The invasion of the furcation area of multirooted teeth by periodontitis represents a serious complication in periodontal therapy. The furcation area is often inaccessible to adequate instrumentation, and the roots frequently present concavities and furrows which make proper cleaning of the area impossible (see Chapter 40). As long as the pathologic process only extends a small distance (<5 mm; class I and II involvements) into the furcation area, further progress of the disease can usually be prevented by scaling and root planing, provided a proper oral hygiene program is established after treatment. In more advanced cases (5–6 mm; class II involvements), the initial cause-related treatment

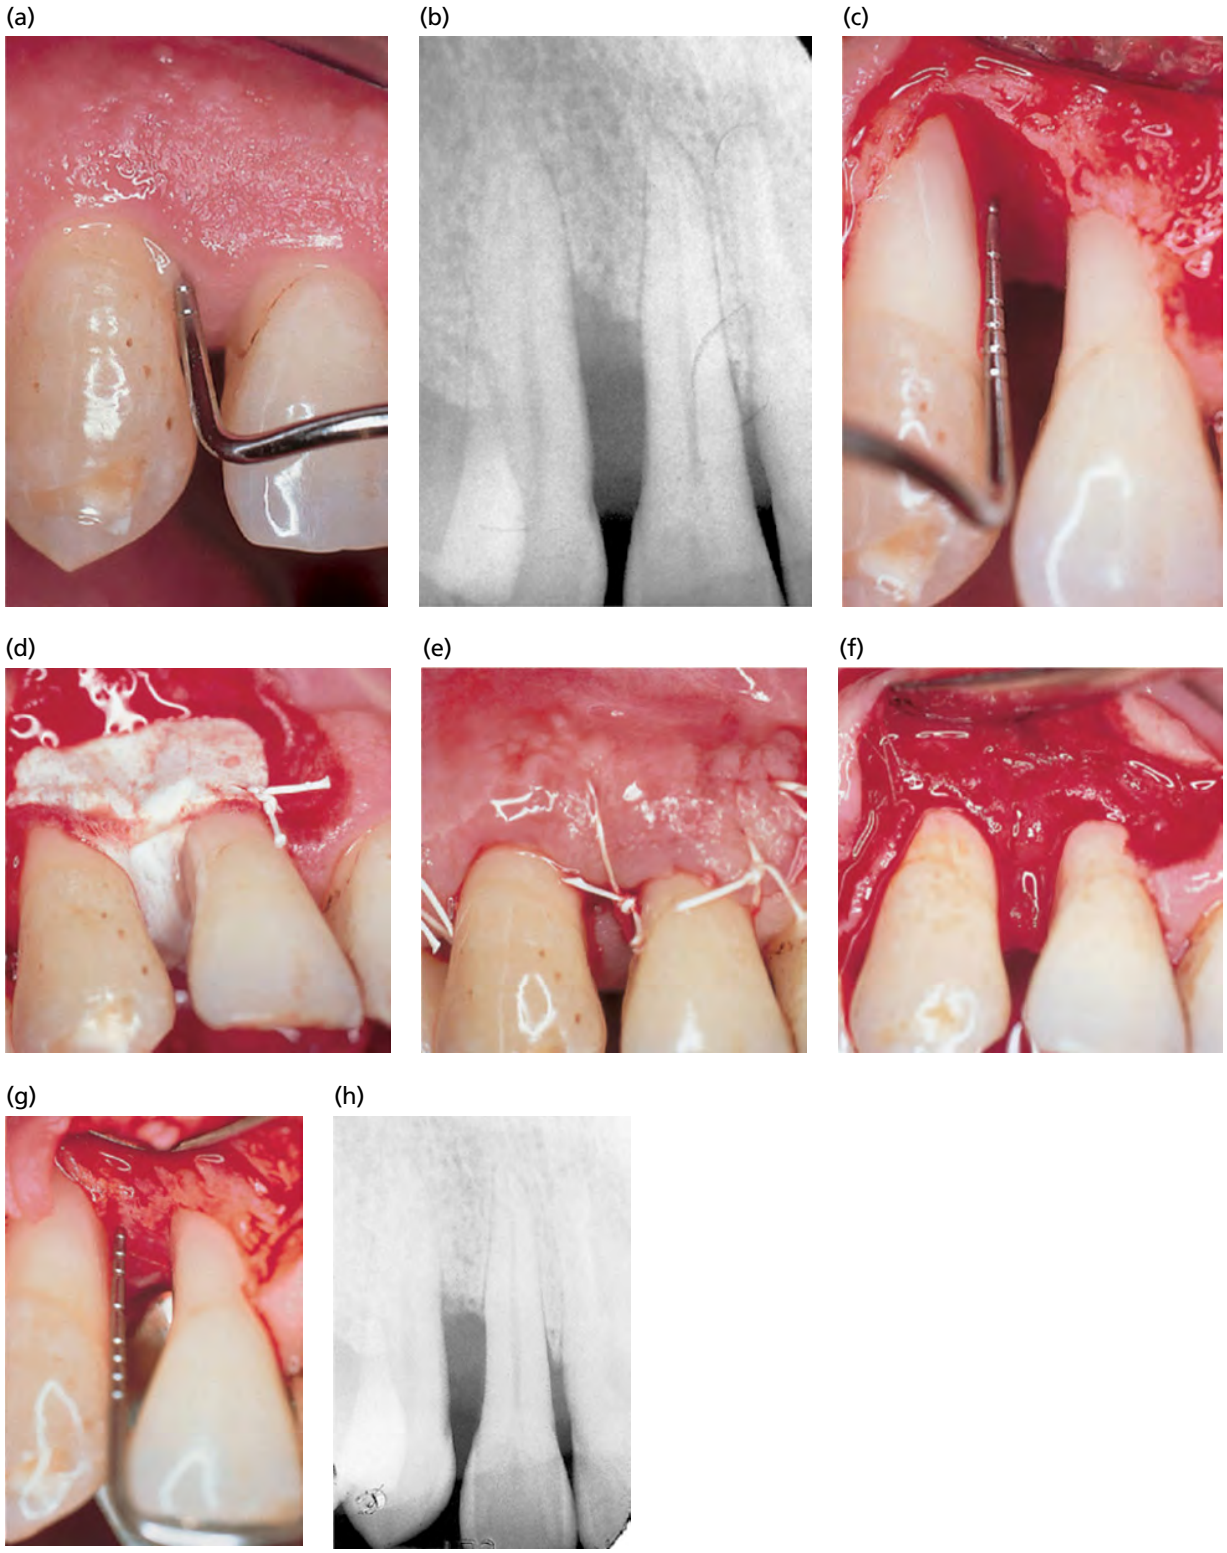

Fig. 38-39 Intrabony defect on the mesial aspect of a right maxillary canine treated with a non-bioresorbable barrier membrane. (a) Pocket depth was 9 mm and loss of clinical attachment was 10 mm. (b) Radiograph showing the presence of an interproximal intrabony defect. (c) After full-thickness flap elevation, defect debridement, and root planing, a 4-mm intrabony defect was evident. (d) An expanded polytetrafluoroethylene (e-PTFE) non-bioresorbable barrier membrane was tailored, positioned, and tightly sutured around the teeth adjacent to the defect. (e) Flap was repositioned and sutured to cover the membrane. Optimal preservation of the soft tissues was accomplished with an intrasulcular incision. (f) After removal of the membrane at 5 weeks, the defect appeared to be completely filled with newly formed tissue. (g) Treated site was surgically re-entered after 1 year. The intrabony defect was completely filled with bone. (h) One-year radiograph confirmed the complete resolution of the intrabony defect.

is frequently supplemented with surgery involving contouring of the interradicular bone (osteoplasty) or reduction of the tooth prominence at the furcation entrance by grinding (odontoplasty), in order to reduce the horizontal extension of the furcation involvement. In cases where the involvement extends even deeper into the furcation area (>5 mm; class II involvements), or a through-and-through defect (class

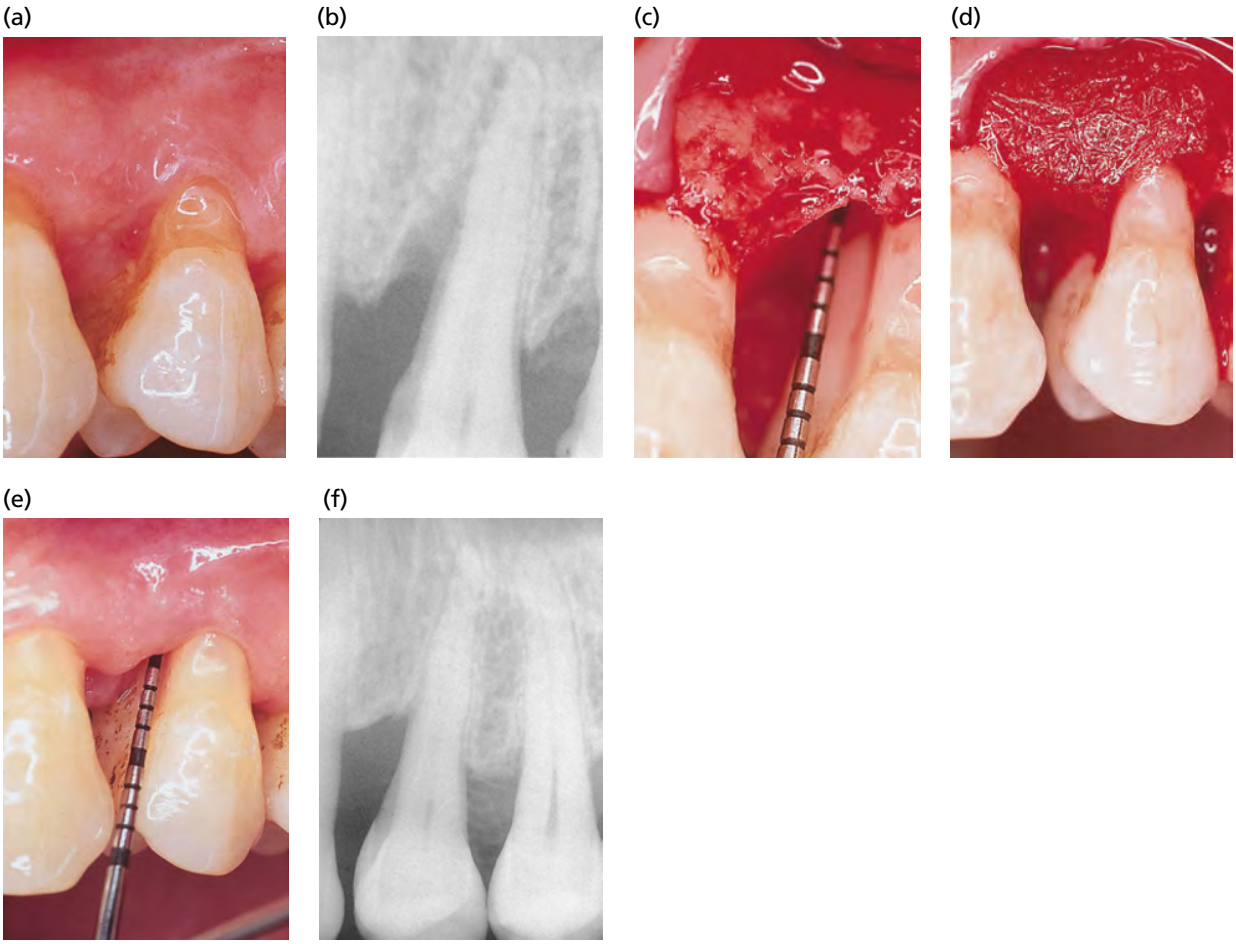

Fig. 38-40 Intrabony defect on the mesial aspect of a left maxillary premolar treated with a bioresorbable barrier membrane. (a) Clinical attachment loss was 12 mm. (b) Radiograph showing the presence of a deep interproximal intrabony defect approaching the apex of the tooth. (c) A 7-mm interproximal intrabony defect was measured after flap elevation, defect debridement, and root planing. (d) A bioresorbable barrier membrane was placed and sutured to cover the defect. (e) At 1 year, a 4-mm pocket depth and 5-mm clinical attachment length gain were recorded. (f) One-year radiograph showed that the intrabony defect was almost resolved.

III involvements) has developed, tunnel preparation or root resection has been advocated as the treatment of choice. However, both of these treatments run a risk of complications on a long-term basis. Following tunnel preparation, caries frequently develops in the furcation area and root-resected teeth often present complications of a non-periodontal nature, although controversial reports exist regarding the long-term results of these treatment modalities (Hamp *et al*. 1975; Langer *et al*. 1981; Erpenstein 1983; Bühler 1988; Little *et al*. 1995; Carnevale *et al*. 1998).

Considering the complexity of current techniques for the treatment of furcation problems, and in view of the long-term results and complications reported following treatment of advanced furcation involvements by traditional resective therapy, predictable regeneration of the periodontium at furcation-involved sites would represent considerable progress in periodontics.

Mandibular class II furcations

Pontoriero *et al*. (1988) reported a controlled randomized clinical trial in which significantly greater H-CAL gain (3.8 ± 1.2 mm) were obtained in 21 mandibular class II furcations treated with e-PTFE membranes compared with those in a control group treated with OFD alone (H-CAL gain of 2.0 ± 1.2 mm). Complete closure of the furcation was observed at 67% of the test sites and at only 10% of the control sites. Results from later studies, however, have not been as promising (Becker *et al*. 1988; Lekovic *et al*. 1989; Caffesse *et al*. 1990). Analysis of a series of studies published between 1988 and 1996 demonstrates a great variability in the clinical outcomes (Figs. 38-41, 38-42). Table 38-6 summarizes the outcomes of 21 clinical trials in which a total of 423 mandibular class II furcations were treated with different types of non-bioresorbable and bioresorbable barrier membranes. The weighted mean of the reported results showed an H-CAL gain of 2.3 ± 1.4 mm (95% CI 2.0–2.5 mm) in defects with a baseline horizontal PPD of 5.4 ± 1.3 mm. The reported number of complete furcation closures after GTR ranged from 0% to 67%. In three studies none of the treated furcations was closed (Becker *et al*. 1988; Yukna 1992; Polson *et al*. 1995b), in seven studies <50% were closed (Schallhorn & McClain 1988; Blumenthal 1993; Bouchard *et al*. 1993; Parashis & Mitsis 1993; Laurell *et al*. 1994; Mellonig *et al*. 1994;

Hugoson *et al*. 1995), and in only one study were >50% of the treated furcations completely resolved (Pontoriero *et al*. 1988).

A subset analysis of the studies reported in Table 38-6 indicated that furcations treated with non-bioresorbable barrier membranes (287) showed a gain in H-CAL of 1.8 ± 1.4 mm (95% CI 1.5–2.1 mm) as compared with 2.3 ± 1.2 mm (95% CI 2–2.6 mm) in 174 defects treated with bioresorbable barrier membranes. Five controlled clinical trials compared treatment with non-bioresorbable e-PTFE membranes and treatment with different types of bioresorbable membranes (Table 38-7). In particular, one investigation reported significantly greater H-CAL gain in the non-bioresorbable group (Bouchard *et al*. 1993), while another trial (Hugoson *et al*. 1995) showed a significantly greater H-CAL gain in the bioresorbable group. The remaining three investigations failed to detect any significant differences between the outcomes of treatment with bioresorbable or non-bioresorbable membranes. Generally, the results indicate that the predictability of GTR in the treatment of mandibular class II furcations is questionable if the treatment objective is the complete resolution of the furcation involvement.

Significant gain in V-CAL and reduction in PPD was also reported by several investigators following treatment of mandibular class II furcation defects (Pontoriero *et al*. 1988; Lekovic *et al*. 1989, 1990; Blumenthal 1993; Machtei *et al*. 1993, 1994; Black *et al*. 1994; Laurell *et al*. 1994; Mellonig *et al*. 1994; Wang *et al*. 1994; Hugoson *et al*. 1995; Polson *et al*. 1995b). The reported mean values ranged from 0.1 mm to 3.5 mm for V-CAL gain and from 1 mm to 4 mm for PPD reduction.

The effect of using barrier membranes for the treatment of mandibular class II furcations was investigated in six controlled randomized clinical trials in which GTR procedures were directly compared to flap surgery (Table 38-8). Sixty-six furcations treated with flap surgery and 87 treated with GTR were included. Three of the four studies reporting H-CAL

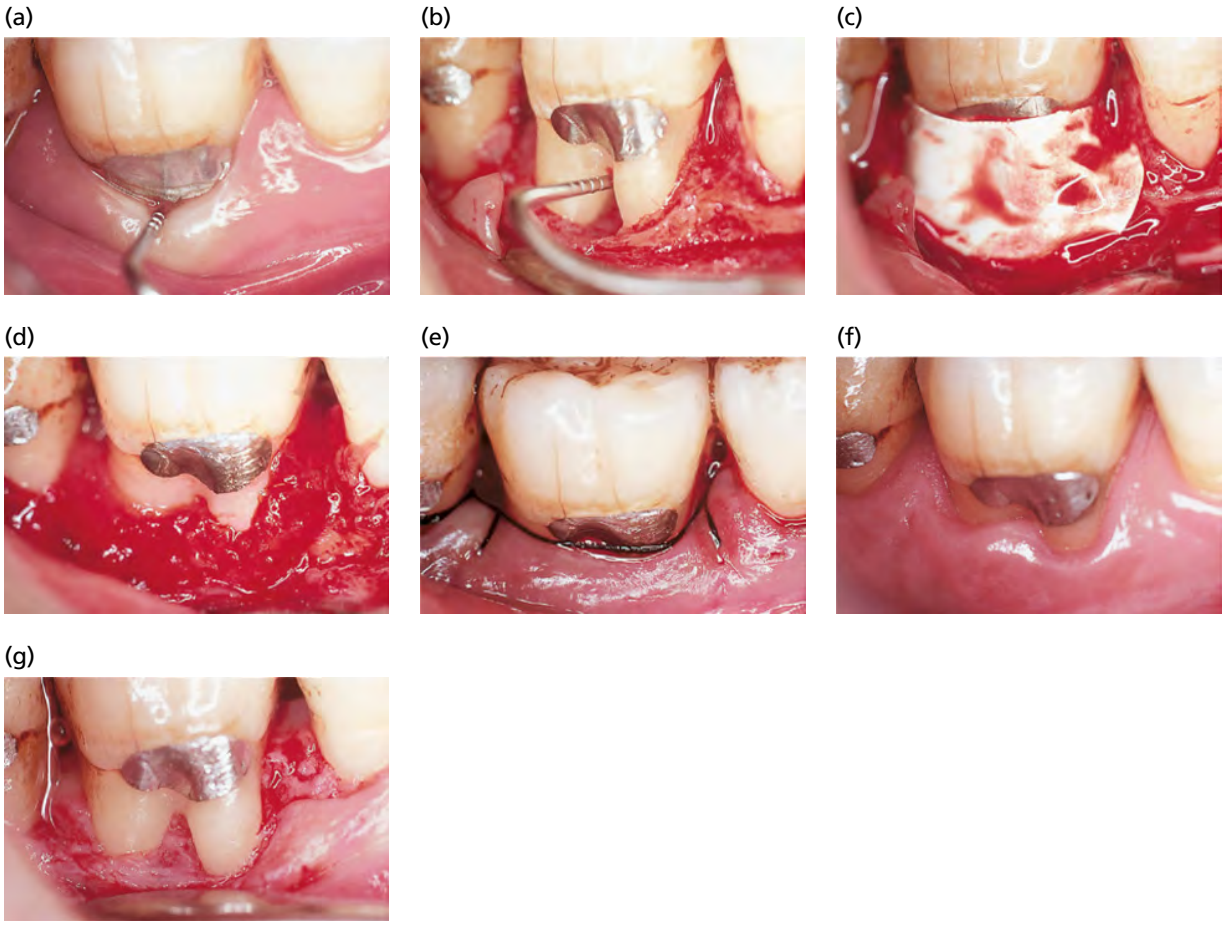

Fig. 38-41 (a) Right mandibular first molar presenting with a degree II furcation involvement. (b) Full-thickness buccal flaps were raised, the defect debrided, and the root carefully planed. (c) A non-bioresorbable barrier membrane was placed to cover the defect. (d) After membrane removal, newly formed tissue appeared to fill the furcation completely. (e) Regenerated tissue was covered with the flap. (f) Clinical appearance and surgery entry (g) after 1 year showed that the class II furcation was almost completely resolved.

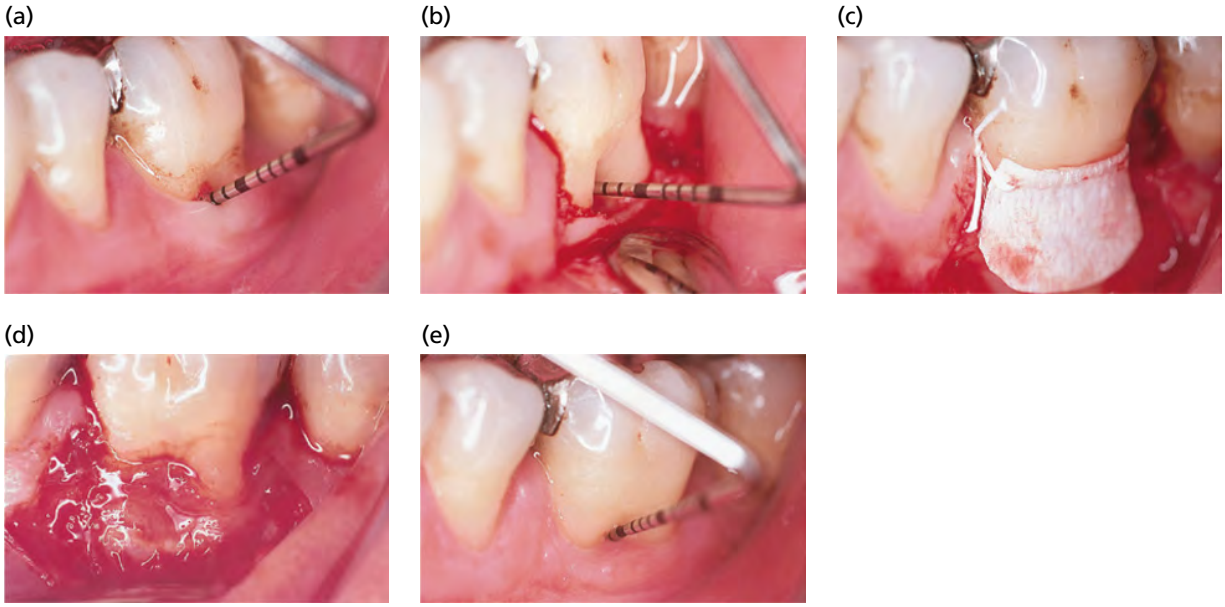

Fig. 38-42 (a) Left mandibular first molar presenting with a deep class II furcation involvement. (b) Horizontal loss of tooth support of 7 mm was probed. (c) An expanded polytetrafluoroethylene (e-PTFE barrier) membrane was trimmed and sutured to cover the furcation. (d) At membrane removal after 5 weeks, newly formed tissue filled the furcation completely. (e) At 1 year, a 3-mm gain of tooth support was measured, but a residual 4-mm class II furcation involvement was still present.

gains concluded that GTR resulted in statistically significantly greater H-CAL gains than flap surgery (Pontoriero *et al*. 1988; Van Swol *et al*. 1993; Wang *et al*. 1994). The weighted mean of the results of these studies for H-CAL gain in furcations treated with GTR was 2.5 ± 1 mm (95% CI 2.1–2.9 mm), and 1.3 ± 1 mm (95% CI 0.8–1.8 mm) for furcations treated with flap surgery. These results indicate an added benefit from GTR in the treatment of mandibular class II furcations.

Maxillary class II furcations

Results reported in three controlled studies (Metzeler *et al*. 1991; Mellonig *et al*. 1994; Pontoriero & Lindhe 1995a) comparing GTR treatment of maxillary class II furcations with non-bioresorbable e-PTFE membranes and with OFD indicated that GTR treatment of such defects is generally unpredictable. In a study including 17 pairs of class II furcations, Metzeler *et al*. (1991) measured CAL gains of 1.0 ± 0.9 mm in the GTR-treated sites versus 0.2 ± 0.6 mm in the control sites. Following re-entry, horizontal PAL gains (H-OPAL) of 0.9 ± 0.4 mm and 0.3 ± 0.6 mm were detected in the GTR- and flap-treated furcations, respectively. None of the furcations of the two groups was completely resolved. Similarly, Mellonig *et al*. (1994) treated eight pairs of maxillary class II furcations and reported H-OPAL gains of 1.0 mm (GTR sites) and 0.3 mm (flap-treated sites). Again, none of the treated furcations in the two groups was completely closed. On the other hand, in a study of 28 maxillary class II furcations, Pontoriero and Lindhe (1995a) found a

significant gain in CAL (1.5 mm) and horizontal bone (1.1 mm) in buccal class II furcations. Although these three investigations show a slight clinical improvement following treatment of class II maxillary furcations with GTR, the results are generally inconsistent.

Class III furcations

Four investigations of the treatment of mandibular class III furcations (Becker *et al*. 1988; Pontoriero *et al*. 1989; Cortellini *et al*. 1990; Pontoriero & Lindhe 1995b) indicate that the treatment of such defects with GTR is unpredictable. A controlled study by Pontoriero *et al*. (1989) showed that only eight of 21 "through-and-through" mandibular furcations treated with non-bioresorbable barrier membranes healed with complete closure of the defect. Another 10 defects were partially filled and three remained open. In the OFD-treated control group, 10 were partially filled and 11 remained open. Similar results were reported by Cortellini *et al*. (1990) who, in a case cohort of 15 class III mandibular furcations, found that 33% of the defects had healed completely, 33% were partially closed, and 33% were still through-and-through following treatment. Becker *et al*. (1988) did not observe complete closure of any of 11 treated class III mandibular furcations. Similarly, in a controlled clinical trial by Pontoriero and Lindhe (1995b) of 11 pairs of maxillary class III furcations randomly assigned to GTR or flap surgery, none of the furcation defects was closed.

Conclusion: Based on current evidence, it seems that mandibular class II furcations in the first or second molars, either buccal or lingual, with deep pockets at baseline and a gingival thickness of >1 mm, may benefit from GTR treatment.

Bone replacement grafts

Grafts for intrabony defects

BRGs comprise a heterogeneous group of materials of human (autologous or allogeneic), animal, or synthetic origin. Some consist of bone or exoskeletal minerals; others contain mainly bone matrix. There is evidence for periodontal regeneration for only a few of these materials. A randomized controlled clinical trial provided histologic support that the healing outcome following application of DFDBA in intrabony defects has a regenerative component in the apical to middle portion of the depth of the defect (Bowers *et al*. 1989a–c). Isolated evidence also supports the fact that allograft and bovine bone mineral may yield a regenerative outcome when used alone (i.e. without other regenerative materials such as barrier membranes or biologically active regenerative materials [BARGs]; see also Chapter 28) (Nevins *et al*. 2000).

BRGs were the first periodontal regenerative materials to be applied clinically. Today they are widely used in North America as DFDBAs and are frequently used in combination with other regenerative materials (GTR and/or BARG). Biologic principles supporting the use of *autologous and heterologous grafts* include osteoconductivity and osteoinductivity, but also their capacity for space provision and blood clot stabilization (Rosen *et al*. 2000; Trombelli & Farina 2008).

The clinical efficacy of allografts in terms of bone fill and CAL gain is supported by a meta-analysis of 27 controlled studies indicating that additional bone fill of 1 mm and additional CAL gain of 0.4 mm were observed (see Fig 38-8) (Reynolds *et al*. 2003). The total number of defects contributing to this meta-analysis however was relatively small (136 for CAL gain and 154 for bone fill). Furthermore, no large-scale multicenter trial has ever been performed and hence the applicability of these results to clinical practice settings remains to be established.

BRGs can be applied alone following elevation of a PPF for the treatment of intrabony defects. The graft is applied to overfill the defect to compensate for an expected degree of shedding of the graft in cases of imperfect containment of the graft by the closed flap. A study has suggested using BRGs in combination with an antibiotic powder to enhance control of the bacterial contamination of the surgical wound (Yukna & Sepe 1982). This study reported improved outcomes from mixing the graft with tetracycline powder. DFDBAs have been successfully used along with MIS (Harrel 1999).

Grafts for furcation involvement

A series of controlled clinical trials has evaluated the clinical performances of BRGs in the flap approach to the treatment of furcation defects. Reynolds *et al*. (2003) in their review found an overall PPD reduction ranging from 1.9 mm to 2.31 mm in class II furcations treated with BRGs, compared with 0–1.8 mm for those treated with OFD alone. For class III defects, BRGs produced a PPD change of 0.7–2.6 mm, as compared −1–2.6 mm in the controls. CAL changes were similar for mandibular class II and III furcations, ranging from 1.5 to 2.5 mm for grafted sites compared with 0–1.5 mm for the flap controls. The authors concluded that the results of these studies suggest that BRGs alone add relatively modest clinical benefit in the treatment of class II and III furcations, especially if complete closure of the furcation is the desired end point of treatment. More recently, Tsao *et al*. (2006b) tested a solvent-preserved, mineralized human cancellous bone allograft (MBA) with or without a collagen membrane in the treatment of 27 mandibular class II furcations. Their results indicated that solvent-preserved MBA, with or without a collagen membrane, can significantly improve bone fill in mandibular class II furcation defects.

Biologically active regenerative materials

Preclinical and clinical evidence for the use of BARGs has been reviewed (see also Chapter 28). The adoption of *biologic products/compounds* is based on their

ability to induce or accelerate the processes of matrix formation and cell differentiation (Bosshardt 2008). These products promote the healing process but lack mechanical properties to aid space provision and blood clot stabilization. Some of these, therefore, are loaded on solid, bioresorbable carriers to add some mechanical properties (Palmer & Cortellini 2008; Trombelli & Farina 2008). Currently, preparations based on growth factors or amelogenins are available for use in periodontal regeneration. Significant preclinical evidence supports the positive effect of both on periodontal wound healing and regeneration (Howell *et al*. 1997; Bosshardt 2008).

Growth factors for intrabony defects

Support for the clinical use of growth factors comes from two multicenter studies on recombinant human-derived growth factor (Nevins *et al*. 2005; Jayakumar *et al*. 2011) and two on fibroblast growth factor-2 (FGF-2) (Kitamura *et al*. 2008, 2011). Nevins *et al*. (2005) treated 180 defects comprising both intrabony and furcation defects with one of two concentrations of PDGF (0.3 mg/mL and 1.0 mg/mL) combined with the β-TCP delivery device or TCP alone. Results were assessed at 3 and 6 months and included both clinical and radiographic assessments. CAL gains at 6 months failed to demonstrate a significant benefit for either concentration of PDGF compared with the BRG alone. With regards to radiographic assessments, however, the lower tested concentration of PDGF resulted in significantly higher percentages of bone fill of the defect (57% versus 18%) and linear bone growth (2.6 mm versus 0.9 mm). The results of this study led to the approval of this material by the US Food and Drug Administration. The authors interpreted the dichotomy between the reported added benefit in terms of radiographic parameters and the lack of significant changes in CAL as the result of the biologic action of the growth factor formulation in shortening the healing time of the hard tissues.

In the Jayakumar *et al*. (2011) study, 54 patients were treated with rhPDGF-BB combined with the β-TCP delivery device or TCP alone. CAL gain, bone growth, and percent bone fill at 6 months were significantly greater in the test group as compared with the TCP control group.

The study of 74 patients by Kitamura *et al*. (2008) compared three different concentrations of a FGF-2 vehicle with 3% hydroxypropylcellulose (HPC) to HPC alone. No difference was reported in terms of CAL gain between the test and control groups. However, a significant difference in terms of bone gain was reported in favor of the 0.3% concentration of FGF-2 as compared with HPC alone. The other two concentrations (0.03% and 0.1%) did not show any advantage in terms of bone gain. A second randomized, double-blind, placebo-controlled clinical trial on 253 adult patients compared 0.2%, 0.3%, or 0.4% FGF-2 to vehicle alone in two- or three-walled vertical bone defects (Kitamura *et al*. 2011). Each dose of FGF-2 showed significant superiority over vehicle alone (P <0.01) for the percentage of bone fill at 36 weeks after administration. No significant differences were observed between the groups in CAL gain.

No clinical safety problems were reported in any of the four cited studies.

Drawing conclusions from the four studies, it is apparent that both the tested growth factors resulted into a measurable added benefit compared with controls in terms of bone gain, while three of the four studies did not reach a significant difference in terms of CAL gain. Both efficacy and effectiveness of rhPDGF-BB and FGF-2 have to be further explored for use in private settings.

A recent controlled study evaluated clinical and histologic wound healing/regeneration following surgical implantation of recombinant human growth/differentiation factor-5 (rhGDF-5) adsorbed onto a particulate β-TCP carrier (rhGDF-5/β-TCP) into periodontal defects in 28 patients (Stavropoulos *et al*. 2011). Control defects were treated with OFD alone. The authors reported greater PPD reduction, CAL gain, alveolar bone regeneration, and periodontal regeneration at sites that received rhGDF-5/β-TCP compared with control sites. However, these differences were not statistically significant. Block biopsies of the defect sites were collected at 6 months post-surgery. Histologically, bone regeneration height was almost three-fold greater for the rhGDF-5/β-TCP treatment compared with OFD alone (2.19 ± 1.59 mm versus 0.81 ± 1.02 mm; P = 0.08). Similarly, an almost twofold increase was observed for periodontal ligament (2.16 ± 1.43 mm versus 1.23 ± 1.07 mm; P = 0.26), cementum (2.16 ± 1.43 mm versus 1.23 ± 1.07 mm; P = 0.26), and bone regeneration area (0.74 ± 0.69 mm^2 versus 0.32 ± 0.47 mm^2; P = 0.14). Root resorption/ankylosis was not observed. Future studies with larger sample sizes need to be conducted to verify these findings.

Growth factors for furcation involvement

A human clinical trial (Camelo *et al*. 2003) was designed to evaluate the clinical and histologic response to rhPDGF-BB delivered in bone allograft for the treatment of advanced class II furcation defects. Three mandibular and one maxillary molar furcation defects were treated: two received 0.5 mg/mL and two 1.0 mg/mL of rhPDGF-BB, in all cases mixed with DFDBA. Both concentrations of rhPDGF-BB resulted in substantially improved horizontal (mean 3.5 mm) and vertical (mean 4.25 mm) probing depths and attachment levels (mean 3.75 mm). Histologic evaluation revealed periodontal regeneration, including new bone, cementum, and periodontal ligament coronal to the reference notch. This study documented the favorable tissue response to rhPDGF-BB treatment at

both the clinical and microscopic levels and demonstrated that periodontal regeneration can be achieved in advanced class II furcation defects using a combination of purified recombinant growth factor and bone allograft. These outcomes were confirmed by a second study of 15 sites presenting with class II furcations in which the PDGF was loaded on DFDBA (Nevins *et al*. 2003), and in another study of four class III furcations in which the growth factor was loaded on TCP (Mellonig *et al*. 2009).

Promising histologic and clinical outcomes can be envisioned from these pilot studies. However, larger controlled clinical trials are needed to assess the real potential of growth factors in the treatment of teeth with furcation involvement.

Enamel matrix derivatives for intrabony defects

EMDs have been in clinical use for over 10 years and their clinical efficacy is very well established. The benefit of use of EMD gel in the treatment of intrabony defects is supported by human histologic evidence, case report studies, meta-analysis of randomized controlled clinical trials, and a large multicenter trial (Heijl *et al*. 1997; Heden *et al*. 1999; Sculean *et al*. 1999b; Silvestri *et al*. 2000; Heden 2000; Tonetti *et al*. 2002; Giannobile & Somerman 2003; Heden & Wennström 2006) (Figs. 38-26, 45-27, 38-43). The prospective multicenter randomized controlled clinical trial (Tonetti *et al*. 2002) was designed to compare the clinical outcomes of PPF surgery with or without the application of EMDs in 172 patients with advanced chronic periodontitis in 12 centers in seven countries. All patients had at least one intrabony defect of 3 mm or deeper. Heavy smokers (>20 cigarettes/day) were excluded. The surgical procedures included access for root instrumentation using either the SPPF or the MPPT in order to obtain optimal tissue adaptation and primary closure. After debridement, roots were conditioned for 2 minutes with a gel containing 24% EDTA. EMDs were applied to the test subjects and omitted in the controls. A total of 166 patients were available for the 1-year follow-up. On average, the test defects gained 3.1 ± 1.5 mm of CAL, while the control defects yielded a significantly lower CAL gain of 2.5 ± 1.5 mm. Pocket reduction was also significantly higher in the test group (3.9 ± 1.7 mm) compared with the controls (3.3 ± 1.7 mm). A multivariate analysis indicated that the treatment, the clinical centers, cigarette smoking, baseline PPD, and defect corticalization significantly influenced CAL gain. A frequency distribution analysis of the studied outcomes indicated that EMDs increased the predictability of clinically significant results (CAL gain >4 mm) and decreased the probability of obtaining negligible or no gain in CAL (CAL gain <2 mm). The results of this trial indicated that regenerative periodontal surgery with EMDs offers an additional benefit in terms of CAL gain, PPD reduction, and predictability of outcomes over PPF alone.

A secondary analysis of the multicenter trial has shown that, in intrabony defects, the added benefit of EMDs was greater in three-wall defects than in one-wall defects (Tonetti *et al*. 2002). Furthermore, another secondary analysis of the trial, but this time assessing the effect of the radiographic angle of the defect angle on the outcome (Tsitoura *et al*. 2004), uncovered a negative association between this angle and the CAL

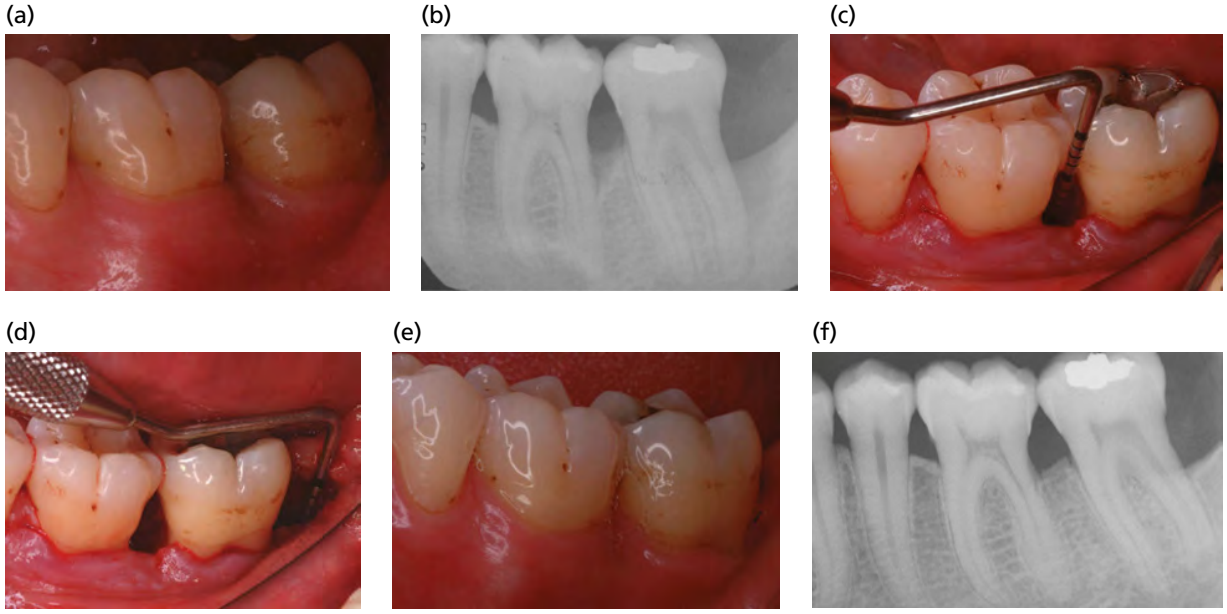

Fig. 38-43 Clinical case illustrating the use of enamel matrix derivatives (EMDs) to regenerate defects located on two adjacent teeth. At re-evaluation, deep pockets associated with deep intrabony defects were evident on the distal aspect of the first and second molars (a, b). Defects were accessed with the modified papilla preservation technique (MPPT) on the distal aspect of the first molar and with the use of a crestal incision in the retromolar area (c, d). Deep defects were exposed following debridement and root instrumentation (c, d). Following application of EMDs in gel form, primary closure was obtained with multilayered sutures. At 1-year follow-up, shallow probing depths associated with the elimination of the defects were observed (e, f).

gain observed at 1 year. These data have questioned the suitability of the gel formulation of EMDs for the treatment of defects with a non-supporting anatomy (wide defects with missing bony walls) and spurred considerable research interest in the incorporation of EMDs into a variety of BRGs in order to enhance wound stability and space maintenance. At this stage, however, no systematic evidence is available to support the use of such combinations.

More recently, EMDs have been successfully used in combination with minimally invasive techniques from MIS (Harrel *et al*. 2005), to MIST (Cortellini & Tonetti 2007a, b; Cortellini *et al*. 2008; Ribeiro *et al*. 2011a), and to M-MIST (Cortellini & Tonetti 2009a, 2011). This product is very well suited to sites where flap reflection is minimal since its positioning does not require any flap extension and the improved stability provided by MIS to the wound seems to favor the expression of its activity (Cortellini *et al*. 2008; Cortellini & Tonetti 2009a).

Clinically, the rate of wound healing following application of EMDs seems to be enhanced. A study looking at soft tissue density in the surgical site by using underexposed radiographs (Tonetti *et al*. 2004b) found that the rate of increase in density following application of EMDs may be faster than in the access flap control. Such modulation has been interpreted as the outcome of the local release of growth and differentiation factors by the cells involved in local wound healing. Given their hydrophobic nature, enamel matrix proteins for clinical use are mixed in a gel carrier at low pH. Following an increase in pH in the periodontal wound and rapid elimination of the gel, enamel matrix proteins (consisting mainly of EMDs) are deposited in the wound environment and the root surface. While the mechanism(s) of action of EMDs are not fully understood, significant evidence suggests that periodontal ligament cells exposed to EMDs switch their phenotype by increasing expression of a host of growth and differentiation factor-related genes (Brett *et al*. 2002; Parkar & Tonetti 2004), including transforming growth factor-beta (Lyngstadaas *et al*. 2001). A recent review (Bosshardt 2008) concluded that: (1) EMDs increase the cell proliferation of periodontal ligament and gingival fibroblasts and cells of osteoblast and chondrocyte lineage; (2) EMDs have biologic effects on cells of the osteoblast lineage, including up-regulation of markers of bone formation; (3) specific small amelogenin polypeptides (5 kDa) have osteoinductive properties when tested in an ectopic bone-forming model; and (4) the evidence does not demonstrate an inductive role for EMDs on cementogenesis.

Enamel matrix derivatives for furcation involvement

Treatment of mandibular class II furcations with EMDs was attempted by Jepsen *et al*. (2004). A randomized intraindividual study of 45 patients was designed to compare EMDs and bioresorbable barriers. Both treatment modalities led to a significant clinical improvement. The authors reported a median reduction of open furcation depth of 2.8 mm in the EMD-treated sites compared with a reduction of 1.8 mm in the barrier-treated sites. Complete furcation closure was recorded in eight of 45 EMD-treated sites and three of 45 barrier-treated sites. Differences between test and control sites were not statistically significant. Chitsazi *et al*. (2007) reported an H-CAL gain that was significantly greater in EMD-treated mandibular class II furcations than in OFD controls ($P = 0.002$).

Another randomized study (Casarin *et al*. 2008) compared the use of EMDs with open flap alone in 15 patients with contralateral proximal maxillary class II furcations. At 6 months, the V-CAL gains in the control and test groups were 0.39 ± 1.00 mm and 0.54 ± 0.95 mm, respectively, while the H-CAL gains were 1.21 ± 2.28 mm and 1.36 ± 1.26 mm, respectively ($P = 0.05$). The vertical bone level and horizontal bone level gains of the control group were 1.04 ± 1.12 mm and 1.00 1.79 mm, respectively, and of the test group were 0.82 ± 1.82 mm and 1.17 ± 1.38 mm, respectively ($P = 0.05$). However, a statistically significant greater number of reduced/closed furcations was observed in the test group ($P = 0.05$). The authors concluded that the use of EMDs in proximal furcations does not promote a superior reduction in PPD or a gain in clinical and osseous attachment levels but can result in a higher rate of conversion of class II to class I furcations.

Controversial outcomes have been so far observed in the treatment of class II either maxillary or mandibular furcations with EMDs. Their use seems, however, to provide an added benefit compared with flap treatment alone.

Combination therapy

Combination therapy for intrabony defects

Biologic principles supporting *combination therapy* relate to the possibility of obtaining an additive effect from combining different regenerative principles, including osteoconductivity and osteoinductivity, capacity for space provision and blood clot stabilization, and ability to induce or accelerate the processes of matrix formation and cell differentiation that are inherent in barriers, grafts, and bioactive substances.

Compromised results after GTR may be observed in cases where the gingival flap, eventually supported by a membrane, collapses/falls (partially or totally) into the defect and/or towards the root surface, thereby reducing the space available for blood clot formation and growth of new tissues capable of forming periodontal ligament and bone in particular. Reduced amounts of regenerated bone due to membrane collapse were noted in early studies of GTR. In the study of Gottlow *et al*. (1984), it was observed that collapse of the membrane towards the root surface

resulted in new cementum formation on the entire exposed root surface, whereas bone regeneration was minimal. Although the authors reported that the degree of coronal regrowth of bone was unrelated to the amount of new cementum formation, they did not comment on what effect membrane collapse might have had. Experimental studies, however, recognized the negative effect of membrane collapse on periodontal regeneration generally and on bone formation in particular (Caton *et al*. 1992; Haney *et al*. 1993; Sigurdsson *et al*. 1994; Sallum *et al*. 1998). Haney *et al*. (1993) observed a highly significant correlation between the space provided by the membrane and the amount of regenerated alveolar bone in a supra-alveolar defect model in dogs. This finding corroborates that of Cortellini *et al*. (1995c) who reported that clinical application of self-supporting (reinforced with titanium) e-PTFE membranes, which could be positioned more coronally than ordinary e-PTFE membranes, yielded a statistically significant increase in PAL gain in intrabony defects. A particular risk for gingival flap/membrane collapse exists in cases where the configuration of the defect is incapable of supporting/preserving the membrane at the position where it was originally placed.

As already discussed, membrane materials must possess certain characteristics in order to be efficient. Among these, the membrane needs to be capable of keeping its shape and integral features, thereby maintaining the space created adjacent to the root surface. The e-PTFE membranes reinforced with titanium are the closest to meeting these requirements, but they have the disadvantage that they are non-bioresorbable. At present there are no bioresorbable membranes available that fulfil this requirement sufficiently, which means that the placement of a bioresorbable membrane on, for instance, a wide one-wall defect involves the risk of membrane collapse. The collapse may be prevented by implantation of a biomaterial into the defect to support the membrane so that it maintains its original position (Figs. 38-24, 38-44). While biologic products can enforce the healing process, they also lack mechanical properties to aid space provision and blood clot stabilization. A potential solution, therefore, could be to load the biologic products onto solid, bioresorbable carriers to provide the necessary mechanical properties (Palmer & Cortellini 2008; Trombelli & Farina 2008). However, the biomaterial to be used for this purpose must not interfere with the process of periodontal regeneration and ideally it should also promote bone regeneration.

