance of bone mass, vitamin D has emerged as an important regulator of innate immune responses in infectious diseases (Adams & Hewison 2008), with positive effects on periodontal status (Miley *et al*. 2009; Garcia *et al*. 2011). Additional micronutrients that have been investigated with respect to their association with periodontal status include both antioxidant (vitamin E, carotenoids, polyphenols, glutathione) and non-antioxidant molecules (vitamin B, omega-3 polyunsaturated fatty acids). In general, epidemiologic studies reveal that periodontitis is associated with low serum/plasma micronutrient levels (Van der Velden *et al*. 2011; Lee *et al*. 2020; O'Connor *et al*. 2020), whereas early evidence from interventional studies (Campan *et al*. 1997; Staudte *et al*. 2005; Jenzsch *et al*. 2009; Chapple *et al*. 2012; Woelber *et al*. 2016, 2019; Díaz Sánchez *et al*. 2017) suggests that adjunctive nutritional supplementation may result in improved periodontal therapy outcomes. Additional research from randomized, placebo-controlled trials is needed to further document these effects, and to facilitate the development of evidence-based nutritional recommendations in the prevention and control of periodontal diseases (Dommisch *et al*. 2018).

Osteoporosis

Osteoporosis is a disease characterized by loss of bone mineral density that can lead to bone fragility and increase susceptibility to fractures (Eastell 1998; Compston *et al*. 2019). Female gender, advanced age, family history of osteoporosis, ethnicity (Caucasian or Asian), history of a low-impact bone fracture, thin skeletal frame, and early menopause are non-modifiable risk factors/markers for osteoporosis. High alcohol intake, smoking, low body mass index, vitamin D deficiency, and physical inactivity are other important modifiable risk factors. The femur and spine are most commonly affected and bone density at these sites can be quantified using dual-energy X-ray absorptiometry (DXA) scans to define a diagnostic T score (NIH Consensus Development Panel on Osteoporosis Prevention & Therapy 2001). The T score compares bone density for a given patient to the mean peak bone density for an individual of the same sex and is reported as the number of standard deviations below that mean. A T score of −1 or above is considered normal and a score of −2.5 or lower signifies osteoporosis. Scores lower than −1.0 and greater than −2.5 indicate osteopenia, an intermediate state between health and osteoporosis.

Several clinical studies have drawn attention to the possible link between osteoporosis and periodontal disease, as both conditions involve bone loss and share common risk factors and pathogenic mechanisms (Otomo-Corgel 2012). However, and as reviewed in Chapter 6, many of the clinical studies published thus far are uncontrolled, cross-sectional, had small sample sizes, or were restricted to postmenopausal women (von Wowern *et al*. 1994; Mohammad *et al*. 1996, 1997; Tezal *et al*. 2000; Renvert *et al*. 2011; Manjunath *et al*. 2019). Larger studies, such as one based on the Korean National Health and Examination Survey (Kim *et al*. 2014) and two recent reports from an epidemiologic study in Thailand (Mongkornkarn *et al*. 2019; Niramitchainon *et al*. 2020) demonstrated a negative association between bone mineral density and periodontitis severity, but data from longitudinal studies are inconclusive (LaMonte *et al*. 2013; Pereira *et al*. 2015; Kaye *et al*. 2017). Nevertheless, the most recent systematic reviews (Wang & McCauley 2016; Goyal *et al*. 2017) concluded that there is a significant, positive association between osteoporosis and periodontitis.

It has been proposed that low bone mineral density in the maxilla and mandible as a result of osteoporosis may contribute to periodontal pathology by accelerating alveolar bone resorption that is initiated by the periodontal infection (Wactawski-Wende 2001).

In addition, factors affecting systemic bone remodeling (e.g. heredity, shared risk factors such as smoking, hormonal influences [estrogen deficiency, parathyroid hormone effects], calcium and vitamin D deficiencies, effects of inflammatory mediators and disruption of the RANKL and OPG axis) appear to perturb the local homeostatic mechanisms at the dento-gingival niche and to result in enhanced destruction of the periodontal tissues (Wang & McCauley 2016).

Skeletal bone loss in those affected by osteoporosis is usually gradual and painless. Often, there are no obvious symptoms until a fracture occurs and thus early identification of those affected by or at-risk for osteoporosis is important. Dental professionals may be able to recognize clinical risk factors for osteoporosis among their patients and observe radiographic changes, such as thinning and porosity of the inferior border of the mandible in available panoramic radiographs or cone beam computed tomographs (Horner *et al*. 2010; Koh & Kim 2011; Nagi *et al*. 2014; de Castro *et al*. 2020). Discussion of such findings and referral for further investigation by a medical colleague of those identified as potentially at-risk for osteoporosis can be beneficial in prevention of osteoporotic fractures.

Finally, it is important for dental professionals to keep in mind that, with increasing longevity, osteoporosis prevalence will continue to rise and that many female, but also male, dental patients may be affected and be under lifelong antiresorptive medications. Dentists need to review medication history, including method of delivery (oral or intravenous), duration and dose, and consult with the patient's physician in view of periodontal treatment. For those patients on bisphosphonates, careful planning and consultation with the treating physician is important, especially when periodontal therapy may involve extractions or other extensive surgical procedures and the patient has been on the medication for more than 2–3 years. Such patients should be informed of the risks and possible effects of bisphosphonates on dental treatment outcomes. Any acute lesions must be treated immediately, oral hygiene instruction must be thorough, and the periodontal condition must be carefully monitored. Systemic use of antibiotics and use of antimicrobial mouth rinses can be considered. The potential complication to prevent is osteonecrosis of the jaw (ONJ), a rare condition defined as an exposure of bone in the mandible or maxilla persisting for more than 8 weeks in a patient who previously received, or is currently under, treatment with a bisphosphonate and who has no history of radiation therapy to the jaws (Khosla *et al*. 2007). More recently, additional pharmacotherapies such as treatment with vascular endothelial growth factor inhibitors, tyrosine kinase inhibitors, and humanized antibodies that affect osteoclastic action have also been reported to initiate ONJ (Kanwar *et al*. 2020).

Clinically, ONJ may present as exposed alveolar bone occurring spontaneously or after dental surgery that caused bone trauma. The sites are usually painful, have soft tissue swelling or ulceration, mobile teeth, and induration with drainage. Radiographically, if teeth are present, there may be sclerosis of the alveolar lamina dura, loss of the alveolar lamina dura, and/or widening of the periodontal ligament space. Depending on the severity of ONJ, treatment strategies may include antibacterial mouth rinses, symptomatic treatment with oral antibiotics and analgesics, superficial debridement, and in severe cases surgical debridement/resection. The patient's treating physician must always be contacted and informed. Mitigating ONJ through preventive dental care and understanding of risk factors is of paramount importance (Wan *et al*. 2020).

Stress

Stress results from interactions between individuals and their environment. It has been defined as a state of mental or bodily tension stemming from factors that tend to alter an existent equilibrium, or as a condition or feeling experienced when a person perceives that demands exceed the personal and social resources they are able to mobilize. Stressors, the stimuli that cause stress in an individual, may be acute (short term, often due to time-limited events) or chronic (longer lasting, not always attributed to a discreet event) (Herbert & Cohen 1993), and are often categorized as (1) disasters or crises (unpredictable events completely out of the control of the individual, such as natural disasters, pandemics, wars), (2) major negative life events (such as death of a loved one, divorce, a serious new diagnosis or injury, dismissal from work), or (3) micro-stressors (daily small negative events) which, as they accumulate, can have the same impact as a major stressor, but are usually different for each individual. No single assessment can accurately measure stress or stress responses. Self-perceived stress is often measured using structured interviews/surveys and other self-reported tools. Clinically, the term "allostatic load" has been used to describe the cumulative exposure to stressors and is an aggregate of multiple parameters or mediators (neuroendocrine, metabolic, immunological, respiratory, cardiovascular, and anthropometric) many of which are, as expected, biologically interconnected (McEwen 1998).

There are numerous psychological and physical conditions that have been linked to stress, including depression, anxiety disorders, hypertension, cardiovascular and cerebrovascular events, obesity, immune system disturbances that increase susceptibility to infections, viral disorders ranging from the common cold and herpes to AIDS, certain cancers, as well as autoimmune diseases like multiple sclerosis (Spiegel & Giese-Davis 2003; Ziemssen & Kern 2007; Chida *et al*. 2008; Chida & Mao 2009; Falagas *et al*. 2010; Puder & Munsch 2010; Artemiadis *et al*. 2011; Bender & Alloy 2011; Blashill *et al*. 2011; Proietti *et al*. 2011; Wardle *et al*. 2011; Rosenthal & Alter 2012). Stress can also have direct effects on the skin and

the gastrointestinal tract, and can contribute to sleep disturbances (Kim & Dimsdale 2007; Basavaraj *et al*. 2011; O'Malley *et al*. 2011).

As expected, stress can also negatively affect the periodontium. This concept is not new; stress has been reported as an important risk factor for necrotizing ulcerative gingivitis and periodontitis for many decades. The effects of stress on the periodontium can be described as indirect or direct. Indirect effects are those mediated through lifestyle changes that can exacerbate periodontal destruction, such as compromised oral hygiene, inattention to dental visits for prevention/care, deterioration of metabolic control in diabetes, increase in smoking or alcohol and illicit drug use, and inability to maintain healthy eating habits. Direct effects may be mediated both via modification of the composition of the subgingival biofilm and/or exaggeration of the host inflammatory response.

In the first large-scale study aiming to explore the link between stress and periodontal status, 1426 adults in the US were evaluated (Genco *et al*. 1999). Subjects under high levels of financial stress and with poor coping responses were reported to have significantly more severe alveolar bone loss and attachment loss than those with low levels of stress within the same coping group, after adjustment for age, sex, and cigarette smoking. Many other studies in subjects with different types of psychosocial stress, such as academic, workplace or home related, and poor coping behaviors have provided similar results (Moss *et al*. 1996; Croucher *et al*. 1997; Deinzer *et al*. 1998, 1999; Mengel *et al*. 2002; Giannopoulou *et al*. 2003; Kamma *et al*. 2004; Ishisaka *et al*. 2007, 2008; Johannsen *et al*. 2007, 2010; Furugen *et al*. 2008; Islam *et al*. 2019; Wellappulli & Ekanayake 2019; Coelho *et al*. 2020). Of interest is the fact that adequate coping behaviors, as evidenced by high levels of problem-based coping, may reduce the stress-associated risk.

The variability associated with self-reported or clinical measures of stress and the use of different periodontal parameters as outcomes across studies investigating the link between stress and periodontitis make comparisons of such studies and the interpretation or generalizability of results difficult. However, it is fair to conclude that accumulating evidence to date supports that a positive association exists between psychosocial stress and poor periodontal status.

In response to stressful events, the hypothalamus–pituitary–adrenal axis is stimulated, leading eventually to increased production and secretion of cortisol, a hormone that can dysregulate the immune system. Further, the autonomic nervous system is stimulated, leading to secretion of catecholamine and substance P that can also impact the immune/inflammatory response and affect bacterial colonization and growth. Indeed, several stress markers have been reported in the blood, saliva, and GCF of periodontitis patients, have been shown to be positively associated with the extent and severity of periodontitis, and appear to mediate the detrimental effects of stress on the periodontal tissues (Axtelius *et al*. 1998; Hilgert *et al*. 2006; Johannsen *et al*. 2006; Ishisaka *et al*. 2007, 2008; Rai *et al*. 2011; Bakri *et al*. 2013; Mesa *et al*. 2014; Cakmak *et al*. 2016). A 2020 systematic review (Decker *et al*. 2020) concluded that a positive correlation exists between stress-related biomarkers and clinically measurable periodontal outcomes, but that whether periodontal disease severity follows or stems from stress levels is still unknown. Experimental studies using animal models and cell culture systems have provided further evidence for a link between stress and the severity of periodontal inflammation/destruction, mediated at least in part through proinflammatory molecules (Gomes *et al*. 2013; Lu *et al*. 2016).

The potential effect of stress on bacterial growth and virulence, although biologically plausible, is less studied and understood. A few studies have reported that stress hormones significantly increase the growth of periodontal pathogens (Roberts *et al*. 2002; Jentsch *et al*. 2013). More recently, *in vitro* studies revealed that cortisol directly increases the transcriptional activity of certain microorganisms and, more importantly, induces shifts in the gene expression profile of the oral microbiome, leading to a community response similar to the one observed *in vivo* in periodontitis (Duran-Pinedo *et al*. 2018). It appears that human hormones can be used by the microorganisms as signals to sense challenges in their environment and modify their profile to fit the new conditions better, but the exact mechanisms by which this crosstalk may occur remain unknown.

Unequivocally, stress is part of human life, is commonly present to varying degrees, and although it may have different consequences in different individuals, its potential effect on periodontal disease presentation and the response to therapy should not be underestimated. The dental team needs to remember that identification/understanding of potential stressors, periodontal disease prevention, meticulous monitoring, and careful maintenance strategies are all important in the management of patients under stress, especially those under chronic stress and those who appear to cope inadequately.

Introduction

Periodontitis is a chronic inflammatory disease of the supporting tissues of the teeth. In subjects susceptible to destructive periodontal disease, there is an imbalance between the host's immune system and the oral bacteria. In these individuals, certain microbial pathogens can proliferate and this leads to the induction of inflammatory reactions in the periodontal tissues. These inflammatory reactions slowly destroy the periodontium. If left untreated, the teeth lose their ligamentous support to the alveolar bone and alveolar bone is resorbed, with the consequence that the affected teeth become mobile and are eventually lost.

The oral cavity is one of the most complex ecosystems of the human body and contains myriads of different bacterial species. These species co-evolved with the human organism and the oral microbiota adapted to the environmental conditions provided by the host. The evolution of this ecosystem was subjected to strong selection pressures in a biologically active environment and it is considered to have largely developed for mutual benefit. The normal oral microbiota protects the host from extrinsic pathogens and the immune system controls bacterial proliferation to maintain homeostasis. The complex interplay between intrinsic and extrinsic factors, i.e. the immune system, pathogens in the oral cavity, and consequences of lifestyle factors is largely regulated by genes. Genes encode immune receptors as well as molecules, which influence receptor specificity and sensitivity to bacterial species. They regulate and influence the intensity of the inflammatory response by encoding and adapting the signal transduction pathways that mediate inflammatory signals, and allow a flexible response of the organism to external and internal stimuli.

The interplay of the microbiota, the immune system, and lifestyle habits (smoking, stress, diet, etc.) underlie the constant changes to which the host's

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

physiology must adapt to maintain health: the bacterial species change in number and proportions, and may also change in characteristics, for example by horizontal gene transfer or mutation. The host's immune system changes over time and can be positively or negatively influenced by lifestyle factors, other diseases, or age. Additionally, the genetic constitution of the host may change during life, for example by epigenetic effects or somatic mutations. As a result, periodontitis is considered to be a complex disease.

Genetic research can improve the understanding of the factors that mediate the immune response and explain why this response often greatly differs between individuals who have the same environmental context and comparable lifestyle habits. An important objective of genetic research is to identify the genes underlying disease and to estimate the genetic effects of potential risk variants within these loci. Genetic variation most often affects the regulatory regions of the genes, which lead to subtle changes in their expression. It is important to identify these genetic elements and to characterize their modes of action to understand how the expression of target genes in a tissue is regulated. This knowledge is indispensable for the understanding of the molecular etiology of periodontitis.

The genetic basis of periodontitis was demonstrated by formal genetic studies, and many genetic variants were analyzed for their involvement in disease physiology. However, within recent years, there have been enormous developments in the tools for genetic analysis and, for many common, complex human diseases, in knowledge of the relevant genetic factors. In this chapter, we will describe the underlying concepts and methodologic principles necessary for the understanding of the current genetic basis of periodontitis. We will comment on the limitations of and the progress achieved with recent studies, the different paths that are opening up in the efforts to identify the full spectrum of genetic risk factors for periodontitis, and how this newly acquired knowledge can be used to improve diagnosis and in an emerging personalized medical care. We will also illustrate the current state of genetic research in periodontitis and give an overview on the risk genes that are currently regarded as validated. Additionally, we will discuss the likely directions of genetic research in the field of periodontitis in the near future. We will provide an evaluation of the current predictive ability of genetic tests for monogenetic and complex diseases and give an outlook on future possibilities of personal genome testing.

Evidence for the role of genetics in periodontitis

Until the middle of the last century, it was thought that subjects with a longstanding history of poor oral hygiene would develop periodontitis. This was mainly because all forms of periodontitis were largely shown to be associated with bacterial pathogens and many studies demonstrated immunologic responses to these. In addition, the prevalence and proportions of periodontal pathogens were regarded to be higher in periodontitis patients compared with healthy controls (Griffen *et al*. 1998; van Winkelhoff *et al*. 2002). It remained an open discussion whether or not periodontitis was solely caused by one or more specific periodontal pathogens. If it were, periodontitis should develop in most infected subjects. However, periodontal pathogens show a relatively high prevalence in healthy subjects as well as in subjects with gingivitis or minor periodontitis. For example, in a study of 222 healthy children aged 0–18 years from Ohio, USA, pathogenic strains of *Aggregatibacter actinomycetemcomitans* and *Porphyromonas gingivalis* were detected in 48% and 36% of the children, respectively, and both species were detected in infants as young as 20 days old (Lamell *et al*. 2000). Interestingly, in a large group of subjects with gingivitis or minor periodontitis (mean age 52 years), *A. actinomycetemcomitans* and *P. gingivalis* were similarly prevalent (38% and 32%, respectively) (Wolff *et al*. 1993). In the last decades, epidemiologic studies as well as longitudinal clinical studies have shown that the presence of bacteria does not invariably induce periodontal attachment loss, but that host factors are also required for periodontitis. The concept of high-risk groups was added to the pathogenesis model and was one of the factors that developed the hypothesis that periodontitis may have a genetic background.

A study from 1966 was one of the earliest to deduce that certain individuals are more at risk for periodontitis than others (Trott & Cross 1966). This study investigated the principal reasons for tooth loss in over 1800 subjects. The study showed that in each age category, many teeth are lost due to periodontitis in relatively few patients. This phenomenon was confirmed in a 28-year longitudinal study of a dentate American population. It was found that 14.4% of this population who became edentulous accounted for 64% of all teeth lost in that period. Among those who lost teeth but remained partially dentate, 13.8% were responsible for 60.2% of all teeth lost in that group. Analysis showed that gingivitis was the strongest risk factor for tooth loss (Burt *et al*. 1990). The same phenomenon was found in two longitudinal studies, which evaluated the effect of periodontal therapy in periodontitis patients over more than 15 years (Hirschfeld & Wasserman 1978). These studies showed that 20% of the patient populations accounted for about 75% of all lost teeth.

The concept of high risk for the development of periodontitis was further confirmed in longitudinal studies investigating the natural history of periodontal disease. In a population in Sri Lanka without access to dental care and absence of oral hygiene, Löe *et al*. (1986) were able to identify three subpopulations: a group with no progression (11%), a group

with moderate progression (81%), and a group with rapid progression of periodontal breakdown (8%). In a more recent study, the initiation and progression of periodontal breakdown was studied in a remote village in West Java that was deprived of regular dental care (Van der Velden *et al*. 2006). The authors found that 20% of the subjects developed severe breakdown, whereas the remaining population developed minor-to-moderate breakdown, and suggested that not everybody is equally susceptible to periodontitis. This shaped the hypothesis that host susceptibility may have a genetic background: the antimicrobial response of the host is defined in part by genes and can vary across the population. Genetic variants in the genes which encode the pathways of the host's antibacterial response, but also in the bacterial factors that are targeted by the host's immune system, have the potential to deleteriously affect the interplay of the immune system, environment, and lifestyle factors. In some cases they can lead to disease development. Figure 12.1 illustrates this hypothesis and shows how an almost continual exposure to bacteria may or may not cause disease symptoms. It also shows how interventions may be effective before disease manifestation. The individual's immune response, which determines the extent of periodontal destruction, is additionally challenged by other internal and external factors, like systemic diseases (e.g. diabetes), smoking, stress, nutrition, and age (Kinane *et al*. 2006; Jauhiainen *et al*. 2020), which are again determined by the individual's genetic constitution. This interplay between the oral microbiota, internal and external factors which influence the immune system, and the host's general genetic constitution forms the individual susceptibility of a subject to periodontitis.

Heritability

Heritability measures the proportion of phenotypic variation that can be attributed to genetic variation. For example, members of a family may have a large variation of body weight that can be expressed by the body mass index (BMI). The observed variation can be due to different dietary habits among the family members. However, genetic factors can also influence the BMI independent of diet and can be

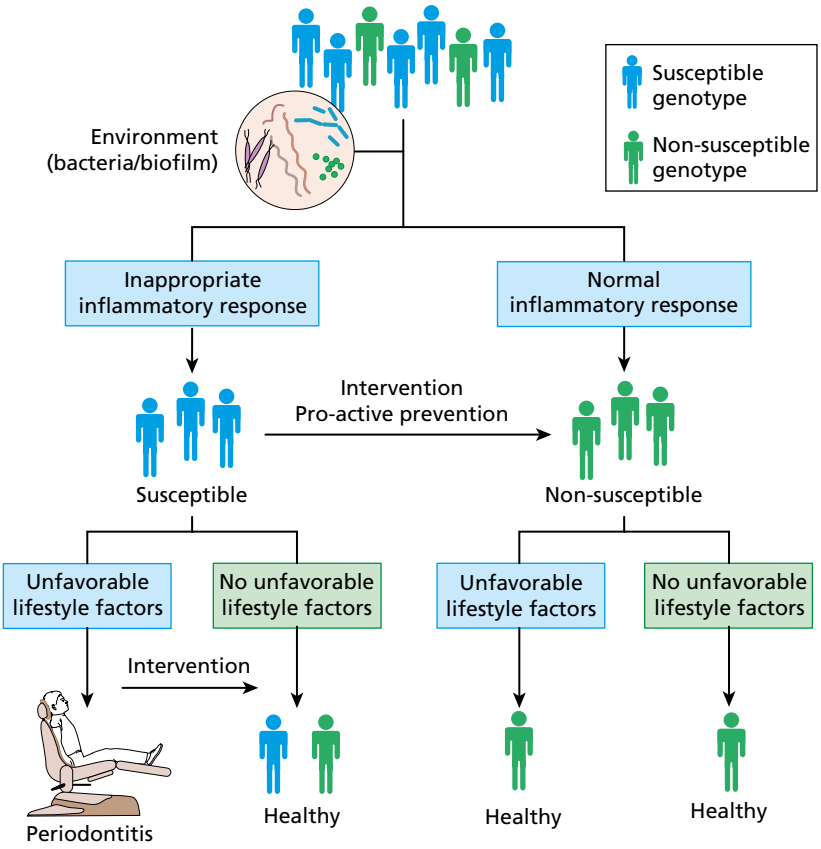

Fig. 12-1 Variations in the antimicrobial response of the host may be important features of the pathogenesis of periodontitis. In this model, the population, consisting of non-susceptible and susceptible hosts, is exposed to prevalent oral bacteria. Non-susceptible individuals with a normal, effective antibacterial response do not develop the disease, whereas susceptible individuals are at risk of developing the disease if key environmental factors are present. An understanding of the immune system alterations that make individuals susceptible may allow for interventions that aim to render the individual insensitive to the environmental stimuli that induce disease (proactive prevention), or that can alleviate or cure the disease after it has become manifest. This model suggests that it is critical to learn more about the factors that influence host–microbial homeostasis. However, it is possible that long-term effects of additive, deleterious lifestyle factors in conjunction with a compromised immune system at advanced age also lead to the manifestation of periodontitis independent of specific genetic risk factors. (Source: Adapted from Foxman & Iwasaki 2011. Reproduced with permission from John Wiley & Sons.)

shared between some of the related family members (Schousboe *et al*. 2003). Heritability measures the fraction of the phenotype variability that is due to genetic variation between the individuals of the sample. Heritability is also always specific to a particular population in particular surroundings. If, for example, a family shows uniformity in dietary habits, the heritability will be higher than if the family shows high variation in dietary habits. In the context of oral health, in a sample that shows uniformity in oral hygiene habits, the heritability will be higher compared with a sample that has strong variation in oral hygiene.

Heritability of periodontitis among young people

Siblings of young patients (e.g. 8–21 years of age) with periodontitis frequently also suffer from periodontitis. This observation was based on family studies as well as on reports of single cases. The largest family study included 227 young probands with periodontitis (Marazita *et al*. 1994). Of these probands, 104 had at least one first-degree relative who was clinically examined. Also, a segregation analysis was carried out on 100 families, which included 527 cases and healthy subjects. A segregation analysis is a method of formal genetic analysis employed to determine whether or not a phenotype is inherited. It tests whether the transmission pattern in human families over different generations is consistent with Mendelian conditions. This method allows the mode of inheritance to be determined, for example if the genetic factor has a dominant or a recessive effect on the phenotype. The authors concluded that the most likely mode of inheritance in the examined families was autosomal dominant (see Box 12-1), with a penetrance of the causative genetic factors of about 70%.

Familial segregation of cases indicates that genetic factors may be important in the susceptibility to periodontitis, but results from segregation analyses need to be interpreted with caution as they may also reflect exposure to common lifestyle factors like oral hygiene, diet, and smoking. Certain infectious agents may also cluster in families. Additionally, segregation studies with human families are hampered by various methodologic factors, which often are the lack of adequate statistical power due to small numbers of families, too small or incomplete families, and a high heterogeneity between families.

A preferred alternative method to determine the evidence for genetic factors in the familial aggregation is the study on monozygotic twins. Twins arise in two ways. The parallel fertilization of two ova by two different spermatozoa results in dizygotic (DZ) twins. These comparatively common cases have the same genetic relationship as siblings. However, infrequently after fertilization, the ovum divides in two, resulting in a pair of monozygotic (MZ) twins who are genetically identical. Severe, typically early-onset forms of periodontitis, sometimes with a molar/incisor phenotype, for which it is believed that genetic factors are particularly important in influencing disease susceptibility, have a comparatively low prevalence in the general population and it is very difficult to identify enough affected MZ twins to provide sufficient statistical power to test the concordance of this disease phenotype. Nevertheless, the most conclusive indication of whether or not the disease has a genetic cause is obtained by a comparison of the presence of the same disease phenotype in both members of a pair of twins. This is expressed by a comparison of the concordance rate of MZ and DZ twins. For example, twins are concordant when both have or both lack a given phenotype.

The degree of concordance for early-onset periodontitis was estimated by Corey *et al*. (1993). Information on periodontal disease was available for 4908 twin pairs. The mean age at diagnosis of periodontitis in these twins was 31 years. A total of 349 twins reported a history of periodontal disease in one or both pair members. Of these, 116 were MZ and 233 were DZ twins; 70 twins were concordant. The concordance rate for the history of periodontal disease in MZ and DZ twin pairs based on this study is given in Table 12-1. The proband-wise concordance rate showed more than a two-fold increased risk for early-onset periodontitis for the genetically identical MZ twins compared with the DZ twins. It also indicated that in a high proportion of cases factors other than genetic factors were important in triggering this disease phenotype. The mean age difference at diagnosis for the concordant MZ twin pairs was 1 year, while the corresponding difference in concordant DZ twin pairs was 5.4 years (information on age at diagnosis of periodontal disease was only available for both members in 34 of the 70 concordant twin pairs). This reduced mean difference of age at first diagnosis for the MZ twins may also point to an influence of heritable factors in periodontitis.

Heritability of periodontitis in adults

A few twin studies have assessed the heritability of a periodontal disease status in adults and almost all have reported a heritable component for periodontitis (Michalowicz *et al*. 1991, 2000; Corey *et al*. 1993; Michalowicz 1994). One of the first studies included 110 pairs of adult twins (mean age 40.3 years), including 63 MZ and 33 DZ twin pairs reared together, and 14 MZ twin pairs reared apart. The periodontal parameters probing depth, clinical attachment loss, gingivitis, and plaque were examined, and it was estimated that 38–82% of the variance in these measures could be attributed to genetic factors (Michalowicz *et al*. 1991). Another population-based twin study on 117 twin pairs (Michalowicz *et al*. 2000) assessed the heritability of the genetic and environmental variation in periodontitis and gingivitis. It showed that the investigated MZ twins (64 pairs) were more

Box 12-1 Human genes, genetic variation, and useful definitions.

Genes direct the production of proteins with the assistance of enzymes and messenger molecules. In humans, the genes are located on 23 pairs of chromosomes: 22 pairs of *autosomal* chromosomes (autosomes) and one pair of *sex chromosomes* (the gonosomes, XX for females and XY for males). From each pair, one chromosome is inherited from the father and one from the mother. The complete set of chromosomes is called the *genome*. Each chromosome contains a long duplex of deoxyribonucleic acid (DNA). DNA consists of sequences of nucleotides, which are chemically linked by a sugar–phosphate backbone. The nucleotides are the "building blocks" of the DNA and are made up of nitrogenous bases. Four nitrogenous bases exist: adenine (A), guanine (G), cytosine (C), and thymine (T).

In the chromosomes, DNA is arranged in a double helix: two polynucleotide chains are associated together by hydrogen bonding between the nitrogenous bases. The pairing of the two single-stranded nucleotide chains is complementary: G pairs only with C, and A pairs only with T; these are called base pairs (bp). The order of these four nucleotides determines the meaning of the information encoded in that part of the DNA molecule, just as the order of letters determines the meaning of a word. Virtually every single cell in the body contains a complete copy of the approximately 3 milliard (US; English 3 billion) DNA base pairs that make up the genome (National Human Genome Research Institute [NHGRI], National Institutes of Health [NIH], www.genome.gov). The genetic code is read in groups of three nucleotides; each trinucleotide sequence (triplet) is called a *codon*, which encodes a specific amino acid.

A gene usually consists of various parts. The *promoter region* is a specific sequence of nucleotides upstream of the coding region that is essential for the regulation and initiation of the transcription of the coding region. *Introns* are sequences of non-protein coding nucleotides and surround the *exons*, which code for the sequence of amino acids of a protein (Fig. 12-2). The collection of known exons in the genome is called the *exome*.

Genes can be transcribed in alternative ways, such that each of the estimated 20 000 protein coding genes in the human genome codes for an average of four protein variants (ENCODE-Project-Consortium 2012). Proteins make up body structures like organs and tissues, carry signals between cells, and are the enzymes that control biochemical reactions. If a cell's DNA is mutated, an abnormal protein or abnormal protein quantities may be produced, which can disrupt the body's usual processes and lead to a disease.

For translating the information contained in the DNA into cellular function, the DNA must be transcribed into corresponding molecules of ribonucleic acid (RNA), referred to as transcripts. There are various kinds of RNA transcripts. The type that carries the information that codes the amino acid sequence of the proteins is called messenger RNA (mRNA) and is transcribed from the exons. Non-protein coding RNAs, such as *microRNAs* or long non-coding RNAs (ncRNA), largely function in the regulation of gene expression. The collection of all transcripts present in a given cell is called the *transciptome*.

Sequencing technologies determine the exact order of the nucleotides in a strand of DNA. After the finished high-quality version of the sequences of all human chromosomes was published in 2006 by the international *Human Genome Project*, the 1000 Genomes Project set out to provide a comprehensive description of common human genetic variation. By sequencing the genomes of 2504 individuals from 26 human populations, in total over 88 million variants were identified in humans (84.7 million *single nucleotide polymorphisms (SNPs)*, 3.6 million short insertions/deletions (indels), and 60 000 structural variants) (1000 Genomes Project *et al*. 2015) (Fig.12.3). The majority of these variants are rare, and only approximately 8 million have a frequency >5%. Nevertheless, the majority of variants observed in a single genome are common: just 40 000 to 200 000 of the variants in a typical genome (1–4%) have a frequency <0.5%. It was found that a typical genome contained >100 sites with protein truncating variants, >10 000 sites with peptide sequence-altering variants, about 2000 variants per genome associated with complex traits through genome-wide association studies (GWAS), and >20 variants per genome implicated in rare disease.

The alternative variants at a specific chromosomal region (*locus*) of the DNA are called *alleles*, and the collection of alleles in an individual's chromosomes is termed the *genotype*. Two or more alleles for a given locus may exist in nature and occur with different frequencies. The *minor allele frequency* (MAF) is the proportion of the least frequent allele in a population and can range from 0% to 50%. Variants with a MAF of >5% are termed *common variants*. If the MAF of a variant ranges between 1% and 5% it is called a *rare variant*. Genetic variants with frequencies of <1% are called *mutations*.

A mutation or a genetic variant may have no effects or may have moderate to strong effects. For example, if a mutation occurs within the coding region of a gene, it may result in an amino acid substitution and therefore an altered protein structure, which may affect the protein's function (non-synonymous SNP). Or, when such a mutation occurs in a regulatory region of a gene (e.g. the promoter or an enhancer element), it may alter

(*Continued*)

the gene's expression level. Accordingly, genotypic differences among individuals can contribute to phenotypic variation, termed *genetic variance*. The strength with which a genetic variant affects the susceptibility to a disease is defined as the *genotype relative risk* (GRR), the ratio of the risk of disease between individuals with and without the genotype. A ratio of 1.1 equates to a 10% increase in risk and is often expressed as the odds ratio (OR). However, carriership of a genetic variant or mutation does not inevitably lead to disease, as only a proportion of individuals with a mutation or risk variant will develop the disease. This proportion is described as the *penetrance*. The severity of the disease in individuals who have the risk variant and the disease is described as the *expressivity* of the variant.

Despite the existence of many genetic variants, only a fraction of the genotypic differences contributes to phenotypic variation. Where in the chromosomes the causative variants are located and how they interact is mostly unknown. Testing all of the several millions of common and rare SNPs in a person's chromosomes would be extremely expensive. Variants that are near each other tend to be inherited together; for example, individuals who have an A rather than a G at a particular location in the chromosome can have identical genetic variants at other SNPs in the chromosomal region surrounding the A. This non-random association between alleles at different loci is termed *linkage disequilibrium* (LD) and the regions of linked variants are known as *haplotypes* (www.hapmap.ncbi.nlm.nih.gov). Determining the identity of a common SNP on a haplotype, the *tag SNP*, uniquely identifies all other linked variants on the same haplotype. Identifying an individual's tag SNPs, a process known as *genotyping*, enables the haplotypes in the chromosomes to be identified. If patients with the same disease tend to share a particular haplotype, variants contributing to the disease might be somewhere within or near that haplotype. The number of tag SNPs that contain most of the information about the patterns of genetic variation of a genome is estimated to be 300 000–600 000, which is far fewer than 10 million common SNPs, and much less expensive to genotype. Thus, the information from the HapMap has been instrumental in mapping variants contributing to the disease.

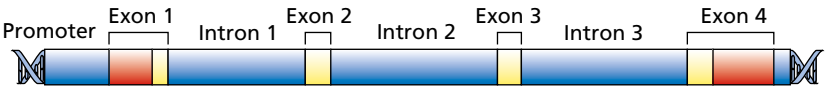

Fig 12-2 Structure of a gene. This gene has four exons (yellow bands), but in reality genes can have many more exons. The first exon is preceded by an untranslated region, the 5′-UTR (left red band), and the last exon is followed by another untranslated region, the 3′-UTR (right red band).

	n	Concordance rate
Monozygotic	116	0.38
Dizygotic	233	0.16

A twin pair was considered to be concordant if information was provided by one or both pair members and indicated that both pair members were affected. (Source: Data from Corey *et al*. 1993. Reproduced with permission from John Wiley & Sons.).

similar than the DZ twins (53 pairs) for attachment loss and probing depth, and showed statistically significant genetic variance for the severity and extent of the disease. The heritability was estimated to be ~50%, which was unaltered following co-variate adjustments for smoking, dental hygiene, age, and gender (Table 12-2). It is noteworthy that this study showed no evidence of heritability for gingivitis and attributed this disease phenotype entirely to disease-related behaviors such as oral hygiene and smoking.

Table 12-2 Heritability estimates for clinical parameters of periodontitis.

	Age and gender adjusted	Fully adjusted[c]
Attachment loss[a] (%)	52	50
Deepened probing depth[b] (%)	50	50
Gingival index (%)	52	0

[a] Mean percentage of teeth with attachment loss of ≥3 mm.
[b] Mean percentage of teeth with probing depth of ≥4 mm.
[c] Adjustments for age, gender, and oral hygiene as described in Michalowicz *et al*. (2000).(Source: Adapted from Michalowicz *et al*. (2000). Reproduced with permission from John Wiley & Sons.)

A recent study systematically reviewed the literature to refine the heritability of gingivitis and

Box 12-2 Genetic association studies.

Studies designed to localize chromosomal regions (loci) that contribute to a disease susceptibility analyze the allele frequencies of variants in a study population and test their co-occurrence with the disease, in comparison with a study population not having the disease (control group). The intention of such *genetic association studies* (or association mapping) is to determine whether an individual carrying one or two copies of a specific allele is at increased risk of developing a disease. The principle of the commonly used case–control association study is illustrated in Fig. 12-4. This study is a powerful method to detect associations of certain alleles with a disease phenotype, and it has been employed for the identification of the genetic risk factors in periodontitis.

An important prerequisite of case–control studies is to ensure a good match between the genetic background of cases and controls, so that any genetic difference between them is related to the disease under study and not to biased sampling. Therefore, cases and controls should have similar ethnic descent. A further prerequisite is a *case selection strategy* that is designed to enrich susceptibility alleles of a specific disease. This includes efforts to minimize phenotypic heterogeneity by stringent diagnosis criteria, and should focus on extreme cases, defined, for example, by a particularly early age of disease onset or severe disease or both.

In most circumstances, and particularly when the total sample size has financial or operational constraints, efforts to enrich case selection with the most severe phenotypes are very likely to improve the *statistical power* of a study due to an increase in the frequency of the risk genotype (McCarthy *et al*. 2008). Related to this and compulsory for the identification of a true genetic risk factor, are case–control analysis populations, which are large enough to provide the necessary statistical power. The statistical power increases with sample size and correlates with allele frequency and the genetic effect of the respective variant (Kathiresan *et al*. 2004). This is why common variants or variants with a high odds ratio (OR) are more likely to be detected in genome-wide association studies (GWAS) than rare variants or variants with a small effect (Fig. 12-5). However, most disease-associated variants increase the susceptibility rather modestly and to identify a common variant with a modest genetic effect, often >1000 well-defined cases and at least the same number of controls are necessary to reach a sufficient statistical power.

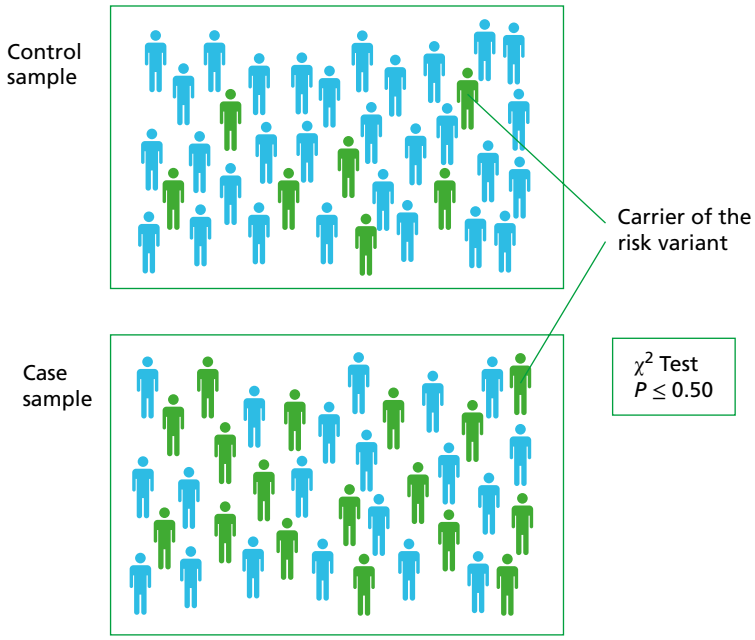

Fig 12-4 Case–control studies compare the frequency of single nucleotide polymorphism (SNP) alleles in two well-defined groups of non-related individuals: controls, who are either known to be unaffected or who have been randomly selected from the population, and cases who have been diagnosed with the disease under study. An increased frequency of an SNP allele or genotype in cases compared with controls indicates that the presence of the SNP allele may increase the disease risk. The potential association is a mere statistical association and always requires a replication in an independent sample. Significance can be assessed with various methods, but most often the χ^2 statistic is used in contingency table analyses, which provide an assessment of the departure from equal SNP allele frequencies in cases and controls (*P* value). Association studies can also be used to estimate the disease risk conferred by the SNP allele, which is expressed by the odds ratio (OR). The OR is the ratio of allele carriers to non-carriers in cases compared with that in controls, which gives the increase in disease risk for carriers compared to non-carriers (Source: Data from Lewis 2002. Reproduced with permission from John Wiley & Sons.).

(*Continued*)

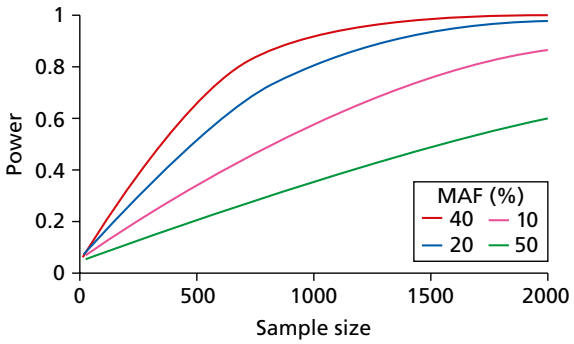

Fig 12-5 Statistical power in relation to the sample size, allele frequency, and odds ratio (OR). To identify a genetic risk variant with a minor allele frequency (MAF) of, for example, 20% in the general population, approximately 1000 cases and 2000 controls are required to achieve the necessary statistical power of 0.8. The statistical power was calculated as described by Dupont and Plummer (1998) for an average OR of 1.3, and twice as many controls as cases were considered. A power of 0.8 is regarded as statistically significant. (Source: Data from Dupont & Plummer 1998. Reproduced with permission from John Wiley & Sons.)

The findings of case–control studies are mere statistical associations, which describe differences of allele frequencies between two independent samples; importantly, they should not be regarded as causative associations. By a preassigned significance threshold of 0.05, one in every 20 allelic variants tested will pass the commonly preassigned significance threshold of a P value of <0.05 by chance alone. Allele frequencies between independently sampled populations are also liable to stochastic fluctuations (random allele drifts across and between populations, without selection pressure). For these reasons, *replication* of the initial findings is the gold standard for genetic association studies. Notably, the replication needs to be performed in an independent case–control sample of the same phenotype (diagnosis criteria) and the same ethnic background. A repetition of the study with samples from different ethnic groups, with different diagnostic criteria or with independent cases but the same controls, cannot be considered as a replication and does not test the initial finding properly. Only after confirmation by replication is it useful to validate the initial finding of an association study in different subphenotypes or in different ethnicities.

As genes are usually patchworks of different haplotypes, being mostly in poor-to-moderate linkage disequilibrium (LD), the information on the potential association of one haplotype provides little to no information on the association or non-association with another haplotype within that gene (Slatkin 2008). Thus, association studies should capture the complete haplotype information of the gene of interest before drawing an unambiguous conclusion of the association findings for that gene, positive or negative (Slatkin 2008).

Candidate gene association studies

Until the early years of this millennium, investigations of selected candidate genes based on literature reviews and perceived pathophysiologic pathways was the most important strategy for the identification of risk genes that contribute to a disease. A major disadvantage of candidate gene studies is the requirement for an *a priori* hypothesis on the involvement of the gene in disease risk and on the presence of a functional variant within this particular gene (Wilkening *et al*. 2009). Essentially, there are two different selection strategies for a candidate gene, which depend on the question addressed. When it is of interest to ask whether or not specific loci within a regulatory signaling pathway are involved in the increase of the genetic risk of periodontitis, or there is functional evidence of the effect of a variant from the study of other diseases, it is reasonable to select genes from this pathway or the specific variants. This approach will determine whether or not the selected genes carry genetic variants which increase the risk of the disease.

Another question which addresses the classical objective of molecular genetics is more difficult to answer: which specific genes and pathways influence the disease risk? As the formulation of the hypothesis for the selection of the candidate gene is entirely dependent on the current knowledge of the molecular biologic mechanisms of the disease, hundreds of loci and/or genes which can have an influence on the disease will not be selected because their function might be unknown or their function lies within pathways that have not yet been implicated in the disease. As the knowledge on these genes is very incomplete, selection of candidate genes is necessarily arbitrary. Accordingly, most associations observed in these studies cannot be successfully replicated. Obviously, this does not rule out the finding of a true positive association if the correct candidate gene was selected *a priori*, but with this approach it is not possible to identify hitherto unknown genes that are disease relevant.

Genome-wide association studies

In contrast, for 10–15 years, GWAS has provided an unbiased and hypothesis-free approach. A large number of SNPs (currently 500 000 to >1 000 000 markers) distributed across the whole genome serve as proxies for multiple other SNPs in LD. Nevertheless, genome-wide testing of polymorphisms also entails problems. First, if by chance alone, one in every 20 markers tested gives a P value of <0.05, the probability of statistical errors rises with increasing number of single SNP association tests, so-called type 1 errors (false-positive association findings). If 500 000 markers or more are independently tested, the P value obtained from the χ^2 statistics must be corrected for multiple testing. This is addressed by setting a genome-wide significance threshold by correcting

for the number of tests performed (Balding 2006). The current standard for declaring statistical significance at genome-wide level for common variants is a combined *P* value (including "initial discovery" GWAS and replication cohorts) of $<5 \times 10^{-8}$ (Manolio 2010). Because rare variants are more numerous and less correlated with each other than common variants, this threshold is not enough to declare significance in association studies that target rare variants. Thus, rare variant associations suffer from an increased multiple testing burden and a decrease in statistical power owing to the rarity of individuals carrying these variant alleles. However, the sample sizes that are required to achieve such significance thresholds may be unrealistic for the study of less common diseases. The resulting lack of statistical power is the major factor that leads to type 1 and type 2 errors (false positive and false negatives), that is, the failure to detect a true association.

periodontitis by including information from >50 000 human subjects (Nibali *et al*. 2019). The heritability of periodontitis was estimated at 0.38 in twin studies and 0.15 in other family studies, and increased with disease severity and smoking habits. No heritability was found for clinically measured gingivitis. This systematic review confirmed that a substantial proportion of the phenotypic variance of periodontitis in the population is due to genetic susceptibility and that genetic factors contribute more to disease risk for severe early-onset traits and younger individuals.

Gene mutation of major effect on human disease and its association with periodontitis

Complex diseases such as periodontitis are caused by an intricate interplay of many genetic and non-genetic factors. In contrast, monogenic diseases such as Huntington's disease and cystic fibrosis are fully heritable and people who carry a causative allele in a single gene specific for the monogenic disease will inevitably become affected, unless treated. The Papillon–Lefèvre syndrome (PLS) is relatively unique in the group of monogenic diseases, in that severe fast progressive periodontitis forms a significant component of the phenotype and is a defining clinical feature (Toomes *et al*. 1999). Both the deciduous and permanent dentitions are affected, resulting in prepubertal periodontitis and premature tooth loss. Additionally, palmoplantar keratosis, varying from mild psoriasiform scaly skin to overt hyperkeratosis, typically develops within the first 3 years of life. Keratosis also affects other sites such as the elbows and knees. Most PLS patients display both periodontitis and hyperkeratosis. Some patients have only one or the other, and periodontitis is rarely mild or of late onset.

The causative mutations of PLS are located in the *CTSC* (cathepsin C) gene on chromosome 11; over 50 mutations in the gene are now recognized. The protein encoded by this gene is cathepsin C, a lysosomal cysteine proteinase, that appears to be a central coordinator for activation of various serine proteinases. It is expressed at high levels in polymorphonuclear leukocytes (PMNs) and alveolar macrophages and their precursors (Rao *et al*. 1997). It was proposed that minimal cathepsin C activity (~13%) was necessary to prevent the clinical features of PLS, but the exact mechanism by which an altered function of cathepsin C plays a role in the pathogenesis of PLS-associated prepubertal periodontitis is unknown (Hewitt *et al*. 2004). It is speculated that cathepsin C is essential for activation of many serine proteinases in immune-inflammatory cells, including cathepsin G, neutrophil serine proteases, proteinase 3, and elastase (Dalgic *et al*. 2011). The inactive forms of these neutrophil serine proteases result in dysregulation of the host immune response. Increased susceptibility to infections has been attributed to impaired neutrophil and T- and B-cell functions (Ryu *et al*. 2005). The impaired localized PMN response in inflamed periodontal tissues leads to periodontitis, most likely due to improper phagocytosis and digestion of Gram-negative periodontal pathogens. Likewise, the mutation in the *CTSC* gene seems to result in the incapacity of PMNs to kill *A. actinomycetemcomitans* in an anaerobic environment (de Haar *et al*. 2006).

Identification of genetic risk factors of periodontitis

To reiterate the important aspects of the pathophysiology of periodontitis, we summarize here that, in contrast to monogenic diseases like PLS, periodontitis is a complex disease that is caused by a combination of genetic, environmental, and lifestyle factors. Thus, genetic factors represent only part of the risk associated with complex disease phenotypes and a genetic predisposition means that an individual has a genetic susceptibility to develop a certain disease but it does not mean that a person harboring such a genetic tendency is destined to develop the disease. Instead, the development of the disease phenotype largely depends on a person's environment and lifestyle. However, some individuals develop periodontitis at a young age. In such cases, environment and lifestyle factors only act in the short term and they are often shared with individuals who do not develop the disease. Thus, an early age of disease onset often indicates a genetic predisposition. This does not imply carriage of a single genetic variant with a strong effect; rather, patients with an early onset often carry specific combinations of various

risk alleles. In this regard, the different phenotypes of periodontitis can be considered as different parts of a large range of similar conditions, which can be attributed to the effects of different combinations of genetic risk loci that form the genetic constitution. Furthermore, different disease manifestations are not confined entities but share risk alleles and covariates. The central problem in efforts to elucidate the genetic susceptibility factors of a complex disease is that millions of genetic variants exist in the genome with most having no effects, while only a very small fraction contributes to the disease risk with minute effects of each effect allele. However, these add in specific individual combinations that make up the personal risk genotype. Because no hypotheses can be developed that allow a direct selection of the effect alleles, since in most cases the causal variants do not change the amino acid of a protein, essentially all variants of the human genome need to be tested for their role in the disease susceptibility.

About a decade ago, technical advances allowed the hypothesis-free approach of simultaneously testing millions of SNPs across the genome of a single patient. These studies are called genome-wide association studies (GWAS, see Box 12-2). In this type of study, it can be determined which alleles are more frequent in a sample with disease or the trait of interest compared with a control sample. An increased frequency of a specific allele points to a genetic location of the variant that likely has a role in the trait or disease. This new era of genetic research largely began with the milestone publication of the Wellcome Trust Case Control Consortium (2007). Because of the small effects of the risk alleles, large case–control populations are indispensable (see Box 12-2) (Visscher *et al*. 2017). Several thousands of well-defined cases and many more controls are needed to detect a genetic variant with a small effect that is observed commonly for complex diseases. This realization eventually resulted in the formation of extensive international consortia for the recruitment of the appropriate case and control numbers, which eventually included over tens of thousands of cases and controls.

In recent years, all common genetic risk factors for any complex human disease like type 2 diabetes, coronary artery disease, or rheumatoid arthritis have been unveiled. Table 12-3 gives a snapshot of the recent findings in terms of the numbers of identified genetic risk loci of major complex inflammatory diseases, some of which are co-morbidities of periodontitis, and the numbers of cases and controls employed in the largest of these studies. Most of the identified genes were initially not thought of as likely candidate genes.

For periodontitis, despite >100 candidate-gene association studies that have been performed, evidence that is based on statistically solid associations is scarce. Difficulties in generating large case samples of individuals with a homogenous ethnic background have been the major cause for the slow progress in the discovery of genetic risk loci of periodontitis compared with other complex human diseases. Consequently, few genes can currently be considered as true genetic susceptibility factors for periodontitis.

The reader who is interested in lists of genetic variants that had been proposed to be associated with periodontitis can find compilations in Schaefer *et al*. (2013) and da Silva *et al*. (2017). Many variants had been implicated as potential risk factors, but few, if any, had been established definitively. Several factors undermined the validity of previous published reports, and included inappropriately small sample sizes, multiple subgroup comparisons, and publication bias. Publication bias, a crucial stratification factor in the short-term advancement of research, is explained by the fact that positive results are much easier published than negative findings, which results in biased publications and accumulation of false positive findings in the scientific literature in contrast to publications of true negative findings. This will result in false positive results from meta-analyses of publications but not from meta-analyses that used unbiased data such as GWAS-meta-analyses.

In the following discussion, instead of compiling a long list of studies with often ambiguous results, we

Table 12-3 Number of identified risk gene variants for a selection of inflammatory diseases. The total population size included in the explorative study and the replication is given for the largest of the current studies.

Disease	Total number of associations ($P < 10^{-5}$)	Population size of largest study (cases and controls)
Coronary artery disease	928	304 591 (Klarin *et al*. 2017)
Type 2 diabetes mellitus	2244	659 316 (Xue *et al*. 2018)
Rheumatoid arthritis	1391	105 000 (Laufer *et al*. 2019)
Systemic lupus erythematosus	834	35 844 (Morris *et al*. 2016)
Crohn's disease	893	77 064 (Jostins *et al*. 2012)

(Source: Data from the NHGRI-EBI Catalog of published genome-wide association studies, 03/2020. Reproduced with permission from John Wiley & Sons.)

focus on those loci that have been identified in GWAS that fulfill at least one of the following criteria:

- genome-wide significance of association with at least a P value of 5.5×10^{-8} (as a result of the combined discovery GWAS and the replication cohort). This is the gold-standard to declare significance in GWAS.
- independent replication in samples of the same disease phenotype with sufficient statistical power.
- independent validation of the associations in samples with sufficient statistical power of different disease manifestations such as the fast-progressive periodontitis phenotype often seen in teenagers and young adults, and the moderate progressive periodontitis form mainly seen in middle-aged and older adults.
- independent identification through different systematic approaches.

For future perspectives on the discovery of the missing heritability of genetic susceptibility factors the reader is referred to Box 12-3.

Sialic acid binding IG like lectin 5 (*SIGLEC5*) and other potential variants

A GWAS on periodontitis with evidence of fast progress (1116 cases and 7654 controls from Germany, the Netherlands, and Turkey) identified associations with the gene *SIGLEC5* on chromosome 19;

Box 12-3 Future perspectives.

When GWAS began a decade ago, it was widely believed that complex disease is largely attributable to a moderate number of common variants, each of which explains several percent of the risk in a population (Pritchard & Cox 2002). In contrast to this, GWAS identified an unexpectedly large number of common variants that contribute to disease risk (Table 12-3). This means that each individual will carry a number of alleles that increase and a number of alleles that decrease a disease risk. There are so many possible combinations of these sets of alleles that each individual is likely to have a unique combination. In GWAS that are designed to detect individual associated loci, the effect size of each allele is measured across the context of an averaged background. Thus, the effect size for the individual variant is generally found to be small (Visscher *et al*. 2017). However, although the number of associations increased to hundreds for most diseases (Table 12-3), they only explain a small proportion of the disease heritability. Where the missing heritability is likely to lie is currently debated. One model argues that a very large number of the genes contribute indirectly to a disease and show relatively small effect sizes and these genes are classified as peripheral and are thought to show a large amount of pleiotropy. In this model, additional genetic variants with relatively large effects sizes also exist and play a more direct role in a disease. The genes that harbor those less common disease-specific variants are classified "core" genes (Boyle *et al*. 2017). However, this intuitive concept of only a few "core" genes with higher effects, that would also represent good diagnostic and therapeutic targets, is discussed critically (Wray *et al*. 2018). First, common diseases are actually uncommon in a population, that is. most people are healthy. This indicates an inherent robustness in the biological system, which is why an etiology of many core genes should be assumed. This implies an indistinguishability between peripheral and core genes. Accordingly, large exome and genome sequencing studies showed that rare coding-region variants at known risk loci of diseases have a negligible role in susceptibility (Hunt *et al*. 2013; Genovese *et al*. 2016), or they failed to identify rare variants that could explain the missing heritability for common diseases (Fuchsberger *et al*. 2016; Genovese *et al*. 2016). Secondly, a disease that impacts only a small fraction of the population with a genetic architecture of many risk loci with similar effect sizes can be explained by a high non-linear relationship between probability of a disease and burden of risk alleles. This implies that polygenic disease is non-additive on the disease scale but rather caused by interacting effects of the genetic variants.

However, it is likely that different diseases have different genetic architectures – the joint distributions of effect size and allele frequency at the risk loci – and contribute in various degrees to different diseases. The debate on the contribution of genetic variation to disease over the coming years will center on how variants interact. A straightforward hypothesis states that common variation influences the expression and activity of genes in molecular pathways, establishing the background susceptibility to the disease that is then further modified by other variants (Fig. 12.6). Figure 12.6 illustrates gene × gene interaction under the assumption that disease is generally a threshold-dependent response that is superimposed on a continuous physiologic characteristic.

As only a proportion of the genetically predisposed and/or pathogen-exposed individuals develop a disease, simple genetic explanations for individual susceptibility to chronic inflammatory diseases such as periodontitis have not been forthcoming. The challenge for future research will be, apart from identifying as many susceptibility factors as possible, to discern the relevant patterns within the generated data, in other words to model the effects of SNP–SNP interactions (Renz *et al*. 2011).

(*Continued*)

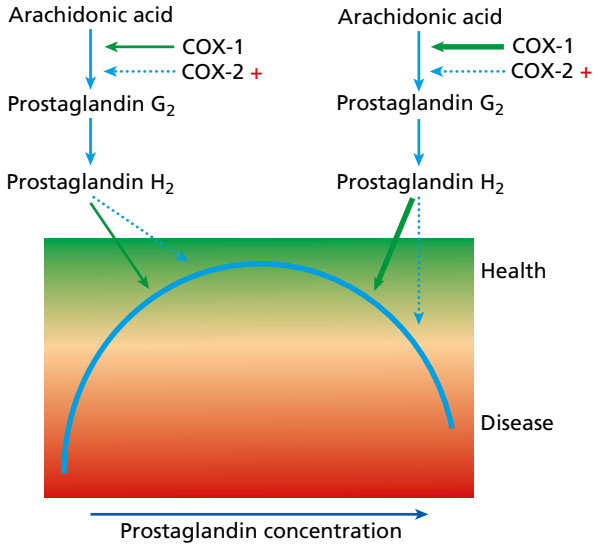

Fig 12-6 It is hypothesized that common variants influence the expression and activity of genes in pathways establishing the background susceptibility to disease that is then further modified by less common variants with larger effects. Prostaglandins are produced by a cascade of biochemical reactions following the sequential oxidation of arachidonic acid by the cyclooxygenases COX-1 and COX-2 and terminal prostaglandin synthases. Whereas COX-1 is responsible for the baseline levels of prostaglandins, COX-2 produces prostaglandins by specific stimulation in scenarios of periodontal inflammation. In this fictitious example, the half circle represents a range of prostaglandin concentrations in the lesion of a given population. The prostaglandin concentration is influenced by the interplay of the individual genetic constitutions, and the individual physiologic and environmental states. Prostaglandin concentrations at the low and high ends are associated with disease, while an intermediate concentration is physiologic and compatible with health. In this hypothetical illustration, genetic variation somewhere within the prostaglandin synthesis pathway results in some individuals having lower prostaglandin levels (left, normal COX-1 activity, indicated by the green horizontal arrow from COX-1) than others (right, genetic variation in COX-1 that establishes the background susceptibility to disease; indicated by the thick green horizontal arrow from COX-1). The variation in individuals with a background susceptibility is still within the healthy range. The effect of an additional variant that increases COX-2 synthesis (indicated by the "+" sign and blue dashed arrows) upon inflammatory stimulation is conditional on this liability, pushing those with a high concentration of prostaglandin that is genetically determined by the background susceptibility (those on the right) beyond the disease threshold and towards the development of periodontitis (into the red danger zone), whereas those with a low concentration of prostaglandin on the left can accommodate the genetic variation and remain in the green safe zone. (Source: Adapted from Gibson 2012. Reproduced with permission from John Wiley & Sons.)

this association was validated in a cohort of patients with less fast progress, consisting of 2211 cases of periodontitis and 1817 controls (Munz *et al*. 2017). A GWAS meta-analysis employing 17353 cases with moderate progressing periodontitis and 28210 controls, replicated the association of *SIGLEC5* variants with periodontitis (Shungin *et al*. 2019). *SIGLEC5* is a member of the human CD33-related siglecs and is broadly expressed in various myeloid cells of the innate immune system and in B-cells. It is classified as an inhibitory receptor with a function in maintaining leukocytes in the quiescent state until activation is triggered via appropriate receptors. Accordingly, *SIGLEC5* seems to modulate the activation of myeloid cells to prevent inappropriate reactivity against self-tissues, which is important during wound healing, for example. The ability to distinguish foreign pathogens from self and to make an appropriate response is also essential to avoid bystander damage to host cells.

Another large GWAS on periodontitis was performed with genotypes from the Hispanic Community Health Study/Study of Latinos that included 10935 participants (Sanders *et al*. 2016). As the most significant finding, an association of a rare variant at the gene *TSNAX-DISC1* on chromosome 1 was reported (SNP rs149133391, minor allele [C] frequency = 0.01%) to pass the genome-wide significance threshold ($P = 5 \times 10^{-8}$) with $P = 7.9 \times 10^{-9}$. However, owing to the rarity of individuals carrying these variant alleles, and because rare variants are more numerous and less correlated with each other than common variants, rare variant associations suffer from an increased multiple testing burden and a decrease in statistical power. Thus, a $P = 5 \times 10^{-8}$ threshold is not enough to declare significance in association studies that target rare variants (Auer & Lettre 2015). Therefore, this association should be regarded with caution.

No further associations that met the genome-wide significance thresholds for common or rare alleles were directly identified in other GWAS in studies including patients with the slow or moderate progressing rate of the disease. On the one hand it is discussed that these unremarkable results are reflections of an underlying trait heterogeneity of periodontitis. However, on the other hand, the non-findings of these studies are more likely caused by

the small sample sizes that were employed in most GWAS on periodontitis. Complex diseases with an adult onset and moderate progression usually have a large contribution of additive effects of non-genetic factors, for example for periodontitis this is smoking, oral hygiene, nutrition, stress, and the general decline of the immune system during ageing. The effects of simple genetic variants are weak. Consequently, increased sample sizes are required in GWAS that focus on a complex, moderate progressive, and adult-onset disease phenotype.

Defensin alpha-1 and -3 (*DEFA1A3*)

In the GWAS of 2017, in addition to the discovery of *SIGLEC5* as a risk gene for periodontitis, associations for periodontitis with the *DEFA1A3* gene at a genome-wide significance level were also identified (Munz *et al*. 2017). The association located at the intergenic region that separates the antimicrobial peptides *DEFA1* and *-4*. These genes belong to the family of alpha defensins that cluster on chromosome 8 and are believed to play a role in phagocyte-mediated host defense against bacteria, fungi, and viruses. The genes *DEFA1* and *DEFA3* are highly copy variable and differ only by a single base substitution in the coding sequence. They seem to be interchangeable occupants of a 19-kb-long copy-variable repeat unit, with both *DEFA1* and *DEFA3* gene numbers showing variation (Khan *et al*. 2013). For this reason, the composite designation *DEFA1A3* was suggested (Aldred *et al*. 2005).

CDKN2B antisense RNA 1 (*CDKN2B-AS1*)

CDKN2B-AS1 (also known as *ANRIL*) was identified by GWAS as the first genetic risk factor for myocardial infarction (Wellcome Trust Case Control Consortium 2007). Strong evidence of association between the presence of coronary artery disease (CAD) and periodontitis was derived from multiple randomized clinical trials, demonstrating that the association between both diseases is independent of smoking, which is the shared risk factor (Lockhart *et al*. 2012). In this context, *CDKN2B-AS1* was selected as a candidate gene for periodontitis in the investigation of a putative shared genetic basis for coronary artery disease and periodontitis. Early-onset forms (<35 years of age at first diagnosis) were chosen because of the higher heritability and to ensure that shared covariates of periodontitis and CAD, such as smoking, type 2 diabetes mellitus, and age contribute less to the development of the disease. *CDKN2B-AS1* was the first published genetic risk factor for these early-onset forms of periodontitis (Schaefer *et al*. 2011). This finding was independently replicated (Ernst *et al*. 2010; Munz *et al*. 2018). *CDKN2B-AS1* is associated with highly severe early-onset periodontitis but not with more moderate late onset forms. Because of this, it has not yet reached genome-wide significance because the analyses samples were too small to reach the very stringent threshold of genome-wide significance of $P < 5\times 10^{-8}$). However, because of the repeated replication of associations of the same variants, it is considered as a true genetic risk factor of severe early-onset periodontitis.

Miscellaneous genetic associations with periodontitis

The largest meta-analysis that combined genotype data from various GWAS (Divaris *et al*. 2013; Teumer *et al*. 2013; Munz *et al*. 2017) employing a total of 5095 periodontitis cases and 9908 controls of North-West European descent, additionally identified an association of genome-wide significance with the SNP rs729876 ($P = 2.1 \times 10^{-8}$). The variant is located within the intronic region of the long intergenic noncoding RNA (lincRNA) LOC107984137, the function of which is unknown. Currently, it is not clear if this SNP does affect the function of this lincRNA and/or of other genes. Experimental work suggests that it is linked to the function of RUNX1 (runt-related transcript factor 1) (Huang *et al*. 2004). RUNX1 plays a role in hematopoiesis and bone formation (Ono *et al*. 2007).