As previously described, periodontal regeneration has been attempted with a variety of grafting materials, among which DFDBAs apparently facilitate regeneration in humans (Ouhayoun 1996). In three controlled clinical trials, the treatment of a total of 45 pairs of intrabony defects with DFDBA grafting and GTR was compared with GTR treatment alone (Table 38-9). The weighted mean of the results of the reported investigations showed similar gain in CAL in the GTR group (2.1 ± 1.1 mm; 95% CI 1.6–2.6 mm) and in the GTR + DFDBA group (2.3 ± 1.4 mm; 95% CI 1.7–2.9 mm). The differences between the two treatments did not reach statistical significance, thus indicating no added effect of combining DFDBAs with barrier materials in the treatment of intrabony defects. Guillemin *et al*. (1993) compared the effect of DFDBAs alone with a combination of barrier materials plus DFDBAs in 15 pairs of intrabony defects. Both treatments resulted in significant CAL gain and bone fill at 6 months, but no difference was found between the treatments. Reynolds *et al*. (2003), in their systematic review, highlighted that clinical improvements from graft/barrier combinations were often obtained in large non-space maintaining defects. They concluded that the combination of graft and barriers can provide a significant gain in CAL and PPD reduction and a non-significant increase in bone fill when compared with graft alone.

Promising clinical results with a PAL gain of 1.0–5.5 mm were obtained in human case reports in which the GTR technique was combined with grafting of Bio-Oss®, an anorganic bovine bone xenograft, for the treatment of intrabony periodontal defects (Lundgren & Slotte 1999; Mellonig 2000; Paolantonio *et al*. 2001). The combined use of Bio-Oss® and GTR treatment resulted in greater PPD reduction, PAL gain, and defect fill compared to implantation of Bio-Oss® alone in case series (Camelo *et al*. 1998) and to flap surgery alone in a split-mouth study (Camargo *et al*. 2000).

In a randomized controlled clinical study including 60 patients (Stavropoulos *et al*. 2003), Bio-Oss® alone or impregnated with gentamicin was used as an adjunct to GTR in the treatment of one-wall or two-wall intrabony defects, and the outcomes were compared with those obtained following GTR or flap surgery alone. Treatment with a membrane alone (Fig. 38-45) resulted in a mean PAL gain of 2.9 mm, while it was 3.8 mm and 2.5 mm, respectively, when Bio-Oss® grafts with or without gentamicin were placed in the defects prior to membrane coverage (Fig. 38-46). The control defects treated with flap surgery demonstrated a PAL gain of only 1.5 mm. The clinical improvements in defects treated with GTR alone or in combination with Bio-Oss® grafting were significantly better than those obtained with flap surgery, whereas the differences between the groups treated with membranes were not statistically significant. A prospective multicenter randomized controlled clinical trial (Tonetti *et al*. 2004b) was designed to compare the clinical outcomes of PPF surgery with or without the application of a GTR/bone replacement material. One hundred and twenty-four patients with advanced chronic periodontitis were treated in 10 centers in seven countries. All patients had at least one intrabony defect of at least 3 mm. One year after treatment, the test defects gained 3.3 ± 1.7 mm of CAL, while the control defects yielded a significantly lower

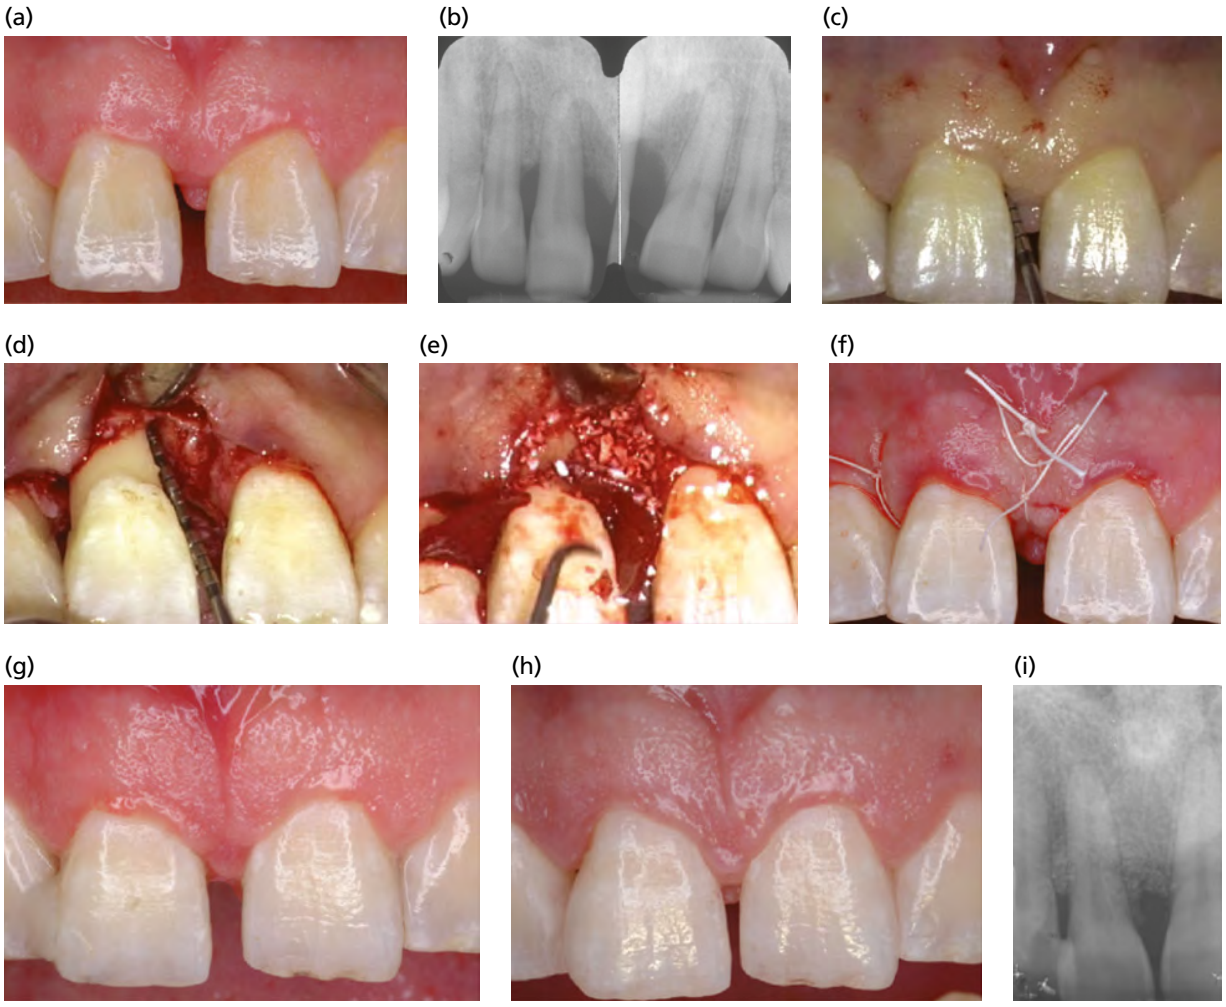

Fig. 38-44 Clinical case illustrating the application of a bone replacement graft (BRG) to support a bioresorbable membrane in a defect with poor space maintaining anatomy. Following control of periodontitis and risk factors, the upper right central incisor presented with a 12-mm deep pocket associated with a defect extending close to the apex of the tooth (a–c). The defect was accessed with the modified papilla preservation flap to reveal an 8-mm intrabony component (d). A BRG was placed under a bioresorbable collagen membrane (e). Primary closure was achieved with a multilayered suture technique (f). Excellent early healing was observed already at the 2-week follow-up (g). At 1 year, periodontal regeneration resulted in shallow probing depths and good resolution of the intrabony defect (h, i). Radio-opaque BRG particles were visible within the newly formed mineralized tissue.

Table 38-9 Controlled clinical trials evaluating the combined effects of decalcified freeze-dried bone allografts (DFDBAs) and barrier membranes in deep intrabony defects.

Study	Design (GTR treatment)	Number[a]	Gains in CAL (mm)		*P* value	Residual PPD (mm)		*P* value
			GTR	GTR + DFDBA		GTR	GTR + DFDBA	
Chen *et al*. (1995)	Intraindividual (collagen)	8	2.0 ± 0.4	2.3 ± 0.5	>0.05, NS	4.2 ± 0.4	4.2 ± 0.5	>0.05, NS
Mellado *et al*. (1995)	Intra-individual (e-PTFE)	11	2.0 ± 0.9	2.0 ± 1.4	0.86, NS	NA	NA	NA
Gouldin *et al*. (1996)	Intra-individual (e-PTFE)	26	2.2 ± 1.4	2.4 ± 1.6	NS	3.7 ± 1.6	3.7 ± 1.8	NS
Weighted mean		**45**	**2.1 ± 1.1**	**2.3 ± 1.4**		**3.8 ± 1.3**[b]	**3.8 ± 1.5**[b]	

[a] Defects per treatment arm.
[b] *n* = mean (34) ± SD (34).
CAL, clinical attachment level; e-PTFE, expanded polytetrafluoroethylene; GTR, guided tissue regeneration; NA, not available; NS, not significant.

CAL gain of 2.5 ± 1.5 mm. Pocket reduction was also significantly higher in the test group (3.7 ± 1.8 mm) when compared with the controls (3.2 ± 1.5 mm). A multivariate analysis indicated that the treatment, the clinical centers, baseline PPD and baseline full-mouth bleeding score (FMBS) significantly influenced CAL gains. The OR for achieving above-median CAL gains were significantly improved

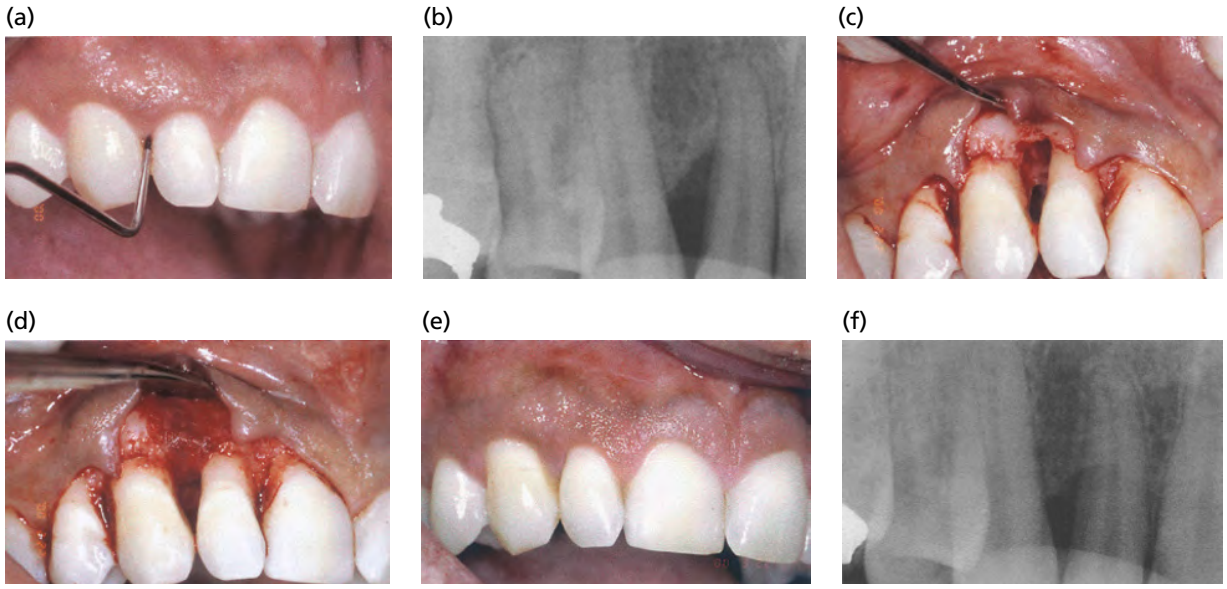

Fig. 38-45 Right lateral maxillary incisor with an 8-mm deep pocket associated with an intrabony defect on the distal aspect (a), as seen on the radiograph (b). Full-thickness buccal and palatal flaps were raised and the defect was debrided (c). A bioresorbable membrane was placed over the defect (d). The level of the interdental gingiva was maintained after 1 year (e) and the intrabony defect (f) had resolved.

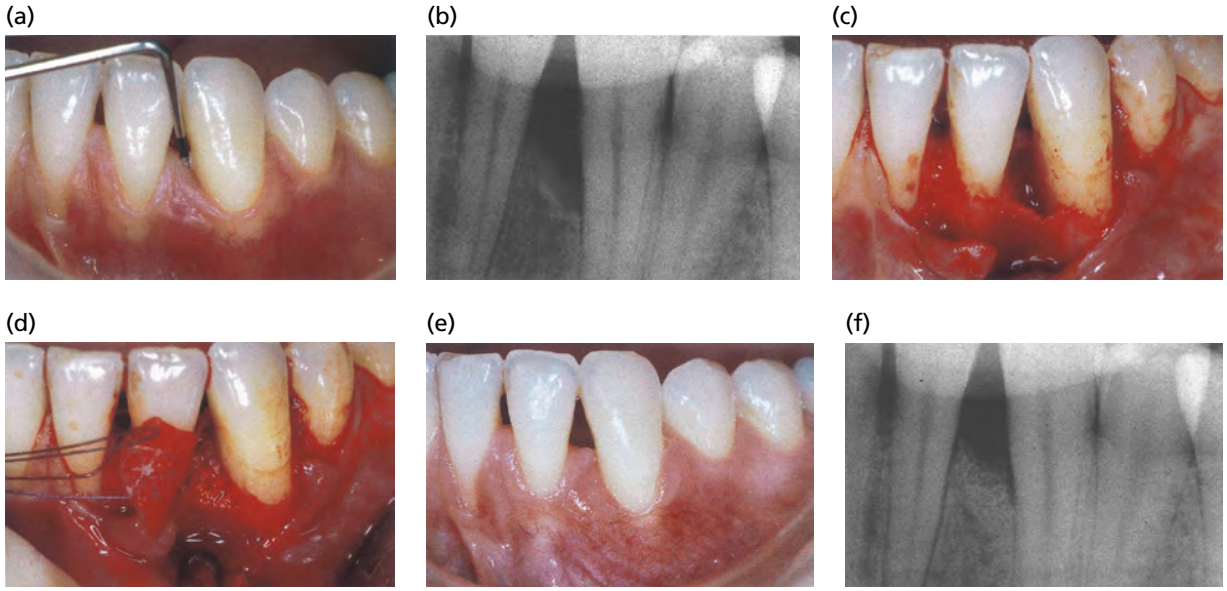

Fig. 38-46 Left mandibular canine with an 8-mm deep pocket (a) associated with an intrabony defect on its mesial aspect (b). The defect was debrided after flap elevation (c) and Bio-Oss® particles were placed in the defect (d) prior to placement of a bioresorbable membrane. After 1 year (e), no gingival recession had occurred and the intrabony defect had almost resolved (f).

by the test procedure (OR 2.6, 95% CI 1.2–5.4) and by starting with deeper PPD (OR 1.7, 1.3–2.2), but were decreased by receiving treatment at the worst-performing clinical center (OR 0.9, 0.76–0.99). The results of this trial indicated that regenerative periodontal surgery with a GTR/bone replacement material offers an additional benefit in terms of CAL gain, PPD reduction, and predictability of outcomes with respect to PPF alone.

In a controlled study (Pietruska 2001), similar clinical improvements were obtained when Bio-Oss® combined with GTR was compared with the use of enamel matrix protein (Emdogain®).

Camelo *et al*. (1998) and Mellonig (2000) presented histologic data indicating that the use of Bio-Oss® under a membrane may result in partial regeneration of the periodontal apparatus, but in all the cases most of the defect was still occupied by deproteinized bone particles. Bone was not observed near the root, and the connective tissue fibers of the "new" periodontal ligament were mostly oriented parallel to the root surface. These results corroborate findings reported by Paolantonio *et al*. (2001), who observed only limited bone formation in the vicinity of the pre-existing bone in a biopsy, taken from a site treated 8 months earlier with Bio-Oss® and a collagen membrane.

Most of the space in the defect was occupied by Bio-Oss® particles embedded in connective tissue. However, in a case report where intrabony defects were treated with Bio-Oss® combined with intraoral autogenous bone and GTR, new attachment formation had occurred consistently, but a major portion of the regenerated osseous tissue consisted of deproteinized bone particles (Camelo *et al*. 2001).

Combination therapy including use of EMDs plus barrier membranes and/or grafting materials have been tested. A systematic review (Trombelli & Farina 2008) concluded that there is evidence to support the use of EMDs either alone or in combination with grafts to effectively treat intraosseous defects and the additional use of a graft seems to enhance the clinical outcome with EMDs alone. The combined use of rhPDGF-BB and P-15 with a graft biomaterial has shown beneficial effects in intraosseous defects; contrasting results were reported for PRP and graft combinations. A systematic review by Tu *et al*. (2010) concluded that there was little evidence to support the additional benefits of EMDs in conjunction with other regenerative materials when compared with EMDs alone. When different types of bone grafts and barrier membranes were used, EMDs with bovine bone grafts showed greatest treatment effects.

More recently, combination therapy has been successfully used in sites treated with minimally invasive surgeries. Cortellini and Tonetti (2011) proposed a combination of EMDs and Bio-Oss® with the M-MIST, and Trombelli *et al*. (2010) a combination of a bioresorbable barrier and a graft with the single flap approach.

Combination therapy for furcation involvement

Schallhorn and McClain (1988) reported on improved clinical results in intrabony defects and class II furcations, following a combination therapy including barrier membranes plus DFDBA and citric acid root conditioning. The authors reported a complete furcation closure in 75% of the treated sites (McClain & Schallhorn 1993).

In one study, barrier membranes alone were compared to combination therapy with hydroxyapatite. The difference in clinical outcomes between the two treatments was not statistically significant, but the combination therapy resulted in a greater extent of furcation fill (Lekovic *et al*. 1990).

In three studies on mandibular class II furcations, GTR treatment alone was compared with GTR treatment combined with DFDBA. In one of these investigations, a statistically significant improvement was found in terms of H-OPAL in the group of furcations treated with the combination therapy (Anderegg *et al*. 1991). In a second investigation, a non-bioresorbable barrier with and without DFDBA was tested in six patients with 17 mandibular class II buccal molar furcal invasions (Wallace *et al*. 1994). Ten teeth were randomly selected as test sites (e-PTFE + DFDBA) and seven as controls (e-PTFE alone). After 6 months, all sites were re-entered and both soft tissue and open surgical measurements were recorded. The addition of DFDBA to the GTR procedure did not significantly improve any of the mean soft tissue and open surgical measurements between the control and test groups. Both treatment procedures resulted in significant decreases in PPD, distance from the cementoenamel junction to the bottom of the defect (CEJ–BD), and horizontal bone fill and a significant increase in recession. In a third study, a bioresorbable barrier with and without DFDBA was tested in 14 subjects with paired class II mandibular molar furcation defects (Luepke *et al*. 1997). When the bioresorbable barrier alone was compared with the bioresorbable barrier in combination with DFDBA, PPD reduction was significantly (P <0.01) in favor of the combination therapy. Vertical bone gain was significant greater with the combination treatment (P <0.02). The authors concluded that the combination therapy of bioresorbable barrier plus DFDBA is superior to the control therapy of bioresorbable barrier alone.

Lekovic *et al*. (2003) tested a combination of PRP, bovine porous bone mineral (BPBM), and GTR in 52 class II furcations (26 treated with the test material and 26 with OFD, which served as controls). The experimental group presented with significantly greater pocket reduction (4.07 ± 0.33 mm for experimental and 2.49 ± 0.38 mm for control sites), CAL gain (3.29 ± 0.42 mm for experimental and 1.68 ± 0.31 mm for control sites), vertical defect fill (2.56 ± 0.36 mm for experimental and −0.19 ± 0.02 for control sites), and horizontal defect fill (2.28 ± 0.33 mm for experimental and 0.08 ± 0.02 mm for control sites) than the control group. The authors concluded that the PRP/BPBM/GTR combined technique is an effective modality of regenerative treatment for mandibular grade II furcation defects. However, further studies are necessary to elucidate the role played by each component of the combined therapy in achieving these results.

Houser *et al*. (2001) compared the use of Bio-Oss® in combination with a bioresorbable collagen barrier (BioGide®) to OFD surgery in human mandibular class II furcation defects. A total of 31 furcations (18 test, 13 control) in 21 patients were treated. There was a statistically significant improvement in most clinical parameters for the experimental group, with minimal improvement noted for the flap control group. Vertical PPD reduction of 2.0 mm and horizontal PPD reduction of 2.2 mm were reported for the experimental group, while 0.3 mm and 0.2 mm reductions, respectively, were reported for the control group. Hard tissue measurements showed 2.0 mm of vertical furcation bone fill for the test group and 0.5 mm for the control group. The test group had 3.0 mm of horizontal furcation bone fill and the control group had 0.9 mm. The test group had a defect resolution of 82.7% compared with 42.5% in the flap control group. There was a statistically significant difference between the two groups in all soft and hard tissue

measurements with the exception of attachment level, recession, and alveolar crest resorption. The authors concluded that the combination of Bio-Oss® and Bio-Gide® is effective in the treatment of mandibular class II furcations.

Belal *et al*. (2005) treated 50 furcations in 20 patients with five different approaches (bioresorbable membrane or a connective tissue graft with or without bioresorbable hydroxylapatite, and flap alone as a control therapy). All experimental groups showed statistically significant improvement in the clinical parameters and bone density as compared with the control group. However, no statistically significant differences were observed between any of the experimental groups. Percentages of complete furcation closure ranged from 20% to 40% in the experimental groups, but was 0% in the flap control group.

Root surface biomodification

The effect of combining citric acid root biomodification with GTR treatment was evaluated in two randomized controlled clinical trials in intrabony defects. The first investigation (Handelsman *et al*. 1991) demonstrated significant CAL gain in both the test (e-PTFE membranes + citric acid; 3.5 ± 1.6 mm) and control sites (e-PTFE membranes alone; 4.0 ± 1.4 mm). Less favorable results following these two treatment modalities were reported by Kersten *et al*. (1992) who found CAL gains of 1.0 ± 1.1 mm in the test group and of 0.7 ± 1.5 mm in the control group. Both studies, however, failed to demonstrate any added effect of the use of citric acid in combination with non-bioresorbable barrier membranes.

Root surface biomodification with tetracycline alone and in combination with GTR was evaluated in two controlled studies on class II furcations (Machtei *et al*. 1993; Parashis & Mitsis 1993). Both investigations failed to show significant differences between sites treated with non-bioresorbable barrier membranes alone or in combination with tetracycline root surface biomodification. Similarly, the use of other surface-active chemicals like EDTA also failed to provide a significant added effect to GTR treatment in humans (Lindhe & Cortellini 1996).

The suggested role of root surface biomodification for improving periodontal regeneration has been assessed in a systematic review (Mariotti 2003). The results of that exhaustive review of the evidence indicated that there was no evidence for a measurable improvement following root conditioning with agents like citric acid, tetracycline–HCl, phosphoric acid, fibronectin, or EDTA.

Clinical potential and limits for regeneration

From the very beginning of modern periodontal regeneration it was apparent that periodontal tissues could express a surprising regenerative potential under favorable circumstances. Sparse case reports demonstrated that very deep defects reaching the apical third of the root could be filled with new bone and new clinical attachment (Pini Prato *et al*. 1988; Becker *et al*. 1988; Cortellini *et al*. 1990). Larger studies suggested that in deeper defects, greater clinical improvement is generally obtained (Tonetti *et al*. 1993a, 1996a; Garrett *et al*. 1998; Slotte *et al*. 2007). These observations raised a question about the "potential" for regeneration: is the potential greater in deeper defects? Cortellini *et al*. (1998) addressed this question in a controlled study and reported similar attachment gain in defects presenting with an intrabony component of ≤3 mm (76% defect resolution) and defects of ≥4 mm (77% defect resolution), indicating that the potential for regeneration is similar in both shallow and deep intrabony components. The conclusions of this study are indirectly supported by the results of large controlled clinical trials performed with the application of different successful regenerative approaches (Cortellini *et al*. 1995c, 1996b, 2001; Tonetti *et al*. 1998, 2002, 2004b). Unpublished subanalyses of these experimental populations, in which the treated defects were clustered according to defect depth, showed that CAL gain is obtained in all defects from shallow to deep, but deeper defects gain more attachment in millimeters than shallow ones. In other words, regeneration seems to express its potential as much as the "container" allows it, independent of the "regenerative approach" chosen, within the panel of the well tested, sound regenerative approaches. A recent controlled study has challenged the limits of the periodontium to repair or regenerate (Cortellini *et al*. 2011). The aim of this randomized, long-term clinical trial was to compare clinical and patient-based outcomes following periodontal regeneration or extraction and replacement of hopeless teeth with attachment loss to or beyond the apex. Twenty-five hopeless teeth were treated with a regenerative strategy. Most of the treated teeth had a periodontal lesion exceeding the apex of the tooth and involving three to four sides of the root (Fig. 38-47). Twenty-three of the 25 regenerated teeth obtained extensive clinical improvements. The average CAL gain was 7.7 ± 2.8 mm, the radiographic bone gain 8.5 ± 3.1 mm, and the PPD reduction 8.8 ± 3 mm. Most of the regenerated teeth showed a decrease in tooth mobility. Only two teeth showing unsatisfactory outcomes were extracted at 1 year. The 23 successfully regenerated teeth (92%) were in good health and function at the 5-year follow-up visit and 84% did not develop biologic complications during the recall period. The authors concluded that regenerative therapy can be successfully applied even to hopeless teeth and has the potential to change their prognosis. However, it should be underlined that the reported outcomes were obtained in a carefully selected patient population, and by applying "state of the art" regenerative therapy by very experienced clinicians, within a high-quality program of periodontal and dental therapy

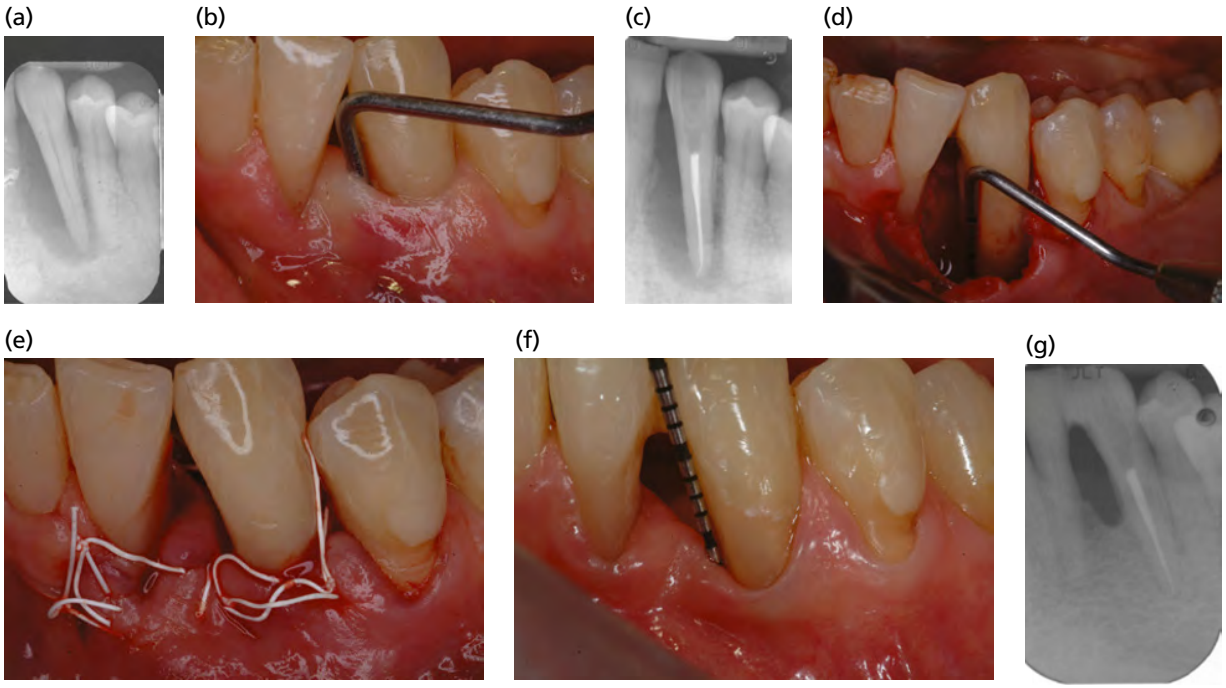

Fig. 38-47 Treatment of a very severe periodontal defect with periodontal regeneration. Baseline radiograph showed a very severe defect extending far beyond the apex of the tooth (a). A pocket deeper than 15 mm was evident at the mesial aspect of the lower left cuspid (b). The tooth was root canal treated (c). The area was accessed with a large flap: bone destruction almost all around is evident (d). The gingival flap was repositioned and sutured with a multilayer technique (e). At 1 year, a 4-mm pocket was probed (f). The radiograph showed the resolution of the periodontal defect (g).

and a strict periodontal supportive care program. In other words, it is apparent from the cited studies that to succeed in extreme conditions, a sound strategy has to be adopted.

A 10-year follow-up of the aforementioned RCT was recently published (Cortellini *et al*. 2020b). Three subjects in the test group exited the study due to extraction of the experimental tooth (two at year 1 for inadequate improvement following regeneration, and one at year 8 due to trauma on the experimental tooth). Four subjects (two in the test and two in the control groups) were lost to follow up after 6 and 7 years: three were unavailable to continue participation and one subject died for study unrelated reasons. The 10-year survival of regenerated teeth was 88% while the 10-year survival of implant or tooth retained fixed partial dentures to replace the extracted teeth was 100%. There was no statistically significant difference comparing test and control treatments ($P = 0.08$, Mantel–Cox log rank test). The 95% confidence interval for the complication free survival time was 6.7–9.1 years for the regeneration group and 7.3–9.1 years for the extraction and tooth replacement group. The difference was statistically not significant ($P = 0.788$, Mantel–Cox log rank test). Periodontal regeneration was more cost-effective than replacement. Sustained improvements in patient reported outcomes and quality of life measures were observed for both groups. The authors concluded that periodontal regeneration is the treatment of choice for compromised teeth with deep vertical intrabony defects.

Clinical strategies

Periodontal regeneration in intrabony defects has been successfully attempted with a variety of different approaches. As discussed, meta-analyses of randomized controlled clinical trials as well as human and animal histologic findings support the potential of barrier membranes (Nyman *et al*. 1982; Gottlow *et al*. 1986), DFDBAs (Bowers *et al*. 1989a–c), combinations of barrier membranes and grafts (Camelo *et al*. 1998; Mellonig 2000), and the use of EMDs (Mellonig 1999; Yukna & Mellonig 2000) or growth factors (Howell *et al*. 1997) to induce periodontal regeneration. Controlled clinical trials report that these approaches provide added benefits in terms of CAL gain as compared with OFD alone (Needleman *et al*. 2002; Trombelli *et al*. 2002; Giannobile & Somerman 2003; Murphy & Gunsolley 2003; Esposito *et al*. 2009; Needleman *et al*. 2006; Darby & Morris 2013). Comparisons between some of the regenerative approaches failed to demonstrate a clear superiority of any of the tested materials (Giannobile & Somerman 2003; Murphy & Gunsolley 2003; Reynolds *et al*. 2003).

The existing evidence, therefore, does not support any particular single regenerative approach. In addition, all the cited studies have shown a substantial degree of variability in terms of CAL gain, reporting failures or unsatisfactory outcomes in part of the treated population.

Research conducted mostly in the past decade has clearly established that the variability observed in outcomes of periodontal regenerative procedures is

dependent on a variety of patient-, defect-, and surgical-associated factors. This is not unexpected since each individual patient presents with unique characteristics as well as each defect presenting with very different and unique anatomies. The outcomes of the randomized studies indicates clearly that none of the regenerative approaches can solve all the different patient/defect presentations. It is therefore mandatory to build up a clinical decision tree that allows clinicians to apply the regenerative strategy most appropriate to each individual case.

While relevant patient factors include cigarette smoking, residual periodontal infection, and oral hygiene, factors associated with the morphology of the defect are consistently found to be of relevance to the final outcome (Tonetti *et al*. 1998; Cortellini *et al*. 2001). Interestingly, however, the number of residual bony walls defining the defect seems to impact the outcomes of different periodontal regenerative materials in a divergent way. Non-bioresorbable (e-PTFE and titanium-reinforced e-PTFE) barrier membranes and bioresorbable barriers supported by a graft do not seem to be affected by the number of residual bony walls of the defect (Tonetti *et al*. 1993a, 1996a, 2004b), while EMDs result in better outcomes in three-wall defects (Tonetti *et al*. 2002). Furthermore, healing following application of bioresorbable barriers and non-bioresorbable e-PTFE barriers as well as EMDs is associated with the radiographic width of the intrabony defect (Tonetti *et al*. 1993a; Falk *et al*. 1997; Tsitoura *et al*. 2004). No such association has been found for the use of a xenogenic BRGs and bioresorbable barrier combination (Tonetti *et al*. 2004b).

Among the technical/surgical factors, membrane exposure and contamination have been associated with poorer outcomes (Selvig *et al*. 1992; Nowzari & Slots 1994; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b). Similar problems were also encountered with bone grafting (Sanders *et al*. 1983). Poorer outcomes were also observed when the regenerated tissue was not properly protected with the flap on removal of non-bioresorbable barrier membranes (Tonetti *et al*. 1993a; Cortellini *et al*. 1995c).

A controlled clinical trial demonstrated that the combination of a PPF and titanium-reinforced e-PTFE membrane resulted in greater CAL gain as compared with a conventional flap approach with an e-PTFE membrane (Cortellini *et al*. 1995c). This evidence, also partly supported by a systematic review (Murphy & Gunsolley 2003), strongly suggests that optimization of the surgical approach and control of surgical variables, particularly in relation to flap design and management and selection of the regenerative material, could improve outcomes. In the context of periodontal regeneration, several flap designs aimed specifically at the full preservation of the soft tissues during access to the defect have been described (Cortellini *et al*. 1995c, d, 1996c, 1999a; Murphy 1996; Cortellini & Tonetti 2007a, 2009b). Experimental testing of these regenerative flaps showed great improvements in achieving primary closure during the surgical session, with optimal interdental closure being obtained in virtually all cases (Cortellini *et al*. 1995c, d, 1999a, 2001; Tonetti *et al*. 2004b). During the subsequent healing, however, dehiscence of the interdental tissue and membrane exposure was observed in up to a third of the cases. The ability to accomplish and maintain primary closure of the tissues over a GTR membrane was further improved by the use of a microsurgical approach that resulted in maintenance of primary wound closure in 92.3% of the treated sites for the whole healing period (Cortellini & Tonetti 2001, 2005, 2007a, b, 2009b, 2011).

This body of evidence has been utilized together with a degree of clinical experience to develop an "evidence-based regenerative strategy" to guide clinicians through a decision-making process aimed at the optimization of the clinical outcomes of periodontal regeneration in intrabony defects (Cortellini & Tonetti 2000a, 2005). Key steps of this process are the careful evaluation of the patient and of the defect, access to the defect with a PPF, choice of the most appropriate regenerative technology/material, and ability to seal the regenerating wound from the contaminated oral environment with optimal suturing techniques.

The performance of this clinical strategy has been assessed in a 40-patient consecutive case series (Cortellini & Tonetti 2005). Following completion of initial, cause-related periodontal therapy, subjects presented FMPSs of 10.2 ± 2.7% and full-mouth bleeding scores at baseline of 7.9 ± 2.8%. At the intrabony defects, CAL was 10.2 ± 2.4 mm and PPD 8.9 ± 1.8 mm. The radiographic defect angle was 29 ± 5.9°. CEJ–BD was 11.2 ± 2.7 mm and the intrabony component of the defects (INFRA) was 6.6 ± 1.7 mm. In this population, the SPPF could be used in 37.5% of sites, while the MPPT was selected in 45% of cases. The remaining sites, presenting with defects adjacent to edentulous areas, were accessed with a crestal incision.

Based on defect anatomy, non-bioresorbable titanium-reinforced e-PTFE barrier membranes were used in 30% of cases. In these cases, defect angles ranged from 27° to 42° (average 32.4 ± 4.3°), and eight of the 11 selected defects had a one-wall intrabony subcomponent of 1–3 mm (the average one-wall component of the 12 sites was 1.4 ± 1.2 mm). Ten of the 11 defects treated with bioresorbable membranes supported with a BRG presented a one-wall subcomponent of 1–5 mm (the average one-wall component of the 11 sites was 1.8 ± 1.3 mm); defect angles in this group ranged from 21° to 45° (average 31.4 ± 7°). Bioresorbable barriers alone were used in seven sites presenting with a prevalent two- and three-wall morphology and narrow defect angles, ranging from 20° to 28° (average 24.1 ± 3.7°). EMDs were applied to ten defects with a prevalent three-wall component. The defect angle in this group ranged from 19° to 31° (average 26.5 ± 4.3°).

Primary closure was obtained at completion of the surgical procedure for all treated sites. At the

1-week follow-up, when sutures were removed, two sites, both accessed with a SPPF, presented with a small interdental wound dehiscence: one had been treated with a bioresorbable membrane and BRG, the other with EMDs. At week 2, two additional small wound dehiscences were detected: one accessed with MPPT and treated with a bioresorbable membrane and BRG, the other accessed with SPPF and treated with a bioresorbable barrier alone. All the other sites (90%) remained closed during the entire early healing phase.

The 40 patients presented at the 1-year follow-up visit with excellent levels of plaque control and low levels of BoP. The 1-year CAL gain was 6 ± 1.8 mm (range 4–11 mm). No sites gained <4 mm of CAL; 77.5% gained ≥5 mm and 40% >6 mm. Residual PPDs were 2.7 ± 0.6 mm, with an average reduction of 6.1 ± 1.9 mm. Only four sites showed a residual PPD of 4 mm; all the other sites had a 1-year PPD of ≤3 mm. A minimal increase of 0.1 ± 0.7 mm in gingival recession between baseline and 1 year was recorded.

This study indicated that, whenever the treatment choice was made according to the protocol (i.e. based on: width of the interdental space to select the papilla preservation surgery; morphology of the defect to select the regenerative material; and choice of the material and local anatomy to select the suturing approach), all four approaches gave excellent results with CAL gains equal to 88–95% resolution of the original depth of the intrabony component of the defect (Cortellini & Tonetti 2005).

The CAL gain of 6 ± 1.8 mm at 1 year was obtained in defects with an intrabony component of 6.6 ± 1.7 mm. The percentage CAL gain therefore was 92.1 ± 12%. This indicates that a large part of the intrabony component of the defects was resolved. Using the Ellegaard criteria (Ellegaard & Loe 1971), resolution of the intrabony component of the defect was either satisfactory or complete in all treated cases. In particular, 40.5% of defects had CAL gains equal to or greater than the baseline depth of the intrabony component, while the defect with the worst response showed a 71.4% CAL gain. Historical comparison with clinical experiments using bone grafting or GTR clearly indicates that the results of this trial approach were in the top percentiles in terms of CAL gains and defect resolution (Cortellini & Tonetti 2000a; Rosen *et al*. 2000).

A novel, more comprehensive clinical strategy has been developed to further improve the clinical capacity to ensure appropriate therapy for each patient/defect. This approach takes into proper account the relevance of the patient characteristics, as described earlier in this chapter, and is based on the need to satisfy the three major contributors to periodontal regeneration: (1) space for the formation of the blood clot at the interface between the flap and root surface (Haney *et al*. 1993, Sigurdsson *et al*. 1994, Cortellini *et al*. 1995b, c; Tonetti *et al*. 1996a; Wikesjo *et al*. 2003; Kim *et al*. 2004); (2) stability of the blood clot to maintain a continuity with the root surface and thereby avoid the formation of a long junctional epithelium (Linghorne & O'Connel 1950; Hiatt *et al*. 1968; Wikesjo & Nilveus 1990; Haney *et al*. 1993); and (3) soft tissue protection of the treated area to avoid bacterial contamination (Selvig *et al*. 1992; Nowzari *et al*. 1995; De Sanctis *et al*. 1996a, b; Sanz *et al*. 2004; Polimeni *et al*. 2006). *Space* and *blood clot stability* are self-provided in the so-called "containing defects", particularly the narrow three-wall defects (Goldman & Cohen 1958; Schallhorn *et al*. 1970; Selvig *et al*. 1993; Cortellini & Tonetti 1999; Tsitoura *et al*. 2004; Linares *et al*. 2006). The "non-containing defects", the large one- or two-wall defects, require an intervention to supplement the deficient anatomy (Tonetti *et al*. 1993a, 1996a, 2002, 2004a, b; Falk *et al*. 1997). The intervention can be based on the use of biomaterials such as "exoskeleton"-like barriers or "endoskeleton"-like grafts that are able to support the soft tissues and to stabilize the blood clot, or a combination of the two approaches. In other words, the anatomic deficiencies of the defects have to be supplemented by the additional use of biomaterials. The same goal could be obtained by adopting different surgical strategies in which tissues are minimally elevated to increase their stability (the MIST and the M-MIST approaches) (Cortellini & Tonetti 2007a, b, 2009a, b). Blood clot stability is also clearly influenced by tooth hypermobility: splinting teeth with class II or III mobility is mandatory to avoid the disruption of the blood clot in the early healing phase (Cortellini *et al*. 2001; Trejo & Weltman 2004).

Protection of the regenerating area has to be provided with the adoption of specifically designed surgical approaches. The different surgical approaches differ in terms of flap design and suturing technique. In addition to their ability to provide protection to the regenerating area, they could differently contribute to improving one or more of the many aspects potentially relevant to the wound healing process. The traditional PPF (Cortellini *et al*. 1995a, 1999a) were designed as wide and very mobile flaps in order to allow for perfect visibility of the defect area, for easy placement of biomaterials, and for the coronal positioning of the buccal flap to cover barriers and biomaterials. In other words, PPF do not have the mechanical characteristics to improve wound stability or the capacity to independently create space for regeneration. The MIST (Cortellini & Tonetti 2007a, b), in contrast, was designed to reduce flap extension and mobility as much as possible to increase the capacity for primary wound closure and blood clot stability. This potential was illustrated in two studies that demonstrated the reduced impact of the number of residual bony walls and of the defect width on the outcomes obtained with EMDs under a MIST (Cortellini *et al*. 2008; Cortellini & Tonetti 2009a), and recently confirmed in a comparative study demonstrating similar outcomes between MIST alone and MIST plus EMDs (Ribeiro *et al*. 2011a).

A further development of the surgical approach was the M-MIST (Cortellini & Tonetti 2009b, 2011). This advanced flap design further enhanced the potential of the flap to provide space and stability for regeneration by leaving the interdental papillary soft tissues attached to the root surface of the crest-associated tooth and by avoiding any palatal flap elevation. The interdental soft tissues are the stable "ceiling" of a "room" into which blood flows and forms a clot. In addition, the hanging papilla prevents the collapse of the soft tissues, thereby maintaining space for regeneration: the anatomic bone deficiencies are potentially supplemented by the peculiar novel flap design that provides additional "soft tissue walls" in place of the missing bony walls and thus improves stability. The walls of the "room" are the residual bony walls, the root surface, and the buccal/lingual soft tissues. The minimal flap extension and elevation also reduces greatly the damage to the vascular system. It is clear that such a flap is not designed to allow the positioning of a barrier, but biologicals or grafts can easily be used with it.

Clinical flowcharts

Clinical flowcharts have been developed that take into account also the scientific contributions on surgical and postsurgical events, like chair time, side effects, and postoperative pain.

The step-by-step clinical approach to the treatment of intrabony defects includes two presurgical flow charts dealing with patient and local factors and four surgical flow charts (surgical nodes). The development of the surgical nodes was driven by the wish to treat any given defect with the procedure judged fastest, easiest, least burdened by side effects, and best tolerated by the patients. Lastly, postoperative care is suggested.

The step-by-step approach starts with control of patient-associated characteristics (see Fig. 38-10): low levels of plaque and residual infection, high levels of compliance, and absence of adverse conditions like smoking, stress, and uncontrolled diabetes or other systemic diseases have to be well established.

A few conditions, like endodontic condition, local contamination, and mobility of the involved tooth, must be controlled before surgery (Fig. 38-48). Endodontic diagnosis and eventual treatment should be performed well in advance of the regenerative approach (Cortellini & Tonetti 2001). Vital teeth should preferably be kept vital, with the only exception being a tooth whose apex is involved with the periodontal lesion (Cortellini *et al*. 2011). Non-vital teeth must be properly treated with root canal therapy. Existing root canal therapies should be carefully evaluated: improper treatments should be corrected. Local contamination of the defect-associated pocket should be as low as possible (Heitz-Mayfield *et al*. 2006). The presence of BoP (i.e. bacteria) should be controlled with additional gentle root planing and then the additional use of local antimicrobials (Tunkel *et al*. 2002; Hanes & Purvis 2003) a few weeks before regeneration (Cortellini *et al*. 2011). Teeth with mobility of class II or III should be splinted before or immediately after the surgical procedure (Cortellini *et al*. 2001; Trejo & Weltman 2004). Tooth hypermobility should be re-evaluated during the early healing phase: any detected increase in mobility should be taken care of.

The surgical access to the intrabony defects is selected from three different approaches: the SPPF (Cortellini *et al*. 1999a), the MPPT (Cortellini *et al*. 1995d), and the crestal incision (Cortellini & Tonetti 2000a) (Fig. 38-49). The SPPF is chosen whenever the width of the interdental space is 2 mm or less, as measured at the level of the supracrestal portion of the papilla. The MPPT is used at sites with an interdental width of >2 mm; the crestal incision is applied next to an edentulous area.