Epigenetic signatures

The strategies described previously for identifying genetic risk factors of periodontitis explore changes within the nucleotide sequence in the DNA. However, it is now becoming clear that a full understanding of the interactions of the environment and lifestyle factors with the genome will also require the consideration of epigenetic mechanisms. Epigenetics can be defined as the structural (mitotically or meiotically) heritable or reversible adaptation of chromosomal regions so as to register, signal, or perpetuate altered gene activity states (Bird 2007), which refers to changes in gene expression that do not involve a change in the DNA nucleotide sequence, but encompass an array of molecular modifications to both DNA and chromatin (Li 2002; Klose & Bird, 2006). These modifications are conferred by methylation of cytosines in CpG dinucleotides, changes to chromatin, and packaging of DNA by post-translational histone modifications, mechanisms that control the higher level organizations of chromatin within the nucleus, which have a range of effects on gene expression. In this context, the low concordance rates in MZ twins, who do not always show the same disease susceptibility, also raised the possibility of epigenetic differences arising during early development as well as with aging (Wong *et al*. 2005). Accordingly, it has been reported that young twins have similar amounts of DNA methylation, whereas older twins differ considerably in the amounts and patterns of this modification (Fraga *et al*. 2005). It is a subject of speculation whether the amounts and patterns of

epigenetic alterations could give rise to the divergent disease predispositions of some MZ twins. However, unambiguous, reliable epigenetic data for twins and unrelated humans are scarce and generalizations and interpretations should be handled with prudence. Data from model organisms have suggested long-term and transgenerational epigenetic effects on gene expression (Morgan *et al*. 1999; Rakyan *et al*. 2003; Anway *et al*. 2005). Evidence for potential mechanisms that modify the epigenome of the gingiva and link environmental and lifestyle influences to the genetic constitution was given for tobacco smoking by two epigenome-wide association studies (EWAS) of buccal cells and solid gingival tissues (Teschendorff *et al*. 2015; Richter *et al*. 2019). These studies showed that the genes *CYP1B1* (cytochrome P450 family 1 subfamily B member 1) and *AHRR* (aryl-hydrocarbon receptor repressor) have an important role in xenobiotic metabolism of tobacco smoke in the oral mucosa. For periodontitis, no EWAS was performed with gingival tissues to date. However, an EWAS with individuals who self-reported gingival bleeding and tooth mobility was conducted in whole blood (Kurushima *et al*. 2019). For tooth mobility, the two most associated CpG sites were located in the gene body of the *IQCE* (IQ Motif Containing E) gene and in the gene body of the *XKR6* (XK Related 6) gene. *IQCE* is associated with a variety of different traits like alcohol consumption, food allergy, and underweight. *XKR6* is associated with a variety of different traits like alcohol consumption, smoking behavior, body mass index or wellbeing, but also with co-morbidities of periodontitis such as diabetes mellitus and systemic lupus erythematosus. It is possible that the different methylation of these genes in blood is not directly related to periodontitis but related to exposure of risk factors of periodontitis. This underlines the necessity to use oral mucosal tissues to identify differential methylation caused by oral inflammation or environmental factors that exert their effects in the oral cavity.

From genetic disease susceptibility to improved oral care

Despite great breakthroughs in human genetics in recent years, in a substantial number of inflammatory diseases few direct improvements in clinical care have resulted to date. This is largely because of the complexity of most heritable diseases, as described earlier. Most of the identified common risk factors have only moderate effects, and in most cases the true causative variants that mediate the effect at the molecular biologic level, as well as the underlying mechanism, still await elucidation. In this context it is of interest to look at the present potential of genetic health tests. Over time, these tests have evolved from testing a few variants for the prediction of a single disease, to testing hundreds of thousands of genetic variants genome-wide for multiple diseases simultaneously (Janssens & van Duijn 2010). The prediction ability of these tests is very imprecise and differs considerably between monogenic and complex diseases,

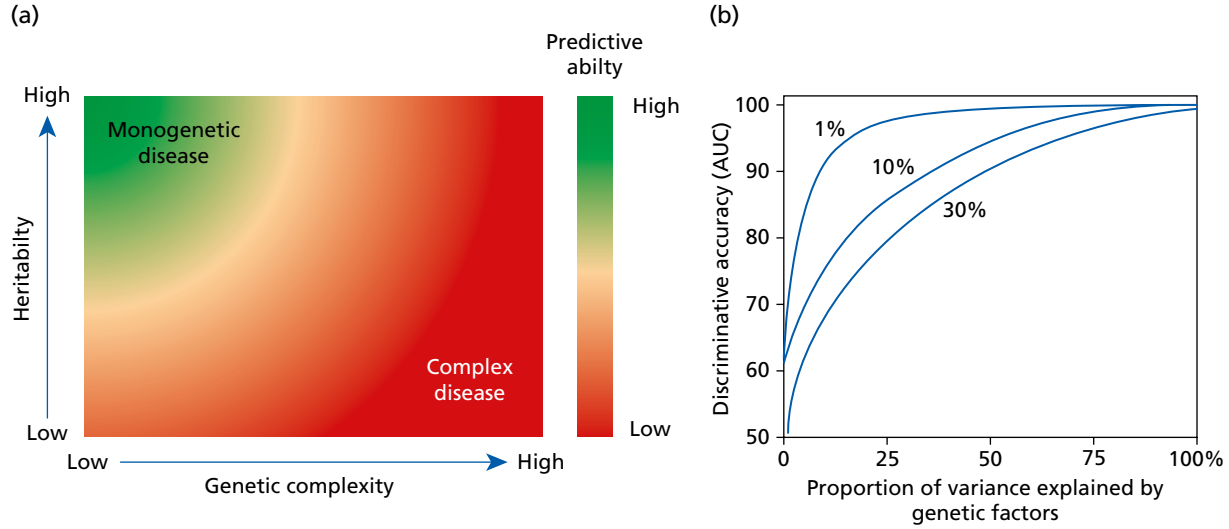

Fig 12-7 (a, b) Relationship between the heritability, genetic complexity, and predictive ability in personal genome testing. The predictive ability is highest if the heritability is high and the genetic complexity is low. The discriminative accuracy, assessed as the area under the operating characteristic curve (AUC), is the extent to which predicted risks can discriminate between individuals who will develop a disease of interest, like periodontitis, and those who will not. The AUC is the probability that the test correctly identifies the person who will develop the disease from a pair of whom one will be affected and one will remain unaffected, and ranges from 50% (complete lack of discrimination) to 100% (perfect discrimination). The percentages on the graph refer to the risk of disease prevalence in the population. Underlying this is the assumption that the total heritability can be explained, but whether or not this is realistic depends on the complexity of the genetic etiology. The discriminative accuracy for the more moderate or slow progressing phenotype of periodontitis often with the adult onset, will always be low; however, for the fast-progressing phenotype of periodontitis with often a more early onset history, the discriminative accuracy is expected to be higher. (Source: Data from Janssens *et al*. 2008. Reproduced with permission from John Wiley & Sons.)

which is explained by the different genetic complexities of these diseases (Fig. 12-7). Monogenic diseases such as cystic fibrosis or Huntington's disease are fully heritable and a mutation in a single specific gene is sufficient to cause these diseases. Testing for the absence or presence of these mutations gives an accurate estimate of future disease development. When diseases have a high heritability and a low genetic complexity, such as monogenetic disorders, genetic tests will be very accurate. In contrast, for complex diseases, the predictive ability of genetic tests is determined by the combined effect of all genetic, environmental, and lifestyle factors tested (Janssens & van Duijn 2010). Only when diseases have a high heritability can we expect that the maximum discriminative accuracy is reliable, nevertheless only under the assumption that all variants are identified. A good predictive ability of a genetic test will theoretically be possible for a disease with a very high heritability and a low genetic complexity. Such diseases are commonly severe and have an early age of onset and a low frequency (<1%) in the population. Thus, reliable genetic testing may become possible for the early-onset and relatively fast progressing forms of periodontitis, on the condition that the genetic susceptibility factors are completely identified. In contrast, late-onset periodontitis being diagnosed in middle-aged or older individuals, having moderate and greatly variable phenotypes as well as a high risk in the population, have numerous underlying low-risk genetic variants, which may interact with each other and with other non-genetic risk factors in countless different ways. Therefore, currently, predictive testing models of increased or decreased risks for periodontitis based on genetic testing, are highly unreliable due to the very complex multidimensional interactions between multiple genes, lifestyle factors, microbial factors, and present or hidden comorbidities.

Part 5: Trauma from Occlusion

Chapter 13

Effect of Load on Periodontal and Peri-Implant Tissues

Jan Lindhe[1], Niklaus P. Lang[2], and Tord Berglundh[1]

[1] Department of Periodontology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden
[2] Department of Periodontology, School of Dental Medicine, University of Bern, Bern, Switzerland

INTRODUCTION

The tissues surrounding teeth and implants are presented in Chapters 1, 4, and 5. It is documented that the periodontal ligament plays an important role in responding to the occlusal forces to the crown portion of a tooth during function. The corresponding tissue around implants is comprised of bone that has formed in direct contact with the metal surface. While the periodontal ligament harbors a large number of cells that are capable of responding to alterations in occlusion, the bone tissue in the zone of osseointegration contains groups of cells apparently less able to respond to altered load conditions during function (see Chapter 5) This is one important reason why the effect of load on implants and teeth is described in different sections (Part I and Part II).

PART I: PERIODONTAL TISSUES

Definition and terminology

Trauma from occlusion is a term that was used to describe pathologic alterations or adaptive changes which develop in the periodontium as a result of undue force produced by the masticatory muscles. It is only one of many terms that have been used to describe such alterations in the periodontium. Other terms often used are: *traumatizing occlusion*, *occlusal trauma*, *traumatogenic occlusion*, *periodontal traumatism*, and *overload*. In addition to damaging the periodontal tissues, traumatic occlusal force may also injure, for example, the temporomandibular joint, the masticatory muscles, and the pulp tissue. This part of the chapter deals exclusively with the effects of occlusal trauma on the periodontal tissues.

The World Health Organization (WHO) in 1978 defined trauma from occlusion as "damage in the periodontium caused by stress on the teeth produced directly or indirectly by teeth of the opposing jaw". Occlusal trauma is an injury to the attachment apparatus that results from excessive occlusal force(s). A new terminology was proposed at the 2017 World Workshop on Classification of Periodontal and Peri-Implant Diseases and Conditions (Jepsen *et al*. 2018). Thus, *traumatic occlusal force* was defined as any occlusal force resulting in injury of the teeth and/or the periodontal attachment apparatus, while *occlusal trauma*

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

describes the injury to the periodontal attachment apparatus.

Traumatizing forces may act on an individual tooth or on groups of teeth in a premature contact relationship; they may occur in conjunction with parafunctions such as clenching and bruxism, or in conjunction with loss or migration of premolar and molar teeth with an accompanying, gradual spread of the anterior teeth of the maxilla.

The tissue injury associated with trauma from occlusion is often divided into *primary* and *secondary*. The *primary* form includes tissue reactions (damage) elicited around a tooth with normal periodontium height, while the *secondary* form is related to situations in which occlusal forces cause injury to a periodontium of reduced height. The distinction between a primary and a secondary form of injury–primary and secondary occlusal trauma–serves no meaningful purpose, since the alterations which occur in the periodontium as a consequence of occlusal trauma are similar and independent of the height of the target tissue, that is the periodontium. It is, however, important to understand that symptoms of occlusal trauma may develop only in situations when the magnitude of the load elicited by occlusion is so high that the periodontium around the exposed tooth cannot properly withstand and distribute the resulting force without altering the position and stability of the tooth involved. This means that in cases of severely reduced height of the periodontium, even comparatively small forces may produce adaptive changes in the periodontium.

Occlusal trauma and plaque-associated periodontal disease

Ever since Karolyi (1901) postulated that an interaction may exist between "*trauma from occlusion*" and "*alveolar pyrrohea*", different opinions have been expressed regarding the validity of this claim. In the 1930s, Box (1935) and Stones (1938) reported experiments in sheep and monkeys, the results of which seemed to indicate that "trauma from occlusion is an etiologic factor in the production of that variety of periodontal disease in which there is vertical pocket formation associated with one or a varying number of teeth" (Stones 1938). The experiments by Box and Stones, however, have been criticized because they lacked proper controls and because their design did not justify the conclusions drawn.

The interaction between occlusal trauma and plaque-associated periodontal disease in humans was frequently discussed in the period 1955–1970 in connection with "case reports", "in my opinion" statements, etc. Even if such anecdotal data may have some value in clinical dentistry, it is obvious that conclusions drawn from research findings are much more pertinent. Research-based conclusions are not always indisputable, but they invite the reader to critique them, which anecdotal data do not. In this section, therefore, the presentation will be limited to findings from endeavors involving clinical and preclinical research.

Clinical trials

In addition to the presence of angular bony defects and infrabony pockets, *increased tooth mobility* is frequently listed as an important sign of occlusal trauma. Conflicting data have been reported regarding the periodontal condition of mobile teeth. In one clinical study by Rosling *et al*. (1976), patients with advanced periodontal disease associated with multiple angular bony defects and mobile teeth were exposed to subgingival scaling after flap elevation followed by meticulous supportive therapy. Healing was evaluated by probing attachment level measurements and radiographic monitoring. The authors reported that "the infrabony pocket located at hypermobile teeth exhibited the same degree of healing as those adjacent to firm teeth". In another study, however, Fleszar *et al*. (1980) reported on the influence of tooth mobility on healing following periodontal therapy, including both subgingival scaling and occlusal adjustment. They concluded that "pockets of clinically mobile teeth do not respond as well to periodontal treatment" (including tooth debridement) "as do those of firm teeth exhibiting the same disease severity".

Pihlstrom *et al*. (1986) studied the association between occlusal trauma and periodontitis by assessing a series of clinical and radiographic features at maxillary first molars: probing depth, probing attachment level, tooth mobility, wear facets, plaque and calculus, bone height, and widened periodontal space. The authors concluded from their examinations that teeth with increased mobility and widened periodontal ligament space had deeper pockets, more attachment loss, and less bone support than teeth without these symptoms.

In another clinical trial, Burgett *et al*. (1992) studied the effect of occlusal adjustment in the treatment of periodontitis. Fifty patients with periodontitis were examined at baseline and subsequently treated for their periodontal condition with root debridement ± flap surgery. Twenty-two of the 50 patients additionally received comprehensive occlusal adjustment. Re-examinations performed 2 years later disclosed that probing attachment gain was on average about 0.5 mm greater in patients who received the combined treatment, that is debridement and occlusal adjustment, than in patients who did not receive occlusal adjustment.

Nunn and Harrel (2001) and Harrel and Nunn (2001) examined the relationship between occlusal discrepancies and periodontitis in two studies. Their sample included about 90 patients who had been referred for treatment of periodontal disease and who had at least two (≥1 year apart) complete periodontal records, including an analysis of their occlusion. The patients were examined with respect

to probing pocket depth, tooth mobility, and furcation involvement (at multirooted teeth). In addition, occlusal contact relationships were studied, such as (1) discrepancies in centric relation and centric occlusion and (2) premature occlusal contacts in protrusive movements (lateral and frontal) of the mandible in working and non-working quadrants. A treatment plan, including both periodontal and occlusal measures, was subsequently designed for each patient. About one-third of the patients decided to abstain from treatment, about 20 accepted only a non-surgical approach to periodontal therapy (scaling and root planing [SRP]), and about 50% accepted and received comprehensive treatment that included surgical pocket elimination (tooth debridement; SRP + surgery) as well as occlusal adjustment (if indicated). Some teeth in the SRP group received occlusal therapy, whereas other teeth with occlusal discrepancies were left untreated. It was observed that teeth with occlusal discrepancies had significantly deeper pocket depth values and higher mobility scores than teeth without occlusal "trauma", and also that teeth exposed to occlusal adjustment responded better (reduction in pocket depth) to SRP than teeth with remaining occlusal discrepancies.

Mobile teeth and probing depth

The findings in some of the clinical studies referred to above lend some support to the concept that occlusal trauma (and increased tooth mobility) may have a detrimental effect on the periodontium. Neiderud *et al*. (1992), however, in a Beagle dog study demonstrated that tissue alterations which occur at mobile teeth with clinically healthy gingivae (and normal height of the tissue attachment) may reduce the resistance offered by the periodontal tissues to probing. In other words, if the probing depth at two otherwise similar teeth–one non-mobile and one hypermobile–is recorded, the tip of the probe will penetrate 0.5 mm deeper at the mobile than at the non-mobile tooth. This finding must be taken into consideration when the above clinical data are interpreted.

Preclinical studies

Orthodontic-type trauma

In early experiments, the reaction of the periodontium was studied following the application of forces applied to teeth in one direction only. Biopsy specimens, including tooth and periodontium, were harvested after varying intervals and prepared for histologic examinations. Analysis of the sections (Häupl & Psansky 1938; Reitan 1951; Mühlemann & Herzog 1961; Ewen & Stahl 1962; Wærhaug & Hansen 1966; Karring *et al*. 1982) revealed that when a tooth is exposed to unilateral forces of a magnitude, frequency, or duration that its periodontal tissues are unable to withstand and distribute while maintaining the stability of the tooth, certain well-defined reactions develop in the periodontal ligament, eventually resulting in an adaptation of the periodontal structures to the altered functional demand. If the crown of a tooth is affected by such horizontally directed forces, the tooth tends to tilt (tip) in the direction of the force (Fig. 13-1). The forces result in the development of *pressure* and *tension zones* within the marginal and apical parts of the periodontium. The tissue reactions which develop in the *pressure zone* are characteristic of a mild inflammation (increased number of vessels, increased vascular permeability, vascular thrombosis, and disorganization of cells and collagen fiber bundles). If the magnitude of forces is within certain limits, the vitality of the periodontal ligament cells is maintained and bone-resorbing osteoclasts soon appear on the bone surface of the alveolus in the *pressure zone*. A process of *direct bone resorption* is initiated.

If the force applied is of higher magnitude, the periodontal ligament tissue in the *pressure zone* may become necrotic and undergo *hyalinization*. "Direct bone resorption", therefore, cannot occur. Instead, osteoclasts appear in marrow spaces within the adjacent bone tissue where the stress concentration is lower and a process of undermining or "*indirect bone resorption*" is initiated. Through this reaction the surrounding bone is resorbed until there is a breakthrough to the hyalinized tissue within the *pressure zone*. This breakthrough results in a reduction of the stress in this area, and cells from the neighboring bone or adjacent areas of the periodontal ligament can proliferate into the *pressure zone* and replace the previously hyalinized tissue, thereby re-establishing

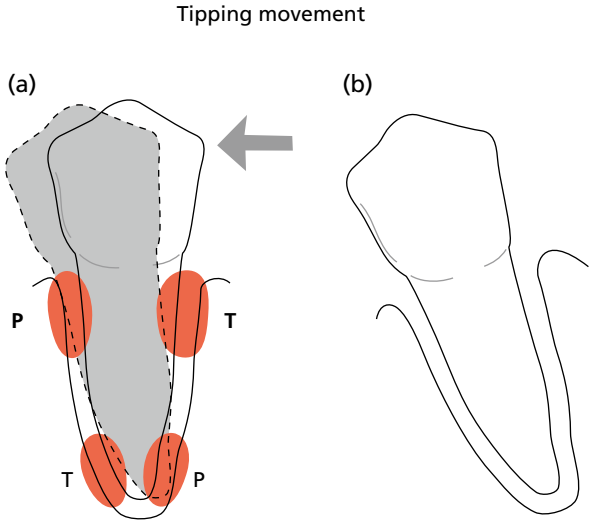

Fig. 13-1 (a) If the crown of a tooth is exposed to excessive, horizontally directed forces (arrow), pressure (P) and tension (T) zones will develop within the marginal and apical parts of the periodontium. The supra-alveolar connective tissue remains unaffected by force application. Within the pressure and tension zones, tissue alterations take place and eventually allow the tooth to tilt in the direction of the force. (b) When the tooth is no longer subjected to the trauma, complete regeneration of the periodontal tissues takes place. There is no apical downgrowth of the dentogingival epithelium.

the prerequisites for "direct bone resorption". Irrespective of whether the bone resorption is of a direct or an indirect nature, the tooth moves (tilts) further in the direction of the force.

Concomitant with the tissue alterations in the *pressure zone*, apposition of bone occurs in the *tension zone* in order to maintain the normal width of the periodontal ligament in this area. Because of the tissue reactions in the *pressure* and *tension* zones, the tooth becomes hypermobile. When the tooth has moved (tilted) to a position where the effect of the forces is nullified, healing of the periodontal tissues takes place in both the *pressure* and the *tension zones*, and the tooth becomes stable in its new position. In orthodontic tilting (tipping) movements, neither gingival inflammation nor loss of connective tissue attachment will occur at teeth with a healthy periodontium.

These tissue reactions do not differ fundamentally from those which occur as a consequence of *bodily tooth movement* in orthodontic therapy (Reitan 1951). The main difference is that the *pressure* and *tension zones*, depending on the direction of the force, are more extended in an apicocoronal direction along the root surface than in conjunction with the tipping movement (Fig. 13-2). The supra-alveolar connective tissue is not affected by the force, either in conjunction with tipping or in conjunction with bodily movements of the tooth. Unilateral forces exerted on the crowns of teeth, therefore, will not induce inflammatory reactions in the gingiva or cause loss of connective tissue attachment.

Studies have demonstrated, however, that orthodontic forces producing bodily (or tipping) movement of teeth may result in gingival recession and loss of connective tissue attachment (Steiner *et al*. 1981; Wennström *et al*. 1987). This breakdown of the attachment apparatus occurred at sites with gingivitis when, in addition, the tooth was moved through the envelope of the alveolar process. At such sites bone dehiscence became established and, if the covering soft tissue was thin (in the direction of the movement of the tooth), recession (attachment loss) occurred.

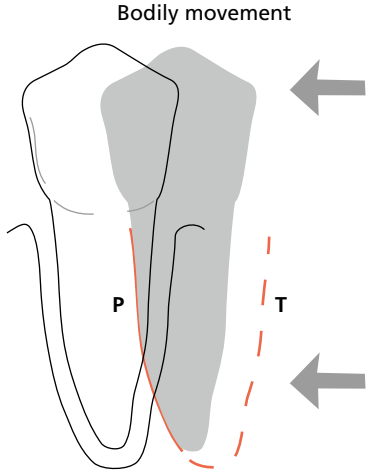

Fig. 13-2 When a tooth is exposed to forces which produce "bodily tooth movement", for example in orthodontic therapy, the pressure (P) and tension (T) zones, depending on the direction of the force, are extended over the entire tooth surface. The supra-alveolar connective tissue is not affected in conjunction either with tipping or with bodily movements of teeth. Forces of this kind, therefore, will not induce inflammatory reactions in the gingiva. No apical downgrowth of the dentogingival epithelium occurs.

Criticism has been directed at experiments in which only unilateral trauma is exerted on teeth (Wentz *et al*. 1958). It has been suggested that in humans, unlike in the animal experiments described above, the occlusal forces act alternately in one and then in the opposite direction. Such forces have been termed *jiggling forces*.

Jiggling-type trauma

Healthy periodontium with normal height

Experiments have been reported in which traumatic forces were exerted on the crowns of the teeth, alternately in the buccal/lingual or mesial/distal directions, and the teeth were not allowed to move away from the force (e.g. Wentz *et al*. 1958; Glickman & Smulow 1968; Svanberg & Lindhe 1973; Meitner 1975; Ericsson & Lindhe 1982). In conjunction with "*jiggling-type trauma*" no clear-cut *pressure* and *tension zones* can be identified, but rather there is a combination of pressure and tension on both sides of the jiggled tooth (Fig. 13-3).

The tissue reactions in the periodontal ligament provoked by the combined *jiggling* forces were found to be rather similar to those reported to occur in the pressure zone at orthodontically moved teeth, but with one important difference. The periodontal ligament space at jiggled teeth gradually increased in width on both sides of the tooth. During the phase when the periodontal ligament gradually increased in width, (1) inflammatory changes were present in the ligament tissue, (2) active bone resorption occurred, and (3) the tooth displayed signs of gradually increasing (*progressive*) mobility. When the effect of the forces applied had been compensated for by the increased width of the periodontal ligament space, the ligament tissue showed no signs of increased vascularity or exudation. The tooth was hypermobile but the mobility was no longer *progressive* in character. Distinction should thus be made between *progressive* and *increased* tooth mobility.

In *jiggling-type trauma* experiments performed in animals with a normal periodontium, the supra-alveolar connective tissue was not influenced by the occlusal forces. This means that a gingiva which was healthy at the start of the experiment remained healthy. It was also observed that an overt gingival lesion was not aggravated by the jiggling forces.

Healthy periodontium with reduced height

Progressive periodontal disease is characterized by gingival inflammation and a gradually developing loss of connective tissue attachment and alveolar bone. Treatment of periodontal disease, that is removal of plaque and calculus and elimination of

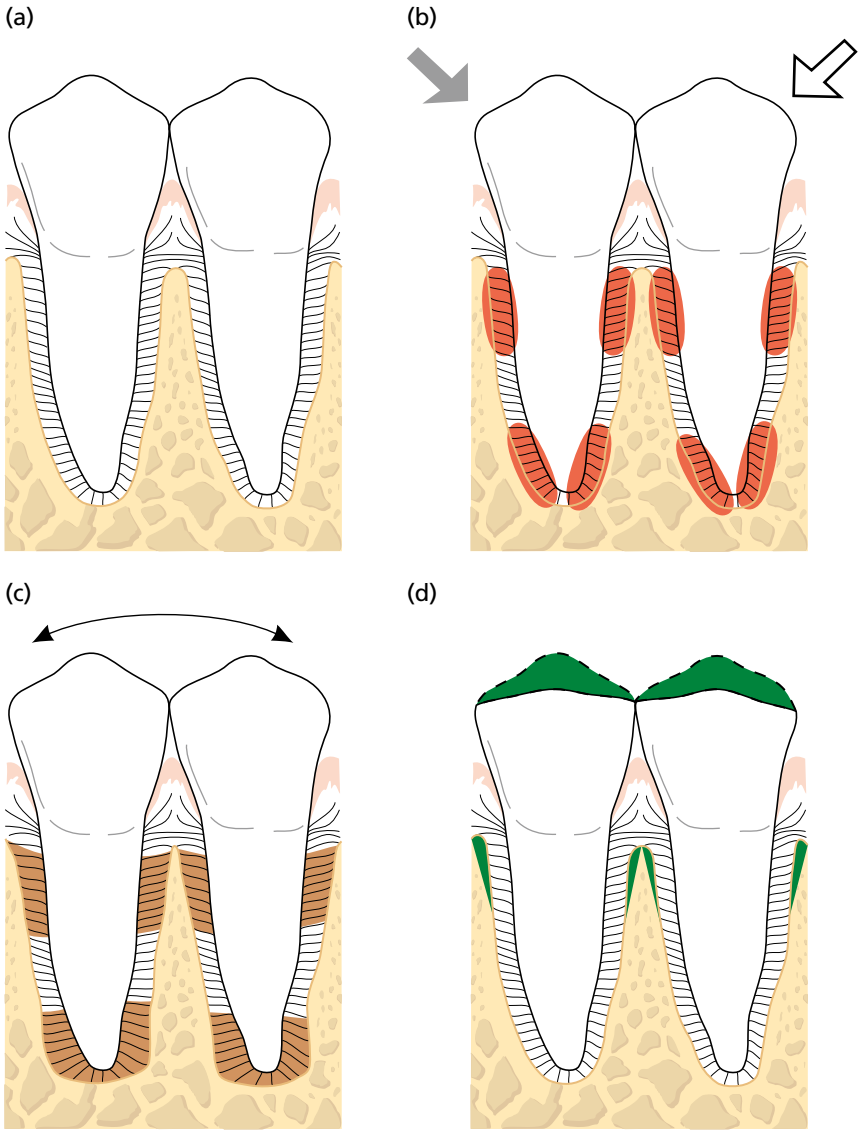

Fig. 13-3 Two mandibular premolars with normal periodontal tissues (a) are exposed to jiggling forces (b), as illustrated by the two arrows. The combined tension and pressure zones (encircled areas) are characterized by signs of acute inflammation, including collagen resorption, bone resorption, and cementum resorption. As a result of bone resorption, the periodontal ligament space gradually increases in size on both sides of the teeth as well as in the periapical region. (c) When the effect of the force applied has been compensated for by the increased width of the periodontal ligament space, the ligament tissue shows no signs of inflammation. The supra-alveolar connective tissue is not affected by the jiggling forces and there is no apical downgrowth of the dentogingival epithelium. (d) After occlusal adjustment the width of the periodontal ligament becomes normalized and the teeth are stabilized.

pathologically deepened pockets, will result in the re-establishment of a healthy periodontium but with reduced height. The question is whether a healthy periodontium with reduced height has a capacity similar to that of the normal periodontium to adapt to traumatizing occlusal forces (secondary occlusal trauma).

This problem has also been examined in a preclinical study (Ericsson & Lindhe 1977). Destructive periodontal disease was initiated in premolars of dogs by allowing the animals to accumulate plaque and calculus. When around 50% of the periodontal tissue support had been lost, the involved teeth were exposed to debridement and surgical pocket elimination. Following healing, these teeth had a reduced but healthy periodontium (Fig. 13-4a). During the subsequent months of continued plaque control, certain premolars were exposed to traumatizing jiggling forces (Fig. 13-4b). The periodontal tissues in the combined *pressure* and *tension zones* reacted to the application of forces with inflammation as well as by bone resorption. In the initial phase, the traumatized teeth displayed signs of *progressive* tooth mobility and a progressive increase of the size of the periodontal ligament. After several weeks of jiggling, there was no further increase in the mobility (Fig. 13-4c). The active bone resorption had ceased and the markedly widened periodontal ligament tissue had regained its normal composition. The teeth were hypermobile at this stage, but surrounded by a periodontal ligament which had adapted to the altered functional demands.

During the entire experimental period the supra-alveolar connective tissue remained unaffected by the jiggling forces. There was no further loss of connective tissue attachment and no further downgrowth of dentogingival epithelium. The results from this study clearly revealed that, within certain limits, a healthy periodontium with reduced height has a capacity similar to that of a periodontium with normal height to adapt to altered functional demands. Removal of the jiggling forces ("occlusal adjustment") will in this situation result in a normalization of the width of the periodontal ligament (Fig. 13-4d).

Plaque-associated periodontitis

Experiments carried out on humans and animals have demonstrated that *occlusal trauma* cannot induce pathologic alterations in the supra-alveolar connective tissue, in other words cannot produce inflammatory lesions in a normal gingiva or aggravate a gingival lesion and cannot induce loss of connective tissue attachment. The question remains whether or not abnormal occlusal forces can influence the spread of the plaque-associated lesion and enhance the rate of tissue destruction in periodontal disease. This has been studied in animal experiments (Lindhe & Svanberg 1974; Meitner 1975; Nyman *et al*. 1978; Ericsson & Lindhe 1982; Polson & Zander 1983) in which progressive and destructive periodontal disease was first initiated in dogs or monkeys by allowing the animals to accumulate plaque and calculus. Some of the premolars that were involved in a progressive periodontal disease process (periodontally involved) were also exposed to occlusal trauma.

"Traumatizing" jiggling forces (Lindhe & Svanberg 1974) were exerted on periodontally involved

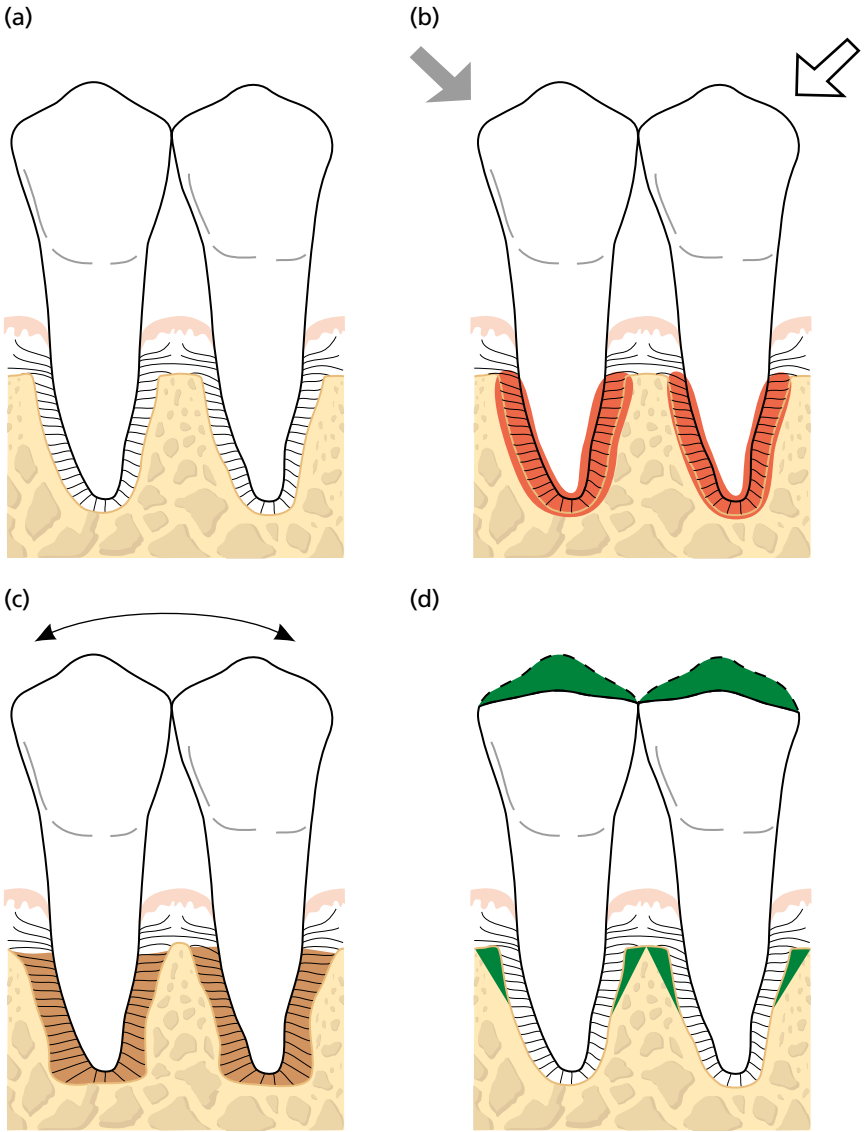

Fig. 13-4 (a) Two mandibular premolars are surrounded by a healthy periodontium with reduced height. (b) If such premolars are subjected to traumatizing forces of the jiggling type, a series of alterations occurs in the periodontal ligament tissue. (c) These alterations result in a widened periodontal ligament space and increased tooth mobility, but do not lead to further loss of connective tissue attachment. (d) After occlusal adjustment, the width of the periodontal ligament is normalized and the teeth are stabilized.

premolars and were found to induce certain tissue reactions in the combined *pressure/tension zones*. Within a few days of the onset of the jiggling forces, the periodontal ligament tissue in these zones displayed signs of inflammation. On the adjacent bone surfaces a large number of osteoclasts were present. Since the teeth could not orthodontically move away from the jiggling forces, the periodontal ligament on both sides of the tooth gradually increased in width, the teeth became hypermobile (*progressive* tooth mobility), and angular bony defects could be detected on the radiographs. The effect of the forces was eventually nullified by the increased width of the periodontal ligament.

If the forces applied were of a magnitude to which the periodontal structures could adapt, the *progressive* increase of the tooth mobility terminated within a few weeks. The active bone resorption ceased, but the angular bone destruction persisted as well as the increased tooth mobility. The periodontal ligament had an increased width, but a normal tissue composition. Biopsy specimens including the periodontally involved teeth revealed that this process of adaptation had occurred with no further attachment loss (Fig. 13-5) (Meitner 1975). This means that occlusal forces which allow adaptive alterations to occur in the *pressure/tension* zones of the periodontal ligament will not aggravate a plaque-associated periodontitis (Fig. 13-6).

If, however, the magnitude and direction of the jiggling forces were such that, during the course of the study, the tissues in the pressure/tension zones could not adapt, the injury had a more permanent character. For several months the periodontal ligament in the pressure/tension zones displayed signs of inflammation and osteoclastic bone resorption. This resulted in a gradual widening of the periodontal ligament (Fig. 13-7). As a consequence, the resulting angular bone destruction was continuous and the mobility of the teeth remained progressive. In this dog model, additional portions of the connective tissue attachment were lost and periodontal tissue destruction became more severe (Figs. 13-8, 13-9) (Lindhe & Svanberg 1974).

On the other hand, findings from more short-term experiments using a monkey model (Polson & Zander 1983), failed to support the observations of Lindhe and Svanberg (1974) and Ericsson and Lindhe (1982). Polson and Zander (1983) reported that trauma superimposed on periodontal lesions associated with angular bony defects caused increased loss of alveolar bone, but failed to produce additional loss of connective tissue attachment.

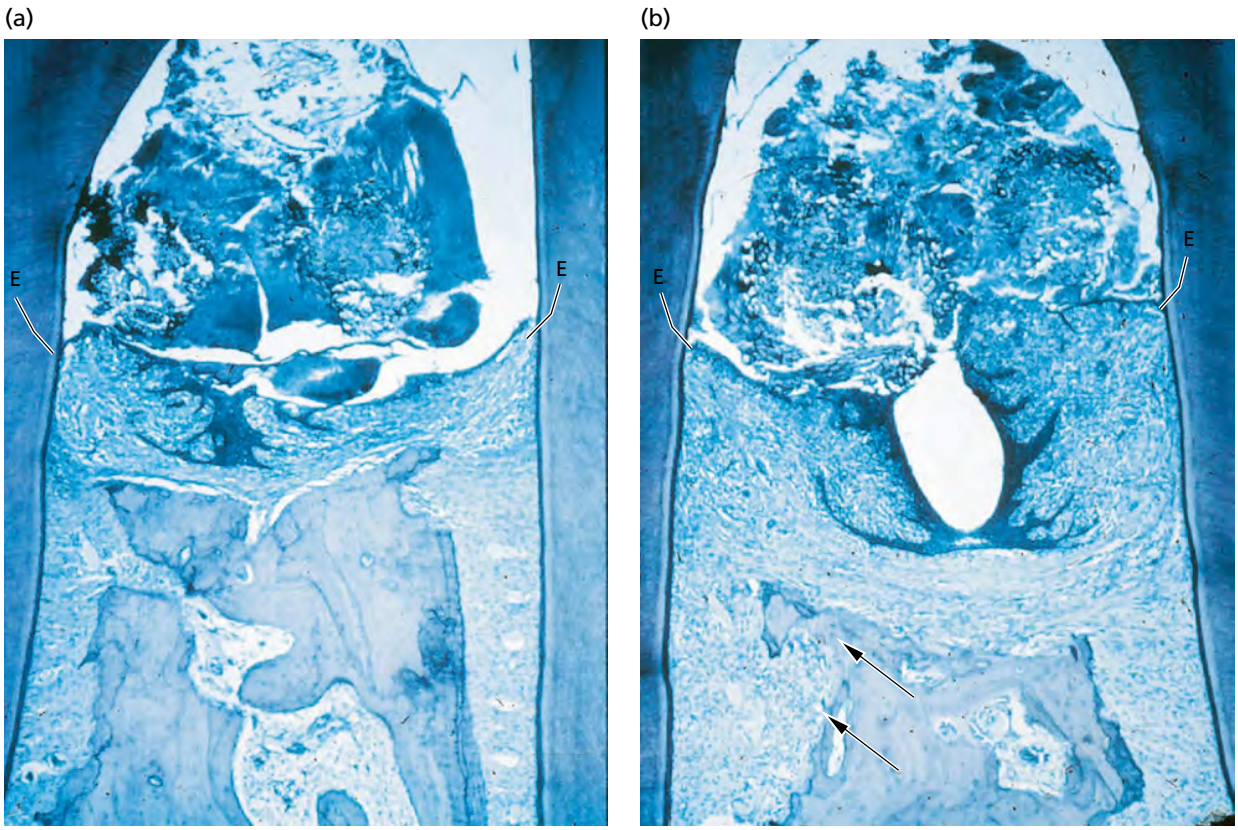

Fig. 13-5 (a) A composite photomicrograph illustrating the interdental space between two pairs of teeth. The teeth have been subjected to experimental, ligature-induced periodontitis and in (b) also to repetitive mechanical injury. In (b), there is considerable loss of alveolar bone and an angular widening of the periodontal ligament space (arrows). However, the apical downgrowth of the dentogingival epithelium in the two areas in (a) and (b) is similar. E indicates the apical level of the dentogingival epithelium. (Source: Courtesy of S.W. Meitner.)

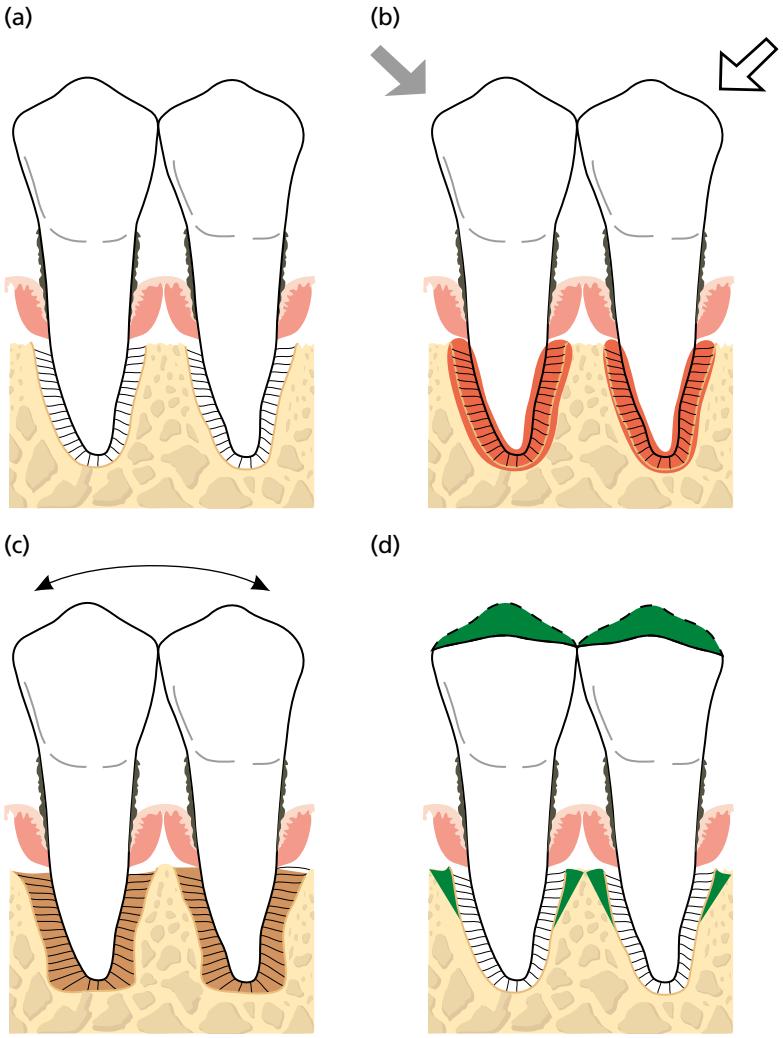

Fig. 13-6 (a) Two mandibular premolars with supra- and subgingival plaque, advanced bone loss, and periodontal pockets of a suprabony character. Note the connective tissue infiltrate (shadowed areas) and the uninflamed connective tissue between the alveolar bone and the apical portion of the infiltrate. (b) If these teeth are subjected to traumatizing forces of the jiggling type, pathologic and adaptive alterations occur within the periodontal ligament space. (c) These tissue alterations, which include bone resorption, result in a widened periodontal ligament space and increased tooth mobility, but no further loss of connective tissue attachment. (d) Occlusal adjustment results in a reduction of the width of the periodontal ligament and in less mobile teeth.

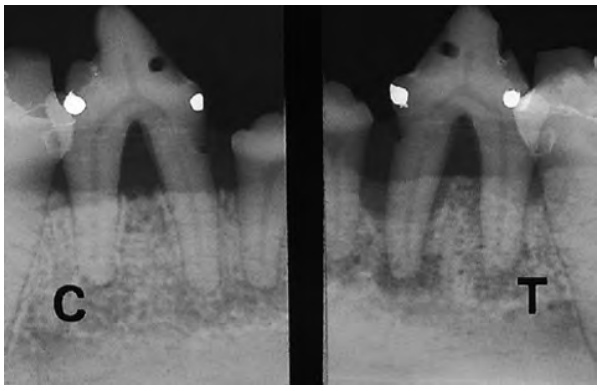

Fig. 13-7 Radiographic appearance of one test tooth (T) and one control tooth (C) at the termination of an experiment in which periodontitis was induced by ligature placement and plaque accumulation, and in which trauma of the jiggling type was induced. Note the angular bone loss particularly around the mesial root of the mandibular premolar (T) and the absence of such a defect at the mandibular premolar (C). (Source: Lindhe & Svanberg 1974. Reproduced with permission from John Wiley & Sons.)

Conclusion

Clinical and preclinical studies have produced convincing evidence that neither unilateral forces nor jiggling forces, applied to teeth with a healthy periodontium, result in pocket formation or in loss of connective tissue attachment. *Occlusal trauma cannot induce periodontal tissue breakdown*. Occlusal trauma does, however, result in resorption of alveolar bone, leading to an increased tooth mobility which can be of a transient or permanent character. This bone resorption with resulting increased tooth mobility should be regarded as a physiologic adaptation of the periodontal ligament and surrounding alveolar bone to the traumatizing forces, that is to altered functional demands.

In teeth involved in progressive periodontitis, occlusal trauma may, under certain conditions, enhance the rate of progression of the disease. It is important to realize that in such cases, treatment directed towards the trauma alone, that is occlusal adjustment or splinting, may reduce the mobility of

Fig. 13-8 Microphotographs from one control (C) and one test (T) tooth after 240 days of experimental periodontal tissue breakdown and 180 days of trauma from occlusion of the jiggling type (T). The arrowheads denote the apical position of the dentogingival epithelium. The attachment loss is more pronounced in T than in C. (Source: Lindhe & Svanberg 1974. the traumatized teeth and result in some regrowth of bone, but it will not influence the features of the plaque-associated lesion.

PART II: PERI-IMPLANT TISSUES

Endosseous osseointegrated oral implants have been suggested to serve as anchorage for orthodontic appliances where the existing dentition does not provide sufficient anchorage. Both clinical (Turley *et al*. 1988; Ödman *et al*. 1988; Haanaes *et al*. 1991; Ödman *et al*. 1994) and experimental (Wehrbein & Diedrich 1993; Wehrbein *et al*. 1996) studies have demonstrated that osseointegrated implants were able to provide sufficient and stable anchorage for tooth movement during the time period of orthodontic therapy, thereby eliminating the need to observe Newton's third law according to which an applied force can be divided into an *action* component and an equal and opposite *reaction* moment.

In long-term clinical studies of various two-stage submerged implant systems, however, implant losses have been attributed to *overloading* or *excessive loading*. In patients with edentulous (Adell *et al*. 1981; Lindquist *et al*. 1988) and partially edentulous jaws (Jemt *et al*. 1989; Quirynen *et al*. 1992), most of the implant losses were considered to be the result of excessive occlusal loading. Although it has been shown that early loading of oral implants may impede successful osseointegration (Sagara *et al*. 1993), the effect of excessive occlusal functional forces following successful osseointegration has not been documented so far. However, studies by Isidor (1996, 1997) have demonstrated that loading of implants through the creation of a massive supraocclusion, leading to excessive–and most likely non-physiologic–laterally directed occlusal forces, established a high risk for the loss of osseointegration in loosely trabecular bone. Nevertheless, in one of four experimental animals, even such excessive loading forces were unable to jeopardize the interfacial union of the alveolar bone with the implant surface.

The forces applied in the studies mentioned were characterized as being very high and of short duration. However, they could not be quantified. None of the experimental studies analyzed the direct relationship between changes in the stress and strain applied to oral implants during functional loading, and the tissue reactions of the surrounding alveolar bone. For the evaluation of the etiology and pathogenesis of implant losses due to overload, such information would appear to be of crucial importance.

Orthodontic loading and alveolar bone

In order to evaluate the tissue reactions adjacent to oral implants following loading with well-defined forces and to relate these to the strain values applied on the trabecular surface of the alveolar bone, an animal study was performed using finite element analysis (FEA) to determine the cellular activity (Melsen & Lang 2001). In six adult monkeys, the lower first and the second premolars as well as the second molars were removed. After 6 months, two specially designed screw implants were inserted in the region of the lower left second premolar and second molar. After a further 3 months, a square rod with three notches at different levels was inserted and tightened to the top of the implants. The notches served as a reference for the measurements of the implant displacement. A flat disk was placed between the implant and the rod. To this disk two extensions were welded buccally and lingually in a way that allowed a coil spring to be placed as close as possible to the estimated level of the center of resistance (Fig. 13-10). Immediately before the buccal and lingual springs were inserted, the extensions were placed on the occlusal surface of the implants. Impressions of each segment were taken. Subsequently, two measurements were performed with an electronic strain gauge-based measuring device. For anchorage of the device, a cast splint was fitted to the anterior segment of the dentition and each of the implant screws. One measurement was taken between the notches close to the implant connection, and another between the notches close to the top of the square rod extensions. These were repeated after 11 weeks, in other words at the termination of the orthodontic loading period.

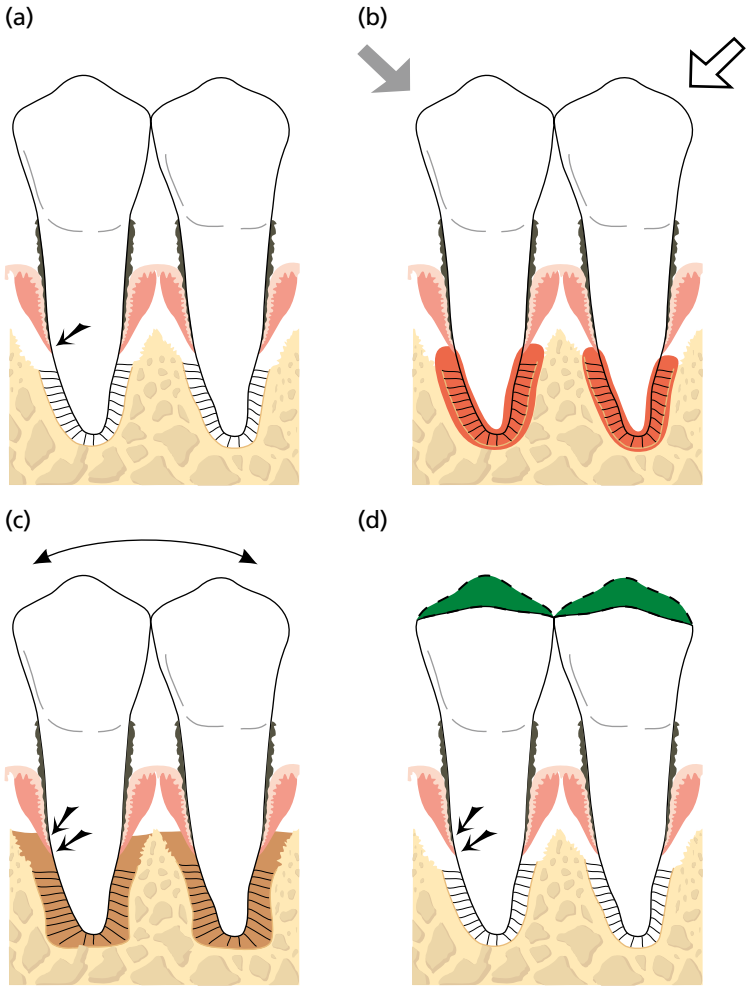

Fig. 13-9 (a) A tooth where subgingival plaque has mediated the development of an infiltrated soft tissue (shadowed area) and an infrabony pocket. (b) When trauma from occlusion of the jiggling type is inflicted (arrows) on the crown of this tooth, the associated pathologic alterations occur within a zone of the periodontium which is also occupied by the inflammatory cell infiltrate (shadowed area). In this situation, the increasing tooth mobility may also be associated with an enhanced loss of connective tissue attachment and further downgrowth of dentogingival epithelium; compare arrows in (c) and (d). Occlusal adjustment will result in a narrowing of the periodontal ligament, less tooth mobility, but no improvement of the attachment level (d). (Source: Lindhe & Ericsson 1982. Reproduced from the American Academy of Periodontology.)

The direction and magnitude of the displacement of the implant as a result of loading could thus be calculated in the sagittal plane.

Following the baseline recordings, springs extending from the anterior to the posterior implant were attached to the power arms buccally and lingually (Fig. 13-10). Total load applied to each implant varied from 100 to 300 cN. One monkey served as a control with the implants in this animal not subjected to any loading.

At the end of the experiment, the monkeys were sacrificed. Subsequently, parallel horizontal tissue sections from the coronal to the apical end of the implants were cut and stained with fast green. A grid consisting of three concentric circular lines was projected onto the sections, with each of these lines intersected by four equidistant radial lines starting at the center of the grid and coinciding with the central axis of the implants. The four radial lines divided the circle into eight areas, two in the direction of the force (A: compression zone), two in the opposite direction (B: tension zone), and four lateral to the implants (C and D: shear zone) (Fig. 13-11).

At a magnification of ×160, the extent of resorption lacunae and the extent of the trabecular bone surfaces covered by osteoid as a fraction of the total were assessed. Also, using morphometry, bone density

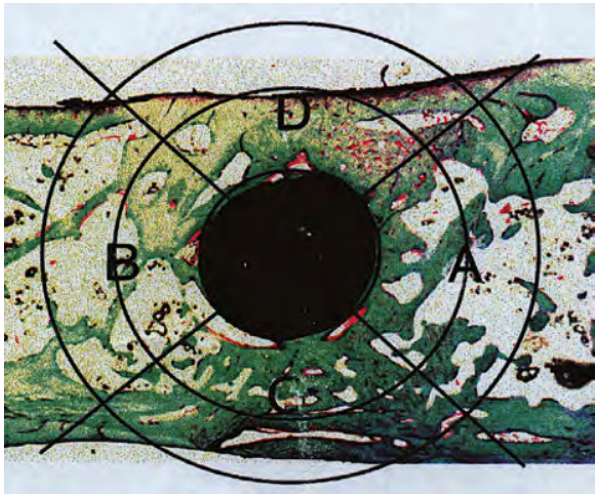

Fig. 13-11 Horizontal section of the implant with the projected grid used for the histomorphometric evaluation of different regions surrounding the implant. Region A is submitted to compression, region B to tension, and regions C and D to shearing forces.

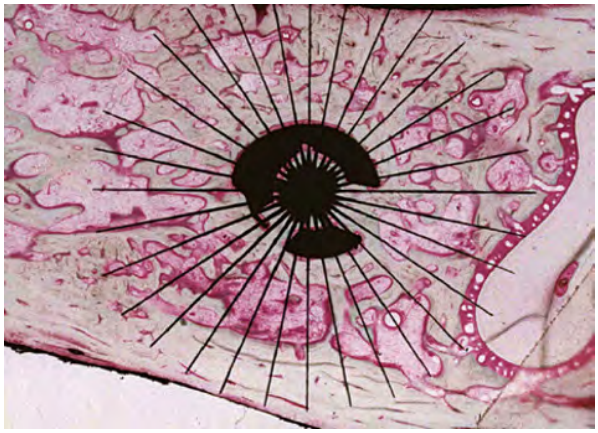

Fig. 13-12 Horizontal section of the implant onto which a grid with 32 radial lines was projected. The evaluation of the osseointegration included the determination of the percentage of direct bone–implant contact (×160).

was evaluated within each quadrant. Furthermore, to measure the amount of osseointegration, the proportion of direct bone–implant contact was calculated by projecting a grid consisting of 32 radial lines extending from the center of the implants onto the section to be analyzed (Fig. 13-12).

None of the implants had lost osseointegration after 11 weeks of orthodontic loading, but loading significantly influenced the turnover of the alveolar bone in the vicinity of the implants. Bone apposition was most frequently found, when the calculated strain varied between 3400 and 6600 μstrain. On the other hand, when the strain exceeded 6700 μstrain, the remodeling of the bone resulted in a net loss of bone density.

This study clearly supports the theory that apposition of bone around an oral implant is the biologic response to a mechanical stress below a certain threshold, whereas loss of marginal bone or complete loss

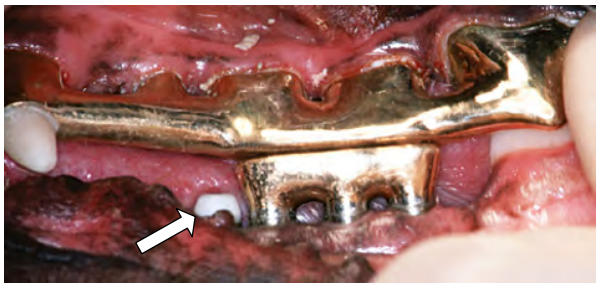

Fig. 13-13 The fixed dental prosthesis (FDP) supported by maxillary canines and premolars. The FDP is installed on implants in the mandible to provide masticatory function. The non-loaded control implant is mesial to the FDP (arrow). (Source: Berglundh *et al*. 2005. Reproduced with permission from John Wiley & Sons.)

of osseointegration may be the result of mechanical stress beyond this threshold. Hence, occlusal forces would have to substantially exceed the physiologic range before occlusal contacts could jeopardize the tissue integrity of an implant.

Several other studies using orthodontic forces have confirmed apposition or increase in bone density surrounding an oral implant, rather than loss of bone (Roberts *et al*. 1984; Wehrbein & Diedrich 1993; Asikainen *et al*. 1997; Akin-Nergiz *et al*. 1998).

Bone reactions to functional loading

A study addressed the reaction of peri-implant bone after longstanding functional loading compared with non-loaded controls (Berglundh *et al*. 2005). After extraction of all mandibular premolars, four implants were placed in one side of the mandible, and four implants were installed in the contralateral side. Three months after abutment connection, fixed dental prostheses (FDPs) were placed on the maxillary canines and premolars (Fig. 13-13). FDPs were also installed on three of the four mandibular implants in both sides. The fourth implant remained unloaded and served as a control (Fig. 13-14). Radiographs were obtained from each site following implant installation, abutment connection, and FDP placement. All radiographs were repeated after 10 months of functional loading. At this time, biopsies were obtained and analyzed histologically.

Radiographic analysis revealed that the largest amount of bone loss occurred following implant installation and abutment connection. However, as a result of functional loading, bone loss was small and did not differ significantly from the unloaded control sites (Fig. 13-15).

Histologic analysis showed that implants exposed to 10 months of functional loading had more direct bone–implant contact than their unloaded counterparts (Fig. 13-16).

Based on the radiographic and histologic results, this study demonstrated that *functional loading of implants may enhance osseointegration* (direct bone–implant contact) rather than induce marginal bone

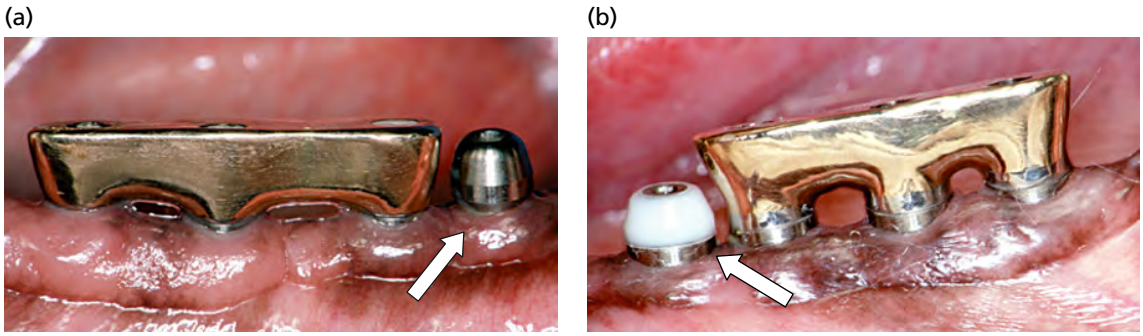

Fig. 13-14 Fixed dental prostheses fabricated of gold and installed on implants for functional loading. Unloaded implant as control (arrows). (a) Right and (b) left side of the mandible. (Source: Berglundh *et al*. 2005. Reproduced with permission from John Wiley & Sons.)

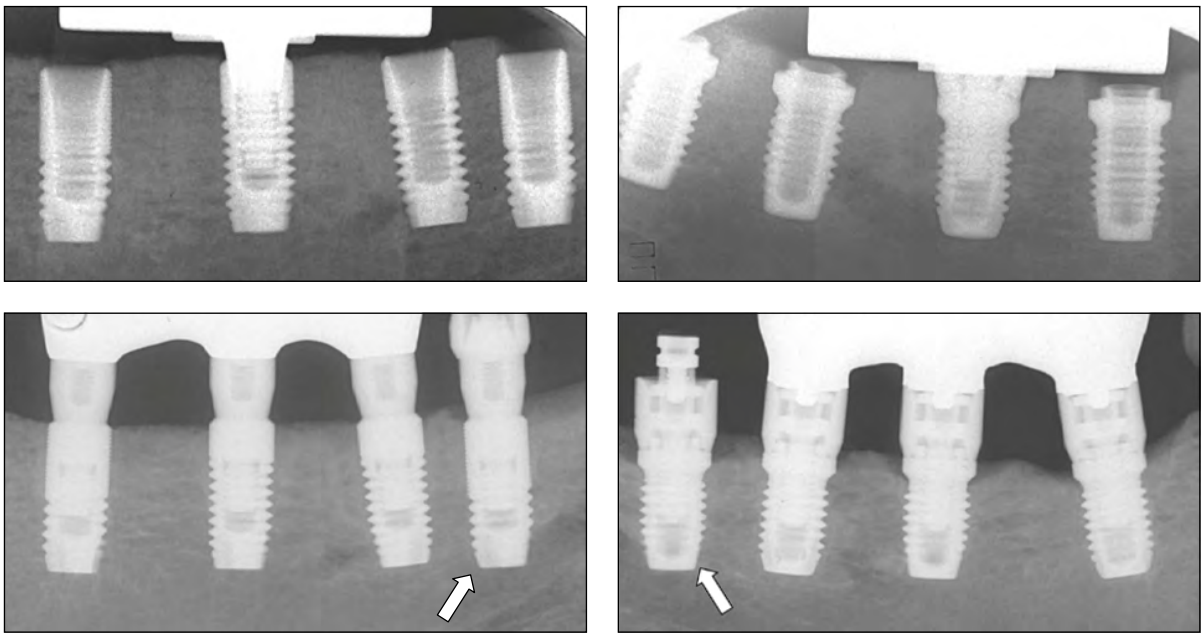

Fig. 13-15 Radiographs obtained from implants on the left and right side immediately after implant installation (top row) and following 10 months of functional loading (bottom row). Unloaded control implants are indicated with arrows.

loss and hence, any bone loss should not be attributed to loading of implants. Whenever marginal bone loss is observed around implants in function, peri-implantitis should be considered (see Chapter 20).

Excessive occlusal load on implants

The effect of *excessive occlusal load* following placement of titanium implants in the presence of healthy peri-implant mucosal tissues was evaluated in an experimental study (Heitz-Mayfield *et al*. 2004). In six dogs, two titanium plasma-sprayed (TPS) implants and two sandblasted, large grit, acid-etched (SLA) implants were placed on each side of the mandible (Fig.13-17a). A total of 45 implants were evaluated. Following 6 months of healing (Fig. 13-17b), gold crowns were placed on implants on the test side of the mandible. The crowns were in supraocclusal contact with the opposing teeth in order to create an excessive occlusal load (Fig. 13-17c). Implants on the control side were not loaded. Plaque control was performed throughout the experimental period. Clinical measurements and standardized radiographs (Fig. 13-17d) were obtained at baseline and 1, 3, and 8 months after loading. At 8 months, all implants were osseointegrated, the dogs were euthanized, and histologic analyses were performed. The mean probing depth was 2.5 ± 0.3 and 2.6 ± 0.3 mm at the unloaded and loaded implants, respectively. Radiographically, the mean distance from the implant shoulder to the marginal bone level was 3.6 ± 0.4 mm in the control group and 3.7 ± 0.2 mm in the test group. There were no statistically significant changes in any of the parameters from baseline to 8 months in the loaded and unloaded implants.

Histologic evaluation (Fig. 13-18) showed a mean mineralized bone–implant contact of 73% in the control implants and 74% in the test implants, with no statistically significant difference between test and control implants.

Table 13-1 shows the level of osseointegration in relation to the total length of the implant after 8 months of excessive loading or non-loading. These values were generally slightly below those of the alveolar bone height (Table 13-2) for all sites and surfaces in both test and control implants. The

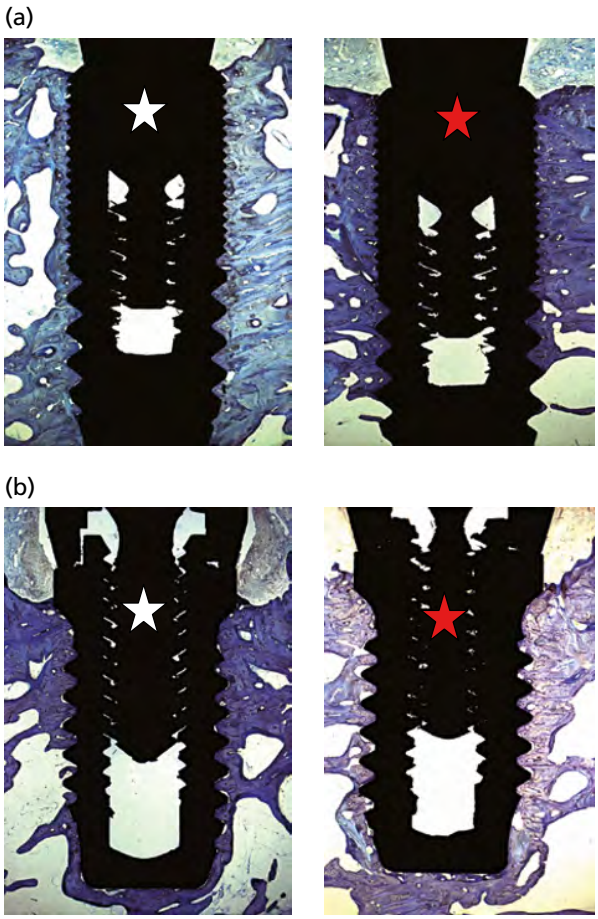

Fig. 13-16 (a) Non-loaded control implant (AstraTech®) after 10 months (white star) and functionally loaded (AstraTech®) implant (red star) after 10 months. (b) Non-loaded control implant (Brånemark®) after 10 months (white star) and functionally loaded (Brånemark®) implant (red star) after 10 months. (Source: Berglundh *et al*. 2005. Reproduced with permission from John Wiley & Sons.)

differences varied between 1.1% and 3.7% and were not statistically significant.

Likewise, there were no statistically significant differences between the excessively loaded and the unloaded implants in terms of peri-implant bone density either at the implant–bone interface or at 1 mm from the implant surface (Fig. 13-18) after 8 months.

Since none of the clinical, radiographic, or histologic parameters yielded statistically significant differences between non-loaded and excessively loaded implants, the study clearly demonstrates that, in the presence of peri-implant mucosal health, a period of 8 months of *excessive occlusal load* on titanium implants does *not* result in loss of osseointegration or marginal bone loss when compared with non-loaded implants.

More recently, implants (with both SLA and SLActive surfaces) that were excessively loaded using cantilever reconstructions were evaluated for stability over a period of 6 months using resonance frequency analysis (RFA) (Lima *et al*. 2019). In five dogs, all mandibular premolars were extracted bilaterally. After 3 months, full thickness flaps were raised, and six implants (three SLA and three SLActive) were installed in a block-randomized split-mouth design (day 0). After 4 weeks, implants were restored on each side of the mandible as follows: one single crown with stable occlusal contacts (SC); one crown and a 13.5-mm cantilever unit with excessive occlusal contacts (OL); and one non-loaded implant (NL) protected by the cantilever unit (Fig. 13-19). The vertical dimension was increased by 3 mm. RFA was evaluated on day 0 and weekly for 2–10 weeks after surgery, and at 12 weeks and 24 weeks after loading.

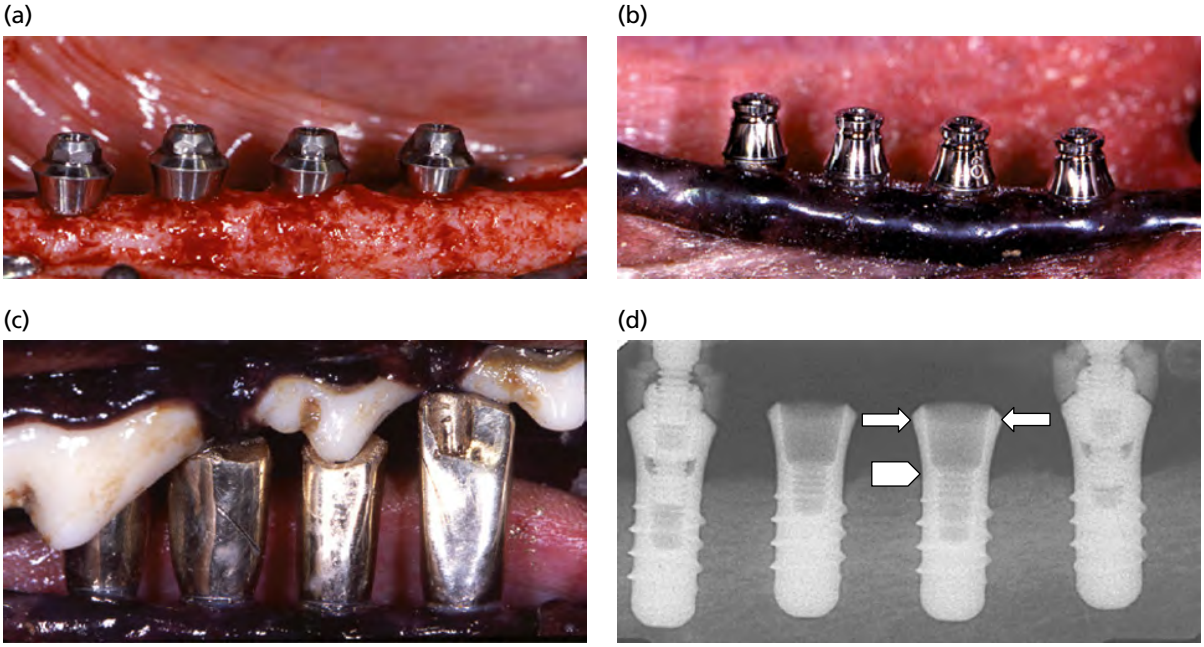

Fig. 13-17 (a) Four implants at the time of placement in one side of the mandible. (b) The implants after 6 months of non-submerged healing. (c) The test side of the mandible in one dog. Note the four single gold crowns in supraocclusal contact with the opposing teeth. (d) Standardized radiograph showing the level of the implant shoulder (arrows), and the first bone–implant contact visible in the radiograph (arrowhead) at the mesial and distal surfaces of the implant.

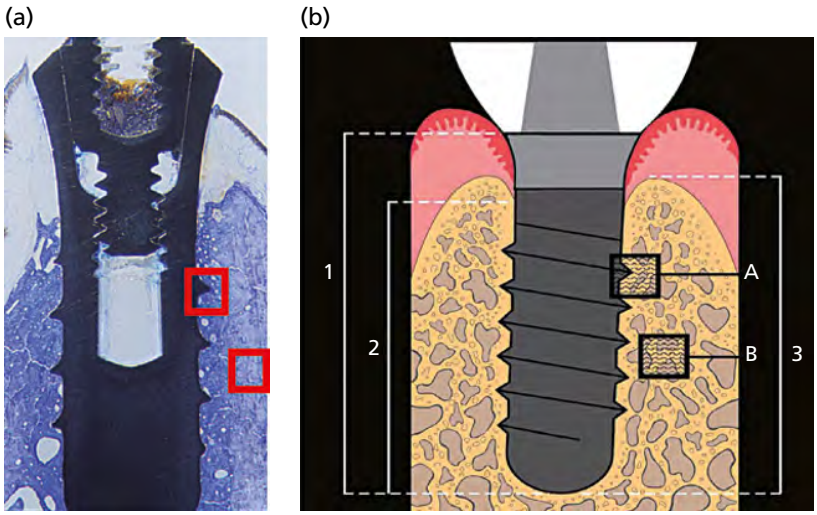

Fig. 13-18 (a) Histologic and (b) schematic representation of the histomorphometric measurements. 1, Implant length = distance from the base of the implant to the implant shoulder; 2, distance from the base of the implant to the most coronal point of bone–implant contact; 3, distance from the base of the implant to the alveolar bone crest. A, Percentage of mineralized bone density adjacent to the implant surface and B, 1 mm distant from the implant surface. Red frames in (a) correspond to zones A and B in (b).

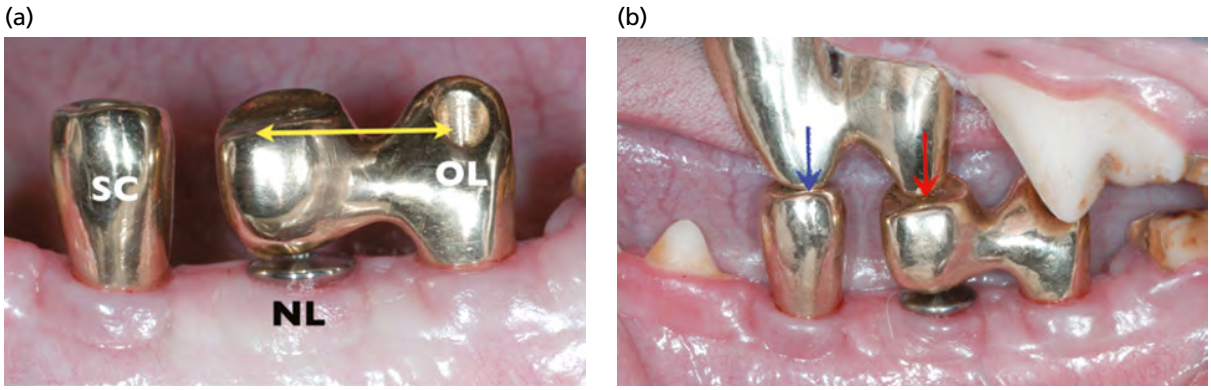

Fig. 13-19 Osseointegrated implants (a) not in occlusal contact and (b) in occlusal contact: a single crown unit with normal occlusal contacts and stable occlusion (SC) (blue arrow); a single non-loaded implant (NL) protected by a cantilever beam of 13.5 mm in length (yellow arrow); and an overloaded abutment (OL) with overt occlusal contacts through the cantilever beam (red arrow).

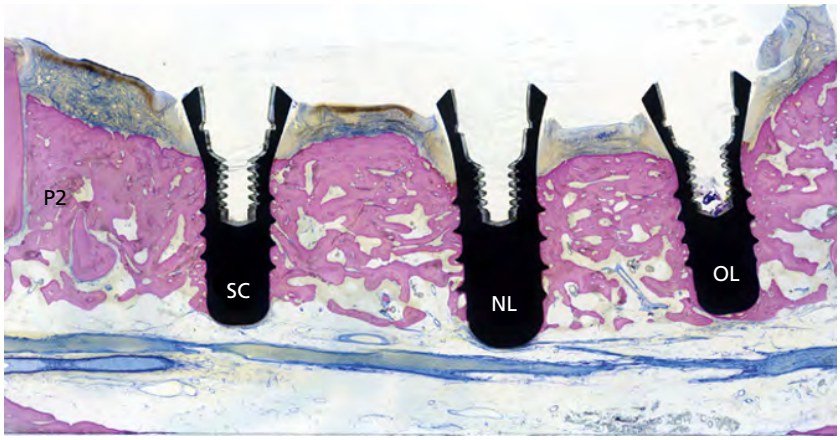

Fig. 13-20 Histological micrograph representing SC (single crown, normally occlusally loaded), NL (non-loaded), and OL (excessively occlusally loaded) implants after 6 months in function. P2, second mandibular premolar. Irrespective of loading conditions, full osseointegration of all units was achieved. Although the junctional epithelium had a normal length and was confined to the smooth surface part of the implants, the coronal-most bone in contact with the implant was on the rough part of the implant surface. Ground section, 80-µm thick. (Source: Lima *et al*. 2019. Reproduced with permission from Wiley.)

The mean implant stability quotient (ISQ) assessed by the RFA ranged from 58 to 67 for implants immediately after placement, and then increased to 74–78 at the time of crown placement 4 weeks later. Six months after loading, ISQ values varied between 74 and 80 with no significant differences between NL, SC, and OL sites. This was confirmed by a subsequent histological analysis of block sections prepared from the three different sites (Fig. 13-20) (Lima *et al*. 2019). This confirms previous results and documents that excessive occlusal load on implants does not affect osseointegration.

Static and cyclic loads on implants

While the study by Berglundh *et al*. (2005) addressed the possible influence of functional loading on the marginal bone levels of implants by applying a flat occlusal plane scheme and physiologic forces, many authors have studied the influence of loading forces exceeding physiologic functional conditions and impacting on the implants in a non-axial direction (Barbier & Schepers 1997; Gotfredsen *et al*. 2001a–c, 2002; Heitz-Mayfield *et al*. 2004).

The bone tissue reaction to axial loading was evaluated using conventional three-unit FDPs in the mandible of dogs, and compared with that to non-axial loading provoked by installing a distal cantilever of two implants (Barbier & Scheppers 1997). Bone remodeling was modest at the implant sites supporting conventional FDPs, while the non-axial load induced by the cantilever FDPs yielded a more pronounced bone response, including a higher activity of osteoclasts in the peri-implant bone. However, bone levels were not affected. This was interpreted as an adaptive phenomenon within the peri-implant bone as a result of non-axial loading.

The bone reactions around osseointegrated implants to static load were analyzed in three studies in dogs (Gotfredsen *et al*. 2001a–c, 2002). In the first study (Gotfredsen *et al*. 2001a), a lateral static load was induced by an orthodontic expansion screw at eight implants with a rough surface (TPS) in each dog. After a loading period of 24 weeks, during which time the screws were activated every 4 weeks from 0.0, 0.2, 0.4, to 0.6 mm, histologic and histometric analysis revealed no marginal bone loss at loaded and unloaded implant sites. Peri-implant bone density and mineralized bone–implant contact was higher at the loaded than the unloaded implant sites. This, again, was interpreted as lateral static load resulting in an *adaptive remodeling of the peri-implant bone*.

In the second study (Gotfredsen *et al*. 2001b), two TPS and two turned, "smooth" surface implants were exposed to the 24-week loading period in each dog using orthodontic expansion screws. These were activated by 0.6 mm every 4 weeks. The histologic and histometric analysis showed higher marginal bone levels around TPS implants than around turned implants. Likewise, the peri-implant bone density and mineralized bone–implant contact was higher around the rough surface than the smooth surface implants. Hence, it was concluded that surface roughness influences the bone reactions to the applied load. This, in turn, indicates that surface roughness may also be a determining factor in the remodeling process triggered by load at the bone–implant interface.

The third study (Gotfredsen *et al*. 2001c) analyzed the dynamics of applying a static load for various durations to implants in three dogs. After 24 weeks, the static load was maximally activated onto the implants of the right mandibular side giving a total loading period of 46 weeks at sacrifice. At 60 weeks, maximal activation of static load was set onto the implants of the left mandibular side, giving a total loading period of 10 weeks at sacrifice.

Fluorochrome labeling was performed at weeks 62, 64, 66, and 68. The dogs were sacrificed at week 70. A similar distribution of bone markers, bone

density, and bone–implant contact was observed at 10 and 46 weeks of static lateral loading. However, higher fluorochrome proportions were seen at 10 weeks compared with 46 weeks of lateral loading, suggesting higher adaptive activity at 10 weeks. Nevertheless, the structural adaptation appeared to be similar at the two observation periods.

In all three studies, greater bone–implant contact was identified at implants exposed to lateral static load application compared with non-loaded implants. Moreover, lateral static load failed to induce peri-implant bone loss or to enhance peri-implant bone loss. Hence, *lateral static load* does *not* appear to be detrimental to implants exhibiting peri-implant mucositis or peri-implantitis (Gotfredsen *et al*. 2001a–c).

In contrast to these findings are those from a study in dogs by Hoshaw *et al*. (1994). In this study, excessive cyclic axial forces were applied to implants (high cyclic [500 cycles/day] axial tension [10–300 N] for 5 consecutive days) placed in the tibiae of 10 animals. Bone loss was observed to occur around the neck of the implants after 1 year. Similar results were reported for a rabbit model (Duyck *et al*. 2001) in which dynamic load on implants resulted in the establishment of marginal crater defects, while no effects on osseointegration could be identified in other parts of the implants.

Load and loss of osseointegration

It has been reported (Isidor 1996, 1997) that excessive occlusal load may–under certain circumstances–lead to loss of osseointegration along the entire length of the implant, resulting in implant mobility. In this study, four monkeys received 18 self-tapping screw implants in the mandible after the first molars (n = 7), premolars (n = 8), and incisors (n = 3) had been extracted. Using an opposing maxillary splint in heavy supraocclusal contacts, *excessive occlusal load*, predominantly in the non-axial (lateral) direction, was applied to eight implants. Furthermore, cotton ligatures for increased plaque retention were placed around another 10 implants, resulting first in mucositis and later in peri-implantitis (Lindhe *et al*. 1992; Lang *et al*. 1993). After 18 months of excessive occlusal loading, two of the eight implants subjected to excessive occlusal load were lost. Two of the 10 implants with the cotton ligatures revealed partial loss of osseointegration as a result of plaque-induced peri-implantitis (Fig. 13-21a). Of the retained six implants subjected to excessive load, two showed complete loss of osseointegration with a connective tissue capsule formed around the entire outline of the implants (Fig. 13-21b). Radiographically, the two implants showing complete loss of osseointegration and clinical mobility showed a peri-implant radiolucency after 18 months of excessive occlusal load. However, no loss of marginal bone height was evident.

Another two excessively loaded implants (in one monkey) showed no loss of osseointegration whatsoever. Instead, an increase in bone density and the highest percentage of bone–implant contact area was seen at these implants compared with the remaining implants. This monkey also did not develop ligature-induced peri-implantitis (at three implants). Two implants under excessive occlusal load revealed a reduced bone–implant contact.

Thus, the study demonstrated that excessive occlusal load can, indeed, result in loss of osseointegration characterized by a fibrous connective tissue capsule around the implant, in contrast to the marginal bone loss encountered at implants with ligature-induced peri-implantitis. It must be noted, however, that the bone trabecular structure around the implant loosing osseointegration as a result of excessive occlusal load (Fig. 13.21b) was much less dense than that of, for example, the implants subjected to experimental peri-implantitis (Fig. 13.21a). Thus, this study does not support the concept that occlusal overload may lead to implant losses. Rather, it supports the fact that marginal bone loss at implants is associated with peri-implant disease.

Masticatory occlusal forces on implants

Closing and occlusal functional force distributions have been studied using one- (Lundgren *et al*. 1987, 1989; Falk *et al*. 1989, 1990) or three-dimensional

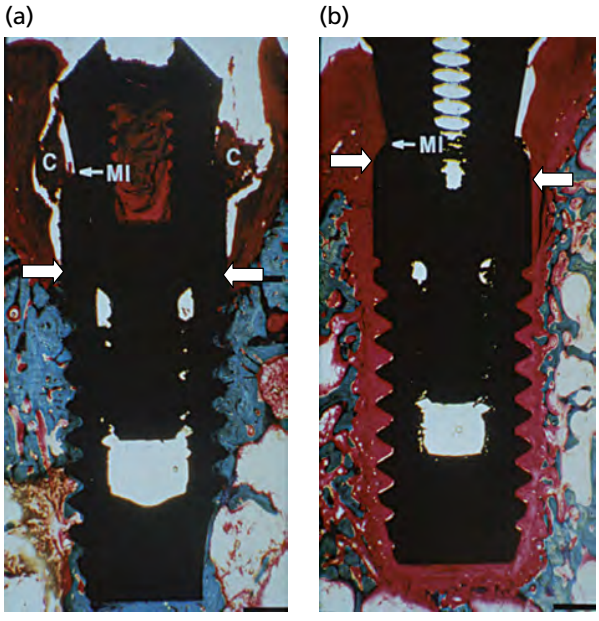

Fig. 13-21 (a) Osseointegrated implant with plaque accumulation. The marginal bone level is located apical to the margin of the implant. (b) Excessively loaded implant with complete loss of osseointegration. The marginal bone level is located near the margin of the implant. Fig. 13-22 (a) Eight strain gauge transducers placed into a maxillary completely removable prosthesis (A, anterior; P, posterior) and occluding against an implant-supported fixed mandibular dental prosthesis with cantilever beams of 16 mm. (Source: Lundgren *et al*. 1989. Reproduced from Quintessence.) (b) Chewing forces amounting to a maximum biting force of 80 N on the preferred (right) chewing side and 64 N on the non-preferred (left) chewing side (P, posterior; F, Front). While masticating, higher forces are applied to the cantilever beams than to the implant-supported part of the mandibular FDP. (Source: Data from Lundgren *et al*. 1989)

piezoelectric force transducers (Mericske-Stern *et al*. 1996, 2000; Mericske-Stern 1997, 1998).

Eight strain gauge transducers were mounted bilaterally in a maxillary complete denture to occlude with a mandibular implant-supported fixed cantilever prosthesis (Fig. 13-22a) (Lundgren *et al*. 1989). The study demonstrated that closing and chewing forces *increased* distally along the cantilever beams when occluding with complete dentures. Moreover, on both the preferred and non-preferred chewing sides, significantly larger closing and chewing forces were measured over the cantilever segments than over the implant-supported area (Fig. 13-22b). Also, the distally increasing force distribution pattern could be changed to a distally *decreasing* force distribution pattern by infra-occluding the second cantilever unit by as little as 100 µm. Such slight reductions in posterior occlusal contacts on cantilevers may need to be considered whenever the opposing masticatory unit is a complete removable dental prosthesis. However, maximal biting and chewing forces *decreased* distally along the cantilever beams when occluding with tooth-supported FDPs (Fig. 13-23) (Lundgren *et al*. 1987).

From this series of experimental clinical studies it was concluded that forces directed onto the implants *per se* are difficult to evaluate using the transducer methodology. Nevertheless, maximal closing forces were always substantially greater than chewing forces. In addition, each subject in these studies developed a preferred chewing side that was associated with higher chewing forces than the non-preferred chewing side (Lundgren *et al*. 1987, 1989; Falk *et al*. 1989, 1990).

Occlusal force distribution patterns have been studied using three-dimensional piezoelectric transducers for mandibular overdentures that were mounted onto two mandibular implants in the canine region designed to support either a ball joint- or a bar-retained mandibular complete removable prosthesis. Rigid bars provided the best distribution of forces in a vertical direction onto the two mandibular implants (Mericske- Stern *et al*. 1996; Mericske-Stern 1998). Moreover, short distal bar extensions did not negatively influence the force pattern (Mericske-Stern 1997).

When ball joint anchors were used to retain the mandibular overdenture, rather low forces were measured on the implants, particularly in a vertical direction (Mericske-Stern 1998). Vertical forces amounted to 60–140 N, while horizontal forces were much smaller (15–60 N).

Tooth–implant supported reconstructions

In reconstructing patients with inadequate masticatory function, oral implants are often used to increase the patients' chewing comfort (see Chapter 44) and provide additional chewing units in an edentulous posterior region. Occasionally, reconstruction of a chewing side may be contemplated, with the reconstruction supported by both a tooth and an implant (Fig. 13-24). In this way, problems with the location of the mental nerve in an area of a planned implant installation or lack of an adequate bone volume may be overcome.

Combined tooth–implant reconstructions have been associated with numerous clinical problems, including root intrusion as a potential clinical hazard of non-rigid connection. Hence, it has been claimed that natural teeth should not be connected to implants beneath a fixed prosthesis.

However, experimental studies have clearly established that no detrimental effects on the periodontium of abutment teeth can be demonstrated despite the different biomechanical condition mediated by a periodontal ligament as opposed to the ankylotic anchorage of an implant (Biancu *et al*. 1995).

In vivo measurements of vertical forces and bending moments during biting and chewing were carried out on 10 three-unit prostheses in the posterior mandibles of five patients. Each patient had two prostheses, one supported by two implants and the other supported by one implant and one tooth. The results demonstrated no major difference in functional load magnitudes between the support types. Obviously, functional loads were shared between the teeth and the implants (Rangert *et al*. 1991, 1995; Gunne *et al*. 1997).

Further studies using FEA showed no increased risk of stress concentrations at the neck of the implant (Gross & Laufer 1997; Laufer & Gross 1998).

Clinical studies reporting life table statistics in combined implant and tooth restorations do not show adverse effects of splinting teeth to implants. No increased risk of tooth intrusion was reported if the implant was rigidly connected to the tooth (Fugazzotto *et al*. 1999; Lindh *et al*. 2001; Naert *et al*. 2001a, b).

For 843 consecutive patients treated in a private practice set-up (Fugazzotto *et al*. 1999) with 1206 natural tooth–implant supported prostheses utilizing 3096 screw-fixed attachments, after 3–14 years in function, only nine intrusion problems were noted. All problems were associated with fractured or lost screws.

Probably the most relevant clinical study is a 10-year randomized controlled prospective study of 23 patients with residual mandibular anterior teeth (Gunne *et al*. 1999). Each patient received two three-unit FDPs either supported by two implants or, on the contralateral side, by one implant and one tooth, thus permitting intraindividual comparison. The distribution of the two types of FDPs in each jaw was randomized. Implant success rates, marginal bone changes, and mechanical complications were studied. The tooth–implant connection did not demonstrate any negative influences on the overall success rates for the 10-year period when compared with the implant–implant supported FDPs (Fig. 13-25). Hence, it was suggested that a prosthetic construction supported by both a tooth and an implant may be recommended as a predictable and reliable treatment alternative in the posterior mandible (Gunne *et al*. 1999).

Based on the available evidence, it can be stated that a combination of implant and tooth support for FDP is acceptable (Belser *et al*. 2000).

Although a systematic review (Lang *et al*. 2004) indicated that tooth–implant reconstructions have a 5-year survival rate of 94.1%, thus comparing very well with the 5-year survival rate of implant–implant reconstructions of 95.0% (Pjetursson *et al*. 2004), the 10-year survival rate of tooth–implant reconstructions (77.8%) appears to be significantly lower than the 10-year survival of implant–implant reconstructions (86.7%). However, owing to the fact that the former 10-year survival rate was based on only 60

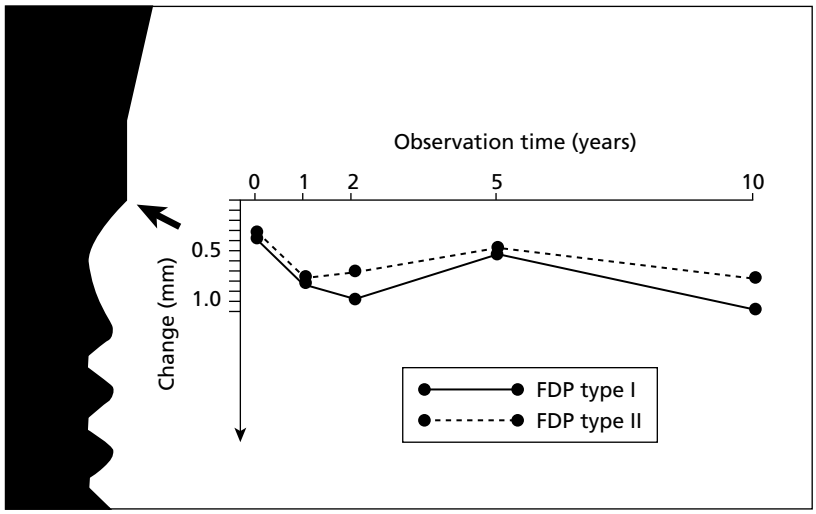

Fig. 13-25 Ten-year randomized controlled clinical trial of three-unit fixed dental prostheses (FDP), either implant–implant (type I) or tooth–implant (type II) supported. No differences in the crestal bone levels after 1, 2, 5, and 10 years in function. (Source: Lundgren *et al*. 1987. Reproduced with permission from Elsevier.)

(I–T) FDPs and the latter on only 219 (I–I) FDPs, the reliability of such 10-year survival rates has to be questioned.

The biomechanical aspects of implant–tooth-supported FDPs have been presented (Lundgren & Laurell 1994). As the implant is rigidly fixed within the alveolus and the tooth is surrounded by a periodontal ligament that allows minute movement, rigid FDP designs have been advocated.

The movement of the natural tooth abutment affects the load-bearing capacity of the FDP whenever a long-span FDP is constructed (e.g. a beam length of 24 mm or two premolar or molar pontics). Before the occlusal load is applied, the FDP acts as a cantilever construction. Upon loading, an angular deflection of the implant–crown unit of approximately 50 µm is noted. Along with bending of the long-span beam, an apical deflection of the tooth of approximately 50 µm is allowed, leading to bilateral (tooth and implant) support for the FDP.

If the tooth and implant only support a short-span FDP (e.g. a beam length of 12 mm or one premolar pontic only), however, the angular deflection of the implant–crown unit of approximately 50 µm and the bending of the short-span beam are insufficient to provide bilateral support for the bridge. Apical deflection of the tooth will not be achieved, and the implant will bear the entire occlusal load applied to the FDP. As indicated above, there is no doubt that osseointegration will cope with such functional loads.

Part 6: Periodontal Pathology

Chapter 14

Non-Plaque-Induced Gingival Diseases

Palle Holmstrup[1] and Mats Jontell[2]

[1] Department of Periodontology, School of Dentistry, University of Copenhagen, Copenhagen, Denmark
[2] Oral Medicine and Pathology, Institute of Odontology, The Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Introduction

Gingival inflammation, clinically presenting as gingivitis, is not always due to accumulation of plaque on the tooth surface, and non-plaque-induced inflammatory gingival reactions often present with characteristic clinical features (Holmstrup 1999; Holmstrup *et al*. 2018). They may have several causes, such as specific bacterial, viral, or fungal infection. The non-plaque-induced gingival lesions are often manifestations of systemic conditions but they may also represent pathological changes limited to gingival tissues. Inherited gingival lesions are seen in hereditary gingival fibromatosis, and several mucocutaneous disorders manifest as gingival inflammation. Typical examples of such disorders are lichen planus, pemphigoid, pemphigus vulgaris, and erythema multiforme. Allergic and traumatic lesions are other examples of non-plaque-induced gingival inflammation. Dentists, and especially specialists in periodontology, are the key healthcare providers in the diagnostic unraveling and treatment of patients affected by such lesions.

This chapter focuses on some of the most relevant non-plaque-induced inflammatory diseases of the gingival tissues, either because they have a serious outcome, are common, or because they are important examples for the understanding of the variety of tissue reactions that take place in the periodontium. For further information, the reader is referred to oral medicine textbooks and current reviews.

Although non-plaque-induced gingival diseases are less common than plaque-induced gingival disease it is important to note that they are often of major significance for the patients. A classification of the wide spectrum of lesions based upon their etiology (Box 14-1) was proposed at the 2017 World Workshop on Classification of Periodontal Diseases arranged by American Academy of Periodontology and European

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Box 14-1 Classification of non-plaque-induced gingival diseases and conditions.

Genetic/developmental disorders
- **Hereditary gingival fibromatosis**

Specific infections
- **Bacterial origin**
  - *Neisseria gonorrhea*
  - *Treponema pallidum*
  - *Mycobacterium tuberculosis* (tuberculosis)
  - *Streptococcus* gingivitis (strains of streptococcus)
- **Viral origin**
  - Coxsackie virus (hand, foot, and mouth disease)
  - Herpes simplex virus types 1 and 2 (primary or recurrent)
  - Varicella zoster virus (chicken pox or shingles affecting V nerve)
  - Molluscum contagiosum
  - Human papilloma virus
    - Squamous cell papilloma
    - Condyloma acuminatum
    - Verruca vulgaris
    - Focal epithelial hyperplasia
- **Fungal origin**
  - Candidosis
  - Other mycoses (e.g. histoplasmosis, aspergillosis)

Inflammatory and immune conditions
- **Hypersensitivity reactions**
  - Contact allergy
  - Plasma cell gingivitis
  - Erythema multiforme
- **Autoimmune diseases of skin and mucous membranes**
  - Pemphigus vulgaris
  - Pemphigoid
  - Lichen planus
  - Lupus erythematosus
- **Granulomatous inflammatory conditions (orofacial granulomatosis)**
  - Crohn's disease
  - Sarcoidosis

Reactive processes
- **Epulides**
  - Fibrous epulis (± calcification)
  - Calcifying fibroblastic granuloma
  - Pyogenic granuloma (vascular epulis)
  - Peripheral giant cell granuloma (or central)

Neoplasms
- **Premalignant (potentially malignant)**
  - Leukoplakia
  - Erythroplakia
- **Malignant**
  - Squamous cell carcinoma
  - Leukemia
  - Lymphoma

Endocrine, nutritional, and metabolic diseases
- **Vitamin deficiencies**
  - Vitamin C deficiency (scurvy)

Traumatic lesions
- **Physical/mechanical insults**
  - Frictional keratosis
  - Mechanically induced gingival ulceration
  - Factitious injury (self-harm)
- **Chemical (toxic) burn**
  - Etching
  - Chlorhexidine
  - Acetylsalicylic acid
  - Cocaine
  - Hydrogen peroxide
  - Dentifrice detergents
  - Paraformaldehyde or calcium hydroxide
- **Thermal insults**
  - Burns to gingival mucosa

Gingival pigmentation
- Melanoplakia
- Smoker's melanosis
- Drug-induced pigmentation (antimalarials; minocycline)
- Amalgam tattoo

Federation of Periodontology (Chapple *et al*. 2018). The content of this chapter is written based on this most recent classification system.

Genetic/developmental disorders

Hereditary gingival fibromatosis

Gingival hyperplasia (synonymous with gingival overgrowth, gingival fibromatosis) may occur as a side effect in response to systemic medications, including phenytoin, cyclosporine, and nifedipine. These lesions are to some extent plaque dependent and they are reviewed in Chapter 15. Gingival hyperplasia may also be of genetic origin. Such lesions are known as hereditary gingival fibromatosis (HGF) (Coletta & Graner 2006; Alminana-Pastor *et al*. 2017), which is an uncommon condition characterized by diffuse gingival enlargement, sometimes covering major parts of or the entire tooth surfaces. The lesions develop irrespective of effective plaque removal.

HGF may be an isolated disease entity or part of a syndrome (Gorlin *et al*. 1990), associated with other clinical manifestations, such as hypertrichosis (Horning *et al*. 1985; Cuestas-Carneiro & Bornancini 1988), mental retardation (Araiche & Brode 1959), epilepsy (Gorlin *et al*. 1990), hearing loss (Hartsfield *et al*. 1985), growth retardation (Bhowmick *et al*. 2001), and abnormalities of the extremities (Nevin *et al*. 1971; Skrinjaric & Baci 1989). Most cases are related to an autosomal dominant mode of inheritance, but cases have been described with an autosomal recessive background (Emerson 1965; Jorgensen & Cocker 1974; Singer *et al*. 1993). The most common syndrome of HGF includes hypertrichosis, epilepsy, and mental retardation; the latter two features, however, are not present in all cases (Gorlin *et al*. 1990).

Typically, HGF presents as large masses of firm, dense, resilient, insensitive fibrous tissue that covers the alveolar ridges (Coletta & Graner 2006) and extends over the teeth, resulting in extensive pseudopockets. The color may be normal or erythematous if inflamed (Figs. 14-1, 14-2). Depending on the extent of the gingival enlargement, patients complain of functional and esthetic problems. The enlargement may result in protrusion of the lips and the patient may chew on a considerable hyperplasia of tissue covering the teeth. HGF is seldom present at birth but may be noted at an early age. If the enlargement is present before tooth eruption, the dense fibrous tissue may interfere with or prevent the eruption (Shafer *et al*. 1983).

Studies have suggested that an important pathogenic mechanism may be enhanced production of transforming growth factor-beta1 (TGF-β1) which reduces the proteolytic activities of HGF fibroblasts, which again favors the accumulation of extracellular matrix (Coletta *et al*. 1999; Han *et al*. 2019). A locus for autosomal dominant HGF has been mapped to a region on chromosome 2 (Hart *et al*. 1998; Xiao *et al*. 2000), although at least two genetically distinct loci seem to be responsible for this type of HGF (Hart *et al*. 2000) and a novel locus for maternally inherited human gingival fibromatosis has been reported at human chromosome 11p15 (Zhu *et al*. 2007). Also, mutations of "Son of Sevenless" genes (*SOS1* and *SOS2*) may account for HGF (Hart *et al*. 2002)

The histologic features of HGF include moderate hyperplasia of a slightly hyperkeratotic epithelium with extended rete pegs. The underlying stroma is almost entirely made up of dense collagen bundles with only a few fibroblasts. Local accumulation of inflammatory cells may be present (Shafer *et al*. 1983). Histologic examination may facilitate the differential diagnosis from other genetically determined gingival enlargements, such as Fabry's disease, characterized by telangiectasia.

The treatment is surgical removal, often in a series of gingivectomies, but relapses are not uncommon. If the volume of the overgrowth is extensive, a repositioned flap to avoid exposure of connective tissue by gingivectomy may better achieve elimination of pseudopockets. Recently, an original approach for screening of optimal miRNAs with antifibrotic functions and pinpoint miR-335-3p has been suggested as a novel potential therapeutic target for HGF (Gao *et al*. 2019).

Fig. 14-1 Hereditary gingival fibromatosis. Facial aspect with partial coverage of teeth.

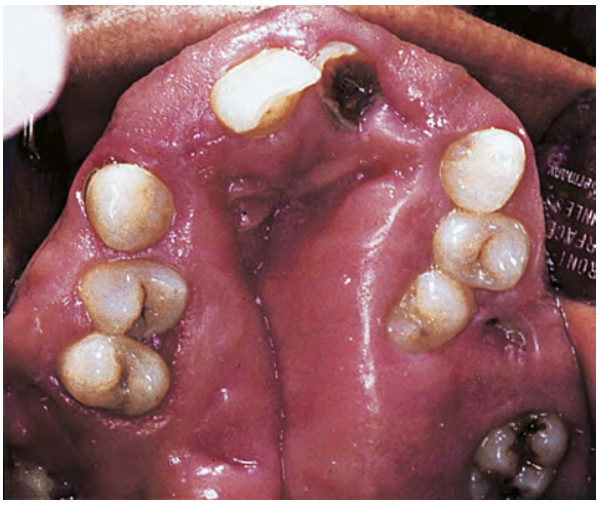

Fig. 14-2 Same patient as shown in Fig. 14-1. The maxillary gingival fibromatosis is severe and has resulted in total disfiguration of the dental arch.

Specific infections

Bacterial origin

Infective gingivitis and stomatitis may occur on rare occasions in both immunocompromised and non-immunocompromised individuals, when the homeostasis between innate host resistance and non-plaque-related pathogens is not maintained (Rivera-Hidalgo & Stanford 1999). The lesions may be due to bacteria and oral lesions may be the primary presentation of the infection. Typical examples of such lesions are due to infections with *Neisseria gonorrhea* (Scully 1995; Siegel 1996), *Treponema pallidum* (Scully 1995; Ramirez-Amador *et al*. 1996; Siegel 1996; Rivera-Hidalgo & Stanford 1999), Streptococci, *Mycobacterium chelonae* (Pedersen & Reibel 1989), *Mycobacterium tuberculosis* (Bansal *et al*. 2015), or other organisms (Blake & Trott 1959; Littner *et al*. 1982). Although oral manifestations of syphilis and gonorrhea are most likely to be observed during secondary disease, all stages of the disease can give rise to oral lesions. The gingival lesions manifest as fiery red edematous painful ulcerations, as asymptomatic chancres or mucous patches, or as atypical non-ulcerated, highly inflamed gingivitis. Biopsy supplemented by microbiologic examination reveals the background of the lesions.

Viral origin

A number of viral infections may manifest in the oral mucosa including gingiva (Clarkson *et al*. 2017).

Coxsackie virus (hand, foot, and mouth disease)

Hand, foot, and mouth disease (HFMD) is a viral illness caused most commonly by coxsackievirus A16 (CVA16) and enterovirus 71 (EV71) (Kimmis *et al*. 2018). It is a mild virus infection that mainly occurs during summer and autumn. The infection usually affects children under 10 years of age and spreads quickly across childcare centers and elementary schools. Adults may also be infected and usually after contact with infected children. The clinical characteristics of the disease is blisters in the oral mucosa, mainly the tongue, buccal mucosa, and the throat. A slight fever may occur. The patient also gets deep-seated blisters on the skin, mainly on the palms and around the fingers and toes. The infection debuts with red, dot-shaped changes that develop into vesicles, which rapidly rupture and become sores (Fig. 14-3).

Herpes simplex type 1 and 2

A number of viral infections are known to cause gingivitis (Scully *et al*. 1998b). The most important are the herpes viruses: herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2) and varicella zoster virus. These viruses usually enter the human body in childhood and may give rise to oral mucosal disease followed by periods of latency and sometimes reactivation. HSV-1 usually causes oral manifestations, whereas herpes HSV-2 is mainly involved in anogenital infections and only occasionally is involved in oral infection (Scully 1989; Petti & Lodi 2019).

Primary herpetic gingivostomatitis

HSV infections are among the most common viral infections. HSV is a DNA virus with low infectiosity, which after entering the oral mucosal epithelium, penetrates a neural ending and by retrograde transport through the smooth endoplasmic reticulum (200–300 mm/day) travels to the trigeminal ganglion where it can remain latent for years. The virus has also been isolated in extraneural locations such as the gingiva (Amit *et al*. 1992). Sometimes HSV may also be involved in recurring erythema multiforme. It is presently unknown whether the virus plays a role in other oral diseases, but HSV has been found in gingivitis (Ehrlich *et al*. 1983), acute necrotizing gingivitis (Contreras *et al*. 1997), and periodontitis (Parra & Slots 1996).

When a newborn is infected, sometimes from the parent's recurrent herpes labialis, he/she is often wrongly diagnosed as "teething". With increased hygiene in industrialized societies, more and more primary infections occur at older ages than occur during adolescence or adulthood. It has been estimated in the USA that there is about half a million cases of primary infection per year (Overall 1982). The primary herpetic infection may run an asymptomatic course in early childhood, but may also give rise to severe gingivostomatitis, which occurs mostly before adolescence (Fig. 14-4). This manifestation includes painful severe gingivitis with redness, ulcerations with serofibrinous exudate, and edema accompanied by stomatitis (Figs. 14-5, 14-6). The incubation period is 1 week. A characteristic feature is the formation of vesicles, which rupture, coalesce, and leave fibrin-coated ulcers (Scully *et al*. 1991; Miller & Redding 1992). Fever and lymphadenopathy are other classic features. Healing occurs spontaneously without scarring in 10–14 days (Fig. 14-6). During this period, pain can render eating difficult.

Fig. 14-4 Herpetic gingivostomatitis in a 3-year-old child. Erythematous swelling of attached gingiva with serofibrinous exudate along the gingival margin.

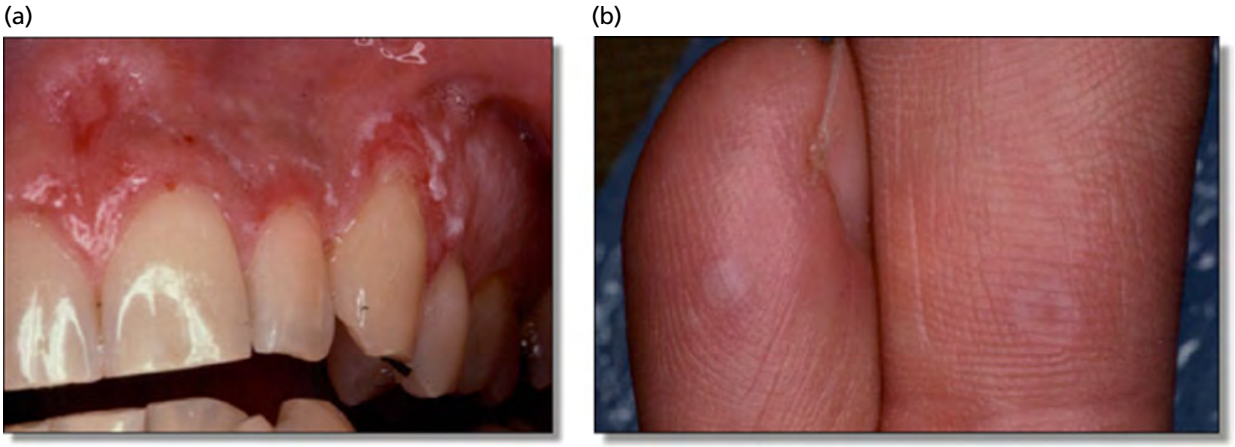

Fig. 14-3 Hand-foot-and-mouth disease. Gingival lesions (a) are rare but common on hands and feet (b).

The virus remains latent in the ganglion cell, probably through integration of its DNA in that of the chromosomal DNA (Overall 1982). Reactivation of the virus occurs in 20–40% of primary infected individuals (Greenberg 1996) and usually presents as herpes labialis, but recurrent intraoral herpes infections are also seen. Herpes labialis occurs in general more than once per year, usually at the same location on the vermilion border and/or the skin adjacent to it, where neural endings are known to cluster. A large variety of factors trigger reactivation of latent virus: trauma, ultraviolet light exposure, fever, menstruation, and others (Scully *et al*. 1998b).

While recurrences at the vermilion border are well recognized, recurrent intraoral herpes lesions often remain undiagnosed because they are considered to be aphthous ulcerations (Lennette & Magoffin 1973; Sciubba 2003), irrespective of the fact that aphthous ulcers do not affect keratinized mucosa. Recurrent intraoral herpes typically presents a less dramatic course than does the primary infection. A characteristic manifestation is a cluster of small painful ulcers in the attached gingiva and hard palate (Yura *et al*. 1986) (Fig. 14-7). The diagnosis can be made on the basis of the patient history and clinical findings supported by isolation of HSV from lesions. The polymerase chain reaction (PCR) has largely superseded most other methods and is a rapid and reliable diagnostic tool providing subtype diagnosis. Laboratory diagnosis may also involve examination of a blood sample for increased antibody titer against HSV. However, this is most relevant in cases of primary infection, because the antibody titer remains elevated for the rest of the individual's lifetime. The histopathologic features of cytologic smears from the gingival lesions are not specific, but the presence of giant cells and intranuclear inclusion bodies may indicate intracellular activity of the virus (Burns 1980).

Immunodeficient patients, such as human immunodeficiency virus (HIV)-infected individuals, are at increased risk of acquiring the infection (Holmstrup & Westergaard 1998). In the immunocompromised

Fig. 14-5 Herpetic gingivostomatitis affecting palatal gingivae. Numerous vesicles and small ulcerations.

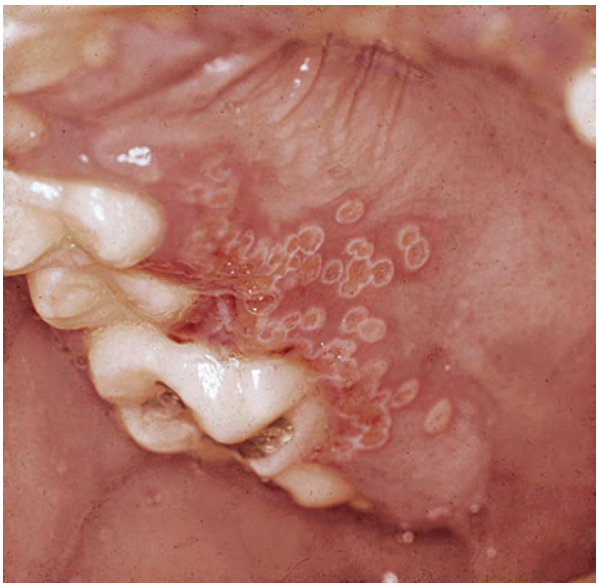

Fig. 14-7 Recurrent intraoral herpes infection. Ruptured vesicles of right palatal gingivae and mucosa.

(a)

(b)

Fig. 14-6 Herpetic gingivostomatitis in a 38-year-old woman. Widespread ulceration of the lower lip mucosa and gingivae (a). Same patient 4 weeks later (b). Healing without loss of tissue or scar formation.

patient the recurrence of herpes infection, either gingival or elsewhere, may be severe and even life threatening.

The treatment of herpetic gingivostomatitis includes careful plaque removal to limit bacterial superinfection of the ulcerations, which delays their healing. In severe cases, including patients with immunodeficiency, the systemic use of antiviral drugs such as acyclovir, valacyclovir, or famciclovir is recommended (O'Brien & Campoli-Richards 1989; Mindel 1991; Arduino & Porter 2006). There is only weak evidence for treating children with acyclovir. However, it may be considered within the first 72 hours of symptom onset, but only if clear symptoms of gingivostomatitis exist and if the patient suffers from substantial pain or dehydration (Goldman 2016). Resistance to acyclovir, especially among immunodeficient patients on long-term therapy, is a growing concern (Westheim *et al*. 1987) and explains why other antiviral drugs may be relevant. Prophylactic antiviral treatment before dental treatment has been recommended for patients at risk of a recurrence, as well as to minimize transmission of the disease (Miller *et al*. 2004).

Varicella zoster virus

Varicella zoster virus causes varicella (chicken pox) as the primary self-limiting infection. It occurs mainly in children and later reactivation of the virus in adults causes herpes zoster (shingles). Both manifestations can involve the gingiva (Straus *et al*. 1988; Scully 1995). Chicken pox is associated with fever, malaise, and a skin rash. The intraoral lesions are small ulcers, usually on the tongue, palate, and gingiva (Miller 1996; Scully *et al*. 1998b). The virus remains latent in the dorsal root ganglion from where it can be reactivated years after the primary infection (Rentier *et al*. 1996). Later reactivation results in herpes zoster, with unilateral lesions following the infected nerve (Miller 1996). The reactivation normally affects the thoracic ganglia in elderly or immunocompromised patients. Reactivation of virus from the trigeminal ganglion occurs in 20% of reported cases (Hudson & Vickers 1971). If the second or third branch of the trigeminal nerve is involved, skin lesions may be associated with intraoral lesions, or intraoral lesions may occur alone (Eisenberg 1978), for instance affecting the palatal gingiva (Fig. 14-8). Initial symptoms are pain and paraesthesia, which may be present before lesions occur (Greenberg 1996). The associated pain is usually severe. The lesions, which often involve the gingiva, start as vesicles. They soon rupture to leave fibrin-coated ulcers, which often coalesce to irregular forms (Millar & Troulis 1994) (Fig. 14-8). In immunocompromised patients, including those infected with HIV, the infection can result in severe tissue destruction with tooth exfoliation and necrosis of alveolar bone and high morbidity (Melbye *et al*. 1987; Schwartz *et al*. 1989). The diagnosis is usually obvious due to the unilateral occurrence of lesions associated with severe pain. Healing of the lesions usually takes place in 1–2 weeks.

Fig. 14-8 Herpes zoster of left palatal gingiva and mucosa. Irregular fibrin-coated ulcerations with severe pain.

Treatment consists of a soft or liquid diet, rest, atraumatic removal of plaque, and diluted chlorhexidine rinses. This may be supplemented by antiviral drug therapy. Postherpetic neuralgia is a dreaded complication of herpes zoster, which can persist for months to years, potentially resulting in marked debilitation and reduced quality of life. Targeting individuals aged 60 years and above, vaccination appears to be cost-effective (Carpenter *et al*. 2019).

Molluscum contagiosum virus

Molluscum contagiosum is a contagious self-limited viral infection that commonly affects the skin. Involvement of mucous membranes is rare. The disease can affect individuals of any age, but its prevalence is higher among infants (2–5 years), sexually active adults, and immunocompromised individuals (de Carvalho *et al*. 2012). It is caused by a member of a DNA pox virus, and it has an incubation period of 2–7 weeks. It is characterized by a single/multiple, round/dome-shaped, pink waxy papule ranging from 1 mm to 5 mm on face, eyelids, neck, axilla, and thigh (Fornatora *et al*. 2001). Gingival affection has been reported but is extremely rare. The histopathological features are characteristic, and the presence of Molluscum bodies is diagnostic.

Human papillomavirus

Close to 200 genotypes or strains of human papillomavirus (HPV) have been identified. Viruses selectively infect mucous membranes and skin squamous epithelium. However, only very few of the genotypes are associated with infections in the oral mucosa (Syrjänen 2018). Unlike herpes infections,

HPV infections are more chronic and rarely cause any symptoms. Up to 80% of the population of the western world are infected at a specific time-point. Oral sex behaviors and open-mouthed kissing are probably reasons for oral HPV infection, but it remains unclear whether other pathways of infection exist (Jiang & Dong 2017). The infections are associated with several tumor-like conditions, benign as well as malignant. There are 15 subtypes of HPV that are associated with high risk of malignant change. Of these, HPV type 16 and 18 are the most common causes of HPV-associated cancer. As the gingival pocket is the only site in the oral mucosa in which basal cells, the known targets of HPV at other mucosal sites, are normally exposed to the environment, it has been hypothesized that this could be the site of a latent HPV infection in oral mucosa. Different treatment strategies are available for papillomas/condylomas, verrucas, and focal epithelial hyperplasia such as cryotherapy, electrosurgery, surgical removal, laser therapy, and trichloroacetic acid. An increased awareness of HPV-positive squamous cell carcinomas is the background of increasing utilization of HPV vaccines, and there is some epidemiological evidence that HPV vaccine may provide a possible solution for preventing oral HPV infection. Biological and epidemiological data regarding the link between sexual behavior and HPV-associated cancers indicate a connection, but definitive data are lacking.

Squamous cell papilloma and verruca vulgaris

Squamous cell papilloma and verruca vulgaris are the most common clinical types of intraoral HPV infections. Papillomas are probably caused by HPV types 6 and 11, while verruca vulgaris is associated with HPV types 2, 4, and 57. Clinically, there is no clear dividing line between the two changes. They can be manifested as small white icicle-like projections (Fig. 14-9), but the lesions can also have a more cauliflower-like appearance and, if so, they are usually the same color as the surrounding mucosa. The size rarely exceeds 10 mm. The patient may be aware of the infections, but they rarely give rise to any symptoms.

Condyloma acuminatum

Condyloma acuminatum (Fig 14-10) has been reported to affect the mucosa of the gingiva, cheeks, lips, and hard palate. This HPV infection was previously considered as a completely separate entity, but since condylomas are associated with the same subtypes as papillomas, it now seems questionable whether the two clinical types should be separated. There are no clear differences with regard to the clinical characteristics.

Focal epithelial hyperplasia

Focal epithelial hyperplasia (FEH) is an intraoral HPV infection which is strongly associated with subtypes 13 and 32. The infection is a benign familial disorder with autosomal-recessive inheritance. FEH is most prevalent among Native American and Mexican Indians, Indigenous peoples of South America, and Eskimos. Clinically, this HPV infection differs from the others in that it exhibits multiple warty circular swellings of the mucosa. The size may vary, but rarely exceeds 5 mm. FEH has the same color as the healthy oral mucosa. Sometimes the changes may coalesce into larger lesions.

Fungal origin

Fungal infection of the oral mucosa includes a range of diseases such as aspergillosis, blastomycosis, candidosis, coccidioidomycosis, cryptococcosis, histoplasmosis, mucormycosis, and paracoccidioidomycosis infections (Scully *et al*. 1998b), but some of the infections are very uncommon and not all of them manifest as gingivitis. This section focuses on candidosis and histoplasmosis, both of which may cause gingival infection.

Fig. 14-9 Squamous cell papilloma of palatal gingiva.

Fig. 14-10 Gingival condyloma acuminatum.

Candidosis

Various *Candida* species are recovered from the mouth of humans, including *C. albicans, C. glabrata, C. krusei, C. tropicalis, C. parapsilosis,* and *C. guillermondii* (Cannon *et al*. 1995). The most common fungal infection of the oral mucosa is candidosis, mainly caused by the organism *C. albicans* (Scully *et al*. 1998b). *C. albicans* is a normal commensal of the oral cavity but also an opportunistic pathogen (Lewis & Williams 2017). The prevalence of oral carriage of *C. albicans* in healthy adults ranges from 3% to 48% (Scully 1995), the large variation being due to differences in examined populations and the procedures used. The proportion of *C. albicans* in the total oral yeast population can reach about 50–80% (Wright *et al*. 1985). The proteinase-positive strains of *C. albicans* are associated with disease (Negi *et al*. 1984; Odds 1985) and invasion of keratinized epithelia such as that of the gingiva. Invasion and increased desquamation is due to hyaluronidase production. Infection by *C. albicans* usually occurs as a consequence of reduced host defense (Holmstrup & Johnson 1997), including immunodeficiency (Holmstrup & Samaranayake 1990) (Figs. 14-11, 14-12, 14-13), reduced saliva secretion, smoking, and treatment with corticosteroids, but may be due to a wide range of predisposing factors. The occurrence of oral candidosis may act as a predictor of immune and virologic failure in HIV-infected patients treated with antiviral drugs (Miziara & Weber 2006). Disturbances in the oral microbial flora, such as after therapy with broad-spectrum antibiotics, may also lead to oral candidosis. The predisposing factors are, however, often difficult to identify. Based on their site, infections may be defined as superficial or systemic. Candidal infection of the oral mucosa is usually a superficial infection, but systemic infections are not uncommon in debilitated patients.

In otherwise healthy individuals, oral candidosis rarely manifests in the gingiva. This is surprising when considering the fact that *C. albicans* is frequently isolated from the subgingival flora of patients with severe periodontitis (Slots *et al*. 1988). The most common clinical characteristic of gingival candidal infections is redness of the attached gingiva, often associated with a granular surface (Fig. 14-12).

Various types of oral mucosal manifestations are pseudomembranous candidosis (also known as thrush in neonates), erythematous candidosis, plaque-type candidosis, and nodular candidosis (Holmstrup & Axell 1990). Pseudomembranous candidosis shows whitish patches (Fig. 14-11), which can be wiped off the mucosa with an instrument or gauze to leave a slightly bleeding surface. The pseudomembranous type usually has no major symptoms. Erythematous lesions can be found anywhere in the oral mucosa (Fig. 14-13). The intensely red lesions are usually associated with pain, which is sometimes severe. The plaque type of oral candidosis usually affects smokers and presents with a whitish plaque, which cannot be removed. There are usually no symptoms and the lesion is clinically indistinguishable from oral leukoplakia. Nodular candidal lesions are infrequent in the gingiva. Slightly elevated nodules of a white or reddish color characterize them (Holmstrup & Axell 1990).

A diagnosis of candidal infection can be accomplished on the basis of culture, smear, and biopsy. Definitive identification of *Candida* can be made through a variety of supplemental tests usually involving evaluation of morphological and physiological characteristics of an isolate. Increasingly, molecular-based methods are being employed with a number of species-specific PCR approaches for *Candida* being used (Williams & Lewis 2000). A culture on Nickerson's medium at room temperature is easily handled in the dental office. Microscopic examination of smears from suspected lesions is another easy diagnostic procedure, either performed as direct examination by phase-contrast microscopy or as light microscopic examination of periodic acid–Schiff-stained or Gram-stained smears. Mycelium-forming cells in the form of hyphae or pseudohyphae and blastospores are seen in great numbers among masses of desquamated cells. Since oral carriage of *C. albicans* is common among healthy individuals, positive culture and smear does not necessarily imply candidal infection (Rindum *et al*. 1994). Quantitative assessment of the mycologic findings and the presence of clinical changes compatible with the above types of lesions are necessary for a reliable diagnosis, which can also be obtained on the basis of identification of hyphae or pseudohyphae in biopsies from the lesions.

Topical treatment involves application of antifungals, such as nystatin, amphotericin B, or miconazole. Nystatin may be used as an oral suspension. Because it is not resorbed, it can be used in pregnant or lactating women. Miconazole exists as an oral gel. It should not be given during pregnancy and it can interact with anticoagulants and phenytoin. The treatment of severe or generalized forms also involves systemic antifungals such as fluconazole. It should be emphasized that fluconazole has several pharmacokinetic drug–drug interactions (Niwa *et al*. 2014).

There are indications that candidal infection is the background of cases of gingival inflammation sometimes denoted linear gingival erythema (Fig. 14-14) (Winkler *et al*. 1988; Robinson *et al*. 1994), but studies have revealed a microflora comprising both *C. albicans* and a number of periopathogenic bacteria

Fig. 14-14 Candidal infection of maxillary gingiva, sometimes denoted linear gingival erythema in an HIV-infected patient. Red banding along the gingival margin, which does not respond to conventional therapy.

consistent with those seen in conventional periodontitis, that is *Porphyromonas gingivalis*, *Prevotella intermedia*, *Actinobacillus actinomycetemcomitans*, *Fusobacterium nucleatum*, and *Campylobacter rectus* (Murray *et al*. 1988, 1989, 1991).

Histoplasmosis

Histoplasmosis is a granulomatous disease caused by *Histoplasma capsulatum*, a soil saprophyte found mainly in feces from birds and cats. The infection occurs in the North-Eastern, South-Eastern, mid Atlantic, and central states of the USA. It is also found in Central and South America, India, East Asia, and Australia. Histoplasmosis is the most frequent systemic mycosis in the USA. Airborne spores from the mycelial form of the organism mediate it (Rajah & Essa 1993). In the normal host, the course of the infection is subclinical (Anaissie *et al*. 1986). The clinical manifestations include acute and chronic pulmonary histoplasmosis, and a disseminated form, mainly occurring in immunocompromised patients (Cobb *et al*. 1989). Oral lesions have been seen in 30% of patients with pulmonary histoplasmosis and in 66% of patients with the disseminated form (Weed & Parkhill 1948; Loh *et al*. 1989). The oral lesions may affect any area of the oral mucosa (Chinn *et al*. 1995), including the gingiva, which appears to be one of the most frequent sites affected (Hernandez *et al*. 2004). The lesions start as nodular or papillary, and later may become ulcerative with loss of gingival tissue and pain (Figs. 14-15, 14-16). They are sometimes granulomatous and the clinical appearance may resemble a malignant tumor (Boutros *et al*. 1995). The diagnosis is based on clinical appearance and histopathology and/or culture, and the treatment consists of systemic antifungal therapy.

Inflammatory and immune conditions

Hypersensitivity reactions

Contact allergy

Allergic manifestations in the oral mucosa are uncommon. Several mechanisms may be involved in allergy, which is an exaggerated immune reaction. Oral

Fig. 14-15 Gingival histoplasmosis with loss of periodontal tissue around the lower right second premolar.

Fig. 14-16 Same patient as shown in Fig. 14-15. Lingual aspect with ulceration in the deeper part of the crater-like lesion.

Fig. 14-17 Drug-induced erythema multiforme sometimes involves the gingiva. This is a mucosal lesion due to azathioprine, which is an antimetabolite used for immunosuppression.

mucosal reactions may be type I reactions (immediate type), which are mediated by IgE, or more often they are type IV reactions (delayed type) mediated by T cells. The rare intraoral occurrence may be due to the fact that much higher concentrations of allergen are required for an allergic reaction to occur in the oral mucosa than in skin and other surfaces (Amlot *et al*. 1985; Luders 1987; Holmstrup 1999). This section covers allergies to dental restorative materials, toothpastes, mouthwashes, chewing gum, and food.

The clinical manifestation of type IV allergy (contact allergy) occurs after a period of 12–48 hours following contact with the allergen. The effects on oral mucosa have been denoted contact lesions and prior contact with the allergen resulting in sensitization is a prerequisite for these reactions to occur (Holmstrup 1991). Oral mucosal reactions to restorative materials include reactions to mercury, nickel, gold, zinc, chromium, palladium, and acrylics (Ovrutsky and Ulyanow 1976; Zaun 1977; Bergman *et al*. 1980; Council on Dental Materials Instruments and Equipment Workshop. Biocompatibility of metals in dentistry – Recommendations for Clinical Implementation 1984; Fisher 1987). The lesions, which may infrequently affect the gingiva, have clinical similarities with those for oral lichen planus, which is why they are denoted oral lichenoid lesions (see later in this chapter) or oral leukoplakia (Fig. 14-17). They are reddish or whitish, sometimes ulcerated lesions, but one of the crucial diagnostic observations is that the lesions resolve after removal of the offending material (Feller *et al*. 2017). Additional patch testing to identify the exact allergen gives supplementary information (Larsen *et al*. 2017), but for dental amalgam it has been shown that there is no obvious correlation between the result of an epicutaneous patch test and the clinical result after removal of the fillings (Skoglund 1994). A clinical manifestation confined to the area of contact with the offending restorative material and the result after replacing this material indicate the diagnosis (Bolewska *et al*. 1990).

Contact allergy rarely occurs after the use of toothpastes (Sainio & Kanerva 1995; Skaare *et al*. 1997) and oral rinses (Sainio & Kanerva 1995; Larsen *et al*. 2017). The constituents responsible for the allergic reactions may be flavor additives, for instance carvone and cinnamon (Drake & Maibach 1976) or preservatives (Duffin & Cowan 1985). These flavoring additives may be used also in chewing gum and result in similar forms of gingivostomatitis (Kerr *et al*. 1971). The clinical manifestations of allergy include a diffuse, fiery red edematous gingivitis, sometimes with ulcerations or whitening (Fig. 14-18). The labial, buccal, and tongue mucosa may be similarly affected, and

Fig. 14-18 Lichenoid contact lesion of the left buccal mucosa due to type IV hypersensitivity to mercury. The lesion is confined to the zone of contact with the amalgam fillings. These lesions usually recover after replacement of the mercury-containing fillings with composites or other materials devoid of allergy-provoking components.

cheilitis may also be seen. These characteristic clinical manifestations form the basis of the diagnosis, which may be supported by resolution of the lesions after stopping use of the allergen-containing agent.

The gastrointestinal tract is the largest immunologic organ in the body. It is constantly bombarded by a myriad of dietary proteins. Despite the extent of protein exposure, very few patients develop food allergies due to development of oral tolerance to these antigens (Chehade & Mayer 2005). Allergic reactions attributable to food may manifest both as type I and type IV reactions. Type I reaction with severe swelling has been described after intake of food components such as peanuts or pumpkin seeds. Birch pollen allergy is associated with some types of oral mucosal allergy, and >20% of patients with oral allergy may be hypersensitive to kiwi, peach, apple, chestnut, and salami (Yamamoto *et al*. 1995; Antico 1996; Asero *et al*. 1996; Liccardi *et al*. 1996,; Rossi *et al*. 1996; Helbling 1997; Wuthrich 1997). Another food allergen that can result in gingivitis or gingivostomatitis is red pepper (Serio *et al*. 1991; Hedin *et al*. 1994). Unless it has been demonstrated that the lesions resolve after removal of the allergen, the diagnosis is difficult to establish.

Plasma cell gingivitis

Plasma cell gingivitis (PCG) is an unusual benign inflammatory condition of unclear etiology (Jadwat *et al*. 2008), although it is thought to be a hypersensitive reaction to an allergen. PCG is most often encountered in young people (Hedin *et al*. 1994). It is often observed in the anterior part of the gingiva and often extending to the mucogingival junction. The lesion is generally asymptomatic and it is characterized by macular lesions that are bright red, velvety, sharply circumscribed, and flat to slightly elevated (Fig 14-19). Histopathologically, PCG is defined mainly by a dense, bandlike infiltrate of plasma cells in the lamina propria. The diagnosis is not well defined and different gingival conditions where plasma cells dominate have been classified as PCG. Supported by debridement, the condition usually heals spontaneously, although it may take years before it disappears.

Fig. 14-19 Diffuse gingivitis and cheilitis due to contact allergy to a flavor additive in toothpaste.

Erythema multiforme

Erythema multiforme (EM) is a reactive acute, sometimes recurrent, vesiculobullous disease affecting mucous membranes and skin. A general malaise often precedes the lesions. The spectrum of the disease is from a self-limited, mild, exanthematic, cutaneous variant with minimal oral involvement to a progressive, fulminating, severe variant with extensive mucocutaneous epithelial necrosis. The latter form of the disease has been described as Stevens–Johnson syndrome, with widespread mucous membrane lesions, that is oral, ocular, and genital, in addition to skin lesions (Lozada-Nur *et al*. 1989; Assier *et al*. 1995; Bystryn 1996; Ayangco & Rogers 2003). The multilocular entity has to be differentiated from other disorders such as Reiter's and Behçet's syndromes, which also affect the eyes, the oral mucosa, and often the genitalia. The pathogenesis of EM remains unknown, but the disease appears to be a cytotoxic immune reaction against keratinocytes (Ayangco & Rogers 2003) precipitated by a wide range of factors, including HSV (Lozada & Silverman 1978; Nesbit & Gobetti 1986; Ruokonen *et al*. 1988; Miura *et al*. 1992; Aurelian *et al*. 1998; Lucchese 2018), *Mycoplasma* pneumonia (McKellar & Reade 1986; Stutman 1987), and various drugs (Bottiger *et al*. 1975; Gebel & Hornstein 1984; Kauppinen & Stubb 1984; Celentano *et al*. 2015) (Fig. 14-20).

EM may occur at any age but most frequently affects young individuals. It may or may not involve the oral mucosa, but oral involvement occurs in as many as 25–60% of cases (Huff *et al*. 1983); sometimes it is the only involved site. The characteristic oral lesions comprise swollen lips often with extensive crust formation of the vermilion border (Fig. 14-21). The basic lesions, however, are bullae that rupture and leave extensive ulcers, usually covered by heavy yellowish fibrinous exudates sometimes described as pseudomembranes (Fig. 14-22). Such lesions may also involve the buccal mucosa and gingiva (Huff *et al*. 1983; Lozada-Nur *et al*. 1989; Scully *et al*. 1991; Barrett *et al*. 1993). The skin lesions are characteristic

Fig. 14-20 Plasma cell gingivitis.

Fig. 14-21 Erythema multiforme with crust formation of the vermilion border of the lower lip.

Fig. 14-22 Erythema multiforme with ulceration covered by heavy fibrin exudate.

Fig. 14-23 Erythema multiforme. Skin lesion with characteristic iris appearance. A central bulla is surrounded by a blanched halo within an erythematous zone.

due to the iris appearance with a central bulla surrounded by a blanched halo within an erythematous zone (Fig. 14-23). Similar intraoral lesions do occur but they are infrequent. The disease is usually self-limiting but recurrences are common. Healing of the lesions may take several weeks (Fabbri & Panconesi 1993).