The next surgical step (Fig. 38-50) concerns the selection of the flap design. Whenever a defect involves one or two sides of a root and can be cleaned

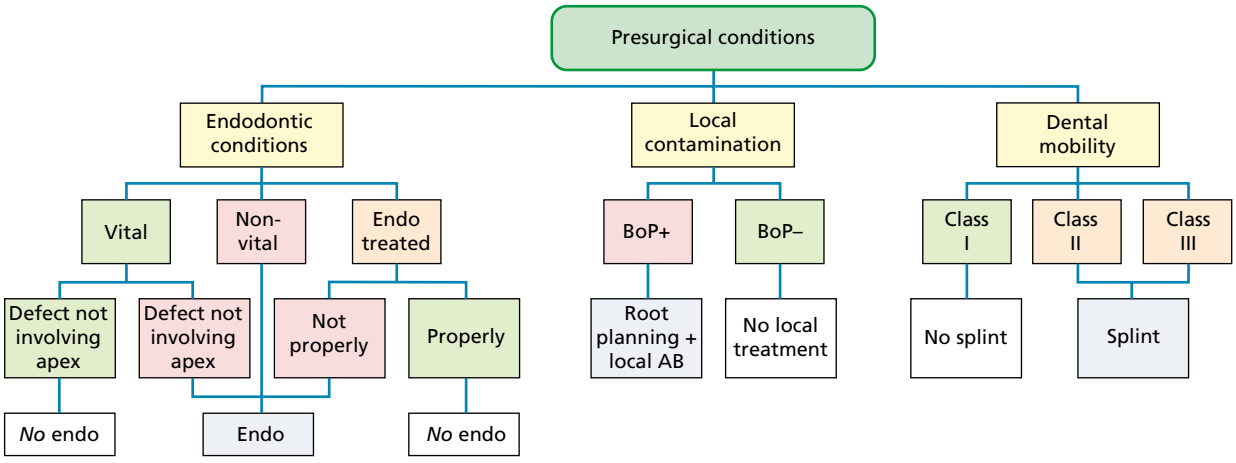

Fig. 38-48 Decision-making algorithm highlighting the clinical conditions to be checked before periodontal regeneration. These relate mainly to the endodontic status, presence of local contamination, and dental hypermobility of the tooth to be treated with periodontal regeneration. BoP, bleeding on probing; AB, antibiotic.

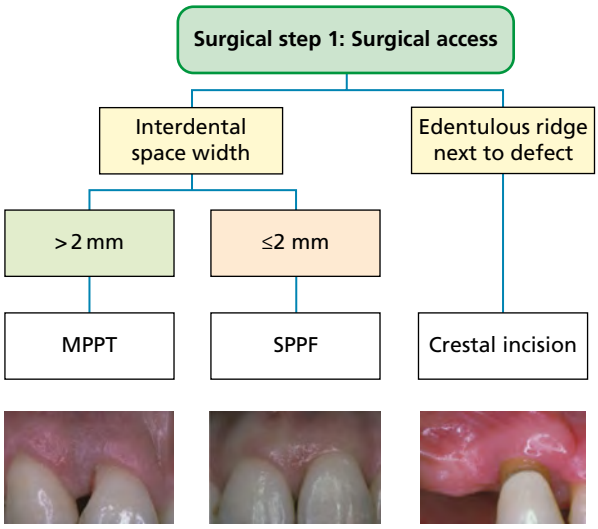

Fig. 38-49 Decision-making algorithm for obtaining access to an intrabony defect: the simplified papilla preservation flap (SPPF) is used for narrow interdental spaces (2 mm or narrower), while the modified papilla preservation technique (MPPT) is used to access defects associated with wider interdental spaces (3 mm or wider). Crestal incision is applied at a tooth neighboring an edentulous ridge.

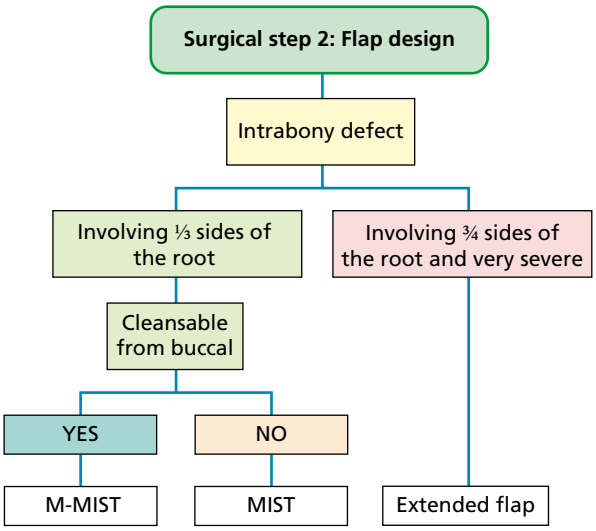

Fig. 38-50 Decision-making algorithm for choice of flap design. The type of surgical access from very small to very ample is chosen according to the severity and extension of the periodontal defect. MIST, minimally invasive surgical technique; M-MIST, modified minimally invasive surgical technique.

through a tiny buccal window, an M-MIST is applied (Cortellini & Tonetti 2009b, 2011). In some instances, the M-MIST can be applied to both the interdental spaces neighboring the defect-associated tooth, allowing for instrumentation of a defect involving up to three sides of a root. If the defect cannot be cleaned through the buccal window, the interdental papilla is elevated by applying a MIST approach (Cortellini & Tonetti 2007a; Cortellini *et al*. 2008). A large flap, extended to the neighboring teeth and including also an eventual periosteal incision and/or vertical releasing incisions, is chosen in the presence of a very severe and deep defect, involving three or four sides of the root, which requires ample visibility for instrumentation and the use of either endo- or exo-skeletons (Cortellini *et al*. 1995d, 1999a).

Step 1 and step 2 might follow a different path when the pocket is associated with a 2-wall intrabony with a missing buccal bony wall and without a consistent lingual/palatal involvement. In this instance, EPP might be the flap design of choice.

Selection of the regenerative material is based on the defect anatomy and on the flap design chosen to expose the defect (Fig. 38-51). If an M-MIST approach is applied, EMDs or no regenerative materials are the elective choices (Cortellini & Tonetti 2009b, 2011). If a MIST is applied, EMDs can be used alone in containing defects or in combination with a filler in non-containing defects (Cortellini & Tonetti 2007a; Cortellini *et al*. 2008; Ribeiro *et al*. 2011a). If a large flap is elevated, the area should be stabilized by applying barriers or fillers, or a combination of barriers and fillers, or a combination of EMDs/growth factors and fillers. EMDs alone

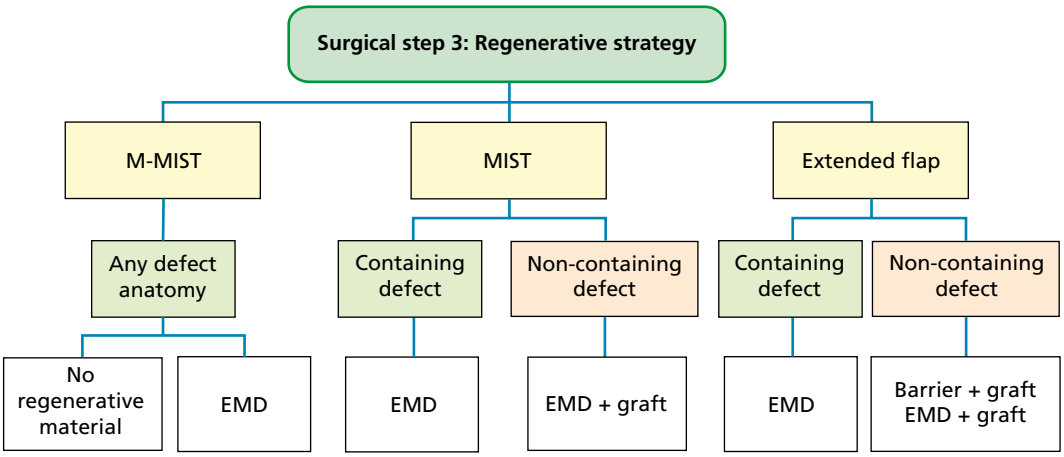

Fig. 38-51 Decision-making algorithm for choice of currently available technologies for application of regeneration in the treatment of intrabony defects. The clinical decision is based on two main parameters: (1) type of surgical access performed; (2) morphology of the periodontal defect. MIST, minimally invasive surgical technique; M-MIST, modified minimally invasive surgical technique; EMD, enamel matrix derivative.

are preferred in defects with a prevalent three-wall morphology or in well-supported two-wall defects.

The suturing approach is selected according to the type of regenerative strategy applied (Fig. 38-52). It will consist of a single internal modified mattress suture when an M-MIST or an MIST approach is chosen and EMDs alone are applied (Cortellini & Tonetti 2007a, 2009a, 2011; Cortellini *et al*. 2008). When a large flap with a periosteal incision is used in association with a barrier or a graft or a combination of these, the suturing approach will consist of two internal mattress sutures applied at the defect-associated interdental area to achieve primary closure of the papilla in the absence of any tension (Cortellini *et al*. 1995b, c, 1999a; Cortellini & Tonetti 2000a, 2005).

The surgical procedure is preferably performed with the aid of magnification such as loupes or an operating microscope (Cortellini & Tonetti 2001, 2005; Wachtel *et al*. 2003). Microsurgical instruments and materials should be utilized to complement the normal periodontal set.

Postsurgical and early home-care protocols are derived from the experiences gained from running many controlled clinical trials (Cortellini *et al*. 1995c, 1996b, 2001; Tonetti *et al*. 1998, 2002, 2004b). An empirical protocol for the control of bacterial contamination consisting of doxycycline (100 mg b.i.d. for 1 week), 0.12% chlorhexidine mouth rinsing t.i.d., and weekly prophylaxis is prescribed. Sutures are removed after 1 week. Patients are requested to avoid normal brushing, flossing, and chewing in the treated area for periods of 6–10 weeks. A postsurgical soft toothbrush soaked in chlorhexidine is adopted from week 1 to gently wipe the treated area. Nonbioresorbable membranes are removed after 6 weeks. Patients can resume full oral hygiene and chewing function in the treated area 2–4 weeks after membrane removal or when bioresorbable membranes are fully resorbed. Patients treated with EMDs can resume full oral hygiene after a period of 4–5 weeks. At the end of the "early healing phase", patients are placed in a 3-month recall system. A general suggestion to avoid any invasive clinical maneuver, like hard subgingival instrumentation, restorative dentistry, orthodontics, and additional surgery, for a period of about 9 months is also part of the strategy to optimize the clinical outcomes of periodontal regeneration.

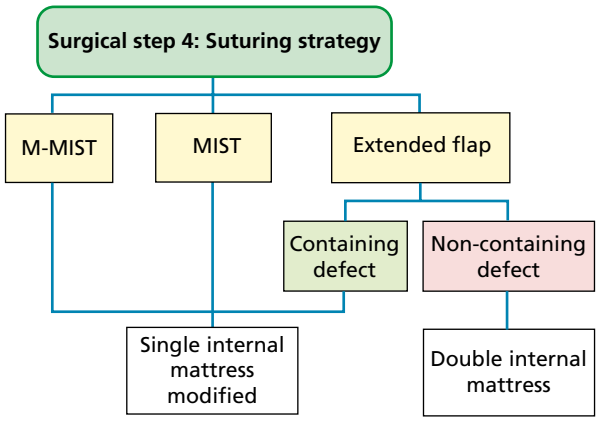

Fig. 38-52 Decision-making algorithm for the choice of suturing technique. MIST, minimally invasive surgical technique; M-MIST, modified minimally invasive surgical technique.

Conclusion

Periodontal regeneration has demonstrated significant clinical improvements in intrabony defects far beyond those achieved with debridement alone, with many different regenerative materials, including barrier membranes, grafts, active biologic compounds, and combinations of these. Different surgical approaches have been proposed and tested in combination with the various regenerative materials, but none has demonstrated a clear superiority over the others. Moreover, all of the proposed regenerative approaches have shown a high degree of clinical variability in terms of CAL gain: none has demonstrated the capacity to solve all the different and unique patient/defect presentations. Therefore, to treat a given defect, the regenerative strategy has to be chosen from a panel of options. The adoption of a clinical strategy for optimal application of materials and surgical approach could increase the efficacy of periodontal regeneration and give a clear advantage in terms of improved clinical outcomes. Periodontal regeneration expresses its potential in defects of any depth, from very shallow to very deep, and in extreme conditions can change the prognosis of teeth from hopeless to maintainable units.

Clinical outcomes obtained with periodontal regeneration can be maintained on a long-term basis, provided good oral hygiene and infection control within a stringent recall program are enforced. Current data indicate that, in patients participating in a supportive periodontal care program, 96% of teeth with severe intrabony defects and treated with a periodontal regenerative procedure could be retained for a period of up to 15 years.

Introduction

Mucogingival therapy is a general term used to describe periodontal treatments involving surgical procedures for the correction of defects in the morphology, position, and/or amount of soft tissue and underlying bone support at teeth and implants (American Academy of Periodontology 2001).

The term *mucogingival surgery* was introduced by Friedman (1957) and was defined as "surgical procedures designed to preserve gingiva, remove aberrant frenulum or muscle attachments, and increase the depth of the vestibule". The term "mucogingival surgery" at this time was used to describe all surgical procedures that involved both the gingiva and the alveolar mucosa. Consequently, not only were techniques designed to enhance the width of the gingiva and to correct particular soft tissue defects regarded as mucogingival procedures, but also pocket elimination approaches were too. In 1993, Miller proposed the term *periodontal plastic surgery*, considering that mucogingival surgery had moved beyond the traditional treatment of problems associated with gingival augmentation and root coverage procedures to also include correction of alveolar ridge deformities and soft tissue esthetics.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Embracing this concept, the American Academy of Periodontology defined periodontal plastic surgery as "surgical procedures performed to prevent or correct anatomic, developmental, traumatic or disease-induced defects of the gingiva, alveolar mucosa or bone" (Proceedings of the 1996 World Workshop in Periodontics 1996). In 2014, the 10th European Workshop in Periodontology redefined periodontal plastic surgery procedures as the surgical interventions aimed at modifying the position of the gingival margin and/or the amount and characteristics of marginal soft tissues, at teeth and dental implants (Tonetti & Jepsen 2014)

Among treatment procedures that may fall within this definition are various soft and hard tissue procedures aimed at:

- Gingival augmentation
- Root coverage
- Correction of mucosal defects at implants
- Crown lengthening
- Gingival preservation at ectopic tooth eruption
- Removal of aberrant frenulum.

The focus of this chapter, however, will be restricted to treatment procedures for corrections of soft tissue defects in relation to the tooth, while alveolar ridge augmentation procedures will be covered in Chapter 41 and treatment of the marginal soft tissues around dental implants in Chapter 45.

Mucogingival conditions

The 1999 AAP Workshop for the Classification of Periodontal Diseases and Conditions defined a number of mucogingival deformities and conditions around teeth (1. Gingival/soft tissue recession; 2. Lack of keratinized gingiva; 3. Decreased vestibular depth; 4. Aberrant frenum/muscle position; 5. Gingival excess and 6. Abnormal color). This 1999 classification was modified in the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions with additional information for more accurate case definitions, such as periodontal phenotype, recession severity, dimension of the residual gingiva, presence/absence of caries and non-carious cervical lesions, aesthetic concern of the patient, and presence of dentin hypersensitivity. The resulting list of mucogingival deformities and conditions around teeth is depicted in Table 39-1 (Cortellini & Bissada 2018).

Normal mucogingival conditions have been defined as any variation of individual anatomy and morphology where there is absence of pathosis (i.e. gingival recession, gingivitis, periodontitis). However, there will be conditions without obvious pathology in which the deviation from what is considered "normal" in the oral cavity lies outside of the range of individual variability. At the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions. two main case definitions of mucogingival conditions were defined (Jepsen *et al*. 2018):

Table 39-1 Mucogingival deformities and conditions around teeth. (Source: Cortellini & Bissada 2018. Reproduced with permission from John Wiley & Sons.)

1. Periodontal phenotype
   a. Thin scalloped
   b. Thick scalloped
   c. Thick flat
2. Gingival/soft tissue recession
   a. Facial or lingual surfaces
   b. Interproximal (papillary)
   c. Severity of recession (Cairo RT1, 2, 3)
   d. Gingival thickness
   e. Gingival width
   f. Presence of NCCL/cervical caries
   g. Patient aesthetic concern (Smile Esthetic Index)
   h. Presence of hypersensitivity
3. Lack of keratinized gingiva
4. Decreased vestibular depth
5. Aberrant frenum/muscle position
6. Gingival excess
   a. Pseudo-pocket
   b. Inconsistent gingival margin
   c. Excessive gingival display
   d. Gingival enlargement
7. Abnormal color

1. *Mucogingival condition without gingival recessions*. This case definition in the absence of gingival recession describes different conditions in relation to the gingival phenotype (gingival thickness [GT] and keratinized tissue [KT] width), either at the entire dentition, or at individual sites. Relevant features contributing to the description of this condition might be tooth position, aberrant frenum, or vestibular depth.
2. *Mucogingival condition with gingival recessions*. A case with gingival recession presents with an apical shift of the gingival margin apical to the cemento enamel junction (CEJ) resulting in exposure of the root surface. Relevant features contributing to the description of this condition are: (1) the interdental clinical attachment level, (2) the gingival phenotype (GT and KT width), (3) root surface condition (presence/absence of non-carious cervical lesion [NCCL] or caries), (4) detection of the CEJ, (5) tooth position, (6) aberrant frenum, and (7) number of adjacent recessions.

Some of these "mucogingival conditions and deformities" listed previously are not necessarily associated with the development of pathosis and in many individual cases they are associated with periodontal health. Therefore, the need for professional intervention must be assessed individually

Mucogingival condition without gingival recession

The term periodontal phenotype has been used in several dental disciplines (periodontal, orthodontic, restorative dentistry, etc.) to describe a series of anatomical characteristics including: (1) the gingival phenotype defined by the GT and the KT width; (2) the bone morphotype (BM) defined by the thickness of the labial bone plate; and (3) the tooth dimension.

A systematic review using these characteristics has classified the "phenotypes" in three categories (Zweers 2014):

- *Thin scalloped phenotype* in which there is an association with a slender triangular crown, subtle cervical convexity, interproximal contacts close to the incisal edge and a narrow zone of keratinized tissue, clear thin delicate gingiva, and a relatively thin alveolar bone.
- *Thick flat phenotype* associated with more square-shaped tooth crowns, pronounced cervical convexity, large interproximal contact located more apically, a broad zone of KT, thick, fibrotic gingiva, and a comparatively thick alveolar bone.
- *Thick scalloped phenotype* associated with a thick fibrotic gingiva, slender teeth, narrow zone of keratinized tissue, and a pronounced gingival scalloping.

The strongest association within the different parameters used to identify the different phenotypes has been found among GT, KTW, and BM.

GT is assessed by:

- *Transgingival probing* using fine endodontic files with stops and assessed by a gauge. Although this technique may have an accuracy to the nearest 0.5 mm it requires local anesthetic, thus increasing the patient discomfort.
- *Ultrasonic measurement*. Although it has also shown high accuracy in research environments (within 0.5–0.6 mm range) there are currently no validated devices for clinical use (Eger *et al*. 1996).
- *Probe visibility* after its placement in the buccal gingival sulcus. This method has shown a high reproducibility (De Rouck *et al*. 2009) mainly with the use of colour coded probes that will become visible through the gingiva when the thickness is ≤1 mm. Using this method GT has been defined as thin (≤1.0 mm) or thick (>1 mm).

KT width is easily measured with a periodontal probe positioned between the gingival margin and the mucogingival junction.

Bone thickness (BM) can be assessed through cone beam computed tomography, although the high radiation dosages needed preclude this diagnostic method for routine assessment of the patient's phenotype.

At the 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions the term "periodontal phenotype" was adopted instead of "biotype" (Jepsen *et al*. 2018) since the phenotype indicates a dimension that may change through time being determined not only by the gingival phenotype (gingival thickness, keratinized tissue width), and bone morphotype (thickness of the buccal bone plate), but also by the tooth position and therapeutic interventions.

Gingival dimensions and periodontal health

For many years the prevailing concept was that a narrow zone of gingiva (Fig. 39-1) was insufficient (1) to protect the periodontium from injury caused by friction forces encountered during mastication and (2) to dissipate the pull on the gingival margin created by the muscles of the adjacent alveolar mucosa (Friedman 1957; Ochsenbein 1960). Moreover, it was believed that an "inadequate" zone of gingiva would (1) facilitate subgingival plaque formation because of the improper pocket closure resulting from the movability of the marginal tissue (Friedman 1962) and (2) favor attachment loss and soft tissue recession because of less tissue resistance to apical spread of plaque-associated gingival lesions (Stern 1976; Ruben 1979). It was also considered that a narrow gingiva in combination with a shallow vestibular fornix might (1) favor the accumulation of food particles during mastication and (2) impede proper oral hygiene measures (Gottsegen 1954; Rosenberg 1960; Corn 1962; Carranza & Carraro 1970).

Fig. 39-1 Mandibular front tooth region. The gingiva on the buccal aspect of tooth 41 (arrow) has a narrow width and shows more pronounced signs of inflammation than adjacent gingival units with a wider zone of gingiva.

The opinions expressed concerning what could be regarded as being an "adequate" or "sufficient" dimension of the gingiva varied. While some authors suggested that ≥1 mm of gingiva may be sufficient (Bowers 1963), others claimed that the apicocoronal height of keratinized tissue ought to exceed 3 mm (Corn 1962). A third category of authors had a more biologic approach to the question and stated that an adequate amount of gingiva is any dimension that (1) is compatible with gingival health or (2) prevents retraction of the gingival margin during movements of the alveolar mucosa (Friedman 1962; De Trey & Bernimoulin 1980).

One of the first studies in which attempts were made to evaluate the significance of the gingival zone for the maintenance of periodontal health was carried out by Lang and Löe (1972) on dental students who had their teeth professionally cleaned once a day for 6 weeks. All buccal and lingual sites were examined for plaque, gingival conditions, and apicocoronal height of the gingiva. The results showed that despite the fact that the tooth surfaces were free from plaque, all sites with <2 mm of gingiva exhibited persisting clinical signs of inflammation. Based on this observation, the authors suggested that 2 mm of gingiva is an adequate width for maintaining gingival health. Subsequent clinical trials (Grevers 1977; Miyasato *et al*. 1977), however, failed to substantiate this concept of a required minimum dimension of gingiva. In fact, these clinical trials demonstrated that it is possible to maintain clinically healthy marginal tissues even in areas with <1 mm of gingiva.

The question whether a firmly attached portion of gingiva is critical for the protection of the periodontium was addressed by Wennström and Lindhe (1983a, b) utilizing the Beagle dog model. In these studies, dentogingival units with different clinical characteristics were experimentally established: (1) units with only a narrow and mobile zone of keratinized tissue and (2) units with a wide, firmly attached gingiva (Fig. 39-2).

With mechanical plaque-control measures performed daily, the gingival units could be maintained free from clinical as well as histologic signs of inflammation irrespective of the presence or absence of an attached portion of gingiva. When bacterial plaque was allowed to accumulate (for 40 days), clinical signs of inflammation (redness and swelling) developed that were more pronounced in tooth regions with mobile gingiva (Fig. 39-3b) than in areas with a wide and firmly attached gingival zone (Fig. 39-3a).

However, histologic analysis revealed that the size of the inflammatory cell infiltrate and its extension in an apical direction (an assessment which indirectly may be used as an estimate of the apical migration of the bacterial plaque) were similar in the two categories of dentogingival units. The finding that the clinical signs of gingival inflammation did not correspond with the size of the inflammatory cell infiltrate illustrates the difficulties inherent in the interpretation of data from clinical examinations made in areas with varying gingival widths. This should be kept in mind when interpreting the data from the human study by Lang and Löe (1972) showing that clinically visible signs of inflammation, such as redness and swelling, were more frequent in areas with <2 mm of gingiva than in areas with a wider zone of gingiva.

The necessity for and effectiveness of gingival augmentation in maintaining periodontal attachment was examined by Dorfman *et al*. (1980). Ninety-two patients with bilateral facial tooth surfaces exhibiting minimal keratinized tissue (i.e. <2 mm) had a free gingival graft placed on one side, while the contralateral side served as the untreated control. Prior to and after surgery the patients were subjected to scaling and root planing and instruction in oral hygiene measures. Not surprisingly, the investigators found a significant increase (approximately 4 mm) in the width of keratinized tissue at the grafted sites. This increased width of gingiva, as well as the clinical attachment level, was maintained throughout the 2 years of follow-up. In the control sites, the gingival width was <2 mm and did not vary significantly

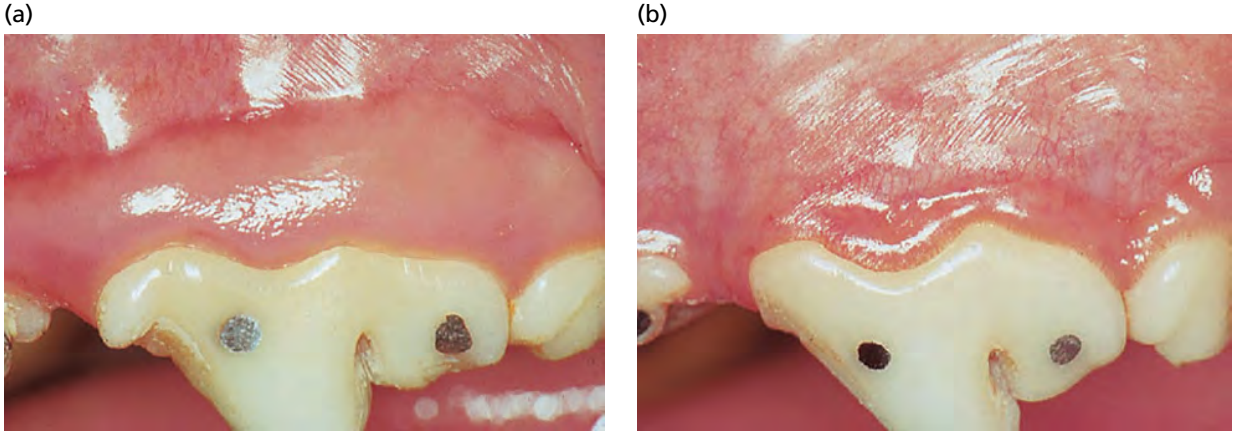

Fig. 39-2 Two teeth in a dog with varying dimensions of the marginal gingiva. (a) Buccal tooth site with a wide zone of attached gingiva. (b) Site with an unattached, narrow band of gingiva.

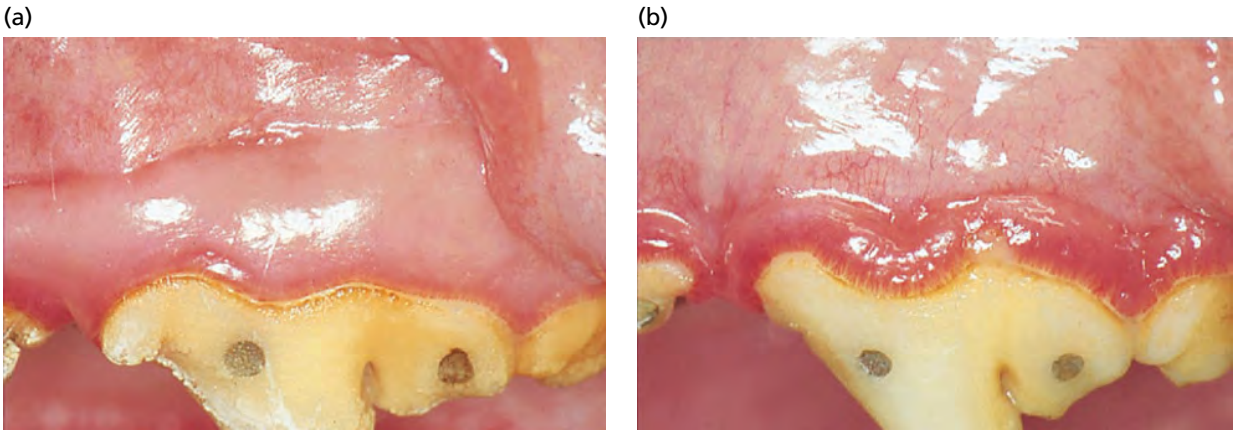

Fig. 39-3 Same teeth as in Fig. 39.2 after 40 days of plaque accumulation. The clinical signs of inflammation are more pronounced at the site with the narrow band of gingiva (b) than at the site with the wide zone of attached gingiva (a).

during the observation period. However, the attachment level was also maintained unchanged in the non-grafted areas. Thus, the resistance to continuous attachment loss was not linked to the height (width) of the gingiva, a conclusion that was further substantiated by subsequent 4- and 6-year follow-up reports of this patient material (Dorfman *et al*. 1982; Kennedy *et al*. 1985).

Further support for the conclusion that a minimal zone of gingiva may not compromise periodontal health is available from a number of other longitudinal clinical studies (e.g. De Trey & Bernimoulin 1980; Hangorsky & Bissada 1980; Lindhe & Nyman 1980; Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). Hence, Hangorsky and Bissada (1980), who evaluated the long-term clinical effect of free soft tissue grafts, concluded that while the free gingival graft is an effective method to widen the zone of the gingiva, there is no indication that this increase has direct influence upon periodontal health.

Conclusion: Gingival health can be maintained independent of its dimensions. Furthermore, there is evidence from both experimental and clinical studies that, in the presence of plaque, areas with a narrow zone of gingiva possess a similar degree of "resistance" to continuous attachment loss as areas with a wide zone of gingiva. Hence, the traditional dogma of the need for an "adequate" width (in millimeters) of gingiva, or an attached portion of gingiva, for prevention of attachment loss is not scientifically supported.

Gingival augmentation

The introduction of surgical procedures for gingival augmentation was based on the assumption that the presence of a wide band of keratinized and attached gingiva around the tooth was critical for maintaining gingival health and preventing attachment loss and soft tissue recession (Nabers 1954; Ochsenbein 1960; Friedman & Levine 1964; Hall 1981; Matter 1982).

Indications for gingival augmentation

Scientific data obtained from well-controlled clinical and experimental studies have unequivocally demonstrated that the apicocoronal width of gingiva and the presence of an attached portion of gingiva are not of decisive importance for the maintenance of gingival health and the height of the periodontal tissues. Consequently, the presence of a narrow zone of gingiva *per se* cannot justify surgical intervention (Lang & Karing 1994; Proceedings of the 1996 World Workshop in Periodontics 1996). However, gingival augmentation should be considered in situations where, for example, the patient experiences discomfort during toothbrushing and/or chewing due to interference from a lining mucosa at teeth or implants. Furthermore, when orthodontic tooth movement is planned and the final positioning of the tooth can be expected to result in an alveolar bone dehiscence, an increase of the *thickness* of the covering soft tissue may reduce the risk for development of soft tissue recession. An increase of the *thickness* of the gingiva may also be considered when subgingival restorations are placed in areas with a thin marginal tissue.

Gingival augmentation procedures

Gingival augmentation operations comprise a number of surgical techniques, the majority of which have been developed mainly on an empiric basis. The earliest of these techniques were the "vestibular extension operations", which were designed mainly with the objective of extending the vestibular depth (Bohannan 1962a, b). In recent years, however, pedicle or free soft tissue grafts have become the most commonly used techniques in the management of "insufficient" gingival dimensions, because of higher predictability of the healing result.

Vestibular/gingival extension procedures

The "denudation techniques" included the removal of all soft tissue within an area extending from the

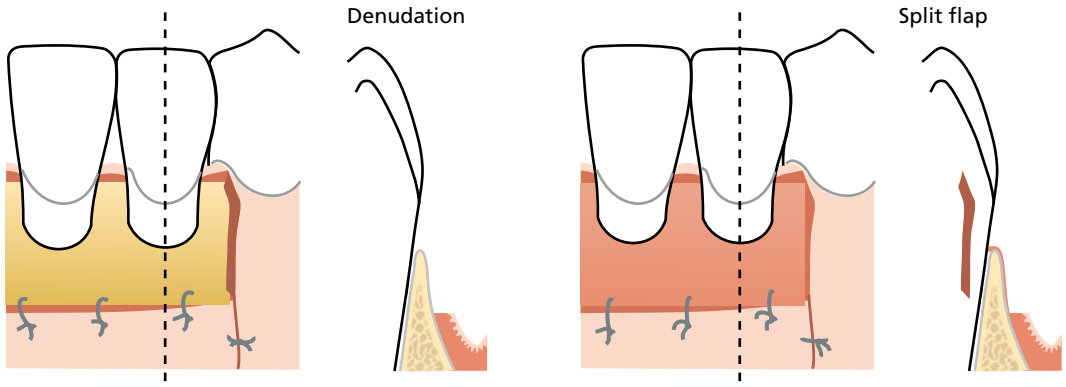

Fig. 39-4 Use of vestibular extension operations for increasing the width of the gingiva involves the production of a wound extending from the gingival margin to a level some millimeters apical to the mucogingival junction. With the "denudation" technique, all soft tissue is removed, leaving the alveolar bone exposed. With the "split flap" procedure, only the superficial portion of the oral mucosa is removed, leaving the bone covered with connective tissue. (Sources: Staffileno *et al*. 1963, 1966; Wilderman 1963; Pfeifer 1965. Reproduced with permission from John Wiley & Sons.)

gingival margin to a level apical to the mucogingival junction, leaving the alveolar bone completely exposed (Ochsenbein 1960; Corn 1962; Wilderman 1964) (Fig. 39-4). Healing following this type of treatment resulted often in an increased height of the gingival zone, although in some cases only a very limited effect was observed. However, the exposure of alveolar bone produced severe bone resorption with permanent loss of bone height (Wilderman *et al*. 1961; Costich & Ramfjord 1968). In addition, the recession of marginal gingiva in the surgical area often exceeded the gain of gingiva obtained in the apical portion of the wound (Carranza & Carraro 1963; Carraro *et al*. 1964). Due to these complications and severe postoperative pain for the patient, the use of the "denudation technique" can hardly be justified.

With the "periosteal retention" procedure or "split-flap" procedure (Fig. 39-4), only the superficial portion of the oral mucosa within the wound area was removed, leaving the bone covered by periosteum (Staffileno *et al*. 1962, 1966; Wilderman 1963; Pfeifer 1965). Although the preservation of the periosteum implies that less severe bone resorption will occur than following the "denudation technique", loss of crestal bone height was also observed following this type of operation unless a relatively thick layer of connective tissue was retained on the bone surface (Costich & Ramfjord 1968). If a thick layer was not secured, the periosteal connective tissue tended to undergo necrosis and the subsequent healing closely resembled that following the "denudation technique" described above.

These vestibular/gingival extension procedures were based on the assumption that it is the frictional forces during mastication that determine the presence of a keratinized tissue adjacent to the teeth (Orban 1957; Pfeifer 1963). Therefore, it was believed that by the displacement of muscle attachments and the extension of vestibular depth, the regenerating tissue in the surgical area would be subjected to physical impacts and adapt to the same functional requirements as those met by "normal" gingiva (Ivancie 1957; Bradley *et al*. 1959; Pfeifer 1963). Later studies, however, showed that the characteristic features of the gingiva are determined by inherent factors in the tissue rather than being the result of functional adaptation and that the differentiation (keratinization) of the gingival epithelium is controlled by morphogenetic stimuli from the underlying connective tissue (see Chapter 4).

Grafting procedures

The gingival and palatal soft tissues will maintain their original characteristics after transplantation to areas of the alveolar mucosa (see Chapter 4). Hence, the use of transplants offers the potential to predict the postsurgical result. The type of transplants used can be divided into (1) pedicle grafts, which maintain their connection to the donor site after placement at the recipient site (Fig. 39-5), and (2) free grafts that are completely deprived of their connection with the donor area (Fig. 39-6). For gingival augmentation, free grafts from the palate have been used most commonly (Haggerty 1966; Nabers 1966; Sullivan & Atkins 1968a; Hawley & Staffileno 1970; Edel 1974). As an alternative to the use of a mucosal graft from the palate, various allogenic graft materials, for example acellular freeze-dried dermal matrix (ADM) (Wei *et al*. 2000; Harris 2001) and human fibroblast-derived dermal substitute (McGuire & Nunn 2005) may be used, but the increase in the width of keratinized tissue following the use of these grafts may not be as predictable as with the use of autogenous grafts. Based on a systematic review of soft tissue augmentation techniques, Thoma *et al*. (2009) concluded that: (1) there is evidence for an increased width of keratinized tissue and attached gingiva following apically repositioned flap/vestibuloplasty; (2) the addition of an autogenous tissue graft significantly increases the width of attached gingiva; and (3) the use of allogenic grafts produces dimensional increases in keratinized tissue similar to those produced with autogenous tissue. More recently, collagen matrixes of porcine

(b) Frenulum is released, and a split flap of keratinized tissue is dissected from the area of the neighboring tooth, mobilized laterally and secured in position at the recipient site. (c) Healing result 1-year post-treatment shows the establishment of a broad zone of keratinized tissue without interfering frenulum.

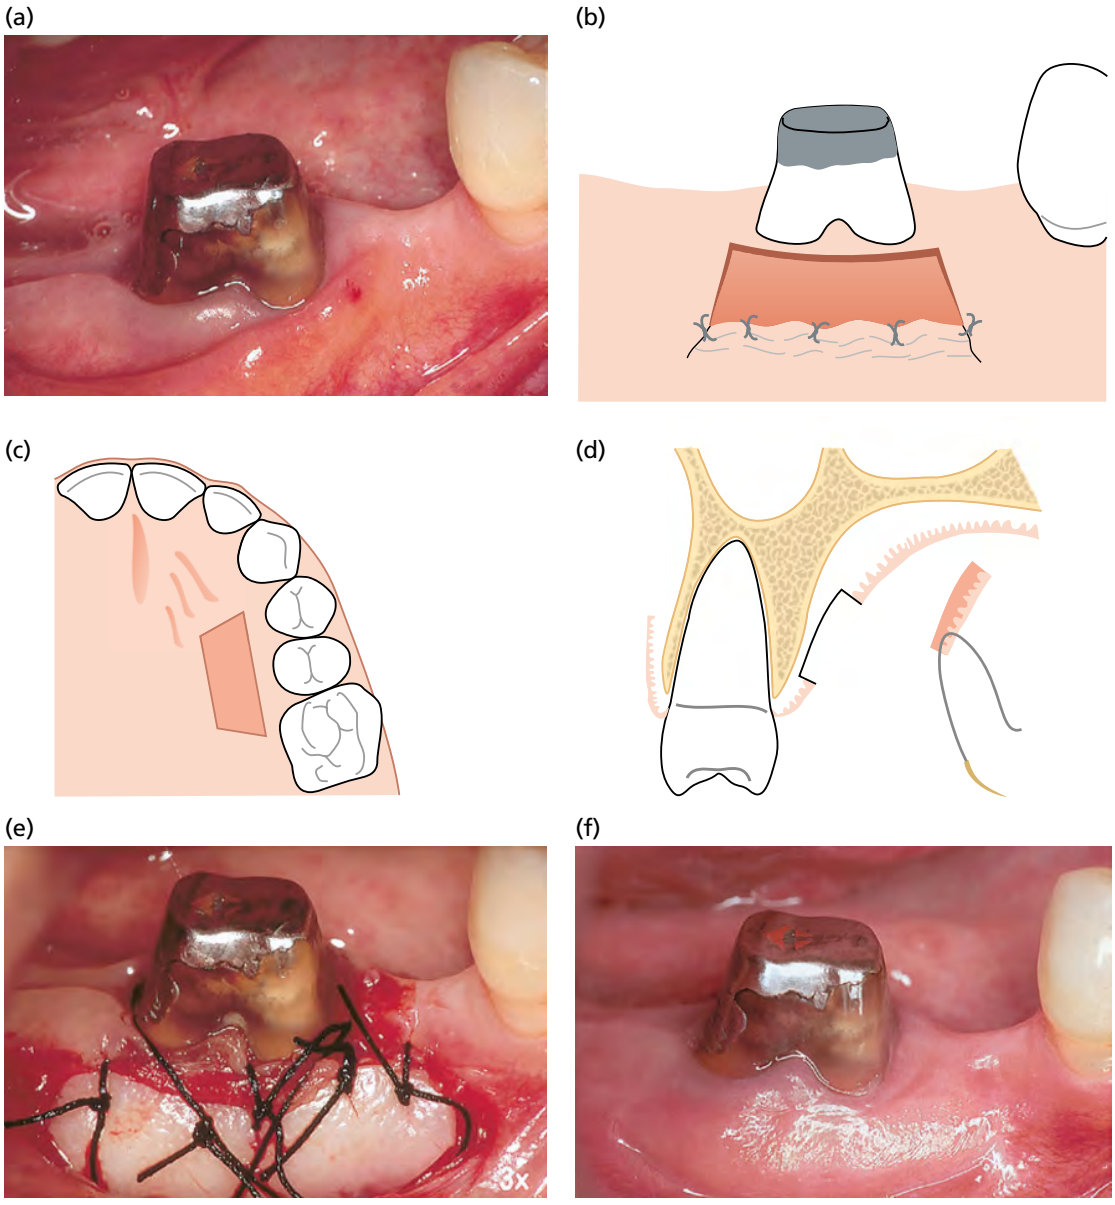

Fig. 39-6 Grafting procedure for gingival augmentation. (a) Lower molar at which the patient experiences discomfort during toothbrushing due to interfering lining mucosa and high attachment of a frenulum. The decision was made to displace the attachment of the frenulum apically and augment the gingival zone through the placement of a free graft. (b) Partial-thickness flap is dissected to prepare a recipient bed. The flap is displaced apically and sutured. (c, d) Graft with a thickness of 1.5–2 mm and of sufficient size and contour (a foil template of the recipient site may be used) is dissected from the palatal mucosa in the region of the premolars. (e) Graft is immediately transferred to the prepared recipient bed and anchored by sutures to secure a close adaptation of the graft to the recipient bed. (f) Following healing, a broad zone of keratinized tissue has been established. (Source: Courtesy of Professor Giampaolo Pini Prato.)

origin have shown to be as effective and predictable as the free autogenous connective tissue grafts (CTGs) in increasing the band of keratinized tissue at teeth and implants, but with significantly lower patient morbidity (Sanz *et al*. 2009; Nevins *et al*. 2011; Lorenzo *et al*. 2012). With the use of the alternative graft materials the preparation of the recipient site is similar to that using an autogenous graft.

Technique

1. The surgical procedure is initiated with the preparation of the recipient site (Fig. 39-6a, b). A periosteal bed free from muscle attachment and of sufficient size is prepared by sharp dissection. The partial-thickness flap is displaced apically and sutured.
2. In order to ensure that a graft of sufficient size and proper contour is removed from the donor area, the palatal mucosa in the region of the premolars is usually the region of choice. It is recommended to use a foil template of the recipient site, which is transferred to the donor site where it is outlined by a shallow incision (Fig. 39-6c). A graft with a thickness of approximately 1.5–2 mm is then dissected from the donor area (Fig. 39-6d).
3. The graft is immediately transferred to the prepared recipient bed and sutured (Fig. 39-6e). In order to immobilize the graft at the recipient site, the sutures must be placed in the periosteum or the adjacent attached gingiva. After suturing, pressure is exerted against the graft for 5 minutes in order to eliminate blood and exudate from between the graft and the recipient bed. The palatal wound may be protected with a palatal stent.
4. The sutures are removed after 1–2 weeks.

For a description of the pedicle graft procedure, see Root coverage procedures, later.

Healing following gingival augmentation procedures

Vestibular/gingival extension procedures

Since the specificity of the gingiva is determined by some inherent factor in the tissues, the postoperative results of vestibular extension procedures depend on the degree to which the various tissues contribute to the formation of granulation tissue in the wound area (Karring *et al*. 1975). Following the "denudation" or "split-flap technique", the wound area is filled with granulation tissue derived from the periodontal ligament, the tissue of the bone marrow spaces, the retained periosteal connective tissue, and the surrounding gingiva and lining mucosa (Fig. 39-7). The degree of bone resorption induced by the surgical trauma influences the relative amount of granulation tissue that grows into the wound from these various tissue sources. The resorption of crestal bone exposes varying amounts of the periodontal ligament tissue in the marginal area, allowing granulation tissue from the periodontal ligament to fill out the coronal portion of the wound. The greater the bone loss, the greater is the portion of the wound that becomes filled with granulation tissue from the periodontal ligament. This particular tissue possesses the capability to induce keratinization of the covering epithelium. This means that the widening of the keratinized tissue following "denudation" and "split flap" operations

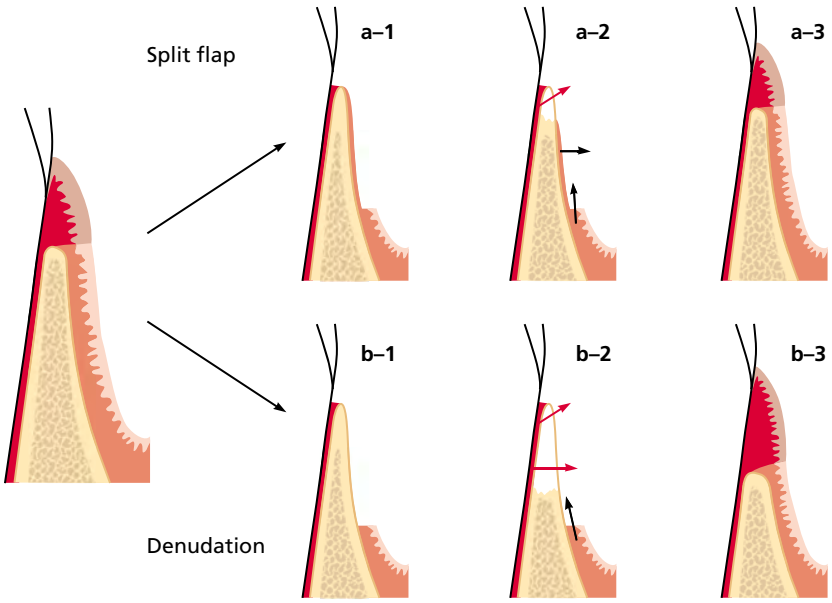

Fig. 39-7 The different stages of healing following the "split flap" (a) and "denudation" (b) techniques. Cells from the oral mucosa, bone, and periodontal ligament (arrows) participate in granulation tissue formation. Due to the difference in the degree of bone resorption (a-2, b-2), a larger area of the coronal portion of the wound is filled with granulation tissue from the periodontal ligament following "denudation" than following the "split flap" technique. Since granulation tissue from the periodontal ligament possesses the ability to induce a keratinized epithelium, "denudation" usually results in a wider zone of keratinized tissue than is the case following the "split flap" technique (a-3, b-3).

is achieved at the expense of a reduced bone height. The "denudation technique" usually results in more bone loss than the "split-flap technique". Therefore, a greater amount of granulation tissue with the capability of inducing a keratinized epithelium develops in the marginal area following the "denudation technique" than following the "split-flap technique". This is in accordance with the clinical observation that the "denudation technique" usually is superior to the "split-flap technique" in terms of increasing the width of keratinized tissue (Bohannan 1962a, b).

It can be concluded that the success or failure in extending the width of keratinized tissue by the "denudation" or "split-flap" techniques rests with the origin of the granulation tissue, which is related to the extent of bone loss induced by the surgical trauma. This in turn means that the result with respect to increasing the gingival width by methods involving periosteal exposure or denudation of the alveolar bone is unpredictable. The use of such methods is therefore not justified in periodontal therapy. The procedures discussed merely represent examples of how lack of knowledge about basic biologic principles may lead to the development of inappropriate therapeutic methods.