The histopathology of EM shows intra- or subepithelial separation of the epithelium from connective tissue with perivascular inflammation (Reed 1985). Immunohistochemical findings are non-specific and in most instances the diagnosis relies on the clinical findings. Although periodontal lesions are not the most frequent intraoral manifestation, they can sometimes pose a differential diagnostic problem. The typical crusty ulcerations of the vermilion border and the heavy fibrin exudates covering intraoral lesions are indicative of EM, and therefore are sometimes denoted erythema multiforme exudativum. The mucosal ulcerations may take weeks to heal and they are painful (Lozada-Nur *et al*. 1989).

As for any intraoral ulcerations, gentle plaque control and professional cleaning are mandatory. The treatment often involves systemic corticosteroids, but topical treatment may be effective in cases with minor lesions. Cases of recurrent EM caused by herpes infection may require prophylactic use of 400 mg acyclovir twice daily.

Autoimmune diseases of skin and mucous membranes

A variety of mucocutaneous disorders present gingival manifestations, sometimes in the form of desquamative lesions or ulceration of the gingiva. The most important of these diseases are lichen planus, pemphigoid, pemphigus vulgaris, erythema multiforme, and lupus erythematosus.

Pemphigus vulgaris

Pemphigus is a group of autoimmune diseases characterized by formation of intraepithelial bullae in skin and mucous membranes (McMillan *et al*. 2015). The group comprises several variants of which pemphigus vulgaris (PV) is the most common and most serious (Barth & Venning 1987).

Individuals of a Jewish or Mediterranean background are more often affected by PV than others. This is an indication of a strong genetic background to the disease (Pisanti *et al*. 1974). The disease may occur at any age but is typically seen in the middle-aged or elderly. It presents with widespread bulla formation, often including large areas of skin, and if left untreated the disease is life threatening. Intraoral onset of the disease with bulla formation is very common and lesions of the oral mucosa, including the gingiva, are frequently seen. Early lesions may resemble aphthous ulcers (Fig. 14-24), but widespread erosions are common at later stages (Fig. 14-25). Gingival involvement may present as painful desquamative lesions or as erosions or ulcerations, which are the remains of ruptured bullae. Such lesions may be indistinguishable from benign mucous membrane pemphigoid (Zegarelli & Zegarelli 1977; Sciubba 1996) (Fig. 14-26). Since the bulla formation is located in the

Fig. 14-24 Pemphigus vulgaris. Initial lesion resembling recurrent aphthous stomatitis.

Fig. 14-25 Pemphigus vulgaris. Erosions of soft palatal mucosa. The erosive lesions are due to loss of the superficial part of the epithelium, leaving the connective tissue covered only by the basal cell layers.

spinous cell layer, the chance of seeing an intact bulla is even more reduced than in benign mucous membrane pemphigoid. Involvement of other mucous membranes is common (Laskaris *et al*. 1982). The ulcers heal slowly, usually without scar formation, and the disease runs a chronic course with recurring bulla formation (Zegarelli & Zegarelli 1977).

Diagnosis of PV is based on the characteristic histologic feature of intraepithelial bulla formation due to destruction of desmosomes resulting in acantholysis. The bullae contain non-adhering free epithelial cells, denoted Tzank cells, which have lost their intercellular bridges (Coscia-Porrazzi *et al*. 1985; Nishikawa *et al*. 1996). Mononuclear cells and neutrophils dominate the associated inflammatory reaction. Immunohistochemistry reveals pericellular epithelial deposits of IgG and C3. Circulating autoantibodies against interepithelial adhesion molecules are detectable in serum samples of most patients, but at the initial stage of the intraoral disease, antiepithelial antibody may not be elevated (Melbye *et al*. 1987; Manton & Scully 1988; Lamey *et al*. 1992; Lever & Schaumburg-Lever 1997). The background to bulla formation in PV is damage to the intercellular adhesion caused by autoantibodies to cadherin-type epithelial cell adhesion molecules (desmoglein 1 and 3) (Nousari & Anhalt 1995; Nishikawa *et al*. 1996; Lanza *et al*. 2006). The mechanism by which these molecules trigger the formation of autoantibodies has not yet been established.

Immediate referral of patients with PV to a dermatologist or internal medicine specialist is important because when recognized late (Daltaban *et al*. 2020), the disease can be fatal, although systemic corticosteroid therapy can presently treat most cases. Supplementary local treatment consists of gentle plaque control and professional cleaning, as mentioned for the chronic inflammatory oral mucosal diseases earlier. Sometimes, additional topical corticosteroid application is needed to control the intraoral disease activity

Pemphigoid

Pemphigoid is a group of disorders in which autoantibodies towards components of the basement membrane result in detachment of the epithelium from the connective tissue. Bullous pemphigoid predominantly affects the skin, but oral mucosal involvement may occur (Brooke 1973; Hodge *et al*. 1981). If only mucous membranes are affected, the term benign mucous membrane pemphigoid (BMMP) is often used. The term cicatricial pemphigoid is also used to describe subepithelial bullous disease limited to the mouth or eyes and infrequently other mucosal areas. This term is problematic for the oral lesions, because usually oral lesions do not result in scarring, whereas this is an important concern for ocular lesions. It is now evident that BMMP comprises a group of disease entities characterized by an immune reaction involving autoantibodies directed against various basement membrane zone antigens (Scully & Laskaris 1998). These antigens have been identified as hemidesmosome or lamina lucida components (Leonard *et al*. 1982; Leonard *et al*. 1984; Manton & Scully 1988; Domloge-Hultsch *et al*. 1992; Domloge-Hultsch *et al*. 1994), and sera from patients with oral lesions have been shown to recognize the alpha-6 integrin subunit (Rashid *et al*. 2006). In addition, complement-mediated cell destructive processes may be involved in the pathogenesis of the disease (Eversole 1994). The trigger mechanisms behind these reactions, however, have not yet been revealed.

The majority of affected patients are female with a mean age at onset of 50 years or older (Shklar & McCarthy 1971). Oral involvement in BMMP is almost inevitable and usually the oral cavity is the first site of disease activity (Silverman *et al*. 1986; Gallagher & Shklar 1987). Any area of the oral mucosa may be involved in BMMP, but the main manifestation is desquamative lesions of the gingiva presenting as intensely erythematous attached gingiva (Laskaris *et al*. 1982; Silverman *et al*. 1986; Gallagher & Shklar 1987) (Fig. 14-26). The inflammatory changes, as always when not caused by plaque, may extend

Fig. 14-26 Mucous membrane pemphigoid affecting the attached gingiva of both jaws. The lesions are erythematous and resemble erythematous lichen planus lesions. They result in pain associated with oral procedures, including eating and oral hygiene procedures.

Fig. 14-27 Mucous membrane pemphigoid with intact and ruptured gingival bulla.

over the entire gingival width and even over the mucogingival junction. Rubbing the gingiva may precipitate bulla formation (Dahl & Cook 1979). This is denoted a positive Nicholsky sign and is caused by the destroyed adhesion of the epithelium to the connective tissue. The intact bullae are often clear to yellowish or they may be hemorrhagic (Figs. 14-27, 14-28). This, again, is due to the separation of epithelium from connective tissue at the junction, resulting in exposed vessels inside the bullae. Usually, the bullae rupture rapidly leaving fibrin-coated ulcers. Sometimes, tags of loose epithelium can be found due to rupture of bullae. Other mucosal surfaces may be involved in some patients. Ocular lesions are particularly important because scar formation can result in blindness (Williams *et al*. 1984) (Fig. 14-29).

Fig. 14-28 Mucous membrane pemphigoid with hemorrhagic gingival bulla. The patient uses chlorhexidine for daily plaque reduction.

Fig. 14-29 Mucous membrane pemphigoid. Eye lesion with scar formation due to coalescence of palpebral and conjunctival mucosa.

The separation of epithelium from connective tissue at the basement membrane area is the main diagnostic feature of BMMP. A non-specific inflammatory reaction is a secondary histologic finding. In addition, immunohistochemical examination can help distinguish BMMP from other vesiculobullous diseases, in particular pemphigus, which is life threatening. Deposits of C3, IgG, and sometimes other immunoglobulins as well as fibrin are found at the basement membrane zone in the vast majority of cases (Laskaris & Nicolis 1980; Daniels & Quadra-White 1981; Manton & Scully 1988). It is important to involve perilesional tissue in the biopsy because the characteristic features may have been lost within lesional tissue (Ullman 1988). Circulating immunoglobulins are not always found in BMMP by indirect immunofluorescence (Laskaris & Angelopoulos 1981).

However, a study has shown that 75% of 20 patients with oral pemphigoid phenotype without scarring possessed circulating autoantibodies against the BP180 molecule, indicating a prominent role for this protein as a target antigen in this type of pemphigoid with only oral lesions (Calabresi *et al*. 2007).

Therapy consists of professional atraumatic plaque removal and individual instruction in gentle, but careful, daily plaque control, eventually supplemented with daily use of chlorhexidine and/or topical corticosteroid application if necessary. As for all the chronic inflammatory oral mucosal diseases, oral hygiene procedures are very important and controlling the infection from plaque bacteria may result in a considerable reduction of disease activity and symptoms. It is also important to prevent the development of attachment loss due to periodontitis in those patients with difficulties in maintaining oral hygiene (Tricamo *et al*. 2006). However, the disease is chronic in nature and formation of new bullae is inevitable in most patients. Topical corticosteroids, preferably applied as a paste at night, temper the inflammatory reaction. A systematic review has preliminarily suggested that patients with oral PV or BMMP appear somewhat more susceptible to periodontitis, which in turn may potentially trigger the bullous disorders. Obviously, these patients should be encouraged by dermatologists to pursue collaborative professional periodontal follow-up by dentists (Jascholt *et al*. 2017).

Lichen planus

Lichen planus is the most common mucocutaneous disease manifesting on the gingiva. The disease may affect the skin and oral as well as other mucosal membranes in some patients, while others may present with either skin or oral mucosal involvement alone. Oral involvement alone is common and concomitant skin lesions in patients with oral lesions have been found in 5–44% of cases (Andreasen 1968; Axell & Rundquist 1987). The disease may be associated with severe discomfort and since it has been shown to possess a premalignant potential (Holmstrup 1992), it is important to diagnose and treat the patients and to follow them at the regular oral examinations (Holmstrup *et al*. 1988; Mattson *et al*. 2002; Mignogna *et al*. 2007).

The prevalence of oral lichen planus (OLP) in various populations has been found to be 0.1–4% (Scully *et al*. 1998a). The disease may afflict patients at any age, although it is seldom observed in childhood (Scully *et al*. 1994).

Skin lesions are characterized by papules with white striae (Wickham striae) (Fig. 14-30). Itching is a common symptom, and the most frequent locations are the flexor aspects of the arms, thighs, and neck. In the vast majority of cases, the skin lesions disappear spontaneously after a few months, which is in sharp contrast to the oral lesions, which usually persist for many years (Thorn *et al*. 1988).

A variety of clinical appearances is characteristic of OLP. These include:

- Papular (Fig. 14-31)
- Reticular (Figs. 14-32, 14-33, 14-40)
- Plaque-type (Fig. 14-34)
- Erythematous (atrophic) (Figs. 14-35, 14-36, 14-37, 14-38, 14-39)
- Ulcerative (Figs. 14-36, 14-41)
- Bullous (Fig. 14-43).

The simultaneous presence of more than one type of lesion is common (Thorn *et al*. 1988). The most characteristic clinical manifestations of the disease and the basis of the clinical diagnosis are white papules (Fig. 14-31)

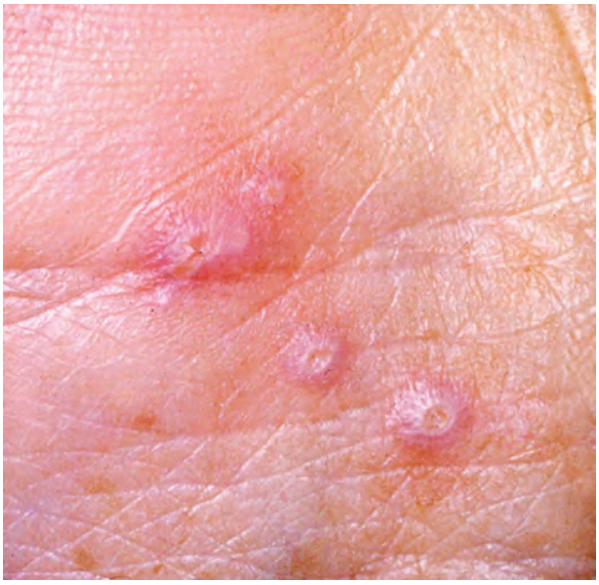

Fig. 14-30 Skin lesions of lichen planus. Papules with delicate white striations.

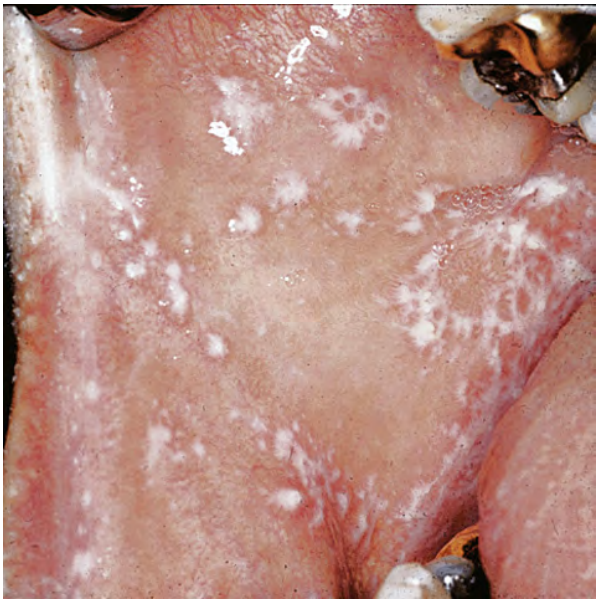

Fig. 14-31 Oral lichen planus. Papular lesion of right buccal mucosa.

Fig. 14-32 Oral lichen planus. Reticular lesion of lower lip mucosa. The white striations are denoted Wickham's striae.

Fig. 14-34 Oral lichen planus. Plaque-type lesion of maxillary gingivae.

Fig. 14-35 Oral lichen planus. Erythematous lesions of facial maxillary and mandibular gingiva. Such lesions were previously termed desquamative gingivitis. Note that the margin of the gingiva has a normal color in the upper incisor region, which distinguishes the lesions from plaque-induced gingivitis.

Fig. 14-36 Oral lichen planus. Erythematous and ulcerative lesion of the maxillary gingivae.

Fig. 14-37 Oral lichen planus. Erythematous and reticular lesion of maxillary gingivae. Several types of lesions are often present simultaneously.

and white striations (Figs. 14-32, 14-33, 14-40), which often form reticular patterns (Thorn *et al*. 1988), usually bilaterally (Ingafou *et al*. 2006). Sometimes erythematous and ulcerative lesions are referred to as erosive (Rees 1989). Papular, reticular, and plaque-type lesions

Fig. 14-38 Oral lichen planus. Erythematous and reticular lesion of the lower left canine region. Plaque accumulation results in exacerbation of oral lichen planus, and erythematous lesions compromise oral hygiene procedures. This may lead to a vicious circle that the dentist can help in breaking.

Fig. 14-39 Oral lichen planus. Erythematous and reticular lesion of right maxillary gingiva in a patient using an electric toothbrush, which is traumatic to the marginal gingiva. The physical trauma results in exacerbation of the lesion with erythematous characteristics and pain.

Fig. 14-40 Same patient as shown in Fig. 14-39 after modified toothbrushing instructions with no traumatic action on the marginal gingiva. Pain is no longer noted by the patient.

usually do not give rise to significant symptoms, whereas erythematous and ulcerative lesions are associated with moderate-to-severe pain, especially in relation to oral hygiene procedures and eating. Any area of the oral mucosa may be affected by OLP, but the lesions often change in clinical type and extent over the years. Such changes may imply the development of plaque-type lesions, which are clinically indistinguishable from oral leukoplakia. This may give rise to a diagnostic problem if other lesions more characteristic of OLP have disappeared (Thorn *et al*. 1988).

Fig. 14-41 Oral lichen planus. Erythematous and ulcerative/reticular lesions of the maxillary and mandibular incisor regions. This 48-year-old woman suffered from severe discomfort when eating, drinking, and toothbrushing.

Fig. 14-42 Same patient as shown in Fig. 14-41 after periodontal treatment and extraction of teeth with deep pockets. An individual oral hygiene program, which ensured gentle, meticulous plaque removal, has been used by the patient for 3 months. The erythematous/ulcerative lesions are now healed and there are no longer any symptoms.

Fig. 14-43 Oral lichen planus. Bullous/reticular lesion of the left palatal mucosa.

Fig. 14-44 Gingival discoid lupus erythematosus lesion. A central erythematous area with small white dots is surrounded by delicate white striae.

A characteristic histopathologic feature in OLP is a subepithelial, band-like accumulation of lymphocytes and macrophages characteristic of a type IV hypersensitivity reaction (Eversole *et al*. 1994). The epithelium shows hyperortho- or hyperparakeratinization and basal cell disruption with transmigration of lymphocytes into the basal and parabasal cell layers (Eversole 1995). The infiltrating lymphocytes have been identified as CD4- and CD8-positive cells (Buechner 1984; Walsh *et al*. 1990; Eversole *et al*. 1994). Other characteristic features are Civatte bodies, which are dyskeratotic basal cells. Common immunohistochemical findings of OLP lesions are fibrin in the basement membrane zone, and deposits of IgM, C3, C4, and C5 may also be found. None of these findings is specific for OLP (Schiodt *et al*. 1981; Kilpi *et al*. 1988; Eversole *et al*. 1994).

The subepithelial inflammatory reaction in OLP lesions is presumably due to an unidentified antigen in the junctional zone between the epithelium and connective tissue or to components of basal epithelial cells (Holmstrup and Dabelsteen 1979; Walsh *et al*. 1990; Sugerman *et al*. 1994). A lichen planus-specific antigen in the stratum spinosum of skin lesions has been described (Camisa *et al*. 1986), but does not appear to play a significant role in oral lesions since it is rarely identified there. It is still an open question whether OLP is a multivariate group of etiologically diverse diseases with common clinical and histopathologic features or a disease entity characterized by a type IV hypersensitivity reaction to an antigen in the basement membrane area. The clinical diagnosis is based on the presence of papular or reticular lesions. The diagnosis may be supported by histopathologic findings of hyperkeratosis, degenerative changes of basal cells, and subepithelial inflammation dominated by lymphocytes and macrophages (Holmstrup 1999).

The uncertain background of OLP results in several border zone cases of so-called oral lichenoid lesions (OLLs), a final diagnosis for which is difficult to establish (Thornhill *et al*. 2006). The most common OLLs are probably lesions in contact with dental restorations (Holmstrup 1991) (see later in this chapter). Other types of OLL are associated with various types of medications, including antimalarials, quinine, quinidine, non-steroidal anti-inflammatory drugs, thiazides, diuretics, gold salts, penicillamine, and beta-blockers (Scully *et al*. 1998a). Graft-versus-host reactions are also characterized by a lichenoid appearance (Fujii *et al*. 1988) and a group of OLLs is associated with systemic diseases including liver disease (Fortune & Buchanan 1993; Bagan *et al*. 1994; Carrozzo *et al*. 1996). This appears to be particularly evident in Southern Europe and Japan where hepatitis C has been found in 20–60% of OLL cases (Bagan *et al*. 1994; Gandolfo *et al*. 1994; Nagao *et al*. 1995).

Several follow-up studies have demonstrated that OLP is associated with increased development of oral cancer, the frequency of cancer development being in the range of 0.5–2% (Holmstrup *et al*. 1988; Mattson *et al*. 2002; Rodstrom *et al*. 2004; Ingafou *et al*. 2006; Mignogna *et al*. 2007).

When gingiva is involved, the most important part of the therapeutic regimen is atraumatic meticulous plaque control, which results in significant improvement in many patients (Holmstrup *et al*. 1990) (Figs. 14-39, 14-40, 14-41, 14-42). Individual oral hygiene procedures with the purpose of effective plaque removal without traumatic influence on the gingival tissue should be established for all patients with symptoms. In cases of persistent pain, typically associated with atrophic and ulcerative lesions, antifungal treatment may be necessary if the lesions host yeast, which is the case in 37% of OLP cases (Krogh *et al*. 1987). In painful cases, who have not responded to the treatment above, the use of therapeutic agents may be considered, and several agents have been investigated. Among these are corticosteroids, retinoids, cyclosporine, and phototherapy, in addition to other treatment modalities. A systematic review of clinical trials (Al-Hashimi *et al*. 2007) showed that topical corticosteroids particularly are often effective, preferably in a paste or an ointment to be used three times daily for a number of weeks. However, in such cases, relapses are very common, which is why intermittent periods of treatment may be needed over an extended period of time. Aloe vera shows promising results especially with no adverse effects compared with various adverse effects of corticosteroids (Ali & Wahbi 2017). It appears that topical tacrolimus is an effective alternative to topical clobetasol and may be considered as a first-line therapy in the management of painful OLP (Chamani *et al*. 2015).

Lupus erythematosus

Lupus erythematosus (LE) is a group of autoimmune connective tissue disorders in which autoantibodies

form to various cellular constituents, including nucleus and cytoplasmic membrane. All parts of the body may be affected, and the disease is much more prevalent among women than among men. The etiology of LE remains unknown, but deposits of antigen–antibody complexes appear to play a role in the tissue damage characteristic of the disease (Schrieber & Maini 1984). The prevalence of LE has been estimated at 0.05% (Condemi 1987).

There are two major traditional forms: discoid LE (DLE) and systemic LE (SLE), which may involve a range of organ systems, including the kidney, heart, central nervous system, vascular system, and bone marrow. Two additional forms, acute and subacute cutaneous LE, have more recently been added to the classification, and represent different degrees of disease activity and increased risk of development of SLE (Wouters *et al*. 2004).

DLE is a mild chronic form, which involves skin and mucous membranes, sometimes including the gingiva as well as other parts of the oral mucosa (Schiodt 1984; Schiodt & Pindborg 1984). The typical lesion presents as a central atrophic area with small white dots surrounded by irradiating fine white striae with a periphery of erythema (Fig. 14-44). The lesions can be ulcerated or clinically indistinguishable from leukoplakia or erythematous OLP (Fig. 14-45) (Schiodt 1984). Sometimes patients present with brownish gingival lesions, which are a side effect of antimalarial drugs prescribed to these patients as part of their treatment (Fig. 14-46). Eight percent of patients with DLE develop SLE, and ulcerations may be a sign of SLE (Rodsaward *et al*. 2017), which has a 25–40% prevalence of oral lesions (Schiodt & Pindborg 1984; Pisetsky 1986; Jonsson *et al*. 1988). The characteristic Bordeaux-colored "butterfly" skin lesions are photosensitive, scaly, erythematous macules located on the bridge of the nose and the cheeks (Standefer & Mattox 1986). The systemic type, which can still be fatal because of nephrologic and hematologic complications, also shows skin lesions on the face, but they tend to spread over the entire body.

Fig. 14-45 Gingival plaque-type discoid lupus erythematosus lesion resembling frictional keratosis and leukoplakia.

Fig. 14-46 Antimalarial drugs may result in brownish gingival discoloration. This is a patient with discoid lupus erythematosus receiving an antimalarial drug, chloroquine, as part of the treatment regimen.

Diagnosis is based on clinical and histopathologic findings. The epithelial changes, characteristic of oral LE lesions, are hyperkeratosis, keratin plugging, and variation in epithelial thickness, as well as liquefaction degeneration of basal cells and increased width of the basement membrane. The subepithelial connective tissue harbors inflammation, sometimes resembling OLP, but often with a less distinct band-shaped pattern (Schiodt & Pindborg 1984). Immunohistochemical investigation reveals deposits of various immunoglobulins, C3, and fibrin along the basement membrane (Reibel & Schiodt 1986).

Systemic corticosteroid and other anti-inflammatory treatment regimens are required for SLE. Additional topical treatment is sometimes needed for the resolution of symptomatic intraoral lesions.

Granulomatous inflammatory lesions (orofacial granulomatosis)

Crohn's disease

Crohn's disease (CD) is characterized by chronic granulomatous infiltrates of the wall of the last ileal loops, but any part of the gastrointestinal tract can be affected. As the oral cavity is part of the gastrointestinal tract, it is not surprising that CD can occur from the rectum to the lips. When the oral mucosa is involved as part of CD, the oral component is classified as oral Crohn´s disease. Orofacial granulomatosis (OFG) is a rare chronic inflammatory disorder confined to lips, gingivae, buccal mucosa and floor of the mouth. The exact relationship between OFG and oral Crohn´s disease remains unknown, but at present the two diseases are considered as separate entities (Sanderson *et al*. 2005; Zbar *et al*. 2012; Gale *et al*. 2016).

The number of reports of lesions involving the periodontium is limited (van Steenberghe *et al*. 1976), which is probably related to a tradition by many clinicians of using the term aphthous lesions for any ulcerative disease of the oral mucosa. The oral lesions have striking similarity to those of the intestinal tract, that is, irregular long ulcerations with elevated borders with a cobblestone appearance. Usually, the periodontal lesions appear after the diagnosis has been established based on the intestinal involvement, but sometimes the oral lesions are the first findings that lead to diagnosis. Characteristic clinical findings are mucosal foldings of the buccal or labial sulcus (Fig. 14-47) and in the gingiva an erythematous cobblestone or granulomatous appearance may be observed (Fig. 14-48, 14-49). Exacerbations of the oral lesions appear in parallel with those of the intestine. An increased risk of periodontal destruction has been reported to be associated with a defective neutrophil function (Lamster *et al*. 1982).

Sarcoidosis

Granulomatous inflammatory conditions have been used as a collective term for CD, OFG, and sarcoidosis, because these diseases show the same histopathologic features: non-caseating, epithelioid cell granulomas in the affected tissue. Rarely, all three diseases may present with gingival lesions, characterized by swellings (Pindborg 1992; Mignogna *et al*. 2001) and sarcoidosis, which is sometimes present as a fiery red granular gingival overgrowth (Fig. 14-50). Of 45 cases of oral sarcoidosis, 13% had gingival lesions (Blinder *et al*. 1997). A study of 35 patients with OFG demonstrated ileal and colonic abnormalities in 54%, and granulomas were revealed in gut biopsies of 64% of the patients. Intestinal abnormality was significantly more likely if the age of onset was <30 years (Sanderson *et al*. 2005).

Local treatment of disconfiguring lip swelling as part of oral granulomatous inflammatory conditions consists of intralesional steroid injection (El-Hakim

Fig. 14-47 A frequent oral finding in patients with Crohn´s disease is mucosal foldings, usually located in the buccal or labial sulcus. Such lesions may be the first clinical finding that leads to the diagnosis of the disease. Histopathologic examination of biopsies from these foldings reveals epithelioid cell granulomas. The foldings are also characteristic for the other types of orofacial granulomatosis.

Fig. 14-48 Gingival lesion in a Crohn's patient. Cobblestoning may be seen in the gingiva. Histopathologic examination of biopsies from this type of lesion very often contain granulomas. Thus, if such a lesion is present, a biopsy should be taken from this location.

Fig. 14-49 Gingival lesion in a Crohn's patient. Erythema and swelling with a granular surface.

Fig. 14-50 Granulomatous gingival hyperplasia may be due to sarcoidosis, which is one of the orofacial granulomatoses; others are Crohn's disease and Melkersson–Rosenthal syndrome.

and Chauvin 2004; Mignogna *et al*. 2004) or paste application daily or twice daily during painful exacerbations, and meticulous oral hygiene to reduce additional inflammation of the oral cavity. Treatment of any inflammatory condition in the oral region, including periodontitis, periapical inflammation, and even mucosal lesions due to hypersensitivity to restorative dental materials, is important for resolution in some cases (Guttman-Yassky *et al*. 2003). An important differential diagnosis is a gingival lesion presumably associated with mouth breathing. This type of lesion, which may resemble those of OFG, is confined to the area between the maxillary canine teeth. The erythematous surface has a dry and shiny appearance, and the lesion is primarily seen in patients with impaired lip closure. Deposition of bacteria on the facial side of the front teeth and the gingiva, facilitated by mouth breathing, may play a role in the development of this type of gingival lesion, which may also be seen in conjunction with lichenoid lesions of the mucosal side of the upper lip (Backman & Jontell 2007).

Reactive processes

Epulis

Epulis is a localized tumor of the gingiva. Most of these gingival lesions are reactive processes with a presumed exogenic origin, such as trauma, calculus, etc. This is in contrast to epulides, which are true neoplasms, characterized by genetic loss of its proliferative regulation. The most common reactive processes in the gingiva are:

- Fibrous epulis (Fig. 14-51)
- Calcifying fibroblastic granuloma (Fig. 14-52)
- Pyogenic granuloma (vascular epulis) (Fig. 14-53, 14-54)
- Peripheral giant cell granuloma (or central) (Fig. 14-55)

Fibrous epulis

A fibrous epulis (focal fibrous hyperplasia, fibroepithelial hyperplasia) is a reactive process often

Fig. 14-51 Fibrous epulis.

Fig. 14-52 Calcifying fibroblastic granuloma of the lower right premolar region.

covered by a normal epithelium and are usually the same color as the surrounding oral mucosa. Proliferation of the subepithelial connective tissue is induced by chronic trauma or other local factors. By definition, an epulis is confined to the gingiva, but the same type of lesion is often observed in buccal mucosa as a result of a tooth gap. It should be distinguished from fibroma, which is a true neoplasm (Babu & Hallikeri 2017).

Calcifying fibroblastic granuloma

Calcifying fibroblastic granuloma (CFG) is a true epulis, as it can only affect the gingiva (Fig. 14-52). Clinically, it is difficult to discriminate between CFG and a fibrous epulis, and the diagnosis is established by histopathology where calcifying tissues are seen as part of the connective tissue (Andersen *et al*. 1973). The CFG derives from the undifferentiated mesenchymal cells of the periodontal ligament and are induced by local irritants.

Pyogenic granuloma

Pyogenic granuloma (PG) may occur at any site of the oral mucosa. As an epulis, it is often clinically

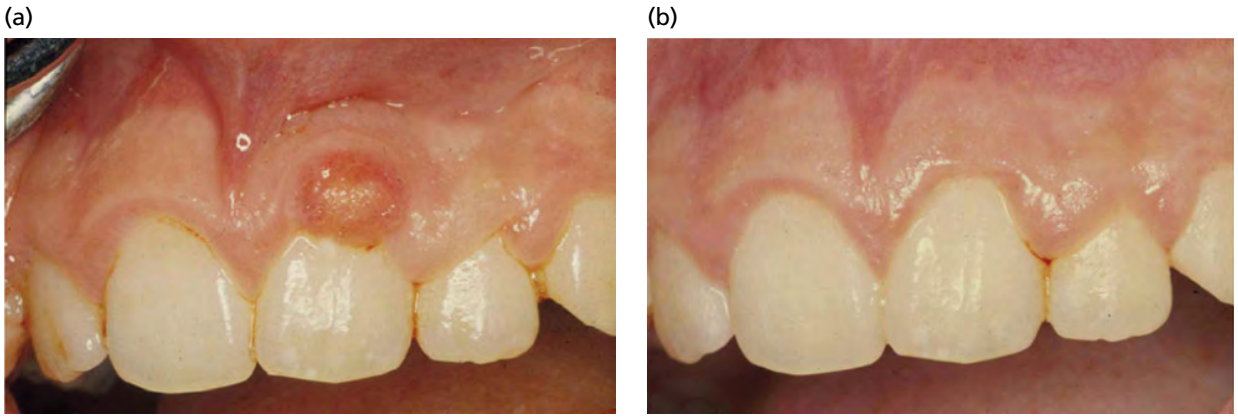

Fig. 14-53 Pyogenic granuloma of upper incisor region before (a) and after treatment (b).

Fig. 14-54 Large pyogenic granuloma of the maxillary premolar/molar region.

Fig. 14-55 Peripheral giant cell granuloma of the mandibular canine/premolar region.

distinguishable from fibrous epulis and CFG. A variety of blood vessels can be seen in the connective tissue, giving PG a complex coloration, with both red and yellowish ulcerated elements. The size of the lesion, which may be large, is also a distinguishing factor (Fig. 14-53, 14-54). The main contributing factors to PG are the presence of plaque and calculus. A definite correlation has been observed between serum estrogen, progesterone hormone, and PG during pregnancy (Daley *et al*. 1991).

Peripheral giant cell granuloma

Peripheral giant cell granuloma (PGCG) is characterized by numerous multinucleated giant cells and a fibrocellular stroma. The origin of the giant cells is not known, but most likely they relate to osteoclasts and endothelial cells. As a true epulis, PGCG is often observed as a tumor located in the interdental papilla, edentulous alveolar margin, or at the marginal gingival level, emanating from the periodontal ligament and periosteum. The color of a PGCG often ranges from dark red to purple or blue (Fig. 14-55). As surgical excision alone shows a considerable recurrence rate, excision followed by an additional therapy, either curettage or peripheral osteotomy, should be the first choice of treatment for PGCG (Chrcanovic *et al*. 2018).

Neoplasms

Premalignant (potentially malignant)

Leukoplakia

Leukoplakia, which is still a challenging condition (Villa & Sonis 2018), is a clinical diagnosis of a predominantly white lesion of the oral mucosa that cannot be diagnosed as any other lesion. The prevalence of leukoplakia has been estimated at around 4% in Sweden (Axell 1976), but differs dependent on lifestyle. Leukoplakias, which are usually asymptomatic, occur most frequently on the mandibular gingiva, buccal mucosa, tongue, and the floor of the mouth. Homogenous leukoplakia is characterized by a whitish color with a more or less corrugated surface (Fig. 14-56), while non-homogenous leukoplakia is characterized by a whitish-reddish color (Fig. 14-57a). Verrucous leukoplakia is characterized by white papillary lesions. Lesions exhibiting exophytic growth and invasion of the surrounding tissues are referred to as proliferative verrucous leukoplakia (Fig. 14-58), a high-risk subtype of non-homogenous leukoplakia (van der Waal & Reichart 2008). The significance of leukoplakia relies on the fact that they are premalignant with an annual rate of malignant transformation

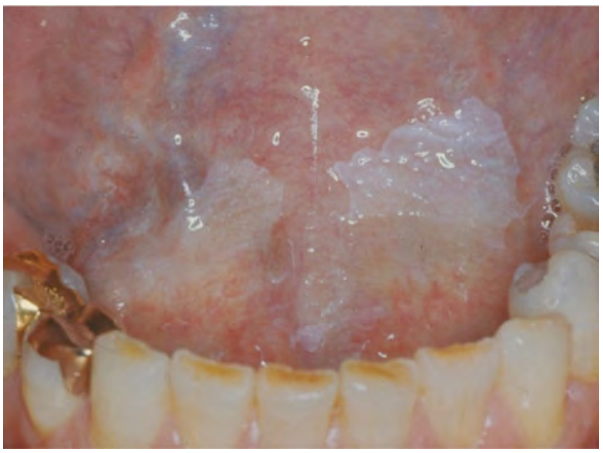

Fig. 14-56 Homogenous leukoplakia of the sublingual area.

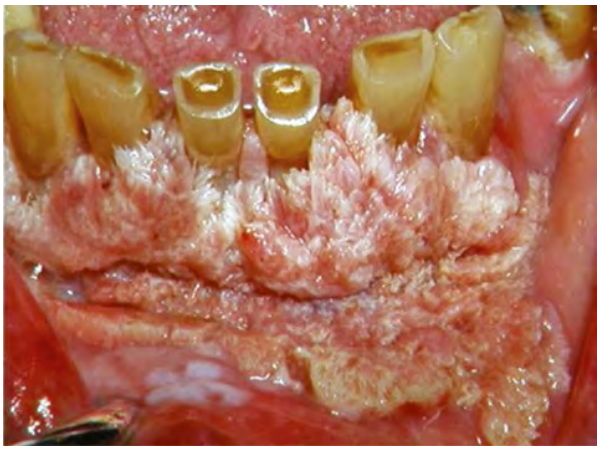

Fig. 14-58 Proliferative verrucous leukoplakia with exophytic growth and invasion of the surrounding tissues.

(a)

(b)

Fig. 14-57 (a) The combined red and white areas is characteristic of this non-homogenous gingival leukoplakia of the lower right molar region. (b) The lesion developed into a carcinoma after a 2 year follow-up. (Source: Courtesy of Dr. Henrik Nielsen.)

of 2–3% (van der Waal 2014). The lesions may demonstrate some degree of epithelial dysplasia or frank carcinoma upon biopsy and several oral cancers are preceded by a long-standing area of leukoplakia. While the prognosis of leukoplakia has been shown to depend on homogenous or non-homogenous appearance and size, the significance of epithelial dysplasia as a prognostic marker has been questioned (Holmstrup *et al*. 2006; Brouns *et al*. 2014) as has the reliability of a biopsy of the lesions (Holmstrup *et al*. 2007).

The basic concept of handling oral premalignant lesions is to prevent malignant transformation, but no universally approved standard therapy regimen has yet been developed (Holmstrup & Dabelsteen 2016), and surgical removal does not appear to reduce malignant development in long-term follow-up studies (Holmstrup *et al*. 2006; Balasundaram *et al*. 2014). This is why continuous follow-up of patients is important, whether or not the lesions are surgically removed.

Erythroplakia

Erythroplakia is an uncommon lesion, which cannot be diagnosed as any other disease. It is the red counterpart of leukoplakia, characterized by a fiery, sharply demarcated red area situated slightly below the surrounding mucosa (Holmstrup 2018). This is in contrast to other red lesions, which are usually diffusely demarcated. Erythroplakia appears to have a higher premalignant potential than leukoplakia (Dionne *et al*. 2015). The lesions may uncommonly affect the gingiva (Fig. 14-59).

Malignancy

Squamous cell carcinoma

The WHO has estimated that 657 000 cases of cancers of the oral cavity and oropharynx occur worldwide each year, and more than 330 000 deaths. When detected early, oral cancers can have an 80–90% survival rate. At more advanced stages, the death rate

decreases to about 40% at 5 years from diagnosis. These figures emphasize that physical examination of the oral mucosa is important, but, unfortunately, it too often receives minimal attention in routine practice. Oral squamous cell carcinoma (OSCC) is by far the most common cancer in the oral cavity, representing more than 90% of all oral cancer forms (Johnson *et al*. 2011). There is substantial evidence that lifestyle factors, including use of tobacco, alcohol, and betel quid will cause the vast majority of instances of OSCC (Johnson *et al*. 2011; Mortazavi *et al*. 2017).

The 5-year survival rate is more than 90% for those with an early diagnosed OSCC, but only around 20% for patients with stages 3 and 4. Unfortunately, in the majority of cases, the cancer is diagnosed in these advanced stages with lymph node metastasis. One reason is that OSCC does not often give rise to any significant symptoms, which avert the patient from seeking healthcare.

As early detection is critical for a successful outcome, it is important to be able to recognize how OSCC may present itself at an initial stage. Although OSCC is often described as an ulcer that will not heal (Fig. 14-60), the primary stage is in fact not always an ulcer but characterized as a proliferation of epithelial cells reflected clinically by small nodules (Fig. 14-61). The nodular appearance of the tumor surface is a characteristic of OSCC (Fig. 14-62). An OSCC can develop within a few of months, from clinically being a relatively innocent lesion (Fig. 14-61) to an advanced tumor with ulcerations and tissue necrosis (Fig. 14-57b). Thus, this is also a reason why immediate diagnosis and treatment is necessary to improve the prognosis. A rare variant is the verrucous carcinoma, which sometimes affects the gingiva. This tumor is characterized by a slightly exophytic projection of the surface (Fig. 14-63).

Leukemia

Leukemia is a malignant hematologic disorder with abnormal proliferation and development of leukocytes and their precursors in blood and bone marrow. It can involve any of the subsets of leukocytes, polymorphonuclear leukocytes, lymphocytes, or monocytes. Normal hematopoiesis is suppressed and, in most cases of leukemia, the white blood cells appear in the circulating blood in immature forms.

Fig. 14-60 Gingival cancer characterized by a persisting ulcer.

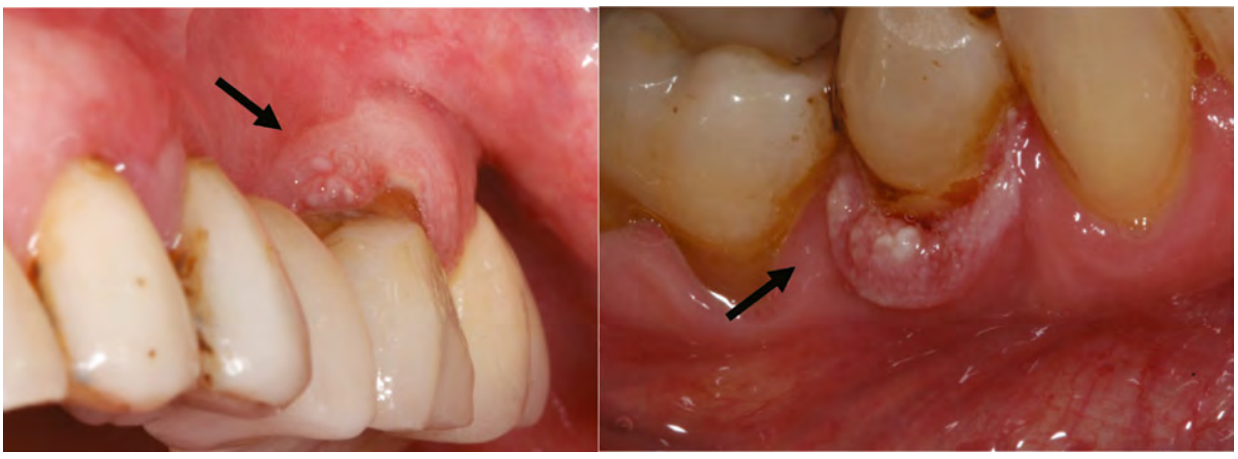

Fig. 14-61 Early squamous cell carcinomas clinically demonstrating small nodules (arrows).

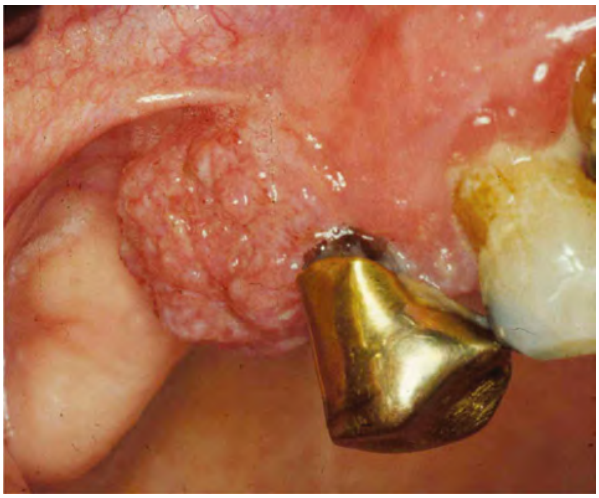

Fig. 14-62 Gingival cancer characterized by proliferating small nodules on the surface.

Fig. 14-63 Verrucous carcinoma of the mandibular lingual gingivae.

As a consequence of the inability to produce sufficient functional white blood cells and platelets, death may result from infection or bleeding associated with neutropenia and thrombocytopenia, respectively.

The classification of leukemia is based on its course, acute or chronic, and origin of the cells involved. The basic forms are: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML). Acute leukemias have an aggressive course, resulting in death within 6 months if untreated. They are rather rare and patients are usually either under 20 or over 60 years of age. Chronic leukemias, of which the lymphocytic form is the most common, have less pronounced bone marrow failure and a more indolent course, usually lasting several years. They occur during adulthood and normally after the age of 40 years. Whereas the peripheral granulocyte count is markedly elevated in chronic leukemia, it may be elevated, decreased, or normal in acute leukemia (McKenna 2000).

Gingival manifestations in leukemia, which include extensive swelling (Fig. 14-64), ulceration (Fig. 14-65), petechiae (Fig. 14-66), and erythema, are much more common in acute than in chronic forms. Sometimes, the oral manifestations lead to the diagnosis of leukemia; 69% of patients with acute leukemia had oral signs of leukemia on examination and 33% of the patients had gingival swelling (Pindborg 1992). In another study, gingival swelling was observed in 21% of AML patients, but in no patients with ALL (Meyer *et al*. 2000). The pronounced gingival swelling seen

Fig. 14-64 Acute myelogenous leukemia with extensive swelling of the gingivae

Fig. 14-65 Acute lymphocytic leukemia with gingival ulceration in a child.

Fig. 14-66 Acute myelogenous leukemia with petechiae and swelling of the gingiva. This patient had several episodes of spontaneous bleeding from the gingiva, which prevented oral hygiene procedures from being undertaken.

in patients with leukemia is mostly due to plaque-induced inflammation, since stringent plaque control appears to resolve the swelling (Barrett 1984); it may also be due to the presence of leukemic infiltrates, although this has been reported to be an uncommon feature of patients with leukemia (Barrett 1984). Gingival bleeding, which may be a major problem, due to secondary thrombocytopenia, is a common sign in patients with leukemia. It has been reported as the initial sign in 17.7% of patients with acute leukemias and in 4.4% of patients with chronic forms (Lynch & Ship 1967).

In general, the periodontal treatment of patients with leukemia is important; it aims to reduce plaque as a source of bacteremia and damage to the periodontal tissues, both during the disease course and during periods of chemotherapy. In such periods, potentially pathogenic bacteria occur in plaque simultaneously with granulocytopenia (Peterson *et al*. 1990). The reduction of periodontal inflammation may also prevent episodes of gingival bleeding. As with many other patients, chemical plaque control in combination with mechanical debridement appears to be most effective and is the preferred method of periodontal therapy in patients with leukemia (Holmstrup & Glick 2002). However, the increased tendency to bleeding in many of these patients may necessitate the use of alternative methods to toothbrushing. A study of professional plaque removal preceding mouth rinsing with 0.1% chlorhexidine in patients with AML showed that the additional initial removal of plaque and calculus was more effective in reducing gingival inflammation than mouth rinsing with chlorhexidine alone (Bergmann *et al*. 1992). A 1-day antibiotic prophylaxis regimen with a combination of piperacillin and netilmicin was given prior to and after the mechanical debridement. Periodontal treatment always involves a close cooperation with the medical department or specialist responsible for coordination of the patient's treatment.

Lymphoma

Next to malignant salivary gland tumors, oral lymphomas represent the third most common malignancy in the oral cavity. Lymphoma is a general term for tumors of the lymphoid system and lymphoma represents the most common hematologic malignancy. Lymphoma may originate from B-lymphocytes and T-lymphocytes cell lines. There are two main types of lymphoma: Hodgkin's lymphoma and non-Hodgkin's lymphoma, the former being one-sixth as common as non-Hodgkin's lymphoma. In contrast to non-Hodgkin's lymphoma, oral manifestations of Hodgkin's lymphoma are extremely rare (Fornatora *et al*. 2004; Gowda *et al*. 2013; Valera *et al*. 2015). It may mimic abscesses emanating from a tooth, and therefore lymphomas may be an optional diagnosis when a process is not responding as expected after endodontic or periodontal treatment (Fig. 14-67). Clinically, it can be observed as discrete swelling of the mucosa including the gingiva and the patient is usually unaware of the tumor until its later stages.

Fig. 14-67 Gingival non-Hodgkin's lymphoma of the mandibular molar region.

Endocrine, nutritional, and metabolic diseases

Vitamin deficiencies

Vitamin C deficiency (scurvy)

Ascorbic acid (vitamin C) is necessary for various metabolic processes in the connective tissue as well as in the formation of catecholamines. Acting as an antioxidant against reactive oxygen species ascorbic acid is of crucial importance in the maintenance of periodontal tissue homeostasis (Chapple & Matthews 2007). Ascorbic acid deficiency ("scurvy") has been a severe burden on humans, and even in the nineteenth century an epidemic of scurvy occurred in central Europe. Characteristic clinical findings in scurvy are gingival bleeding and sore gums as well as a depressed immune response. Interestingly, the concentration of ascorbic acid in gingival crevicular fluid in gingival health is higher than in plasma (Meyle & Kapitza 1990), and there appears to be an inverse relationship between plasma ascorbic acid concentration and the severity of periodontitis (Pussinen *et al*. 2003; Kuzmanova *et al*. 2012).

Traumatic lesions

Traumatic lesions of the gingiva are very common and may be caused by a wide range of physical, chemical, and thermal incidents. The background to traumatic lesions of the oral tissues may be self-inflicted, iatrogenic, or accidental (Armitage 1999).

Physical/mechanical trauma

Frictional keratosis

Oral hygiene agents, including toothbrushes, and inexpedient procedures can be injurious to the gingival tissues. If physical trauma is limited, the gingival response is hyperkeratosis, resulting in a white leukoplakia-like, frictional keratosis (Almazyad *et al*. 2020) (Fig. 14-68).

Mechanically induced gingival ulceration

In cases of more aggressive soft tissue trauma, the damage varies from superficial gingival laceration to major loss of tissue resulting in gingival recession (Axell & Koch 1982; Smukler & Landsberg 1984). Abrasiveness of toothpaste, strong brushing force, and horizontal movement of the toothbrush contribute to the gingival injury even in young patients. Characteristic findings in these patients are extremely good oral hygiene, cervical tooth abrasion, and unaffected tops of the interdental papillae at the site of injury (Figs. 14-69, 14-70, 14-71, 14-72). The condition has been termed traumatic ulcerative gingival lesion (Axell & Koch 1982). Dental flossing may also cause gingival ulceration and inflammation primarily affecting the top of the interdental papillae (Fig. 14-73). The prevalence of such findings is unknown (Gillette & Van House 1980). Diagnosis of physical injuries is based on the clinical findings. An important differential diagnosis is necrotizing gingivitis (Blasberg *et al*. 1981) (see Chapter 19). The latter normally reveals itself as a necrotic gingival margin and interdental papillae, while brushing trauma leads to ulceration of a few millimeters of the gingival margin.

Fig. 14-68 Frictional keratosis due to an aggressive tooth brushing habit. Note the cervical abrasion of adjacent teeth.

Fig. 14-69 Gingival wounding due to improper toothbrushing. Note the characteristic horizontal extension of the lesion, affecting the most prominent part of the tooth arch.

Fig. 14-70 Gingival wounding due to improper toothbrushing. Note the characteristic horizontal extension of the lesion and the uninflamed, unaffected interdental papillae.

Factitious injury (self-harm)

Self-inflicted physical injury to the gingival tissues can occur; sometimes these lesions are termed gingivitis artefacta. The lesions often show ulceration of the gingival margin and this is often associated with recession. Such lesions are most common in children and young adults and two-thirds appear to occur in female patients. The lesions, which may be hemorrhagic, are usually produced by picking at or scratching the gingiva with a finger or a fingernail (Fig. 14-74). Sometimes the lesions are made by instruments (Pattison 1983). The correct diagnosis is often difficult to establish based on clinical findings, and identification of the cause may be impossible.

Fig. 14-71 Severe gingival recession and wounding due to improper toothbrushing technique. Note the unaffected interdental papillae.

Fig. 14-72 Healing of the lesion shown in Fig. 14-71. The damage to the periodontal tissues is severe, leaving extensive gingival recession.

Chemical (toxic) burn

Surface etching by various chemical products with toxic properties may result in mucosal reactions, including reactions of the gingiva. These lesions are usually reversible and resolve after removing the toxic influence. In most instances, the diagnosis is obvious from the combination of clinical findings and patient history. Chlorhexidine-induced mucosal desquamation (Flotra *et al*. 1971; Almqvist & Luthman 1988) (Fig. 14-75), acetylsalicylic acid burn (Najjar 1977), cocaine burn (Dello Russo & Temple 1982), hydrogen peroxide (Rees & Orth 1986; Rostami & Brooks 2011), and slough due to toothpaste detergents are examples of such reactions (Muhler 1970). Chemical injury to the gingival tissue may be caused by incorrect use of caustics by dentists. Paraformaldehyde used for pulp mummification may give rise to inflammation and necrosis of the gingival tissue if the cavity sealing is insufficient (Di Felice & Lombardi 1998).

Fig. 14-73 Lesions after dental flossing are common and sometimes result in permanent fissuring of the gingival tissue.

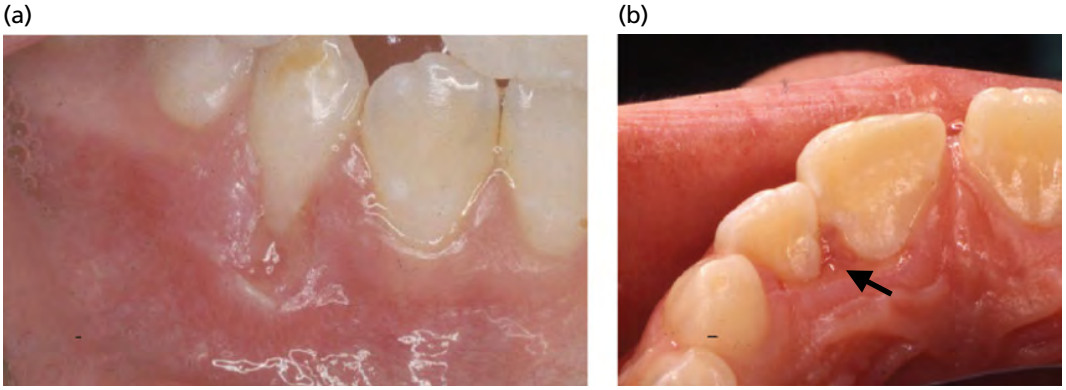

Fig. 14-74 (a) Self-inflicted gingival recession with an ulcerated margin in a 7-year-old boy because of fingernail scratching. (b) Gingival ulceration (arrow) of the palatal gingiva of the upper right incisor region in the same boy as shown in (a). This lesion was also caused by fingernail scratching.

Thermal insults

Extensive thermal burns of the oral mucosa are very rare, but minor burns particularly from hot beverages, are seen occasionally. Their site of predilection is the palatal and labial mucosa, but any part of the oral mucosa can be involved, including the gingiva (Colby *et al*. 1961). The area involved is painful and erythematous, and may slough a coagulated surface. Vesicles may also occur (Laskaris 1994) and sometimes the lesions present as ulceration, petechiae, or erosion (Fig. 14-76). Obviously, the history is important for reaching the correct diagnosis. Common causes are hot coffee, pizza, or melted cheese, but dental treatments involving improper handling of hot hydrocolloid impression material, hot wax, or cautery instruments are other causes (Colby *et al*. 1961).

Gingival pigmentation

Melanoplakia

Oral pigmentation in the form of melanoplakia may be associated with a broad variety of exogenous and endogenous circumstances previously mentioned (Holmstrup *et al*. 2018). These include genetics, endocrine disturbances (Addison's disease), syndromes (Albright syndrome, Peutz-Jegher syndrome (Fig. 14-77)), and postinflammatory reactions (Hassona *et al*. 2016). Physiologic pigmentation is usually symmetrical occurring on the gingiva, buccal mucosa, hard palate, lips, and tongue (Hedin & Larsson 1978).

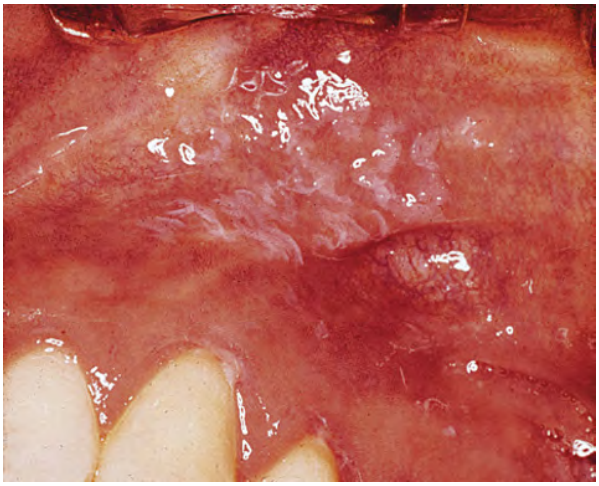

Fig. 14-75 Chlorhexidine-induced mucosal desquamation. This is a reversible type of lesion, which is completely normalized after stopping chlorhexidine use.

Fig. 14-76 Thermal burn with slight erosion and petechiae of palatal gingiva due to hot coffee intake.

Smoker's melanosis

A common cause of melanocytic pigmentation of the oral mucosa is cigarette smoking. Smoker's melanosis occurs most frequently on the mandibular anterior facial gingiva (Hedin 1977; Sarswathi *et al*. 2003; Nwhator *et al*. 2007) (Fig. 14-78). The pigmentation may gradually improve or completely resolve upon smoking cessation.

Drug-induced pigmentation

Drug-induced pigmentation (DIP) may be caused by the accumulation of melanin, deposits of drug or drug metabolites, synthesis of pigments under the influence of a drug, or deposition of iron as a consequence of damage to the vessels.

Quinine derivatives such as quinolone (Fig. 14-46), hydroxyquinolone, and amodiaquine are antimalarial

Fig. 14-77 Pigmentation in left buccal mucosa in a patient with Peutz-Jegher syndrome

Fig. 14-78 Smoker's melanosis of mandibular anterior gingiva.

Fig. 14-79 Amalgam tattoo of the attached gingiva.

drugs causing bluish grey or black mucosal pigmentation most frequently seen on the hard palate including the palatal gingiva (Kleinegger *et al*. 2000; de Andrade *et al*. 2013).

Long-term use of minocycline may be associated with pigmentation of the alveolar bone and teeth. When such changes in bone are viewed through a thin overlying mucosa, the gingiva may appear grey. This is seen primarily in the maxillary anterior region. Minocycline-induced soft tissue pigmentation is much less common and occurs primarily on the tongue, lip, buccal mucosa, and gingiva (Treister *et al*. 2004; LaPorta *et al*. 2005).

Amalgam tattoo

Another type of tissue reaction is established through epithelial ulceration allowing entry of foreign material into the gingival connective tissue. This can happen via abrasion or cutting (Gordon & Daley 1997b), a route of tissue injury, which is best exemplified by the amalgam tattoo (Buchner & Hansen 1980) (Fig. 14-79). Gingival inflammation associated with foreign bodies has been termed foreign body gingivitis. A clinical study of this condition has shown that it often presents as a red or combined red–white painful chronic lesion which is frequently misdiagnosed as lichen planus (Gordon & Daley 1997a). An X-ray microanalysis of foreign body gingivitis showed that most of the identified foreign bodies were of dental material origin, usually abrasives (Gordon & Daley 1997b). Another way in which foreign substances can enter the tissues is self-inflicted injury, for instance due to chewing on sticks or self-induced tattooing (Gazi 1986). It is uncertain whether the inflammatory reaction in such cases is due to a toxic or an allergic reaction.

Clinical features of plaque-induced gingivitis

Plaque-induced gingivitis is defined at the site level as "an inflammatory lesion resulting from interactions between the dental plaque biofilm and the host's immune-inflammatory response, which remains contained within the gingiva and does not extend to the periodontal attachment (cementum, periodontal ligament, and alveolar bone). Such inflammation remains confined to the gingiva and does not extend beyond the mucogingival junction and is reversible by reducing levels of dental plaque at and apical to the gingival margin" (Chapple *et al*. 2018).

Plaque-induced gingival inflammation begins at the gingival margin and can spread throughout the remaining gingival unit (Table 15-1). The features of a gingivitis lesion include clinical signs of inflammation that are confined to the gingiva, presence of bacteria-laden plaque to initiate and/or exacerbate the severity of the lesion, and reversibility of the disease by removal of etiology(ies). The gingivitis lesion may be either associated with an intact periodontium (which exhibits no loss of periodontal attachment or alveolar bone) or a reduced periodontium. The clinical findings for plaque-induced gingivitis on a reduced periodontium are similar to those for plaque-induced gingivitis in an intact periodontium, except for the presence of pre-existing attachment/bone loss (Trombelli *et al*. 2018).

A site showing a clinically manifest plaque-induced gingivitis usually presents (Chapple *et al*. 2018) (Fig. 15-1):

- swelling, seen as loss of knife-edged gingival margin and blunting of papillae
- bleeding on gentle probing
- redness
- discomfort on gentle probing.

The symptoms a patient may report include:

- bleeding gums (metallic/altered taste)
- pain (soreness)
- halitosis
- difficulty eating
- appearance (swollen red gums).

The intensity of the clinical signs and symptoms of gingivitis varies between individuals even when there appears to be no quantitative nor qualitative difference in plaque accumulation (Abbas *et al*. 1986; Trombelli *et al*. 2004a; Nascimento *et al*. 2019). In a clinical study on systemically healthy young adults,

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Table 15-1 Common clinical changes from gingival health to gingivitis.

Parameter	Normal gingiva	Gingivitis
Color	Coral pink (correlated to mucocutaneous pigmentation)	Red/bluish-red hue
Contour	Scalloped outline that envelops teeth Papillary gingiva fills interdental space while marginal gingival forms a knife-edged appearance with tooth surface	Edema blunts marginal tissues leading to loss of knife edge adaptation to tooth and produces bulbous papillary tissues resulting in minimization of tissue scalloping
Consistency	Firm and resilient	Tissue is soft and exhibits pitting edema
Bleeding on provocation	Negative	Positive
Gingival exudate Sulcular temperature	Minimal ~34°C	Significantly increased Slight increase

Fig. 15-1 Site-specific changes in gingival color and contour associated with plaque-induced gingivitis in an intact periodontium.

two subpopulations of individuals presenting a substantially different gingival inflammatory response to plaque have been identified in a 3-week experimental gingivitis trial. These individuals showed significantly different severity of gingivitis to similar plaque exposure (Trombelli *et al*. 2004a) (Fig. 15-2). Evidence also indicates that individuals differ in the rate at which their gingiva develop an inflammatory response after *de novo* plaque accumulation (Nascimento *et al*. 2019). Data stemming from experimental gingivitis trials support the hypothesis that differences observed by Trombelli *et al*. (2004a) are an early indication of an individual susceptibility to plaque-induced gingival inflammation. First, differences could still be observed even when self-performed supragingival plaque control was re-established (Trombelli *et al*. 2004b). Second, a consistently high or low inflammatory response to

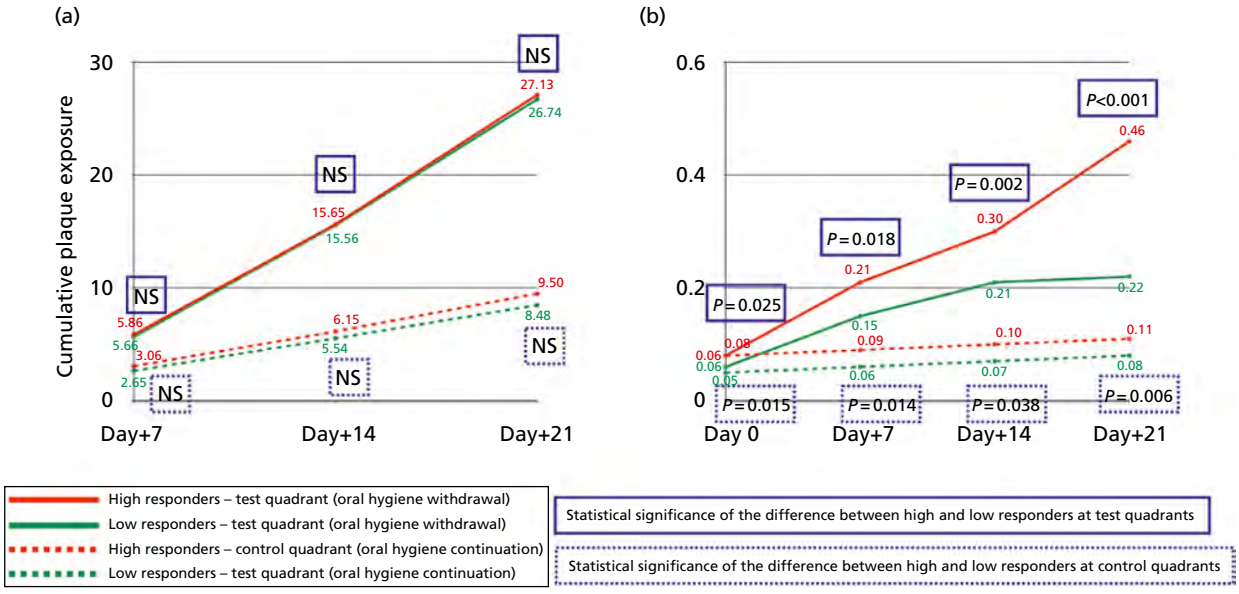

Fig. 15-2 Two subpopulations of individuals presenting a substantially different gingival inflammatory response to plaque exposure. (a) Cumulative plaque exposure. (b) Gingival crevicular fluid. NS, not significant. (Source: Based on Trombelli *et al*. 2004a.)

de novo plaque accumulation was observed in a percentage of repeatedly tested participants (Watts 1978; van der Weijden *et al*. 1994; Trombelli *et al*. 2008) (Fig. 15-3). The potential microbiological and immunological biomarkers associated with resistance to the development of gingivitis or its regression remain to be elucidated (Lee *et al*. 2012; Morelli *et al*. 2014; Kaczor-Urbanowicz *et al*. 2018; Zemouri *et al*. 2019). Interestingly, susceptibility to gingivitis was shown to be related to susceptibility to periodontitis (Dietrich *et al*. 2006; Trombelli *et al*. 2006a) (Fig. 15-4), thus potentially representing one of the key elements underlying the transition from gingivitis to periodontitis in a fraction of the population (Trombelli 2004). Patient-related modifying factors that may influence the inflammatory gingival response to plaque have been widely investigated (Trombelli *et al*. 2004c; Scapoli *et al*. 2005; Trombelli *et al*. 2005, 2006a,b; Scapoli *et al*. 2007; Trombelli *et al*. 2008, 2010; Farina *et al*. 2012; see Tatakis & Trombelli 2004 and Trombelli & Farina 2013 for review), and will be discussed in detail, together with local modifying factors for gingivitis, later in this chapter.

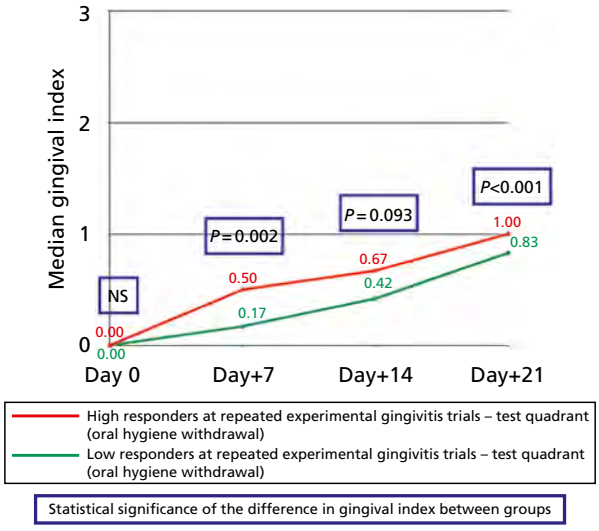

Fig. 15-3 Gingival inflammatory response to similar plaque deposits as measured in consistently low responder and high responder subjects at repeated experimental trials. (Source: Based on Trombelli *et al*. 2008.)

Diagnostic criteria to assess a gingivitis lesion

Clinical methods to assess the presence and severity of plaque-induced gingival inflammation at the site level are based on the evaluation of crude macroscopic changes occurring in the marginal gingival tissues during the healthy-inflamed transition (Lang & Bartold 2018) (Table 15-2). The volume of the gingival crevicular fluid has been largely adopted in clinical trials to assess the severity of gingival inflammation at the site level. However, the most commonly used clinical measures for gingival inflammation mainly consist of qualitative or semiquantitative indices based on visual assessment of gingival characteristics (edema/swelling, redness, etc.) and/or the evaluation of the tendency of the marginal gingiva to bleed upon mechanical stimulation exerted typically by a periodontal probe. These methods were first described more than 45 years ago and have not changed much since then (Trombelli *et al*. 2018).

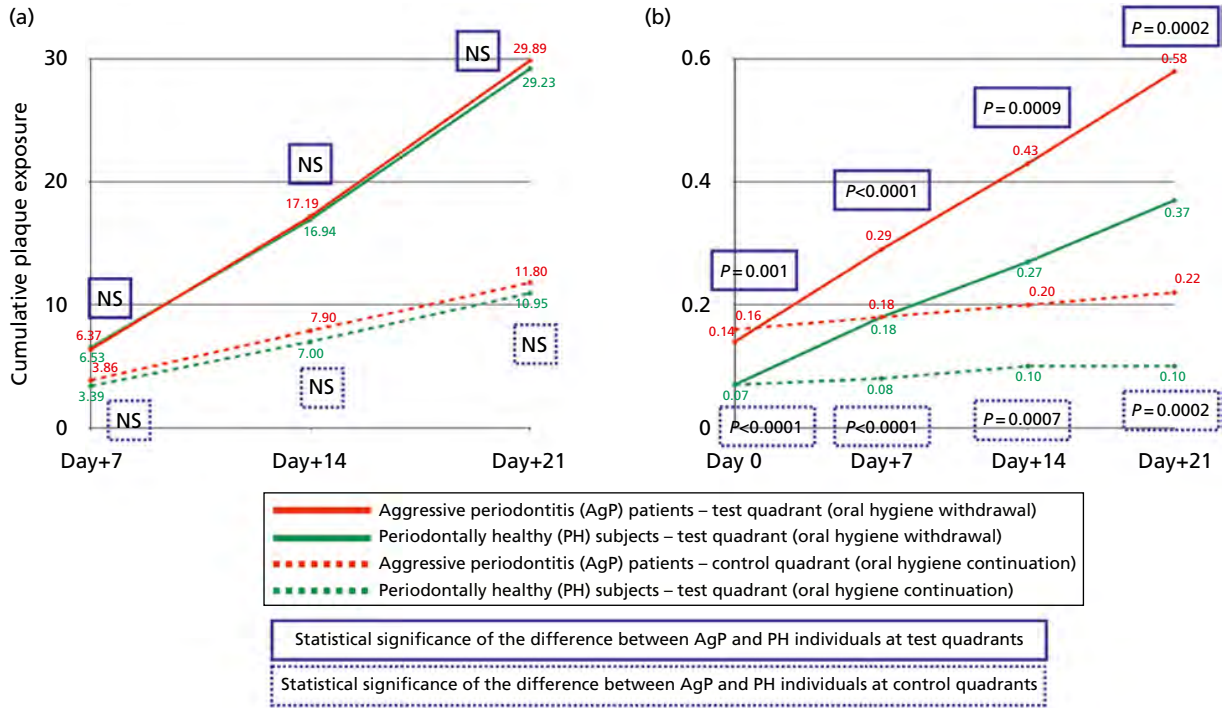

Fig. 15-4 Gingival inflammatory response to plaque in periodontally healthy subjects and aggressive periodontitis patients. (a) Cumulative plaque exposure. (b) Gingival crevicular fluid. NS, not significant. (Source: Based on Trombelli *et al*. 2006.)

Table 15-2 Gingival indices. (Source: Trombelli et al. 2018.)

Index name (authors and year)	Instrument	Sites for assessment	Time delay (seconds)	Graded response
PMA Index (Schour & Massler 1947)	Visual assessment	Each gingival unit is scored Only the labial surfaces are examined	Not stated	P (papillary) 0 = normal; no inflammation 1 = mild papillary engorgement; slight increase in size 2 = obvious increase in size of gingival papilla; hemorrhage on pressure 3 = excessive increase in size with spontaneous hemorrhage 4 = necrotic papilla 5 = atrophy and loss of papilla (through inflammation) M (marginal) 0 = normal; no inflammation visible 1 = engorgement; slight increase in size; no bleeding 2 = obvious engorgement; bleeding upon pressure 3 = swollen collar; spontaneous hemorrhage; beginning infiltration into attached gingivae 4 = necrotic gingivitis 5 = recession of the free marginal gingiva below the CEJ due to inflammatory changes A (attached) 0 = normal; pale rose; stippled 1 = slight engorgement with loss of stippling; change in color may or may not be present 2 = obvious engorgement of attached gingivae with marked increase in redness; pocket formation present 3 = advanced periodontitis; deep pockets evident.
Gingival Index (Löe & Silness 1963)	Probe	It scores the marginal and interproximal tissues (four areas for each tooth The bleeding is assessed by probing gently along the wall of soft tissue of the gingival sulcus	Not stated	0 = normal gingiva 1 = mild inflammation – slight change in color and slight edema but no bleeding on probing 2 = moderate inflammation – redness, edema and glazing, bleeding on probing 3 = severe inflammation – marked redness and edema, ulceration with tendency to spontaneous bleeding
Sulcus Bleeding Index (Mühlemann & Son 1971)	Probe	Four gingival units are scored systematically for each tooth: the labial and lingual marginal gingival (M units) and the mesial and distal papillary gingival (P units)	Not stated	Score 0 = health looking papillary and marginal gingiva no bleeding on probing Score 1 = healthy looking gingiva, bleeding on probing Score 2 = bleeding on probing, change in color, no edema Score 3 = bleeding on probing, change in color, slight edema Score 4 = bleeding on probing, change in color, obvious edema Score 5 = spontaneous bleeding, change in color, marked edema
Gingival Bleeding Index (Carter & Barnes 1974)	Unwaxed dental floss	The mouth is divided into six segments and flossed in the following order: upper right, upper anterior, upper left, lower left, lower anterior and lower right	Not stated; 30 s is allowed for reinspection	Bleeding is recorded as present or absent
Gingival Bleeding Index (Ainamo & Bay 1975)	Probe	Gentle probing of the orifice of the gingival crevice	10	If bleeding occurs within 10 seconds a positive finding is recorded

Table 15-2 (*Continued*)

Index name (authors and year)	Instrument	Sites for assessment	Time delay (seconds)	Graded response
Papillary Bleeding Index (Mühlemann 1977)	Probe	A periodontal probe is inserted into the gingival sulcus at the base of the papilla on the mesial aspect, and then moved coronally to the papilla tip. This is repeated on the distal aspect of the papilla	Not stated	Score 0 = no bleeding Score 1 = a single discreet bleeding point Score 2 = several isolated bleeding points or a single line of blood appears Score 3 = the interdental triangle fills with blood shortly after probing Score 4 = profuse bleeding occurs after probing; blood flows immediately into the marginal sulcus
Papillary Bleeding Score (PBS) (Loesche 1979)	Wooden interdental cleaner	This is performed using a Stim-U-dent®, which is inserted interproximally. The PBS is determined on all papillae anterior to the second molars	Not stated	0 = healthy gingiva, no bleeding upon insertion of Stim-U-dent® interproximally 1 = edematous, reddened gingiva, no bleeding upon insertion of Stim-U-Dent® interproximally 2 = bleeding, without flow, upon insertion of Stim-U-dent ® interproximally 3 = bleeding, with flow, along gingival margin upon insertion of Stim-U-dent® interproximally 4 = copious bleeding upon insertion of Stim-U-dent ® interproximally 5 = severe inflammation, marked redness and edema, tendency to spontaneous bleeding
Modified Papillary Bleeding Index (PBI) (Barnett *et al*. 1980)	Probe	Modified the PBI index (Mühlemann 1977) by stipulating that the periodontal probe should be gently placed in the gingival sulcus at the mesial line angle of the tooth surface to be examined and carefully swept forward into the mesial papilla. The mesial papillae of all teeth present from the second molar to the lateral incisor were assessed	0–30	0 = no bleeding within 30 s of probing 1 = bleeding between 3 and 30 s of probing 2 = bleeding within 2 s of probing 3 = bleeding immediately upon probe placement
Bleeding Time Index (Nowicki *et al*. 1981)	Probe	Inserting a Michigan "0" probe in the sulcus until slight resistance was felt and then the gingiva was stroked back and forth once over an area of approximately 2 mm	0–15	0 = no bleeding within 15 seconds of second probing (i.e. 30 seconds total time) 1 = bleeding within 6–15 seconds of second probing 2 = bleeding within 11–15 of seconds of first probing or 5 seconds after second probing 3 = bleeding within 10 seconds after initial probing 4 = spontaneous bleeding
Eastman Interdental Bleeding Index (Caton & Polson 1985)	Wooden interdental cleaner	A wooden interdental cleaner is inserted between the teeth from the facial aspect, depressing the interdental tissues 1–2 mm. This is repeated four times	0–15	Bleeding within 15 s is recorded as present or absent

(*Continued*)

Table 15-2 (*Continued*)

Index name (authors and year)	Instrument	Sites for assessment	Time delay (seconds)	Graded response
Quantitative Gingival Bleeding Index (Garg & Kapoor 1985)	Toothbrush	Takes into consideration the magnitude of blood stains covering toothbrush bristles on brushing and squeezing gingival tissue units in a sextant	Not stated	0 = no bleeding on brushing; bristles free from blood stains 1 = slight bleeding on brushing; bristle tips stained with blood 2 = moderate bleeding on brushing; about half of bristle length from tip downwards stained with blood 3 = Severe bleeding on brushing; entire bristle length of all bristles including brush head covered with blood
Modified Gingival Index (Lobene *et al*. 1986)	No instrument (visual assessment)	Same as Gingival Index	Not applicable	0 = absence of inflammation 1 = mild inflammation or with slight changes in color and texture but not in all portions of gingival marginal or papillary 2 = mild inflammation, such as the preceding criteria, in all portions of gingival marginal or papillary 3 = moderate, bright surface inflammation, erythema, edema and/or hypertrophy of gingival marginal or papillary 4 = severe inflammation: erythema, edema and/or marginal gingival hypertrophy of the unit or spontaneous bleeding, papillary, congestion or ulceration
Modified Gingival Index (Trombelli *et al*. 2004a)	No instrument (visual assessment)	Same as Gingival Index, but without the bleeding on probing component	Not applicable	0 = normal gingiva 1 = mild inflammation – slight change in color and slight edema 2 = moderate inflammation – redness, edema and glazing 3 = severe inflammation – marked redness and edema, ulceration with tendency to spontaneous bleeding
Bleeding on Interdental Brushing Index (Hofer *et al*. 2011)	Interdental brush	Inserting a light interdental brush placed buccally, just under the contact point and guided between the teeth with a jiggling motion, without force. Bleeding is scored for each interdental site.	30	Bleeding is scored as either present or absent

Diagnostic criteria to define and grade a gingivitis case

Defining and grading a gingival inflammatory condition at the site level (i.e. a "gingivitis lesion") (Murakami *et al*. 2018) is different from defining and grading a gingivitis case (GC) (i.e. a patient affected by gingivitis), because one "gingivitis site" does not necessarily equate to a GC. In fact, when shifting from the description of a "gingivitis site" to the identification of a GC, the classification process is complicated by the absence of clear-cut criteria that allow for discriminating a patient with a certain extent/severity of inflamed gingival sites from a periodontally healthy patient. In this respect, while clinical gingival inflammation is a well-defined site-specific condition for which several measurement systems have been proposed and validated, the concept of a GC is intended as the means to define the disease at the patient level. Such a definition, i.e. the selection of appropriate, distinct, and valid criteria

for a GC, becomes more challenging when applied to a patient who has experienced attachment loss in the past and has been successfully treated. A universal case definition is essential to facilitate population surveillance, for clinicians setting therapeutic targets, and to enable assessment of the efficacy of prevention and/or treatment regimes.

Based on available methods to assess gingival inflammation (Table 15-2), a GC could be simply, objectively, and accurately defined and graded using a bleeding-on-probing percentage (BoP%) score assessed as the proportion of bleeding sites (dichotomous yes/no evaluation) when stimulated by a standardized (dimensions and shape) manual probe with a controlled (~25 g) force to the bottom of the sulcus/pocket at six sites (mesiobuccal, buccal, distobuccal, mesiolingual, lingual, distolingual) on all present teeth (Ainamo & Bay 1975). BoP may be used for: (1) discriminating between a healthy and gingivitis patient (Lang & Bartold 2018), and (2) classifying a GC (localized, generalized) (Murakami *et al*. 2018). Use of BoP to identify a GC case would have the following advantages: (1) it is an objective, universally accepted, reliable, and accurate clinical sign that may be easily assessed and recorded (Lenox & Kopczyk 1973; Carter & Barnes 1974; Greenstein *et al*. 1981; Caton *et al*. 1988; Farina *et al*. 2011, 2013, 2017) as part of probing assessments necessary for a comprehensive periodontal examination; (2) extensive gingival bleeding represents a clinical sign often perceived by the patient, whereas low levels of BoP% are consistent with self-reported perception of healthy gingival conditions (Baser *et al*. 2014); (3) BoP recording is user-friendly, economic, and requires minimal/no technology. With suitable training, it is possible for general dental practitioners to achieve and maintain high levels of interexaminer consistency in assessing bleeding (Eaton *et al*. 1997); and (4) bleeding score can be effectively used to inform and motivate the patient (Mühlemann 1977; Saxer *et al*. 1977; Engelberger *et al*. 1983; Greenstein 1984) as well as monitor the efficacy of preventive and treatment strategies aimed to control periodontal diseases (Lang *et al*. 1986; Schwarz 1989; Lang *et al*. 1990).

Probing to the bottom of the sulcus/pocket may diagnose the presence of gingival inflammation while simultaneously assessing other relevant clinical parameters (attachment level, probing depths). Since a site (and thus, a patient) with gingivitis should not present with attachment loss, a single probing maneuver allows collection of the information necessary to detect the presence of both gingival inflammation and attachment loss.

A GC on an intact periodontium and a GC on a reduced periodontium in a patient without a history of periodontitis, is defined as ≥10% bleeding sites (Trombelli *et al*. 2018) with probing depths ≤3 mm. Localized gingivitis is defined as 10–30% bleeding sites; generalized gingivitis is defined as >30% bleeding sites (Table 15-3). A direct implication of the proposed GC definition is that a patient presenting with a BoP score <10% without attachment/bone loss (intact periodontium) or a reduced periodontium but without a history of periodontitis is considered "clinically periodontally healthy" (Table 15-3). Representative patients for GC on an intact periodontium, GC on a reduced periodontium in a patient without a history of periodontitis, and clinically periodontally healthy condition are illustrated in Figs. 15-5, 15-6, and 15-7, respectively.

Epidemiology of gingivitis

Although epidemiologic studies indicate consistently that gingival inflammation is a highly prevalent condition, there is heterogeneity in the reported prevalence of gingivitis (Table 15-4). Even though part of this heterogeneity can be interpreted in the light of real, genuine differences in disease occurrence among studied populations, it is evident that differences among cohorts may well be related to variations in the diagnostic criteria used to define the disease at the patient level, i.e. the employed GC definition.

Epidemiological studies have based the definition of a patient affected by gingivitis on epidemiological indices such as: Community Periodontal Index of Treatment Need (CPITN/CPI); average severity of gingival inflammation (as assessed using gingival indices or bleeding scores); average extent of gingival inflammation (assessed as the prevalence of sites with a certain gingival index or bleeding score); combinations of severity and extent measures. The majority of epidemiologic studies investigating the prevalence of periodontal diseases, including gingivitis, are based on the use of CPITN (Ainamo *et al*. 1982; World Health Organization 1997). Unfortunately, CPITN is designed to screen for the presence of periodontitis, and consequently none of the clinical parameters

Table 15-3 Diagnostic look-up table for gingival health or plaque-induced gingivitis (when occurring in a non-periodontitis patient) in clinical practice. (Source: Chapple *et al*. 2018.)

Intact periodontium	Health	Gingivitis
Probing attachment loss	No	No
Probing pocket depths (assuming no pseudopockets)*	≤3 mm	≤3 mm
Bleeding on probing*	<10%	Yes (≥10%)
Radiological bone loss	No	No
Reduced periodontium in a non-periodontitis patient		
Probing attachment loss	Yes	Yes
Probing pocket depths (assuming no pseudopockets)*	≤3 mm	≤3 mm
Bleeding on probing*	<10%	Yes (≥10%)
Radiological bone loss	Possible	Possible

* Assumes a light probing pressure of 0.2–0.25 N.

included in the scoring system (i.e. bleeding, supra- or subgingival calculus, pockets) are unique to gingivitis. When using more specific indices to assess gingival inflammation, wide variations of gingivitis prevalence are recorded in relation to varying cut-off values. In general, the more extended and severe the manifestations of the disease that are considered, the less prevalent the gingivitis.

These observations reinforce the need to identify and grade a GC based on the criteria listed in Table 15-3. This new GC definition has been successfully implemented in recent studies on diverse populations, examining various epidemiological (Botelho *et al*. 2019; Erchick *et al*. 2019; Machado *et al*. 2019) (Table 15-4), interventional (Al Asmari *et al*. 2020), and biological (Wang *et al*. 2020a) questions relating to gingivitis.

Impact of gingivitis on patient-reported quality of life

Few studies evaluated the impact of gingivitis on oral health-related quality of life (OHRQoL) (Tsakos *et al*. 2006; Krisdapong *et al*. 2012; Tomazoni *et al*. 2014). In a cohort of 1034 Thai children, Tsakos *et al*. (2006) showed that, while the prevalence of periodontal treatment need (CPI>0) was 97%, the perception of a condition-specific (CS) impact was limited to 27.1% of subjects. Specificity with respect to individuals with no CS-impact among periodontally healthy subjects was 0.83. Similarly, in a sample of 1100 12-year-old and 871 15-year-old Thai children, less than 30% of subjects had CS-impact on their quality of life related to gingivitis and calculus despite the high prevalence (about 80%) of gingivitis and/or calculus. The impact of gingivitis on children's OHRQoL was mostly at low levels of extent and intensity. However, extensive gingivitis was significantly associated with a moderate/higher level of CS-impacts (Krisdapong *et al*. 2012). In a random sample of 1134 12-year-old Brazilian schoolchildren, gingivitis extent showed an impact on OHRQoL, with mean quality of life scores being 1.15 higher for children with ≥15% BoP-positive sites than for children with <15% BoP-positive sites (Tomazoni *et al*. 2014). Extent of gingival bleeding (>15% BoP) was significantly associated with emotional well-being, oral symptoms, functional limitations, and social well-being domains (Tomazoni *et al*. 2014). Evidence suggests that plaque-induced gingivitis is associated with significant changes in somatosensory sensitivity (response to mechanical and thermal stimuli), both at the gingiva and the periodontal ligament (Wang *et al*. 2020a), providing a possible mechanistic explanation for at least part of the altered OHRQoL perception.

Collectively, data from these studies indicate that, although highly prevalent, gingivitis has a limited impact on OHRQoL. However, gingivitis extent, in terms of BoP score, may increase the negative effects on CS and general OHRQoL. Interestingly, an increasing level of agreement between the impact of gingivitis (Community Periodontal Index [CPI] = 1 versus CPI = 2) on patient's quality of life and the presence of a normative need for periodontal treatment has been reported (Tsakos *et al*. 2006).

Impact of gingivitis on systemic inflammation

As for other chronic inflammatory diseases, the relationship between periodontal diseases (including gingivitis) and systemic levels of inflammatory markers has been evaluated (see also Chapter 16). The biological mechanisms supporting the plausibility of this association rely on the entry of pathogenic bacteria from the biofilm of periodontally diseased sites into the blood stream and on the entry into the circulation of "excess" local levels of host-derived inflammatory mediators.

Among the investigated biomarkers, particular attention has been paid to C-reactive protein (CRP), which is produced in response to many forms of trauma or diseases and contributes to host defense as part of the innate immune response. Studies that evaluated the association between gingivitis and serum levels of CRP universally identified gingivitis as a condition characterized by serum CRP levels which are intermediate between those measured in periodontal health and periodontitis, although differences in serum CRP levels observed between gingivitis and

the other periodontal conditions did not consistently reach statistical significance in all studies (Pradeep *et al*. 2010; Bansal *et al*. 2014; Podzimek *et al*. 2015). In subjects with gingivitis, the severity and extent of gingival inflammation were evaluated for their relationship with CRP levels in serum. While in some studies CRP levels were found to be significantly positively correlated with papillary bleeding index (Podzimek *et al*. 2015) or gingival inflammation (Pradeep *et al*. 2010), other authors failed to find an association between CRP levels and gingival inflammation (Bansal *et al*. 2014), BoP (Wohlfeil *et al*. 2009; Bansal *et al*. 2014), or the number of sextants with at least one BoP-positive site (Pitchika *et al*. 2017).

Overall, the abovementioned findings seem to demonstrate that the inflammation of marginal gingival tissues determines an increase in systemic inflammation, assessed in terms of CRP levels. However, other studies have failed to demonstrate potentially relevant systemic effects during gingivitis development (Kinane *et al*. 2015). Therefore, the relationship between severity of gingival inflammation and severity of systemic inflammation in gingivitis patients remains unclear.

Prognostic value of gingivitis

When compared with periodontitis, a peculiarity of plaque-induced gingivitis lesion is the complete reversibility of the clinical tissue alterations once the dental biofilm is removed. Notwithstanding the reversibility of the gingivitis-elicited tissue changes, gingivitis at a site level holds particular clinical significance because it is considered the precursor of periodontitis. The evidence supporting the relationship between gingivitis and periodontitis lesions stems from longitudinal studies, where development and progression of attachment loss was associated with greater baseline levels of gingival inflammation (Löe *et al*. 1986; Ismail *et al*. 1990; Clerehugh *et al*. 1995; Albandar *et al*. 1998; Schätzle *et al*. 2003; Ramseier *et al*. 2017). In contrast, sites with no or minimal progression of attachment loss over time were characterized by the consistent absence of gingival inflammation over time (Page & Sturdivant 2002; Walters & Chang 2003; Schätzle *et al*. 2003; Axelsson *et al*. 2004; Repeke *et al*. 2012; Kina *et al*. 2016). Gingival inflammation has prognostic relevance for periodontal deterioration at the site level, when persistently present during multiple observation intervals. In this respect, it has been demonstrated that sites BoP have higher odds for attachment loss and exhibit greater prevalence of progressive severe attachment loss when compared with non-bleeding sites (Schätzle *et al*. 2003).

Overall, these observations suggest that effective long-term control of gingival inflammation could prevent progressive attachment loss (Schätzle *et al*. 2003).

Potential modifying factors of plaque-induced gingivitis

As mentioned above, individuals may differ in the clinical manifestation of plaque-induced gingivitis, even in the absence of discernible differences in systemic health and plaque accumulation. Such variable responses to similar plaque levels have been ascribed to possible, as yet unidentified, genetic differences (Trombelli *et al*. 2004a,b). However, there are several clearly identified patient factors, both at the systemic and the local level (Tatakis & Trombelli 2004; Trombelli & Farina 2013) that can affect the gingival response to the accumulated plaque, the tissue response to mechanical stimulation with a probe, and/or the underlying level of gingival inflammation in the absence of plaque, thus modifying the development of plaque-induced gingivitis.

Among the systemic factors established as modifiers of plaque-induced gingivitis, the most common or significant ones, such as smoking, changes in sex hormones, malnutrition, specific diseases and conditions, and systemic drugs, will be briefly reviewed here.

Smoking

Smoking, which is an established risk factor for periodontitis (Tomar & Asma 2000), has been consistently shown to suppress the gingival bleeding

response during development of gingivitis (Preber & Bergström 1985; Lie *et al*. 1998; Bergström & Boström 2001; Nair *et al*. 2003; Peruzzo *et al*. 2016). The smoking-induced decreased gingival bleeding in the presence of accumulated plaque is evident across tooth types (Holde *et al*. 2020) and manifests itself even in the presence of other systemic factors known to increase the bleeding response of the gingiva (Tarnowski *et al*. 2018). The potential mechanisms by which smoking alters the gingival inflammatory response to plaque accumulation include qualitative changes in the accumulating biofilm (Shiloah *et al*. 2000; Kumar *et al*. 2011; Matthews *et al*. 2013), alterations of the steady state (Wang *et al*. 2020b) and plaque-elicited gingival immune responses (Kumar *et al*. 2011), and effects on the physiological responses of the gingival vasculature (Morozumi *et al*. 2004; Buduneli & Scott 2018).

Sex steroid hormones

Sex steroid hormone changes, such as those occurring during puberty (Mombelli *et al*. 1989) and pregnancy (Raber-Durlacher *et al*. 1994; Gürsoy *et al*. 2008), impact and exacerbate the inflammatory response of the gingiva, even in the presence of minimal plaque levels (Mombelli *et al*. 1989; Raber-Durlacher *et al*. 1994; Gürsoy *et al*. 2008; Murakami *et al*. 2018). Changes in sex steroid hormones elicit complex changes in the immunobiology of the tissues (Raber-Durlacher *et al*. 1993; Carrillo-de-Albornoz *et al*. 2012; Yarkac *et al*. 2018) and appear to contribute to qualitative alterations of the associated dental plaque (Kornman & Loesche 1980; Raber-Durlacher *et al*. 1994; Balan *et al*. 2018). Although changes in sex steroid hormone levels occur also during the menstrual cycle and in response to oral contraceptive use, the associated gingival changes are typically modest, if not minimal, likely because the associated hormonal changes are also relatively small (Preshaw *et al*. 2001; Baser *et al*. 2009; Becerik *et al*. 2010; Preshaw 2013).

Malnutrition

Malnutrition and lack of specific nutrients have been shown to modify the gingival tissue response to plaque. Scurvy, the severe deficiency of vitamin C (ascorbic acid), is characterized by bleeding gingiva and other manifestations (Lind 1953), explained by the critical contribution of ascorbic acid to collagen synthesis and the significance of the latter to the maintenance of vascular structures and the renewal of blood vessel walls following mechanical trauma. Although scurvy is quite rare today where there is adequate food supply, unique and persistent dietary habits may precipitate the disease (Ellis *et al*. 1984). Controlled nutritional ascorbic acid deficiency experiments in humans (Leggott *et al*. 1986, 1991) result in increased gingivitis, relative to non-deficient controls with similar plaque levels and the same type of microflora. Conversely, dietary intervention, including supplementation with vitamin C and other nutrients with anti-inflammatory properties, results in significant reduction of gingival bleeding in the absence of any apparent microbiological changes (Amaliya *et al*. 2018; Woelber *et al*. 2019).

Specific systemic diseases and conditions

Specific systemic diseases and conditions known to modify the development of plaque-induced gingivitis include trisomy 21 (Down's syndrome), hyperglycemia and diabetes, and hematologic malignancies (e.g. leukemia). *Down's syndrome* patients manifest more extensive and severe gingival inflammation, and much earlier, compared with age- and sex-matched genetically healthy controls, despite no differences in plaque accumulation rates (Reuland-Bosma *et al*. 1986, 1988). Although the specific underlying mechanisms remain unclear, there is no doubting the genetic basis behind this modifying factor. *Hyperglycemia*, whether due to diabetes or other conditions, has been strongly associated with gingival bleeding (Hujoel & Stott-Miller 2011). When diabetic patients are compared with non-diabetics they experience significantly greater gingival inflammation with similar plaque levels, regardless of the underlying diabetic etiology (de Pommereau *et al*. 1992; Cutler *et al*. 1999; Salvi *et al*. 2005). The level of metabolic control (e.g. as expressed by HbA1c levels), is strongly associated with the prevalence of gingival bleeding (Ervasti *et al*. 1985; Hujoel & Stott-Miller 2011) and suggests that the increased

Argentina	de Muniz 1985	7–8- and 12–13-year-old individuals	2279	CPI	CPI = 1	2.7–27.2% (depending on age cohort)
Algeria, Benin, Burkina Faso, Cap Verde, Djibouti, Egypt, Ethiopia, Ghana, Kenya, Lesotho, Libya, Malawi, Mauritius, Morocco, Namibia, Niger, Nigeria, Seychelles, Sierra Leone, Somalia, South Africa, Sudan, Tanzania, Zaire, Zimbabwe	Baelum & Scheutz 2002	15–44-year-old individuals	Reported in each study included for review	CPI	Highest CPI score = 1 (gingival bleeding)	0–52% (depending on the country/study)
Studies employing the new Gingivitis Case Definition						
Portugal	Botelho *et al.* 2019	18 to >80-year-old individuals	1064	BoP	2018 Gingivitis case definition	8% (27.4% in 18–30- year-olds, 3.6–9.3% in all other age groups)
Portugal	Machado *et al.* 2019 (Subsample of the Botelho *et al.* 2019 study)	18 to >80-year-old individuals	571	BoP	2018 Gingivitis case definition	11.7%
Nepal	Erchick *et al.* 2019	15–41-year-old pregnant women	1452	BoP	2018 Gingivitis case definition	40.1% (80.4% of gingivitis cases were localized and 19.6% were generalized)

BoP, bleeding on probing; CPI, Community Periodontal Index; GI, Gingival Index.

bleeding in chronic hyperglycemia is attributable to the attendant microvascular injury. Metabolic control also affects subgingival biofilm composition (Ganesan *et al*. 2017). Furthermore, hyperglycemia causes cellular changes, affecting both immune and connective tissue cells, that result in the establishment of a proinflammatory state (Verhulst *et al*. 2019). Improved metabolic control following appropriate systemic therapy may reduce some but not all of the clinical signs of gingival inflammation (Sastrowijoto *et al*. 1990).

Leukemia, in both children and adults, may result in thrombocytopenia and/or clotting-factor deficiencies and may manifest in the gingiva with excess bleeding and other signs of inflammation (redness, swelling, enlargement) that are not consistent with the observed levels of biofilm acccumulation (Levin & Kennedy 1973; Dreizen *et al*. 1984; Bergmann *et al*. 1992; Guan & Firth 2015). Similarly, heightened gingival inflammation is also evident in patients affected by any of the many forms of *neutropenia* (Andrews *et al*. 1965; Reichart & Dornow 1978; Donadieu *et al*. 2011).

Systemic drugs

Besides the aforementioned systemic conditions and diseases that modify plaque-induced gingivitis, *systemic drugs* are a well-established cause of altered gingival responses to plaque accumulation. Such drugs may include agents that exacerbate the gingival bleeding response because of anticoagulant properties, for example aspirin (Schrodi *et al*. 2002; Royzman *et al*. 2004; Kim *et al*. 2007; Sundram *et al*. 2012). Others include endocrine hormone preparations (e.g. see information on sex steroid hormones previously) and drugs with strong anti-inflammatory activity, which may reduce the typically anticipated gingival inflammation. Both steroidal (Sutton & Smales 1983; Vogel *et al*. 1984; Markitziu *et al*. 1990) and non-steroidal (Vogel *et al*. 1984; Heasman *et al*. 1993) anti-inflammatory medications can have such an effect. Similarly, topical application of anti-inflammatory drugs can also reduce the gingival inflammatory response to plaque accumulation (Vogel *et al*. 1984; Jones *et al*. 1999). Several drugs have been identified that exacerbate the plaque-induced gingival inflammatory response in a more unique and specific manner; they cause severe gingival enlargement (Seymour *et al*. 1996; Seymour 2006). Drugs causing gingival enlargement include antihypertensive calcium channel blockers, for example nifedipine (Nery *et al*. 1995; O'Valle *et al*. 1995), anticonvulsants such as phenytoin (Angelopoulos 1975), and immunosuppressants, for example cyclosporin (Seymour & Jacobs 1992; O'Valle *et al*. 1995). Although the exact mechanisms through which these drugs lead to enlargement are not fully elucidated, it is apparent that direct and indirect effects on gingival connective tissue cells, especially fibroblasts, are involved in these responses (Fu *et al*. 1998; Mariotti *et al*. 1998; Seymour 2006; Gulati 2012).

In addition to the drugs that may modify the gingival response to plaque accumulation, development of gingivitis may also be altered by drugs that either enhance or inhibit plaque accumulation. Systemic antibiotics are a good example of a systemic factor that may limit biofilm development and thus prevent or slow the establishment of gingivitis (Listgarten *et al*. 1979; Heijl & Lindhe 1980). Drugs that may cause *hyposalivation*, such as sedatives, antidepressants, antihistamines, and antihypertensives, can lead to increased plaque accumulation and greater likelihood of caries and other oral complications, including inflammation of the oral mucosa and gingiva (Mizutani *et al*. 2015; Turner 2016). Hyposalivation can also be the result of systemic diseases, such as Sjögren syndrome and diabetes, and of head and neck radiation (López-Pintor *et al*. 2016; Turner 2016).

Local factors

A local factor commonly implicated in increased plaque accumulation and subsequent gingival inflammation is the presence of poor or prominent subgingival *restoration margins*. Inadequate subgingival restoration margins may facilitate plaque development both directly, by providing additional, rough surface areas, and indirectly, by making more difficult plaque removal during oral hygiene procedures. The end result, especially after long-term presence of such restorative irregularities, is detrimental to gingival health (Schätzle *et al*. 2001).

Local factors that may modify the gingival response to plaque have also been identified. One such potential factor is *thin periodontal phenotype*. Although evidence suggests a greater susceptibility of thin gingival tissues to mechanical trauma (Claffey & Shanley 1986; Olsson & Lindhe 1991) the significance of gingival quality/dimensions (i.e. periodontal phenotype) for the gingival bleeding response remains unresolved (Muller & Heinecke 2002; Trombelli *et al*. 2004c). Recent studies identified two other patient groups with gingival anatomical variants that may exhibit a modified response to plaque accumulation. The first group is patients with altered passive eruption, whose gingival response to similar levels of *de novo* plaque accumulation is much more severe than controls and less quick to resolve after reintroduction of oral hygiene measures (Aghazada *et al*. 2019). The second group is patients who have received a subepithelial connective tissue graft to treat gingival recession defects. The sites treated with the autogenous grafts, when compared with contralateral control sites, developed significantly less inflammation following plaque accumulation (Graziano *et al*. 2014). In the case of the grafted sites one could speculate that the graft-induced increase in gingival thickness may explain in part the resulting reduced susceptibility to

gingivitis development. However, in the case of the patients with altered passive eruption the mechanisms underlying the increased susceptibility to gingivitis development remain unclear.

Prevention and management of plaque-induced gingivitis

Tissue alterations that characterize plaque-induced gingivitis may be prevented or completely reversed by proper removal of the dental biofilm to ensure the maintenance or the restoration of a periodontally healthy condition (Table 15-3). The latter is perceived as such by the patient (Baser *et al*. 2014) and associates with better quality of life compared with gingivitis (Tomazoni *et al*. 2014). The reversion from gingivitis to periodontally healthy status holds particular clinical significance due to the well-established relationship between gingivitis and periodontitis as shown in longitudinal studies (Löe *et al*. 1986; Ismail *et al*. 1990; Clerehugh *et al*. 1995; Albandar *et al*. 1998; Schätzle *et al*. 2003; Ramseier *et al*. 2017). Gingivitis treatment also represents the key action to prevent progressive attachment loss in the long-term (Chapple *et al*. 2015; Ramseier *et al*. 2017).

The mechanical disruption of the dental biofilm through self-performed oral hygiene is the primary means to prevent and manage gingivitis (Chapple *et al*. 2015). Treatment success may be facilitated by adequate patient information, motivation, and personalized instruction (Newton & Asimakopoulou 2015), implementation of oral hygiene procedures with powered instruments (Van der Weijden & Slot 2015), proper interdental cleaning devices (Sälzer *et al*. 2015; Worthington *et al*. 2019), and chemical agents with antiplaque and/or anti-inflammatory properties (Van Strydonck *et al*. 2012; Trombelli & Farina 2013; Biesbrock *et al*. 2019; Figuero *et al*. 2019). The adjunctive use of probiotics (Akram *et al*. 2020) and dietary supplements or micronutrients (Montero *et al*. 2017; Amaliya *et al*. 2018) may also be suggested.

When self-performed oral hygiene is not or partly effective in re-establishing a periodontally healthy condition (e.g. due to the reduced ability of the subject or presence of plaque-retaining factors), professional intervention mainly based on mechanical plaque removal and elimination of local plaque-retentive factors is required. In this respect, it has been shown that professional removal of supra- and subgingival plaque in combination with oral hygiene instructions results in a greater reduction of gingival bleeding than no treatment. In the long-term, the frequency of professional sessions should be decided on the basis of the desired effect on plaque and bleeding (Needleman *et al*. 2015).

In instances where the gingival response to the dental biofilm is modified by systemic factors, multidisciplinary management of the gingivitis case involving appropriate medical professionals is recommended.

Introduction

A new classification of periodontal diseases and conditions was introduced in 2018 (Caton *et al*. 2018; Tonetti *et al*. 2018b), following the deliberations and the consensus report (Papapanou *et al*. 2018a) of an International Workshop that took place in Chicago in November 2017. The new system replaced the classification scheme used over the last two decades, which defined *chronic* and *aggressive* as the two principal forms of periodontitis (Armitage 1999). In this chapter, we will first provide a brief overview of terms that have been used in the recent literature to classify the main phenotypes of periodontitis, and their evolvement over the years. We will next explain in detail the main reasons that necessitated the most recent revision and will describe in depth the principles of the current system. Lastly, we will exemplify the implementation process in clinical practice by reviewing a number of clinical cases and highlighting clinical situations that may pose interpretational challenges.

A brief historical perspective: recently used periodontitis classification systems

Specific features defining different periodontitis-related phenotypes have formed the basis of classification systems ever since periodontal pathologies were first described in the literature. Inevitably, these systems have continuously evolved reflecting the prevalent scientific paradigms of the time (for a thorough review of periodontitis classification systems since the late nineteenth century, the reader is referred to Armitage 2002). Here we will briefly account for the main classification systems for periodontitis that have evolved over the past 50 years.

Early epidemiologic findings established that the severity of periodontitis in the population is associated with age and oral hygiene (Scherp 1964). Consequently, the observation that older cohorts, and individuals with poor oral hygiene, inevitably present with a certain amount of clinical attachment loss and bone loss permeated the literature and

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

influenced the definition of the main categories of periodontitis. A "bird's eye" view of the more recent periodontitis classification schemes prior to the introduction of the current system indicates that these systems have largely attempted to segregate patients with levels of periodontal tissue destruction that are commensurate to their age and level of local etiology from those with more severe but less prevalent manifestations (Table 16-1). Barring specific clinical phenotypes whose characteristics were attributed to underlying systemic conditions or necrotizing forms of periodontitis (both of which are still recognized until today as separate entities), a distinction was drawn between periodontitis manifesting itself in adults from those forms that affect children or individuals of young age. For example, the two main categories recognized by the 1989 World Workshop in Clinical Periodontics (Consensus Report, Discussion Section I, 1989) were Adult Periodontitis and Early Onset Periodontitis, setting the age threshold for distinction between the two at 30 years. Early Onset Periodontitis was further subdivided in three subcategories: *prepubertal* (Page *et al*. 1983), *juvenile* (Tsai *et al*. 1981) and *rapidly progressive* periodontitis (Page *et al*. 1983). The first subcategory included children with loss of periodontal tissue support affecting their deciduous teeth. The second included teenagers with a characteristic bone loss pattern affecting incisors and first molars and with periodontal pockets heavily colonized by *Aggregatibacter actinomycetemcomitans* (then termed *Actinobacillus actinomycetemcomitans*). Note that this particular phenotype had been earlier attributed to degenerative processes, including "cementopathia" and "diffuse atrophy of the alveolar bone" (Gottlieb 1928), and was later termed "periodontosis" (Hirschfeld 1948). The third subcategory included individuals in their twenties, with generalized and rapid periodontitis progression. Interestingly, the 1989 classification also included a main category separate from both Early Onset and Adult Periodontitis, termed Refractory Periodontitis, which included patients who were found to be unresponsive to a variety of periodontal treatment modalities.

Acknowledging the difficulties associated with an accurate assessment of the age of onset of periodontitis in many patients, and recognizing that the Refractory Periodontitis category was extremely heterogeneous, a new International Workshop that took place in 1999 abolished these terminologies and defined two major forms of periodontitis termed Chronic and Aggressive Periodontitis (Armitage 1999). Chronic periodontitis now encompassed the more common form of the disease where the extent and severity of tissue loss is largely commensurate with the amount of local etiology. In contrast, Aggressive Periodontitis was characterized by more rapid destruction of the periodontal supporting tissues and manifested itself

Table 16-1 Evolution of the classification systems of periodontal diseases over the last 50 years.

1977	1986	1989	1999	2018
			Gingival diseases A. Dental plaque-induced B. Non plaque-induced	Gingival diseases and conditions
Juvenile periodontitis	Juvenile periodontitis A. Prepubertal B. Localized juvenile c. Generalized juvenile	Early-onset periodontitis A. Prepubertal 1. Localized 2. Generalized B. Juvenile periodontitis 1. Localized 2. Generalized C. Rapidly progressive	Aggressive periodontitis A. Localized B. Generalized	Periodontitis classified according to a 2-vector system on the basis of Stage and Grade
Chronic periodontitis	Adult periodontitis	Adult periodontitis	Chronic periodontitis	
	Necrotizing ulcerative gingivo-periodontitis	Necrotizing ulcerative periodontitis	Necrotizing periodontal diseases A. Necrotizing ulcerative gingivitis B. Necrotizing ulcerative periodontitis	Necrotizing periodontal diseases
	Refractory periodontitis	Refractory periodontitis		
		Periodontitis associated with systemic disease	Periodontitis as a manifestation of systemic diseases	Periodontitis as a manifestation of systemic disease
			Abscesses of the periodontium	
			Periodontitis associated with endodontic lesions	Other conditions affecting the
			Developmental or acquired deformities and conditions	periodontium

in either a localized or a generalized form. Note that imprecision in the stipulated primary and secondary features of these novel categories, along with the fact that age was no longer considered a primary classification criterion – allowing individuals to be classified as having either chronic or aggressive periodontitis irrespective of their age – made the 1999 classification rather difficult to apply in everyday clinical practice.

Need for the new classification

The etiological role of microbial plaque in the initiation of gingivitis has been well-established (Löe *et al*. 1965) and classical experimental animal studies expanded the role of bacteria in the pathogenesis of periodontitis (Lindhe *et al*. 1973). Subsequent longitudinal studies conducted between the early 1970s through the 1980s informed the core principles that allowed successful prevention and treatment of periodontitis (Knowles *et al*. 1972; Axelsson & Lindhe 1981a, b; Ramfjord *et al*. 1982). In subsequent years, however, clinicians and researchers started to report exceptions and variations to the simple paradigms that suggested that periodontitis susceptibility and severity are a mere function of the intensity and the duration of bacterial exposure and that prevention and treatment are predictable outcomes if there is adequate bacterial control (Scherp 1964; Lindhe & Nyman 1975; Nyman *et al*. 1977; Hirschfeld & Wasserman 1978; McFall 1982; Lindhe *et al*. 1984; Löe *et al*. 1986; Westfelt *et al*. 1998). Instead, what has emerged in epidemiologic and treatment studies is that multiple risk factors, including environmental exposures and genetic predispositions, can modify an individual's phenotypic response to the bacterial challenge and/or the outcome of periodontal therapy (Papapanou 1996; see Chapter 6). Although the majority of periodontitis cases respond predictably to mechanical biofilm disruption and subsequent plaque control, a relatively small percentage of patients will respond unfavorably to standard periodontal treatment. Moreover, although average levels of attachment loss at different ages are generally consistent throughout the world, there are individuals in each age group who have experienced a level of disease severity that is disproportionate to that expressed by the majority of their peers (Billings *et al*. 2018).

These clinically observable exceptions in periodontitis expression indicated that there was a need for additional information beyond the current level of severity to more specifically characterize a patient's type of periodontitis. Important questions that arose and challenged older paradigms were (1) whether the clinically observed distinct disease phenotypes are truly different diseases or, rather, variations of a common disease entity; (2) whether these phenotypes were indeed the result of different infections by specific bacteria or bacterial complexes that had been earlier implicated as causative factors; and (3) the exact role of multiple risk factors including genetic susceptibility. Importantly, the acknowledged difficulty to distinguish between chronic and aggressive periodontitis based on clinically identifiable traits (Armitage *et al*. 2010) and the diagnostic imprecision of primary criteria used to classify these principal categories (Armitage 1999) was further sustained by the presence of common microbiological, immunological, and histopathological features of the two entities (Armitage 2010; Ford *et al*. 2010; Smith *et al*. 2010). For example, the postulated differences in the intensity in serum antibody responses between subtypes of periodontities were disproved (Picolos *et al*. 2005; Hwang *et al*. 2014) and transcriptomic profiles of gingival lesions from chronic and aggressive periodontitis were largely overlapping (Kebschull *et al*. 2013). These observations were corroborated by a position paper that reviewed the literature pertaining to aggressive periodontitis (Fine *et al*. 2018) in preparation for the 2017 World Workshop for the Classification of Periodontal and Peri-implant Diseases and Conditions as well as a recent review on the nexus between periodontal inflammation and microbial dysbiosis (Van Dyke *et al*. 2020).

Key concepts and ground rules of the new classification of periodontitis

The new periodontitis classification system is fundamentally different from the 1999 scheme, because, with the exception of specific forms (necrotizing periodontal diseases and periodontitis as a manifestation of systemic disease) (Albandar *et al*. 2018; Herrera *et al*. 2018), periodontitis is recognized as a single nosological entity which is further classified using a two-vector system (*Stage* and *Grade*) (Tonetti *et al*. 2018a). *Stage* reflects the severity of the disease (expressed through *attachment loss* and *bone loss*), but also factors in *tooth loss* that has occurred as a result of periodontitis (Table 16-2). In addition, it reflects the anticipated complexity of the treatment that is required to eradicate/reduce the current level of microbial challenge and inflammation, and to restore patient masticatory function. *Grade* describes additional biological dimensions of the disease including the observed or inferred progression rate, the risk for further deterioration due to environmental exposures (such as smoking) and co-morbidities (such as diabetes), and the risk that the disease or its treatment may adversely affect the particular patient's general health status (Table 16-3). The key steps of the process that need to be followed when implementing the new scheme are outlined in the following sections.

Assessment of Stage

It is important to realize that, before beginning an assessment of Stage, the clinician first needs to determine if the patient in question indeed has periodontitis. This assessment is ideally done on the

Table 16-2 Classification of periodontitis based on Stages defined by Severity (according to the level of interdental clinical attachment loss, radiographic bone loss and tooth loss), Complexity, and Extent and Distribution.

Periodontitis stage		Stage I	Stage II	Stage III	Stage IV
Severity	Interdental CAL at site of greatest loss	1–2 mm	3–4 mm	≥5 mm	≥8 mm
	Radiographic bone loss	Coronal third (<15%)	Coronal third (15–33%)	Extending to middle third of the root	Extending to apical third of the root
	Tooth loss	No tooth loss due to periodontitis		Tooth loss due to periodontitis of ≤4 teeth	Tooth loss due to periodontitis of ≥5 teeth
Complexity	Local	Maximum probing depth ≤4 mm Mostly horizontal bone loss	Maximum probing depth ≤5 mm Mostly horizontal bone loss	In addition to Stage II Complexity: Probing depth 6–7 mm Vertical bone loss ≥ 3 mm Furcation involvement Class II or III Moderate ridge defect	In addition to Stage III Complexity: Probing depth ≥8 mm Need for complex rehabilitation due to: masticatory dysfunction; secondary occlusal trauma; tooth mobility degree ≥2; bite collapse, drifting, flaring; less than 20 remaining teeth (10 opposing pairs); severe ridge defect
Extent and Distribution	Add to Stage as descriptor	For each Stage, describe extent as localized (<30% of teeth affected at the Stage-defining severity level), generalized (≥ 30% of teeth affected), or molar-incisor pattern			

CAL, clinical attachment loss; RBL, radiographic bone loss.

basis of full-mouth clinical attachment loss (CAL) measurements and is *not* an automatic process based on attachment loss thresholds: the determination involves clinical judgment. If interproximal attachment loss is present on at least two different, non-adjacent teeth, and the observed attachment loss cannot be attributed to traumatic factors or non-periodontitis-related etiologies (e.g. root fracture, endodontic infection, surgical trauma), then the patient is considered to have periodontitis. In the absence of interproximal attachment loss, but if attachment loss that cannot be ascribed to non-periodontitis-related causes is present at buccal or lingual surfaces, a diagnosis of periodontitis requires concomitant presence of CAL of ≥ 3 mm and probing depth of ≥3 mm at ≥2 teeth. Clinicians frequently confirm the presence of interproximal attachment loss by assessing presence of alveolar bone loss on periapical or bite-wing radiographs. It must be remembered, however, that tissue loss needs to encompass a substantial portion of the buccal-lingual dimension before it can be visualized by conventional radiographs. Thus, absence of readily discernible bone loss does not preclude presence of frank periodontitis of incipient severity. This is exactly the reason why the diagnosis of periodontitis is based on attachment loss rather than bone loss which is admittedly more widely assessed; use of bone loss as the primary criterion would result in significant under-detection of incipient periodontitis and an increase in "false negatives".

After ascertaining that the patient has periodontitis, the clinician should proceed with an assessment of Stage. A key element of the new classification, supported by our current knowledge, is that Stage I and Stage II adult patients are likely very different from Stage III and Stage IV patients in terms of how the host has coped with and/or has responded to the bacterial challenge. Stage I and II patients show periodontitis of incipient or moderate severity, have not lost any teeth due to the disease, and are likely to respond predictably to standard therapy based on the principles of sustainable reduction of the bacterial burden. In contrast, in stage III and stage IV periodontitis patients, it is most likely that one or several intrinsic or environmental risk factors have adversely affected the ability of the host to respond to the bacterial infection and to contain the tissue damage; thus, these patients seem to have experienced a different "disease trajectory" than patients of the same age with stage I or stage II periodontitis. Moreover, Stages III and IV represent more complex cases (due to angular defects, furcation involvements, tooth mobility, extensive tooth loss, loss of function) that require more specific knowledge, broader training, and more in-depth clinical experience to manage the patient's condition in a sustainably successful manner.

Based on the above, the initial staging of a case should involve a focused, high-level assessment of the patient's medical history, radiographs, and probing measurements to distinguish between Stage I or II versus Stage III or IV periodontitis, using two key discriminatory variables that can differentiate between the two aggregate groups: (1) the severity of tissue damage and (2) the presence of

Table 16-3 Classification of periodontitis based on Grades that reflect biologic features of the disease including evidence of, or risk for, rapid progression, anticipated treatment response, and effects on systemic health.

	Periodontitis grade		Grade A Slow rate of progression	Grade B Moderate rate of progression	Grade C Rapid rate of progression
Primary criteria	Direct evidence of progression	Longitudinal data (PA radiographs or CAL loss)	Evidence of no loss over 5 years	<2 mm over 5 years	≥2 mm over 5 years
	Indirect evidence of progression	Bone loss/age	<0.25	0.25–1.0	>1.0
		Case phenotype	Heavy biofilm deposits with low levels of destruction	Destruction commensurate with biofilm deposits	Destruction exceeds expectation given biofilm deposits; specific clinical patterns suggestive of periods of rapid progression and/or early onset disease, e.g. molar incisor pattern; lack of expected response to standard bacterial control therapies
Grade modifiers	Risk factors	Smoking	Non-smoker	Smoker <10 cigarettes/day	Smoker ≥10 cigarettes/day
		Diabetes	Normo-glycemic, no prior diagnosis of diabetes	HbA1c <7.0 in diabetes patient	HbA1c ≥7.0 in diabetes patient
Risk of systemic impact of periodontitis	Inflammatory burden	High sensitivity CRP	< 1 mg/L	1-3 mg/L	>3 mg/L
Biomarkers	Indicators of CAL/bone loss	Saliva, GCF, serum	?	?	?

CAL, clinical attachment loss; CRP, C reactive protein; GCF, gingival crevicular fluid; PA, periapical.

periodontitis-associated tooth loss. Note that the second point is an important novelty of the new classification when compared with its predecessors, as it incorporates in the diagnosis past experience of periodontitis that is inevitably not measurable at the current time point. For example, consider a situation when most periodontitis-affected teeth have been lost already, and the patient has been left with teeth that are intact, or affected at much lower severity. Assessment of the patient's overall susceptibility status on the basis of these "healthy survivor" teeth would be unquestionably erroneous.

This high-level assessment uses a narrow set of parameters to make a first distinction of whether a periodontitis case is either Stage I or II versus Stage III or IV, as indicated by the vertical red line in Fig. 16-1, and provides a starting point for a more detailed assessment. The distinction between Stage I and II periodontitis will be primarily carried out by evaluating whether the severity of bone loss at the areas of the dentition that exhibit the most advanced destruction extends either within or beyond one half of the coronal third (i.e. up to 15% of the root length versus between 15% and 33% of the root length). Clearly, the point here is not to scrutinize the level of bone loss with precision extending to single percentage points, but to distinguish between an incipient stage of periodontitis that has barely resulted in alveolar bone loss, from more substantial bone loss that extends within the coronal third of the root length. Readily discernible interproximal bone loss within the coronal third of the root length will, in most situations, be commensurate with Stage II rather Stage I disease. In contrast, Stage I disease is usually characterized by incipient attachment loss in the presence of early radiographic evidence of disruption in the alveolar bone support (for example, a break in the integrity of *the lamina dura*) rather than pronounced increase in the cementoenamel junction (CEJ)–bone crest distance.

If the high-level assessment indicates the patient is more likely to be a Stage III or IV, the clinician will need to evaluate the more complex parameters listed to the right of the red vertical line in Fig. 16-1. In this step, the clinician needs to study in detail the available full-mouth periodontal charting and full-mouth series of intraoral radiographs. The distinction between these two stages will be based either on the amount of tooth loss that can be attributed to periodontitis (1–4 teeth versus 5 or more teeth lost) or on the presence of the various complexity factors listed in Fig. 16-1 that need to be appreciated in detail. It must be realized that either Stage III or Stage IV disease may reflect severe or very severe periodontitis. However, the primary distinction between the two requires that an experienced clinician ponders the following two central questions that essentially represent a distillation of the case's treatment: (1) does the patient's extent and severity of periodontitis constitute a threat for the survival of *individual teeth* or rather of the survival of *the entire dentition*? and (2) does the total therapy envisioned to address the sequelae of periodontitis in the particular patient involve extensive, multidisciplinary oral rehabilitation? If the assessment is that the current level of periodontitis threatens the entire dentition and, consequently, treatment requires extensive oral rehabilitation involving collaboration of multiple experts (beyond the need for occasional extractions and a limited prosthetic reconstruction), then the

Staging a Periodontitis Patient		Initial Periodontitis	Moderate	Severe with potential for tooth loss	Advanced with potential for dentition loss
Periodontitis stage		Stage I	Stage II	Stage III	Stage IV
Severity	Interdental CAL at site of greatest loss	1 to 2 mm	3 to 4 mm	≥ 5 mm	≥ 5 mm
	Radiographic bone loss	Coronal third (<15%)	Coronal third (15% to 33%)	Extending to mid-third of root and beyond	Extending to mid-third of root and beyond
	Tooth loss	No tooth loss due to periodontitis		Tooth loss due to periodontitis of ≤ 4 teeth	Tooth loss due to periodontitis of ≥5 teeth
Complexity	Local	Maximum probing depth ≤ 4 mm Mostly horizontal bone loss	Maximum probing depth ≤5 mm Mostly horizontal bone loss	In addition to stage II complexity: Probing depth ≥ 6 mm Vertical bone loss ≥ 3 mm Furcation involvement Class II or III Moderate ridge defect	In addition to stage III complexity: Need for complex rehabilitation due to: Masticatory dysfunction Secondary occlusal trauma (tooth mobility degree >2) Severe ridge defect Bite collapse, drifting, flaring Less than 20 remaining teeth (10 opposing pairs)
Extent and distribution	Add to stage as descriptor	For each stage, describe extent as localized (<30% of teeth involved), generalized, or molar/incisor pattern			

Fig. 16-1 The initial assessment of Stage distinguishes between Stage I or II versus Stage III or IV periodontitis (on either side of the red line), on the basis of the severity of the loss of supporting tissue and the presence of periodontitis-associated tooth loss.

appropriate Stage for the patient is IV rather than III. Importantly, this determination involves a *collective* assessment of the potential complexity factors, rather than a mere "checking of a box" approach of isolated features.

It needs to be emphasized that Stage is a *patient based-attribute*, not a *tooth-based assessment*; consequently, a single Stage is ascribed to an individual patient at a given time. After Stage has been determined, Extent is added as a secondary descriptor, and reflects the percentage of teeth in the dentition that are affected by attachment or bone loss at the level of severity that defined the Stage (Sanz *et al*. 2020). For example, in a particular case that has been diagnosed to exhibit Stage III periodontitis, the Extent will be determined to be "localized", if the percentage of teeth with bone loss *beyond* the coronal third of the root is less than 30%. In contrast, if a larger proportion of teeth is affected by bone loss of that severity, the Extent will be considered "generalized". Note that because a patient with localized Stage III periodontitis may frequently include segments of the dentition with mild or moderate severity of attachment/bone loss, Extent describes the distribution of the severity that is characteristic of Stage III in the specific patient (Sanz *et al*. 2020) *not* the fraction of the dentition that is affected by periodontitis at any level of severity. Therefore, whenever communicating with patients or with each other, clinicians need to acknowledge this important distinction and to report the presence of less severely affected teeth that still need treatment in the "narrative" portion of the case description.

Another frequently raised question is whether a patient's Stage can change over time. If a patient who has been staged at a given time point experiences significant disease progression or disease recurrence after therapy that results in increased severity and/or more complex treatment needs, then stage must be shifted upwards at the time of the subsequent examination, as appropriate. However, although the severity of attachment loss and/or bone loss can be reduced substantially in case of successful regeneration therapy, it is advised that the patient retains the Stage originally assigned prior to the treatment.

Assessment of grade

Research data that have accumulated over the past decades indicate that the majority of periodontitis patients are on a disease trajectory that is compatible with predictably favorable clinical responses, provided that adequate therapy is rendered and diligent plaque control and maintenance visits at appropriately scheduled intervals are sustained. However, a proportion of patients ranging between 20% and 25% are on a different trajectory and are less likely to respond predictably to these standard approaches (Giannobile *et al*. 2013). The primary goal of grading is thus to determine the disease trajectory that a specific patient is likely following, and to use this information to guide the most appropriate intervention strategy to achieve a successful outcome.

The assessment of Grade is based on three fundamental principles:

- Not all individuals are equally susceptible to periodontitis (Baelum *et al*. 1986; Löe *et al*. 1986; Billings *et al*. 2018).
- Periodontitis progression and severity is a function of multiple influences that interact with each other, modify the individual patient's host response to the microbial challenge, and influence the clinical phenotypes (Struch *et al*. 2008; Giannobile *et al*. 2013; Morelli *et al*. 2017).
- More comprehensive strategies are required for certain subsets of patients to successfully treat their periodontitis and arrest its progression (McGuire 1991).

Consequently, the assessment of Grade serves three primary purposes:

- To stratify patients with respect to periodontitis trajectory in one of two groups: one group that includes patients with minimal likelihood of disease progression, and with expected predictable clinical responses to prevention and treatment based on standard principles of biofilm disruption and regular plaque control; or a second group that consists of patients with an increased likelihood of disease progression and less predictable clinical responses.
- To assist in developing new protocols for clinical and behavioral management of periodontitis cases that are less likely to respond favorably to current standard principles.
- To assist in determining additional approaches to the management of periodontitis that may also favorably influence systemic health.

Grade is thus defined as a three-level variable: a moderate rate of progression of periodontitis (Grade B) is assumed as the default Grade, unless the current clinical status and the overall oral and general health history either provide evidence of more rapid progression or presence of risk factors that increase the probability of more rapid progression (Grade C), or suggest a slower rate of progression than one might expect given the amount of current etiology and the patient's age (Grade A). Consequently, factors to be assessed to determine the patient's grade include *observed* or *inferred* rate of periodontitis progression and presence and control of risk factors. It is expected that accumulating data on the effects of periodontitis on the systemic inflammatory status, and reliable biomarkers of periodontitis presence and progression, will also be incorporated in the assessment of Grade in the future.

Currently, disease progression or stability is currently most accurately captured by serial assessments

of radiographic bone loss or CAL over time. However, since longitudinal data are typically not available, the progression rate for an individual can be inferred using the observed bone loss at the most affected segment of the dentition in relation to the patient's age, i.e. the ratio of the maximum percentage bone loss over age. The assessment of bone loss as a percentage of the root length is inherently a rough estimate based on the clinician's best interpretation of the radiographic images regarding the most apical location of the alveolar bone support, the location of the CEJ, and the location of the apex of the root. In a 50-year-old patient, bone loss extending to 60% of the root length at the most affected site would represent a percent bone loss/age ratio greater than 1.0 which would classify the patient as being Grade C based on rate of progression. The same severity of bone loss in a 90-year-old patient would result in a ratio of 0.66 and translate into Grade B. Given the limited precision of assessments used to calculate the ratio of greatest radiographic bone loss by age, the clinician should use clinical judgment if the ratio is very close to 1.0.

In addition to the direct or indirect assessments of periodontitis progression, the assessment of Grade factors in the patient's risk profile, as well as aspects related to the potential impact of periodontitis on systemic health.

Impact of risk factors

Periodontitis is a chronic disease of multifactorial etiology; individual exposures influence susceptibility to the disease and responsiveness to therapy in either an additive or a synergistic fashion. The Grade table explicitly includes the two most established risk factors for periodontitis, namely smoking (Bergström 1989; Haber *et al*. 1993; Johnson & Guthmiller 2007) and diabetes mellitus (Hugoson *et al*. 1989; Taylor *et al*. 1998; Lalla & Papapanou 2011) and stipulates threshold levels of current smoking or of metabolic control in diabetes, in an attempt to 'quantify' the risk conferred by these exposures. However, the clinician is encouraged to carefully consider additional risk factors that may influence the progression of periodontitis and its response to treatment in the assessment of Grade. These include obesity, other chronic inflammatory diseases such as rheumatoid arthritis, chronic depression, and other factors that emerge from a comprehensive medical history (Monteiro da Silva *et al*. 1996; Genco *et al*. 1999; Mercado *et al*. 2000; Suvan *et al*. 2014; Morelli *et al*. 2017). The goal for the clinician is to identify patients who are likely to require more intensive monitoring, intervention, and physician collaboration to help control systemic factors that may complicate host modulation of the chronic inflammatory component of severe periodontitis.

Patients classified with incipient (Stage I) or moderate (Stage II) periodontitis will most likely not display evidence of sufficient periodontitis progression to qualify for Grade C, unless they are very young and have a bone loss/age ratio of >1. However, some Stage I or II patients may be heavy smokers or have poorly controlled Type II diabetes and may therefore qualify for a Grade C diagnosis through their risk profile. The exposures that account for a Grade C should certainly be targets for behavioral modification (i.e. smoking cessation) or additional therapeutic intervention in collaboration with the patients' physician (i.e. better metabolic control in diabetes), as they entail greater risk for less predictable clinical outcomes using standard principles of disease management.

In Stage III and IV patients, assessment of Grade may often be defined indirectly by the apparent rapid bone loss relative to the patient's age; however, Grade modifiers, beyond being informative of the risk of further progression and the likelihood of a successful treatment outcome are obvious interventional targets.

Systemic health considerations

Evidence indicates that the presence of certain chronic inflammatory diseases influence the likelihood of a second chronic disease to be concomitantly manifested (Dregan *et al*. 2014, 2019; Dregan 2018). Although there is substantial evidence associating periodontitis with other diseases such as cardiovascular disease, Type 2 diabetes, and adverse pregnancy outcomes, evidence that treatment of periodontitis will result in predictable benefits with respect to any of those systemic conditions is rather limited (Beck *et al*. 2019). The systemic inflammatory burden of periodontitis is well-documented, at least as measured by high sensitivity C-reactive protein (hsCRP) (Amabile *et al*. 2008; Demmer *et al*. 2013; Artese *et al*. 2015). Given the well-established role of elevated hsCRP in cardiovascular diseases and other chronic conditions, the impact of effective treatment of periodontitis on hsCRP levels may be an important parameter to monitor in certain patients with Stage III or IV periodontitis.

The role of biomarkers

Current evidence indicates that certain combinations of salivary biomarkers may add value in the assessment of periodontal therapy relative to the stability of the case post-treatment (Kinney *et al*. 2011; Salminen *et al*. 2014). It is expected that additional evidence of their clinical utility and further advances in the field of novel biomarkers will better inform and refine an objective assessment of Grade. Likewise, the currently defined boundaries for smoking and metabolic control may be revised in the future, and stratification based on the severity of additional chronic conditions or novel risk factors that are presently not included in the Grade table may be appended, as new research data accumulate.

A common question is whether Grade can change over time. An upwards revision of Grade is possible if the percentage bone loss/age ratio increases substantially, or the risk profile of the patient deteriorates. Conversely, downgrading is also possible, if the determinants of Grade when it was originally assigned are no longer prevalent. However, the clinician is urged to carry out such modifications judiciously and after thorough consideration of the totality of the risk factors at play as well as of the consequences of the altered Grade on the patient's overall management plan.

Implementation of the current classification: clinical examples

For assisting in the implementation of this new classification of periodontitis in clinical practice, advisory algorithms have been published to guide the clinician into the decision-making process of defining a periodontitis case and then further assisting in the definition of the Stage and Grade (Tonetti & Sanz 2019). It is important, however, to emphasize the need for a *holistic* interpretation of the variables involved in the correct diagnosis, rather than uncritical adherence to particular threshold values quoted. As stated above, CAL is the primary diagnostic tool for detecting a patient with periodontitis. Therefore, clinicians should recognize the signs of CAL and differentially diagnose other clinical conditions also associated with CAL that are not attributed to periodontitis. Detecting alveolar bone loss from diagnostic quality radiographs may also be used as a proxy measure of CAL.