Grafting procedures

Healing of free soft tissue grafts placed entirely on a connective tissue recipient bed were studied in monkeys by Oliver *et al*. (1968) and Nobuto *et al*. (1988). According to these authors, healing can be divided into three phases (Fig. 39-8):

1. *Initial phase (from 0 to 3 days)*. During these first days of healing, a thin layer of exudate is present between the graft and the recipient bed. During this period the grafted tissue survives with an avascular "plasmatic circulation" from the recipient bed. Therefore, it is essential for the survival of the graft that a close contact is established to the underlying recipient bed at the time of operation. A thick layer of exudate or a blood clot may hamper the "plasmatic circulation" and result in rejection of the graft. The epithelium of the free graft degenerates early in the initial healing phase, and subsequently is desquamated. In placing a graft over a recession, part of the recipient bed will be the avascular root surface. Since the graft is dependent on the nature of its bed for diffusion of plasma and subsequent revascularization, the utilization of free grafts in the treatment of gingival

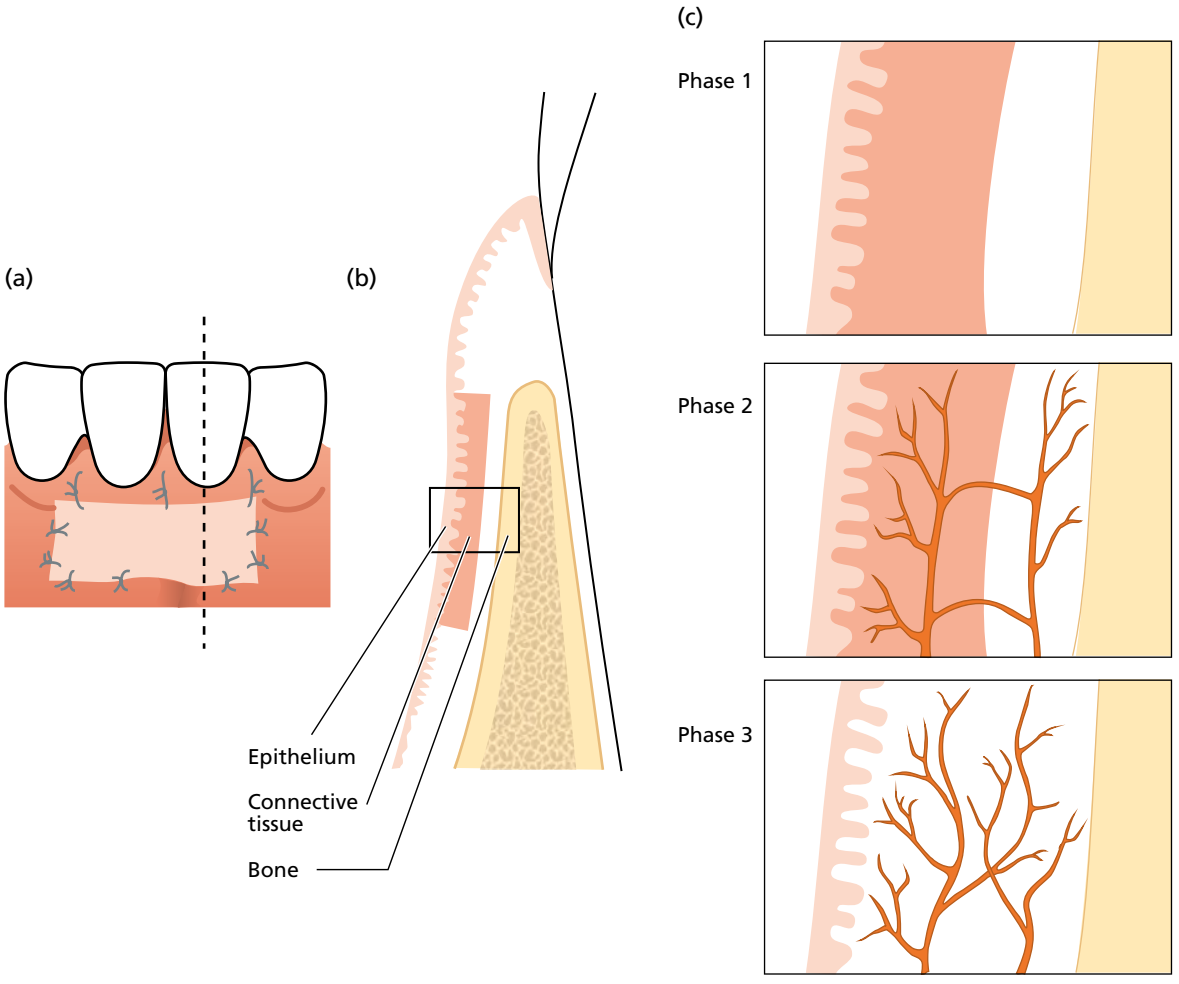

Fig. 39-8 Healing of a free gingival graft placed entirely on a connective tissue recipient bed (a). (b) Cross-section through the area. The framed areas (c) illustrate the three phases into which the healing process can be divided.

recessions involves a great risk of failure. The area of the graft over the avascular root surface must receive nutrients from the connective tissue bed that surrounds the recession. Thus, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area.

2. *Revascularization phase (from 2 to 11 days)*. After 4–5 days of healing, anastomoses are established between the blood vessels of the recipient bed and those in the grafted tissue. Thus, the circulation of blood is re-established in the pre-existing blood vessels of the graft. The subsequent time period is characterized by capillary proliferation, which gradually results in a dense network of blood vessels in the graft. At the same time, a fibrous union is established between the graft and the underlying connective tissue bed. The re-epithelialization of the graft occurs mainly by proliferation of epithelium from the adjacent tissues. If a free graft is placed over the denuded root surface, apical migration of epithelium along the tooth-facing surface of the graft may take place at this stage of healing.
3. *Tissue maturation phase (from 11 to 42 days)*. During this period, the number of blood vessels in the transplant is gradually reduced, and after approximately 14 days the vascular system of the graft appears normal. Also, the epithelium gradually matures with the formation of a keratin layer during this stage of healing.

The establishment and maintenance of a "plasmatic circulation" between the recipient bed and the graft during the initial phase of healing is critical in this kind of therapy. Therefore, in order to ensure ideal conditions for healing, blood between the graft and the recipient site must be removed by exerting pressure against the graft following suturing.

Mucogingival condition with gingival recessions

Gingival recession is defined as the apical shift of the gingival margin with respect to the CEJ. It is associated with attachment loss and with exposure of the root surface to the oral environment (Cortellini & Bissada 2018).

Gingival recessions are a common feature in populations with high standards of oral hygiene (e.g. Sangnes & Gjermo 1976; Murtomaa *et al*. 1987; Löe *et al*. 1992; Serino *et al*. 1994), as well as in populations with poor oral hygiene (e.g. Baelum *et al*. 1986; Yoneyama *et al*. 1988; Löe *et al*. 1992; Susin *et al*. 2004). In populations maintaining high standards of oral hygiene, loss of attachment and marginal tissue recession are predominantly found at buccal tooth surfaces (Löe *et al*. 1992; Serino *et al*. 1994) and are frequently associated with the presence of a "wedge-shaped defect in the crevicular area of one or several teeth" (Sangnes & Gjermo 1976) (Fig. 39-9). In contrast, all tooth surfaces are usually affected by soft tissue recession in periodontally untreated populations, although the prevalence and severity are more pronounced at single-rooted teeth than at molars (Löe *et al*. 1978; Miller *et al*. 1987; Yoneyama *et al*. 1988; Löe *et al*. 1992).

Fig. 39-9 Maxillary cuspid with gingival buccal buccal recessions illustrating the presence of a "wedge-shaped defect in the buccal tooth surface".

Although the etiology of localized gingival recessions remains unclear, several predisposing factors have been suggested.

Periodontal phenotype and attached gingiva

A thin periodontal phenotype, absence of attached gingiva, and reduced thickness of the alveolar bone due to abnormal tooth position in the arch have been considered risk factors for the development of gingival recession (Kim & Nieva 2015) (Fig. 39-10).

Cross-sectional studies have shown that a correlation exists between the presence of recession defects and the height (width) of the gingiva (e.g. Stoner & Mazdyasna 1980; Tenenbaum 1982), which has often been interpreted as evidence that a narrow zone of

Fig. 39-10 Mandibular tooth segment with multiple buccal recessions illustrating the association proposed between a thin phenotype and attachment loss

gingiva is a contributing factor in the development of soft tissue recessions (Fig. 39-9). It should be realized, however, that this data was derived from cross-sectional studies, which can neither prove nor disprove a cause–effect relationship. In fact, data obtained from prospective, longitudinal studies of patients showing areas with only a minimal zone of gingiva favor the conclusion that a certain quantity of gingiva is not essential for the prevention of soft tissue recessions. Lindhe and Nyman (1980) examined the alterations of the position of the gingival margin following periodontal surgery in 43 patients with advanced periodontal breakdown. Following active treatment, all patients were recalled once every 3–6 months for maintenance care. The position of the soft tissue margin in relation to the CEJ was assessed on the facial aspect of all teeth after initial healing and after 10–11 years of maintenance. The results showed that both in areas with and without visible keratinized tissue after healing, a small coronal regrowth (≈1 mm) of the soft tissue margin had occurred during the period of maintenance. In other words, no recession was observed in this group of patients maintained on a careful prophylaxis program.

Dorfman *et al*. (1982) reported a 4-year follow-up study including 22 patients with bilateral tooth areas exhibiting gingival recession and lack of firmly attached marginal soft tissue. In conjunction with scaling and root planing, a free gingival graft was placed on one side, while the contralateral control side was treated by scaling and root planing only. All patients were recalled for prophylaxis once every 3–6 months during a 4-year period. The data obtained from the examinations of the non-grafted control areas revealed that no further recession of the soft tissue margin or loss of probing attachment had occurred despite the lack of attached marginal tissue. In fact, there was a slight gain of probing attachment. The authors concluded that recession sites without attached gingiva might not experience further attachment loss and recession if the inflammation is controlled. In a subsequent report, Kennedy *et al*. (1985) presented data on 10 patients who had not participated in the maintenance program for a period of 5 years. In these patients, plaque and clinical signs of inflammation as well as some further recessions were noted at the 5-year examination as compared with the data obtained after termination of active treatment. However, except for the clinical signs of inflammation, which were more pronounced in non-grafted sites, no differences were observed between control sites with <1 mm or complete lack of attached gingiva and grafted sites.

The lack of relationship between the height of the gingiva and the development of soft tissue recession is further validated by results from longitudinal clinical studies (Schoo & van der Velden 1985; Kisch *et al*. 1986; Wennström 1987; Freedman *et al*. 1999). The prospective study by Wennström (1987) reported observations made at 26 buccal sites surgically deprived of all keratinized tissue. A baseline examination carried out 6 months after treatment revealed that these sites had regained a zone of gingiva which was, however, not attached or had only a minimal (<1 mm) portion attached to the underlying hard tissues (Figs. 39-11a, 39-12a). Adjacent teeth with a broad zone of attached gingiva were also included in the examinations. In most sites, the position of the soft tissue margin was maintained unchanged over 5 years (Figs. 39-11b, 39-12b).

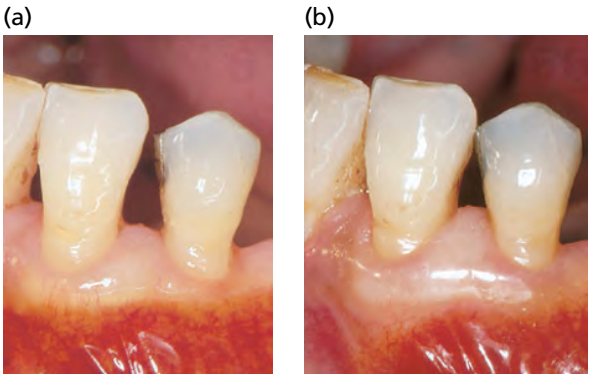

Fig. 39-11 (a) A canine and a first premolar in the mandibular jaw with <1 mm of attached portion of gingiva 6 months after surgical treatment. (b) Note the increase of the width of the gingiva at the facial aspect of the teeth and the more coronally positioned gingival margin 5 years later.

In conclusion, evidence from prospective longitudinal studies shows that the gingival height is not a critical factor for the prevention of marginal tissue recession, but that the development of a recession will result in loss of gingival height.

Recessions associated with mechanical factors, predominantly toothbrushing trauma

Traumatizing toothbrushing and tooth malposition are the factors that have been most frequently associated with marginal tissue recession (Sangnes 1976; Vekalahti 1989; Checchi *et al*. 1999; Daprile *et al*. 2007). Tissue trauma caused by vigorous or "improper" toothbrushing is considered a predominant causative

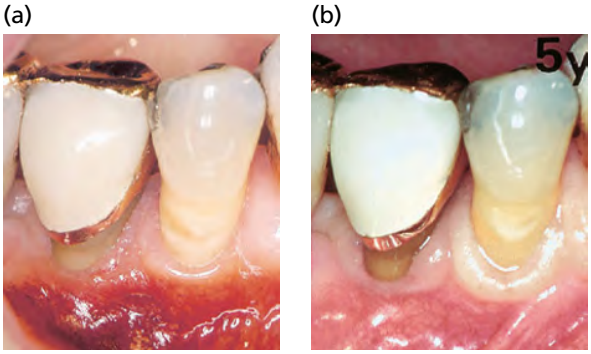

Fig. 39-12 (a) Mandibular canine and first premolar tooth region showing a very narrow zone of gingiva 6 months after surgical therapy. (b) No major change in the position of the soft tissue margin has occurred during a 5-year period despite the lack of attached gingiva.

factor for the development of recessions, particularly in young individuals. These recessions are often found at sites with clinically healthy gingiva and where the exposed root has a wedge-shaped defect, the surface of which is clean, smooth, and polished (Fig. 39-13).

Studies have reported that duration of toothbrushing, brushing force, frequency of changing the toothbrush, brush (bristle) hardness (Khocht *et al*. 1993), and tooth-brushing technique may be contributing factors. However, a a systematic review was not able to fully validate these hypotheses (Rajapakse *et al*. 2007). Among the 18 examined studies, one concluded that the toothbrushing significantly reduced recessions on facial tooth surfaces over 18 months, two concluded that there appeared to be no relationship between toothbrushing frequency and gingival recession, whereas eight studies reported a positive association between toothbrushing frequency and recession.

Recessions associated with localized plaque-induced inflammatory lesions

Other local factors that have been associated with marginal tissue recession are the presence of: (1) alveolar bone dehiscences (Bernimoulin & Curilovic 1977; Löst 1984), (2) high muscle attachment and frenum pull (Trott & Love 1966), (3) plaque and calculus (van Palenstein Helderman *et al*. 1998; Susin *et al*. 2004), and (4) iatrogenic factors related to restorative and periodontal treatment procedures (Lindhe & Nyman 1980; Valderhaug 1980).

Fig. 39-13 Recessions associated with toothbrushing trauma. The marginal gingiva is clinically healthy, and an abrasion wedge-shaped defect can be noted in the exposed root.

Fig. 39-14 Recession associated with a localized plaque-induced inflammatory lesion.

Such recessions may be found at teeth that are prominently positioned, where the alveolar bone is thin or absent (bone dehiscence), and where in addition the gingival tissue is thin (delicate) (Fig. 39-14). An inflammatory lesion that develops in response to subgingival plaque occupies the connective tissue adjacent to the dentogingival epithelium. Measurements made by Waerhaug (1952) suggest that the distance between the periphery of microbial plaque on the tooth surface and the lateral and apical extension of the inflammatory cell infiltrate seldom exceeds 1–2 mm. Thus, if the free gingiva is voluminous, the infiltrate will occupy only a small portion of the connective tissue. In a thin and delicate gingiva, on the other hand, the entire connective tissue portion may be engaged. Proliferation of epithelial cells from the oral as well as the dentogingival epithelium into the thin and degraded connective tissue may bring about a subsidence of the epithelial surface, which clinically becomes manifest as recession of the tissue margin (Baker & Seymour 1976).

Recessions associated with cervical restorative margins

A systematic review (Kim & Nieva 2015) reported clinical observations suggesting that sites with minimal or no gingiva associated with intrasulcular restorative margins were more prone to gingival recession and inflammation. However, these conclusions were based mainly on clinical observations (low level of evidence).

The placement of restoration margins subgingivally may not only create a direct operative trauma to the tissues (Donaldson 1974), but may also facilitate subgingival plaque accumulation, with resultant inflammatory alterations in the adjacent gingiva and recession of the soft tissue margin (Parma-Benfenati *et al*. 1985; Lang 1995; Günay *et al*. 2000). Over a 10-year period, Valderhaug (1980) evaluated longitudinally the soft tissue alterations taking place at facial sites of 286 teeth with subgingivally or supragingivally placed crown margins in 82 patients. The re-examination performed 1 year after insertion of the

restorations revealed that the gingivae at teeth with subgingival restoration margins were more commonly inflamed than at those with supragingivally placed borders. Of the 150 teeth which had the facial crown margin located subgingivally at the time of cementation, 40% already showed supragingival exposure of the crown margin after 1 year, and at the 10-year examination as many as 71% had become supragingivally positioned due to recession of the soft tissue margin. Compared with teeth with supragingivally placed crown margins, the amount of recession and clinical attachment loss was greater at sites with subgingivally placed restoration margins.

Stetler and Bissada (1987) evaluated the periodontal conditions at teeth with subgingivally placed restoration margins and showed that in subgingivally placed restorations with plaque accumulation, if the adjacent gingiva was thin, there was a potential risk for the development of soft tissue recession. Accordingly, if recession is to be prevented, either the plaque-control standard has to be improved or the *thickness* of the gingival margin has to be increased.

Recessions associated with orthodontic treatments

Results from clinical and experimental research have documented that most forms of orthodontic therapy are innocuous to the periodontium (see Chapter 47). The clinician may observe, however, that some patients respond to frontal movements of incisors and lateral movements of posterior teeth by gingival recession and loss of attachment (Maynard & Ochsenbein 1975; Coatoam *et al*. 1981; Foushee *et al*. 1985) (Fig. 39-12). In fact, a systematic review (Kim & Nieva 2015) has reported that the direction of the orthodontic tooth movement and the bucco-lingual thickness of the gingiva may contribute to marginal gingival recession during orthodontic treatment. The reported prevalence of gingival recessions at the end of orthodontic treatment ranges between 5% and 12%, although authors have reported an increase of the prevalence up to 47% in long-term observation (5 years) (Renkema et al 2015). Based on these clinical observations it has been suggested that a grafting procedure to increase the gingival dimensions should precede the initiation of orthodontic therapy in such areas (Boyd 1978; Hall 1981; Maynard 1987).

As discussed previously, the presence of an alveolar bone dehiscence is a prerequisite for the development of a marginal tissue recession, since this dehiscence may establish an environment that is conducive for loss of gingival tissue. With respect to orthodontic therapy, this would imply that as long as a tooth is moved exclusively within the alveolar bone, soft tissue recession will not develop (Wennström *et al*. 1987). On the other hand, predisposing alveolar bone dehiscences may be induced by uncontrolled facial expansion of a tooth through the cortical plate, thereby rendering the tooth liable to the development of soft tissue recession. In this context it is interesting to note that experimental studies have shown that labial bone will reform in the area of a dehiscence when the tooth is retracted towards a proper positioning of the root within the alveolar process (Engelking & Zachrisson 1982; Karring *et al*. 1982) (Fig. 39-15). It is therefore likely that the reduction in recession seen at a previously prominently positioned tooth that has

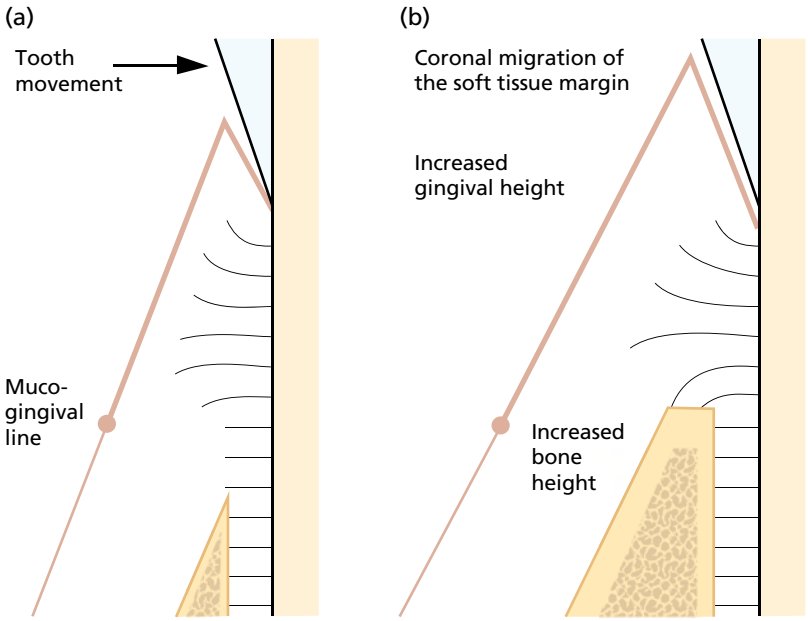

Fig. 39-15 (a) Alterations occurring in the marginal periodontal tissues following lingual movement of a tooth prominently positioned in the arch and having a bone dehiscence. (b) An increase in bone height and gingival height will be seen as well as a coronal migration of the soft tissue margin following lingual positioning of the tooth. (Sources: Engelking & Zachrisson 1982; Karring et al. 1982. Reproduced with permission from John Wiley & Sons.)

been moved into a more proper position within the alveolar process (Fig. 39-16) is also accompanied by bone formation.

Alterations occurring in gingival dimensions and marginal tissue position in conjunction with orthodontic therapy are related to the *direction of tooth movement*. Facial movement results in reduced facial gingival dimensions, while an increase is observed following lingual movement (Coatoam *et al*. 1981; Andlin-Sobocki & Bodin 1993). Recession of the labial gingival margin and loss of attachment were demonstrated in experimental studies in the monkey following either tipping and extrusion movements or bodily movements of incisors (Batenhorst *et al*. 1974; Steiner *et al*. 1981). However, similarly designed studies carried out in dogs (Karring *et al*. 1982; Nyman *et al*. 1982) and humans (Rateitschak *et al*. 1968) failed to demonstrate that labial tooth movement is accompanied by marginal tissue recession and attachment loss. The conflicting results may be related to differences with respect to, for example, (1) the amount of labial tooth displacement, (2) the presence/absence of plaque and gingival inflammation in the regions subjected to tooth movement, and/or (3) differences in gingival dimensions. Wennström *et al*. (1987) experimentally moved teeth orthodontically into areas with varying thickness and quality of the marginal soft tissue. Following extensive bodily movement of incisors in a labial direction through the alveolar bone, most teeth showed a small apical displacement of the soft tissue margin but no loss of connective tissue attachment (Fig. 39-17).

In other words, the apical displacement of the gingival margin was the result of a reduced height of the free gingiva (Fig. 39-18), which in turn may be related to tension ("stretching") in the soft tissues during the facial tooth movement and reduced buccolingual tissue thickness. Similar to results presented by Foushee *et al*. (1985) from a study in humans, no relationship was found between the initial apicocoronal width (height) of the gingiva and the degree of apical displacement of the soft tissue margin during orthodontic therapy. Thus, the findings do not lend support to the concept of a certain zone of gingiva as essential

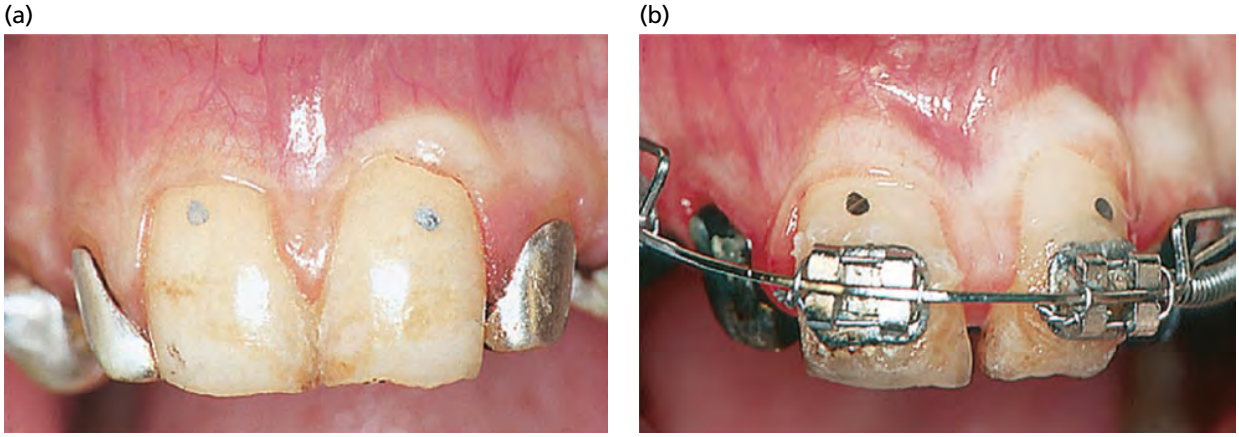

Fig. 39-17 Buccal aspect of the central incisors before (a) and after (b) the labial tooth movement. No obvious change in the location of the gingival margin has occurred despite the pronounced labial displacement of the incisors.

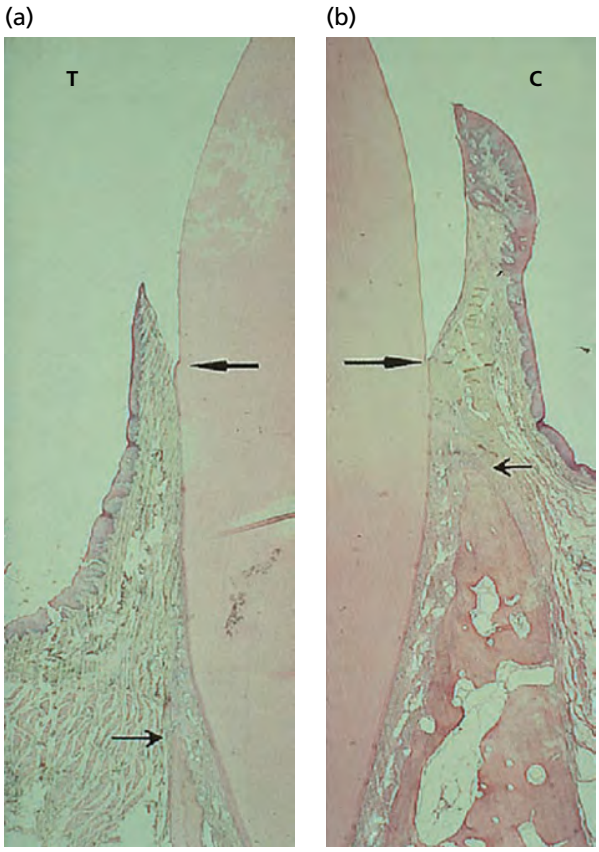

Fig. 39-18 Histologic specimens showing (a) reduced alveolar bone height at an incisor bodily moved in the labial direction and (b) normal alveolar bone height at a non-moved control tooth. Note the maintained level of connective tissue attachment and the reduced height of the free gingiva at the labially displaced incisor (a). Large arrows indicate the position of the cementoenamel junction and small arrows the position of the alveolar bone crest.

for the prevention of recession during orthodontic therapy, but rather corroborate observations reported by Coatoam *et al*. (1981) that the integrity of the periodontium can also be maintained during orthodontic therapy in areas which have only a minimal zone of gingiva.

In the experimental studies by Steiner *et al*. (1981) and Wennström *et al*. (1987), it was observed that teeth experiencing loss of connective tissue attachment when orthodontically moved facially showed obvious clinical signs of inflammation throughout the experimental period. Since it has been demonstrated that, in the presence of plaque-induced suprabony lesions, orthodontic forces generating bodily tooth movement are not capable of causing accelerated destruction of the connective tissue attachment (Ericsson *et al*. 1978), a decreased buccolingual dimension of the border tissue due to "stretching" of the facial gingiva may have favored the destructive effect of the plaque-associated inflammatory lesion. This assumption is validated by the observations that, in the presence of plaque-induced gingivitis, a thin marginal soft tissue is more susceptible to complete breakdown than a thick one (Baker & Seymour 1976). Furthermore, no difference in attachment loss was observed at plaque-infected teeth that were bodily moved *within the alveolar bone*, irrespective of the type of bordering soft tissue (gingiva or lining mucosa) (Wennström *et al*. 1987). Hence, the *thickness rather than the quality* of the marginal soft tissue on the pressure side of the tooth is the determining factor for the development of the recession. This interpretation is supported by findings of clinical studies in humans analyzing factors of importance for the development of recessions during labial movement of mandibular incisors. Melsen and Allais (2005) found that gingival inflammation and a "thin gingival biotype" were significant predictors for gingival recession, and Yared *et al*. (2006) reported that 93% of the teeth that developed recession had a gingival thickness of <0.5 mm. Hence, the observations made in the studies discussed strongly emphasize the importance of adequate infection control during orthodontic treatment.

Conclusion: The clinical implication of the results from the studies discussed is that labial tooth movement should be preceded by careful examination of the dimensions of the tissues covering the facial aspect of the teeth to be moved. As long as a tooth can be moved within the envelope of the alveolar process, the risk of harmful side effects on the marginal tissue is minimal, irrespective of the dimensions and quality of the soft tissue surrounding the tooth. If, however, the tooth movement is expected to result in the establishment of an alveolar bone dehiscence, the volume (thickness) of the covering soft tissue should be considered as a factor that may influence the development of soft tissue recession during, as well as after, the phase of active orthodontic therapy. A thin phenotype may serve as a *locus minorus resistentia* to developing soft tissue defects in the presence of plaque-induced inflammation or toothbrushing trauma.

Recessions associated with generalized forms of destructive periodontal disease

The loss of periodontal support at proximal sites may result in compensatory remodeling of the support at the buccal/lingual aspect of the teeth, leading to an apical shift of the soft tissue margin (Serino *et al*. 1994). In addition, apical displacement of the soft tissue margin is an inevitable consequence of the resolution of periodontal lesions following treatment and is independent of a non-surgical or a surgical treatment approach (Fig. 39-19).

Diagnosis of gingival recessions

Miller (1985a) described a classification of recession defects taking into consideration the anticipated root coverage that it is possible to obtain with the use of grafting techniques (Fig. 39-20);

Fig. 39-19 Recessions associated with generalized forms of destructive periodontal disease. Recession of the soft tissue is found not only at the facial aspect of the teeth but also at proximal sites.

- *Class I*: marginal tissue recession not extending to the mucogingival junction; no loss of interdental bone or soft tissue
- *Class II*: marginal tissue recession extending to or beyond the mucogingival junction; no loss of interdental bone or soft tissue
- *Class III*: marginal tissue recession extending to or beyond the mucogingival junction; loss of interdental bone/soft tissue or malpositioning of the tooth
- *Class IV*: marginal tissue recession extending to or beyond the mucogingival junction; severe loss of interdental bone/soft tissue or severe malpositioning of the tooth.

While complete root coverage (CRC) was considered achievable in class I and II defects, only partial coverage could be expected in class III and IV recession defects. While there seems to be no reason to differentiate between class I and II recession defects, the critical clinical variable to determine the possible outcome of a root coverage procedure was the level of periodontal tissue support at the proximal sites of the tooth.

The recent 2017 World Workshop on the Classification of Periodontal and Peri-Implant Diseases and Conditions has adopted a classification of gingival recessions (Jepsen *et al*. 2018) based on the dimension of the buccal/lingual gingival recession in relation to the interdental clinical attachment loss (Cairo *et al*. 2011) (Fig. 39-21):

- *Recession Type 1 (RT1)*: Gingival recession with no loss of interproximal attachment. Interproximal CEJ is clinically not detectable at both mesial and distal aspects of the tooth.

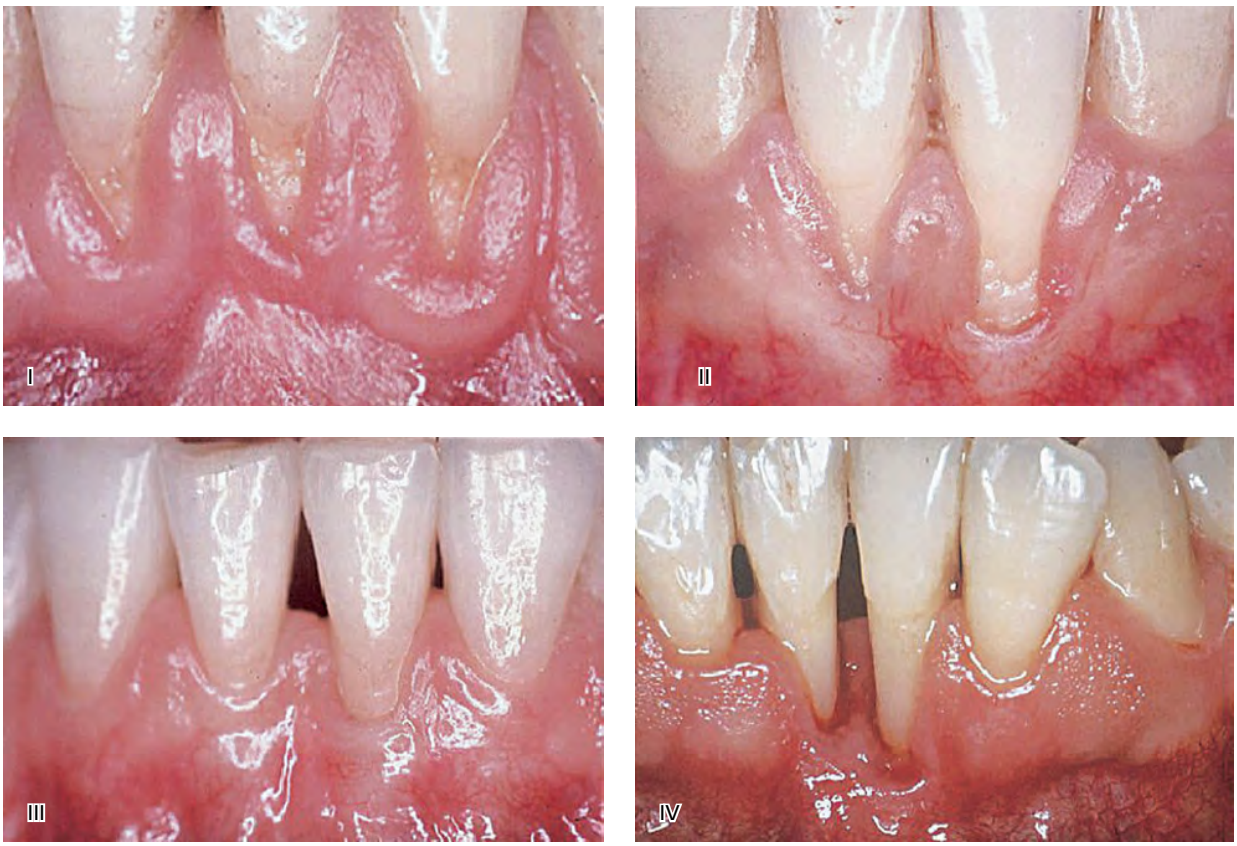

Fig. 39-20 Miller classification of recession defects (see text). (Source: Courtesy of Professor Giampaolo Pini Prato.)

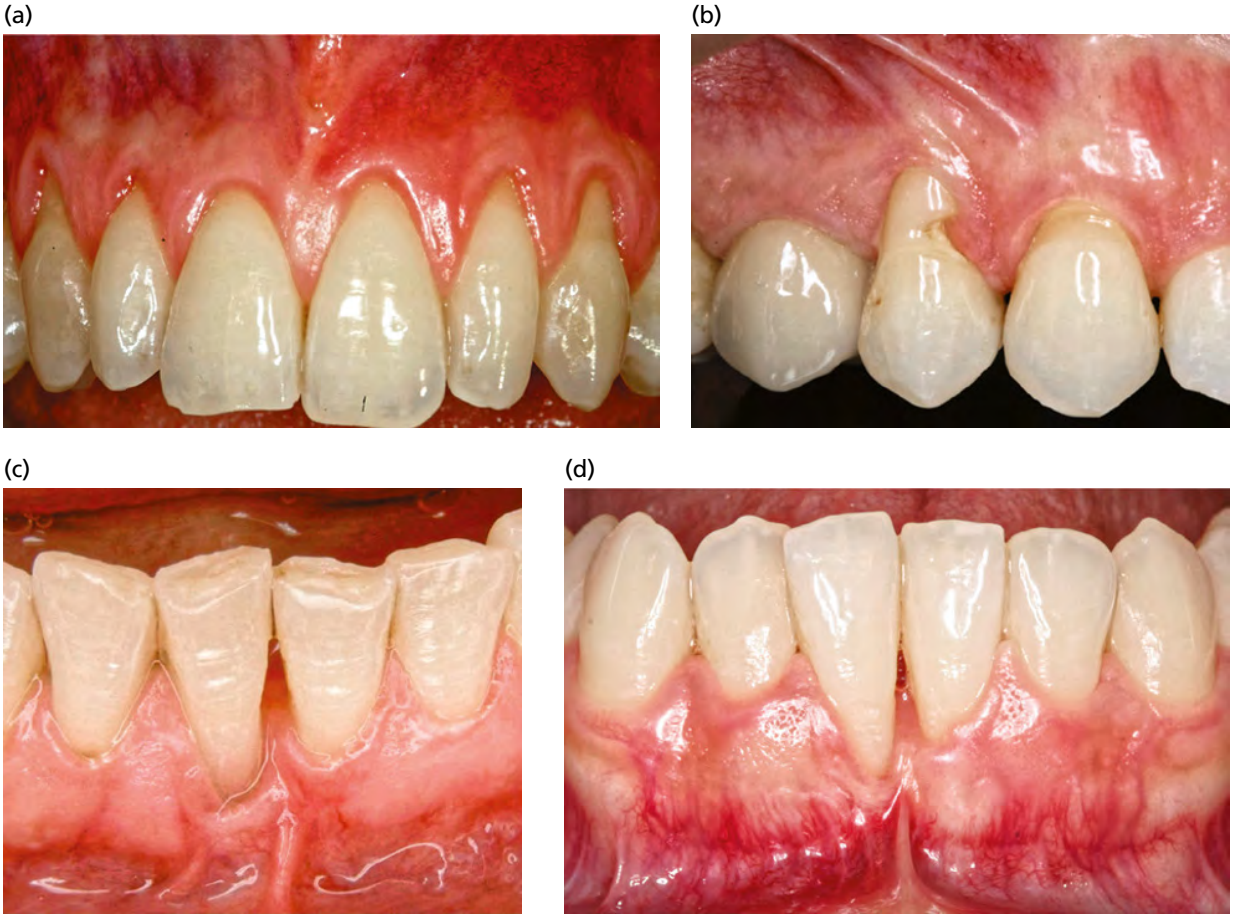

Fig. 39-21 Cairo classification of recession defects (see text). (a) RT1; (b) RT2; (c, d) RT3.

- *Recession Type 2 (RT2)*: Gingival recession associated with loss of interproximal attachment. The amount of interproximal attachment loss (measured from the interproximal CEJ to the depth of the interproximal sulcus/pocket) is less than or equal to the buccal attachment loss (measured from the buccal CEJ to the apical end of the buccal sulcus/pocket).
- *Recession Type 3 (RT3)*: Gingival recession associated with loss of interproximal attachment. The amount of interproximal attachment loss (measured from the interproximal CEJ to the apical end of the sulcus/pocket) is higher than the buccal attachment loss (measured from the buccal CEJ to the apical end of the buccal sulcus/pocket).

This classification is a treatment-oriented classification to forecast the potential for root coverage through the assessment of interdental CAL. In the RT1 (Miller Class I and II) 100% root coverage can be predicted; in the RT2 (overlapping the Miller class III) some randomized clinical trials indicate that depending on the degree of interdental CAL loss CRC may be predictable applying different root coverage procedures; in the Cairo RT3 (overlapping the Miller class IV) full root coverage is not achievable (Tonetti *et al*. 2014)

In order to account for other factors associated with the predictability of root coverage with the different mucogingival surgical interventions, this classification should be supplemented with other relevant diagnostic elements (depth of the gingival recession, gingival thickness, keratinized tissue width, presence of the CEJ, associated cervical lesions).

The development of NCCLs occurs frequently on exposed root surfaces and is associated with deeper gingival recessions. These NCCLs are usually accompanied by the loss of the CEJ and/or formation of lesions on the tooth surface (loss of substance with presence of a root surface concavity >0.5 mm [step]). In the new 2017 classification (Cortellini & Bissada 2018) it is possible to identify four different clinical situations: Class A, when the CEJ is still detectable, with presence/absence of cervical step >0.5 mm; and Class B, when the CEJ is not identifiable, with presence/absence of cervical step >0.5 mm. The diagnosis of these clinical situations should be associated to the type of recession (RT1, RT2, or RT3) and the other diagnostic elements (depth of the recession, gingival thickness, and amount of keratinized tissue) (see Table 39-2) to support the clinician with the decision making in relation to the choice of surgical intervention for root coverage (described later in this chapter).

CEJ, cementoenamel junction (Class A = detectable CEJ. Class B = undetectable CEJ); GT, gingival thickness; KTW, keratinized tissue width; RT, recession type; REC depth, depth of the gingival recession; Step, root surface concavity (Class + = presence of a cervical step >0.5 mm. Class – = absence of cervical step).

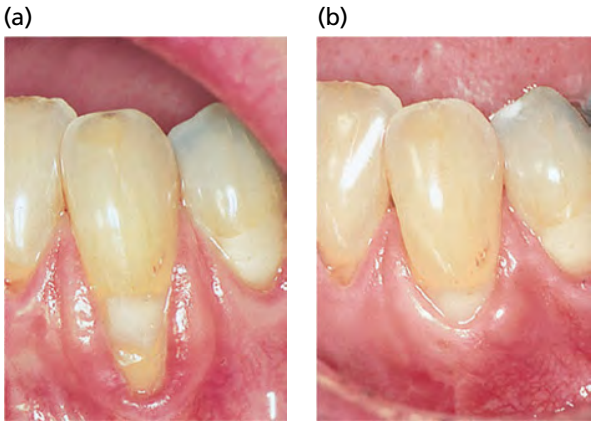

Fig. 39-23 (a) Mandibular canine with a deep recession, which makes self-performed plaque control difficult. (b) To facilitate plaque control, the position of the soft tissue margin was altered surgically.

Treatment of gingival recessions

The main indications for root coverage procedures are esthetic/cosmetic demands (Fig. 39-22). Root sensitivity and changing the topography of the marginal soft tissue in order to facilitate plaque control may also be an indication for root coverage procedures (Fig. 39-23).

Because gingival recessions are not pathological entities *per se* (in absence of gingival inflammation), it is important to justify the decision to treat them with root coverage procedures. A basic question to be answered is: what occurs if an existing gingival recession is left untreated? A systematic review with meta-analysis that assessed the long-term outcomes of untreated facial gingival recession (Chambrone & Tatakis 2016) reported that facial gingival recession in subjects with good oral hygiene is highly likely to result in an increase in the recession depth during long-term follow-up. Agudio *et al*. (2016) compared treated sites with homologous contralateral sites presenting with thin gingival phenotype with or without recessions in a population of highly motivated patients. At the end of the follow-up period (mean of 23.6 ± 3.9 years, range 18–35 years), the extent of the recession was reduced in 83% of the 64 treated sites, whereas it was increased in 48% of the 64 untreated sites. Thin gingival phenotypes augmented by grafting procedures remained more stable over time than thin gingival phenotypes. Even though progression of gingival recession seems not to impair the long-term survival of teeth, it may be associated with problems like esthetic impairment, dentin hypersensitivity, and tooth conditions that concern the patient and the clinician.

Recession defects in children need particular attention. In the growing child, recession defects may be eliminated spontaneously, provided adequate plaque control is established and maintained (Fig. 39-24). Andlin-Sobocki *et al*. (1991) reported from a 3-year prospective study that 25 of 35 recession defects with an initial depth of 0.5–3.0 mm healed spontaneously following improvement of the oral hygiene standard. Furthermore, all but three remaining recessions showed a decrease, and no site demonstrated an increase in depth. Hence, reparative surgical treatment of soft tissue recessions in the developing

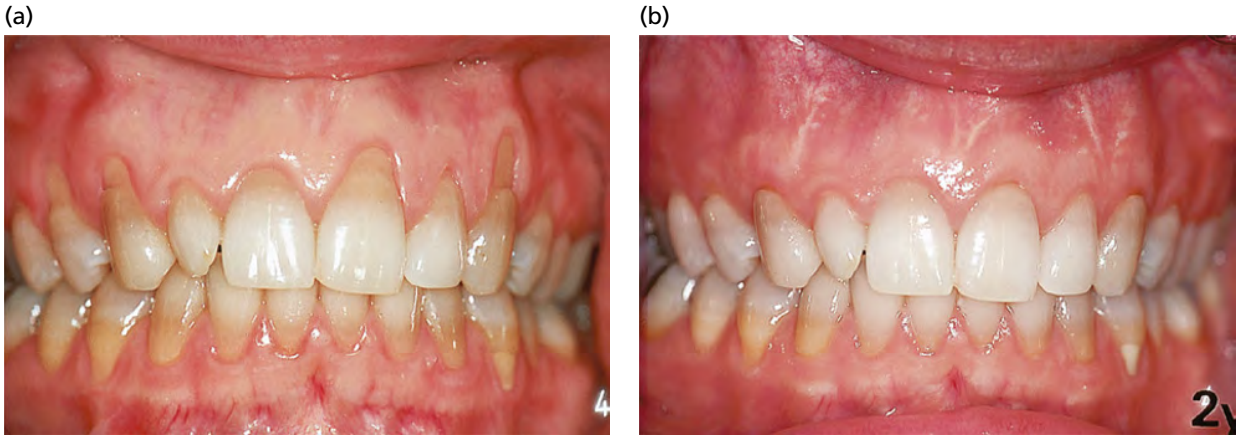

Fig. 39-22 (a) A 25-year-old woman with esthetic concerns due to multiple soft tissue recessions in the maxilla and a high lip line. The gingiva is healthy and several of the exposed root surfaces show abrasion defects, indicating toothbrushing trauma as the causative factor for the development of the recessions. The brushing technique was altered, and root coverage was achieved surgically. (b) Two-year post-treatment view.