The first step in the diagnostic process is to determine if a patient is periodontally healthy, has gingivitis, or has periodontitis. If full-mouth radiographs of good diagnostic quality are available, the clinician should carefully examine them to detect bone loss. If no bone loss is detectable, the clinician should probe around all teeth in the dentition to detect signs of inter-dental CAL. If no CAL is detected, then full-mouth bleeding on probing (BoP) scores will differentiate between a diagnosis of periodontal health (BoP <10%) or gingivitis (BoP ≥10%). If either CAL or bone loss attributed to periodontitis has been detected, the clinician should proceed with a comprehensive examination to determine periodontitis Stage, Grade, and Extent.

The following clinical examples summarize the decision-making process in cases with variable Stage/Grade/Extent combinations.

Case 1 (Fig. 16-2)

The patient is a 24-year-old Caucasian male who has received sporadic dental care during the last decade. The patient has seen his physician recently for a physical examination and routine blood-work, both of which were unremarkable. The patient has never smoked. Clinical examination reveals a full-mouth BoP score of 55%, and a range of probing depths between 1 and 5 mm. Although no interproximal bone loss is readily visible on the available radiographs, interproximal CAL ranging between 1 and 2 mm is noted in more than 30% of the teeth present. No tooth mobility or furcation involvements are present. Given the incipient severity of interproximal attachment loss and the absence of risk factors that may act as Grade modifiers, the patient was diagnosed with periodontitis Stage I, Grade A, generalized.

Case 2 (Fig. 16-3)

The patient is a 29-year-old Hispanic female who reports sporadic dental care; the most recent dental visit was 4 years previously. The patient is under medication for Type I diabetes mellitus diagnosed 8 years ago, and her most recent hemoglobin A1c assessment obtained 2 months ago was 7.8%. The patient is a former smoker with an 8 pack-year history who quit smoking 6 years ago. Available radiographs reveal presence of several teeth with clearly discernible bone loss which extends within the coronal third of the root length. Full-mouth BoP is 89%, probing depths range between 1 and 6 mm, and interproximal attachment loss between 3 and 4 mm is noted at 10 teeth. Degree I furcation involvements are present buccally at both maxillary right molars and at the first maxillary left molar, as well as lingually at the first mandibular left molar. The maxillary lateral incisor shows Degree 1 mobility. Given the maximum severity of bone loss within the coronal third of the root, the presence of interproximal attachment loss between 3 and 4 mm at more than one third of the teeth present, and the poor metabolic control of the patient's diabetes, the assigned diagnosis was periodontitis Stage II, Grade C, generalized.

Case 3 (Fig. 16-4)

The patient is a 19-year-old African-American male freshman college student, who reports attending annual visits to his general dentist for the past few years. The dentist referred him to a periodontist after the last visit after having detected "bone loss at the lower back teeth". The patient has never smoked, and has been recently seen by a student health services physician who carried out a physical examination and obtained a routine blood test; both were unremarkable. The patient reports that his mother has lost several teeth due to "gum disease". Available full-mouth periapical radiographs show intact interproximal bone levels at all areas apart from the mesial surfaces of the first mandibular molars bilaterally, where angular bony defects are visible extending beyond the coronal third of the root. The first right and the first left mandibular molars present with mesial probing depths of 9 and 10 mm, respectively, and corresponding CAL of 7 and 8 mm. No probing

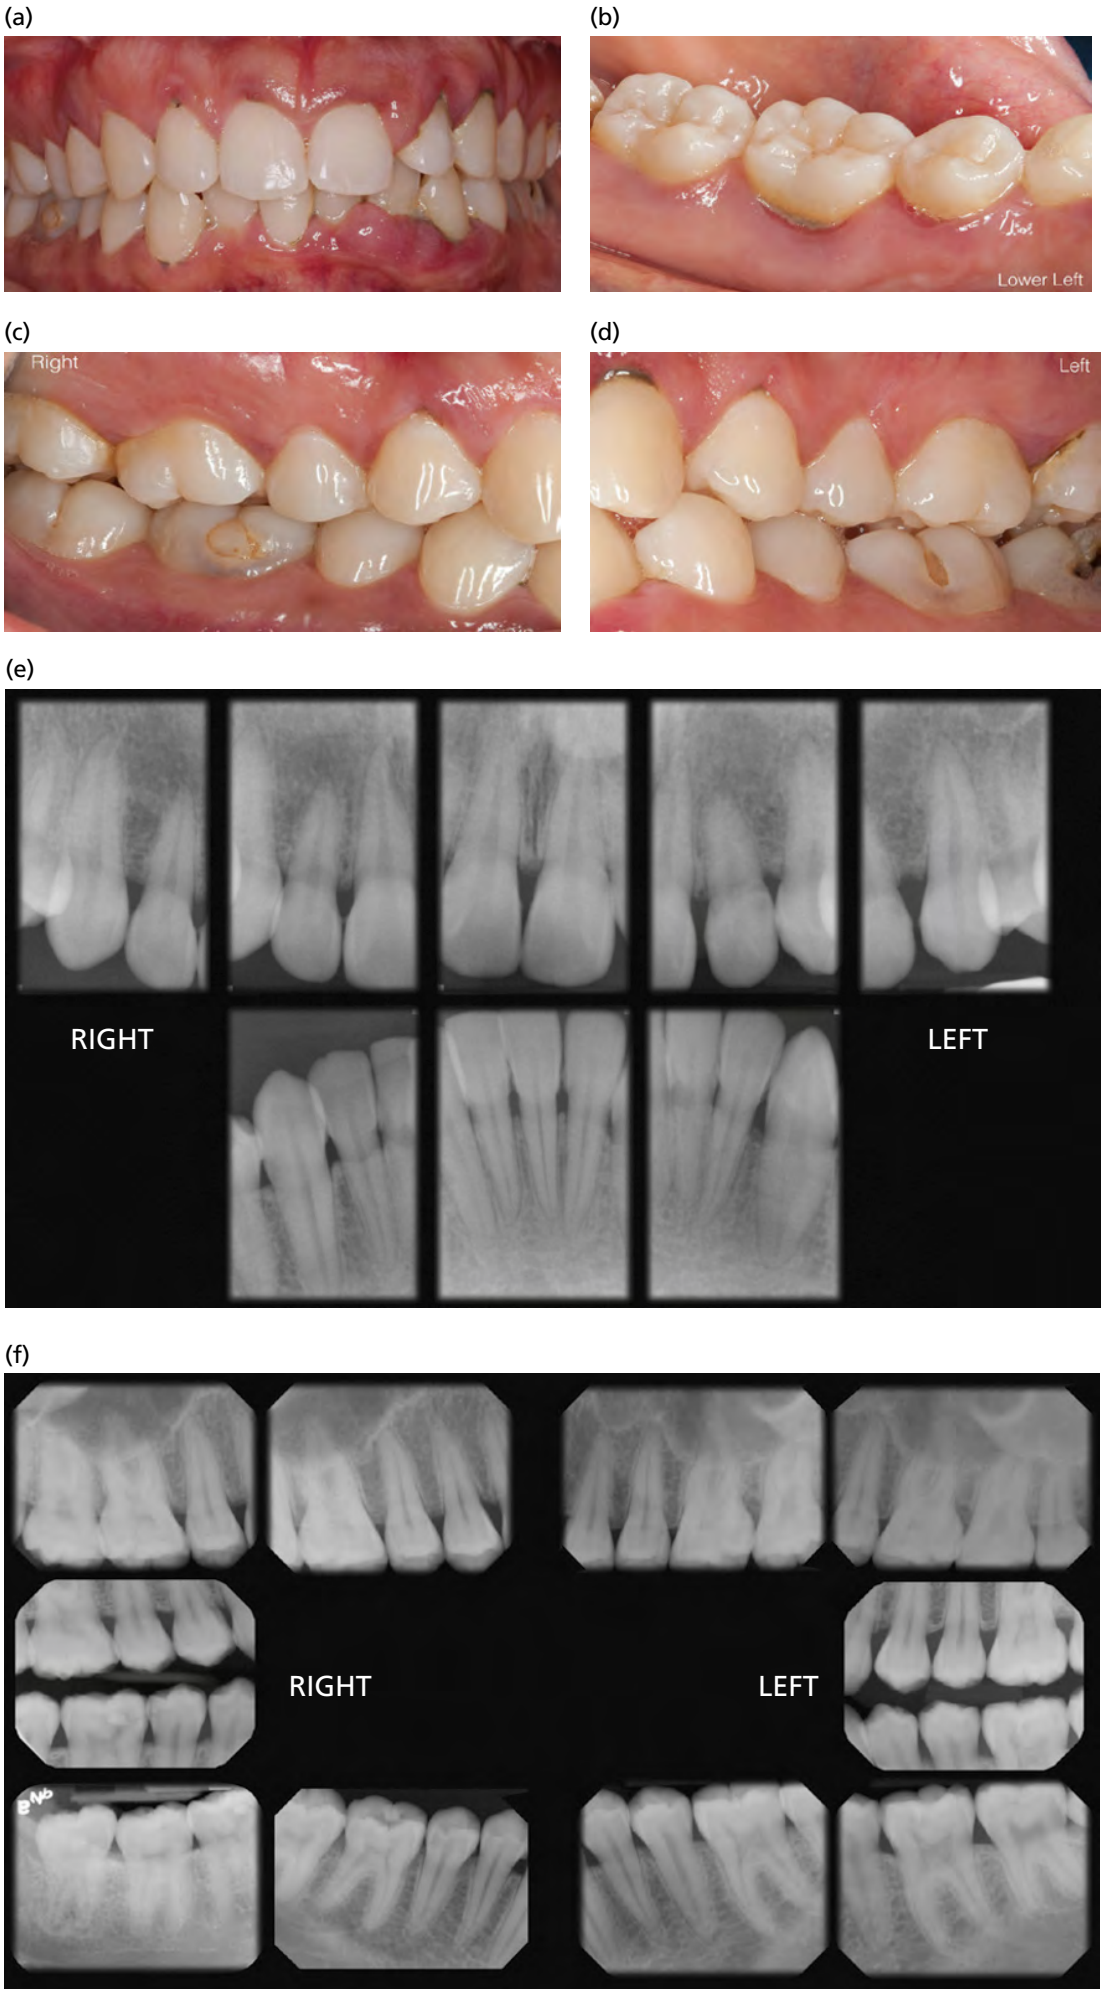

Fig. 16-3 Case 2. (a–d) Clinical and (e, f) radiographic images of a case diagnosed as Stage II, Grade C, generalized. (Source: Courtesy of Dr. Gustavo Avila-Ortiz, University of Iowa, USA.)

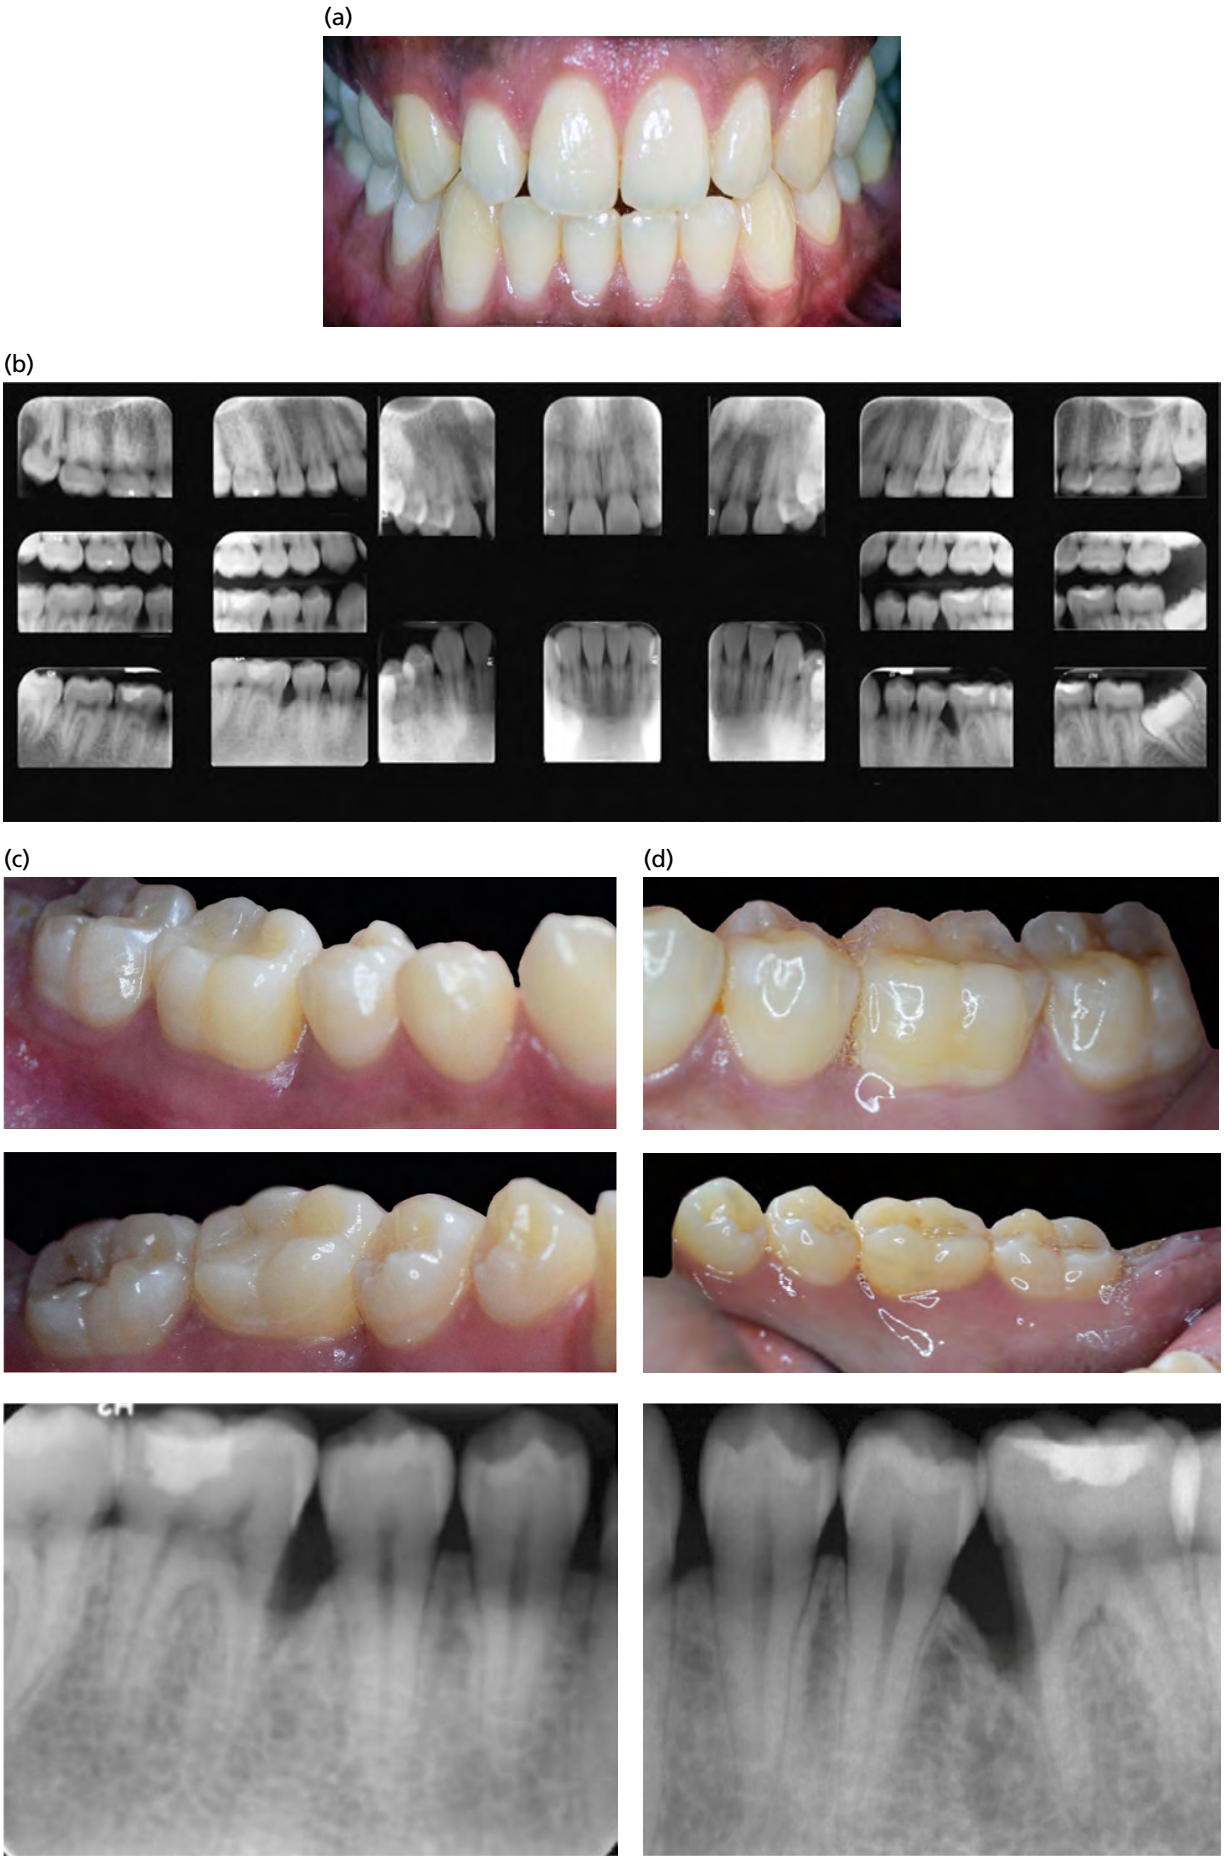

Fig. 16-4 Case 3. (a–d) Clinical and radiographic images of a case diagnosed as Stage III, Grade C, localized. (Source: Courtesy of Drs. Flora Momen-Heravi and Philip Kang, Columbia University, USA.)

depths exceeding 3 mm or any interproximal CAL >1 mm are present at any other teeth. Given the maximum severity of bone loss beyond the coronal third of the root, accompanied by presence of interproximal attachment loss of 7–8 mm, affecting only two teeth in the dentition, and the young age of the patient resulting in a percentage bone loss over age ratio exceeding 1, the assigned diagnosis was periodontitis Stage III, Grade C, localized (molar pattern).

Case 4 (Fig. 16-5)

The patient is a 60-year-old Caucasian female in good general health, and currently medicates for hypercholesterolemia. The patient does not smoke and has been alternating seeing her general dentist and a dental hygienist every 6 months for several years. She is aware that she has "issues with her gums". Available full-mouth periapical radiographs reveal generalized bone loss that extends up to the apical third of the root at the right central mandibular incisor. Clinical charting shows deep pockets between 6 and 8 mm at multiple teeth. There are several teeth with Degree 2 mobility, and the first right mandibular molar shows a lingual furcation involvement. Importantly, radiographs obtained 3 years prior to the current examination are available and indicate progression of bone loss exceeding 2 mm at a number of teeth, notably at the distal surface of the upper left central incisor and the distal surface of the upper first molar. Given the severity of attachment loss and bone loss, and the documented progression of periodontitis, the patient was assigned a diagnosis of periodontitis, Stage III, Grade C, generalized.

Case 5 (Fig. 16-6)

The patient is a 58-year-old Caucasian male who has smoked one pack of cigarettes per day for "as long as he can remember" and is medicated for hypertension and chronic obstructive pulmonary disease. He reports that he has been visiting his dentist sporadically over the years, primarily to have some "shaky teeth removed". He would now like "to get some more teeth to chew better and fill the gaps". The patient has poor plaque control and multiple teeth with probing depths between 6 and 9 mm and Degree 2 mobility. Available radiographs confirm presence of generalized bone loss extending to the apical third of the root. The patient has lost more

than four teeth, most likely due to periodontitis according to his own recollection and consistent with the current status of his remaining dentition. In addition, he requires extensive oral rehabilitation to restore esthetics and function, and also presents with a persisting risk factor for further progression (heavy smoking). Thus, the assigned diagnosis was periodontitis, Stage IV, Grade C (note that assignment of extent is not meaningful in Stage IV periodontitis).

Case 6 (Fig. 16-7)

The patient is a 48-year-old Caucasian male, with non-contributory medical history. He has smoked one pack of cigarettes per day for the past 21 years. The

patient has not seen a dentist for the past 7 years and has only received dental care sporadically prior to his last dental visit. He has noticed that his teeth have become increasingly mobile lately and he reports that he is currently uncomfortable when he chews. Deep pockets with BoP are detected at virtually all teeth and periapical radiographs show terminal bone loss at multiple areas. Although this patient has not yet experienced any tooth loss due to periodontitis, more that five teeth can reasonably be considered to be non-salvageable due to severe loss of support. In this patient, periodontitis is clearly not merely a threat for individual teeth, but rather for the dentition as a whole. Thus, the combination of current periodontitis extent and severity, the presence of heavy smoking, and the need for complex therapy to control periodontitis and rehabilitate function resulted in a diagnosis of periodontitis Stage IV, Grade C.

Interpretational challenges and "gray zones"

In a time of evidence-based healthcare and comparative effectiveness research, some clinicians would desire that a simple algorithm be developed to automatically convert a patient's clinical findings to an accurate determination of Stage and Grade. However, what becomes increasingly apparent across the health sciences is that, despite the exponential increase in new information and the ever-increasing opportunities to formulate evidence-guided clinical decisions, new technologies and more research evidence often expand "gray zones" and do not necessarily contribute to simple decision guidelines (Chandra *et al.* 2015). We must realize that both knowledge and clinical judgment will be required for classification in all instances. Below, we provide narrative examples of

commonly encountered diagnostic "gray zones" and offer suggestions of how they can be addressed.

1. *A male 65-year-old patient has experienced no tooth loss, is radiographically intact, and has no interproximal pockets with a depth greater than 3 m. The level of the gingival margin (GM) interproximally is, at most sites, coronal to the CEJ, with the exception of a few surfaces located at non-adjacent teeth where the GM is located at the CEJ. A loss of attachment of 2 mm is recorded at these few surfaces. Does this patient have periodontitis?*

This is a borderline case. According to the above description, the probe tip apparently penetrates *within* the junctional epithelium to a level *apical* to the CEJ at a few interproximal sites with shallow probing depth, no visible recession, and no radiographic evidence of alveolar bone loss. Since this middle-aged patient appears to be periodontally intact, a diagnosis of "periodontitis" is not justified. It must be emphasized, however, that the same phenotype in a much younger patient, may signify "true" incipient periodontitis. Again, clinical judgment is paramount for arriving at a correct diagnosis after assessing the totality of the patient data.

2. *The severity of periodontitis in a 50-year-old patient, based on radiographic bone loss at the sites of the most advanced destruction, is compatible with Stage II disease (e.g. the bone loss extends within the coronal third of the root). Does presence of one or a few 6 mm pockets necessarily upshift the diagnosis to Stage III?*

Not necessarily. If the severity of bone loss does not extend beyond the coronal third of the root length, presence of a couple of 6 mm pockets does not automatically entail a need for more complex treatment. Upstaging because of "complexity factors" requires a meaningful, integrated appraisal of these factors by an experienced clinician. Correct implementation of the Staging system does not lend itself to automated algorithms based on checkboxes or presence/absence of isolated features.

3. *According to the new classification, a diagnosis of periodontitis requires a minimum of "at least two teeth" affected by interproximal attachment loss. Does this mean that a patient that presents with attachment loss, or bone loss, that affects only a single tooth should not be diagnosed as having periodontitis?*

The requirement of "at least two affected teeth" has been incorporated in the classification to minimize false positives, that is, to preclude an inflation of periodontitis prevalence due to incidental attachment loss. This restriction was also introduced in recognition of the fact that "true" periodontitis seldom affects only a single tooth in the dentition. However, if according to the clinician's judgment an observed attachment loss/bone loss lesion that affects a single tooth in an otherwise intact dentition cannot be ascribed to a cause other than periodontitis (e.g. root fracture, endodontic lesion, etc.), then the clinician should bypass the rule, proceed with assigning a diagnosis of periodontitis, stage it appropriately, and further describe it as "localized".

The value of the 2018 periodontitis classification

Well-controlled longitudinal clinical studies of periodontitis treatment have demonstrated that the standard principles for control of periodontitis are remarkably successful in the long-term control of the disease, but not for everyone. Over the years, classification schemes have drawn attention to different clinical phenotypes that may be expressed in some patients with periodontitis. The 2018 periodontitis classification uses the Stage and Grading vectors (Papapanou *et al*. 2018b; Tonetti *et al*. 2018a), as discussed previously, to allow clinicians to consistently (1) assess the current level of severity of periodontitis and its impact on the treatment required, and (2) determine whether a periodontitis patient is highly likely or less likely to respond predictably to standard principles for treating periodontitis. Importantly, the new classification guides a clinician to recognize factors that indicate that the patient's disease trajectory is more complex and should be managed accordingly. Lastly, the classification is constructed in a way that allows, by design, periodic, evidence-based modifications to incorporate new research data. In other words, new findings will be reviewed regularly and will further inform and refine the threshold values and definitions included in the grids of the Stage and Grade vectors, without radically altering the fundamental principles of the classification scheme. This essential feature of the 2018 classification will hopefully facilitate its seamless utilization by clinicians and researchers for a longer period than its immediate predecessors.

Introduction

The concept that oral and general health are interrelated was already known in ancient civilizations. As "strong teeth" often were a sign of good health, poor oral health was considered an important contributor to distant body complications (O'Reilly & Claffey 2000). It was at the end of the nineteenth century and in the early years of the twentieth century that the dental and medical communities took interest in the concept of "oral sepsis" and "focal infection" (Fig. 17-1). In the article titled "The human mouth as a focus of infection" and published by the American dentist W.D. Miller in 1891, the collective term "oral sepsis" was described for the first time as a possible cause of "chronic dyspepsias, intestinal disorders, ill health, anemias and nervous complaints" (Miller 1891). An influential London physician William Hunter (Hunter 1900, 1910) corroborated this hypothesis when he published in the most eminent medical journals at the time. This was just before the oral–systemic concept evolved into that of "focal infection" (Billings 1912). A localized area of infection of the oropharyngeal space (not only affecting teeth or gingival tissues) was described by Billings as a source of the dissemination of pathogens and thus resulted in infection of contiguous or non-contiguous organs. These beliefs were accompanied by clinical recommendations of removal of these infectious sites

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

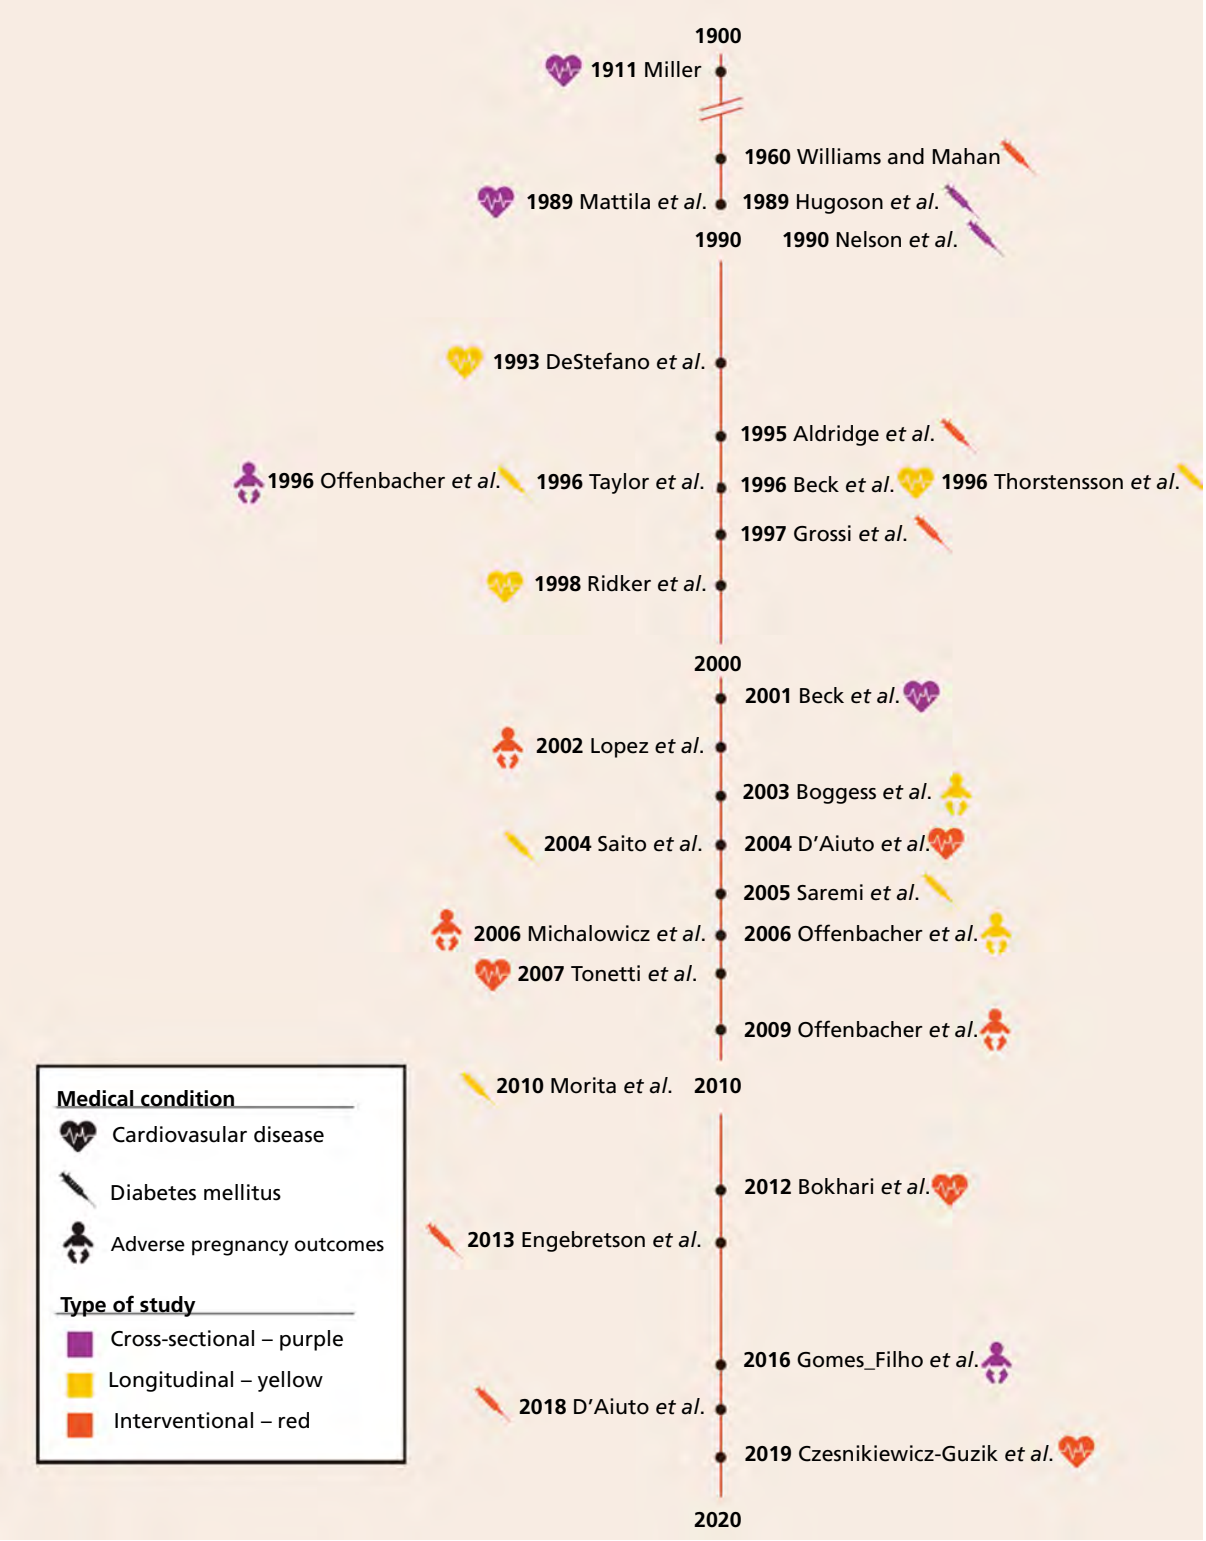

Fig. 17-1 An overview of "landmark studies" in periodontal medicine published during the last 120 years, with particular focus on the effects of periodontitis on three pathologic conditions: cardiovascular disease, diabetes mellitus, and adverse pregnancy outcomes throughout the chapter. The highlighted studies were either the 'first' of their kind, as they provided novel observations or contributed to shifting paradigms. The figure was modified from a figure presented by Beck *et al.* (2019) and presents the studies using symbols to specify the medical outcome (cardiovascular disease, diabetes mellitus, and adverse pregnancy outcomes) while the color of the symbol represents the type of study (cross-sectional, longitudinal, and interventional).

and translated into drastic treatment decisions. The removal of infectious foci of infection was advocated as an essential step in the resolution or even to prevent multiple diseases. As is usually the case, empirical evidence gradually revealed that these radical practices were unsound (Cecil & Angevine, 1938), the purported associations were increasingly refuted, and more conservative approaches to the treatment of oral pathologic conditions eventually prevailed.

At the end of the twentieth century, the accumulation of newer evidence on the potential role of inflammation in the development of many chronic diseases

that were traditionally viewed as non-inflammatory encouraged periodontal researchers to explore the concept that chronic exposure to oral infection/inflammation could impact on other non-communicable diseases. These conditions are responsible for over 70% of overall deaths worldwide, with cardiovascular diseases, cancer, and diabetes being the most prominent (WHO 2013). Most non-communicable diseases share a cluster of common risk factors (tobacco usage, alcohol intake, diet, stress, physical inactivity, social inequalities) which inevitably are linked to poorer oral health and especially to periodontitis. When interpreting the association between periodontitis and other comorbidities, this is an important factor to consider as it would strongly impact on the nature and strength of the association.

A series of experimental studies collectively known as research in "periodontal medicine" describe how periodontal infection/inflammation may impact extraoral health. The number of non-communicable diseases and conditions that have been linked to periodontitis has increased exponentially in the last two decades. A recent umbrella review identified 1219 systematic reviews of clinical trials linking poor oral health to several systemic diseases (Seitz *et al*. 2019) confirming that the two most common oral diseases (periodontitis and dental caries) were associated mainly with type 2 diabetes mellitus and cardiovascular diseases among more than 50 systemic conditions.

This chapter will first briefly focus on the common biological mechanisms and then review the observational and interventional epidemiologic evidence related to the association between periodontitis and (1) atherosclerotic vascular disease; (2) diabetes mellitus; and (3) adverse pregnancy outcomes, with smaller reviews for the newer areas of (4) chronic renal disease; (5) cognitive decline/dementia; and (6) cancer.

The epidemiologic evidence will be reviewed under two different types of studies: (1) *association studies* (cross-sectional, case–control, or longitudinal cohort studies) focusing on either *surrogate markers* of the main disease (i.e. biomarkers of disease) or *clinical outcomes* (i.e. clinical events such as myocardial infarction [MI] or stroke) and (2) *intervention studies, examining the effects of periodontal therapy on disease-related outcomes (surrogate markers or events)*. Data from intervention studies are of public health importance, as they reveal whether targeting a specific exposure (i.e. periodontitis) by means of prevention or therapy translates into substantial benefits in terms of incidence reduction of the disease/systemic outcome or of its complications (this is usually assessed using randomized, placebo-controlled clinical trials).

When interpreting data from epidemiologic studies, it must be realized that in each study the *exposure*, in this case periodontitis as a potential risk factor for the systemic outcome, could have been defined using a variety of clinical measures reflecting a poor periodontal status (either as categorical or continuous parameters). Some studies have used traditional clinical or radiographic parameters, such as average probing pocket depth, number of periodontal pockets greater than a specific threshold of probing pocket depth or attachment level, and presence of gingival inflammation (bleeding), whereas in other epidemiologic studies authors might have used self-reported periodontal health or even surrogate markers, such as tooth loss or edentulism. The latter two, although related to poor periodontal status, are however clearly not synonymous with periodontitis as they could have been the result of other oral diseases (i.e. dental caries, fracture). To further complicate the matter, several epidemiologic studies might have used systemic biomarkers of exposure to periodontitis or the dental biofilm including subgingival microbial profiles or systemic levels of serum antibodies to periodontal bacteria. These markers could reflect the infectious nature of or the immune response to periodontitis rather than its clinical phenotype, as the exposure variable. It is only recently that a universally acceptable case definition of periodontitis has been published and implemented across the dental community (Tonetti *et al*. 2018). Not many studies, however, have been published and/or incorporated these new case definitions in their experimental design.

The last point that needs to be emphasized as a key determinant of the quality of an epidemiologic study is whether the association between the exposure under investigation (i.e. periodontitis) and the outcome (i.e. cardiovascular diseases) has been adjusted for *additional exposures* that are known to affect the systemic disease status (e.g. hyperlipidemia, hypertension, or physical activity in cardiovascular diseases), as well as for potential *confounders*, in other words, common risk factors that are associated with both periodontitis and the systemic disease (e.g. diabetes mellitus or smoking). This last methodological point is that the choice of *exposure variable* to define periodontitis as a risk factor for other non-communicable diseases varied enormously across the published evidence reviewed and could explain at times the inconclusive findings of some studies.

Evidence of common biologic mechanisms

Periodontal diseases, as elegantly discussed in Chapter 16, are chronic inflammatory diseases of the periodontal tissues associated with a dysbiotic supra- and subgingival biofilm enriched with Gram-negative bacteria (Haffajee & Socransky 1994). A progressive gingival inflammation results in the deepening of the periodontal sulcus and in a shift of the composition of the dental biofilm, resulting in levels reaching 10^9 or 10^{10} bacterial cells within a single pathologic periodontal pocket. The ulcerated epithelial lining of the periodontal pocket may constitute a substantial inflamed surface area in cases of generalized periodontitis (Hujoel *et al*. 2001) and is in constant contact with the biofilm of the subgingival

dental plaque. The ulcerated pocket epithelium hence provides a gate through which bacterial toxins/components such as lipopolysaccharide, bacterial outer membrane vesicles, fimbriae, and other antigenic structures may challenge the immune system and elicit not only a local but a substantial systemic inflammatory response (Ebersole & Taubman 1994). This section will briefly review the two main mechanisms linking periodontitis and systemic health outcomes under the heading of (1) oral microbiome and (2) systemic inflammation (Fig. 17-2).

Oral microbiome

Oral bacteria and especially those present in the subgingival dental biofilm can co-locate in other distant sites either via bacteremia or due to the aspiration and/or ingestion.

Several pathogenic species involved in periodontal infections display tissue invasion properties (Meyer *et al*. 1991; Sandros *et al*. 1994; Lamont *et al*. 1995). Further, frequent transient bacteremias occurring as a result of daily activities such as toothbrushing or chewing (Silver *et al*. 1977; Kinane *et al*. 2005; Forner *et al*. 2006; Crasta *et al*. 2009), as well as during invasive oral therapeutic procedures (Heimdahl *et al*. 1990; Lockhart *et al*. 2008) may confer a significant systemic bacterial challenge. Similarly, proinflammatory mediators, including several interleukins, are produced locally in the inflamed gingival tissues (Salvi *et al*. 1998) and can also be disseminated systemically through the bloodstream. A plethora of preclinical and at times clinical experimental studies have examined direct and indirect effects of key pathogenic microbes implicated in the development and progression of periodontitis. This chapter will briefly discuss their role within the context of the relevant non-communicable disease linked to periodontitis.

Systemic inflammation

Periodontitis is known to induce chronic low-grade systemic inflammation which might be relevant to the onset or progression of numerous non-communicable diseases.

Periodontitis patients exhibit higher white blood cell counts, high sensitivity C-reactive protein (hsCRP), and fibrinogen levels (Kweider *et al*. 1993; Ebersole *et al*. 1997; Loos *et al*. 2000) than periodontally healthy controls. These biomarkers are commonly used to characterize systemic inflammation (body response to any pathogenic stimulus). A series of analyses of large studies reporting on the periodontal status (case definition of severe periodontitis) or using alternative measures of periodontal exposure (i.e. high serum IgG levels to *P. gingivalis*) have confirmed that poor periodontal status is associated with increased CRP and fibrinogen levels (Slade *et al*. 2003; Slade *et al*. 2000; Schwahn *et al*. 2004; Dye *et al*. 2005). These associations were independent of age, gender, diabetes mellitus, cigarette use, medical conditions, and use of anti-inflammatory medications.

A recent meta-analysis of observational studies reporting levels of hsCRP (Paraskevas *et al*. 2008) confirmed that patients suffering from periodontitis had consistently higher levels of hsCRP when compared

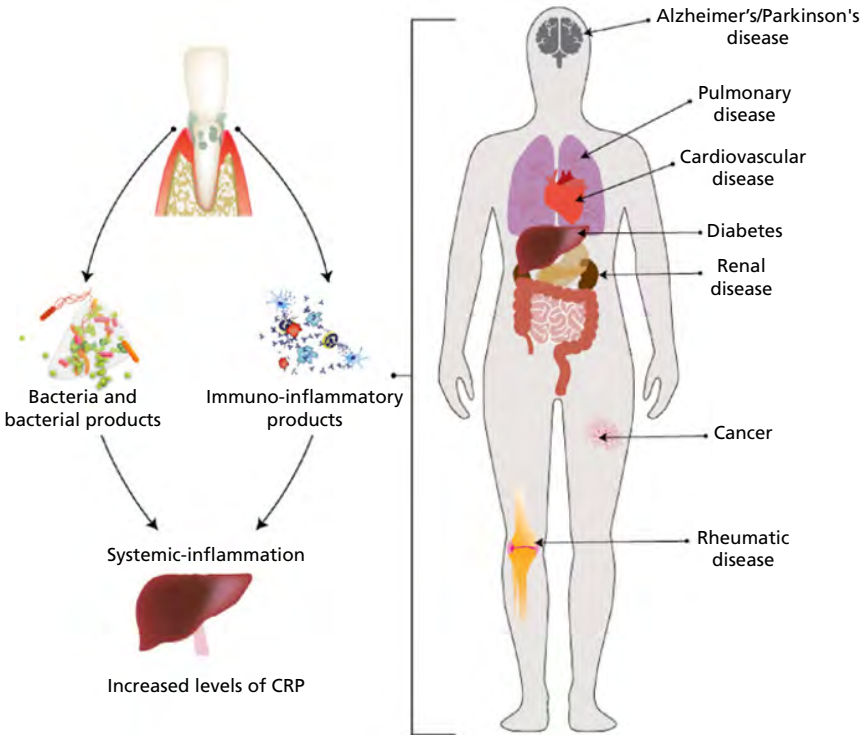

Fig. 17-2 Oro-systemic inflammatory link. Several systemic diseases associated with periodontitis are depicted and the possible common pathways responsible for these associations with emphasis on the role of systemic inflammation.

with controls without periodontitis (average between group difference of 1.56 mg/L). Further evidence on the causal association between periodontitis and systemic inflammation is reported in the same review, as modest evidence confirmed that periodontal treatment resulted in a statistically significant average reduction of 0.50 mg/L in hsCRP levels within 6 months of the therapy (95% CI 0.08–0.93). A heterogeneous response to periodontal treatment in terms of changes in the level of systemic inflammatory biomarkers is now universally acknowledged. Indeed Behle *et al*. (2009) using a composite score ("summary inflammatory score") to represent the aggregate post-treatment response to a panel of 19 individual biomarkers confirmed that approximately one-third of the treated patients with periodontitis showed a marked reduction in inflammation, an almost similar number of participants exhibited an increase in systemic inflammation, whereas the remainder remained seemingly unchanged. The obvious variability in the extent of resolution of systemic inflammation after periodontal treatment should be interpreted within the context that not all individuals will mount the same magnitude of systemic inflammatory response to periodontitis and that it has been widely accepted that periodontal treatment modalities *per se* (i.e. whole mouth instrumentation as opposed to quadrant by quadrant therapy) are responsible for short-term acute inflammatory responses (D'Aiuto *et al*. 2005). This concept was collectively reviewed and interpreted by the periodontal researcher community in a consensus manuscript (Sanz *et al*. 2020).

Atherosclerotic vascular disease

Biologic mechanisms

Atherosclerotic vascular disease (AVD) represents a group of non-communicable conditions, affecting primarily the heart and blood vessels, including coronary heart disease and stroke and to some extent peripheral artery disease. AVD is the most common cause of death worldwide with the largest impact on society and health care systems. Seminal epidemiological work, such as the Framingham Study, helped identify the classic risk factors for AVD including: male sex, increasing age, family history, smoking habit, presence of diabetes, obesity, hypertension, hyperlipidemia, and a sedentary lifestyle (O'Donnell & Elosua, 2008). Emerging AVD risk factors nevertheless have been identified, confirming the crucial role of inflammation in the development of atheroma and to its rupture leading to clinical events such as MI and stroke (Ross 1999; Libby, 2002). Circulating levels of common inflammatory mediators such as CRP or interleukin (IL)-6 confirmed their predictive role as biomarkers of AVD (Ridker, 2003, Hackam and Anand, 2003, Hansson, 2005, Libby *et al*. 2019). Further convincing evidence from large AVD intervention trials highlighted that harnessing upstream systemic inflammation can prevent events like MI and stroke, particularly in patients with high residual inflammatory risk. The extent of chronic systemic inflammation linked to increased future AVD has been defined by serum levels of hsCRP: values between 1 and 2 mg/L are associated with an intermediate future risk for AVD and levels exceeding 3 mg/L are associated with high AVD risk (Ridker 2003). Notwithstanding the opportunity for novel pharmacological approaches to reducing inflammation, the research community is now focused on the identification and management of unconventional but common sources of systemic inflammation as a novel approach to reduced AVD at population level (Libby *et al*. 2018). Periodontitis and its subsequent inflammatory response as described earlier in this chapter might represent an overlooked novel risk factor to AVD.

Further evidence of the link between periodontal infections and AVD comes from several studies confirming the presence of oral bacteria in atheromas (Chiu 1999; Haraszthy *et al*. 2000; Stelzel *et al*. 2002; Fiehn *et al*. 2005) and extended by Kozarov *et al*. (2005) who demonstrated that viable and invasive *Aggregatibacter actinomycetemcomitans* and *Porphyromonas gingivalis* could be recovered from human atheromas. These observations were further corroborated by experimental preclinical studies that demonstrated that oral infection of either atherosclerosis-prone (apolipoprotein-E deficient) or normocholesterolemic animals with *P. gingivalis* resulted in accelerated atherosclerosis and in the concomitant presence of *P. gingivalis* DNA in their aortic tissue (Lalla *et al*. 2003; Jain *et al*. 2003; Gibson *et al*. 2004; Brodala *et al*. 2005). For a comprehensive review of the evidence on the potential biologic mechanisms of periodontitis-induced atherogenesis, the reader is referred to Chapter 18 and the review by Schenkein *et al*. (2020).

Epidemiologic evidence

Observational evidence

Association studies with AVD surrogate markers

Among the first studies that proposed an association between periodontitis and AVD, Mattila *et al*. (1989) documented the association between poor dental health (using a composite index of dental and periodontal diseases) and coronary heart disease, independent of age, total cholesterol, high-density lipoprotein (HDL), triglycerides, C-peptide, hypertension, diabetes, and smoking. Since this publication a series of observational investigations have attempted to confirm an association between periodontitis and traditional or novel cardiovascular risk markers. In particular, a close link between periodontitis and inflammatory biomarkers is highly relevant when assessing its role in the development and progression of atheroma formation. Of interest are those investigations that have focused on the potential link between periodontitis and vascular surrogates of AVD.

Endothelial dysfunction is considered the earliest vascular change preceding the development of atheroma formation and AVD progression (Verma *et al*. 2003). It can be defined as the reduced vasodilator capability of peripheral blood vessels and is assessed by measuring the difference in the diameter of a peripheral artery prior to and after reactive hyperemia induced through occlusion of blood flow (Celermajer *et al*. 1992). When assessed in the coronary arteries this early measure of AVD is linked to future clinical events (Matsuzawa *et al*. 2015). A meta-analysis of 14 prospective studies reported a 13% lowering of future cardiovascular disease for every 1% increase in endothelial function assessed by flow-mediated dilatation of the brachial artery (FMD) (Inaba *et al*. 2010).

There is moderate convincing evidence that endothelial dysfunction is more pronounced in patients with periodontitis than periodontally healthy controls (Amar *et al*. 2003; Mercanoglu *et al*. 2004). A recent systematic review confirmed that patients with periodontitis had stiffer brachial arteries (average difference in vasodilatation of 5.1%; 95% CI 2.08–8.11) than controls with no signs of periodontitis (Orlandi *et al*. 2014).

A separate group of studies have investigated the association between periodontitis and subclinical atherosclerosis, commonly assessed by means of carotid artery intima–media thickness (IMT). Increased IMT has been documented to be directly associated with increased risk of MI and stroke (O'Leary *et al*. 1999). Beck *et al*. (2001) provided the first evidence that periodontitis may be linked to subclinical atherosclerosis. These authors analyzed cross-sectional data from 6017 participants in the Atherosclerosis Risk in Communities (ARIC) Study and demonstrated that severe periodontitis conferred increased odds for higher carotid artery IMT (odds ratio [OR] 2.09; 95% CI 1.73–2.53 for IMT of ≥1 mm). In the same year a prospective population-based survey titled the Bruneck study confirmed that chronic infections (including periodontitis) amplified the risk of atherosclerosis development in the carotid arteries. The association was most pronounced in participants free of carotid atherosclerosis at baseline (age-/sex-adjusted OR 4.08; 95% CI 2.42–6.85 for any chronic infection versus none) and applied to all types of chronic (bacterial) infections (Kiechl *et al*. 2001). A couple of years later, the Oral Infection and Vascular Disease Epidemiology Study (INVEST), a prospective population-based cohort study of 1056 participants aged ≥55 years with no baseline history of stroke, MI, or chronic inflammatory conditions, investigated the relationship between carotid artery plaque and IMT with tooth loss and measures of periodontitis. In a first report based on data from 711 participants (Desvarieux *et al*. 2003), loss of 10–19 teeth were associated with increased prevalence of atherosclerotic plaques (OR 1.9; CI 1.2–3.0). Because a higher number of lost teeth paralleled an increased severity of periodontitis at the remaining teeth in this cohort, it was assumed that tooth loss reflected, in part, current or cumulative periodontitis. In a subsequent publication, Engebretson *et al*. (2005) reported on a subsample of 203 participants from the INVEST cohort with available panoramic radiographs. Bone loss was associated with the presence of carotid atherosclerotic plaque in a dose-dependent manner. A third INVEST report (Desvarieux *et al*. 2005) included 657 participants with available dental and medical variables as described above, as well as data on the prevalence and level of 10 bacterial species. The data revealed that IMT and white blood cell counts increased significantly over tertiles of "etiologic" periodontal bacterial burden (defined as the aggregate colonization per participant by *A. actinomycetemcomitans*, *P. gingivalis*, *Tannerella forsythia*, and *Treponema denticola*).

Interestingly, serum IgG antibody levels to specific periodontal pathogens (in particular combined titer against *Campylobacter rectus* and *Micro monas micros)* were associated with carotid IMT of ≥1 mm in a subgroup of 4585 ARIC participants (Beck *et al*. 2005b). Pussinen *et al*. (2005) reported similar findings on IMT in a subsample of 1023 men aged 46–64 years from the Kuopio Ischemic Heart Disease Risk Factor study. Incident IMT thickening, assessed 10 years postbaseline in participants with no prior cardiovascular diseases, increased significantly across tertiles of IgA titer levels to *A. actinomycetemcomitans* and *P. gingivalis*. Analyzing the progression rate of participants in the INVEST study and based on 430 participants followed up over a median of 3 years with periodontitis, Desvarieux *et al*. (2013) detected a difference in IMT of approximately 0.1 mm in the 3-years follow-up. The clinical relevance of this finding should be interpreted within the context of current evidence suggesting that a 0.03 mm/year increase in IMT is associated with a 2.3-fold increased risk for cardiovascular events (Hodis *et al*. 1998). Two recent systematic reviews and meta-analyses demonstrated that the diagnosis of periodontitis was associated with a mean increase in IMT of 0.08 mm (95% CI 0.07–0.09) (Orlandi *et al*. 2014) and with carotid atherosclerosis (OR 1.27; 95% CI 1.14–1.41) (Zeng *et al*. 2016).

Recent evidence has confirmed a moderate but consistent association between periodontitis and hypertension, defined as values ≥140 mmHg systolic blood pressure (SBP) and/or ≥90 mmHg diastolic blood pressure (DBP). As summarized in a recent systematic review, diagnoses of moderate–severe periodontitis (OR = 1.22; 95% CI 1.10–1.35) and severe periodontitis (OR = 1.49; 95% CI, 1.09–2.05) were associated with hypertension. Meta-analysis of prospective studies confirmed diagnosis of periodontitis increased by at least 50% the likelihood of hypertension occurrence (OR = 1.68; 95% CI, 0.85–3.35) and that patients with periodontitis exhibited higher mean SBP (weighted mean differences [WMD] of 4.49 mmHg; 95% CI 2.88–6.11) and DBP (2.03 mmHg;

95% CI 1.25–2.81) when compared with control participants without periodontitis (Munoz Aguilera *et al*. 2020). A large observational study using genetic variation as a natural experiment to investigate the causal relation between periodontitis and hypertension (Mendelian Randomization) included almost 750 000 participants from two large genome wide association studies (UK-Biobank and ICBP-GWAS). The analysis confirmed a strong link between common genetic variants linked to both periodontitis and hypertension (Czesnikiewicz-Guzik *et al*. 2019).

The stiffness of the large central arterial system, such as the aortic tree, is another surrogate marker of AVD and it has been associated with systolic hypertension (Chae *et al*. 1999), coronary artery disease, and stroke (Sutton-Tyrrell *et al*. 2005). Measurement of pulse wave velocity (PWV) as the gold standard method for the assessment of arterial stiffness has been recommended as a tool to evaluate arterial system damage, vascular adaptation, and therapeutic efficacy (Mancia *et al*. 2014). A meta-analysis of 10 observational studies concluded that periodontitis is associated with an increased arterial stiffness expressed by a PWV mean difference of 0.85 m/s (95% CI 0.53–1.16) (Schmitt *et al*. 2015).

Association studies with clinical events

Longitudinal studies have shed light on the incidence of cardiovascular events in relation to periodontitis as well as the type of individuals most affected. The first of such studies was a national sample of 9760 US adults by DeStefano *et al*. (1993) who found that study participants with periodontitis had a 25% increased risk of coronary heart disease relative to those with minimal periodontitis.

A variety of case-definitions of periodontitis have been used in these studies. A critical appraisal of most observational trials linking periodontitis and AVD events is greatly affected by large heterogeneity of the findings across studies, with many – but clearly not all – reporting statistically significant associations after appropriate adjustments for covariates and potential confounders.

A summary of data from selected epidemiologic studies with a sample size of at least 1000 participants that have used periodontal status as an exposure and have reported AVD outcomes was conducted (Table 17-1). OR, hazard ratios (HR), or relative risk (RR) for clinical AVD outcomes varied from 1.0 to 2.7 for studies focusing on any vascular events (coronary heart, coronary vascular, or cardiovascular diseases), from 1.1 and 3.8 for studies on MI or acute coronary syndrome (ACS) (Table 17-2), and from 1.1 to 2.2 for studies on stroke (Table 17-3). A critical appraisal of most of these studies at a glance is largely affected by heterogeneity of study designs and the findings across studies, with many–but clearly not all – reporting statistically significant associations after appropriate adjustments for co-variates and potential confounders. Although consistently raised estimates of vascular events were reported, a plethora of case-definitions of periodontitis have been used in these studies ranging from self-reported measures to registry case definitions and clinically confirmed diagnoses.

At least seven meta-analyses over the last two decades have been published summarizing the association between periodontitis and AVD clinical outcomes (Danesh 1999; Janket *et al*. 2003; Bahekar *et al*. 2007; Mustapha *et al*. 2007; Humphrey *et al*. 2008; Blaizot *et al*. 2009; Sfyroeras *et al*. 2012) consistently concluding that the available evidence suggests a moderate, but consistent positive association (RR ratios ranging from 1.1 to 1.8) between periodontal diseases and AVD (Fig. 17-3).

Interestingly, the effect of periodontitis on AVD events appears to differ with age and to be stronger with cerebrovascular events. This finding was highlighted already in the first longitudinal study reporting an association between periodontitis and AVD events. De Stefano *et al*. (1993) indeed reported that in men younger than 50 year of age at baseline, periodontitis was a strong risk factor of future coronary heart disease outcomes. Further, in two publications from the Normative Aging Study (NAS) cohort, periodontitis was more strongly associated with incident coronary heart disease (Dietrich *et al*. 2008) and stroke (Jimenez *et al*. 2009) in younger versus older (>60 years) men. Sen *et al*. (2013) studied prospectively a cohort of 106 patients admitted to hospital with stroke or transient ischemic attack. Study participants grouped based on the recorded extent of periodontal attachment loss (highest versus lowest tertile using a threshold of CAL equal to 1.3%) were followed for a median period of 24 months for the occurrence of vascular events such as stroke, acute MI, and death. Participants with a high level of periodontitis experienced about 60% of the total number of recurrent CVD events (16 out of 27 total events including MI, stroke, and vascular death) when compared with those in the group of a low level of periodontitis. Lastly, Chen *et al*. (2016), using a large retrospective cohort of more than 750 000 participants, investigated the impact of periodontitis on the onset of atrial fibrillation, one of the most common causes of cardioembolic stroke. Patients with periodontitis experienced an increased risk of atrial fibrillation when compared with controls over an 11 year follow-up (HR 1.31; 95% CI 1.25–1.36). Two recent meta-analyses of cohort studies confirmed a 1.6–2.9-fold risk of stroke in the presence of periodontitis (Lafon *et al*. 2014; Leira *et al*. 2017).

A contentious issue that has been vigorously debated is whether the association between periodontitis and AVD events (or indeed with other non-communicable diseases) can be attributed to the confounding effect of smoking (Hujoel *et al*. 2002; Spiekerman *et al*. 2003) or may be entirely spurious (Hujoel *et al*. 2006). A series of earlier studies did not present data for patients who

never smoked and adopted suboptimal statistical methodologies to account for a possible residual confounding effect related to tobacco or environmental cigarette exposure. Recent evidence, however, confirmed that periodontitis is linked to AVD also in patients who never smoked. Two case–control studies reported tripled odds of incident strokes among patients who never smoked with periodontitis compared with participants without periodontitis and this was particularly relevant in men (Pussinen *et al*. 2007; Sim *et al*. 2008). US data obtained from the Behavioral Risk Factor Surveillance Survey including 41 891 participants from 22 states showed that, among patients who never smoked, the respective OR for CHD among participants missing 1–5 or 6–31 teeth were 1.39 (95% CI 1.05–1.85) and 1.76 (95% CI 1.26–2.45), respectively (Okoro *et al*. 2005).

Experimental evidence

Intervention studies with surrogate markers

When designing and conducting an intervention trial to reduce AVD events, a number of challenges are faced by researchers: firstly because of the extended time course of evolution of AVD (studies with follow-up of minimum 3 years), then due to the relatively low incidence of AVD-related clinical events (1–3% per year in a high-risk population as for example in patients who already experienced an AVD event). Large sample sizes (more than 4000 participants), longer follow-up (more than 3 years), and logistical challenges in delivering effective periodontal treatment across different centers/countries have impacted on the feasibility of performing such trials as well as highlighting the ethical considerations related to the follow-up of untreated periodontitis over prolonged time periods. Therefore, most intervention

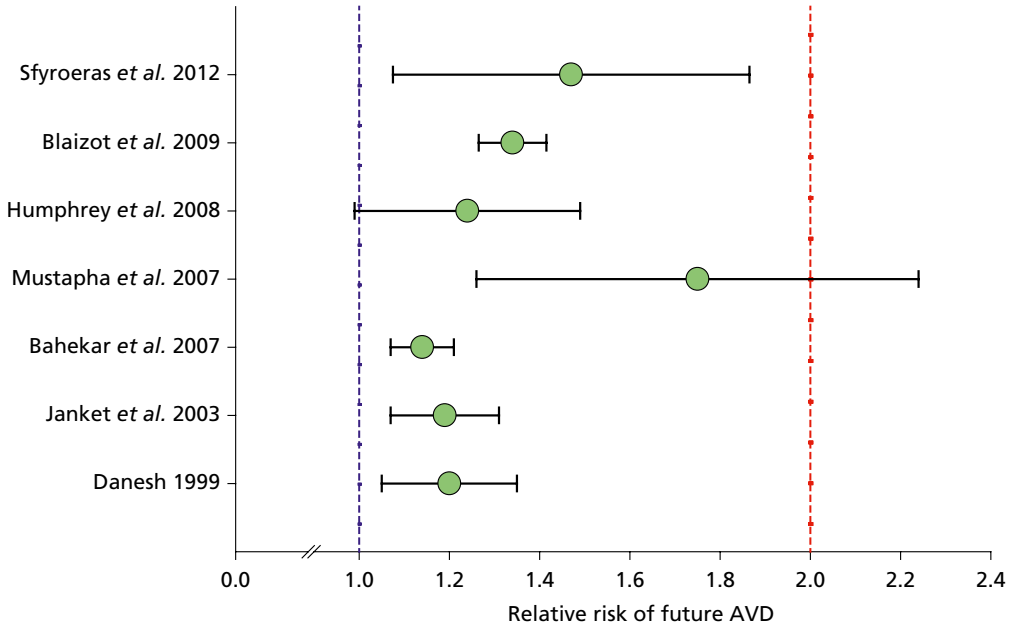

Fig. 17-3 Scatter plot with error horizonal lines of reported adjusted relative risk of observational studies in previous systematic reviews and meta-analysis of the association between periodontitis and atherosclerotic vascular disease (AVD) to date.

trials conducted to date have been largely limited to the study of the effects of periodontal therapy on surrogate markers of AVD or on pathways related to the pathobiology of the disease.

The first intervention study in this area (Ide *et al.* 2004) showed that chronic periodontitis patients undergoing an episode of subgingival scaling experienced changes in their systemic inflammatory status (as assessed by early inflammatory biomarkers such as tumor necrosis factor α and IL-6). In the same year, a randomized trial reported statistically significant reductions in serum IL-6 (median decrease 0.2 ng/L, 95% CI 0.1–0.4 ng/L) and CRP (median decrease 0.5 mg/L, 95% CI 0.4–0.7) in patients with severe generalized periodontitis who received a single-sitting non-surgical periodontal therapy and the use of locally delivered antimicrobials after 6 months and compared with a group who received delayed treatment (D'Aiuto *et al.* 2004). An updated summary of intervention trials on surrogate markers of AVD confirmed limited to moderate evidence that periodontal treatment was associated with reductions of systemic inflammation (reduced CRP and IL-6 serum levels), of blood pressure (reduced systolic blood pressure), and better endothelial function (improved FMD) and subclinical atherosclerosis (reduced IMT) (Table 17-4) (Orlandi *et al.* 2020).

Table 17-4 Summary of the evidence on the effect of periodontal therapy on surrogate markers of cardiovascular diseases.

Effect of periodontal therapy on	Outcome	Number of RCTs since last consensus meta-analysis	Effect	Overall level of evidence
Lipid fractions	Lipids (multiple)	6 RCTs (Caula *et al*. 2014; Kapellas *et al*. 2014; Hada *et al*. 2015; Fu *et al*. 2016; Deepti *et al*. 2017; D'Aiuto *et al*. 2018)	No	Moderate
Blood pressure	Systolic, diastolic	4 RCTs (Hada *et al*. 2015; Zhou *et al*. 2017; D'Aiuto *et al*. 2018; Czesnikiewicz-Guzik *et al*. 2019)	Yes	Moderate
Systemic inflammation	IL-6	3 RCTs (Kapellas *et al*. 2014; Fu *et al*. 2016; Zhou *et al*. 2017)	Yes	Moderate
Systemic inflammation	CRP	5 SR (Ioannidou *et al*. 2006; Paraskevas *et al*. 2008; Freitas *et al*. 2012; Demmer *et al*. 2013; Teeuw *et al*. 2014) 7 RCTs (Bokhari *et al*. 2012; Caula *et al*. 2014; Kapellas *et al*. 2014; Hada *et al*. 2015; Deepti *et al*. 2017; Zhou *et al*. 2017; D'Aiuto *et al*. 2018;Kaushal *et al*. 2019)	Yes	Moderate
Endothelial function	Endothelial function (multiple measures)	2 RCTs (D'Aiuto *et al*. 2018; Saffi *et al*. 2018) 1 SR (Orlandi *et al*. 2014)	Yes	Moderate
Arterial stiffness	Pulse wave velocity	1 RCT (Kapellas *et al*. 2014)	No	Limited
Subclinical atherosclerosis	Common carotid Intima-media thickness	1 RCT (Kapellas *et al*. 2014)	Yes	Limited

RCT, randomized clinical trial; SR, systematic review. (Source: Adapted from Orlandi *et al*. (2020).)

The evidence of the effects of periodontal treatment on vascular surrogate markers of AVD comes, however. from small-sized, intervention studies. A randomized controlled trial involving a total of 120 patients with severe periodontitis, 61 of whom received full-mouth subgingival debridement, completed within a single session and accompanied by extensive application of local antibiotics in all deep periodontal pockets (Tonetti *et al*. 2007), demonstrated a significant improvement in FMD in the test compared with the control treatment group (whole mouth supragingival scaling and polishing in a single session) at a 6-month follow-up examination. A larger and longer intervention study performed in patients suffering from periodontitis and type 2 diabetes confirmed similar benefits in FMD improvement following a standard course of non-surgical and surgical periodontal therapy after 6- and 12-month follow-ups when compared with control therapy (whole mouth supragingival scaling and polishing) (D'Aiuto *et al*. 2018). Similar improvements were reported following non-surgical periodontal treatment in 69 patients with coronary artery disease and severe periodontitis when compared with delayed treatment (Saffi *et al*. 2018).

Promising results have been presented on the beneficial effect of the treatment of periodontitis on arterial blood pressure. In particular, Zhou *et al*. (2017) randomly allocated 107 patients with prehypertension and moderate to severe periodontitis to receive either full-mouth scaling and root planing under local anesthesia or a standard cycle of supragingival scaling and polishing. The authors reported a reduction of systolic BP and diastolic BP levels by 10.3 and 7.2 mmHg, respectively, 6 months following treatment. Further evidence to corroborate these findings came from the first randomized trial using ambulatory blood pressure as a primary endpoint in patients with insufficiently controlled hypertension (Czesnikiewicz-Guzik *et al*. 2019). One hundred and one patients with office blood pressure >140/90 mmHg despite a stable antihypertensive regimen (using at least one medication for over 6 months) and concomitant moderate to severe periodontitis received an intensive or control periodontal

treatment protocol and 2 months after treatment a statistically significant reduction in blood pressure (11.1 mmHg; 95% CI 6.5–15.8) was accompanied by improvements in FMD and inflammatory cellular and biomarkers profiles (Czesnikiewicz-Guzik *et al*. 2019).