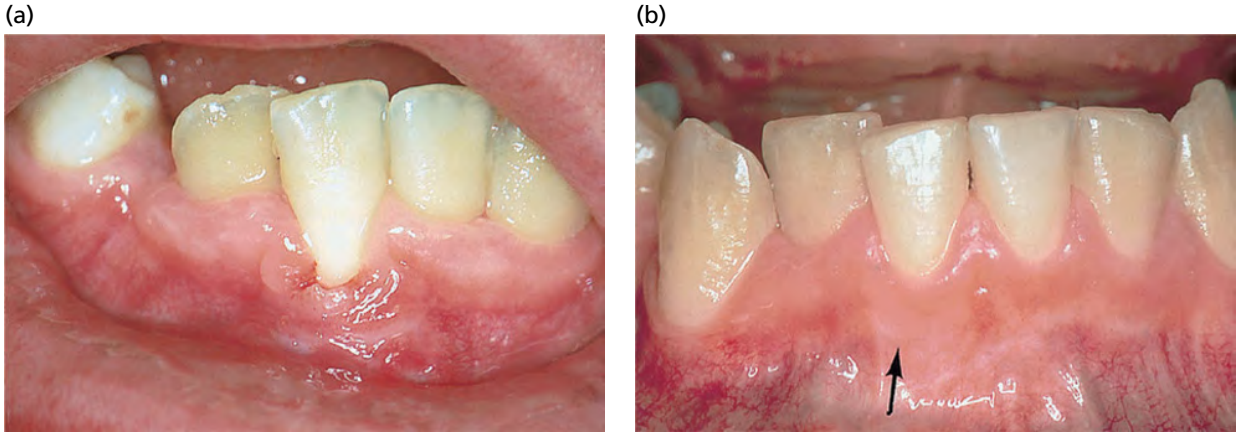

Fig. 39-24 A 9-year-old boy showing recession at tooth 41. (a) Tooth is rotated and buccally positioned. The minimal amount of gingiva found apical to the recession shows pronounced signs of inflammation. The plaque control in the region was improved but surgical intervention was postponed. (b) Same tooth area at the age of 14 years. Note the spontaneous soft tissue repair that has taken place at tooth 41 as a consequence of the improved plaque control and the growth in the alveolar process (arrow).

dentition may not be necessary and should preferably be postponed until the growth is completed.

In patients in need of orthodontic therapy with a gingival recession and a thin phenotype associated with a prominent, facially positioned tooth (Fig. 39-25a), surgical treatment for root coverage should be postponed until the orthodontic therapy is completed when lingual movement of the tooth into a more proper position within the alveolar bone is planned (Fig. 39-25b). In these cases, the recession, as well as the dehiscence, will decrease as a consequence of the orthodontic tooth movement. However, when expansion or rotational tooth movements are expected, the surgical treatment for root coverage should be done prior to the orthodontic treatment in order to prevent further attachment loss.

Root coverage procedures

It should be recalled that the two major causative factors in the development of marginal tissue recession are trauma caused by toothbrushing and plaque-induced periodontal inflammation. The control of these factors will prevent further progression of the recession in most cases. This means that in tooth regions with a thin covering of soft tissue, with or without an incipient recession, the patient should be encouraged to carry out effective, but at the same time non-traumatic, plaque-control measures. With respect to toothbrushing, the Bass method (see Chapter 28) should be avoided and the patient should be instructed to use a technique that creates as little apically directed pressure on the soft tissue margin as possible. A soft toothbrush should, of course, be used.

Before root coverage is attempted, the exposed portion of the root should be rendered free from bacterial biofilms. Preferably, this is achieved by the use of a rubber cup and a polishing paste. Controlled clinical trials showed no differences in terms of root coverage or residual probing depth between teeth that had been instrumented (root planed) or polished only (Oles *et al*. 1988; Pini Prato *et al*. 1999).

The mucogingival surgical procedures used in the treatment of recession defects are classified as (1) pedicle soft tissue graft procedures, (2) free soft tissue

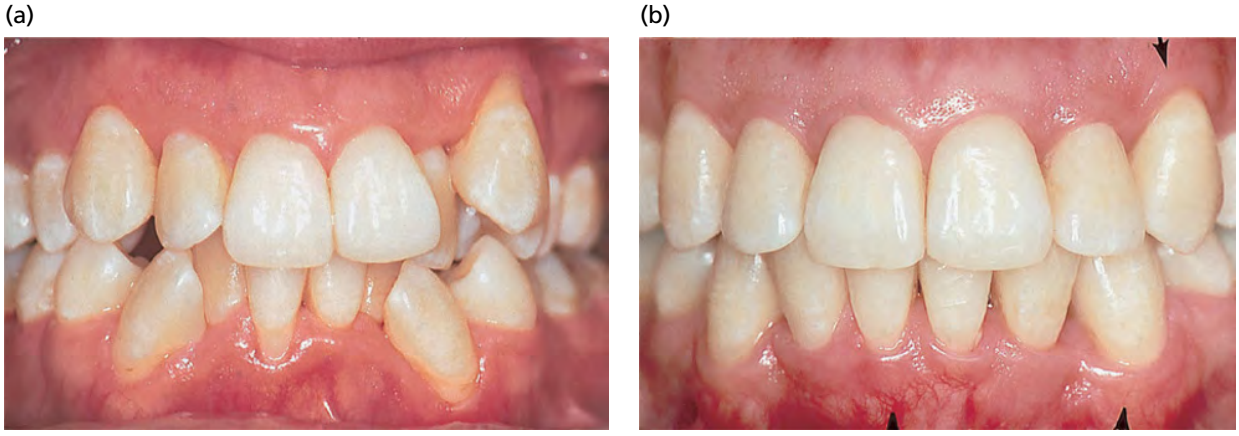

Fig. 39-25 Spontaneous repair of soft tissue recessions following orthodontic tooth movement. (a) A 22-year-old woman showing recessions and thin marginal tissues at prominently positioned teeth, particularly 23, 33, 41, and 43. (b) Following proper alignment of the teeth, the recessions have spontaneously been resolved and an increased gingival height can be noted.

graft procedures combined with either pedicle grafts or envelope/tunnel flaps.

The *pedicle graft procedures* are, depending on the direction of transfer, grouped as (1) *rotational flap procedures* (e.g. laterally sliding flap, double papilla flap, oblique rotated flap) or (2) *advanced flap procedures* (e.g. coronally repositioned flap, semilunar coronally repositioned flap) when there is no rotation or lateral movement of the pedicle graft. Regenerative procedures are also included within the group of pedicle graft procedures, that is, rotational and advanced flap procedures involving the placement of a barrier membrane between the graft and the root or the application of enamel matrix proteins over the root surface.

Free soft tissue autogenous graft procedures may be performed as (1) an epithelialized graft or (2) a subepithelial CTG (non-epithelialized graft), both usually taken from the area of the masticatory mucosa in the palate.

The choice of a root coverage surgical technique depends on several factors that can be categorized essentially as belonging to three groups: the local anatomical characteristics of the site to be treated, the patient's requests, and the surgeon's preferences.

Within the local factors it is important to assess:

- The number of recession defects to be treated
- The size of the recession defect
- The height and width of the interdental soft tissue, and the dimension of papillae near the recession
- The height, thickness, and color of the KT apical and lateral to the root exposure
- The presence of root caries or cervical abrasions
- The depth of the vestibulum
- The presence of marginal frenuli or muscle insertions.

Irrespective of the surgical technique, either using a pedicle flap, an autogenous graft, or a combination, the root surface must be adequately prepared to obtain the adhesion of the soft tissue to the root and a stable clinical result in terms of recession coverage. Root preparation is usually done by scaling and root planing intrasurgically, although extensive root planing should only be performed in situations where a reduced root prominence would be considered beneficial for graft survival or tissue regeneration, or if a shallow root caries lesion is diagnosed. The presence of a filling in the root does not preclude the possibility of root coverage (Fig. 39-26), but preferably the filling should be removed before the root is covered with soft tissue.

The use of root surface demineralization agents has been advocated, not only for the removal of the smear layer, but also to improve the fibrous attachment by exposing the collagen fibrils of the dentin matrix and thus allowing direct interaction with those in the covering connective tissue. However, controlled clinical trials comparing the clinical outcome of root coverage procedures with and without root conditioning (Ibbott *et al*. 1985; Oles *et al*. 1985; Bertrand & Dunlap 1988; Laney *et al*. 1992; Bouchard *et al*. 1997; Caffesse *et al*. 2000) failed to demonstrate a beneficial effect from the use of acid root biomodification. Gottlow *et al*. (1986) evaluated the healing following treatment of localized gingival recessions with coronally positioned flaps and citric acid root biomodification in a controlled study in dogs. Histologic analysis after 3 months of healing disclosed no differences in the amount of root coverage or new connective tissue attachment between citric acid-treated sites and saline-treated control sites. Although root resorption was a common finding among the citric acid-treated teeth in this dog model, such a finding has not been reported to be common in humans. Based on a systematic review on the efficacy of root surface conditioning, Oliveira and Muncinelli (2012) concluded that there is no evidence that root surface biomodification by, for example, citric acid, EDTA, or laser prior to soft tissue root coverage improves the clinical outcome of root coverage procedures.

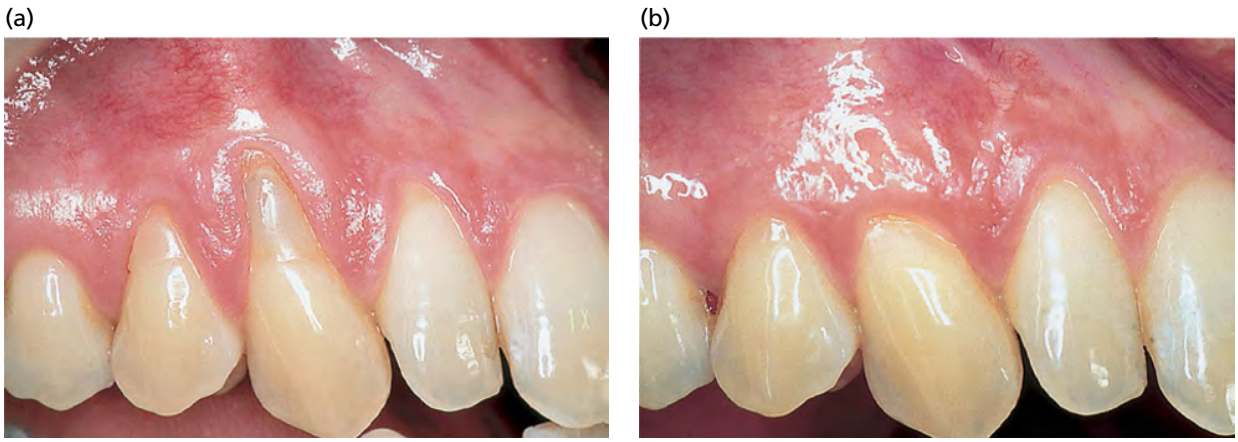

Fig. 39-26 (a) Canine showing pronounced recession and a composite resin restoration in the exposed root. Following removal of the restoration, the exposed root was surgically covered with soft tissue (pedicle graft). (b) Two-year postoperative healing result.

The biological potential of enamel matrix derivatives (EMD) as a differentiation and proliferation factor for mesenchymal cells and fibroblasts derived from the periodontal ligament has been demonstrated in both *in vitro;* and *in vivo;* studies. Furthermore, EMD promotes the transformation of gingival fibroblasts to actively participate in new connective tissue attachment to root surfaces (see detailed biological activity in Chapter 38 on Periodontal Regeneration). There is, however, scarce human histological information on the use of EMD and the coronally advanced flap to treat recession defects, and this data is derived from case reports in hopeless teeth and Miller class III–IV defects. These extreme cases are probably far from the expected clinical use and therefore do not provide histological evidence of the biological potential of this biomimetic approach when applied to the treatment of gingival recessions. The possible added value of EMD to the CTG has also been studied histologically in humans (Carnio *et al*. 2002), but the combination of EMD and CTG did not have a beneficial effect on the nature of the attachment achieved and did not promote regeneration. Similar outcomes were reported by McGuire and Cochran (2003) also reporting that the combination of EMD and CTG did not have a beneficial effect on the nature of the attachment achieved and did not promote regeneration.

Different surgical techniques have been proposed for the treatment of single or multiple gingival recessions.

Pedicle grafts

The following pedicle graft procedures have been used as root coverage procedures to treat single recession defects.

Advanced flaps

Advanced flaps are pedicle flaps that, using elasticity of the alveolar mucosa and gingival tissues, are positioned coronally to the CEJ, thus covering the exposed root surface. The more widely used is the *coronally advanced flap* (CAF), originally proposed by Allen and Miller (1989) (Fig. 39-27). The technique consists of two vertical divergent incisions positioned laterally to the involved tooth at the level of the CEJ and extending into the alveolar mucosa; the incision is connected by a horizontal intrasulcular incision. A split thickness incision is then utilized to raise the flap from the underlying periosteum and the flap is positioned coronal to the CEJ. Pini Prato *et al*. (1992) modified this design by augmenting the dimension of the surgical papillae utilizing a horizontal marginal incision with a "golf club" shape. Two divergent incisions are then executed deep into the alveolar mucosa. These modifications were essentially made

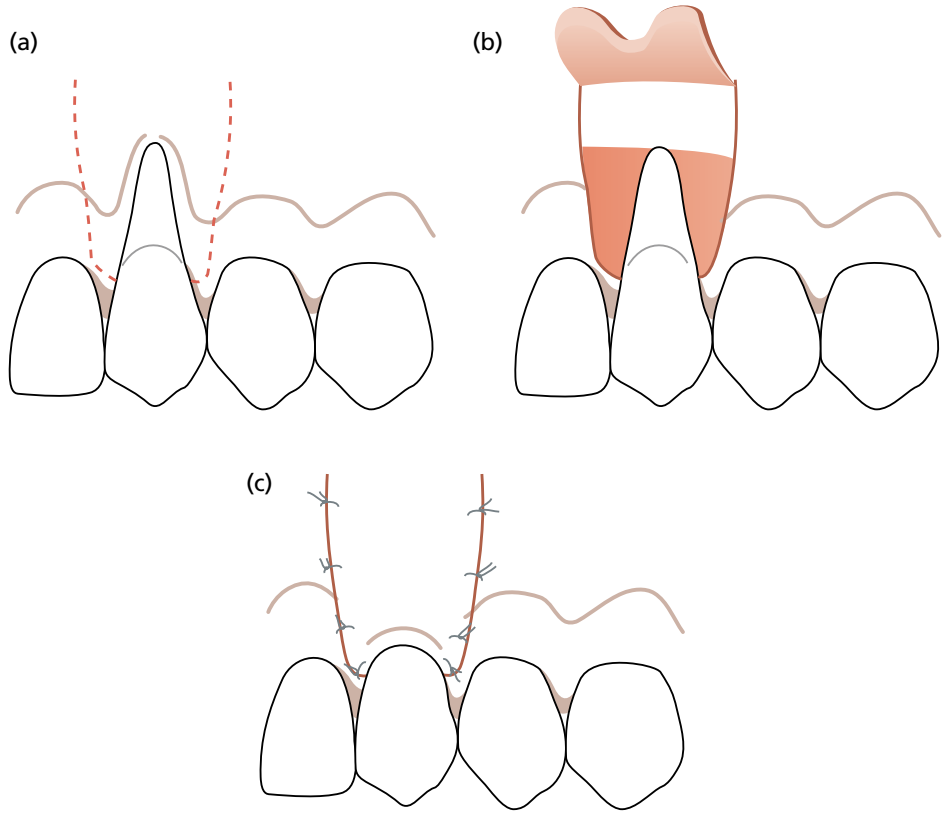

Fig. 39-27 (a–c) Coronally advanced flap procedure. The surgical technique for utilizing coronally advanced pedicle grafts to cover localized recession defects. (Source: Based on Allen & Miller 1989. Reproduced with permission from John Wiley & Sons.)

to increase the dimension of the flap to augment vascularization and thus postsurgical stability.

The design of the CAF has been further modified by De Sanctis and Zucchelli (2007) (Fig. 39-28). The two horizontal incisions must be 3 mm long and should be positioned at a distance from the tip of the papilla that is equivalent to the dimension of the recession plus 1 mm. With these dimensions, the margin of the flap will be stabilized at the end of the coronal advancement, in a position coronal to the CEJ, allowing for postsurgical shrinkage. Two vertical slightly divergent beveled incision are then made deep in the alveolar mucosa in such a way that the bone and the periosteal tissues are not included in the superficial cut and are therefore not involved in the healing process, in an attempt to avoid unsightly scars. The flap is then raised in a split-full-split manner, first raising the surgical papillae with a sharp dissection as far as the gingival sulcus. Using a periosteum elevator, full thickness flap elevation is then performed from the sulcus as far as the buccal bone, thus achieving a thicker tissue for covering the dimension equivalent to the recession. Finally, the last and most apical part of the flap is raised, split thickness, using a blade. Care is taken to detach all muscle insertions from the flap to enable flap mobility.

The flap is then positioned 1–2 mm coronal to the CEJ in such a way that the surgical papillae reaches the tip of the de-epithelialized anatomical papillae and is secured at a level 1-2 mm coronal to the CEJ by suturing the flap to the connective tissue bed in the papilla regions. Additional lateral sutures are placed to carefully close the releasing incisions.

This flap design takes into consideration several biological factors. The vascular support of the flap provided by the pedicle is usually not enough for tissue stability and requires an additional vascular bed provided by the dimensions

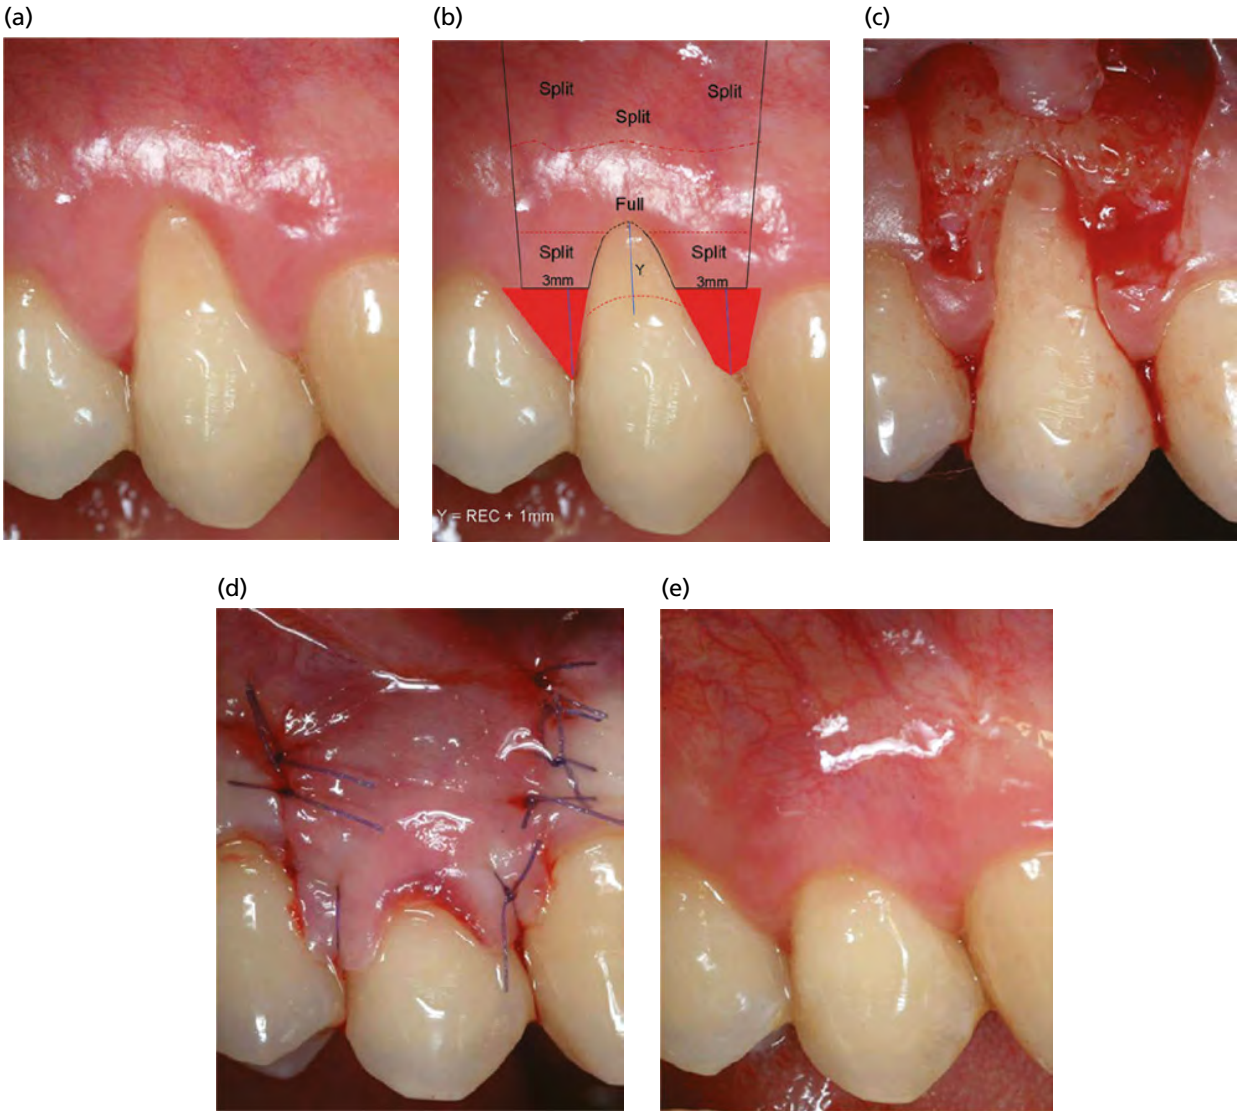

Fig. 39-28 Coronally advanced flap procedure. (a) Recession defect affecting a first premolar. (b) Schematic outline of the flap preparation. Blue line, amount (mm) of intended coronal advancement of the flap; dotted red area, de-epithelialized papillae; split, split-thickness elevation; full, full-thickness elevation. (c) Flap elevated. The papilla areas are then de-epithelialized to allow anchorage of the flap coronal to the cementoenamel junction (CEJ). (d) Flap is advanced and anchored at a level coronal to the CEJ with a sling suture. (e) Clinical healing at 1 year.

of the de-epithelialized papilla and the peripheral area beveled with the two vertical incisions. This combination of internal/external vascular supply provides effective vascular support to the flap. The thin surgical papillae improves the marginal vascular exchange with the recipient bed, while the apical split thickness guarantees flap mobility because of the excision of all muscular insertions. The modulation of the thickness of the flap (split-full-split) also enables the inclusion of the periosteum where it is needed most – to cover the avascular root surface – and provides not only increased thickness but also enhanced healing capacity because of the specific characteristic of the cells within this tissue.

Semilunar coronally positioned flap

The semilunar flap (Sumner 1969; Tarnow 1986; Sorrentino & Tarnow 2009) essentially consists of a semilunar incision, following the outline of the gingival margin. The semilunar incision should be positioned at least 3 mm from the tissue margin in keratinized tissue, the curvature of the flap should be parallel to the curvature of the gingival margin, and the incision should be extended into the adjacent papillae. The flap is then raised split thickness with an intrasulcular incision that will allow for the coronal movement of the flap. This is then positioned coronal to the CEJ and stabilized with slight manual pressure. No sutures are used. This technique can be utilized for the treatment of shallow recessions in the presence of a wide band of thick marginal keratinized tissue (Fig. 39-29).

Rotational flap procedures (e.g. laterally sliding flap, double papilla flap, oblique rotated flap) are those in which the raised flap is mobilized in directions other than coronal, which will require modifying the marginal position of the tissues.

Laterally positioned flap

The laterally positioned flap was first proposed by Grupe and Warren (1956) (Fig. 39-30) and essentially consists of the utilization of the keratinized tissue of a tooth adjacent to a gingival recession and the design of a pedicle flap that is repositioned laterally to cover the exposed root. This flap is designed with two vertical oblique incisions starting from the base of the papillae of the tooth next to the recession (generally the distal tooth), and is extended deep into the alveolar mucosa. The flap is then raised full thickness. In order to reduce the risk of recession on the donor tooth, Grupe (1966) suggested that the marginal soft tissue should not be included in the flap. Staffileno (1964) and Pfeifer and Heller (1971) advocated the use of a split-thickness flap to minimize the potential risk for development of dehiscence at the donor tooth. To mobilize the flap a so-called cut back incision is made at the bottom of the distal vertical incision. The cut back is an oblique incision made in the direction of the movement of the flap. This technique provided an efficient solution in the treatment of localized gingival recession (Smukler 1976; Guinard & Caffesse 1978; Ricci *et al*. 1996).

A *laterally moved coronally advanced flap* (Zucchelli *et al*. 2004) is a modified surgical technique, coupling the lateral and coronal advancement of the flap (Fig. 39-31). The flap is designed starting with a horizontal incision from the CEJ of the tooth to be treated. This incision is continued with a vertical incision parallel to the mesial margin of the recession that extends into the alveolar mucosa. At the opposite edge of the recession, another incision extending to the alveolar mucosa will join the previous incision, thus constructing a wide recipient triangular periosteal bed area where the flap will be secured in place. The flap is then designed with a submarginal

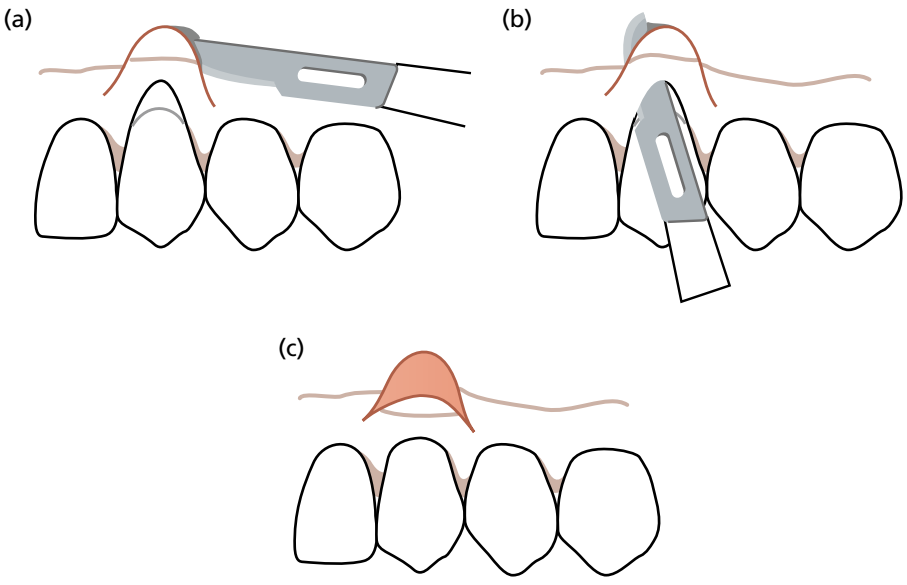

Fig. 39-29 Semilunar coronally repositioned flap procedure. The surgical technique for utilizing coronally displaced pedicle grafts to cover shallow localized recession defects (see text for explanation).

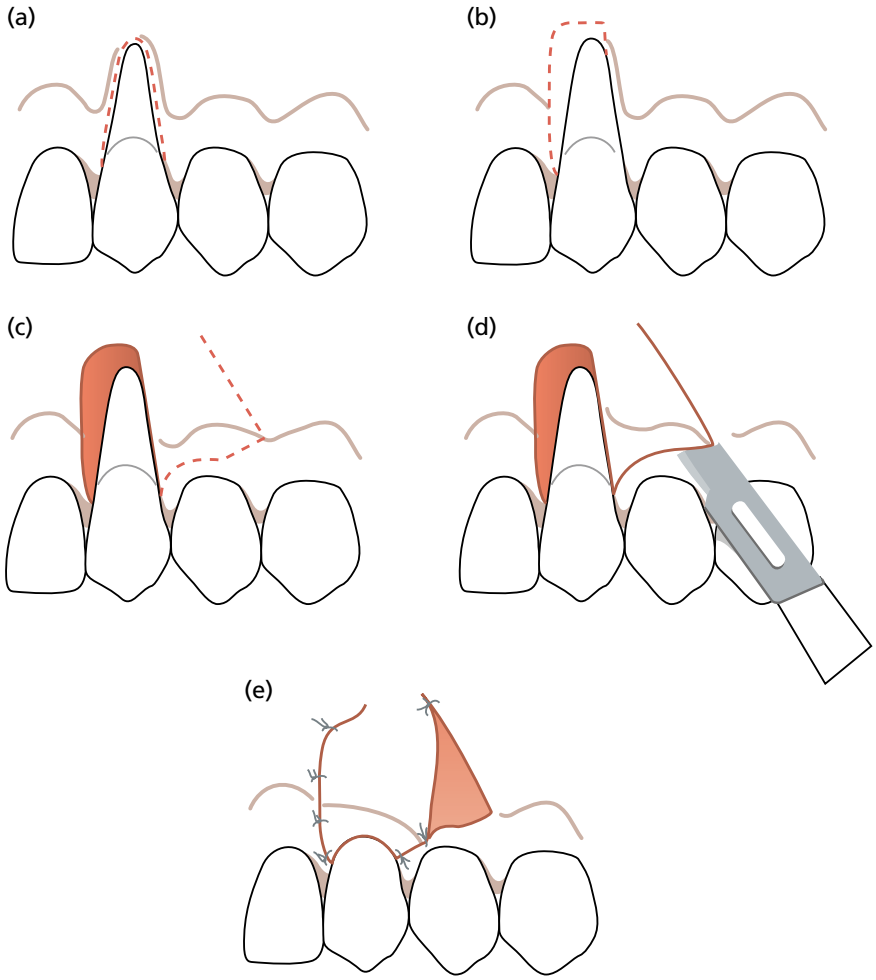

Fig. 39-30 (a–e) Rotational flap procedure. The surgical technique for utilizing rotational pedicle grafts to cover localized recession defects (see text for explanation). (Source: Based on Grupe & Warren 1956. Reproduced with permission from John Wiley & Sons.)

semilunar incision that maintains a collar of keratinized tissue around the donor tooth to avoid any risk of recession on this tooth. The final vertical incision is positioned at the end of the flap and is obliquely oriented in the direction of the movement to facilitate the positioning of the flap over the denuded root. At this point the anatomical papillae mesial and distal to the involved tooth are de-epithelialized and the flap coronally advanced after releasing all muscle insertions. The flap is then coronally positioned in such a way that the surgical papillae will be placed over the de-epithelialized anatomical papillae and secured with a modified suspended suture and single suture on the edge. This technique was compared in a randomized clinical trial with and without a CTG in the treatment of gingival recession at the buccal aspect of upper first molars (Zucchelli *et al*. 2012). The authors concluded that full root coverage and high aesthetic scores can be achieved by both techniques, with no statistically significant difference between them.

The double papilla flap (Cohen & Ross 1968)

The procedure starts with a beveled incision on the margin of the recession. The beveled incision must be reciprocal, that is, internal in one side and external in the opposite one This is due to the fact that the two edges will be overlapped at the end of the papillae movement.

Two oblique incision are than performed 1–2 mm coronal to the CEJ and the two papillae are detached with a split thickness incision. The two parts of the flap are subsequently joined together with single interrupted sutures over the midline of the tooth, taking care that the two parts perfectly overlap. The flap is finally secured by means of a suspended suture (Fig. 39-32).

Several critical factors may explain the infrequent application of this technique: because the integrity of the flap depends on a very small area of anchorage, the sutures are positioned in the most critical area, over an avascular surface, and over the convexity of the root, which is the area of maximum tension.

Other modifications of the procedure are the oblique rotational flap (Pennel *et al*. 1965), the rotation flap (Patur 1977), and the transpositioned flap (Bahat *et al*. 1990).

Gingival recession seldom appears as a single defect. The recessions are more often multiple, affecting an entire quadrant and sometimes the entire mouth. Zucchelli and De Sanctis (2000) have described a flap design for the treatment of multiple

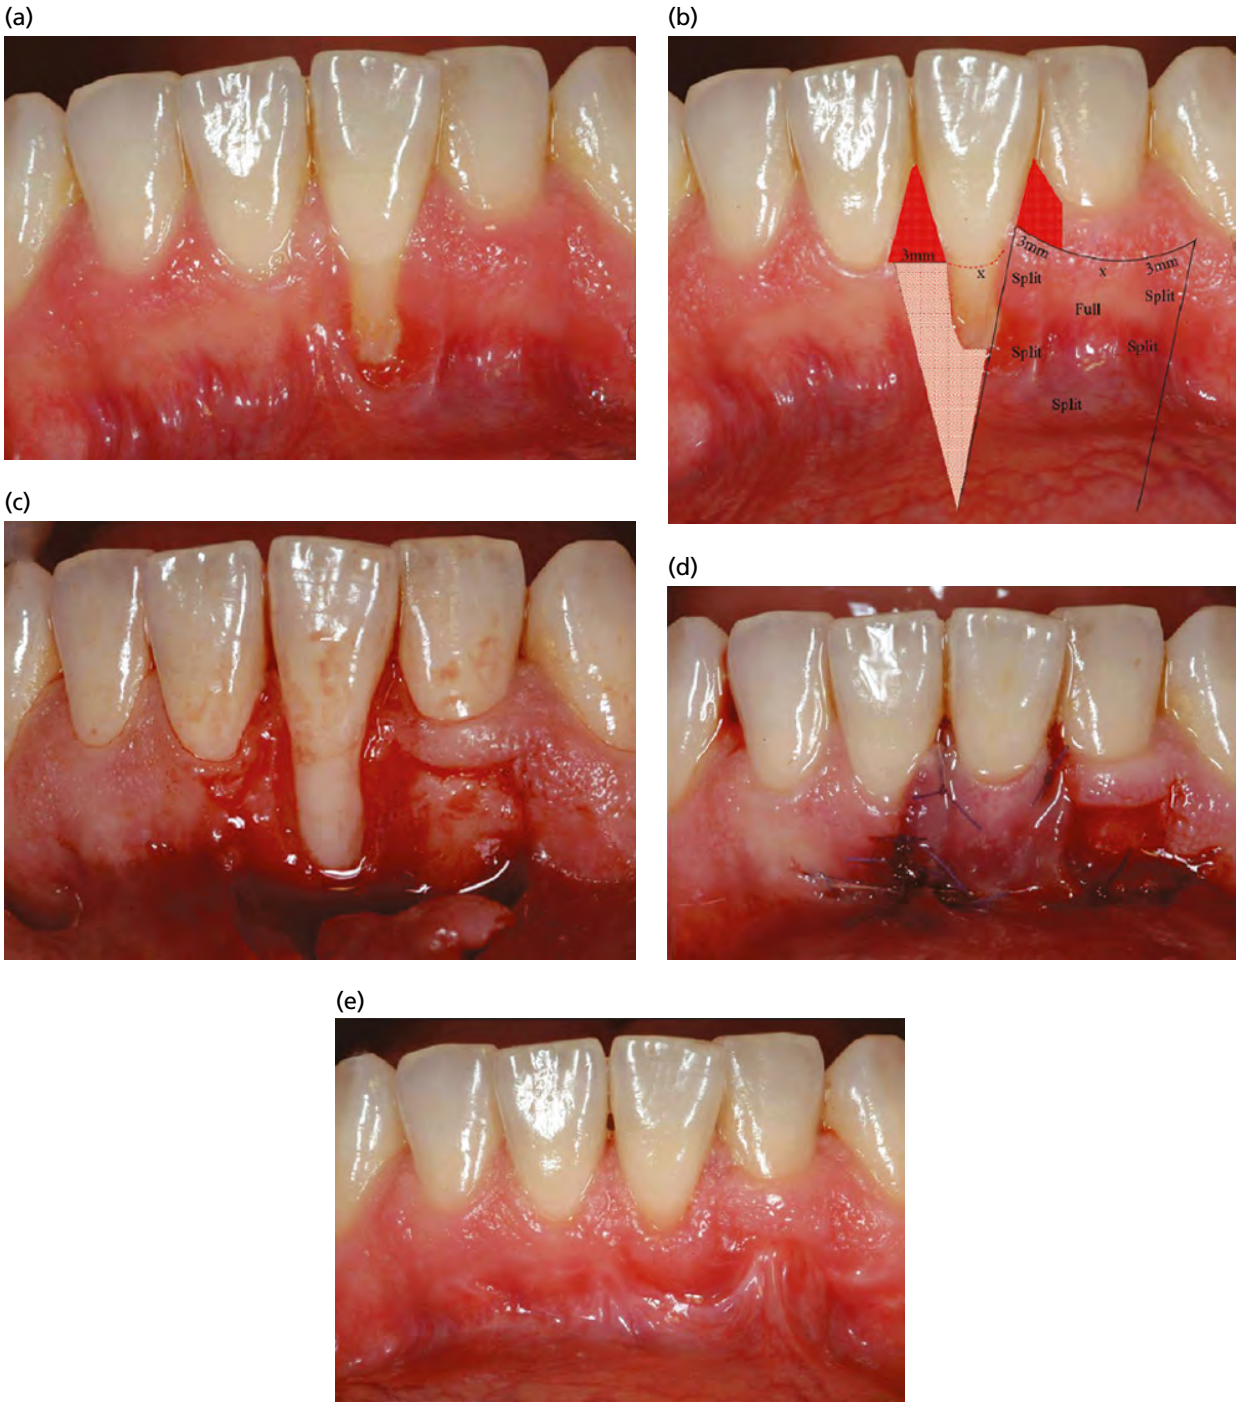

Fig. 39-31 Laterally moved, coronally advanced flap (see text for explanation). (a) A central incisor with recession defect. (b) Schematic outline of the preparation of the recipient site and the pedicle graft. Dotted pink area, receiving area for lateral flap; dotted red area, de-epithelialized papillae; x, recession width at the level of the cementoenamel junction; split, split-thickness elevation; full, full-thickness elevation. (c, d) Flap is transpositioned laterally and coronally, and secured in position by sutures. A horizontal double mattress suture is performed to reduce lip tension on the marginal portion of the flap. (e) Clinical healing at 1 year.

recessions, which allows for optimal adaptation of the flap, following its coronal advancement without placement of vertical releasing incisions

The multiple coronally advanced flap (MCAF)

This flap design consists of an envelope flap without releasing vertical incisions, comprising several teeth or an entire quadrant. The flap design is influenced by the coronal movement of the flap without vertical incisions and is dependent on the tension caused by the anchoring of the flap to the fixed adjacent tissues, thus causing a mesial rotation in all the papillae mesial to the center of the flap and a distal rotation in all distal papillae. In light of this, the flap design starts with two oblique incisions in the tooth positioned at the center of the flap, directed from the mesial and distal papillae to the bottom of the recession of the adjacent teeth (Fig. 39-33). This incision begins at a distance from the tip of the papillae that

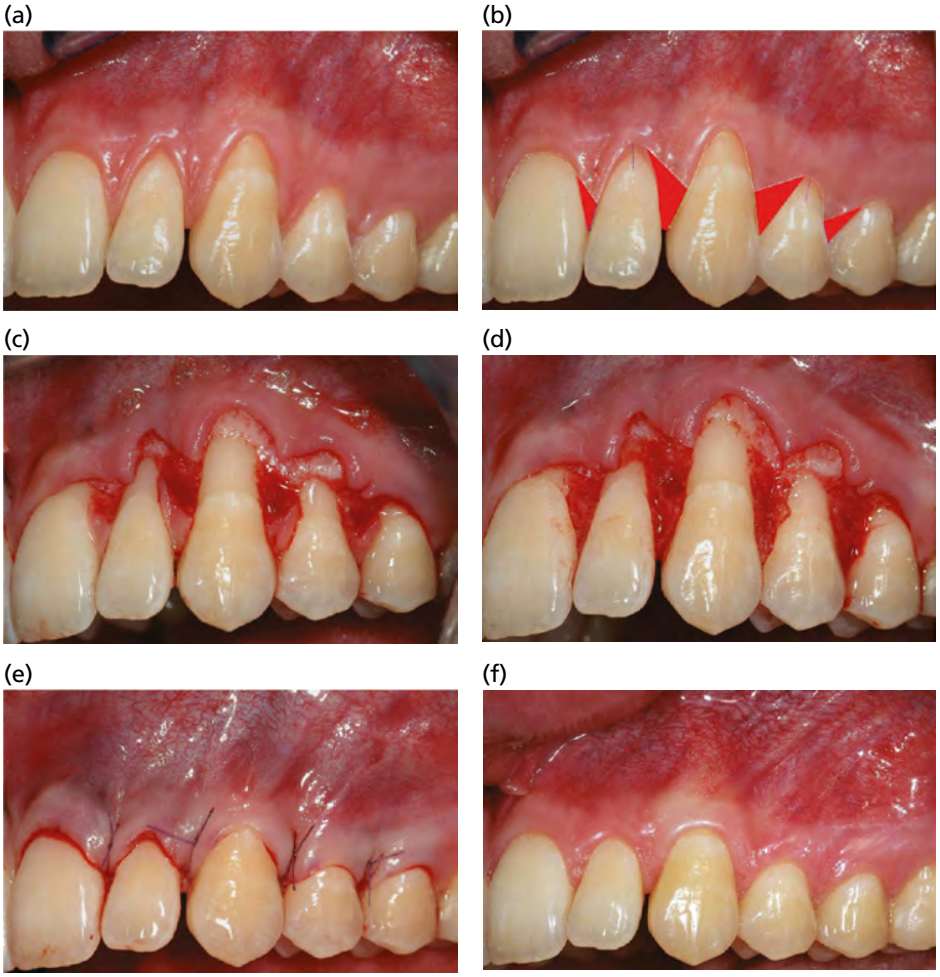

Fig. 39-33 Coronally advanced flap procedure for multiple recessions (see text for explanation). (a–e) Oblique incisions over the interdental areas are placed in such a manner that the "surgically created papillae" mesial to the midline of the surgical field are dislocated apically and distally, while the papillae of the flap distal to the midline are shifted to a more apical and mesial position. (f) One-year post-treatment view.

is commensurate with the size of the recession. These incisions are made in such way that the tip of surgical papillae will be directed mesially in all the papilla of the teeth mesial to the centre of the flap and distally at the distal teeth. The inclination of the papilla will take into account their rotation with the coronal displacement of the flap.

The area of the surgical papillae is then dissected split thickness, taking care not to sever the bottom of the recession with the blade. A periosteum elevator is then placed at the bottom of the sulcus to raise a full thickness flap, thus comprising the entire thickness of the free gingiva, taking care that at least 2 mm of periosteum is included. Finally, the more apical part of the flap is dissected split thickness, and all the muscle insertions are carefully detached from their insertion to the flap. The remaining facial portion of the interdental papillae is de-epithelialized to create connective tissue beds to which the flap can be stabilized and sutured. Following a thorough debridement of root surfaces, the flap is advanced coronally, taking care that the flap margin is positioned at least 1 mm coronal to the CEJ. The flap is then secured in position by means of single modified suspended sutures. Care has to be taken for a perfect adaptation of the flap over the root surface and the de-epithelialized papillae.

The possible impact of vertical releasing incisions was evaluated by Zucchelli *et al*. (2009) comparing the same flap design (CAF for multiple recessions) with and without releasing incisions. The presence of vertical releasing incisions did not influence the patient's perception of the results, because the patient was not able to discern the presence of scars, although CRC was more likely with the flap designed without vertical releasing incisions. Zucchelli *et al*. (2009) and De Sanctis *et al*. (2011) have proposed the multiple coronal advanced flap with a vertical releasing incision as the treatment of choice for recessions affecting mandibular posterior teeth.

Pedicle soft tissue graft procedures combined with a barrier membrane

The use of a barrier membrane, according to the principles of guided tissue regeneration (GTR; see Chapter 38), in conjunction with pedicle soft tissue graft procedures, was introduced as a treatment modality for root coverage by Pini Prato *et al*. (1992). In order to create space for tissue formation between the facial root surface and the membrane, the authors suggested that extensive root planing should be carried out to produce concave root morphology. Both non-absorbable titanium-reinforced expanded polytetra-fluoroethylene (e-PTFE) membranes as well as bioresorbable membranes have been utilized in combination with coronally advanced flaps. Zucchelli *et al*. (1998) compared three different modalities to treat deep recessions utilizing a non-resorbable barrier, a resorbable barrier, and a CTG in conjunction with a coronal advancement of the flap. It was concluded that the mucogingival bilaminar technique is at least as effective as GTR procedures in the treatment of gingival recession ≥4 mm (Fig. 39-34). Furthermore, systematic reviews from randomized clinical trials have not been able to demonstrate any added value on the use of barrier membranes in terms of both the percentage of root coverage and the percentage of CRC when compared with CAF alone or CAF plus CTG (Rocuzzo *et al* 2002; Cairo *et al*. 2014).

Healing of pedicle soft tissue grafts over denuded root surfaces

In the areas surrounding the recession defect, where the recipient bed consists of bone covered by connective tissue, the pattern of healing is similar to that observed following a traditional flap operation. Cells and blood vessels from the recipient bed as well as from the tissue graft invade the fibrin layer, which is gradually replaced by connective tissue. After 1 week,

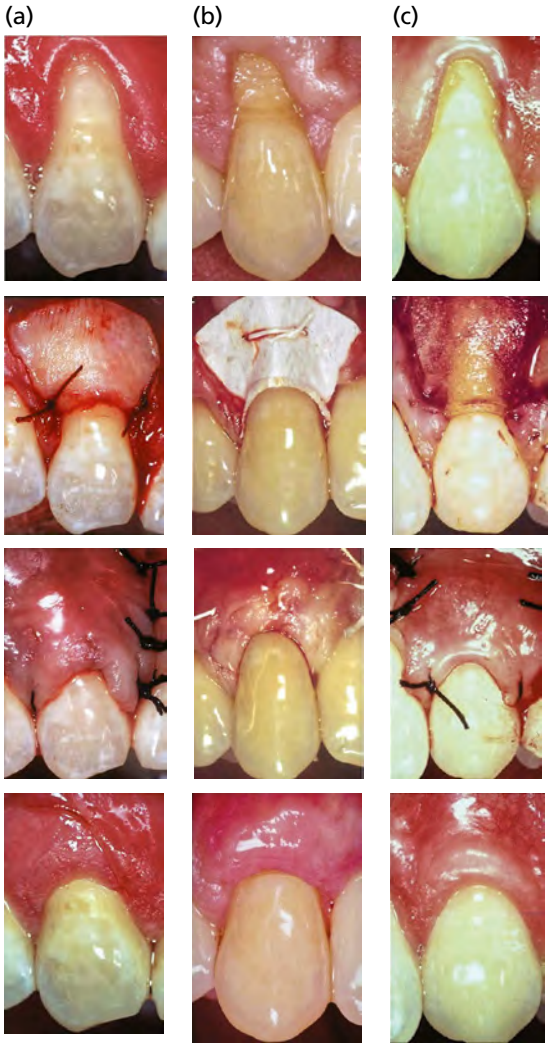

Fig. 39-34 Comparison between three diferent surgical techniques. Column (a) Coronal advanced flap plus connective tissue graft. Column (b) Coronal advanced flap plus non resorbable barrier membrane. Column (c) Coronal advanced flap plus resorbable membrane. Healing at 1 year.

a fibrous reunion is already established between the graft and the underlying tissue.