In contrast, inconclusive evidence exists on the effects of periodontitis treatment on PWV. Vidal *et al*. (2013) reported an improvement in PWV (13.7 [2.4] to 12.5 [1.9]) 6 months after periodontal treatment in hypertensive patients whilst these findings were not observed in two different clinical trials (Kapellas *et al*. 2014; Houcken *et al*. 2016). Ren *et al*. (2016) randomized 108 patients with moderate to severe periodontitis to receive either supragingival scaling and subgingival instrumentation (test) or supragingival scaling and polishing (control). Participants in the test treatment group showed a significantly decreased PWV after 1 month of an average of -0.58 m/s (95% CI -0.06–1.11).

Likewise, a single-arm study conducted on 35 patients with mild-to-moderate periodontitis reported that non-surgical periodontal therapy resulted in a diminished IMT thickness at 6 and 12 months after treatment completion (Piconi *et al*. 2009). In a subsequent randomized trial, 168 Aboriginal Australians suffering from periodontitis presented with an IMT decrease after 12 months of a single session of periodontal therapy (mean difference of −0.026 mm; 95% CI −0.048–−0.003) (Kapellas *et al*. 2014).

Intervention studies with clinical events

To date there is still insufficient evidence to comment on the effects of periodontal therapy on cardiac events. Consistent observational evidence, however, suggests that several oral health interventions including self-performed oral hygiene habits (toothbrushing) (de Oliveira *et al*. 2010; Park *et al*. 2019), dental prophylaxis (Lee *et al*. 2015), increased self-reported dental visits (Sen *et al*. 2018), and periodontal treatment (Lee *et al*. 2015; Park *et al*. 2019; Holmlund *et al*. 2017) are accompanied by a reduction of AVD events.

Cross-sectional data of The Scottish Health Surveys from 1995 to 2003 comprising 11 869 men and women (mean age of 50 years), was linked to a database of hospital admissions and deaths with follow-up until December 2007 (Information Services Division, Edinburgh) (de Oliveira *et al*. 2010). Participants who brushed less than once a day exhibited the highest incidence of AVD events (HR = 1.7; 95% CI 1.3–2.3) compared with those who brushed twice a day. A retrospective nationwide, population-based study in Taiwan, including 511 630 participants with periodontitis and 208 713 controls was conducted to estimate the incidence rate of AVD events from 2000 to 2015 (Lee *et al*. 2015). Patients with periodontitis who received dental prophylaxis presented with reduced incidence of acute MI (HR = 0.90; 95% CI 0.86–0.95) as opposed to those who received more periodontal treatment (including gingival curettage, scaling and root planing, and/or periodontal flap operation and/or tooth extraction) (HR = 1.09; 95% CI 1.03–1.15). Consistent reductions in the incidence rate of stroke were observed in both the dental prophylaxis (HR = 0.78; 95% CI 0.75–0.91) and active periodontal treatment group (HR = 0.95; 95% CI 0.91–0.99) (Lee *et al*. 2015). In a recent cohort of 8999 patients with periodontitis who received a complete (non-surgical and if needed surgical) periodontal treatment protocol and then followed for more than 30 years, poor responders to the treatment had an increased incidence of AVD events (IR = 1.28; 95% CI 1.07–1.53) compared with good responders (Holmlund *et al*. 2017). Similar benefits were reported in self-reported regular dental care users of the 6736 participants of the ARIC substudy who were followed up for 15 years and exhibited lower risk for ischemic stroke (HR = 0.77; 95% CI 0.63–0.94) when compared with episodic care users (Sen *et al*. 2018). Lastly, the largest prospective population-based trial including 247 696 participants from Korea and free from any vascular disease were followed over 14 years and the study confirmed that one additional toothbrushing episode per day was associated with a reduced incidence of AVD events (HR = 0.91; 95% CI 0.89–0.93) and regular professional cleaning reduced the risk even further (HR = 0.86; 95% CI 0.82–0.90) (Park *et al*. 2019).

To date, only a single, multicenter pilot study has examined the effects of periodontal therapy on cardiac events. The Periodontitis and Vascular Events (PAVE) study (Beck *et al*. 2008; Offenbacher *et al*. 2009b) randomized patients with periodontitis and a history of severe AVD to either community care or a study protocol that consisted of oral hygiene instruction and professional mechanical periodontal therapy. Over a 25-month follow-up period, cardiovascular adverse events occurred with similar frequency and high degree of variation in the community control and the periodontal treatment groups (RR = 0.72, 95% CI 0.23–2.22).

Diabetes mellitus

Biological mechanisms

The role of diabetes mellitus as a risk factor for periodontitis is reviewed in detail in Chapter 18. Newer evidence, however, suggests that periodontitis may represent a risk factor and/or modifier of diabetes onset and progression. This is most evident for type 2 diabetes, whilst the evidence linking periodontitis and type 1 diabetes is mainly based on historical observational and intervention studies performed in the early stages of periodontal medicine.

Inflammation is a known driver of insulin resistance with a role in the initiation and evolution of cardiorenal complications in patients with and without diabetes (Hotamisligil *et al*. 1993).

Previous reports have shown that reduction of inflammation by lifestyle interventions (Schellenberg *et al*. 2013) or drug therapy (i.e. IL-1 antagonists)

(Goldfine *et al*. 2011), improves insulin beta-cell secretory function and decreases blood glucose in patients with diabetes.

Preclinical evidence highlighted how experimental periodontitis in animal models (i.e. ligature-induced periodontitis) is accompanied by an adaptive immune response specifically directed against pathogens and derangements in glucose metabolism including insulin resistance (Pontes Andersen *et al*. 2007; Blasco-Baque *et al*. 2017). As reviewed above, periodontal infections cause elevations of serum pro-inflammatory cytokines and prothrombotic mediators (Loos 2005; Orlandi *et al*. 2020) which, in turn, may result in insulin resistance, may adversely impact metabolic control, and, long-term, may lead or contribute to the development of diabetic complications. This was elegantly confirmed in a cross-sectional survey of 630 patients with both type 1 and 2 diabetes. Presence of severe gingival inflammation was associated with higher levels of bacterial endotoxins and systemic inflammation (Masi *et al*. 2014). Several studies have demonstrated that periodontal therapy can reduce systemic inflammation especially in patients with other comorbidities like diabetes and this evidence was confirmed in a recent systematic review. A meta-analysis of randomized clinical trials confirmed a positive effect of periodontal treatment in reducing biomarkers of inflammation in patients with diabetes and periodontitis (Artese *et al*. 2015). A reduction in inflammatory burden of patients with diabetes could have important implications for metabolic control and might, in part, explain the mechanisms linking periodontitis and increased risk for complications in people with type 2 diabetes.

Epidemiologic evidence

Observational evidence

In one of the first studies that demonstrated periodontitis entails higher risk for diabetic complications, Thorstensson *et al*. (1996) followed 39 pairs of patients with type 1 diabetes, each consisting of a person with severe periodontitis, matched with respect to age, sex, and diabetes duration with a person with no or only mild periodontitis. After a median follow-up of 6 years, a significantly higher incidence of proteinuria and cardiovascular complications, including angina, intermittent claudication, transient ischemic attack, MI, and stroke was found in the patients with severe periodontitis. Evidence from three prospective studies of Pima Indians in the Gila River community in Arizona, a population with a high prevalence of type 2 diabetes, confirmed these preliminary findings. In the first report, Taylor *et al*. (1996) demonstrated that severe periodontitis at baseline conferred increased risk for poor glycemic control (glycated hemoglobin A1c [HbA1c] >9%) after 2 years of follow-up. Subsequently, in the same population but over a median follow-up of 11 years, a diagnosis of severe periodontitis increased the risk of cardiorenal mortality (RR = 3.2; 95% CI 1.1–9.3) (Saremi *et al*. 2005) as well as renal complications (microalbuminuria and end-stage renal disease) (Shultis *et al*. 2007) when compared with no, mild, or moderate periodontitis.

Further evidence of association between periodontitis and dysmetabolic imbalances derives from studies confirming a consistent association between diagnosis of periodontitis and elevated glucose levels (a simple marker of insulin resistance) especially within the context of a cluster of cardiometabolic markers named the metabolic syndrome. This condition is characterized by the co-existence of not only hyperglycemia but also elevated blood pressure, obesity, and dyslipidemia (Alberti *et al*. 2006). A systematic review of 32 cross-sectional studies, eight case–control studies, and three cohort studies concluded that diagnosis of periodontitis was consistently associated with 50% greater odds of metabolic syndrome (OR = 1.46; 95% CI 1.31–1.61) (Gobin *et al*. 2020).

At least five cohort studies explored the association between periodontitis in diabetes-free individuals and the development of type 2 diabetes over time. The first used data from 9296 participants in NHANES I and its Epidemiologic Follow-Up study confirming that participants with severe tooth loss at baseline had an adjusted OR of 1.71 (95% CI 1.19–2.45) for incident diabetes when compared with those least affected (Demmer *et al*. 2008). In contrast, no association between baseline periodontitis and incident diabetes could be demonstrated after multiple adjustments in a 7-year prospective study of 5848 participants without diabetes in Japan (HR = 1.28; 95% CI 0.89–1.86) (Ide *et al*. 2011). Miyawaki *et al*. (2016) analyzed a cohort of 2469 men aged 36–55 years and free from diabetes who were followed over 5-year follow-up period. Self-reported measures of periodontitis were weakly associated with incident diabetes (RR = 1.73; 95% CI 1.14–2.64 for tooth loosening and RR = 1.32; 95% CI 0.95–1.85 for gingival bleeding). Two further studies had been reported following these initial results. In Northern Ireland, 1331 dentate, diabetes-free men underwent a detailed periodontal examination and were followed over a median period of 8 years. Adjusted hazard ratios for incident type 2 diabetes in men with moderate/severe periodontitis compared with those with no/mild periodontitis was 1.69 (95% CI 1.06–2.69) (Winning & Linden 2017). Lastly, Joshipura *et al*. (2018) analysed a cohort of 1206 diabetes free participants who were followed over 3 years for incident glucose intolerance and/or diabetes. Increase in periodontal attachment loss from baseline to follow-up was associated with higher prediabetes/diabetes risk (RR = 1.25; 95% CI 1.09–1.42) and increase in pocket depth was associated with >20% fasting glucose increase (RR = 1.43; 95% CI 1.14–1.79). Collectively, the evidence published to date would support the

notion that periodontitis and its progression could increase the odds of a later diagnosis of type 2 diabetes by a measure ranging from 30% to 70%.

Experimental evidence

Several intervention studies have examined the effect of periodontal therapy on diabetes outcomes including the level of HbA1c, one of the key indicators of metabolic control in diabetes.

Williams and Mahan (1960) reported for the first time that seven out of nine patients with diabetes and periodontitis who underwent nonsurgical and surgical periodontal therapy according to their individual needs showed significant subsequent reduction in the amount of insulin required to maintain acceptable glucose levels. By contrast, a five-arm randomized controlled trial enrolling 113 Native Americans with type 2 diabetes and periodontitis found that participants allocated to treatment arms that included systemic doxycycline as an adjunct to scaling and root planing reduced their HbA1c levels by approximately 10% of their baseline values after 3 months (Grossi *et al*. 1997) (Fig. 17-1).

Almost 20 years after the results of the first intervention study, a large multicenter trial including 514 patients suffering from severe periodontitis and type 2 diabetes and with baseline HbA1c levels between 7% and 9% was published. All participants in the study were randomly assigned to either scaling and root planing or delayed periodontal therapy (Engebretson *et al*. 2013). After 6 months of the treatment, the mean HbA1c levels increased by 0.17% in the test group and by 0.11% in the control group, with no difference between the groups. These inconclusive findings (no difference in HbA1c levels between treatments after 6 months) were later confirmed by another randomized trial including 264 patients with type 2 diabetes and moderate to severe periodontitis (D'Aiuto *et al*. 2018). In this study, participants were randomly allocated to either (1) nonsurgical and, if indicated, surgical periodontal therapy then followed by careful maintenance or (2) supragingival debridement at comparable time points. Twelve months after baseline and after adjustments for baseline HbA1c, age, sex, ethnicity, smoking status, duration of diabetes, and BMI, participants in the test group exhibited a statistically significant greater reduction in HbA1c (average of 0.6%; 95% CI 0.3–0.9) when compared with the control group. In the same study, D'Aiuto *et al*. (2018) reported statistically significant improvements of participants in the test group in both endothelial (improved FMD both at 6 and 12 months) and kidney function (better glomerular filtration rate) and patient reported outcomes (measure of quality of life relevant to diabetes).

Since the first systematic review on the evidence from intervention trials in patients with periodontitis and diabetes (Janket *et al*. 2005), 13 additional reviews with meta-analysis have been published (Darre *et al*. 2008; Teeuw *et al*. 2010; Corbella *et al*. 2013; Engebretson & Kocher 2013; Liew *et al*. 2013,; Sgolastra *et al*. 2013; Sun *et al*. 2014; Wang *et al*. 2014; Simpson *et al*. 2015; Li *et al*. 2015; Teshome & Yitayeh 2016; Cao *et al*. 2019; Baeza *et al*. 2020). Collectively most of the reports, including the most recent Cochrane systematic review, concluded that there appears to be a statistically significant effect of periodontal therapy on HbA1c levels, amounting to about 0.40–0.50% reduction but there is limited evidence on the duration of this effect (Fig. 17-4).

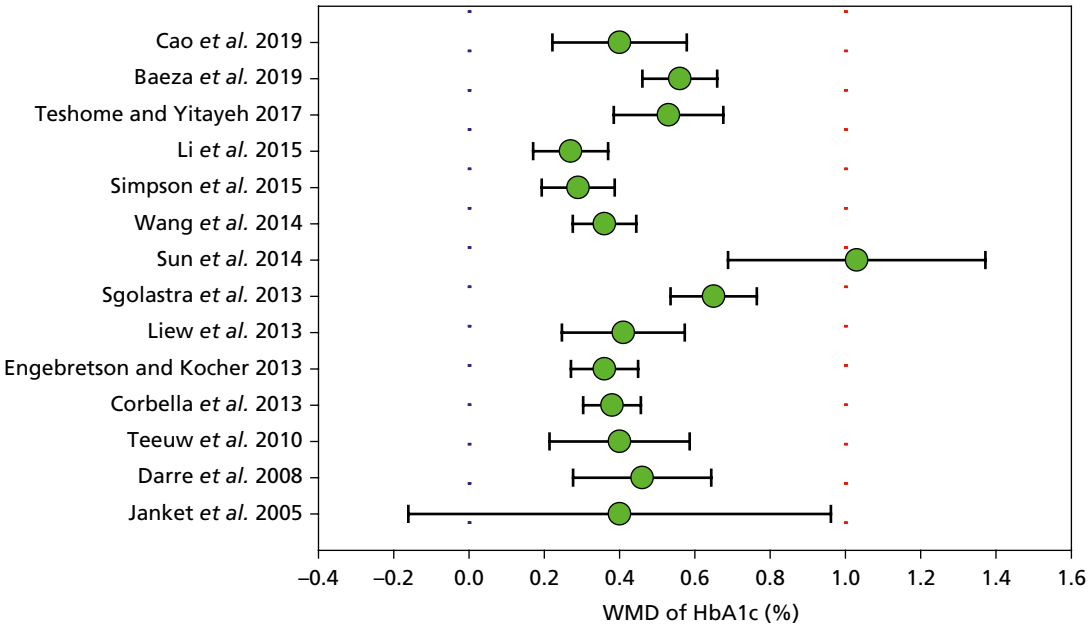

Fig. 17-4 Scatter plot with error horizonal lines of reported adjusted weighted mean differences (WMD) in HbA1c after periodontal treatment in previous systematic reviews and meta-analysis of the association between periodontal treatment and type 2 diabetes outcomes. Please note that the WMDs were originally reported after 6 months of treatment.

Importantly, the magnitude of this effect appears to bear clinical significance within the context of diabetes management: data generated by the United Kingdom Prospective Diabetes Study (Stratton *et al*. 2000) indicate a 35% reduction in the risk of microvascular complications for every percentage point decrease in HbA1c. In addition, an average 0.20% reduction in HbA1c was associated with a 10% reduction in mortality in the general population (Khaw *et al*. 2001). A reduction of 0.5% in HbA1c is comparable with that achieved by adding a second glucose-lowering medication to the management of hyperglycaemia in a patient with diabetes, and hence it is clinically significant. A consensus report endorsed by the respective Federations of Specialist Societies in Periodontology and Diabetes recommended implementation of oral/periodontal assessments as an integral part of diabetes care management (Sanz *et al*. 2018).

Adverse pregnancy outcomes

Biologic mechanisms

Preterm infants are born prior to the completion of 37 weeks of gestation. An estimated 11–13% of pregnancies end in preterm birth (PTB), and this rate appears to be on the rise in several developed countries, despite significant advances in obstetric medicine and improvements in prenatal care utilization (Goldenberg & Rouse 1998; Shapiro-Mendoza & Lackritz 2012). Of interest are the *very preterm infants*, born prior to 32 gestational weeks, the majority of whom require neonatal intensive care due to their increased perinatal mortality, primarily due to impaired lung development and function. The overall contribution of PTB to infant mortality and morbidity is substantial and includes several acute and chronic disorders, including respiratory distress syndrome, cerebral palsy, pathologic heart conditions, epilepsy, blindness, and severe learning disabilities (McCormick 1985; Veen *et al*. 1991).

Preterm infants often weigh less at birth and low birth weight (LBW) (i.e. <2500 g) has been used as a surrogate for prematurity in cases where the exact gestational age at birth is difficult to assess.

Established risk factors for PTB include young maternal age (Scholl *et al*. 1988), multiple gestation (Lee *et al*. 2006), small weight gain during pregnancy (Honest *et al*. 2005), cervical incompetence (Althuisius & Dekker 2005), smoking, alcohol, drug abuse (Myles *et al*. 1998), black race (David & Collins 1997), and a number of maternal infections (uterine tract infections, bacterial vaginosis, chorioamnionitis) (Goldenberg *et al*. 2000; Romero *et al*. 2001). A collective analysis of all established risk factors including obstetric history of PTB as robust markers of future PTB (Mutale *et al*. 1991), however, revealed that approximately 50% of the variance in the incidence of PTB remains unexplained (Holbrook *et al*. 1989).

The possibility that periodontal infections may influence birth outcomes was raised for the first time in the late 1980s (McGregor *et al*. 1988). A subsequent report from Hill (1998) confirmed that amniotic fluid cultures from women with vaginosis rarely contained bacteria common to the vaginal tract, but frequently harbored Fusobacteria of oral origin. A series of experimental studies using common periodontal pathogens in animal models of pregnancy demonstrated that infections from periodontal pathogens caused intrauterine growth retardation, smaller fetuses, and higher inflammation in the amniotic fluid (Collins *et al*. 1994; Boggess *et al*. 2005) . Preliminary clinical evidence confirmed that oral microbes can be identified in the feto-placental unit. However, it is uncertain how pathogens would alter the natural timeline of pregnancy (either via translocation of virulent strains or via increased local relative pathogenic load and by stimulating a neutrophil-driven maternal inflammatory response) (for a comprehensive review of the topic please see Bobetsis *et al*. 2020; Figuero *et al*. 2020).

Epidemiologic evidence

Observational evidence

The first study that reported an association between PTB and periodontitis was a case–control study (Offenbacher *et al*. 1996) of 124 mothers, of whom 93 gave birth to children with a birth weight of <2500 g or prior to 37 weeks of gestation and 46 who delivered infants of normal birth weight at term. Periodontitis, defined as ≥60% of all sites with attachment loss of ≥3 mm, conferred adjusted OR of 7.9 PTB and low weight babies. Twenty years later, a case–control study (Gomes-Filho *et al*. 2016) confirmed that mothers with periodontitis (n = 372) had a sixfold increased likelihood of delivering LBW babies. One of the earlier systematic reviews and meta-analysis published on the association between periodontitis and adverse pregnancy outcomes in case–control studies (Corbella *et al*. 2012) included 17 studies and a total of 10 148 women. The authors reported statistically significant OR for periodontitis and both PTB (OR 1.78; 95% CI 1.58–2.01) and LBW (OR 1.82; 95% CI 1.51–2.20), although the authors cautioned that uncontrolled or inadequately reported confounders may have affected the association demonstrated by the pooled data.

Additional evidence has been reported on the association between periodontitis and other pregnancy outcomes. Longitudinal studies have demonstrated that maternal periodontitis is associated with increased risk for preeclampsia. Periodontitis progression during pregnancy and severe periodontitis at delivery were found to be associated with preeclampsia in a cohort of 1115 healthy pregnant women (Boggess *et al*. 2003). Progression of periodontitis recorded in 1020 pregnant women resulted in an

increased risk for preterm, spontaneous preterm, or very PTBs, independent of traditional risk factors (Offenbacher *et al*. 2006).

A recent overview of systematic reviews including 120 clinical studies grouped in 23 systematic reviews (nine of which had performed a meta-analysis) critically appraised the validity of the published evidence and their conclusions. Seven meta-analyses showed a statistically significant positive association between periodontitis PTB (with ORs and RRs ranging from 1.6 to 3.9). Whereas nine systematic reviews reported on the association between periodontitis and preeclampsia, results from four out of five reviews in which a meta-analysis was performed, confirmed a significant association with ORs/RRs ranging from 2.2 to 2.8. Sixteen systematic reviews reported on the association between periodontitis and LBW with six reviews that performed a meta-analysis resulted in a positive association with ORs/RRs ranging from 1.3 to 4.0. One systematic review investigated the association between periodontitis and small for gestational age suggesting limited evidence on a positive association. Lastly, 17 systematic reviews investigated the association between periodontitis and preterm LBW (a combination of preterm and/or birth weight <2500 g). Seven out of those 17 reviews that performed a meta-analysis reported a significant positive association between periodontitis and preterm LBW with ORs/RRs varying between 2.1 and 5.3. A collective interpretation of these results point towards a prominent role of periodontitis in contributing during pregnancy to the overall risks of PTBs, LBW, and preeclampsia notwithstanding a high percentage (about 11%) of overlap between studies included in different systematic reviews (Daalderop *et al*. 2018).

Experimental evidence

Intervention studies investigating the potential benefit of treating periodontitis during pregnancy with the aim of reducing the incidence of pregnancy complications have had mixed results.

The first published intervention study (Mitchell-Lewis *et al*. 2001) examined a cohort of 213 young, predominantly African-American women who exhibited a particularly high incidence of PTB/LBW (16.5%). Periodontal treatment was associated with a 30% lower incidence of adverse pregnancy outcomes in participants who received the treatment (13.5%) when compared with 18.9% who did not receive the intervention. A subsequent study demonstrated that maternal periodontal therapy reduced the risk of preterm LBW (Lopez *et al*. 2002) confirming a plausible rationale for a number of research groups to plan and conduct larger and multicenter trials on the matter. A few years later, however, two major randomized clinical trials contradicted previous findings of periodontal treatment mitigating risk of PTB (Michalowicz *et al*. 2006, Offenbacher *et al*. 2009a).

Experimental study designs varied across these intervention studies mainly because different active periodontal treatments and controls were chosen. Gazolla *et al*. (2007) for example involved a group of women who "dropped out" of treatment as control therapy whereas Jeffcoat *et al*. (2003) included multiple active treatment groups (including mechanical periodontal treatment with or without systemic administration of metronidazole). Five of the seven studies that were considered to be of higher methodological quality (Jeffcoat *et al*. 2003; Michalowicz *et al*. 2006; Newnham *et al*. 2009; Offenbacher *et al*. 2009a; Macones *et al*. 2010), failed to detect any positive effect of periodontal therapy on pregnancy outcomes, including PTB at <37 or <35 gestational weeks, or LBW of <2500 g or <1500 g. In view of the strong biologic plausibility of the link between maternal periodontal infections and adverse pregnancy outcomes, and of the promising data of the early association studies, at least nine systematic reviews with meta-analyses have been conducted indicating sufficient evidence that periodontal therapy during gestation does result in some improved obstetric outcomes (Polyzos *et al*. 2010; Uppal *et al*. 2010; Chambrone *et al*. 2011; Fogacci *et al*. 2011; George *et al*. 2011; Kim *et al*. 2012; Schwendicke *et al*. 2015; Iheozor-Ejiofor *et al*. 2017; Bi *et al*. 2019). Relative risk reductions reported ranged from 0.6 to 0.9 for PTB and from 0.5 to 1.1 for PBW, confirming a great variation most presumably due to the methodological flaws of the studies included (Fig. 17-5). Further, some preliminary evidence suggests that periodontal treatment during pregnancy significantly decreased risk of perinatal mortality (RR = 0.53; 95% CI 0.30–0.93) (Bi *et al*. 2019).

Interpreting collectively the latest evidence on intervention trials, it is plausible to suggest that performing periodontal treatment is safe during pregnancy and it is associated with a reduced rate of adverse pregnancy outcomes (preterm deliveries and birth weight differences).

Chronic renal disease

Biologic mechanisms

Renal function is commonly measured by means of the glomerular filtration rate (eGFR), which is estimated on the basis of an equation that incorporates the patient's serum creatinine concentration, age, sex, and race (Levey *et al*. 2006). In a healthy adult, eGFR ranges between 100 and 120 mL/min/1.73 m^2 body surface area and any lower values of these estimates define different stages of chronic kidney disease (CKD). Common causes of CKD include diabetes mellitus, glomerulonephritis, and chronic hypertension. Although the prevalence of CKD increases with age, age itself is not regarded as a true risk factor of the disease (Hill *et al*. 2016) as not everyone would develop it despite an average decrease in renal function with age (Lindeman *et al*. 1985).

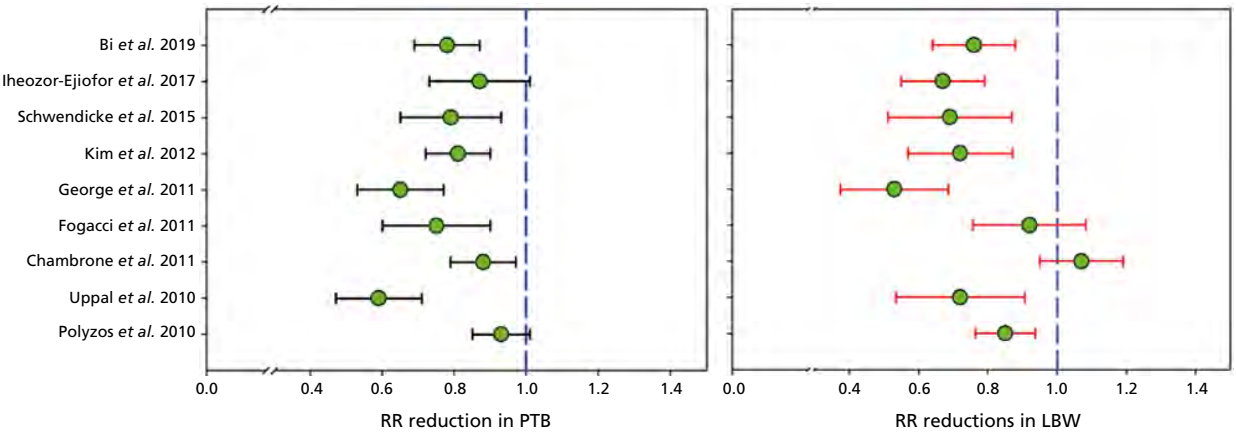

Fig. 17-5 Scatter plot with error horizonal lines of reported adjusted relative risk reductions in adverse pregnancy outcomes (preterm birth [PTB] and low birth weight [LBW]) after periodontal treatment in previous systematic reviews and meta-analysis of the association between periodontal treatment and adverse pregnancy outcomes.

There are various possible causes to explain the link between periodontitis and CKD. Firstly, patients with severe CKD are likely to have an altered immune system because of impaired function of T- and B-lymphocytes as well as monocytes and macrophages (Chatenoud *et al*. 1990; Girndt *et al*. 2016). This could result in a compromised host response to any microbial challenge. In addition, some studies suggested that patients undergoing dialysis are less motivated to maintain good oral hygiene measures because of the intense burden and time-consuming treatment sessions (Borawski *et al*. 2006; Buhlin *et al*. 2007). Confounding diseases like diabetes mellitus and hypertension, which are both major risk factors of CKD, could also further contribute to the severity of periodontitis. A strong association between diabetes and periodontitis could therefore secondarily explain why in patients with CKD, signs of periodontal inflammation and bone loss are observed. Additional confounding variables include age, access to health care or dental care, and renal failure complications (Chen *et al*. 2011a, b).

Evidence supporting the notion that periodontitis triggers a chronic inflammatory response has been reviewed earlier in this chapter. Increased systemic inflammation and oxidative stress burden has been reported in patients with periodontitis and CKD (Ioannidou *et al*. 2011) and it has been directly associated with raised incidence of future CVD events (Arici & Walls 2001; Mathew *et al*. 2008).

Additional evidence on the role of specific periodontitis pathogens, such as *P. gingivalis*, confirmed their presence in epithelial cells, smooth muscle of renal mesangial cells, and neutrophils and macrophages (Kozarov 2012). An increased bacterial load in the systemic circulation is shown to add to the existing inflammatory burden in the renal tissues when examining the association between periodontitis and CKD (Castillo *et al*. 2007; de Souza *et al*. 2007; Stenvinkel 2002; Takeuchi *et al*. 2007).

Epidemiologic evidence

Observational evidence

A series of cross-sectional studies appeared after the year 2000 suggesting a close link between periodontitis and CKD. The first study reported an analysis of data from 5537 participants in the ARIC study confirming that those with either moderate or severe periodontitis had greater odds of eGFR of <60 mL/min/1.73 m^2 when compared with those with no periodontitis or only gingivitis (Kshirsagar *et al*. 2005). Similar estimates were published following the analysis of 6199 participants in the 2001–2004 NHANES study; participants with periodontitis had greater than two-fold higher odds of CKD (Grubbs *et al*. 2011). Evidence of association between exposure to periodontal infections (assessed by IgG antibody levels to specific periodontal pathogens) and impaired renal function was found both in the ARIC (Kshirsagar *et al*. 2007) and NHANES III datasets (Fisher *et al*. 2008). Less conclusive is the evidence reported on the association between periodontitis and kidney function during dialysis with some studies demonstrating that periodontitis was associated with hypoalbuminemia (Kshirsagar *et al*. 2007) and with increased cardiovascular disease- associated mortality (Chen *et al*. 2011a) whereas others reported no association (Castillo *et al*. 2007; Gavaldá *et al*. 2008; Garcez *et al*. 2009; Vesterinen *et al*. 2011).

The first systematic review on the available evidence on the association between periodontitis and CKD concluded that patients with periodontitis had 1.7 greater odds (95% CI 1.4–2.0) of having CKD compared with participants without periodontitis (Chambrone *et al*. 2013). Following up on these results, two separate meta-analyses of cohort studies reported that periodontitis was associated with significant increased risk of incident CKD (RR = 1.73; 95% CI 1.17–2.56) (Deschamps-Lenhardt *et al*. 2019) and of all-cause death when periodontitis was diagnosed (RR = 1.25; 95% CI 1.05–1.50) (Zhang *et al*. 2017).

A summary analysis of cross-sectional surveys expanded on the association between periodontitis and increased odds of CKD (ranging from 1.60 to 1.88) suggesting that these estimates increased with greater severity of periodontitis and accelerated the progression to CKD (OR of association between severe periodontitis and CKD of 2.26; 95% CI 1.69–3.01) (Kapellas *et al*. 2019). This finding was corroborated by Chang *et al*. (2017) who followed 2831 patients over 10 years and reported that periodontal probing pocket depth measures >4.5 mm were associated with faster progression of CKD (HR = 3.1; 95% CI 2.0–4.6).

Experimental evidence

Limited evidence is available on the effects of periodontal treatment on the management of CKD and its complications. A non-randomized trial confirmed that periodontal therapy in 21 predialysis patients and 19 patients without clinical evidence of kidney disease produced improved oral health outcomes, but it was underpowered to show an improvement in renal function (Artese *et al*. 2010). A further study carried out on patients on dialysis found that periodontal therapy was associated with significant reductions in systemic inflammatory biomarkers including hsCRP, IL-6, and serum pro-hepcidin levels (Vilela *et al*. 2011). These results were further confirmed by three additional randomized trials demonstrating that periodontal therapy may not only have a beneficial effect on markers of systemic inflammation, but also renal specific markers such as cystatin C, albumin, and creatinine (Graziani *et al*. 2010; Almeida *et al*. 2017; Grubbs *et al*. 2020). In a recent randomized trial conducted on patients suffering from periodontitis and type 2 diabetes, non-surgical and surgical periodontal therapy was associated with an improvement of kidney function as assessed by eGFR compared with patients who received just scaling and polishing of their teeth over a 12 month period (D'Aiuto *et al*. 2018). The improvement of kidney function was also associated with improved metabolic control, vascular function, and reduced systemic inflammatory burden.

Cognitive decline/dementia

Biologic mechanisms

Alzheimer's disease is the main cause of dementia and one of the great health care challenges of the 21st century. The disease is still defined by the combined presence of amyloid and tau, but researchers are gradually moving away from the simple assumption of linear causality as proposed in the original amyloid hypothesis. The disease is characterized by three clinical phases: a preclinical phase with no symptoms but a distinct pathology, a prodromal phase characterized by cognitive decline and disease-specific lesions. and lastly by the dementia phase. Specific lesions of Alzheimer's disease include neuritic plaques (filaments of beta-amyloid), neurofibrillary tangles (bundles of tau protein), inflammation, and neuronal degeneration. Tau is a crucial component of the neuronal cytoskeleton and its hyperphosphorylation leads to disassembly of microtubules and neuronal functional dysfunction with progressive brain atrophy (Livingston *et al*. 2020).

Hypothetical mechanisms involved in the development of Alzheimer's disease, included (1) amyloid accumulation (Selkoe & Schenk 2003); (2) an uncontrolled inflammatory process affecting neuronal components (McGeer & McGeer 2002); and (3) an infectious hypothesis (Miklossy 2011).

Experimental models of periodontitis including by *P. gingivalis* infection have been linked to increased endotoxemia, brain inflammation, cortical expression of amyloid β42 and β40, and cognitive dysfunction. This concept has been confirmed by several preclinical and clinical studies demonstrating how dysbiotic disorders (including oral dysbiosis) are implicated in Alzheimer's disease pathogenesis (Kamer *et al*. 2009, 2015; Noble *et al*. 2014; Naorungroj *et al*. 2015). Convincing evidence of a possible role of this periodontal pathogen in dementia confirmed that blocking toxic proteases from *P. gingivalis* with drug inhibitors could alter brain colonization and neurodegeneration in an experimental animal model (Dominy *et al*. 2019).

Epidemiologic evidence

Observational evidence

Current evidence consistently suggests that chronic inflammatory diseases increase Alzheimer's disease risk (Kamer 2010). More than 25 observational studies have closely examined the association between periodontitis and cognitive/decline and Alzheimer's disease. Four out of six case–control studies and five out of seven cross-sectional studies reported an association between periodontitis and Alzheimer's disease (Nadim *et al*. 2020). Fourteen cohort studies (seven with prospective and seven with a retrospective design) involving 428 575 participants over a median follow-up of 9 years, concluded that periodontitis or surrogate measures of poor oral health are associated with greater hazard ratios of Alzheimer's disease ranging from 1.06 (95% CI 1.01–1.11) to 2.54 (95% CI 1.30–3.35) (Kamer *et al*. 2020). Similar estimates were reported in cohort studies investigating the association between periodontitis and cognitive decline (Ide *et al*. 2016; Sung *et al*. 2019; Demmer *et al*. 2020). Further in a systematic review and meta-analysis, Leira *et al*. (2017) reported that the association between periodontitis and dementia could be dose dependent with increasing relative risks ranging from 1.86 (95% CI 0.89–3.91) for moderate up to 2.98 (95% CI 1.58–5.62) for severe periodontitis.

Experimental evidence

There is still insufficient evidence on the potential effect of treatment of periodontitis on the onset and progression of Alzheimer's disease. Due to the slow and progressive nature of the disease, it is plausible to hypothesize that any potential benefit in promoting periodontal health in intervention trials would be appropriate if performed during the preclinical and prodromal phase of Alzheimer's disease. A number of logistical and feasibility challenges are faced by researchers who approach this area, but they are not dissimilar, for instance, to those we reviewed earlier in this chapter (larger and long-term studies with ethical considerations of no treatment for periodontitis). Preliminary evidence from Yamamoto *et al*. (2012) suggested that participants (n = 220, ≥65 years of age) who did not attend a dentist regularly had higher hazard ratios for dementia of 1.76 (95% CI 0.96–3.20) when compared with those who had regular dental care (HR 1.44; 95% CI 1.04–2.01). A further small but uncontrolled clinical trial involving 29 patients with mild to moderate Alzheimer's dementia who underwent periodontal treatment, confirmed an improvement in a measure of self-reported and functional cognitive decline (Rolim Tde *et al*. 2014).

Cancer

Biologic mechanisms

Cancer represents still one of the major killers among the non-communicable diseases. Despite great efforts in understanding the pathogenesis of the various forms of cancer, there is still limited evidence on the exact interplay between genetic, environmental, and acquired factors responsible for the development and progression of cancer. Recent evidence suggests that modulating the inflammatory and immune response to specific forms of cancer is set to revolutionize the management and survival rates of the disease. A growing interest in linking chronic infectious/inflammatory diseases like periodontitis and cancer has been reported. The combination of infectious agents and deregulated inflammatory response have been advocated as biological mechanisms linking periodontitis and cancer.

Systemic inflammation for example can increase the risk of development of precancerous and malignant lesions (Siemes *et al*. 2006; Trichopoulos *et al*. 2006; Gunter *et al*. 2011) and cancer development (Federico *et al*. 2007). The presence of severe periodontitis has been claimed to favor the development of phenotypic changes in the mononuclear cell–cytokine system, causing an increased inflammatory response upon exposure to bacterial lipopolysaccharide (Hernichel-Gorbach *et al*. 1994). Diabetes as comorbidity to periodontitis could also increase the risk of cancer development based on the increased inflammatory response and the presence of advanced glycation end product receptor ligands which can directly promote carcinogenesis by stimulating cancer cells and modulating cellular growth in the tumor microenvironment (Logsdon *et al*. 2007). Further, dietary limitations and in particular the assumption of proinflammatory nutrients deriving from tooth loss and masticatory difficulties due to periodontitis have been claimed to increase the risk of cancer development (Mazul *et al*. 2018; Namazi *et al*. 2018).

A variation in bacterial colonization has been observed when comparing oral cancer sites with unaffected areas, suggesting that bacterial microflora may be related to the risk of cancer development (Basith *et al*. 2012; Pushalkar *et al*. 2012). Subgingival bacterial production of endotoxins, metabolic by-products, and enzymes can modify the response of proto-oncogenes and tumor suppressor genes, and potentially interfere with the normal cellular cycle in terms of cellular proliferation and survival (Nwizu *et al*. 2020).

Epidemiologic evidence

Observational evidence

Despite a substantial lack of studies with standardized and comparable methods to speculate about the association between periodontitis and cancer, preliminary evidence suggests a possible link between the two diseases. In a recent systematic review and meta-analysis, 10 studies aimed at investigating the association between periodontitis and total cancer risk were reviewed (Corbella *et al*. 2018). Considering hazard ratios, a statistically significant association of diagnosis of periodontitis was found for all cancers studied (1.14; CI 95% 1.04–1.24) as well as individual cancers; digestive tract cancer (1.34; CI 95% 1.05–1.72), pancreatic cancer (1.74; CI 95% 1.21–2.52), prostate cancer (1.25; CI 95% 1.04–1.51), breast cancer (1.11; CI 95% 1.00–1.23), corpus uteri cancer (2.20; CI 95% 1.16–4.18), lung cancer (1.24; CI 95% 1.06–1.45), hematological cancer (1.30; CI 95% 1.11–1.53), esophagus /oropharyngeal cancer pooled together (2.25; CI 95% 1.30–3.90) and non-Hodgkin lymphoma (1.30; CI 95% 1.11–1.52). Another systematic review confirmed that patients with oral cancer exhibited increased clinical attachment loss, plaque index, bleeding on probing, and radiographic bone loss (Colonia-Garcia *et al*. 2020). Further, limited evidence was available on the possible association between periodontitis and other forms of cancer (i.e. liver, prostatic, hematological, and genitourinary).

Experimental evidence

Limited evidence is available on the potential benefit of improving periodontal health on the onset or progression of a specific form of cancer. Lee *et al*. (2014) found a reduced esophageal cancer risk in males undergoing dental prophylaxis. However, the lack of information regarding the periodontal status

following the treatment and the influence of potential risk factors could have influenced the results. Another study confirmed that the performance of periodontal treatment could reduce the risk of oral cancer (Moergel *et al*. 2013). Although it appears that periodontitis may be related to cancer development, especially in the upper gastrointestinal tract, the causality between periodontitis and risks for all cancers needs further investigation, as multiple methodological and confounding factors exist. Moreover, among the factors that hinder the direct comparison of different studies regarding cancer occurrence in periodontally affected patients, are the different definitions and measurement of periodontitis severity used, the smoking status of the patients, and the relatively scarce number of experimental studies. Nevertheless, the role of oral and systemic inflammation appears of utmost importance to better understand the pathogenetic mechanism behind the potential association between periodontitis and cancer risk.

Conclusion

Somewhat provocatively, it has been stated that modern science tends to *recycle* ideas from the past. This notion certainly applies to some extent to the association between periodontitis and systemic health outcomes. Our views have certainly evolved since the times when the "focal infection" theory prevailed, and our reaction to the potential threat that oral infections may pose to general health are more measured and are geared towards prevention and anti-infective/anti-inflammatory approaches rather than indiscriminate dental extractions. As discussed in this chapter, the proposed associations are not only biologically plausible, but the magnitude of the biologic effects of periodontal diseases on general health outcomes is gradually being refined. It is increasingly evident that periodontal treatment results in lower levels of systemic inflammation, at least in patients who already have another comorbidity (i.e. diabetes). This impact on the host could well represent the main mechanism through which periodontitis influences the onset and progression of several chronic diseases.

Drawing any firm conclusions on whether periodontitis causes other non-communicable diseases is influenced by the limited data on long-term benefits of reduction of new clinical events or complications. This situation is particularly true for chronic diseases, such as periodontitis, that require long-term management but that are predominantly driven by a fine interplay between patients' compliance/behavior and effective dental and periodontal care. Larger and longer clinical trials will be eventually required to demonstrate whether or not periodontitis is a risk factor for poor systemic health outcomes. Ongoing research will hopefully clarify these issues in the near future. It is important to note, however, that we have not reviewed a plethora of studies linking periodontitis with other non-communicable diseases (i.e. inflammatory diseases, arthritic diseases, pulmonary infections and diseases. and many more); hence we urge the reader not only to be aware of these associations but to approach and critique the evidence available with an open-minded spirit.

Expert recommendations from consensus workshops on the association between periodontitis and systemic health outcomes have been published with the aim of easier interpretation of the published evidence for oral health professionals. There are some common motifs in these clinical recommendations such as; (1) to inform and communicate with patients that periodontitis is closely interlinked with other comorbidities and in particular it does share several of the common risk factors responsible for most of these non-communicable diseases; (2) to provide oral health education and a personalized oral hygiene regime as part of an oral examination that includes a comprehensive periodontal evaluation consisting of full-mouth probing and bleeding scores; (3) if no periodontitis is diagnosed, patients should be placed on preventative programmes with regular monitoring (at least once a year) whereas if periodontitis is diagnosed, they should be managed as soon as their systemic health status permits. Appropriate and effective mechanical non-surgical periodontal therapy should be provided as well as dental rehabilitation to restore adequate mastication for proper nutrition. Oral health professionals should also be weary of and diagnose/manage other common oral diseases, especially in high-risk patients (i.e. with diabetes or with immune-suppression disorders) including dry mouth, burning mouth, candida infections, and dental caries.

If a patient with periodontitis presents with established cardiovascular disease, the patient should be informed of the potential risk of suffering future additional cardiovascular complications and they should actively manage their cardiovascular risk factors (such as diabetes, obesity, smoking, hypertension, hyperlipidaemia, and hyperglycaemia). Lastly their periodontitis should be managed as soon as their cardiovascular status permits, and this should be discussed with the relevant general or specialist medical practitioner in charge of the patient's care (Sanz *et al*. 2020).

Patients with diabetes should be advised that they have an increased risk for gingivitis and periodontitis. They should also be told that if they suffer from periodontitis, their glycaemic control may be more difficult to achieve, and they are at higher risk of other complications, such as eye, kidney, and cardiovascular diseases. Initial mechanical periodontal therapy should be provided as soon as feasible, as this may help to improve glycaemic control (Sanz *et al*. 2018).

If the oral health professional is dealing with a female patient during pregnancy, all of the above would apply as soon as the stage of pregnancy has been confirmed. The patient should be made aware

of the potential association between the presence of periodontitis and adverse pregnancy outcomes. It is important to emphasize that all preventive, diagnostic, and therapeutic oral procedures are safe throughout pregnancy and that these measures are effective in improving and maintaining oral health. In particular, non-surgical periodontal therapy (scaling and root surface instrumentation) and extractions are safe during pregnancy, and especially during the second trimester of gestation (Figuero & Sanz 2020).

All the evidence to date underscores that the oral cavity is an integral part of the human body, and that "health" must encompass oral – and periodontal – health as well. Periodontal medicine has provided a unique opportunity for oral health professionals and researchers to expand their investigative sphere, interact fruitfully with colleagues in medicine, and acquire more knowledge.

Irrespective of the definitive conclusions of these research efforts, their byproducts may prove to be just as important as the elucidation of the research task *per se*.

Chapter 18

Periodontitis and Systemic Diseases (Cardiovascular Disease and Diabetes): Biological Perspectives for Oral/Periodontal Implications

Alpdogan Kantarci and Hatice Hasturk

Forsyth Institute, Cambridge, MA, USA

Introduction

The mouth was recognized as a site of infection in the human body since ancient times. In modern medicine, "focal infection" was defined to describe this observation (Miller 1891a). At the beginning of the nineteenth century, when dentistry was becoming an independent discipline with only a handful of dental schools in the world, the focal infection theory was a revolutionary thought. It highlighted the oral cavity as a place where bacteria originated from and disseminated to other sites of the body, eventually causing disease. With this theory, the human body was connected, and the oral cavity was linked to overall health. Dental and oral diseases were seen as the root cause for systemic inflammation; thus, elimination of oral inflammation was a prerequisite to prevent/treat systemic diseases. Ironically, this approach has led to serial extractions of teeth as a "cure" for "gum diseases" and elimination of the infectious "foci" from the body (Miller 1891b; Hale 1931) instead of increased awareness of the prevention of oral diseases and care for oral health. As a result, extensive and unnecessary extractions were performed where edentulism and replacing the permanent teeth with dentures, "the third set of teeth", became rampant. The focal infection concept was abandoned, and the oral cavity and the rest of the body were once again disconnected.

After two world wars and global turmoil, the oral and systemic health link was revisited. Leonard

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

(1946) described that patients with periodontal disease could have systemic problems. In their landmark publication, Karshan *et al*. (1946) linked systemic abnormalities in blood chemistry to periodontal diseases and noted that this link could be bidirectional. In a symposium focused on periodontal disease and systemic health in 1949, pregnancy, diabetes, and leukemia were recognized as systemic diseases with possible associations with periodontal diseases. The first reference to the link between cardiovascular diseases and periodontal diseases was made in 1970 (Brasher & Rees 1970). To date, more than 5000 publications in the English language have reported evidence on the association between oral and systemic health.

While most of the early work was focused on the impact of diet on periodontal health, histological data from animal studies suggested that the link between oral and systemic disease processes was highly complex (Shklar 1974). More than 50 systemic diseases and conditions have been associated with various forms of periodontal diseases either through shared pathways of inflammation, microbial involvement, or a combination of infecto-inflammatory mechanisms. The appreciation of the complexity of periodontal disease pathogenesis as a result of oral immunology, a new scientific field, and recognition of inflammatory pathways of disease in the 1980s paved the way for the understanding of the periodontal–systemic disease link. In this complicated relationship, systemic conditions increase the risk of incidence, severity, and progression of periodontal diseases. In turn, periodontal diseases may negatively impact systemic health. Thus, there exists a bi-directional link between systemic and periodontal diseases. This observation was first coined for the diabetes–periodontal disease link (Taylor 2001) and is now increasingly applied to other systemic diseases.

We will focus on two systemic diseases and present the biological plausibility of their connection to periodontal diseases: diabetes and cardiovascular diseases. In addition to affecting human populations globally, diabetes and cardiovascular diseases have well-established associations with disruptions in periodontal health. Thus, the knowledge gained applies to the understanding of a generalizable link between periodontal diseases and systemic pathologies. We will refer to the atherosclerotic forms of coronary heart disease (angina pectoris, myocardial infarction), ischemic stroke, and peripheral arterial diseases, which all present with inflammatory pathogenesis.

Plausibility of periodontal disease as a risk factor for diseases at distant tissues

The original hypothesis of how periodontal diseases and systemic diseases could be connected proposed three mechanisms: metastatic infections, dissemination of bacterial toxins, and immunological injury (Thoden van Velzen *et al*. 1984). A metastatic spread of microbes (and their products) or inflammatory mediators or both with an unclear immunological injury were suggested to mediate the local tissue disturbances in the periodontium to the distant organs. This approach presenting a linear plausibility, is overly simplistic. Complex diseases that involve both the infection and inflammation consist of a series of highly complex microbiological and immune mechanisms. Whereas circulation can transport the microbes between organs, colonization and pathological consequences of microbial infections at "non-origin sites" are much more complicated processes. Indeed, systemic bacteremia as a result of periodontal infection is rare. To date, only certain species of periodontal bacteria have been recovered from other organs. The underlying reason for the colonization of certain periodontal bacteria of specific extraoral sites while other species cannot is poorly understood. With the advancement of modern molecular microbiological techniques such as pan-metagenomics, we also recognize the complexity of microbe–microbe interactions and appreciate the highly sophisticated spatial organization and site-specificity of microbial communities. Thus, free and random migration of one species from one body site to another is possible but does not necessarily explain the colonization and habitat-building of oral bacteria in non-oral sites.

The concept of inflammatory metastasis is even more complicated. In theory, the inflammatory mediators originated from periodontal inflammation in local tissues can get into the systemic circulation and reach other parts of the body. Cellular and molecular mechanisms of disease can be associated with the levels of these mediators. However, this simplistic view dismisses the complexity of tissue architecture and specificity in different organs. Inflammation is an active process that requires receptor–ligand interactions to progress and resolve and, therefore, protect the host from damage. There is a redundancy of cytokines, chemokines, lipid mediators, and other soluble factors produced from multiple sources and several cell types. Increasing evidence suggests that many cell types, including those that are not immune system cells, are capable of producing the inflammatory mediators, which complicates the linearity of the inflammatory spread paradigm. The inflammatory process is not linear or sporadic; it is continuous and involves multiple overlapping processes and phases with the goal of survival of the organism. Therefore, immunologic dissemination of cellular or soluble structures spreading the inflammation requires a complex mechanism to be associated with the disease process elsewhere in the body.

In the light of technological advances of the last decade and with the help of -omics, the modern view of periodontal disease pathogenesis and its connection to systemic diseases requires a holistic approach. We now recognize the importance of a commonality of similar pathways of diseases that are now

called comorbidities. All clinical forms of periodontal diseases involve an intimate interaction between the specialized microbiome communities and host responses to these communities. Understanding the role of infecto-inflammatory stimulation of the immune cells and non-immune cells of the periodontium in the oral–systemic link, therefore, has led to a paradigm shift (Hasturk & Kantarci 2015).

If one sees the human body as a single entity, a local disruption of the homeostatic balance cannot be merely observed as an isolated phenomenon. The cells and mediators of the inflammatory response are unlikely to remain confined to the organ system in question. Oral tissues, being a niche for one of the most diverse human microbiomes, are never sterile. Commensal species in oral biofilms always have the potential of becoming pathogenic. The evolutionary interaction between the host and the microbiota has led to the development of a highly specialized host response in periodontal tissues where the epithelia and vasculature demonstrate considerable anatomical differences compared with the rest of the body. As a function of this complex interaction, the immune cells travel to distant organs through the systemic circulation. The immune system cells can be challenged by periodontal bacteria and transmit the inflammatory response to other organs (Hayashi *et al*. 2010). Dendritic cells, which are traditionally seen as the "presenters" of antigens, can also serve as "transporters" of bacteria and their virulence factors (Miles *et al*. 2014). The concept of a "mobile oral microbiome" may involve the host's immune system for migration and colonization of the oral resident microbial species to distant organs (Han & Wang 2013).

Plausibility of systemic dissemination of oral bacteria

Periodontal diseases are associated with complex microbiomes. Each microbiome in the oral cavity is distinct. Supra- and subgingival microbiomes are directly associated with periodontal diseases. The other mucosal surfaces (e.g. tongue dorsum) may serve as niches for microbial communities that can spread between different ecological habitats of the oral cavity. Oral bacterial species can enter the circulation following brushing and flossing or professional interventions such as scaling, tooth extraction, and periodontal probing. Although rare, a higher risk of bacteremia may be associated with gingival inflammation and periodontal diseases (Tomas *et al*. 2012; Balejo *et al.*, 2017). Thus, systemic dissemination of microbial species is plausible, supporting the theory that periodontal disease-associated microbes can metastatically cause systemic pathologies in distant organs.

In principle, all microbial organisms and their products can travel throughout the body via the circulation. Bacteremia, which involves the presence of bacteria in the blood and its compartments, results in sepsis. Since bleeding is a common sign and symptom of periodontal inflammation, every time the periodontal pocket bleeds, microbial communities or single species can potentially enter the blood circulation. Circulating microorganisms and their products can be the result of disease activity or due to a mechanical injury by periodontal procedures such as probing or scaling. There is conflicting data on how many bacteria can be found in the systemic circulation following an active burst of periodontal disease, after bleeding on probing, or due to mechanical instrumentation (Lockhart *et al*. 2004; Lockhart *et al*. 2008; Hirschfeld & Kawai 2015). The lack of consensus to this end may be the result of differing sensitivities of detection methods for bacteria and the timing of the bacteremia (Bahrani-Mougeot *et al*. 2008). While bacteremia is an accepted phenomenon (Kinane *et al*. 2005; Crasta *et al*. 2009), it, therefore, remains unclear whether sepsis/septicemia could be the result of periodontal infection or instrumentation.

Nevertheless, periodontal bacteria have been recovered from distant organs and were associated with pathological processes. For example, *Fusobacterium nucleatum* is commonly linked to various forms of cancer (e.g. pancreatic or colon carcinoma) and found in the amnion and placenta associated with adverse pregnancy outcomes. Other periodontal pathogens and their virulence factors (e.g. proteases) were also isolated from distant organs such as the aorta (Deshpande *et al*. 1998; Yumoto *et al*. 2005; Takahashi *et al*. 2006) and brain (Miklossy 2011; Poole *et al*. 2015; Laugisch *et al*. 2018). Cardiovascular lesions have been shown to harbor *Porphyromonas gingivalis* and its virulence factors (Cairo *et al*. 2004; Marcelino *et al*. 2010; Nichols *et al*. 2011; Figuero *et al*. 2014; Range *et al*. 2014; Velsko *et al*. 2014; Ziver *et al*. 2014; Szulc *et al*. 2015; Velsko *et al*. 2015; Kannosh *et al*. 2018; Joshi *et al*. 2019). Recently, gingipains from *P. gingivalis* were detected in the brains of patients with Alzheimer's disease (Dominy *et al*. 2019). The list of periodontal bacteria that can colonize non-oral and distant sites of the body is increasing parallel to the advancement of microbiological detection techniques. The animal models support these human clinical observations. In addition to the bacteria, their products, such as lipopolysaccharides, may be derived from the periodontal microbiota and enter the circulation, presenting a potentially plausible mechanism through which periodontal bacteria can be associated with systemic diseases. How this dissemination takes place and whether the severity of periodontal diseases is associated with the spread of the bacteria is, however, not straightforward. It is also unclear how the periodontal bacteria colonize specific distant organs. An important question is the number of bacteria entering local circulatory routes in local tissues and traveling through the systemic circulation. How many bacteria enter the circulation, and how many are required to cause disease elsewhere in the body? Which organs are more susceptible to

oral bacteria, and why? Regardless of the number of bacteria, a healthy immune system can eliminate and eradicate the invaders quite efficiently. However, is a dysfunctional immune response a prerequisite for the initiation and progression of inflammatory diseases due to migrating bacteria? Is the detection of oral/periodontal bacteria in a distant organ associated with a non-septic transmission of microbial species that are linked to a failed immunologic clearance? These questions need to be addressed.

The duration of bacteremia until the clearance is also critical. Infectious diseases such as tuberculosis and viral infections (e.g. HIV) can lead to a latency of infection, which is essential for the disease outcome. Days to weeks may be required before a full-blown infection and mounting the consequent host response. For oral bacteria disseminating to other parts of the body, this knowledge is limited. According to Koch's postulates, a single species can cause a systemic disease if enough time lapses between the inoculation and infection. This concept has been illustrated in animal models when species animals were inoculated with periodontal bacteria (Gradmann 2014; Kantarci *et al*. 2015). In humans, however, ethical concerns prevent direct inoculation and experimental transfer of periodontal pathogens. Even when interindividual transfer is possible between spouses (Dowsett *et al*. 2002; Van Winkelhoff & Boutaga 2005), there is no clear evidence that either periodontal infections or systemic infections can be attributed to the periodontal microbiota that is introduced. A modification of Koch's postulates was presented by Socransky and Haffajee (1992) to address these limitations.

Another critical factor is the colonization capacity of oral species on non-dental and non-oral surfaces. *in vitro;* models demonstrated that all cell types and structures of the human body could present favorable environments for colonization of individual or multiple oral species under controlled environmental conditions in the laboratory. However, *in vivo;* studies in humans and animals suggest a site-specificity. Periodontal species or their genetic material were found in cardiovascular tissues (Deshpande *et al*. 1998), suggesting that vessel walls can be potential growth sites for pathogenic periodontal microbes such as *Porphyromonas gingivalis*. Likewise, bridging species such as *Fusobacterium nucleatum* have been found in amniotic fluid (Han *et al*. 2004). This area of research needs further exploration, especially in the context of artificial surfaces generated for the repair of different organs and how periodontal species can colonize these.

Inflammatory processes as a link between periodontal and systemic diseases

Clinical and progressive causality between inflammatory diseases cannot be tested in humans; thus, preclinical *in vivo;* systems, *in vitro;* models, and therapy studies are needed. Based on well-designed epidemiological studies, people with periodontal diseases present a higher risk for systemic inflammation, possibly due to an inflammatory predisposition (Holtfreter *et al*. 2013; Boylan *et al*. 2014). Periodontal disease is a chronic inflammation and shares common mechanistic pathways with other systemic inflammatory diseases. There are co-morbid associations between periodontitis, diabetes, and cardiovascular diseases (Sanz *et al*. 2013; Tonetti *et al*. 2013; Chapple & Wilson, 2014; Payne *et al*. 2015).

Periodontal inflammation presents highly intertwined molecular pathways of cellular and non-cellular components and immune and non-immune processes that maintain periodontal health. A healthy periodontium is resistant to microbial intrusion. The epithelial lining of the sulcus wall presents a multilayer barrier to commensal microbes residing in periodontal space. Even in the absence of disease, there is an inflammatory response against microorganisms. At this stage of the homeostatic inflammatory process, the key players are epithelial cells, endothelial cells, complement proteins, neutrophilic granulocytes, and tissue-resident macrophages. Under these "healthy" conditions, the epithelial lining of the sulcus prevents or minimizes bacterial infiltration; vasculature allows balanced extravasation of neutrophils, which will eliminate the microbial organisms and their products through a precise phagocytic and killing mechanism. Neutrophils are short-lived; they are cleared by apoptosis by the other neutrophils and tissue-resident macrophages through a process that ensures the balance of the inflammatory response regulated by cytokines and lipid mediators or inflammatory activation and resolution to prevent tissue damage. Under normal conditions, the resolution of inflammation is an active process and requires a well-orchestrated immune response (Kantarci *et al*. 2006; Hasturk 2012b).

Progression of health to disease in periodontal tissues is a result of unresolved inflammation that becomes chronic. Antigen-presenting cells and lymphocytes join phagocytes, endothelial cells, and fibroblasts gain proinflammatory characteristics, and there is a continuous propagation of neutrophilic and monocytic infiltration to the periodontal tissues. The epithelial lining of the periodontal pocket serves as a gateway for microorganisms leaving the periodontal space and entering the body. Epithelial cells stimulated by the periodontal bacteria recruit an increasingly higher number of neutrophils, a process regulated by chemokines such as interleukin-8 (IL-8). Neutrophil priming results in preactivation of these non-specific immune cells; upon an additional stimulus (e.g. lipopolysaccharides and various microbial factors), primed neutrophils respond with an increased function. Neutrophils have been demonstrated to be primed in various forms of periodontal diseases (Fredriksson *et al*. 2003; Kantarci *et al*. 2003; Matthews *et al*. 2007; Wright *et al*. 2008). The priming of neutrophilic granulocytes can be due to genetics, microbial stimuli, hyperglycemia, smoking, and various other

factors. Primed neutrophils, in turn, will respond to secondary stimuli producing increased levels of reactive oxygen radicals and enzymes. These substances are typically produced to eliminate the bacteria, viruses, and apoptotic cells and return to baseline levels when inflammation resolves. Excessive neutrophil function results in neutrophil-mediated tissue injury of the host. One of the fundamental mechanisms through which neutrophils can link inflammatory processes of distant organs is the transmission of the uncleared bacteria and their products to escape the immune surveillance of the host. This mechanism is referred to as the "Trojan horse" effect (Laskay *et al*. 2003; Eruslanov *et al*. 2005; Fexby *et al*. 2007; Thwaites & Gant 2011; Gutierrez-Jimenez *et al*. 2019; McDonald *et al*. 2020) and would explain how the oral bacteria can be recovered from other sites of the human body.

Chronic and unresolved inflammation also leads to a "leaky" epithelium. A pathological transformation of the epithelial barrier is a critical component of allowing the gut microbiome to disseminate to the other parts of the body, including the brain. It is not entirely clear whether the same modification of the periodontal pocket epithelium takes place and if there are any specific changes inherent to the periodontium; however, this mechanism presents a plausible link between local and systemic diseases through an infecto-inflammatory pathway.

Monocyte infiltration to the diseased periodontal tissues has profound repercussions. Similar to the neutrophils, a preactivation/priming can be seen in monocytic cells. Monocytes differentiate into tissue-resident macrophages with a wide array of functions and a longer life. Macrophage-mediated tissue damage is a critical component of the periodontal pathology. M1-type macrophages, which are involved in the activation of tissue inflammation, are increased, secrete cytokines, tissue-degrading enzymes, and lead to increased activation of the lymphocytic infiltration. M1-macrophages lead to tissue damage through the activation of osteoclastic bone loss, fibroblastic matrix metalloproteinase production, and the endothelial cell activation–pathological process that creates a favorable environment for bacterial invasion. Monocyte-mediated tissue inflammation as a hallmark of hyperglycemia in diabetes and atherosclerosis in cardiovascular diseases is a highly plausible link between periodontal disease and systemic diseases.

A net outcome of increased phagocyte activation is the expansion of immune response to T-cell mediated tissue damage. T-helper 17 (Th17) cells are critical for immunity-driven tissue destruction. This process is referred to as osteoimmunology and includes bone loss as a result of the immune response (Alvarez *et al*. 2019). In addition to the T cells, B-cells were demonstrated to play an active role in the inflammation where the periodontal disease may exacerbate the systemic impact on distant organs (Shin *et al*. 2009; Jagannathan *et al*. 2010).

Biological plausibility of a link between periodontal diseases and cardiovascular diseases

Vascular diseases and their ischemic complications such as myocardial infarction, peripheral vascular diseases, and stroke, lead to morbidity and mortality in cardiovascular tissues. Atherosclerosis is characterized by vascular inflammation and subintimal lipid accumulation. Atherosclerotic plaques may appear early in life and advance to severe, symptomatic "vulnerable" plaques. Rupture of lipid-rich and inflamed coronary plaques triggers thrombosis as in an atherothrombotic event, which can lead to the acute coronary syndrome and sudden ischemic death. Infections and other inflammatory diseases, including HIV and type 2 diabetes, increase the risk for atherosclerotic changes and rupture. As a noncommunicable disease, periodontitis has been shown to impart excess risk for atherosclerosis. The link between periodontal and cardiovascular diseases may involve the metastatic microbial dissemination, inflammatory mediators, and their combination through a dysfunctional endothelium (Tonetti *et al*. 2013; Sanz *et al*. 2019). Low-grade and chronic systemic inflammation is a plausible mechanism through which cardiovascular diseases and periodontal diseases are linked (Carrizales-Sepulveda 2018). This association is bi-directional, where factors involved in the development of cardiovascular diseases also underlie periodontal inflammatory changes. In turn, periodontitis, both as infection and a profound source of inflammatory mediators, leads to the exacerbation of cardiovascular complications. There is a clear epidemiological association between periodontal and atherosclerotic cardiovascular diseases (Dietrich *et al*. 2013). An increased risk of atherosclerotic vascular disease amongst individuals with chronic periodontitis is independent of other established cardiovascular risk factors. In a population-based study from Korea that longitudinally evaluated the risk exposure from untreated oral conditions including periodontal disease and caries, the risk of cardiovascular events, cardiac death, myocardial infarction, stroke, and cardiac failure, was significantly higher, supporting the critical role of periodontal health in patients with cardiovascular risk (Park *et al*. 2019). Figure 18-1 shows the biological plausibility of the link between periodontal and cardiovascular diseases.

Microbial factors

Endothelial cells and their functional roles in vascular integrity are critical for cardiovascular health. Disruption of endothelial function is an early indicator of cardiovascular disease (Vita & Loscalzo 2002; Pober *et al*. 2009; Kolattukudy & Niu 2012). While uncontrolled inflammation is detrimental to endothelial function, the infection can also cause endothelial dysfunction (Vita & Loscalzo 2002; Vaudo *et al*. 2008).