Healing in the area where the pedicle graft is in contact with the denuded root surface was studied by Wilderman and Wentz (1965) in dogs. According to these authors, the healing process can be divided into four different stages (Fig. 39-35):

1. *Adaptation stage (from 0 to 4 days)*. The laterally repositioned flap is separated from the exposed root surface by a thin fibrin layer. The epithelium covering the transplanted tissue flap starts to proliferate and reaches the tooth surface at the coronal edge of the flap after a few days.
2. *Proliferation stage (from 4 to 21 days)*. In the early phase of this stage, the fibrin layer between the root surface and the flap is invaded by connective tissue proliferating from the subsurface of the flap. In contrast to areas where healing occurs between two connective tissue surfaces, growth of connective tissue into the fibrin layer can only take place from one surface. After 6–10 days, a layer of fibroblasts is seen in apposition to the root surface. These cells are believed to differentiate into cementoblasts at a later stage of healing. At the end of the proliferation stage, thin collagen fibers are formed adjacent to the root surface, but a fibrous union between the connective tissue and the root has not been observed. From the coronal edge of the wound, epithelium proliferates apically along the root surface. According to Wilderman and Wentz (1965), the apical proliferation of epithelium may stop within the coronal half of the defect, although further down-growth of epithelium was also frequently observed.
3. *Attachment stage (from 27 to 28 days)*. During this stage of healing, thin collagen fibers become inserted into a layer of new cementum formed at the root surface in the apical portion of the recession.
4. *Maturation stage*. This last stage of healing is characterized by continuous formation of collagen fibers. After 2–3 months, bundles of collagen fibers insert into the cementum layer on the curetted root surface in the apical portion of the recession.

Results of experimental studies in monkeys and dogs on the healing characteristics of the periodontal wound have been interpreted to indicate that gingival connective tissue lacks the ability to form a new connective tissue attachment to the root but may induce root resorption (see Chapter 21). This finding is of particular interest when considering the rationale for the treatment of recession defects by free or pedicle soft tissue grafts. Since, in these surgical

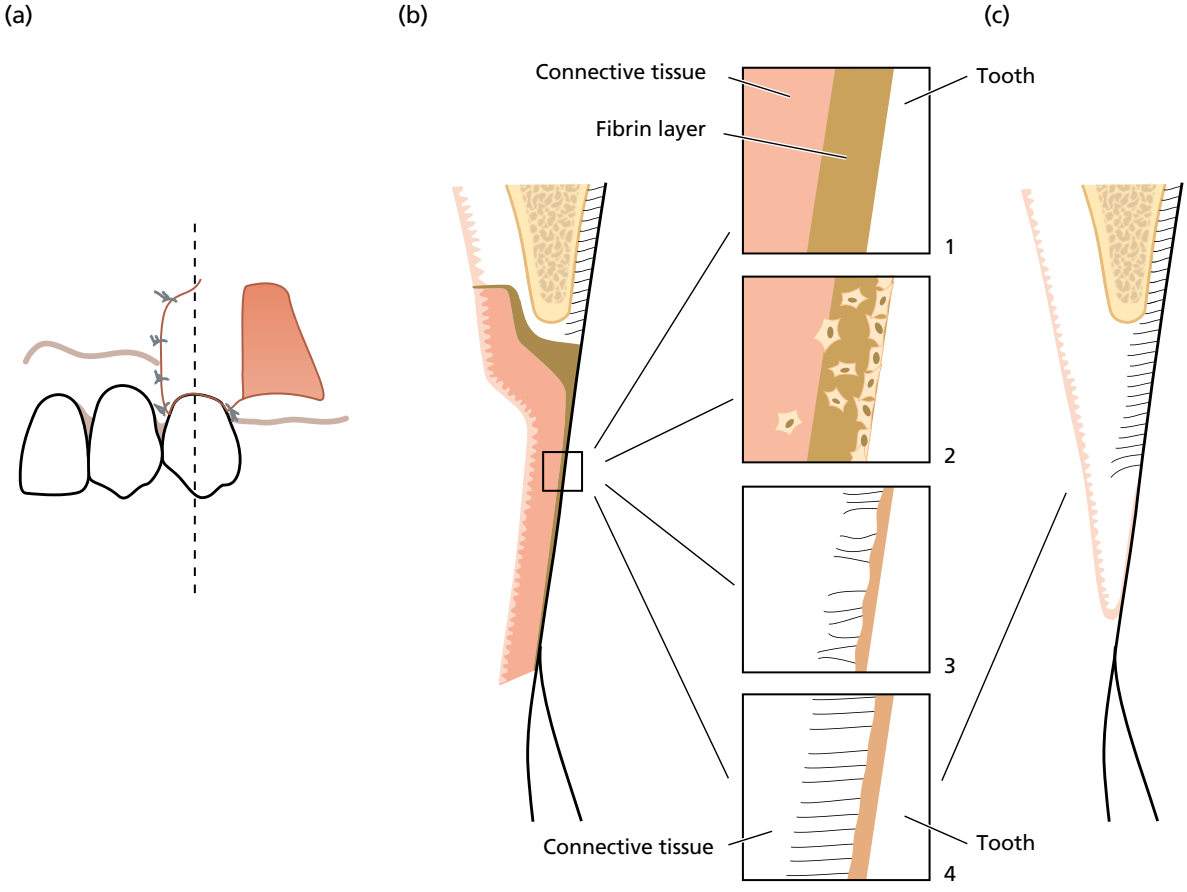

Fig. 39-35 (a) Healing following treatment of a localized soft tissue recession with a pedicle graft. (b) Cross-section through the area immediately after operation. The framed areas (1–4) illustrate the four stages into which the healing process can be divided. (c) Area after healing. Approximately 50% of the successfully covered defect may show new connective tissue attachment.

procedures, gingival connective tissue is placed in contact with a denuded root surface, root resorption should be expected to occur. The reason why it is not a common complication following this type of treatment can be explained by two possible events: either cells from the periodontal ligament form a fibrous attachment to the root surface or epithelial cells proliferate apically, forming a root-protective barrier (long junctional epithelium) towards the gingival connective tissue. Histologic studies to determine whether it is one or the other type of attachment that results following treatment of recessions with pedicle grafts indicate that new connective tissue attachment may form in the most apical part of the defect. In the study by Wilderman and Wentz (1965), a connective tissue attachment of around 2 mm and an epithelial attachment of the same height had formed in the soft tissue-covered portion of the defect, that is about 50% of the successfully covered defect showed new connective tissue attachment. Gottlow *et al*. (1986) examined the result of healing following treatment of experimentally produced recession type defects with a coronally advanced flap in dogs (Fig. 39-36). The histologic analysis after 3 months of healing disclosed that, on average, 20% of the apicocoronal length of the original defect had been exposed due to recession during healing (i.e. about 80% root coverage was achieved), 40% was covered by epithelium, and 40% demonstrated connective tissue attachment with cementum formation (Fig. 39-37). Determining

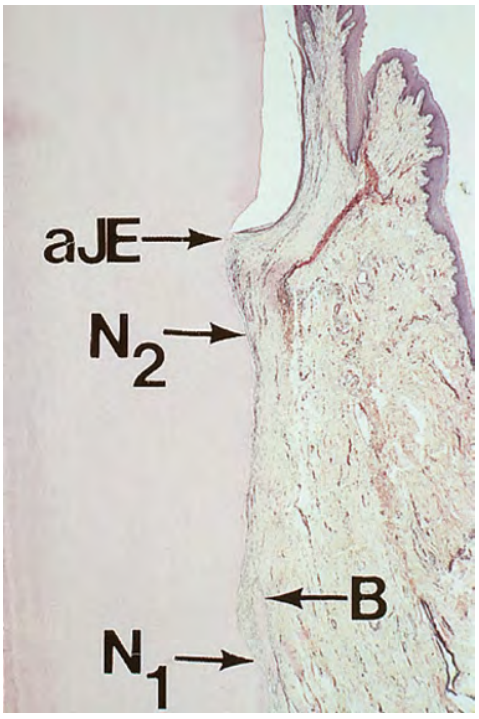

Fig. 39-37 Microphotograph of the healing following a coronally displaced flap in the same dog as in Fig. 39-36. A new connective tissue attachment is formed and extends coronally from the apical border of the notch prepared at the bottom of the bone dehiscence (N_1) to the apical termination of the epithelium (aJE) located within the notch indicating the presurgical level of the soft tissue margin (N_2). B, alveolar bone crest.

factors for the type of healing result were the size and the shape of the defect. The possibility of achieving a new connective tissue attachment in the apical portion of the defect seemed to be considerably better in narrow recession defects than in wider ones, most likely because the periodontal ligament at the lateral parts of the defect will serve as a source of granulation tissue from which a new connective tissue attachment can develop.

Healing following pedicle graft procedures has also been histologically studied in monkeys (Caffesse *et al*. 1984; Gottlow *et al*. 1990), and in these studies 38–44% of the successfully covered recession defects demonstrated formation of new connective tissue attachment. The study by Gottlow *et al*. (1990) also showed that the use of a GTR membrane between the root surface and the pedicle graft generated significantly more new connective tissue attachment (79% of the covered part of the recession defect). A significantly increased amount of cementum formation with inserting collagen fibers was also demonstrated following the utilization of enamel matrix proteins in combination with a coronally advanced flap for treatment of experimentally produced recession defects in dogs (Sallum *et al*. 2004).

Some case reports with human block sections provide further evidence that new connective tissue attachment may be formed following pedicle graft procedures. Histologic evaluation of two teeth treated with a laterally positioned flap revealed that connective tissue attachment was re-established in the apical quarter of the successfully covered portion of the root (Sugarman 1969). Cortellini *et al*. (1993) examined histologically a tooth treated with the GTR procedure and showed that connective tissue faced 74% of the length of the recession defect. New cementum with inserting collagen fibers, that is new connective tissue attachment, covered 48% of the distance between the apical border of the root instrumentation and the soft tissue margin. In addition, histomorphometric assessments of a tooth treated with enamel matrix proteins revealed that new cementum covered 73% of the original defect (Heijl 1997).

Use of free soft tissue graft procedures

A free soft tissue graft of masticatory mucosa is usually selected when there is no acceptable donor tissue present in the area adjacent to the recession defect or when a thicker marginal tissue is desirable. The procedure can be used for the treatment of a single tooth as well as for several adjacent teeth. The graft used may either be (1) an epithelialized graft or (2) a subepithelial CTG of palatal masticatory mucosa.

Epithelialized soft tissue graft

The epithelialized free soft tissue graft procedure can be performed either as a two-step surgical technique, where an epithelialized free soft tissue graft is placed apical to the recession and following healing is positioned coronally over the denuded root (Fig. 39-38) (Bernimoulin *et al*. 1975; Guinard & Caffesse 1978), or as a one-step technique by which the graft is placed directly over the root surface (Sullivan & Atkins 1968a, b; Miller 1982) (see Fig. 39-42). The latter technique has been the most commonly used.

Zucchelli and De Sanctis (2013) proposed a modification of the original two-stage technique to overcome the esthetic problems due to the excess of marginal keratinized tissue in the transplanted area (Fig. 39-39). This modification could be useful in lower anterior cases where the recession has reached the base of the vestibule or in instances with shallow vestibule when adjacent teeth do not have a large band of keratinized tissue to perform a lateral sliding flap. The procedure starts with the preparation of a recipient bed at the base of the recession, then the epithelialized graft is harvested from the palate. Care should be taken to design the correct dimension of the graft: (1) the height of the graft should be equal to the height of the keratinized tissue present on teeth

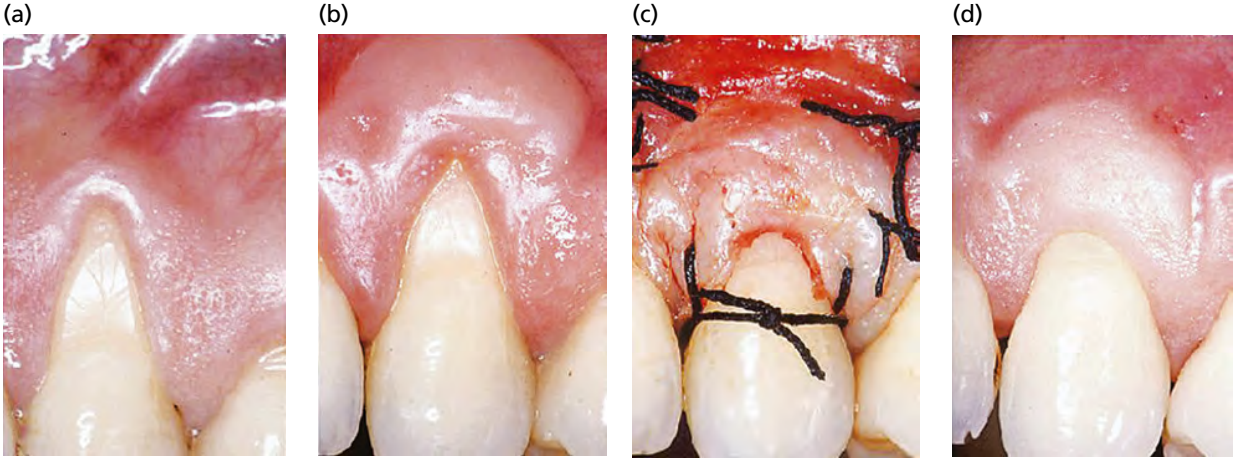

Fig. 39-38 Two-stage epithelialized free soft tissue graft procedure. (a–c) Epithelialized soft tissue graft is placed apical to the recession and allowed to heal. At a second-stage surgery, a coronally advanced flap procedure is performed to achieve coverage of the denuded root. (d) One-year postoperative result. (Source: Courtesy of Professor Giampaolo Pini Prato.)

adjacent to the treated area; (2) the width should correspond to the width of the recession plus the dimension of the anatomical interdental papillae.

Once the graft is harvested it is stabilized apical to the recession over the prepared periosteal bed. Three months after the first surgery, a flap is raised with the same technique described for CAF with a split-full-split approach and positioned 1–2 mm coronal to the CEJ.

The same authors also proposed utilizing a laterally moved and coronally advanced flap with the same two-step approach but positioning the free gingival graft apical to the band of keratinized tissue of the tooth adjacent to the one to be treated (Fig. 39-40). This design is indicated when the vestibule is too shallow or the recession reaches the bottom of the vestibule, that is, in a situation where positioning of a free gingival graft is very difficult or impossible. Three months later a lateral and coronal sliding flap is performed to treat the recession defect. Using the one-step technique, the surgical principles of utilizing free mucosal grafts were outlined by Sullivan and Atkins (1968a, b) and later modified by Miller (1982):

1. Before any incisions, the exposed root surface is carefully scaled and root planed (Fig. 39-41a). The convexity of the root may be reduced to minimize the mesiodistal avascular recipient bed.
2. As in the treatment with pedicle grafts, the preparation of the *recipient bed* is crucial for the success of the free graft procedure. A 3–4-mm wide recipient connective tissue bed should be prepared apical and lateral to the recession defect (Fig. 39-41b). The area is demarcated by first

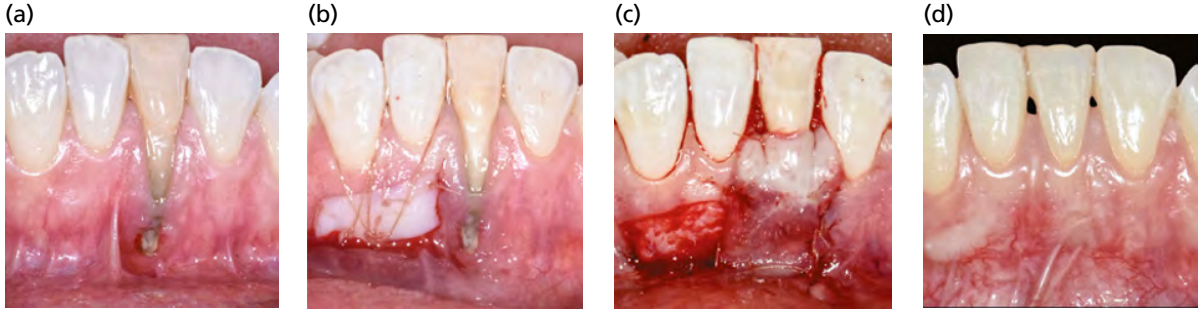

Fig. 39-40 Two stage laterally moved and coronally advanced flap. (a) Very deep recession on a mandibular central incisor. (b) Epithelio-connective free gingival graft on adjacent area. (c) Laterally moved and coronally advanced flap. (d) One-year healing.

placing a horizontal incision, at the level of the CEJ, in the interdental tissue on each side of the tooth to be treated. Subsequently, two vertical incisions, extending from the incision line placed in the interdental tissue to a level approximately 4–5 mm apical to the recession, are placed. A horizontal incision is then made connecting the two vertical incisions at their apical termination. Starting from an intracrevicular incision, a split incision is made to sharply dissect the epithelium and the outer portion of the connective tissue within the demarcated area.

3. To ensure that a graft of sufficient size and proper contour is removed from the donor area, a foil template of the recipient site is prepared. This template is transferred to the donor site, the palatal mucosa in the region of the premolars, and the required size of the graft is outlined by a shallow incision. A graft with a thickness of 2–3 mm is then dissected from the donor area. It is advocated to place sutures in the graft before it is cut completely free from the donor area because this may facilitate its transfer to the recipient site. Following the removal of the graft, pressure is applied to the wound area for control of bleeding.
4. The graft is immediately placed on the prepared recipient bed. In order to immobilize the graft at the recipient site, sutures must be anchored in the periosteum or in the adjacent attached gingiva. Adequate numbers of sutures are placed to secure close adaptation of the graft to the underlying connective tissue bed and root surface. Pressure is exerted against the graft for some minutes in order to eliminate blood from between the graft and the recipient bed.
5. The sutures are usually maintained for 2 weeks. The appearance of a grafted area after 3 months of healing is shown in Fig. 39-41d. A gingivoplasty may be indicated to achieve a satisfactory esthetic appearance of the grafted area (Fig. 39-41e, f).

Connective tissue grafts combined with pedicle grafts

This technique involves utilizing a CTG placed directly over the exposed root and then covered with a mucosal flap mobilized coronally (Fig. 39-42) (Langer & Langer 1985; Nelson 1987; Harris 1992; Bruno 1994; Zucchelli *et al*. 2003). These designs are generally termed as *bilaminar techniques* since their

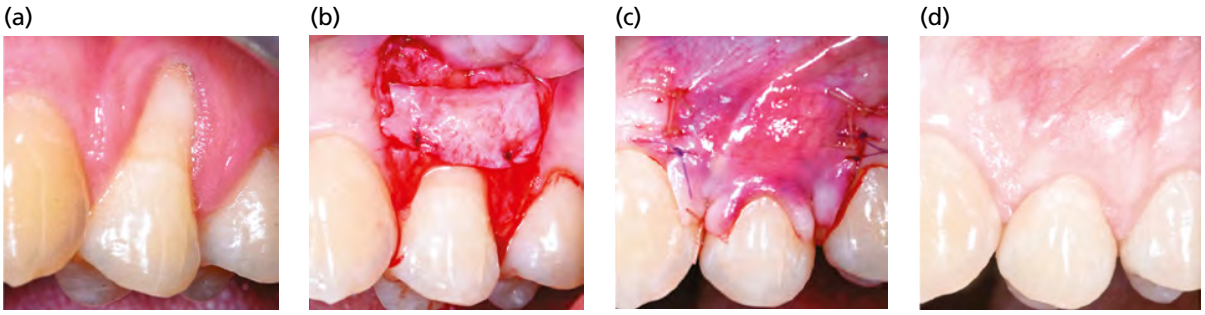

Fig. 39-42 Free connective tissue graft combined with a coronally advanced flap procedure for the treatment of a single recession defect. (a) Deep gingival recession at a premolar with minimal height of keratinized tissue apical to the root exposure. (b) Flap is raised split-full-split and graft has been sutured at the base of de-epithelialized papillae. (c) Flap has been advanced coronally and sutured. (d) Clinical healing at 1 year.

rationale is to use the coronally advanced flap to assure appropriate vascular supply and to use the CTG to modify the gingival phenotype by increasing the thickness of the tissue in the marginal area, thus augmenting the postsurgical stability of the newly formed tissues over the root. A literature review (Graziani *et al*. 2014) has indicated that when the phenotype is increased, the effectiveness of root covering is enhanced. Compared with the epithelialized graft, the CTG is preferable due to a less invasive palatal wound and an improved esthetic result. As an alternative to the CTG, xenogenic collagen matrixes may be used (McGuire & Scheyer 2010; Jepsen *et al*. 2013).

The flap design is the same as described for the CAF. Although it may be raised split thickness, the use of a split-full-split approach is suggested to ensure the maximum stability for the marginal soft tissue.

The connective tissue is harvested from the palate or the retromolar area. Several techniques have been proposed to harvest palatal connective tissue using one, two, or three incisions to raise a primary flap to "open the door" that gives access to the deeper layer of the tissue that is harvested with a fourth incision and withdrawn, making sure that the periosteum is left in position (Fig. 39-43). The primary flap is then closed, and the wound will heal by primary intention.

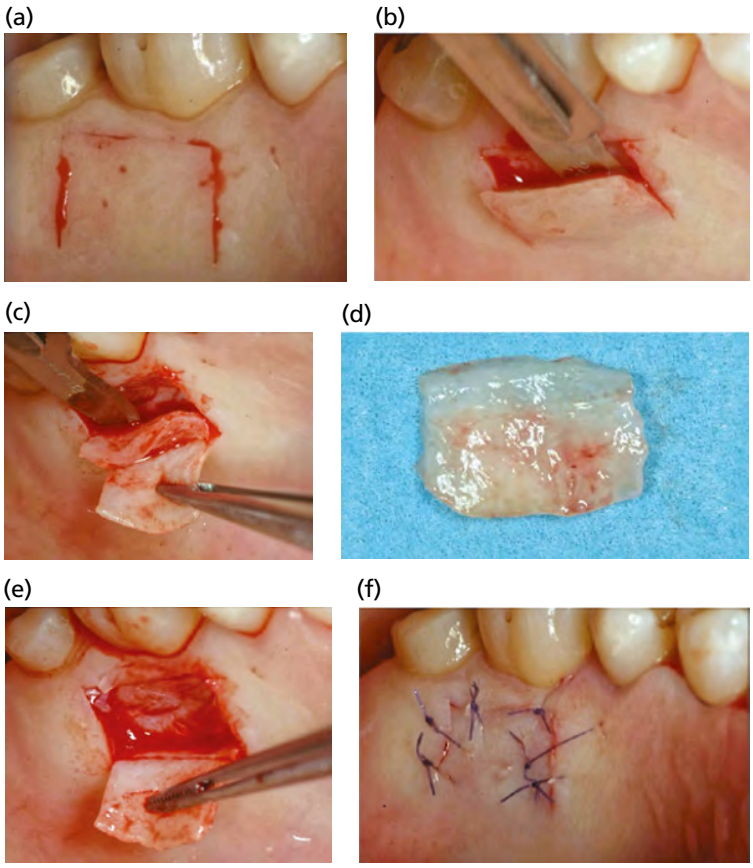

Fig. 39-43 "Trap door technique". (a) Three incisions are performed. (b) Primary flap is raised with a superficial incision. (c) Deep incision to delineate the thickness of the graft. (d) Connective tissue is harvested. (e) Epithelial-connective superficial flap. (f) "Trap door" is closed.

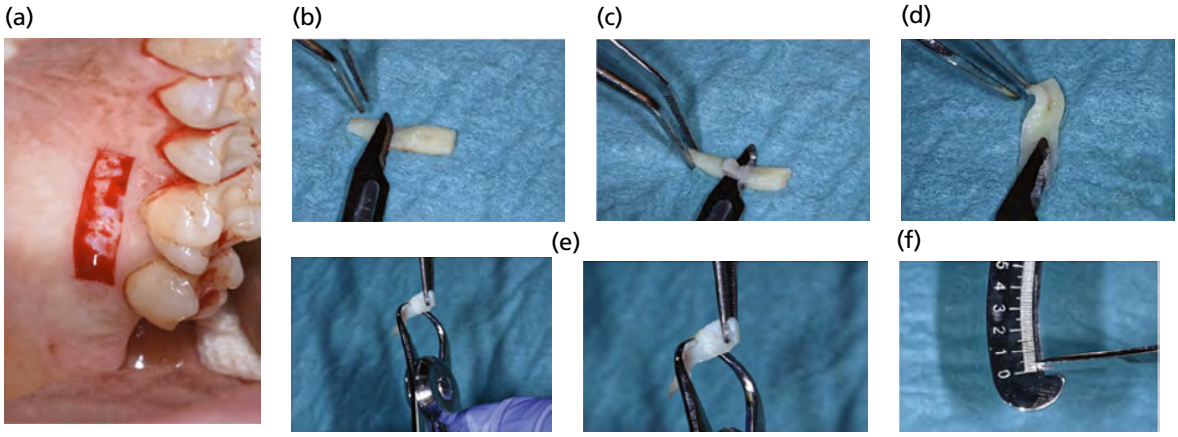

Fig. 39-44 (a) Epithelial-connective tissue is harvested from the palate. (b, c, d) De-epithelization. (e, f) Thickness.

An alternative technique is to harvest epithelial-connective tissue, which is subsequently de-epithelialized out of the mouth (Fig. 39-44). The wound in this case will heal by secondary intention. This technique is suggested to avoid the inclusion of fatty or glandular tissue and to include only dense connective tissue because only the more superficial connective tissue is withdrawn. Zucchelli *et al*. (2010) reported that patient discomfort depends more on the depth of the wound that on the healing modality.

The harvested connective tissue is immediately positioned over the exposed root that has been previously treated and stabilized with marginal sutures at the base of the anatomical papilla at both sides of the recession. According to the authors (Zucchelli *et al*. 2003), the connective tissue should be positioned slightly apical to the CEJ, so it does not interfere with the positioning of the marginal portion of the flap. Finally, the flap is positioned coronal to the CEJ, which is similar to the CAF technique.

The CAF plus connective tissue is a technique that has shown successful results for the root coverage of isolated RT1 and RT2 single recession type defects (Rocuzzo *et al*. 2002; Cairo *et al*. 2014). This surgical approach (CAF plus CTG) may also be utilized to treat multiple recession defects. The approach for multiple recessions is the same as described for the MCAF and once the flap is raised in a split-full-split manner, a connective graft is harvested from the palate and positioned over the previously treated roots (Fig. 39-45). The dimension of the flap is dependent on the number of recessions to be treated.

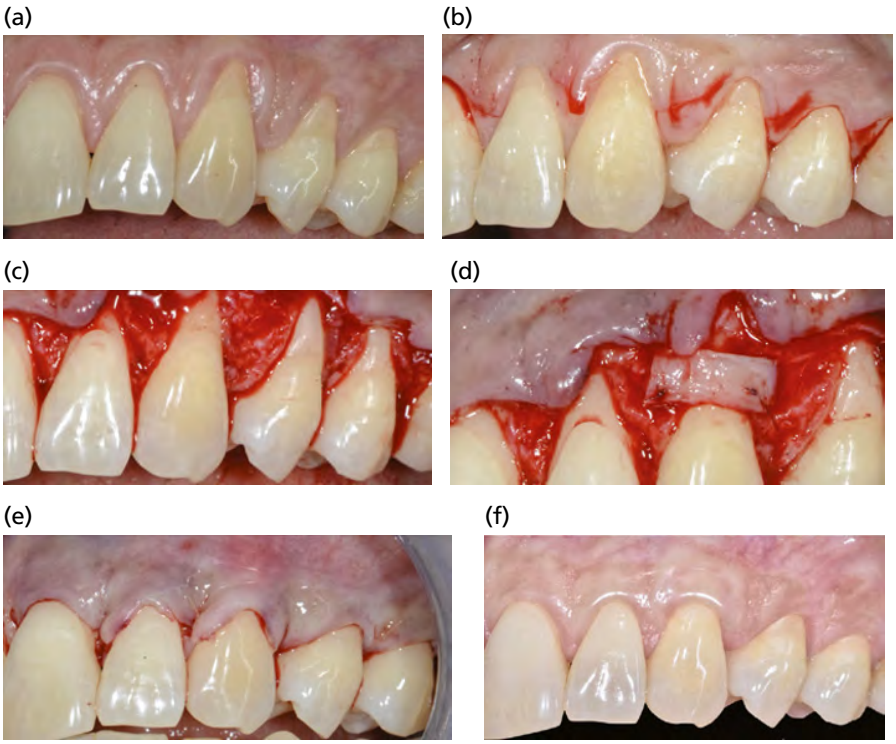

Fig. 39-45 Free connective tissue graft combined with a coronally advanced flap procedure. (a) Multiple recessions; (b) incisions; (c) split-full-split flap elevation with de-epithelialization of the anatomical papilla; (d) free connective tissue graft placed on the canine root surface; (e) coronally positioned flap and sutured; (f) one-year post-treatment result.

A literature review on the treatment of multiple recessions (Graziani *et al*. 2014) reported that the technique of choice should be MCAF combined with the use of CTGs. CTGs are not needed in all recessions, but only in those sites where the phenotypic condition of the gingiva is thin. In these sites this combination has yielded better esthetic and long-term predictable results, with minimal patient discomfort (Cairo *et al*. 2014; Stefanini *et al*. 2018; De Sanctis *et al*. 2020).

Tunnel approaches for the treatment of gingival recessions

In 1985 Raetze described the so called "*envelope technique*" for covering localized areas of root exposure using palatal subepithelial connective tissue grafts (SCTG). The technique implies the preparation of a supraperiosteal "envelope" or "*pouch*" using an undermining partial thickness incision in the tissues surrounding the defect, in order to accommodate a SCTG (Fig. 39-46). The graft is positioned directly over the exposed root and fixed to the underlying surfaces by means of tissue glue (i.e. cyanoacrylate) without the use of sutures. Because its major part is placed in the "envelope", adequate protection, stability, and blood supply originating from the surrounding tissues is ensured. In a retrospective study, Rossberg *et al*. (2008) have assessed the long-term clinical and patient-centered esthetic outcomes following treatment of single recessions by means of the envelope technique and SCTG. Clinical re-examinations made at 6–22 years (mean, 11.4 ± 5.4 years) revealed a mean root coverage (MRC) of 89.7% ± 25.1% while CRC was obtained in 82% (i.e. in 32 out of 39) of the defects.

Further developments in the "envelope" technique resulted in the various types of tunnel approaches. Allen (1994) and Zabalegui *et al*. (1999) described a further extension of the supraperiosteal envelope over several teeth, thus enabling the coverage of multiple adjacent gingival recessions (Fig. 39-47).

The technique described by Zabalegui *et al*. (1999) implied the placement of intrasulcular incisions, followed by preparation of supraperiosteal envelopes at the respective teeth, which subsequently are connected with each other following careful undermining of the papillae. Following preparation of the tunnel, a large SCTG is harvested from the palate, carefully pulled in the tunnel, and adapted so that the gingival recessions are covered. When using this technique, no attempts are made to coronally advance the tunnel to cover the graft and the exposed root surfaces, thus leaving the coronal part of the graft exposed. At 1 year following therapy, the authors reported an MRC of 91.6% and a CRC of 66.7% respectively, thus pointing to the clinical relevance of this surgical approach.

Later, the tunnel approach described by Allen (1994) and Zabalegui *et al*. (1999) was further modified to coronally displace the tunneled flap to completely cover the soft tissue graft with the purpose of improving graft survival and aesthetics (Zuhr *et al*. 2007). A number of case series and randomized clinical studies have evaluated the outcome of this

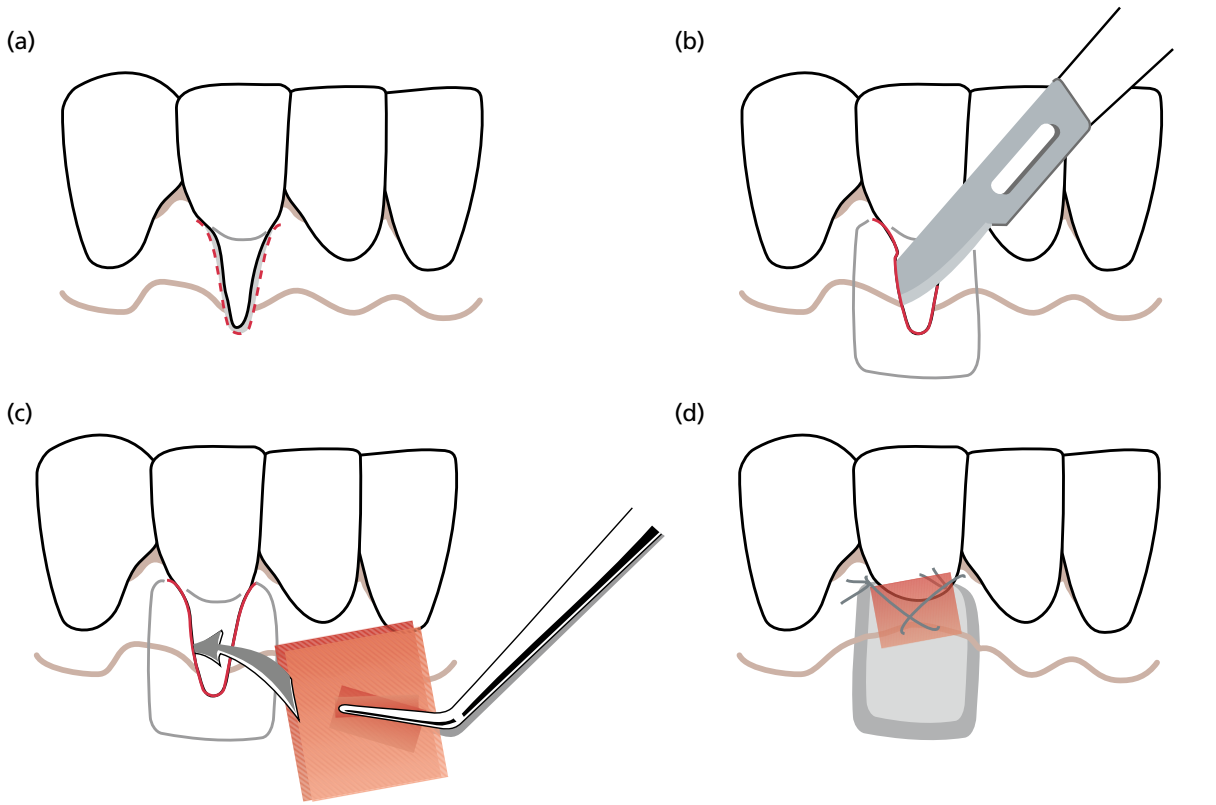

Fig. 39-46 (a–d) The "envelope technique".

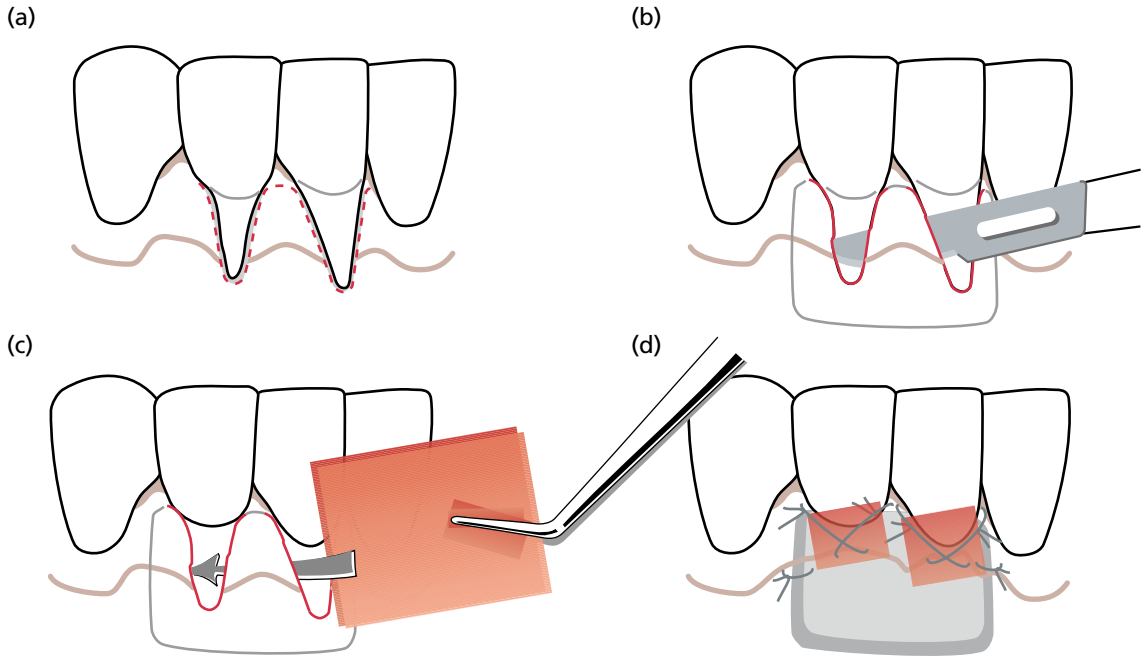

Fig. 39-47 (a–d) Free connective tissue graft procedure: the "tunnel technique". (Sources: Allen 1994; Zabalegul *et al*. 1999. Reproduced with permission from John Wiley & Sons.)

"so called" modified coronally advanced tunnel (MCAT) for the treatment of maxillary multiple adjacent gingival recessions and also for the treatment of single mandibular recessions (Aroca *et al*. 2010, 2013; Sculean *et al*. 2014, 2016, 2017). The major advantage of MCAT is because the prepared tunnel (pouch) is coronally advanced to cover the graft and the exposed root surfaces, thus improving the vascular supply of the graft and subsequently its potential for survival. The most important steps in the design of MCAT are depicted in Fig. 39-48. Following local anesthesia, gentle root planing of the exposed root surface is performed to remove the biofilm using Gracey curettes. Subsequently, intrasulcular incisions at the treated teeth are placed using microsurgical blades and, if needed, extended one tooth mesially or distally. Using specially designed tunneling knives, a full-thickness pouch is raised and prepared beyond the level of the mucogingival junction leaving the interdental papillae intact. The mucoperiosteal pouch is then carefully extended mesially and distally under the neighbouring papillae until the adjacent recessions are connected. Attaching inserting collagen fibres are removed from the inner aspect of the tunneled flap (i.e. connected pouches) using 15c surgical and/or microsurgical blades until tension-free coronal mobilization is obtained. If needed, the interdental parts of the papillae are also gently undermined using specially designed tunneling knifes. Care should be taken not to disrupt the interdental papillary tissues and/or to avoid perforation of the tunnel. After tunnel preparation, a palatal SCTG 1–1.5 mm thick is harvested using the single incision technique described by Hürzeler and Weng (1999) and Lorenzana and Allen (2000). Immediately after closure of the palatal wound, the SCGT is pulled into the tunnel using single or mattress sutures and fixed at the inner surface of the tunnel flap. Subsequently, the graft is imobilized at the CEJ or slightly below using a sling suture to obtain complete stability. Finally, the tunnel flap is advanced coronally to completely cover the graft and the exposed root surface using sling sutures. Sutures are usually removed 14 days after surgery. In a case series consisting of a total or 54 adjacent maxillary RT1 and RT2 (i.e. Miller Class I, II, or III) they were consecutively treated with the MCAT in conjunction with an EMD and SCTG (Sculean *et al*. 2016). Out of 54 recessions, 49 were classified as RT1 and 5 as RT2 recessions. At 12 months following surgery, statistically and clinically significant root coverage was obtained in all patients and defects. CRC was obtained in 40 RT 1 recessions and in one Miller Class III recession representing an MRC of 96% (Fig. 39-48). Follow-up examinations have shown that the obtained results can be maintained on a long-term basis provided that an adequate level of oral hygiene is maintained.

Comparable results were also obtained by Aroca *et al*. (2010), who treated RT2 multiple adjacent gingival recessions by means of MCAT in conjunction with SCTG either with or without an EMD. In that study, the MRC was 82% in the test group (i.e. MCAT + SCGT + EMD) and 83% in the control group (i.e. MCAT + SCGT) respectively, while CRC amounted to 38% in both groups. Interestingly, the additional use of EMD did not seem to influence the clinical outcomes.

Recently, the MCAT was also successfully applied for the coverage of single and multiple RT1 and RT2 gingival recessions at crown-restored teeth in the aesthetic area (Sculean *et al*. 2017) (Fig. 39-49). A total of 23 single or multiple maxillary RT1 and RT2

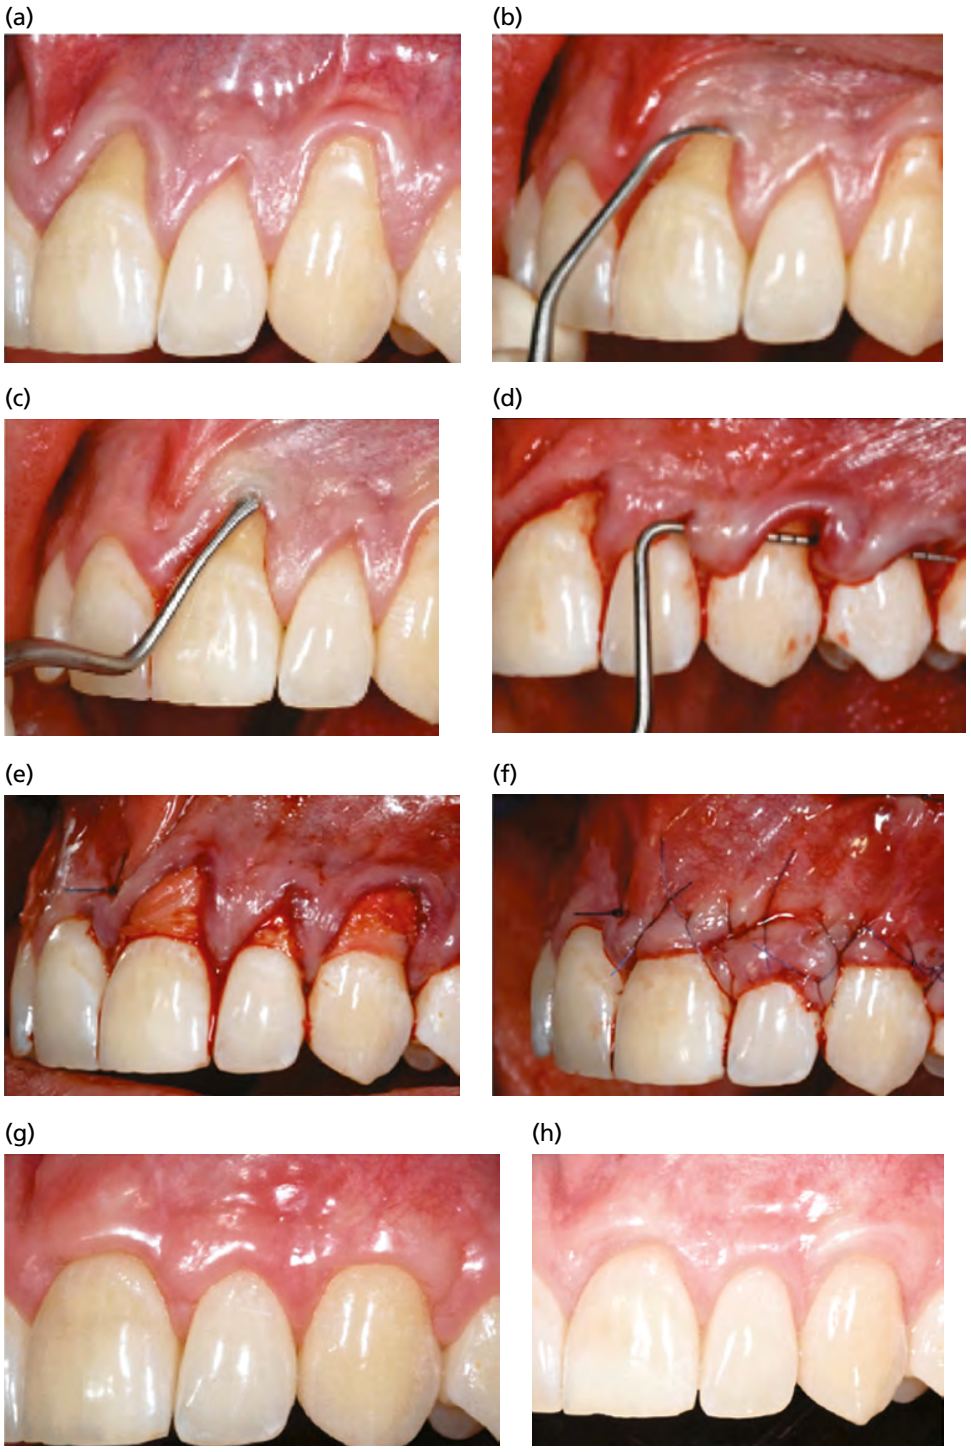

Fig. 39-48 (a) Preoperative view depicting RT1 multiple adjacent gingival recessions. (b) Gentle scaling of the root surfaces to remove the biofilm. (c) Preparation of the tunnel with specially developed tunnel instruments. (d) Prepared tunnel. Please note the tension free mobilization. (e) Subepithelial palatal connective tissue graft (SCTG) sutured at the cementoenamel junction. (f) The tunneled flap is sutured coronally to completely cover the recessions and the SCTG. (g) At 2-years postoperatively, complete recession coverage is evident. (h) At 11 years postoperatively a stable clinical situation is still visible. A slight relapse of the soft tissue can be observed at tooth at 21.

gingival recessions were consecutively treated with MCAT in conjunction with SCTG. Out of the 23 recessions, 16 were classified as RT1 and seven as RT2. All patients presented at least one facial gingival recession at a crown-restored tooth, located in the maxillary anterior area. In all cases, the facial recession was associated with an impaired esthetic appearance. At 12 months, statistically highly significant (P <0.0001) root coverage was obtained in all patients and defects. CRC was obtained in 22 out of the 23 recessions (e.g. in all 16 RT1 and in six out of the seven RT2 recessions) (Fig. 39-49). Taken together, the available results suggest that the use of the MCAT in conjunction with SCTG represents a valuable option for treating RT1 and RT2 multiple gingival recessions in the maxillary aesthetic area.

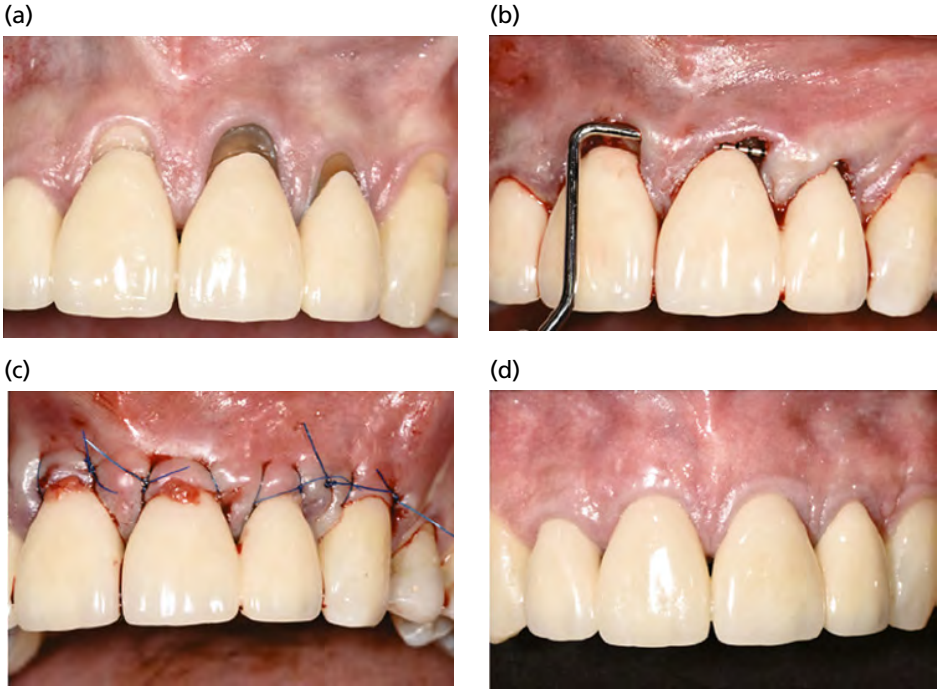

Fig. 39-49 (a) Preoperative view depicting multiple adjacent gingival recessions at crown-restored teeth in the maxillary esthetic area. (b) Prepared tunnel. (c) Coronally sutured tunnel to completely cover the exposed root surfaces and the SCTG. (d) At 2 years post-treatment, complete coverage of the exposed surfaces is evident.

The clinical relevance of the MCAT has also been evaluated in the treatment of isolated mandibular recessions (Sculean *et al*. 2014; Nart & Valles. 2016). In a case series including 16 patients with one isolated RT1 and RT2 mandibular recession, treatment was performed by means of MACT combined with EMD and SCTG (Sculean *et al*. 2014). At 12 months following surgery, statistically and clinically significant root coverage was obtained in all 16 defects. MRC amounted to 96.25% while CRC was measured in 12 out of the 16 defects (75%).

However, in deep isolated mandibular recessions located in the anterior area, tension free coronal displacement of the tunnel flap can be extremely difficult and may result in decreased vestibulum depth and/or flap dehiscence due to increased flap tension. In order to minimize these potential shortcomings, a novel surgical technique (e.g. the laterally closed tunnel or LCT) has been specifically designed and tested for the treatment of deep isolated mandibular RT1 and RT2 recessions (Fig. 39-50) (Sculean & Allen 2018). The LCT implies the placement of slightly beveled intrasulcular incisions by means of microsurgical blades followed by the preparation of a mucoperiosteal pouch (e.g. tunnel) using specially designed microtunnelling instruments. No special attempts are usually made to additionally remove the epithelium surrounding the margins of the pouch, because this is removed by means of the bevelled intrasulcular incisions. The pouch is then mobilized apically beyond the mucogingival line and extended mesially and distally from the recession defect by undermining the facial surface of the interdental papillae (Fig. 39-50). Collagen fibres inserting apically and laterally at the inner surface of the pouch are released using conventional and microsurgical blades until tension-free mesial and distal displacement of the pouch margins is obtained. Special attention needs to be paid in order not to disrupt the interdental papillae or to perforate the tunneled flap. As a result of this procedure, the margins of the pouch can be approximated without tension mesially and distally to cover either completely or the greatest part of the graft and the exposed root surface. Subsequently, a palatal SCTG is harvested as described earlier and pulled into the tunnel using mattress sutures and fixed mesially and distally at the inner aspect of the tunnel. The graft is additionally adapted to the CEJ by means of a sling suture and, finally, the margins of the pouch are pulled together over the graft and sutured with interrupted sutures to accomplish tension free complete or partial coverage of the graft and of the denuded root surface.

This novel surgical technique has been evaluated in a consecutive case series including 24 patients exhibiting one single deep mandibular RT1 or RT2 gingival recession at a depth of ≥4 mm. At 12 months, CRC was obtained in 17 out of the 24 defects representing 70.83% of the defects, whereas in the remaining seven defects RC amounted to 80–90% (in six cases) and 79% (in one case), respectively. The results obtained at isolated mandibular recessions with both MCAT and LCT compared well with those reported by Zucchelli *et al*. (2014) using the CAF. In a randomized controlled clinical study, Zucchelli *et al*. (2014) have evaluated the treatment of isolated RT1 gingival recessions located at mandibular incisors by means of CAF + SGCT with or without removal

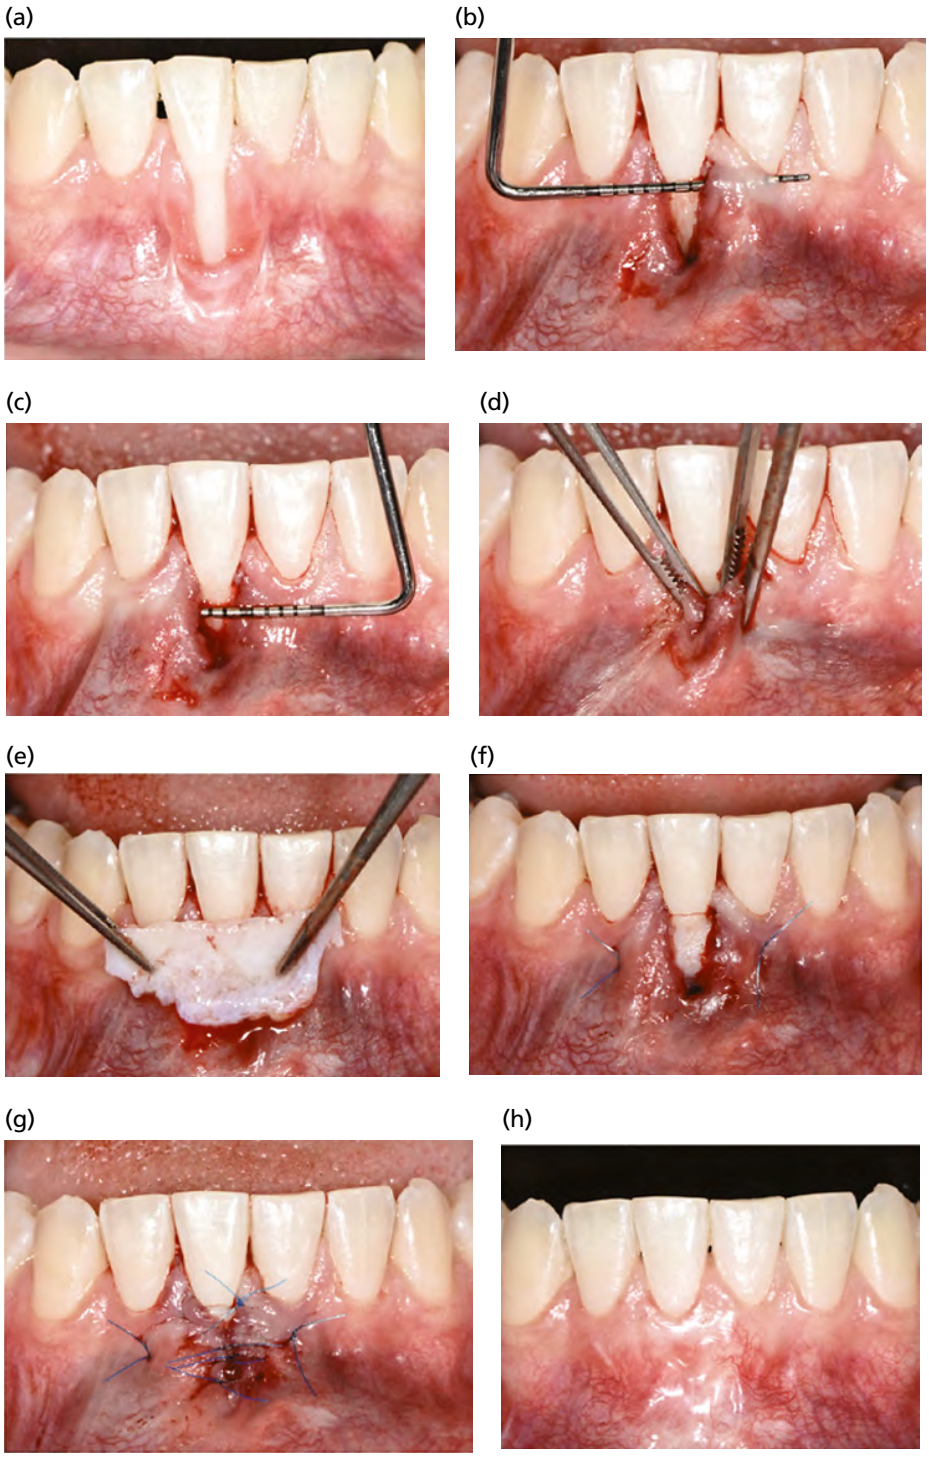

Fig. 39-50 (a) Preoperative view depicting a deep RT1 gingival recession located at tooth 41. (b) Prepared mesial tunnel. (c) Prepared distal tunnel. (d) Following tunnel preparation, tension free mobility of the soft tissue margins is evident. (e) Harvested subepithelial connective tissue graft (SCTG). (f) SCTG sutured at the cementoenamel junction. (g) Tension-free, lateral closure of the tunnel enabling an almost complete coverage of the SCTG. (h) At 1 year after treatment, complete root coverage is evident.

of labial submucosal tissue (LST). The results have shown predictable recession coverage, while the additional removal of LST yielded a tesion-free flap, thus resulting in less graft exposure and statistically significantly better CRC (e.g. 48% vs. 88%). Despite the fact that is is difficult to directly compare the results obtained at mandibular isolated recessions following the use of a CAF with those obtained with MACT or LCT, the results point to the pivotal role of a tension-free coronal mobilization of the soft tissues surrounding the recessions to obtain predictable CRC.

A number of clinical studies have been conducted to compare the outcomes following coverage of single and multiple gingival recessions by means or either the tunnel technique or CAF. The data indicate that CAF+CTG and MCAT+CTG provided comparable clinical and aesthetic improvements in

the treatment of single maxillary gingival recessions (Neves *et al*. 2020). A recent systematic review with meta-analysis has evaluated the efficacy of the tunnel technique in the treatment of localized and multiple gingival recessions and compared the outcomes with those obtained with CAF (Tavelli *et al*. 2018). The overall calculated MRC of the tunnel technique for localized gingival recessions was 82.75% ± 19.7% and 87.87% ± 16.45% for multiple recessions, respectively. Taken together, despite the still limited evidence comparing the tunnel technique with CAF, the available data indicate that both the tunnel approach and CAF may lead to excellent and comparable clinical outcomes in terms of root coverage and esthetics. However, when the same types of grafts were used, CAF was associated with a higher percentage of CRC compared with the tunnel approaches (Tavelli *et al*. 2018).

The use of soft tissue substitutes for the treatment of gingival recessions

Because use of SGCT always requires a second surgical site for harvesting the autogenous tissue graft, with its associated increased patient morbidity and more frequent postsurgical complications such as pain and/or bleeding (Chackartchi *et al*. 2019), a number of soft tissue replacement materials have been developed and investigated for replacing autologous grafts in root coverage procedures. These include mainly the use of ADM or various types of xenogeneic collagen matrices (Bohac *et al*. 2018; de Carvalho Formiga *et al*. 2020).

ADM is an allograft obtained from human skin that is chemically processed to remove all cells while preserving the extracellular dermal matrix (Bohac *et al*. 2018; de Carvalho Formiga *et al*. 2020). ADM has been frequently used for tooth recession coverage using either the CAF or tunnel approaches (Ozenci *et al*. 2015; Tavelli *et al*. 2019). In a randomized clinical trial, Woodyard *et al*. (2004) have shown that on a short-term basis (i.e. at 6 months), the use of ADM in conjunction with CAF resulted in higher recession coverage and increased soft tissue thickness than treatment with CAF alone. Very recent data suggest, however, that on a long-term basis (i.e. up to 12 years) a statistically significant relapse of the gingival margin may occur, irrespective of the used surgical technique (CAF or tunnel) (Tavelli *et al*. 2019).

A 3D xenogeneic porcine-derived bioresorbable collagen matrix (CM) has been evaluated in a histological (Vignoletti *et al*. 2011) and in randomized controlled clinical studies comparing treatment of RT1 single recessions by means of CAF alone or in conjunction with either CM or CTG (McGuire & Scheyer 2010; Cardaropoli *et al*. 2012; Jepsen *et al*. 2013; Moreira *et al*. 2016; Tonetti *et al*. 2018). The results from these studies have provided evidence that in RT1 recessions, the treatment with CAF + CM may result in higher gains of keratinized tissue compared to CAF alone (Jepsen *et al*. 2013; Moreira *et al*. 2016). However, in terms of root coverage, CM yielded either comparable or slightly less results compared with the outcomes obtained with CTG (de Carvalho Formiga *et al*. 2020). However, the use of CM was associated with statistically significantly reduced surgical time and patient morbidity compared with the use of CTG (McGuire & Scheyer 2010; Cardaropoli *et al*. 2012; Tonetti *et al*. 2018; de Carvalho Formiga *et al*. 2020).

The use of CM has also been evaluated in case series and in an RCT for the treatment of RT1 multiple adjacent recessions using MCAT (Aroca *et al*. 2013; Molnár *et al*. 2013). When compared with SCTG (Aroca *et al*. 2013), both treatments resulted in statistically significant improvements of CRC, MRC, KTW, and GT compared with baseline (P <0.05). However, CRC was found at 42% of test sites and at 85% of control sites, respectively (P <0.05) thus indicating superior results for SCTG. However, duration of surgery and patient morbidity were statistically significantly lower in the test compared with the control group. The long-term (i.e. up to 5 years) outcomes following treatment of isolated gingival recession by means of CAF + CM or CAF + SCTG have been evaluated by McGuire and Scheyer (2016). The results have failed to show statistically significant differences in terms of keratinized tissue width, probing depths, and recession coverage between the two groups indicating similar outcomes for both types of grafts.

Another type of collagen matrix is a porcine-derived acellular dermal collagen matrix (PADM) (Cosgarea *et al*. 2016; Pietruska *et al*. 2019). Pietruska *et al*. (2019) have compared the outcomes of the MCAT technique used in conjunction with either PADM or SCTG for the treatment of mandibular RT1 MAGR. The results revealed statistically significant recession coverage in both groups, but CRC was achieved in nine out of 45 (20%) defects treated with PADM and in 31 out of 39 (67%) treated with SCTG, thus indicating superior results for SCTG.

Taken together, the available evidence suggests that the use of the available soft tissue replacement materials may lead to short-term outcomes comparable with the use of autogenous grafts and also to less patient morbidity. However, the long-term stability of the results still needs to be demonstrated.

Healing of free soft tissue grafts

Survival of a free soft tissue graft placed over a denuded root surface depends on diffusion of plasma and subsequent revascularization from those parts of the graft that are resting on the connective tissue bed surrounding the dehiscence. The establishment of collateral circulation from adjacent vascular borders of the bed allows the healing phenomenon of "bridging" (Sullivan & Atkins 1968a). Hence, the amount of tissue that can be maintained over the root surface is limited by the size of the avascular area (Oliver

et al. 1968; Sullivan & Atkins 1968a). Other factors considered critical for the survival of the tissue graft placed over the root surface are that a sufficient vascular bed is prepared around the dehiscence and that a thick graft is used (Miller 1985b).

Another healing phenomenon frequently observed following free graft procedures is "creeping attachment", that is, coronal migration of the soft tissue margin. This occurs as a consequence of tissue maturation over a period of about 1-year post-treatment.

There are few histologic evaluations of the nature of the attachment established to the root surface following the use of free grafts for root coverage. Sugarman (1969) reported from a histologic evaluation of a human tooth treated with a free soft tissue graft that new connective tissue attachment was found in the apical quarter of the successfully covered recession defect. Harris (1999) and Majzoub *et al*. (2001), each reporting the histologic outcome of free CTGs in two cases, found only minimal amounts of new cementum formation in the most apical part of the recession defect and that healing resulted in a long junctional epithelium occupying the interface between the covering soft tissue and the root. Carnio *et al*. (2002) performed a histologic evaluation of four cases of root coverage with a CTG combined with application of enamel matrix proteins (Emdogain®). They reported that the healing resulted in connective tissue adhesion to the root surface and that the formation of new cementum was observed only in the most apical end of the grafted area.

Thus, the limited histologic information available from humans on the healing of free soft tissue grafts indicates that a healing pattern similar to the one discussed above following pedicle graft procedures may result, namely that connective tissue attachment may be established in the most apical and lateral parts of the recession defect, but that an epithelial attachment is formed along the major portion of the root. Further, the application of enamel matrix proteins may prevent the apical migration of the epithelium but may not favor the formation of a true connective tissue attachment between the free graft and the root surface.

Selection of surgical procedure for root coverage

For each individual case, several factors have to be taken into consideration when selecting the surgical procedure for achieving root coverage, for example jaw, tooth position, recession depth and width, tissue thickness and quality apical and lateral to the recession, esthetic demands, and compliance. From an esthetic point of view, the soft tissue coverage of exposed root surfaces should be in harmony with the adjacent tissue and hence a pedicle graft would be the preference.

For maxillary teeth, the coronally advanced flap may be considered as the basic procedure to be used for single as well as multiple recessions. If the quality of the mucosa apical to the recessions is considered inadequate for root coverage, the procedure is combined with the placement of a CTG.

In the mandible, the placement of a free CTG with an "envelope" or a "tunnel" preparation is preferred because of a thin mucosa apical to the recession and often the presence of multiple frenula, that is, conditions not suitable for a coronally advanced flap. In case of a localized single recession defect of moderate depth, a rotational flap may be used if keratinized mucosa of sufficient dimensions is available lateral to the recession.

Clinical outcomes of root coverage procedures

Independent of the modality of surgical procedure used to attain soft tissue root coverage, shallow residual probing depths, gain in clinical attachment, and increase in gingival height are the common characteristics of treatment outcome. Although the major indications for performing root coverage procedures are esthetic/cosmetic demands and root sensitivity, few studies have used assessments of these criteria as end points of treatment success. Instead, the common outcome variables used are the amount of root coverage achieved, expressed as a percentage of the initial depth of the recession defect, and the proportion of treated sites showing complete root coverage. Whereas CRC may be a successful outcome with respect to root sensitivity, it is not necessarily equivalent to treatment success from an esthetic point of view because, besides root coverage in harmony with adjacent teeth, factors such as tissue thickness, color, and texture influence the appreciation of the esthetic result.

An overall comparison of the treatment outcome of various root coverage procedures is hampered by the fact that there is substantial heterogeneity between studies (Cairo *et al*. 2008; Chambrone *et al*. 2009). The variability in the treatment outcome for the various procedures, both within and between studies, is large, indicating that the procedures are operator sensitive and that various factors influencing the treatment outcome have not been adequately considered. An analysis with regard to initial Miller class I–II recession defects that may be successfully covered following treatment with coronally advanced flaps, based on the data from randomized controlled studies included in recent systematic reviews (Cairo *et al*. 2008; Chambrone *et al*. 2009), shows that on average about 70% root coverage may be expected (range 34–87%). Complete coverage of the recession defect, which is the ultimate goal of the therapy, may be reached in approximately 35% of treated cases (range 15–60%).

Evidence suggests that the treatment outcome can be improved by adjunctive use of CTG or enamel matrix proteins, with an estimated mean absolute

adjunctive effect of 15–25% for CRC and 13–17% for reduction in recession depth (Cairo *et al*. 2008; Chambrone *et al*. 2009; Buti *et al*. 2013).

Systematic reviews were prepared for the EFP and AAP consensus workshops, respectively (Cairo *et al*. 2014; Chambrone & Tatakis 2015) and it was reported that bilaminar techniques using subepithelial CTGs achieved superior percentages of mean and CRC as well as a significant increase in keratinized tissue. The outcome of these consensus workshops indicated that: CAF was associated with higher probability of CRC and a higher amount of recession reduction than the SCPF. The combination of CAF+CTG seems to be the more effective technique to reach a CRC and recession reduction, when compared with other techniques (CAF plus collagen matrix, free gingival graft, laterally positioned flap, CAF plus barrier membranes). GTR was not able to improve the clinical efficacy of CAF. Studies adding ADM under CAF showed a large heterogeneity and no significant benefits compared with CAF alone. Multiple combinations, using more than a single graft/biomaterial under the flap, usually provide similar or less benefits than simpler, control procedures in term of root coverage outcomes. In the same workshop, Graziani *et al*. (2014) carried out a metanalysis for multiple gingival recessions, with similar outcomes in relation to the different surgical treatment modalities, although with lesser evidence. An even more recent systematic review (Chambrone *et al*. 2019) corroborated these results, reporting that the CAF with or without the use of CTGs or other biomaterials, can be used for the successful treatment of single or multiple recession type defects. The modified CAF and tunnel approaches show the highest percentages of CRC.

Factors influencing the degree of root coverage

Patient-related factors. As with other surgical periodontal treatment procedures, poor oral hygiene will negatively influence the success of root coverage procedures (Caffesse *et al*. 1987). Further, a predominant causative factor in the development of gingival recession is toothbrushing trauma, and hence this factor has to be corrected to secure an optimal outcome for any root coverage procedure. Treatment outcome in terms of root coverage is usually less favorable in smokers than in non-smokers (Trombelli & Scabbia 1997; Zucchelli *et al*. 1998; Martins *et al*. 2004; Erley *et al*. 2006; Silva *et al*. 2006), although some studies showed no differences between these groups (Tolmie *et al*. 1991; Harris 1994).

Site related factors. Among site-specific factors, the level of interdental periodontal support may be of greatest significance for the outcome of root coverage procedures. From a biologic point of view, CRC is achievable in RT1–2 recession defects (Fig. 39-51), whereas when loss of connective tissue attachment and soft tissue height also involves proximal tooth sites (RT3), only partial facial root coverage may be obtainable (Fig. 39-52). An additional factor shown to influence the degree of attainable root coverage is the dimensions of the recession defect. A less favorable treatment outcome has been reported at sites with wide (>3 mm) and deep (≥5 mm) recessions (Holbrook & Ochsenbein 1983; Pini Prato *et al*. 1992; Trombelli *et al*. 1995). In a study comparing the treatment effect of coronally advanced flap and free CTG procedures, Wennström and Zucchelli (1996) reported that CRC was observed in only 50% of the defects with an

initial depth of ≥5 mm compared with 96% for shallower defects.

Technique-related factors. Several technique-related factors may influence the treatment outcome of a pedicle graft procedure. In a systematic review including data from 15 studies (Hwang & Wang 2006), a positive correlation was demonstrated between the thickness of the tissue flap and recession reduction. For complete root coverage, the critical threshold thickness was found to be about 1 mm. However, whether a full- or a split-thickness pedicle graft is used for root coverage may not influence the treatment outcome (Espinel & Caffesse 1981). Elimination of flap tension is considered an important factor for the outcome of the coronally advanced flap procedure. Pini Prato *et al*. (2000a) measured the tension in coronally advanced flaps to compare the amount of root coverage in sites with and without residual flap tension. At sites that had residual tension (mean 6.5 g), the root coverage amounted to 78% 3 months postsurgically and 18% of the treated sites showed complete root coverage. Sites without tension demonstrated MRC of 87% and CRC in 45% of the cases. Furthermore, a statistically significant negative association was shown between the magnitude of residual tension in the flap and the amount of recession reduction. Although the connective tissue areas lateral to the recession defect are considered important for the retention of the advanced flap when positioned over the root surface, the dimension of the interdental papilla area is not a prognostic factor for the clinical outcome of the root coverage procedure (Saletta *et al*. 2001). As can be expected, the position of the gingival margin relative to the CEJ after suturing affects the probability of CRC following healing. Pini Prato *et al*. (2005) demonstrated that for 100% predictability of CRC in the treatment of Miller class I recessions with a coronally advanced flap procedure, the flap margin has to be positioned at least 2 mm coronal to the CEJ.

With regard to free graft procedures, the thickness of the graft influences their success (Borghetti & Gardella 1990). A thickness of the free graft of about 2 mm is recommended.

Tooth-related factors. The development of NCCLs occurs frequently on exposed root surfaces. Several studies showed that these lesions are associated with deeper gingival recessions and with a reduced probability for CRC (Jepsen *et al*. 2018). When NCCLs are present in a site with a gingival recession, a multidisciplinary approach should be considered including mucogingival surgery for root coverage and CEJ reconstruction. It is not yet clear whether the hard tissue damage should be restored before or after the surgical phase, although there is evidence that restorative materials, such as glass ionomer cements or composites, can be combined with a coronal advanced flap (Santamaria *et al*. 2008, 2009, 20 14, 2016, 2018; Silveira *et al*. 2017) (Fig. 39-51). When restoring the CEJ several techniques have been proposed (Zucchelli *et al*. 2006; Cairo *et al*. 2010; Zucchelli *et al*. 2011; Silveira *et al*. 2017; Santamaria *et al*. 2018), although there is not a consensus where to establish the new CEJ. Some authors suggest positioning the composite restoration 1–2 mm apical to the original position in order to allow for an apical shift of the soft tissue margin following the

root coverage procedure and for the restoration to still be effective in reducing the root sensitivity (Silveira *et al*. 2017; Santamaria *et al*. 2018). De Sanctis *et al*. (2020) proposed a combined approach in the treatment of multiple recession presenting NCCL consisting of the re-establishment of the CEJ with the composite restoration extending 1 mm apical to the original anatomical T position combined with the MCAF with or without a vertical releasing incision, utilizing the site-specific application of a CTG as previously discussed. Using this approach, CRC was attained in 90% of all the treated sites at 12 months follow-up

Interdental papilla reconstruction

The loss of papilla height and the establishment of "black triangles" between teeth may occur due to several reasons. In adults the most common reason is loss of periodontal support due to periodontitis, but other factors, such as abnormal tooth shape, improper contours of prosthetic restorations, and traumatic oral hygiene procedures, may also negatively influence the outline of the interdental soft tissues.

Nordland and Tarnow (1998) proposed a classification system regarding the papillary height adjacent to natural teeth, based on three anatomic landmarks: the interdental contact point, the apical extent of the facial CEJ, and the coronal extent of the proximal CEJ (Fig. 39-52):

- *Normal*: the interdental papilla occupies the entire embrasure space apical to the interdental contact point/area
- *Class I*: the tip of the interdental papilla is located between the interdental contact point and the level of the CEJ on the proximal surface of the tooth
- *Class II*: the tip of the interdental papilla is located at or apical to the level of the CEJ on the proximal surface of the tooth but coronal to the level of the CEJ mid-buccally
- *Class III*: the tip of the interdental papilla is located at or apical to the level of the CEJ mid-buccally.

In an observational study in humans, Tarnow *et al*. (1992) analyzed the correlation between the presence of interproximal papillae and the vertical distance between the contact point and the interproximal bone crest. When the vertical distance from the contact point to the crest of bone was ≤5 mm, the papilla was present almost 100% of the time, whereas if the distance was ≥6 mm only partial papilla fill of the embrasure between the teeth was most commonly found. Considering that a supracrestal connective tissue attachment zone of approximately 1 mm is normally found (Gargiulo 1961), the observation indicates that the biologic height of the interdental papilla may be limited to about 4 mm. This interpretation is supported by the observation that in interdental areas denuded following an apically repositioned flap procedure, an up growth of around 4 mm of soft tissue had taken place 3 years after surgery (Van der Velden 1982). Hence, before attempts are made to surgically reconstruct an interdental papilla, it is important to carefully assess (1) the vertical distance between the bone crest and the apical point of the contact area between the crowns and (2) the soft tissue height in the interdental area. If the bone crest–contact point distance is ≤5 mm and the papilla height is <4 mm, surgical intervention for increasing the volume of the papilla could be justified in order to solve the problem of an interdental "black triangle". However, if the contact point is located >5 mm from the bone crest, because of loss of periodontal support and/or an inappropriate interdental contact relationship between the crowns, methods to lengthen the contact area apically between the teeth should be selected rather than a surgical attempt to improve the topography of the papilla.

If loss of papilla height is only caused by soft tissue damage from oral hygiene devices, interproximal hygiene procedures must be initially discontinued to allow soft tissue recovery and then successively modified in order to eliminate/minimize traumatic injury to the papillae.

Surgical techniques

Several case reports have been published regarding surgical techniques for the reconstruction of deficient papillae (e.g. Beagle 1992; Han & Takei 1996; Azzi *et al*. 1998). However, the predictability of the various procedures has not been documented and no data are available in the literature providing information on the long-term stability of surgically regained interdental papillae.

Beagle (1992) described a pedicle graft procedure utilizing the soft tissues palatal to the interdental area (Fig. 39-53). A split-thickness flap is dissected on the palatal aspect of the interdental area. The flap is elevated labially, folded, and sutured to create the new papilla at the facial part of the interdental area. A periodontal dressing is applied on the palatal aspect only, in order to support the papilla.

Han and Takei (1996) proposed an approach for papilla reconstruction ("semilunar coronally repositioned papilla") based on the use of a free CTG (Fig. 39-54). A semilunar incision is placed in the alveolar mucosa facial to the interdental area and a pouch-like preparation is performed into the interdental area. Intrasulcular incisions are made around the mesial and distal half of the two adjacent teeth to free the connective tissue from the root surfaces to allow coronal displacement of the gingival–papillary unit. A CTG, taken from the palate, is placed into the pouch to support the coronally positioned interdental tissue.

Azzi *et al*. (1998) described a technique in which an envelope-type flap is prepared for coverage of a

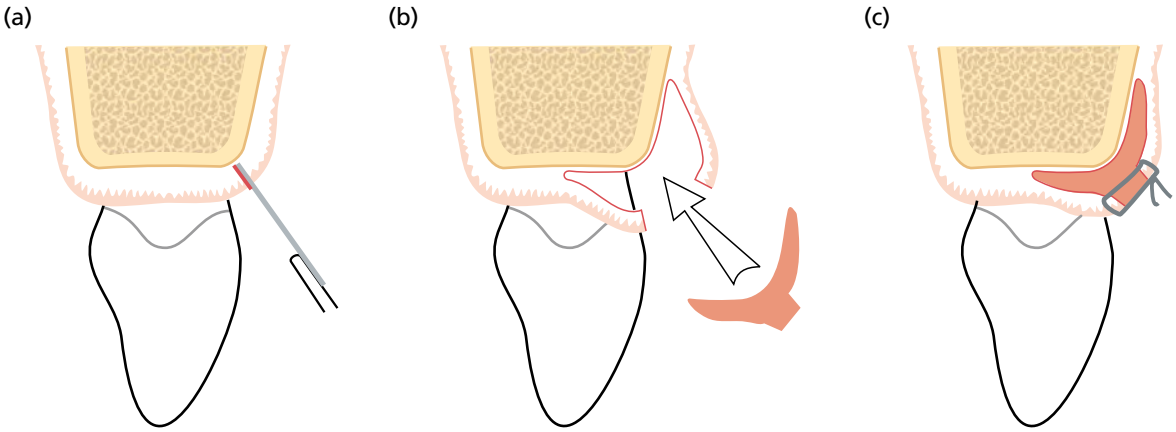

Fig. 39-55 (a–c) Papilla reconstruction: "envelope" technique (see text for explanation).

CTG (Fig. 39-55). An intrasulcular incision is made at the tooth surfaces facing the interdental area to be reconstructed. Subsequently, an incision is made across the facial aspect of the interdental area and an envelope-type split-thickness flap is elevated into the proximal site as well as apically to a level beyond the mucogingival line. A CTG is harvested from the tuberosity area, trimmed to adequate size and shape, and placed under the flaps in the interdental papilla area. The flaps are brought together and sutured with the CTG underneath.

Crown-lengthening procedures

Crown lengthening (CL) is a surgical procedure used to either facilitate restorative dentistry or to satisfy a patient's esthetic demands when there is excessive gingival display when smiling or when gingival enlargement prevents adequate oral hygiene practices (Lee 2004).

Depending on the main objective, whether the aim is to improve esthetic outcomes or for restorative purposes, CL surgical interventions have been categorized as esthetic, in situations of excessive gingival display and/or altered passive eruption, or functional, in situations where subgingival caries or fractures require the exposure of subcrestal sound tooth structure. Both have, however, the common objective of the re-establishment of the biologic width in a more apical position. Although biologic width has been the commonly used clinical term to describe the distance between the base of the gingival sulcus and the height of the alveolar bone, this distance corresponds to the apico-coronal variable dimensions of the junctional epithelium and supracrestal connective tissue attachment, and hence the dimension of the supracrestal attached tissues is currently the preferred term (Jepsen *et al*. 2018). The rationale of crown lengthening is, therefore, to re-establish the supracrestal attached tissues in a more apical position, thus avoiding the violation of this space, since there is available evidence from human and animal studies that its infringement is associated with inflammation and subsequent loss of periodontal supporting tissues, accompanied by an apical shift of the junctional epithelium and supracrestal connective tissue attachment (Jepsen *et al*. 2018).

Excessive gingival display

In most patients, the upper lip line limits the amount of gingiva that is exposed when a person smiles. Patients who have a high lip line expose a broad zone of gingival tissue and may often express concern about their "gummy smile" (Fig. 39-56).

The form of the lips and the position of the lips during speech and smiling cannot be easily changed, but the dentist may, if necessary, modify/control the form of the teeth and interdental papillae as well as the position of the gingival margins and the incisal edges of the teeth. In other words, it is possible by a combination of periodontal and prosthetic treatment measures to improve dentofacial esthetics in this category of patient.

As a base for treatment decisions, a careful analysis of the dentofacial structures and how these may affect esthetics should be performed. It should include the following features:

- Facial symmetry
- Interpupillary line; even or uneven
- Smile line: low, median or high
- Dental midline in relation to facial midline

Fig. 39-56 "Gummy smile" patient exhibiting excessive gingival display when smiling.

Fig. 39-57 "Gummy smile" patient exhibiting excessive gingival display when smiling due to an altered passive eruption

- Gingival display during speech and during a broad, relaxed smile
- Harmony of gingival margins
- Location of gingival margins in relation to the CEJ
- Periodontal phenotype
- Tooth size and proportions/harmony
- Incisal plane/occlusal plane.

Excess gingival display can occur when passive eruption has been delayed. Altered passive eruption is a developmental condition with abnormal dentoalveolar relationships. In the young adult with an intact periodontium, the gingival margin normally resides about 1 mm coronal to the CEJ. However, these patients may have a height of free gingiva that is >1 mm, resulting clinically with an insufficient length of the clinical crowns, with gingival margins (and sometimes bone) located at a more coronal level. In fact, when the bone is located more coronally, the alveolar crest may be located at the level of the CEJ or even beyond, which does not allow appropriate space for the supracrestal connective tissue attachment, which leads to pseudopockets and esthetic concerns. The result is the appearance of short clinical crowns and the usual patient complaint of "small front teeth". In the presence of a medium or high lip line, this condition will be more noticeable, combining the short teeth with an excessive gingival display (Fig. 39-57).

Exposure of sound tooth structure

In some clinical situations, conditions are unfavorable for successful restorative procedures. These include: deep subgingivally located carious lesions, crown and root fractures, pre-existing deep preparation margins, perforations during endodontic therapy, and root resorptions. Similarly, although supragingival placement of restorative margins is generally preferred because it facilitates impression making, finishing of the restoration, verification of its marginal integrity, and maintenance of gingival health, there are certain esthetically demanding clinical situations that require placing the restoration margins deep subgingivally. In these situations when there is not enough available tooth structure, the violation of the supracrestal tissue attachment may result in a periodontal lesion characterized by gingival inflammation, attachment loss, and alveolar bone resorption.

Surgical lengthening of the clinical crown will improve the anatomical conditions and facilitate restorative procedures in these patients that can be divided into two categories:

1. *Subjects who have normal occlusal relationships and incisal guidance*. In this category, the incisal line of the front teeth must remain unaltered, but the clinical crowns can be made longer by surgically exposing the root structure and by locating the cervical margins of the restorations apical to the CEJ (Fig. 39-57).
2. *Subjects who have abnormal occlusal relationships with excessive interocclusal space in the posterior dentition when the anterior teeth are in edge-to-edge contact*. In this category, the length of the maxillary front teeth can be reduced without inducing posterior occlusal interferences. In addition, the marginal gingiva can be resected or relocated to an apical position before crown restorations are made (Fig. 39-58).

In some individuals with an excessive display of gingiva, the size and shape of the teeth and the location of the gingival margins may be perfectly normal. The excessive display of gingiva in these cases is

Fig. 39-58 Patient with a "gummy smile" and restorative needs with a mock-up on depicting planned final tooth shapes and sizes

often caused by vertical maxillary excess and a long mid-face. Periodontal crown-lengthening procedures will not suffice to solve their problems, but rather the maxilla must be altered by a major maxillofacial surgical procedure. The risk-to-benefit and cost-to-benefit ratios must be thoroughly evaluated before recommending this type of surgical therapy to correct esthetic problems.

Selection of the crown lengthening procedure

To select the proper procedure for crown lengthening, there is a need for indidualized analysis of crown–root–alveolar bone relationships. When restorative work is planned, an acrylic *mock-up* should be fabricated depicting the ideal tooth sizes and shapes. This *mock-up* is useful not only for adequate diagnosis and treatment planning, but also for patient acceptance, since the final result is evident (Fig. 39-58).

Gingivectomy

In clinical situations where the excessive gingival display is due only to excessive apical displacement of the gingival tissues (pseudopockets) with a normal dimension of the root–alveolar bone relationships (adequate space for the supracrestal connective tissue attachment from the alveolar crest to the CEJ), the full exposure of the anatomic crown can be accomplished by a gingivectomy/gingivoplasty procedure. In a study by Monefeldt and Zachrisson (1977), the effect of gingivectomies on the clinical facial crown height was assessed on study models from first bicuspids scheduled for extraction for orthodontic reasons. It was observed that the mean clinical crown height increased by 1 mm, whereas the mean probing pocket depth was reduced by 1 mm. In the histologic analyses, no apical migration of the epithelium beyond the CEJ was observed. This led to the conclusion that gingivectomy resulted in a reduction of pseudo pockets and did not displace the connective tissue attachment level apically. Therefore, gingivectomies can only be recommended for the controlled apical dislocation of the soft marginal tissues without altering the alveolar bone crest and connective tissue attachment level. In these situations, the gingivectomy procedure can be carried out either with an externally beveled path of incision what will frequently need extending across the midline and leaving a wide area of gingival tissue to heal by secondary intention, or alternatively, an internally beveled path of incision (internal gingivectomy) usually finished at the gingival margin area with a minimal gingivoplasty for achieving knife edge gingival margins (Fig. 39-59).

Apically positioned flaps

Conventional crown lengthening procedures are typically accomplished by an apically positioned flap (APF) with/without osseous resection (Palomo & Kopczyk 1978). In CL surgical interventions aimed at satisfying high esthetic demands, it is imperative to achieve an ideal position for the gingival margins (Herrero *et al*. 1995) and maintain this position long term (Deas *et al*. 2014). As a general rule, at least 4 mm of sound tooth structure must be exposed at the time of surgery, since during healing, the supracrestal soft tissues will proliferate coronally to cover 2–3 mm of the root (Herrero *et al*. 1995; Pontoriero & Carnevale 2001; Lanning *et al*. 2003), thereby leaving only 1–2 mm of supragingivally located sound tooth structure. When this technique is used for crown lengthening, it must also be realized that gingival tissues have an inherent tendency to bridge abrupt

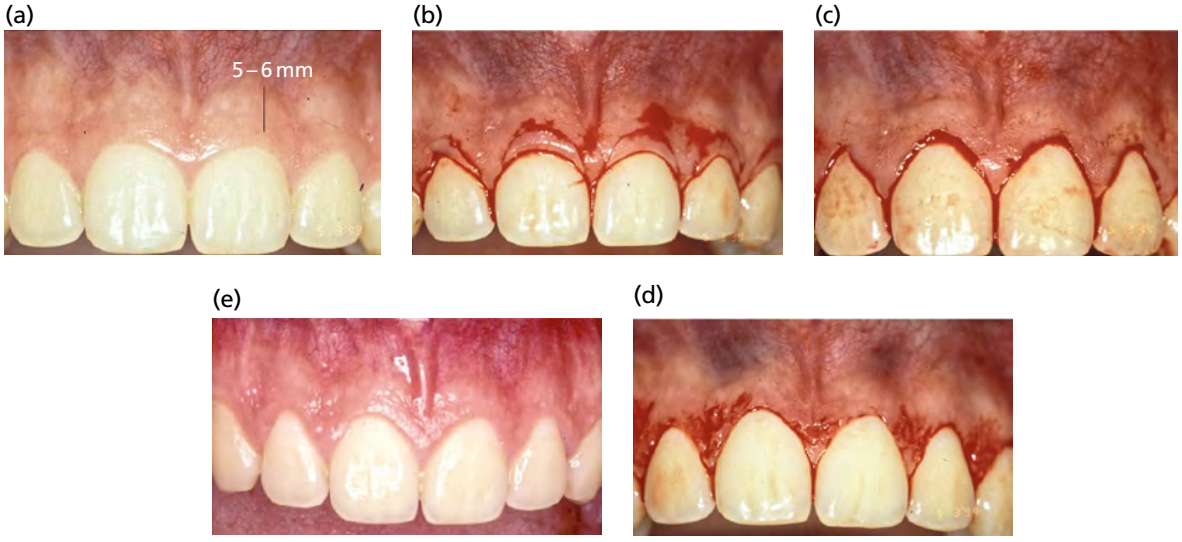

Fig. 39-59 Crown lengthening by *internal bevel gingivivectomy*. (a) Preoperative view depicting wide area of keratinized gingiva. (b) Internal bevel incisions. (c) Removal of excessive gingival tissue. (d) Minimal gingivoplasty to achieve knife edge gingival margins. (e) Three-month postoperative result.

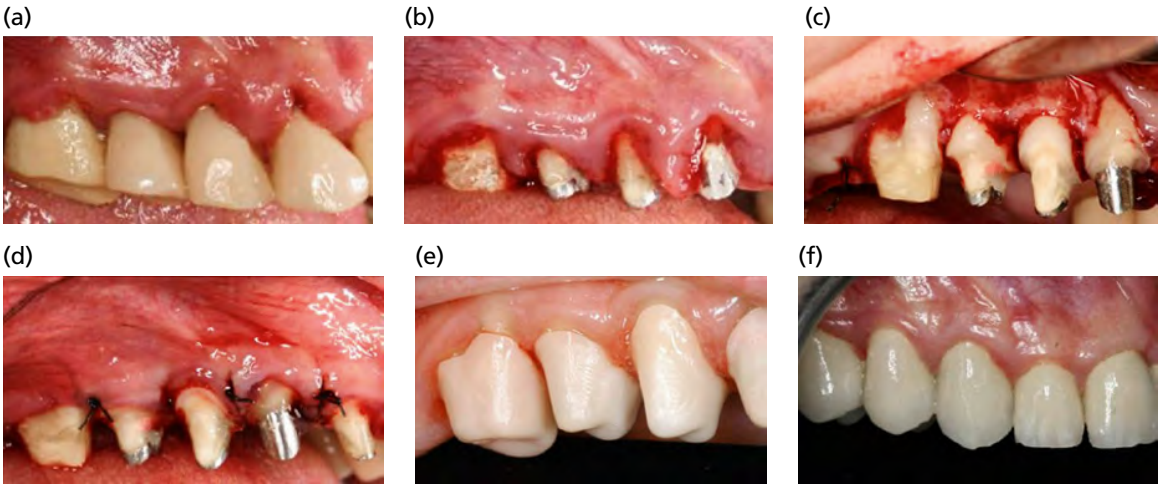

Fig. 39-60 (a) Marked gingival inflammation around prosthetic restoration in posterior right upper sextant. (b) Lack of retention and invasion of the biological width by the existing restoration. (c) Apically positioned flap crown lengthening procedure ensuring enough tooth surface for the retention of the restoration without invading the biological width. (d) Sutures positioning the flap over the bone crest. (e) New crown preparations using the available tooth structure. (f) Final prosthetic restoration with healthy gingival tissues.

changes in the contour of the bone crest. Thus, in order to retain the gingival margin at its new and more apical position, bone recontouring must be performed not only at the problem tooth but also at the adjacent teeth to gradually reduce the osseous profile (Fig. 39-60). Consequently, substantial amounts of attachment may have to be sacrificed when crown lengthening is accomplished with an APF technique. It is also important to remember that, for esthetic reasons, symmetry of tooth length must be maintained between the right and left sides of the dental arch. This may, in some situations, call for the inclusion of even more teeth in the surgical procedure.

In CL surgical interventions aimed at providing enough tooth structure to enable adequate retention for the prosthetic restoration, the amount of ostectomy is guided by the restorative needs. In these situations, it is imperative to consider the remaining periodontium and the presence of furcation entrances, since frequently these interventions must sacrifice supporting bone not only in the affected teeth, but also in adjacent teeth (Fig. 39-60).

The APF is usually carried out as a one-stage procedure in which submarginal scalloped incisions and full thickness flaps are followed by bone recontouring to recreate the space for adequate supracrestal tissue attachment. Incision design and the amount of bone recontouring are usually guided by the presurgical assessment of the CEJ either through transgingival probing or by radiographic examination when no restorative work is needed after the CL procedure. However, when restorative work is planned, an acrylic *mock-up* is fabricated which is useful not only for patient acceptance, but also to design the first incision according to the restorative plan (Fig. 39-61, Fig. 39-62)

The final position of the gingival margin after healing, however, is not always predictable (Christiaens *et al*. 2018) and may result in unfavorable outcomes, such as marginal tissue rebound or gingival recession. Factors such as the position of the gingival margin relative to the bone crest (Lanning *et al*. 2003; Deas *et al*. 2014), the extent of ostectomy performed (Deas *et al*. 2004), the patient's periodontal phenotype, the healing time (Pontoriero & Carnevale 2001), and the experience of the surgeon (Herrero *et al*. 1995) may influence the result.

When performing the two stage APF crown lengthening procedure, once the scallop incision has been designed and the full thickness flaps have been raised, it is important to calculate the space available for the supracrestal connective tissue attachment. When no further restorative work is planned, the distance between the CEJ and the bone crest should be at least 3 mm. When using a mock-up of the restorative plan, the distance between the restoration and the bone crest should be used as a reference. Ostectomy should be carried out using rotary instruments and bone chisels. Care should be taken not to eliminate root surface to avoid subsequent dentin hypersensitivity. Flaps should be then positioned over the bone crest using suspensory sutures to avoid any bone or connective tissue exposure (Fig. 39-62).

To overcome some of these limitations, an alternative CL surgical approach in two stages was proposed (Sonick 1997). This surgical approach involves two staged surgical interventions. In the first surgical phase, after raising a full thickness flap following intrasulcular incisions, the space for supracrestal tissue attachment is recreated by ostectomy and osteoplasty by direct visualization of the CEJ anatomy, and then the flap is repositioned and sutured. Three to four months later, once the supracrestal tissue attachment is re-established, a second minimally invasive surgical intervention is carried out, if needed, by only minor gingival recontouring to attain the ideal gingival margin contours. This approach is expected to reduce the risk associated with the initial removal of

Fig. 39-61 (a) Patient's gummy smile and clear restorative needs. (b) Wax up of the ideal size and shape of the teeth before the crown lengthening procedure. (c) Acrylic mock-up in place with the ideal planned restorations.