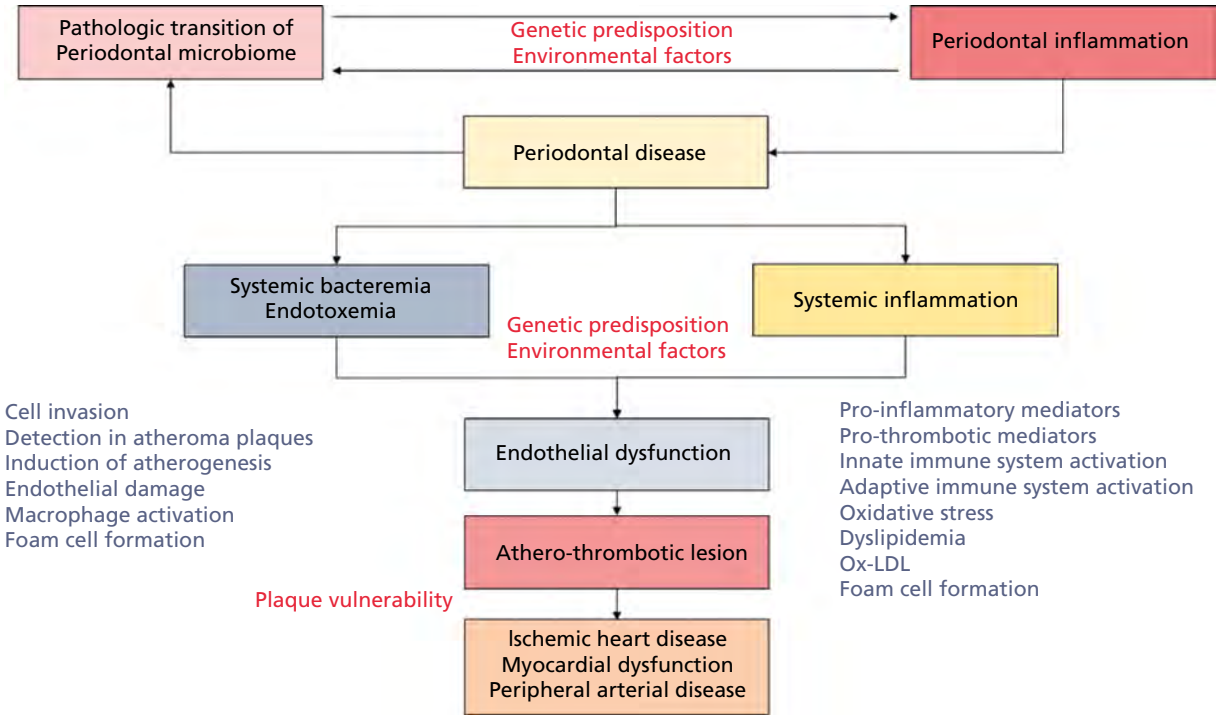

Fig. 18-1 Plausibility of the biological link between periodontal diseases and cardiovascular diseases. Ox-LDL, oxidized low-density lipoprotein.

Fusobacterium nucleatum activates the endothelial cells and promotes an inflammatory phenotype disrupting the vessel-formation capacity of these cells through a hypoxia-mediated mechanism (Mendes *et al*. 2016; Mendes *et al*. 2018). Therefore, an infectious etiology is a potential co-factor for the development of cardiovascular diseases, based on the discovery of co-localization of bacteria in atheromas. An infectious agent can also cause activation of the innate immune system and accelerate atherosclerosis (Richardson *et al*. 1997a, b). Hence, infectious agents (e.g. *Chlamydia pneumonia*) might be an indirect etiological factor for cardiovascular disease providing the necessary inflammatory stimulus (Kuo *et al*. 1993).

Following reports of *Chlamydia* infections to be a risk factor for coronary artery disease in a cardiovascular disease cohort, periodontal infections were strongly associated with the development of atherosclerosis (Mattila 1993). Pathogens from the oral cavity can invade the gingival epithelium and the vascular endothelium and enter atherosclerotic plaque via the bloodstream, which could promote an inflammatory response within the vessel wall or some oral pathogens that produce toxins with proatherogenic action or autoimmune reaction.

Periodontal bacteria are present and cultivable from atheromas (Kozarov *et al*. 2005; Dolgilevich *et al*. 2011). In addition to the periopathogenic species of bacteria, their virulence factors and nucleic acids were isolated from atheroma lesions. There is also a higher association of periodontal microbial invasion of the vascular lesions in patients with periodontitis (Armingohar *et al*. 2014; Mahendra *et al*. 2013). Not only the migration but also the colonization of periodontal species such as *P. gingivalis* and *A. actinomycetemcomitans* in atherothrombotic lesions is plausible. Using 454 pyrosequencing of 16S rRNA, bacteria from the oral cavity and gut were shown to correlate with disease markers of atherosclerosis, specifically atherosclerotic plaque and plasma cholesterol (Koren *et al*. 2011). *Streptococcus* was strongly positively correlated with high-density lipoprotein (HDL) cholesterol and ApoAI (a significant component of HDL), whereas *Neisseria* was strongly negatively correlated with these markers. *Fusobacterium* abundance was positively correlated with low-density lipoprotein (LDL) cholesterol and total cholesterol. Similarly, members of the *Erysipelotrichaceae* and *Lachnospiraceae* families in the gut also positively correlated with LDL cholesterol and total cholesterol.

Analysis of thrombi collected by aspiration during interventions on the coronary arteries of patients who had a myocardial infarction showed 19.7% *A. actinomycetemcomitans*, 3.4% *P. gingivalis*, and 2.3% *T. denticola*. Antibody levels against four major periodontal pathogens, *P. gingivalis, A. actinomycetemcomitans, T. forsythia,* and *T. denticola*, are related to an increased relative risk of myocardial infarction. Clinical studies particularly suggested a direct relationship between the severity of periodontal conditions and left ventricular hypertrophy. *A. actinomycetemcomitans* and *Aggregatibacter aphrophilus* are implicated in 1–3% of all infective endocarditis. Other studies highlighted the critical role of oral *Streptococci* in the development of myocardial infarction. *Streptococcus sanguinis (S. sanguinis)*, a commensal bacterium, profuse in periodontitis, is recognized as an origin of infective endocarditis. Its fimbriae and adhesin facilitate its initial

attachment on the tooth. Then, the production of glucans and eDNA promotes the maturation of *S. sanguinis* biofilm. After accessing the heart, *S. sanguinis* must then adhere to the endocardium. Considering the impact of biofilm formation on adhesion in the oral cavity, it would be conceivable that biofilm formation might be significant for adhesion to endocardial surfaces as well. Indeed, endocarditis is frequently regarded as a model of a biofilm-mediated disease. However, studies have demonstrated that *S. sanguinis* endocarditis causation is not dependent upon biofilm formation. Therefore, in contrast to this situation in the oral cavity, there is no evidence that biofilm formation is important for *S. sanguinis* in the cardiac environment to infective endocarditis (Hashizume-Takizawa *et al*. 2019).

Control of chronic inflammation caused by periodontitis may positively impact the treatment of myocardial hypertrophy, decreasing the risk of acute myocardial infarction. The risk of stroke, described by a meta-analysis of cohort studies, was significantly increased by the presence of periodontitis. Periodontal diseases were significantly correlated with cardioembolic and thrombotic stroke subtypes. Regular dental care utilization was associated with a lower adjusted stroke risk. Pussinen and colleagues have established that *P. gingivalis* may especially be correlated with stroke (Pussinen *et al*. 2007).

Preclinical animal models support human clinical observations. For example, experimental periodontitis induced by a human pathogen (*P. gingivalis*) in mice, rabbits, and pigs led to atheroma formation (Schenkein & Loos 2013; Hasturk *et al*. 2015). *P. gingivalis* can intensify atherosclerosis through the activation of endothelial cells producing specific adhesion molecules that allow macrophage diapedesis and subsequent conversion to foam cells and further atheroma progression. *P. gingivalis* increases the progression of inflammatory plaque accumulation in the arteries with the accumulation of inflammatory mediators and cholesterol esters. Infection with *P. gingivalis* after myocardial infarction in mice enhanced myocardial high mobility group box 1 (HMGB1) expression. HMGB1 is a nuclear protein released from necrotic cells and capable of inducing the inflammatory response. There is a possible relationship between periodontal diseases and postinfarction myocardial inflammation through HMGB-1. Infection with *P. gingivalis* during myocardial infarction generates a prejudicial part in the recuperation procedure of the infarcted myocardium by penetration and invasion of *P. gingivalis* into the myocardium, thus favoring programmed cell death and the MMP-9 action of the myocardium, which successively produces cardiac rupture. Experimental periodontitis in rats was associated with impaired endothelial function in gingival tissues showing that periodontal diseases may generate the disruption of vascular function in oral microcirculation. Other periodontal bacteria species (*Treponema denticola*, *Tannerella forsythia*, and *Fusobacterium nucleatum)* can also cause atheromatous changes (Velsko *et al*. 2014, 2015). Although these studies do not necessarily support that the bacteria directly leads to atheroma formation, they suggest a critical role for human periodontal pathogens in cardiovascular disease pathology.

Other information gained from animal studies is the genetic susceptibility of the individual. Human pathogen-induced periodontal disease requires apolipoprotein E (ApoE) and toll-like receptor (TLR) signaling for atheromatous consequences. Activation of these pathways by the periodontal bacteria and their various components that mediate virulence results in atherothrombotic progression, adhesion, and oxidative stress production by the aortic endothelial cells.

Strain differences within a species may also influence the virulence and their atherogenic capacity (Progulske-Fox *et al*. 1999). *in vitro;* studies demonstrated that the *P. gingivalis* 381-induced gene expression in human coronary artery endothelial cells was fimbriae-dependent and mediated through TLRs (Chou *et al*. 2005; Yumoto *et al*. 2005). *P. gingivalis* W83, which does not express fimbriae, but expresses capsule, induced a substantially lower inflammatory cell response in human coronary artery endothelial cells (Rodrigues *et al*. 2012). On the other hand, another capsule-positive strain, *P. gingivalis* A7436, which also expressed type IV fimbriae, induced a moderate inflammatory response in human coronary artery endothelial cells. *in vivo;* work showed that both W83 and A7436 accelerated atherosclerosis in ApoE-null mice (Li *et al*. 2002; Maekawa *et al*. 2011). The induction of periodontal disease by *P. gingivalis* A7436 strain in an accelerated atherosclerosis model in rabbits has been shown to provoke the atherosclerotic changes and result in a more severe form of the atherosclerotic lesion (Hasturk *et al*. 2015). Collectively, these studies showed that while endothelial dysfunction was critical, additional atherosclerotic properties can be attributed to human oral bacteria independent of their surface characteristics and virulence.

The periodontal bacteria can lead to C-reactive protein (CRP) generation by local vessels in the inflamed periodontium that can cause systemic dissemination of the bacteria by the macrophages, which eventually may become foam cells and involved in atheroma formation. Periodontal bacteria may then be detected in atheroma plaques. TLRs (particularly TLR-2, TLR-4, and TLR-9) are involved in this pattern recognition of periodontal bacteria and their products (e.g. lipopolysaccharide, lipoteichoic acid) and the activation of endothelial cells and macrophages. This theory also supports the lack of finding that periodontal diseases, even at their most severe levels of bacterial burden, do not lead to sustained bacteremia or sepsis. However, periodontal bacteria were detected in atheroma plaques in parallel with the antibody levels against periodontal bacteria in the systemic circulation. IgG levels against *P. gingivalis* had been shown to have a strong association with carotid intima/media

thickening (Beck *et al*. 2005; Champagne *et al*. 2009). A similar response was seen in a study that was done in Finland for *A. actinomycetemcomitans* (Pussinen *et al*. 2005). A meta-analysis of data demonstrated the impact of this link (Mustapha *et al*. 2007). A model for the microbial etiology of atheromatous plaque formation was presented (Kebschull *et al*. 2010; Pollreisz *et al*. 2010). Accordingly, vascular endothelial cells can be invaded by fimbriated pathogens such as *P. gingivalis* (Khlgatian *et al*. 2002; Chou *et al*. 2005; Takahashi *et al*. 2006). Meanwhile, *P. gingivalis* and other periodontal pathogens can induce apoptosis of endothelial cells and smooth muscle cell proliferation in the intima and neointima formation. Plaque rupture can therefore be induced by pathogen-mediated extracellular matrix degradation by endothelial cells, macrophages, T cells, and plasma cells, leading to exposure of prothrombotic plaque components and subsequent vessel occlusion.

Host factors

Local inflammation can lead to systemic and vascular inflammation (Libby & Hansson 2015), possibly through a process that involves an elevated host response, both affecting the innate and acquired arms of the immunity. Periodontitis presents a risk factor for cardiovascular disease as a common determinant of susceptibility. While *P. gingivalis* can induce periodontal inflammation and can increase co-existent atherosclerosis in cholesterol-fed rabbits, *P. gingivalis* was not detectable in the atheroma tissues (Jain *et al*. 2003). Periodontal disease accelerated atherogenesis, changes in the arterial layers, intima, and media, causing smooth muscle cell proliferation leading to medial fibrosis, macrophage infiltration, and necrotic core formation with increased intimal thickness and fibrous cap formation (Hasturk *et al*. 2015). These observations indicate that local inflammatory diseases, in this case, periodontal disease, can accelerate the initiation and progression of another disease in a distant organ.

Several molecules associated with inflammation and host response to microbial challenge have been suggested to play a role in the link between periodontal diseases and cardiovascular diseases (Van Dyke & van Winkelhoff 2013). The most studied molecules are cell- and cytokine-mediated markers of inflammation such as CRP, fibrinogen, inflammatory cytokines, and lipid mediators. These molecules are both involved in the pathogenesis of periodontal diseases and atherothrombogenesis at a "low-level inflammation" (Danesh *et al*. 2000a, b; Danesh & Pepys 2000). Animal studies provide mechanistic insight to this link where experimental periodontitis has been demonstrated as a contributing factor to the incidence and progression of atherosclerotic plaque development (Jain *et al*. 2003; Gibson *et al*. 2004; Hasturk *et al*. 2015). The atheroma plaque also becomes an active source of inflammatory progression with activated immune cells and their production of inflammatory cytokines (interferon, interleukin-1, interleukin-6, and TNF-α). The same cytokines are produced by the adipose tissue, which further contributes to atherogenesis and metabolic syndrome (Hansson 2005). Proinflammatory cytokines produced by the atheroma plaques increase CRP, serum amyloid A, and fibrinogen, exacerbating systemic inflammation. The circulating levels of CRP were significantly elevated by the presence of periodontitis (Hasturk *et al*. 2015). Figure 18-2 shows the impact of experimental periodontitis in a rabbit model and how it can lead to the initiation and progression of atheroma formation. Notably, the resolution of the inflammation prevents periodontal disease and atheromatous plaque disruption, further emphasizing the role of inflammation in the periodontal–cardiovascular disease link.

CRP is an inflammatory mediator produced by the liver. Cytokines such as IL-6 stimulate CRP production. CRP, in turn, opsonizes the bacteria to be presented and eliminated by the cells, which express the receptors for CRP. Neutrophils and macrophages respond to CRP through a ligand-receptor activation. During this process, the complement cascade is involved in phagocyte-mediated and CRP-induced bacterial killing. Atheroma formation has been closely linked to elevated CRP levels, foam cell formation, macrophage activation, and an inflammatory process on the vessel walls impacting the endothelia. As noted, endothelial cells are critical for the periodontal–cardiovascular disease link. Local production of CRP by endothelial cells contributes to local inflammation and increases hepatic CRP production. This observation is also important to demonstrate that any local inflammatory process can lead to CRP production, making it plausible that periodontal diseases can contribute to systemic circulatory CRP levels.

CRP is involved in the elimination of oxidized or enzymatically modified LDL (ox-LDL) cholesterol through opsonization. This process is critical for controlling the levels of ox-LDL and prevents the impact of high-fat intake and obesity. CRP-mediated oxo-LDL elimination involves macrophage phagocytosis and complement activation. In chronic inflammation where CRP is produced in high levels and with the abundance of ox-LDL, this protective process results in foam cell formation and atheromatous changes on the vessel walls.

Periodontal treatment reduces the markers of inflammation and restores endothelial dysfunction in patients with cardiovascular diseases (D'Aiuto *et al*. 2007; Tonetti *et al*. 2007; Teeuw *et al*. 2014), further suggesting a profound role for the systemic inflammation as a plausible mechanism through which periodontal diseases can modulate the cardiovascular diseases. One interesting observation from these studies was the role of not only the macrophages but also neutrophils, potentially both types of phagocytes regulating the endothelial cell function. It is also plausible that the primed/preactivated neutrophils may play a

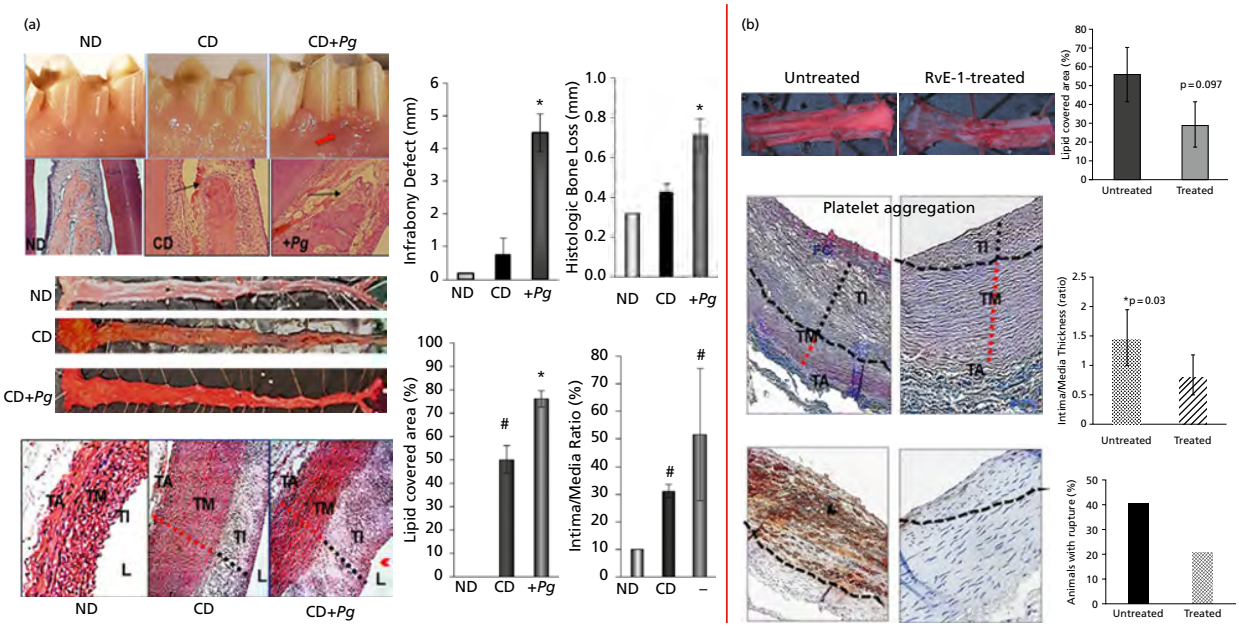

Fig. 18-2 The impact of experimental periodontitis in a rabbit model and how it can lead to the initiation and progression of atheroma formation (Panel A). The resolution of the inflammation prevents periodontal disease and atheromatous plaque disruption (Panel B). (Hasturk *et al*. 2015). critical role in the link between periodontal and cardiovascular diseases. While this issue has been well characterized for aggressive and chronic forms of periodontitis, there are no currently available studies demonstrating the impact of this hyperactivation has any mechanistic impact. This mechanism highlights the role of phagocyte activation in disrupting the endothelial cell function and possibly the integrity of endothelium similar to the periodontal pocket epithelium and leading to a "leaky" lining of the vessel walls. Another interesting observation was that the comorbidities in patients with cardiovascular diseases such as diabetes were also positively impacted by periodontal treatment, further emphasizing the inflammatory resolution of the periodontal lesion and its systemic impact.

Another plausible and emerging mechanism is the activation and aggregation of the platelets (Laky *et al.* 2018). Platelets play a significant immunomodulatory role. They are directly involved in the activation of inflammation and its resolution through cell-cell interactions with leukocytes, particularly with neutrophils. Specific integrins regulate platelet-leukocyte cross-talk. For example, CD62L (P-selectin) on platelets and its ligand (glycoprotein ligand-1; PSGL-1) on leukocytes are critical for platelet function. Likewise, platelet-neutrophil interactions through lipoxygenase cross-talk regulate the resolution of inflammation through the production of lipoxins. Another platelet function during the atherosclerotic process is regulated by GPIIb/IIIa-mediated fibrinogen activation and binding of the platelets to other platelets. CD40L is a modulator of reactive oxygen radical production by the platelets and the atherogenesis. Periodontal treatment restores the platelet function, which furthers emphasizes the impact of periodontal inflammation on the atherogenesis process, vascular function, and systemic inflammation.

Summary

Figure 18-3 summarizes the phases of atherosclerosis, atherothrombosis, and cardiovascular events that the periodontal pathogens and periodontal inflammatory mechanisms can modulate. Inflammation initiates atherosclerosis and destabilizes the atheromatous plaques in the vascular intima leading to plaque rupture. Thrombosis results in infarcts and major cardiovascular events. The vulnerability of atheroma plaques is associated with the inflammatory load. Activation of the inflammatory process around the atheroma plaques results in fibrous cap disruption and plaque rupture. This process, combined with the microbial factors, involves TLR2 activation, the release of pro-inflammatory mediators, and the up-regulation of cell adhesion molecules. A gradient of chemokines recruits monocytes (e.g. monocyte chemoattractant protein 1); monocytes chemotactically migrate into the subendothelial space, transform into macrophages, and subsequently into foam cells

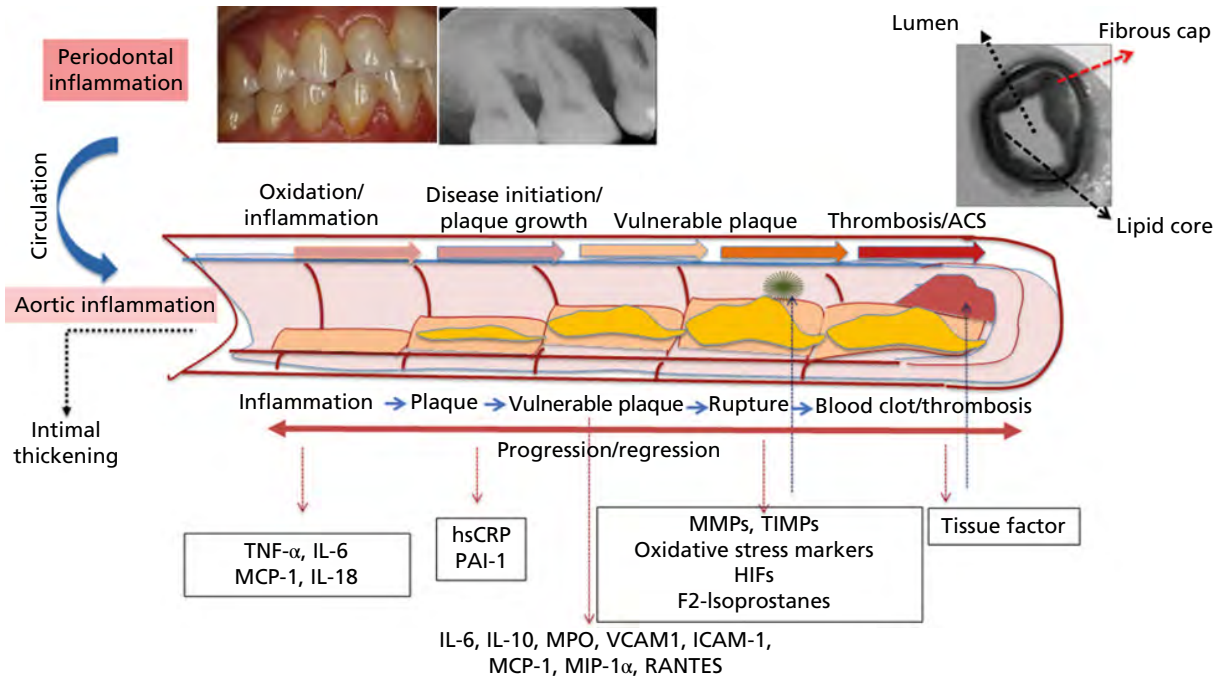

Fig. 18-3 The phases of atherosclerosis, atherothrombosis, and cardiovascular events that the periodontal pathogens and periodontal inflammatory mechanisms can modulate. ACS, acute coronary syndrome; HIFs, hypoxia inducible-factors; hsCRP, high-sensitivity C-reactive protein; ICAM-1, intercellular adhesion protein-1; IL-6, interleukin-6; IL-18, interleukin-18; IL-10, interleukin-10; MCP-1, monocyte chemoattractant protein-1; MIP-1α, macrophage inflammatory protein 1 alpha; MMPs, matrix metalloproteinases; MPO, myeloperoxidase; PAI-1, plasminogen activator inhibitor-1; RANTES, regulated upon activation, normal T Cell expressed and presumably secreted; TIMPs, tissue inhibitor of metalloproteinases; TNF-α, tumor necrosis factor-alpha; VCAM-1, vascular cell adhesion protein-1.

after uptake of oxidized LDL (ox-LDL). Apoptosis of LDL-rich macrophages results in the accumulation of lipids in the subendothelial space. Extracellular matrix build-up leads to the formation of a fibrous cap covering the plaque. Denudation of the fibrous cap and its prothrombotic components occurs after endothelial cell apoptosis.

Biological plausibility of a link between periodontal diseases and diabetes

Diabetes mellitus is a group of metabolic disorders characterized by hyperglycemia occurring over a prolonged period. As a global epidemic, diabetes affects more than 450 million people worldwide. Complications of diabetes significantly affect the quality of life, longevity, and health care costs across both the developed and developing world. Diabetes mellitus, especially if poorly controlled, can increase the risk for periodontal disease and worsen the course of the disease, ultimately resulting in tooth loss. The impact of diabetes on periodontal tissues through hyperglycemia and inflammatory pathways triggering bacteria-induced inflammation are well-described. Periodontal diseases are considered as one of the complications of diabetes (Loe 1993). Although the original observation has been categorically linked to diabetes, it is the uncontrolled glycemia in patients with diabetes that presents with periodontal disease and tissue breakdown. This observation further supports the impact of chronic hyperglycemia on the entire body, including the periodontal tissues. The mechanism that links diabetes and periodontal disease are similar to the other organs, including microangiopathy, altered collagen metabolism, and altered host inflammatory response.

Although periodontal disease and diabetes are distinct diseases affecting different organs with unique etiologies, they share a common mediator of unresolved inflammation. To this end, a chronic and unresolved inflammation presents the strongest plausibility for the detrimental effects of inflammatory events that could also link periodontal disease to diabetes. Consequently, in the case of diabetes–periodontal disease connection, the inflammatory axis is more predominant than the plausibility of a microbial etiology. Periodontal microorganisms have also been associated with increased inflammation, and therefore thought to be a contributory factor in the link to diabetes (Chapple *et al*. 2013). The reciprocal nature of the bidirectional relationship also exists between diabetes and periodontal disease, where in individuals with diabetes, periodontitis can adversely affect glycemic control and increase risk for complications such as cardiovascular disease, retinopathy, and kidney disease. Figure 18-4 summarizes the plausible link between periodontal disease and diabetes and how diabetes can affect periodontal diseases.

Host factors

Hyperglycemia has both acute and chronic effects. Acute-phase proteins and reactive oxygen radicals are responsible for increased systemic inflammation. Chronic hyperglycemia results in metabolic dysregulation and leads to several pathological events such as metabolic syndrome, obesity, and diabetes. The outcomes of chronic hyperglycemia and a dysregulated metabolic control of excessive glucose

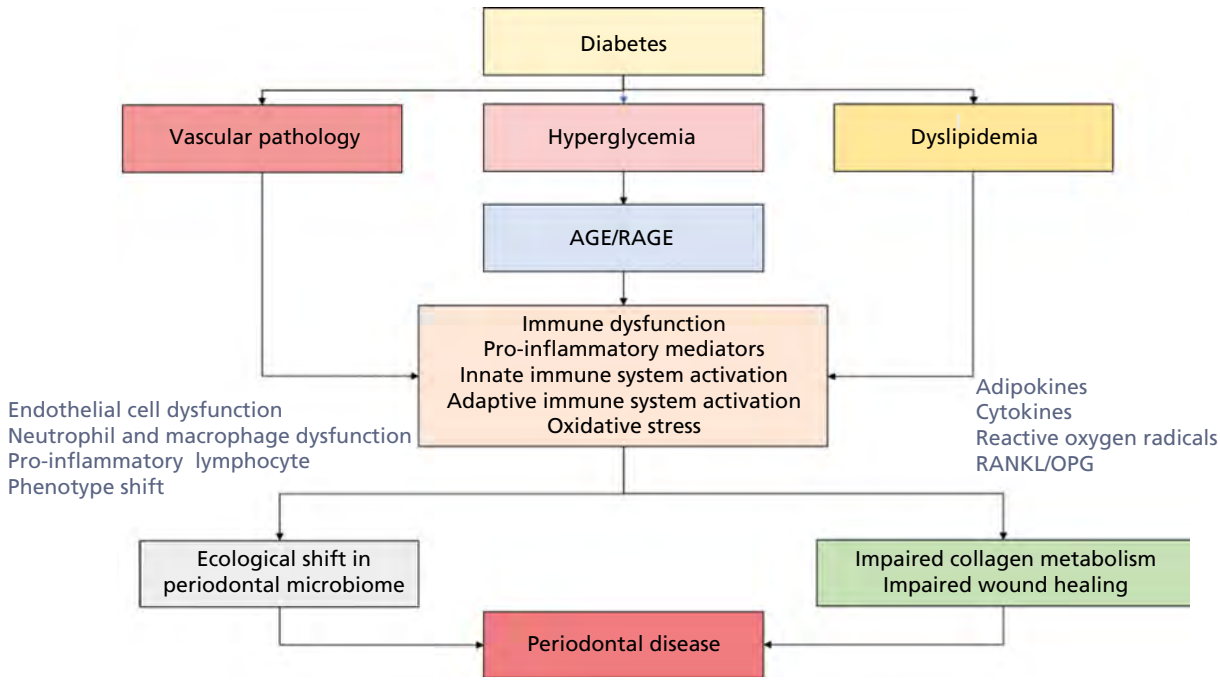

Fig. 18-4 Plausibility of the biological link through which diabetes impacts periodontal health. AGE, advanced glycation end-products; OPG, osteoprotegerin; RAGE, receptor for AGE; RANKL, receptor activator of nuclear factor kappa-B ligand.

are closely related. As one of the ancient diseases of humankind, diabetes mellitus is caused by defective insulin secretion or insufficient insulin production, or both. Unregulated insulin metabolism, in turn, leads to hyperglycemia and dysregulated protein and lipid metabolism. Type 1 diabetes is due to defective insulin production by the pancreatic islet cells and accounts for 5% of patients diagnosed with diabetes. Type 2 diabetes is a chronic disease where insulin production is insufficient to metabolize glucose levels and is closely associated with metabolic syndrome and obesity. Type 2 diabetes accounts for 90–95% of cases of diabetes. Both types 1 and 2 diabetes present with hyperglycemia, poor metabolic control, and macro- and microvascular defects that affect the entire body.

The majority of evidence on how diabetes affects periodontal health comes from patients with type 2 diabetes. Limited but strong data also link type 1 diabetes and periodontal disease. In both forms, chronic and uncontrolled hyperglycemia leads to altered collagen metabolism, vascular response, lipid metabolism, and formation of advanced glycation end products (AGEs). Receptors for AGE (RAGE) are ubiquitous and are expressed in almost all cell types, including the stromal and immune cells. Periodontal diseases can disrupt metabolic health and exacerbate diabetic complications. During this process, periodontal inflammation increases endothelial and immune cell activation. Neutrophils are primed by hyperglycemia and AGEs. A similar process has been shown for macrophages (Yalda *et al*. 1994; Salvi *et al*. 1997a, b). Hyperglycemia caused gingival and periodontal ligament fibroblasts to present with a decreased collagen production and increased collagenolytic activity (Ramamurthy & Golub 1983; Sasaki *et al*. 1992; Yu *et al*. 2012). Similar to neutrophils and macrophages, a hyperinflammatory phenotype of oral epithelial cells has also been associated with diabetes (Amir *et al*. 2011). B cells gain proinflammatory characteristics in patients with diabetes.

Cytokines such as TNF-α are produced at high levels. The disrupted epithelial lining of the periodontal pocket presents a gateway for pathogenic periodontal microbiota, and microbial products further aggravate inflammation. Specifically, TNF-α is linked to defective lipid metabolism, insulin deficiency, and inactivation. Thus, AGEs are critical for the biological plausibility of the link between periodontal diseases and diabetes. AGEs are produced as a result of chronic hyperglycemia and by irreversible non-enzymatic glycation of proteins and lipids. RAGE belongs to the immunoglobulin superfamily and acts as a multiligand signaling receptor (Schmidt *et al*. 1992). Hyperglycemia leads to an increase in RAGE expression, where RAGE mediates the inflammatory complications of diabetes.

In periodontal tissues, RAGE expression has been demonstrated, and its role in alveolar bone loss has been established by treatment with the soluble RAGE competitively binding to RAGE and preventing the effects of AGE (Lalla *et al*. 1998, 2000a,b). AGE proteins were detected in saliva samples from patients with diabetes. Serum AGE levels were associated with the extent of periodontitis in type 2 individuals in parallel with glycated hemoglobin (HbA1c) levels (Karima *et al*. 2005). Further confirmation for the role of RAGE came from studies involving other animal models and human tissues. The receptor-ligand interactions between the RAGE and AGEs result in an unresolved and chronic inflammation, delayed wound healing, impaired bone healing, and destruction of periodontal tissues in diabetes (Santana et al. 2003; Taylor *et al*. 2013). When AGEs bind to RAGE, cellular phenotype and function are critically impacted, and various signaling pathways can be activated. For example, in osteoblasts, the p38-JNK axis is involved, and AGE-RAGE signaling activates caspase three and caspase 8-mediated apoptosis (Alikhani *et al*. 2007). RAGE activation also leads to cross-talk between other receptors that are critically involved in immune cell responses during inflammation. In patients with diabetes, increased expression of TLR2, TLR4, and TLR9 were reported in periodontal tissues. These receptors are critical for the recognition of periodontopathogens and their virulence factors (e.g. LPS). TLR-4 has a significant role in proinflammatory cytokine production by myeloid cells (Bagchi *et al*. 2007). RAGE-TLR cross-talk, mainly TLR-4, can thus stimulate cytokine production (e.g. IL-1b, IL-6, and TNF-α) and augments inflammation through the activation of multiple cell types. As TLRs are also expressed on almost all cell types, RAGE-TLR cross-talk leads non-traditional immune cells to adopt a proinflammatory phenotype in diabetes. For example, circulating TLR-4-positive human B lymphocytes were able to recirculate and promote systemic inflammation in patients with diabetes, presenting a plausible mechanism through which periodontal diseases and antibody responses against periodontopathogens can exacerbate diabetic complications (Wright *et al*. 2008; Shin *et al*. 2009; Jagannathan *et al*. 2010).

AGE-induced oxidative stress is an essential mechanism in the AGE-mediated inflammatory process and tissue damage in the periodontium. Increased inflammation and other pathologic consequences of AGE–RAGE interactions, such as oxidative stress, create a vicious circle for chronic propagation of further AGE formation. Several cell types, including neutrophils and macrophages of the immune system and fibroblasts and endothelial cells of the tissues, contribute to oxidative stress and reactive oxygen radical formation in periodontal tissues during inflammation (Chapple *et al*. 1996; Karima *et al*. 2005; Ding *et al*. 2007; Graves & Kayal 2008; Allen *et al*. 2011). In patients with diabetes, periodontal disease severity is correlated with the neutrophil oxidative burst (Karima *et al*. 2005). Hyperglycemia leads to a hyperactive neutrophil phenotype, which is a primary source of reactive oxygen species. Oxidative

burst and reactive oxygen species lead to the activation of proinflammatory pathways, lipid peroxidation, and insulin resistance in patients with diabetes and periodontal disease (Allen *et al*. 2011; Bastos *et al*. 2012). Hyperglycemia may lead to oxidative stress via several pathways with subsequent effects on inflammatory responses (Graves & Kayal 2008). The mechanism through which proinflammatory cytokine production in response to reactive oxygen species in diabetes involves signaling through MAP kinase, NF-KB, and the NALP3 inflammasome (Graves & Kayal 2008). This mechanism is also critical for understanding alveolar bone loss in patients with diabetes as the Wnt signaling and FoxO transcription factor regulate osteoblast activity. Another net effect of diabetes and hyperglycemia is the increased levels of leptin, which also contributes to oxidative stress.

Levels of CRP, TNF-α, and IL-6 in systemic circulation are elevated in periodontal diseases (Bretz *et al*. 2005; Engebretson *et al*. 2007; Paraskevas *et al*. 2008), posing a plausible link to diabetes. Patients with diabetes and periodontitis exhibit an imbalance in circulating levels of proinflammatory markers (reduced IL-10, IL-4, and adiponectin and increased CRP) (Genco *et al*. 2020). Another level of evidence suggests that there is a correlation between HbA1c and CRP in patients with periodontitis (Demmer *et al*. 2010). Thus, chronic dysregulation and imbalance of peripheral cytokine networks is a central mechanism in the pathogenesis of diabetes and the link with periodontal disease (Kolb & Mandrup-Poulsen 2010), highlighting the importance of the chronicity of inflammation and the risk it poses in susceptible individuals. Periodontal therapy reduces HbA1c, and circulating cytokines (TNF-α) and CRP in people with diabetes (Artese *et al*. 2015; Genco *et al*. 2020).

Human and animal studies have also reported increased levels of IFNγ and macrophage inhibitory proteins (MIP-1, MIP-2), and monocyte chemotactic protein-1 (MCP-1) in people with diabetes and periodontal disease. As diabetes is associated with delayed and impaired wound healing and, therefore, could be linked to the severity of periodontitis, one plausible mechanism may be through an exacerbated and unresolved periodontal inflammation. Indeed, diabetes increases the RANKL-mediated osteoclastic activity, MMP-mediated connective tissue degradation, and reduced levels of collagen and extracellular matrix proteins, all of which will contribute to increased tissue degradation and disrupted wound healing.

Osteoimmunological mechanisms can be activated by diabetes and lead to periodontal destruction (Jiao *et al*. 2015; Graves *et al*. 2020; Huang *et al*. 2020). Osteoclastic bone resorption is regulated by Th17 cells, which also produce RANKL and IL-17. There is also an association between glycemic control and IL-4 and IL-17 levels in gingival crevicular fluid (GCF) samples from patients with diabetes and periodontitis. Patients with poorly controlled diabetes present with elevated Th17 and Treg cells in periodontal tissues, suggesting a mechanism for diabetes-induced periodontal tissue loss. In line with these findings, RANKL levels were shown to be increased in periodontal tissues and GCF samples of patients with diabetes. This mechanism is regulated by the AGE–RAGE axis. A recent study that applied a single cell analysis approach revealed fundamental differences in immune cell function in periodontal tissues of periodontitis patients with type 2 diabetes and periodontal tissues of patients without diabetes, which may account for the increased risk and severity of periodontal disease in subjects with type 2 diabetes (Belkina *et al*. 2020).

Microbial factors

Periodontal diseases as infectious diseases can adversely impact diabetes and its control. This mechanism is summarized in Fig. 18-5. As periodontal diseases lead to the dissemination of oral bacteria into the circulation, there is also a consensus that periodontal microbiota directly impacts the diabetic state or glycemic control. Previous studies investigating the role of oral microbiota demonstrated that the abundance of oral microorganisms increases in diabetes mellitus. There is limited evidence that diabetes has any significant impact on the composition or the amount of oral microbiota, and a diabetic periodontal microbiome is different from other types of periodontitis (Chapple *et al*. 2013; Taylor *et al*. 2013). While hyperglycemia potentially modifies the environment for the periodontal bacterial species and therefore their composition and virulence would change, further studies are needed to identify the impact of diabetes, metabolic syndrome, and mechanistic links on the periodontal microbiome. The impact of periodontal microbiota on diabetes or glycemic control is addressed in a limited number of studies. *P. gingivalis* has been shown to modulate the glycemic control in patients with diabetes (Makiura *et al*. 2008).

Studies based on traditional methods such as checkerboard DNA–DNA hybridization and PCR showed limited detection of a small number of selected species in patients with diabetes compared with patients without diabetes. Table 18-1 summarizes the recent studies reporting the diversity in the periodontal microbiome in the presence of type 2 diabetes. Although few, these studies, utilizing the newer high-throughput and genomic technologies, have revealed new information regarding the complex relationship between diabetes and periodontal disease. 16S rRNA sequencing or 16S rDNA pyrosequencing overall showed a reduced microbial diversity in the subgingival microbiome of subjects with type 2 diabetes compared with those healthy controls or in patients without diabetes with periodontitis. Studies utilizing metagenomic shotgun sequencing revealed functional clues to the microbiome analysis

Table 18-1 Studies reporting reduced diversity in the periodontal microbiome in the presence of type 2 diabetes.

Author	Year	Study title	Study design	Analytical method	Main finding
Casarin *et al.*	2013	Subgingival biodiversity in subjects with uncontrolled type-2 diabetes and chronic periodontitis	12 subjects with uncontrolled (HbA1c >8%) type 2 diabetes and 11 non-diabetic subjects with severe generalized chronic periodontitis	16S rRNA	*Overall: subjects with uncontrolled type 2 diabetes and chronic periodontitis presented significant dissimilarities in subgingival biodiversity compared with subjects without diabetes.* Higher percentages of total clones of TM7, *Aggregatibacter, Neisseria*, *Gemella*, *Eikenella*, *Selenomonas*, *Actinomyces*, *Capnocytophaga*, *Fusobacterium*, *Veillonella*, and *Streptococcus* genera, and lower percentages of *Porphyromonas*, *Filifactor*, *Eubacterium*, *Synergistetes*, *Tannerella*, and *Treponema* genera were found in subjects with diabetes than in subjects without diabetes (P <0.05). *Fusobacterium nucleatum*, *Veillonella parvula*, *V. dispar*, and *Eikenella corrodens* were detected significantly more often in subjects with diabetes than in subjects without diabetes.
Zhou *et al.*	2013	Investigation of the effect of type 2 diabetes mellitus on subgingival plaque microbiota by high-throughput 16S rDNA pyrosequencing	Non-diabetic and type 2 diabetes diabetic subjects with or without periodontitis. Total n = 31	16S rDNA 454 pyrosequencing (V1–V3 region)	*Overall: type 2 diabetes could alter the bacterial composition in the subgingival plaque*. Comparing periodontally healthy samples with periodontitis samples identified 20 health-associated and 15 periodontitis-associated operational taxonomic units (OTUs). In healthy subjects, the abundances of *Prevotella*, *Pseudomonas*, and *Tannerella* genera and nine OTUs were significantly different between subjects with diabetes than in subjects without diabetes. In periodontitis subjects, the abundances of three phyla (Actinobacteria, Proteobacteria, and Bacteriodetes), two genera (*Actinomyces* and *Aggregatibacter*), and six OTUs were also significantly different between patients with diabetes and patients without diabetes. Type 2 diabetes could alter the bacterial composition in the subgingival plaque.
Ganesan *et al.*	2017	A tale of two risks: smoking, diabetes and the subgingival microbiome	Non-smoking normoglycemic and hyperglycemic individuals, and smoking normoglycemic and hyperglycemic individuals with	16S rDNA pyrosequencing (V1–V3 region)	*Overall: smoking and hyperglycemia impact the subgingival microbiome in distinct ways; if these perturbations intersect, their synergistic effect is greater than each effect separately*. Periodontally healthy patients who smoked without diabetes presented similar subgingival microbiome as the subjects without diabetes with periodontitis. Patients with diabetes were dominated by species

Table 18-1 (*Continued*)

Author	Year	Study title	Study design	Analytical method	Main finding
			severe generalized periodontitis (*n* = 25/group) in addition to 75 periodontally healthy subjects		*Fusobacterium*, *Parvimonas*, *Peptostreptococcus*, *Gemella*, *Streptococcus*, *Leptotrichia*, *Filifactor*, *Veillonella*, *TM7* and T*errahemophilus* clustering based on HbA1c levels. Patients who smoked with periodontitis evidenced a robust core microbiome dominated by anaerobes. Patients with diabetes and patients with diabetes who smoked were microbially heterogeneous and enriched for facultative species.
Long *et al*.	2017	Association of oral microbiome with type 2 diabetes risk	98 subjects with incident type 2 diabetes, 99 obese patients without diabetes. and 97 normal weight patients without diabetes	16S rRNA sequencing	*Overall: oral microbiome may play an important role in diabetes etiology*. *Actinobacteria* was significantly less abundant among patients with type 2 diabetes than among the controls. *Actinomyces* and *Atopobium* were associated with 66% and 72% decreased risk of diabetes. *Mobiluncus*, *Corynebacterium* and *Bifidobacterium* were less abundant in patients who were obese without diabetes compared to normal weight individuals without diabetes.
Longo *et al*.	2018	Glycaemic status affects the subgingival microbiome of diabetic patients	21 type 2 diabetes subjects with chronic periodontitis divided into two groups: HbA1c ≥8% and HbA1c <7.8%	16S rRNA sequencing (V5–V6 region)	*Overall: glycemic status modulates subgingival biofilm composition*. Controlled type 2 diabetes presented greater diversity than uncontrolled type 2 diabetes. Uncontrolled type 2 diabetes favored fermenting species associated with propionate/succinate production and unfavored butyrate/pyruvate forming species. Higher abundances of *Anginosus* and *Streptococcus agalactiae* were found in uncontrolled type 2 diabetes. Uncontrolled type 2 diabetes present with altered subgingival microbiome with invasive profile.
Farina *et al*.	2019	Whole metagenomic shotgun sequencing of the subgingival microbiome of diabetics and non-diabetics with different periodontal conditions	12 subjects in four study groups based on the presence/absence of poorly controlled type 2 diabetes mellitus and moderate–severe periodontitis	High-resolution whole metagenomic shotgun sequencing	*Overall: whole metagenomic shotgun sequencing was extremely effective in the detection of low-abundant taxon*. The presence of type 2 diabetes and/or periodontitis were associated with a tendency of the subgingival microbiome to decrease in richness and diversity. The presence of type 2 diabetes was not associated with significant differences in the relative abundance of one or more species in patients either with or without periodontitis. The presence of periodontitis was associated with a significantly higher relative abundance of *Anaerolineaceae bacterium* oral taxon 439 in subjects with type 2 diabetes
Saeb *et al*.	2019	Relative reduction of biological and phylogenetic diversity of the or al microbiota of diabetes and prediabetes patients	15 type 2 diabetes patients, 10 impaired glucose tolerance subjects, and 19 control subjects	16S rRNA sequencing	*Overall: a clear reduction of the biological and phylogenetic diversity in oral microbiota of subjects with diabetes and prediabetes was found compared with oral microbiota in normoglycemic subjects*. The group with diabetes exhibited reduction of species and diversity but the highest evenness value and the highest microbiota bacterial pathogenic content.
Shi *et al*.	2020	The subgingival microbiome associated with periodontitis in type 2 diabetes mellitus	Type 2 diabetes patients (*n* = 15) compared with subjects without diabetes (*n* = 16)	Metagenomic shotgun sequencing	*Overall: patients with type 2 diabetes are more susceptible to shifts in the subgingival microbiome toward dysbiosis, potentially due to impaired host metabolic and immune regulation*. In periodontitis state, the shift in subgingival microbiome from the healthy state was less prominent in type 2 diabetes compared with subjects without diabetes, despite similarity in disease state. Presence of pathogenic species in relative abundance correlated with periodontitis state, but also in the healthy state in type 2 diabetes. A set of microbial marker genes were associated with the clinical states.

and concluded that type 2 diabetes subjects are more susceptible to dysbiosis in subgingival microbiome possibly due to impaired host metabolic and immune regulation. With this approach, an oral taxon that predicted the presence of periodontitis in subjects with type 2 diabetes was detected (Casarin *et al*. 2013; Zhou *et al*. 2013; Ganesan *et al*. 2017; Long *et al*. 2017; Longo *et al*. 2018; Farina *et al*. 2019; Saeb *et al*. 2019; Shi *et al*. 2020). Despite powerful analyses, the results from these studies warrant confirmation from larger and longitudinal studies.

Summary

Diabetes may be associated with an altered inflammatory process that is referred to as "diabetic periodontitis", although there is no consensus on this definition and recognition of patients with diabetes present with a distinct periodontal disease phenotype. It is clear, however, that the severity of periodontitis increases the inflammatory burden in patients with diabetes. A diabetic person experiences a challenge in controlling his/her glycaemia, suffering from oral complications of periodontal disease, e.g. mastication, abscesses, loose teeth, bad breath, esthetic outcomes, increased risk for adiposity, systemic inflammation, cardiovascular disease, kidney disease, and ocular complications (Fig. 18-6). Diabetic control gets worse with increased severity of periodontitis (Karima *et al*. 2005), which increases the systemic inflammatory markers (e.g. CRP) while decreasing the anti-inflammatory cytokines (e.g. IL-10). Clinical cases demonstrate the adversity periodontitis presents in patients with diabetes (Figs. 18-7, 18-8, 18-9).

There are critical modifying factors such as the duration of diabetes, and therefore exposure to hyperglycemia, AGEs, and chronic micro- and macrovascular defects, age of onset, lipidemia, and type of

diabetes. Restoration of diabetic control may reduce or eliminate periodontal pathologies. Likewise, periodontal treatment facilitates diabetic control supporting the bidirectionality of the link between diabetes and periodontal diseases (D'Aiuto *et al*. 2018). Thus, it is plausible that periodontitis in people with diabetes presents with a different biological mechanism (Taylor *et al*. 2001). This view is also supported by epidemiologic evidence (Borgnakke *et al*. 2013).

Conclusion

Lifestyle, genetic and familial predisposition, smoking, gender, and age are the systemic and environmental modifying factors of the biological link between periodontal diseases and systemic diseases. Inflammatory diseases share a common diagnostic and prognostic definition if they remain active: aberrant and uncontrolled inflammation of the target tissues and incurable, progressive outcomes. The severity of the inflammatory pathological condition for human life depends on the affected tissues or organ systems. In vital tissues such as the heart, lung, kidney, or liver, the progression of inflammation can be devastating. In peripheral tissues, however, the inflammatory process can follow a slowly progressive path. Thus, while the mediators may be similar, there exists a tissue specificity for the inflammatory events. Another major issue in understanding inflammation as an entity is the communication between distant organs. Although it is plausible that inflammatory processes in one organ could directly lead to pathologies in another organ or tissue, comorbidity of inflammatory pathways and common signaling mechanisms via cells or soluble mediators are critical for the oral–systemic link (Hasturk *et al*. 2012a).

Figure 18-10 summarizes the plausibility of the link between periodontal and systemic diseases. The transition of health to disease is the result of several factors that affect the body's homeostatic balance. Aging, epigenetics, and infections favor the disease-associated pathological shifts. Activation of inflammation is mediated by molecular pathways and cellular functions that can be measured as markers of pathological transition. A reciprocal transition restores health and requires the resolution of the inflammatory process, which is characterized by health-associated markers. Non-transmittable inflammatory diseases (e.g. obesity, diabetes, cardiovascular diseases, Alzheimer's disease, rheumatoid arthritis, osteoporosis, periodontal disease, and adverse pregnancy outcomes) share similar pathways that affect the body at the local tissue and systemic levels and are therefore connected. Whereas various markers are associated with health, others are linked to disease initiation and severity. These distinctions, however, become blurred as inflammation is an active process that involves both initiation and resolution.

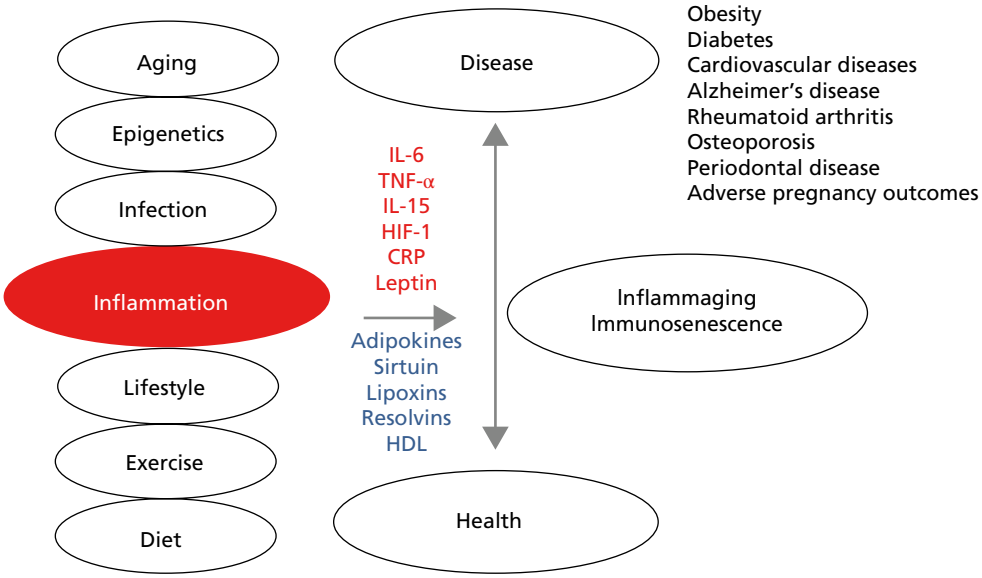

Fig. 18-10 Plausibility of the link between periodontal and systemic diseases. CRP, C-reactive protein; HDL, high-density lipoprotein; HIF-1, hypoxia inducible factor-1; IL-6, interleukin-6; IL-15, interleukin-15; TNF-α, tumor necrosis factor-α.

Chapter 19

Abscesses, Necrotizing Lesions of the Periodontium, and Endo-Periodontal Lesions

David Herrera[1] and Magda Feres[2]

[1]ETEP (Etiology and Therapy of Periodontal and Peri-Implant Diseases) Research Group, Complutense University of Madrid, Madrid, Spain

Introduction

Acute periodontal diseases have been defined as "clinical conditions of rapid onset that involve the periodontium, or associated structures, and may be characterized by pain or discomfort, tissue destruction and infection" (American Academy of Periodontology, 2000). Different diseases and/or conditions have been considered within this category, including gingival abscesses, periodontal abscesses, necrotizing periodontal diseases, herpetic gingivostomatitis, pericoronal abscesses, pericoronitis, and endo-periodontal lesions.

Acute lesions affecting the periodontal tissues often require immediate action, with the patient seeking emergency care because of acute pain, which is not a common situation in the periodontal practice. Moreover, and in contrast with most chronic periodontal diseases and conditions, the onset is rapid and subsequent destruction of periodontal tissues may occur. Diagnosis should be prompt and swift treatment provision is essential (Papapanou *et al*. 2018). Two of these conditions can be considered as solely periodontal diseases: periodontal abscesses and necrotizing periodontal diseases. Abscesses in the periodontium are relevant since they are common dental emergencies, requiring immediate management. They present with rapid destruction of the periodontal tissues, which negatively affects the prognosis of the affected tooth and they may have severe systemic consequences (Herrera *et al*. 2000b, 2014). On the other hand, necrotizing periodontal diseases represent the most severe conditions associated with

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

dental biofilms, with very rapid tissue destruction (Herrera *et al*. 2014).

Endo-periodontal lesions are pathological conditions that affect both the pulp and the periodontal tissues in the same tooth. These lesions may have an acute progression and develop as an abscess, but most of the time they have a chronic course. They may occur as a result of a microbial challenge in the periodontal and/or endodontic tissues, or because of trauma, iatrogenic events, and root resorption. Endo-periodontal lesions are not very common clinical conditions (Rhee *et al*. 2014), but are considered one of the most challenging problems for clinicians as they are relatively difficult to treat and may severely compromise the tooth prognosis (Herrera *et al*. 2018).

Abscesses in the periodontium

Abscesses in the periodontium are a major reason for patients seeking emergency care in the dental clinic. They represent a heterogeneous group of lesions, characterized by the presence of a localized purulent infection in the periodontal tissues. Different etiological factors may explain the occurrence of these lesions: pulp necrosis, periodontal infections, pericoronitis, trauma, or surgery (Gill & Scully 1990). Specific terminology is used to refer to the abscesses associated with pulp necrosis (endodontal, periapical, or dentoalveolar abscess), with periodontal infections (Papapanou *et al*. 2018), or with pericoronitis (pericoronal abscess), which are referred to together as odontogenic or dental abscesses (van Winkelhoff *et al*. 1985).

Periodontal abscess

A periodontal abscess has been defined as a lesion with an expressed periodontal breakdown occurring during a limited period of time, and with easily detectable clinical symptoms, including a localized accumulation of pus located within the gingival wall of the periodontal pocket (Herrera *et al*. 2000b). More recently, the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions, defined periodontal abscesses as "acute lesions characterized by localized accumulation of pus within the gingival wall of the periodontal pocket/sulcus, rapid tissue destruction, and are associated with risk for systemic dissemination".

Classification

Although defined by the general term "periodontal abscesses", this group of acute periodontal conditions has been classified according to the course (chronic or acute), to the number of lesions (single or multiple), or to the location (gingival, restricted to the marginal gingiva, or periodontal, extended to the supporting periodontal tissues). A classification system for these lesions was proposed by Meng (1999a), and included the following categories: *gingival abscesses* (in previously healthy sites, caused by impaction of foreign bodies), *periodontal abscesses* (either acute or chronic, in relation with a periodontal pocket), and *pericoronal abscesses* (in relation with a partially erupted tooth). This classification was included in the revised classification system developed by the American Academy of Periodontology (AAP) International Workshop for a Classification of Periodontal Diseases in 1999, which for the first time included periodontal abscesses as an independent entity. In the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions, a new classification of periodontal abscesses, based on etiological factors, was adopted (Herrera *et al*. 2018; Papapanou *et al*. 2018). The development of a periodontal abscess may occur in an existing periodontal pocket, but it can also initiate in a site without a periodontal pocket. Therefore, two main types of periodontal abscesses can be distinguished: (1) those which require the previous presence of a periodontal pocket and thus, they are only found in patients with periodontitis; and (2) those which can develop without a pre-existing pocket, so they can be found both in periodontitis and in non-periodontitis patients (Herrera *et al*. 2018) (Table 19-1).

Periodontal abscess in periodontitis patients

A periodontal abscess in a patient with periodontitis may be associated with two distinct clinical scenarios, either with a period of disease exacerbation (acute exacerbation) or associated with a therapeutic procedure (after treatment).

Acute exacerbation

Abscesses because of acute exacerbation of periodontitis are favoured by the existence of tortuous pockets, the presence of furcation involvement (Darbar *et al*. 1993), or of a vertical defect (Fasciano & Fazio 1981; Kareha *et al*. 1981; Darbar *et al*. 1993). Acute exacerbation may occur in untreated periodontitis (Dello Russo 1985), in "refractory" periodontitis patients (Fine 1994), or in patients in periodontal maintenance (Kaldahl *et al*. 1996; McLeod *et al*. 1997; Silva *et al*. 2008).

After treatment

Post-treatment periodontal abscesses may occur after the following interventions:

- Scaling and root planing or professional mechanical plaque removal, either because a dislodged fragment of calculus is lodged into the tissues (Dello Russo 1985), or because incomplete scaling allows the presence of calculus in the pocket, while the healing in the coronal area occludes the normal drainage (Kaldahl *et al*. 1996).

Table 19-1 Classification of periodontal abscesses, based on the etiological factors involved, according to the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions (Sources: Herrera *et al*. 2018; Papapanou *et al*. 2018).

Periodontal abscess in a periodontitis patient (abscess in a pre-existing periodontal pocket)						**Periodontal abscess in a non-periodontitis patient** (not mandatory to have a pre-existing periodontal pocket)				
Acute exacerbation			**After treatment**			Impaction (2)	Harmful habits (3)	Orthodontic factors (4)	Gingival overgrowth	Alteration of root surface (5)
Untreated periodontitis	Refractory periodontitis	Supportive periodontal therapy	Post-scaling	Post-surgery	Post-medication (1)					

(1) Systemic antimicrobials, other drugs (nifedipine);
(2) Dental floss, orthodontic elastic, toothpick, rubber dam, or popcorn hulls;
(3) Biting wire, nail biting and clenching;
(4) Orthodontic forces or a cross-bite;
(5a) Severe anatomic alterations: invaginated teeth, dens evaginatus, or odontodysplasia;
(5b) Minor anatomic alterations: cemental tears, enamel pearls, or developmental grooves;
(5c) Perforations: iatrogenic conditions;
(5d) Severe root damage: fissure or fracture, cracked tooth syndrome;
(5e) External root resorption.

- Surgical periodontal therapy, normally associated with the presence of foreign bodies such as membranes for regeneration, sutures, or periodontal dressing (Garrett *et al*. 1997).
- Systemic antimicrobial intake, without concomitant subgingival instrumentation, has been associated with periodontal abscesses in patients with advanced periodontitis (Helovuo & Paunio 1989; Topoll *et al*. 1990; Helovuo *et al*. 1993). Helovuo *et al*. (1993) followed patients with untreated periodontitis who were given broad-spectrum antibiotics (e.g. penicillin, erythromycin) for non-oral reasons and reported that 42% of them developed "marginal" abscesses within 4 weeks of the antibiotic therapy, and they suggest that a plausible explanation was an overgrowth of opportunistic bacteria (Helovuo *et al*. 1993).
- Use of other systemically delivered drugs, such as nifedipine (Koller-Benz *et al*. 1992).

Periodontal abscess in non-periodontitis patients

They may occur both in periodontally healthy sites or in periodontal pockets. Therefore, the pre-existence of a periodontal pocket is not mandatory for abscess development, in contrast with the abscesses described in the previous section. Five different groups of etiological factors are listed in this category:

- Impaction of foreign bodies, including dental floss, orthodontic elastics, toothpicks, rubber dam fragments, pieces of nails, or popcorn hulls.
- Harmful habits, such as biting wire, nail biting, or clenching, that could favour abscess development, either because of subgingival impaction or coronal closure of the pocket/sulcus.
- Orthodontic factors, including inadequate orthodontic forces or a cross-bite.
- Gingival enlargement (Holtzclaw & Toscano 2008).
- Alterations of the root surface, including severe anatomic alterations (invaginated tooth, *dens evaginatus* or grooves, or odontodysplasia), minor anatomic alterations (cemental tears, enamel pearls or developmental grooves), iatrogenic conditions (perforations), severe root damage (vertical root fracture or cracked tooth syndrome extending through the root), or external root resorption.

Etiology, pathogenesis, and histopathology

The development of a periodontal abscess is associated with the inability to maintain the normal drainage of the periodontal pocket/sulcus. This may be caused by a partial or total closure of the coronal portion or by an increase in the material to be drained, because of changes in the composition of the subgingival microbiota, an increase in bacterial virulence, or a decrease in the host defenses. The inability of the appropriate drainage of the pocket/sulcus could lead to an extension of the infection into the surrounding periodontal tissues (Newman & Sims 1979; Kareha *et al*. 1981; DeWitt *et al*. 1985), bacterial invasion of those tissues surrounding the periodontal pocket, and development of an inflammatory process through the chemotactic factors released by bacteria, which attract polymorphonuclear (PMN) leukocytes and other cells. This will trigger intensive release of cytokines, destruction of the connective tissues, encapsulation of the bacterial infection, and the production of pus. Once the abscess is formed, the rate of destruction within the abscess will depend on the growth of bacteria inside the foci and their virulent

capacity, and the local pH (an acidic environment will favor the activity of lysosomal enzymes) (DeWitt *et al*. 1985).

The periodontal abscess contains bacteria, bacterial products, inflammatory cells, tissue breakdown products, and serum. The histopathology of the abscess shows a central area filled with neutrophils, bacteria, and debris of soft tissue destruction. At a later stage, a pyogenic membrane, composed of macrophages and neutrophils, is organized to enucleate this central core. DeWitt *et al*. (1985) studied biopsies sampled from 12 abscesses. These biopsies extended apically to the centre of the abscess and were processed histologically. This revealed a normal oral epithelium and lamina propria, but the presence of an inflammatory cell infiltrate located laterally to the pocket epithelium. Within this infiltrate, there were accumulations of neutrophils and lymphocytes together with tissue destruction and a mass of granular, acidophilic, debris (Fig. 19-1). Some of these biopsies were evaluated by electron microscopy, which demonstrated the presence of Gram-negative bacteria invading the pocket epithelium and the infiltrated connective tissue. From outside to the inside, the following could be observed: a normal oral epithelium and lamina propria; an acute inflammatory infiltrate; intense focus of inflammation with presence of neutrophils and lymphocytes in an area of destroyed and necrotic connective tissue; and a destroyed and ulcerated pocket epithelium (DeWitt *et al*. 1985).

Microbiology

Based on reviews of the literature, it is usually mentioned that purulent oral infections are polymicrobial and mainly caused by endogenous bacteria (Tabaqchali 1988). There are very few studies, however, that have investigated the specific microbiota of periodontal abscesses. Newman and Sims (1979) studied nine abscesses and found that 63.1% of the microbiota was comprised of strict anaerobes. Topoll *et al*. (1990) analysed 20 abscesses in 10 patients who had taken antibiotics prior to the study, and reported that 59.5% of the microbiota was made up of strict anaerobes. Herrera *et al*. (2000a) reported that 45.1% of the bacteria in the abscess material were anaerobes.

These studies have shown that the microbiota of periodontal abscesses (Table 19-2) does not differ from the microbiota of chronic periodontitis lesions. This microbiota is polymicrobial and dominated by non-motile, Gram-negative, strict anaerobic, rod-shaped species. Among these bacteria, *Porphyromonas gingivalis* is probably the most virulent and relevant microorganism. The reported occurrence of *P. gingivalis* in periodontal abscesses ranged from 50% to 100% in studies using bacterial culture (Newman & Sims 1979; van Winkelhoff *et al*. 1985; Topoll *et al*. 1990; Hafstrom *et al*. 1994; Herrera *et al*. 2000a; Jaramillo *et al*. 2005). Eguchi *et al*. (2008), using a commercial molecular test (IAI-PadoTest 4.5; IAI Inc., IAI Institute, Zuchwil, Switzerland), also reported high prevalence of *P. gingivalis, Tannerella forsythia*, and *Treponema denticola*. Other anaerobic species that are usually found include *Prevotella intermedia*, *Prevotella melaninogenica,* and *Fusobacterium nucleatum*. Spirochetes (*Treponema* spp.) were found in most cases. The majority of the Gram-negative anaerobic species are non-fermentative and display moderate to strong proteolytic activity. Strict anaerobic, Gram-positive species frequently present in periodontal abscesses include *Parvimonas micra*, *Actinomyces* spp., and *Bifidobacterium* spp. Facultative anaerobic Gram-negative bacteria that can be isolated from periodontal abscesses include *Campylobacter* spp., *Capnocytophaga* spp., and *Aggregatibacter actinomycetemcomitans* (Hafstrom *et al*. 1994). The presence of Gram-negative enteric rods has also been reported (Jaramillo *et al*. 2005).