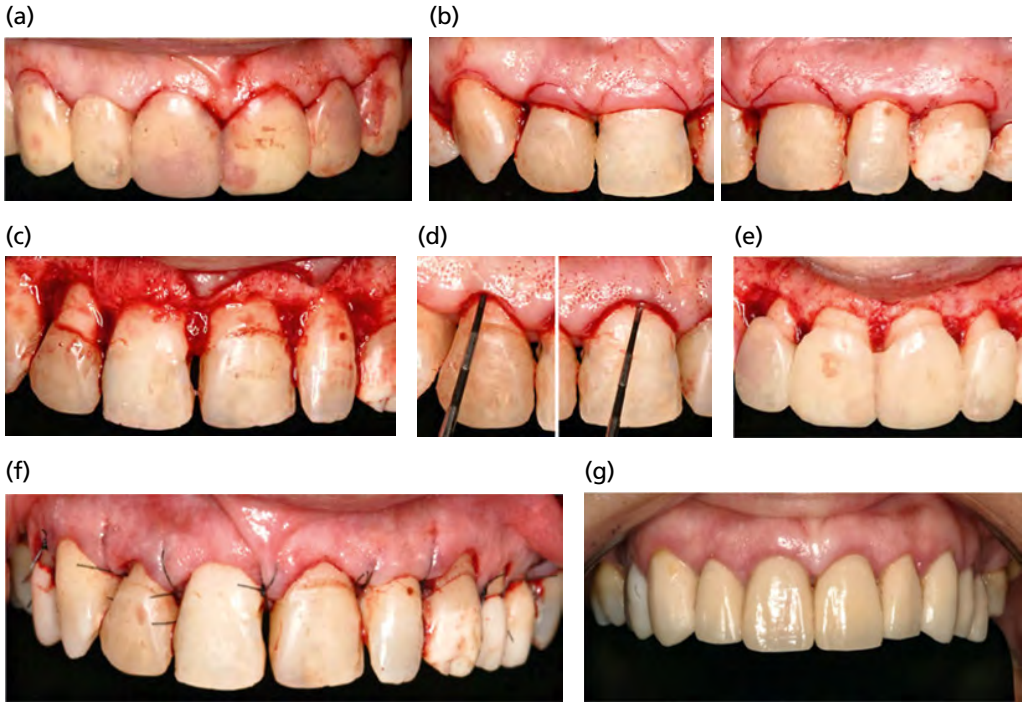

Fig. 39-62 (a) Scalloped first incision is done following the contour of the ideal planned crown (mock-up). (b) Scalloped first incision after removing the mock-up. (c) Available space for supracrestal tissue attachment. (d) Evaluation of the distance between the cementoenamel juntion and the bone crest. soft tissue based on anatomic landmarks that may be difficult to determine with precision, such as the CEJ or the bone crest (Fig. 39-63).

A recent randomized clinical trial comparing the one- versus two-stage CL procedures for esthetic restorative indications reported similar outcomes in terms of the final desired position of the gingival margins, although the two-stage procedure was preferred by the patients and only one third required the secondary minimally invasive procedure (González-Martín *et al*. 2020).

Forced tooth eruption

An alternative technique for gaining clinical crown height by means of orthodontic forced eruption in combination with gingival fiberotomy was described by Pontoriero *et al*. (1987). Fiberotomy is used during the forced tooth eruption procedure when the objective is to retain the crestal bone and the gingival margin at their pretreatment locations. Fiberotomy is usually performed using a scalpel at 7–10-day intervals during the forced eruption to sever the supracrestal connective tissue fibers, thereby preventing the crestal bone from following the root in a coronal direction. If fiberotomy is not carried out and moderate eruptive forces are used, the entire attachment apparatus will move in unison with the tooth. In these situations, once the tooth has reached the intended position and has been stabilized, a full-thickness flap should be elevated and bone recontouring performed to expose sound root structure. For esthetic reasons it is important that the bone and soft tissue levels at adjacent teeth remain unchanged (Fig. 39-64).

Forced tooth eruption can also be used to level and align gingival margins and the crowns of teeth to obtain esthetic harmony. Instead of using surgical procedures to position the gingival margins of unaffected normal teeth apically to the level of a tooth with recession or orthodontic malalignment, the tooth that is malpositioned or has sustained recession is erupted to the level of the normally positioned teeth. The entire attachment apparatus and dentogingival junction will follow the root of the tooth as it is moved coronally.

The forced eruption technique can also be used as a method for reducing pocket depth at sites with angular bony defects (Brown 1973; Ingber 1974, 1976).

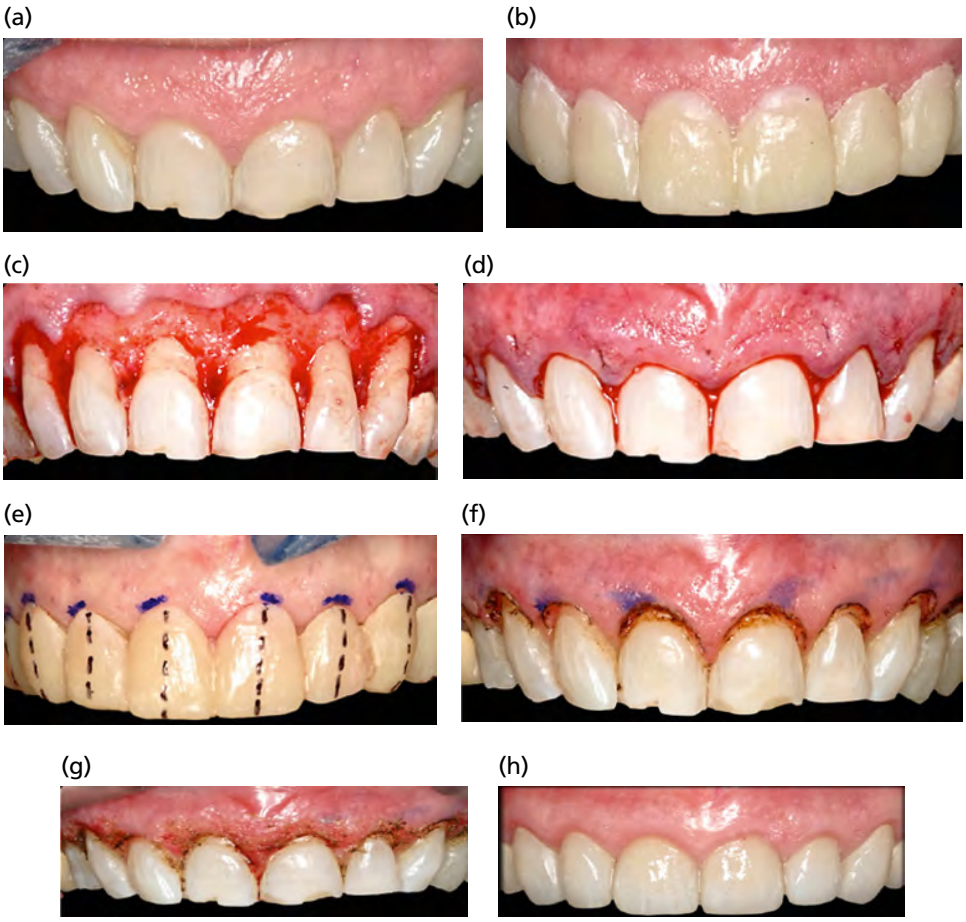

Fig. 39-63 *Two stage crown lengthening procedure*. (a) Preoperative view. (b) Mock-up depicting the contours of the ideal planned crowns. (c) First incision is performed intrasurgically and after raising a full thickness flap the ostectomy is carried out to obtain the ideal supracrestal tissue attachment space. (d) Flaps are repositioned to the same level as presurgery. (e) Six-month postoperatively the mock-up is used to identify whether a gingivectomy should be done to achieve the ideal tooth size and shape. (f) Internal bevel gingivectomy. (g) Gingivoplasty. (h) Final result with the new restoration in place.

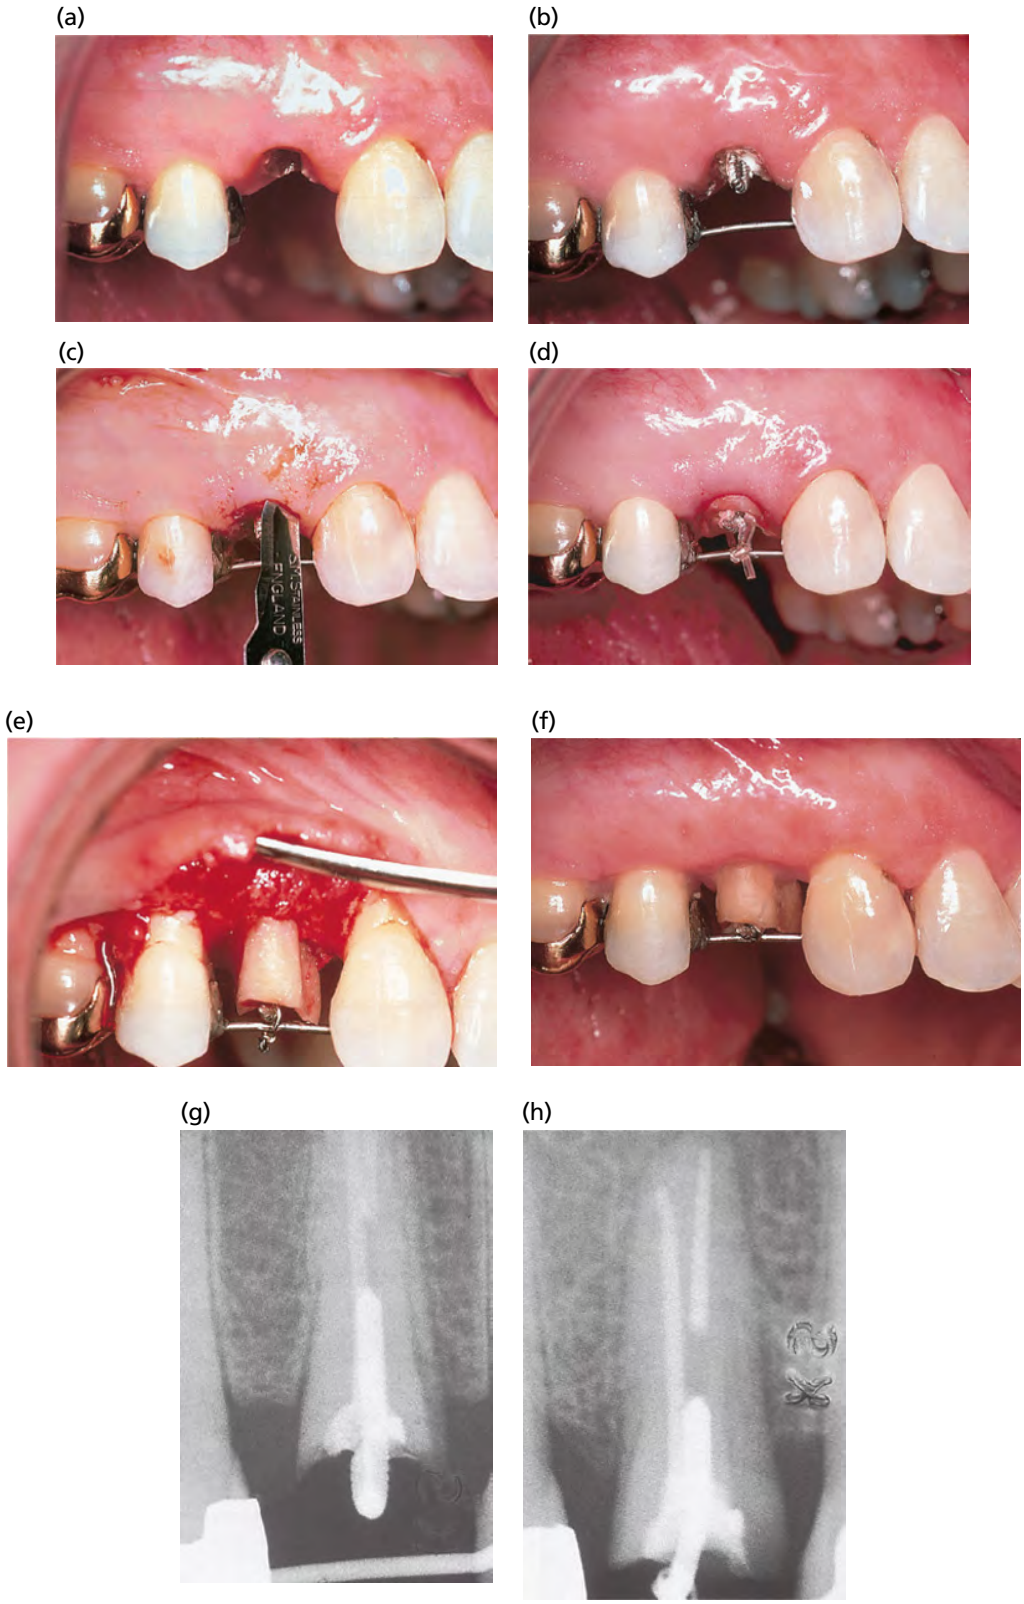

Fig. 39-64 Forced tooth eruption in conjunction with fiberotomy. (a) Buccal view, the fracture on the first premolar extended subgingivally. (b) Soft tooth structure was excavated and a twisted wire with an occlusal hook was temporarily cemented in the root canal. A bar was placed into the amalgam restoration on the premolar and bonded to the lingual surface of the canine. (c, d) Sulcular fiber resection was performed at the mesial half of the tooth to the level of the bone crest. The distal half remained as a control surface. The fiber resection was repeated once a week during the 3-week eruption phase. (e) Tooth was stabilized for 6 weeks, and at that time a full-thickness flap was raised. The bone crest had a "positive" angulation at the distal surface and remained unchanged at the "test" mesial surface. Osseous resection was used to level the bony septum on the distal surface. (f) Ample crown lengthening was obtained, and the gingival margins healed to their former shape and location. (g) Pretreatment radiograph enlarged to show the normal shape of the crests of the interdental septae. (h) Enlargement of the post-eruption radiograph (3 weeks of rapid eruption and 6 weeks of stabilization) to show the "positive" angular crest on the "control" distal side and the unchanged crest on the mesial "test" side. (Source: Courtesy of R. Pontoriero.)

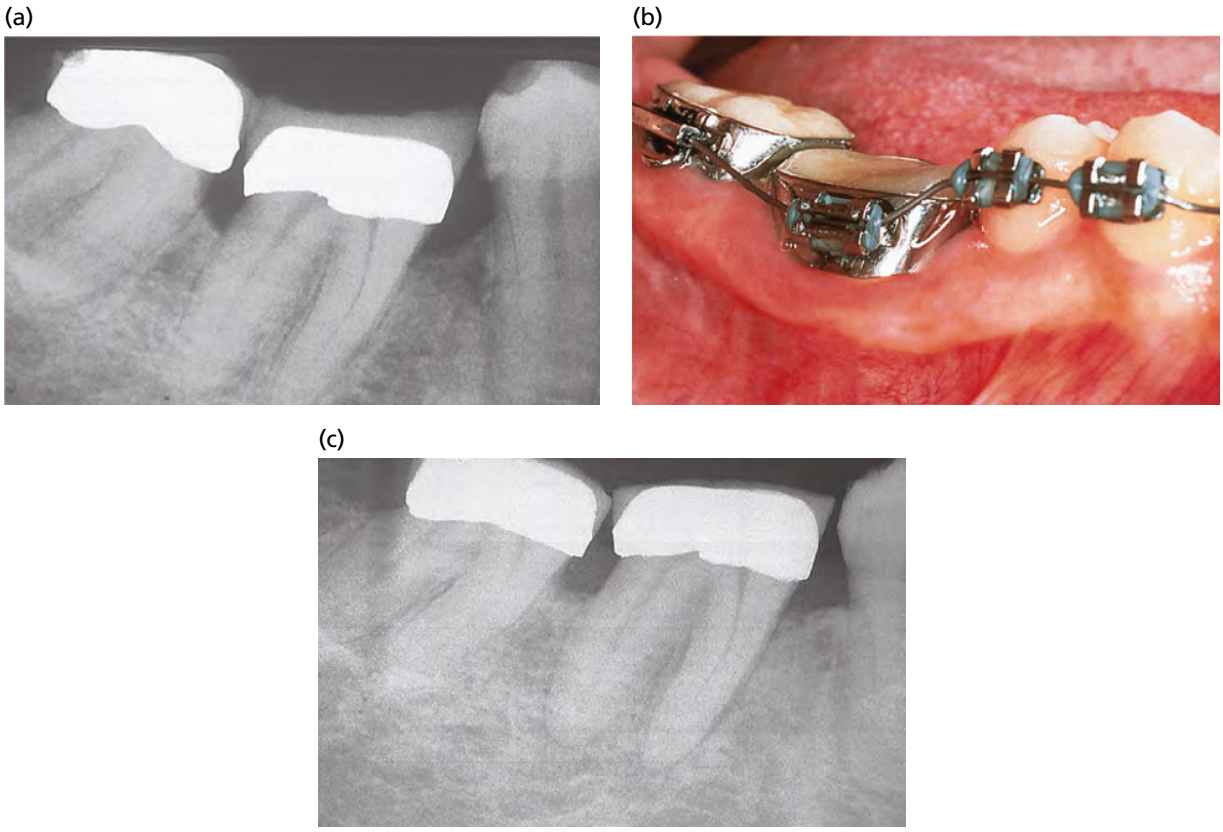

Fig. 39-65 Slow tooth eruption procedure used to level cementoenamel junctions and angular bone crests. (a) Pretreatment radiograph. (b) Nitol wire was used to erupt the molar. (c) Radiograph taken 8 months after the start of treatment. The angular bone defects were leveled.

The angular bony defect at the problem tooth can be reduced, while the attachment level at the adjacent tooth surface remains unchanged (Fig. 39-65).

Forced eruption has the advantage over crown lengthening procedures in that root exposure can be performed without the need for a flap procedure in combination with osseous surgery, which would possibly affect the periodontal tissues of a neighbouring tooth. However, this technique cannot be applied in all situations which require lengthening of the clinical crown, such as prosthetic reconstruction in dentitions with severe attrition.

Gingival preservation at ectopic tooth eruption

Surgical interventions are often indicated for preserving the gingival tissues around teeth erupting ectopically, that is with an eruption position facial to the alveolar process (Fig. 39-66). To create a satisfactory

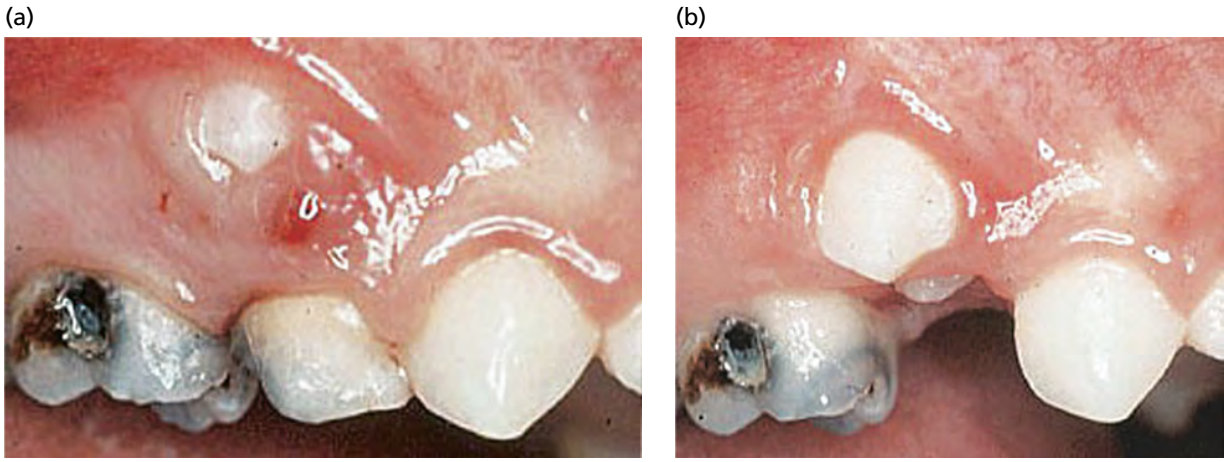

Fig. 39-66 (a, b) Ectopic tooth eruption. The permanent tooth is erupting close to the mucogingival junction. (Source: Courtesy of Professor Giampaolo Pini Prato.)

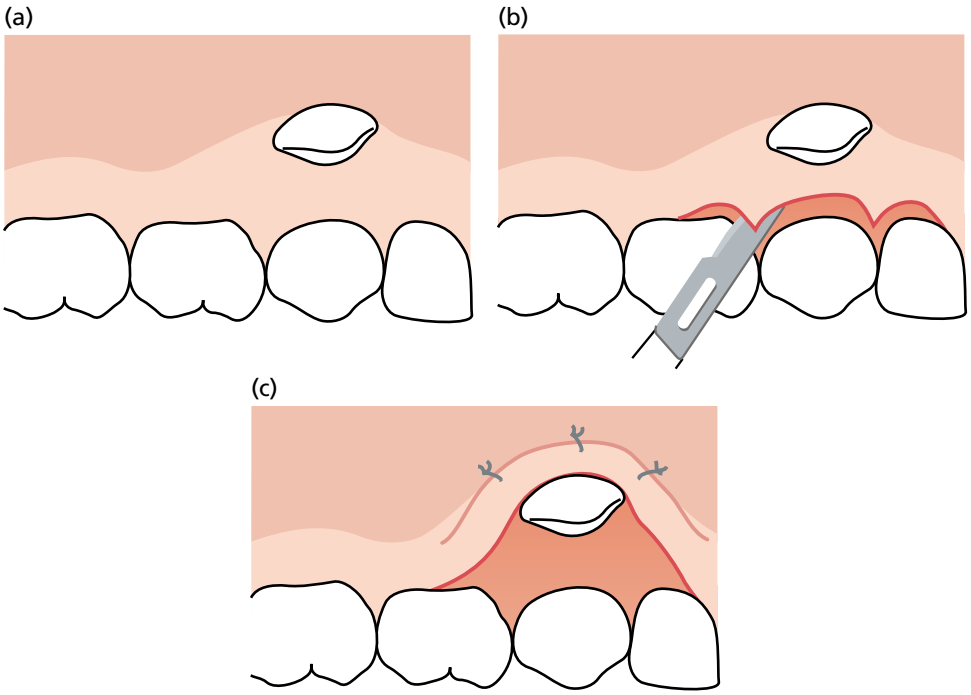

Fig. 39-67 (a–c) Ectopically erupting tooth: double pedicle graft (see text for explanation).

width of the gingiva for the permanent tooth, the tissue entrapped between the erupting tooth and the deciduous tooth is usually utilized as donor tissue (Agudio *et al*. 1985; Pini Prato *et al*. 2000b).

Three different techniques have been described for the interceptive mucogingival treatment of buccally erupting teeth, depending on the distance from the donor site (entrapped gingiva) to the recipient site (area located facially–apically to the erupting permanent tooth) (Agudio *et al*. 1985; Pini Prato *et al*. 2000b):

- *Double pedicle graft* (Fig. 39-67). This flap procedure is indicated when the permanent tooth erupts within the zone of keratinized tissue but close to the mucogingival junction. An intrasulcular incision is performed at the deciduous tooth and extended laterally to the gingival crevice of the adjacent teeth and apically to the erupting permanent tooth. By mobilization of the flap apical to the mucogingival line, the entrapped gingiva can be elevated and transposed for positioning apically to the erupting tooth. Sutures may be placed to secure the position of the gingival tissue facial to the erupting tooth.
- *Apically positioned flap* (Fig. 39-68). When the permanent tooth is erupting apical to the mucogingival junction, vertical releasing incisions have to be placed to allow for apical positioning of the keratinized tissue. Two lateral releasing incisions are made and extended apically beyond the mucogingival junction. An intrasulcular incision is performed at the deciduous tooth and a partial-thickness flap is elevated beyond the ectopically erupting tooth. The mobilized gingival flap is

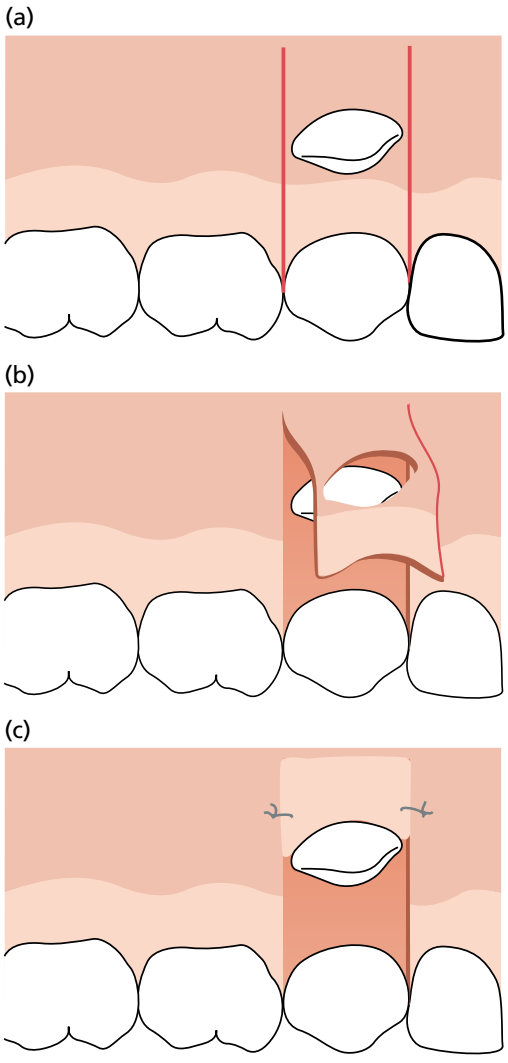

Fig. 39-68 (a–c) Ectopically erupting tooth: apically positioned flap (see text for explanation).

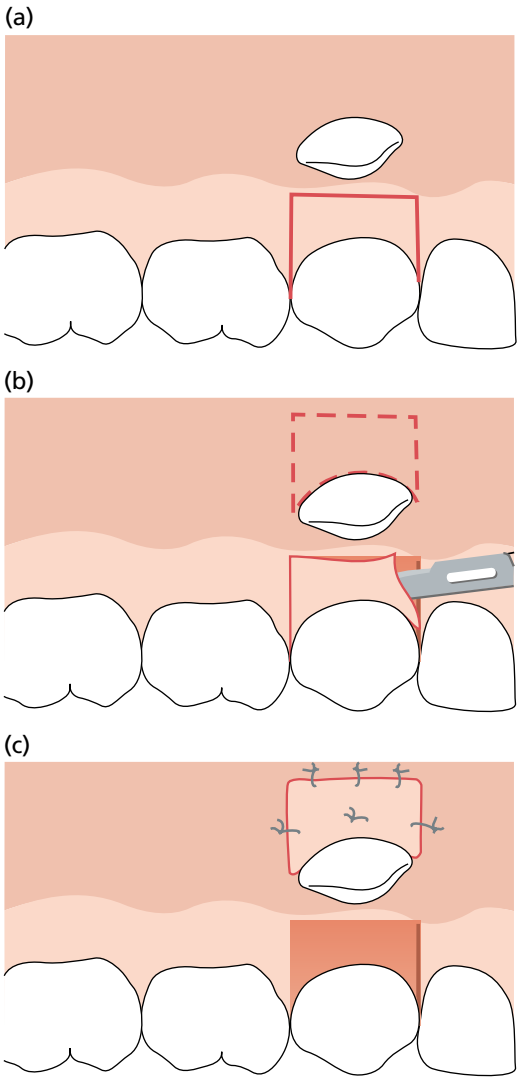

Fig. 39-69 (a–c) Ectopically erupting tooth: free gingival graft (see text for explanation).

moved apical to the erupting tooth and secured in position by sutures.

- *Free gingival graft* (Fig. 39-69). If the tooth is erupting within the alveolar mucosa distant to the mucogingival junction, a free gingival graft procedure may be selected. The entrapped gingiva is removed by a split incision and used as an epithelialized CTG. The free gingival graft is placed at a prepared recipient site facial/apical of the erupting tooth. Careful suturing is performed to secure close adaptation of the graft to the underlying connective tissue bed.

All these procedures have been proven to be effective in establishing a facial zone of gingiva following the alignment of teeth erupting in an ectopic position (Pini Prato *et al*. 2000b, c).

Part 14: Surgery for Implant Installation

Chapter 40

Timing of Implant Placement

Christoph H.F. Hämmerle[1], Maurício Araújo[2], and Jan Lindhe[3]

[1]Clinic of Reconstructive Dentistry, Center of Dental Medicine, University of Zurich, Zurich, Switzerland

Introduction

Restorative therapy performed on implant(s) placed in a fully healed and non-compromised alveolar process has high clinical success and survival rates (Pjetursson *et al*. 2004; Jung *et al*. 2012; Pjetursson *et al*. 2014). Currently, however, implants are also being placed in (1) sites with ridge defects of various dimensions, (2) fresh extraction sockets, (3) the area of the maxillary sinus, etc. Although some of these clinical procedures were first described many years ago, their application has only relatively recently become common. Accordingly, one issue of primary interest in current clinical and animal research in implant dentistry includes the study of tissue alterations that occur following tooth loss and the proper timing thereafter for implant placement.

In the optimal case, the clinician will have time to plan for the restorative therapy (including the use of implants) prior to the extraction of one or several teeth. In this planning, a decision must be made whether the implant(s) should be placed immediately after the tooth extraction(s) or if a certain number of weeks (or months) of healing of the soft and hard tissues of the alveolar process should be allowed prior to implant installation. The decision regarding the timing for implant placement, in relation to tooth extraction, must be based on a proper understanding of the structural changes that occur in the alveolar process following the loss of the tooth (teeth). Such adaptive processes are described in Chapter 3.

The removal of single or multiple teeth will result in a series of alterations within the edentulous segment of the alveolar process. Hence, during socket healing, the hard tissue walls of the alveolus will resorb, the center of the socket will become filled with cancellous bone, and the overall volume of the site will become markedly reduced. In particular, the buccal wall of the edentulous site will be diminished not only in the buccolingual/palatal direction but also with respect to its apico-coronal dimension (Pietrokovski & Massler 1967; Schropp *et al*. 2003). In addition to hard tissue alterations, the soft tissue in the extraction site will undergo marked adaptive changes. Immediately following tooth extraction, there is a lack of mucosa and the socket entrance is thus open. During the first weeks following the removal of a tooth, cell proliferation within the mucosa will result in an increase of its connective tissue volume. Eventually, the soft tissue wound will become epithelialized and a keratinized

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

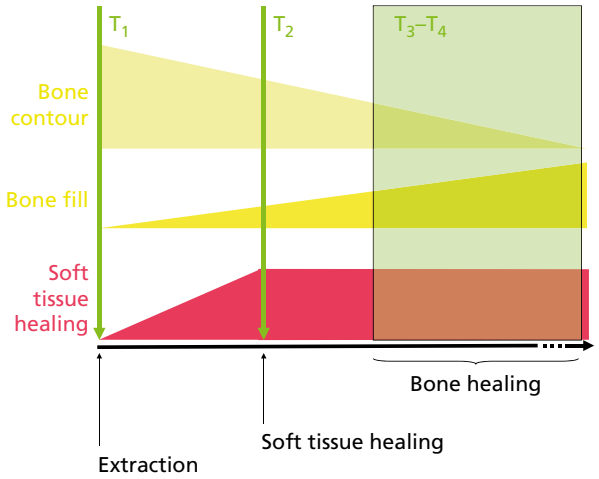

Fig. 40-1 Schematic drawing depicting the changes in the soft and hard tissues following tooth extraction over time. T_1, T_2, T_3, and T_4 represent the four different time points for implant placement.

mucosa will cover the extraction site. The contour of the mucosa will subsequently adapt to follow the changes that occur in the external profile of the hard tissue of the alveolar process. Thus, the contraction of the ridge is the net result of bone loss as well as loss of connective tissue. Figure 40-1 illustrates the tissue alterations described above. It is obvious that no ideal time point exists following the removal of a tooth, when the extraction site has (1) maximum bone fill in the socket and (2) voluminous mature covering mucosa. More recent studies have found an influence of tooth type, intact or deficient buccal bone plates, and the thickness of the buccal bone plate on the degree of ridge alterations following tooth extraction (Chen & Darby 2017; for review see Avila-Ortiz *et al*. 2019). Incisors showed more volume loss than canines and premolars. Intact buccal bone plates showed less volume loss than dehisced and fenestrated bone plates. Finally, thick bone plates were associated with less bone loss than thin bone plates.

A consensus report was published in 2004 describing issues related to the timing of implant placement in extraction sockets (Hammerle *et al*. 2004). Attempts had previously been made to identify the advantages and disadvantages of early, delayed, and late implant placements. Hämmerle and co-workers considered it necessary, however, to develop a new concept (classification) that incorporated the growing knowledge in this field of implant dentistry. This new classification took into consideration data describing structural alterations that occur following tooth extraction as well as knowledge derived from clinical observations.

The classification presented in Table 40-1 was introduced in the consensus report. Important aspects included:

- In clinical practice, the decision to place an implant following tooth extraction is usually determined by some soft and hard tissue characteristics of the healing socket. Healing does not necessarily follow rigid time frames, and may vary according to site and patient factors.
- To avoid temporal-based descriptions, this new classification used numerical descriptors – types 1, 2, 3, and 4 – that reflect the conditions of the hard and soft tissues:
  - Type 1 placement: the implant is placed immediately following the extraction of a tooth
  - Type 2 placement: the implant is placed in a site where the soft tissues have healed and a mucosa is covering the socket entrance
  - Type 3 placement: the implant is placed in an extraction site at which substantial amounts of new bone have formed in the socket
  - Type 4 placement: the implant is placed in a fully healed ridge.
- It was further recognized that there is a clear separation between hard tissue healing and soft tissue healing within and around the extraction socket.

This classification has since been refined (Chen *et al*. 2009).

Advantages and disadvantages of the various timings are shown in Table 40-1.

Two methods for flap closure at implant sites have been described. One approach requires primary wound closure, whereas the other one allows for a transmucosal position of the implant or the healing cap. No differences regarding survival rates and interproximal bone levels were found when these two methods were compared in a split-mouth design (Ericsson *et al*. 1997; Astrand *et al*. 2002; Cecchinato *et al*. 2004; Guarnieri *et al*. 2019). These studies did not, however, analyze in detail the differences between submerged or transmucosal healing in sites of high esthetic importance. Hence, not only the width of the gap but also the width of the alveolar process is a parameter to be considered during treatment planning.

A review analyzed the clinical outcomes of implants placed according to the timing scheme described above (Chen & Buser 2009). Based on the analysis of 91 studies, it was found that bone augmentation procedures were more effective in type 1, 2, and 3 placements than in type 4 placement. Furthermore, it appeared that recession of the facial mucosal margin was more frequent when implants were placed according to the type 1 timing.

Type 1 placement as part of the same surgical procedure as and immediately following tooth extraction

Ridge alterations in conjunction with implant placement

It has become common practice to insert implants immediately after the removal of teeth that were

Table 40-1 Classification of types 1–4 implant placements, and advantages and disadvantages of each type.

Classification	Definition	Advantages	Disadvantages
Type 1	Implant placement as part of the same surgical procedure as and immediately following tooth extraction	Reduced number of surgical procedures Reduced overall treatment time Optimal availability of existing bone	Site morphology may complicate optimal placement and anchorage Thin tissue phenotype may compromise optimal outcome Potential lack of keratinized mucosa for flap adaptation Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 2	Complete soft tissue coverage of the socket (typically 4–8 weeks)	Increased soft tissue area and volume facilitates soft tissue flap management Allows resolution of local pathology to be assessed	Site morphology may complicate optimal placement and anchorage Increased treatment time Varying amounts of resorption of the socket walls Adjunctive surgical procedures may be required Technique-sensitive procedure
Type 3	Substantial clinical and/or radiographic bone fill of the socket (typically 12–16 weeks)	Substantial bone fill of the socket facilitates implant placement Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Varying amounts of resorption of the socket walls
Type 4	Healed site (typically >16 weeks)	Clinically healed ridge Mature soft tissues facilitate flap management	Increased treatment time Adjunctive surgical procedures may be required Large variation in available bone volume

scheduled for extraction for various reasons. Over the years, many claims have been made regarding the advantages of immediate implant placement (Chen *et al*. 2004). These advantages include easier definition of the implant position, reduced number of visits to the dental office, reduced overall treatment time and costs, preservation of bone at the site of implantation, optimal soft tissue esthetics, and enhanced patient acceptance (Werbitt & Goldberg 1992; Barzilay 1993; Schwartz-Arad & Chaushu 1997b; Mayfield 1999; Hammerle *et al*. 2004).

It was proposed that placement of an implant in a fresh extraction socket may stimulate bone tissue formation and osseointegration, and hence counteract the adaptive alterations that occur following tooth extraction. In other words, type 1 implant installation may allow the preservation of bone tissue of the socket and the surrounding jaw. It was in fact recommended (e.g. Denissen *et al*. 1993; Watzek *et al*. 1995; for review see Chen *et al*. 2004) that implant installation should be performed directly following tooth extraction as a means to avoid bone atrophy.

Clinical studies in humans (Botticelli *et al*. 2004; Covani *et al*. 2004) and experiments in dogs (Araújo & Lindhe 2005; Araújo *et al*. 2006a, b) have examined the influence of implant installation in the fresh extraction socket on bone modeling and remodeling in the surgical site.

Botticelli *et al*. (2004) examined hard tissue alterations that occurred in the alveolar process during a 4-month period of healing following implant placement in fresh extraction sockets. Eighteen subjects (21 extraction sites) with moderate chronic periodontitis were studied. The treatment planning of all 18 subjects called for extraction of single teeth, and restoration by means of implants in the incisor, canine, and premolar regions of the dentition. Following sulcus incisions, full-thickness mucosal flaps were raised and the tooth was carefully mobilized and removed with forceps. The site was prepared for implant installation with pilot and twist drills. The apical portion of the socket was pretapped. A non-cutting solid-screw implant with a medium rough surface topography was installed. The implant was positioned in such a way that the marginal level of its rough surface portion was located apical to the marginal level of the buccal and lingual/palatal walls of the socket (Fig. 40-2a). After implant installation (1) the distance between the implant and the inner and outer surface of the buccal and/or lingual bone plates and (2) the width of the marginal gap that was present between the implant and the buccal, lingual, mesial, and distal bone walls were determined with the use of sliding calipers. The soft tissue flaps were replaced and the implants were "semi-submerged" during healing (Fig. 40-2b). After 4 months of healing, a surgical

re-entry procedure was performed (Fig. 40-2c). The clinical measurements were repeated so that alterations that had occurred during healing regarding (1) the thickness and height of the buccal and lingual/palatal socket walls and (2) the width of the marginal gap could be calculated.

Figure 40-3a shows an extraction socket immediately after the removal of a maxillary canine tooth. At re-entry it was realized that the marginal gap had completely resolved. Furthermore, the thickness of the buccal as well as the palatal bone walls had markedly reduced (Fig. 40-3c, d). In Fig. 40-3d, the implant surface can be seen through the very thin remaining buccal bone wall.

Another site from this clinical study is shown in Fig. 40-4. The first maxillary premolar (tooth 14) was removed (Fig. 40-4a) and one implant was placed in the palatal socket of the fresh extraction site. A second implant was placed in the healed edentulous ridge and in position 15 (Fig. 40-4b). At re-entry, it was observed that (1) the marginal gap had completely resolved and (2) the distance between the implant and the outer surface of the buccal bone plate had markedly reduced (Fig. 40-4c).

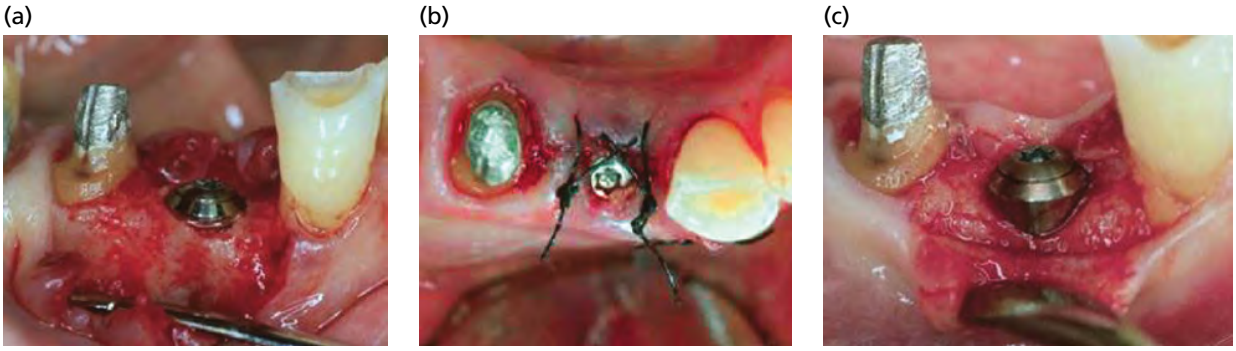

Fig. 40-2 (a) Implant position in the fresh extraction socket. (b) Flaps replaced and sutured. (c) Implant site after 4 months of healing (buccal view).

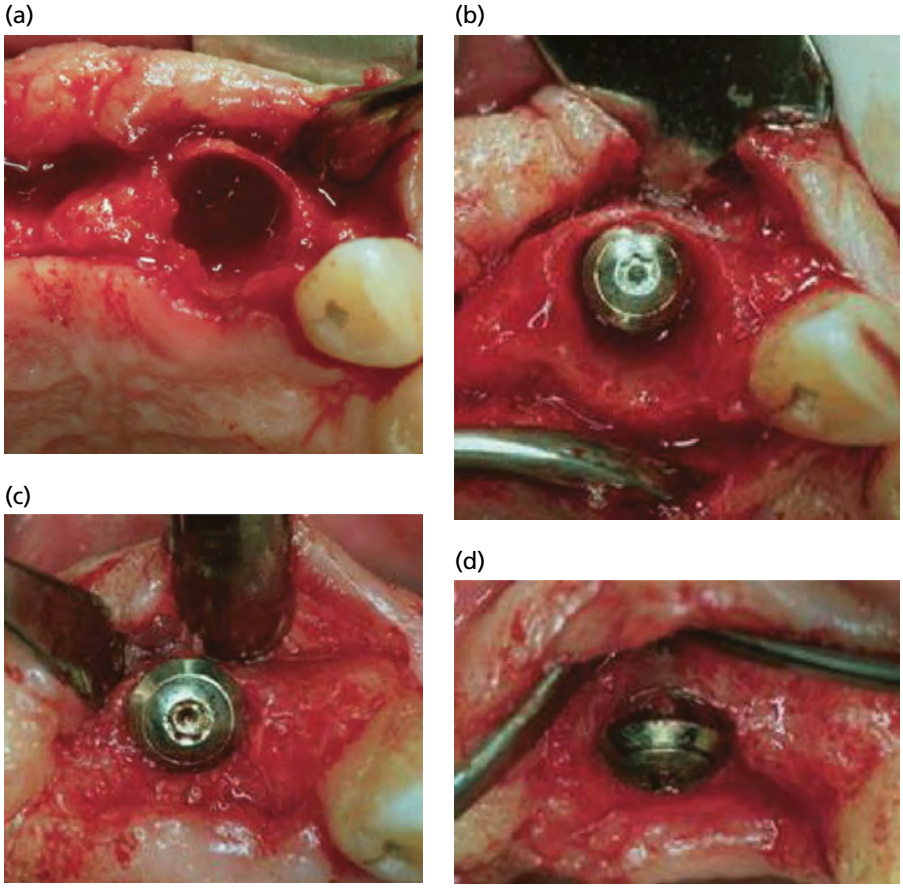

Fig. 40-3 (a) Alveolar socket of a maxillary canine. (b) Implant position in the fresh extraction socket. (c) Implant site after 4 months of healing (occlusal view). (d) Implant site after 4 months of healing (buccal view). Note the very thin bone covering the buccal aspect.

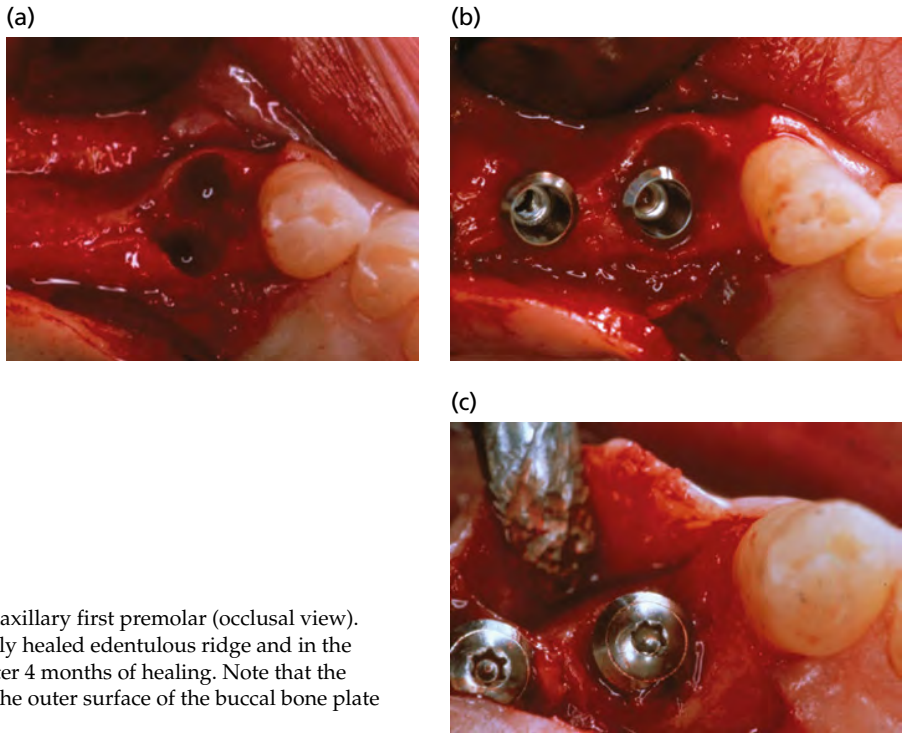

Fig. 40-4 (a) Alveolar socket of a maxillary first premolar (occlusal view). (b) Implants placed in the previously healed edentulous ridge and in the alveolar socket. (c) Implant sites after 4 months of healing. Note that the distance between the implant and the outer surface of the buccal bone plate was markedly reduced.

Botticelli *et al*. (2004) reported that during the 4 months of healing following tooth extraction and implant installation practically all marginal gaps had resolved. At the time of implant placement, the mean distance (18 subjects, 21 sites) between the implant and the outer surface of the buccal bone wall was 3.4 mm, while the matching dimension on the lingual/palatal aspect was 3.0 mm. At re-entry after 4 months, the corresponding dimensions were 1.5 mm (buccal) and 2.2 mm (lingual). In other words, the reduction of the buccal dimension was 1.9 mm (56%), while the equivalent reduction of the lingual dimension was 0.8 mm (27%). The findings by Botticelli *et al*. (2004) strongly indicate that implant placement in a fresh extraction socket may, in fact, not prevent the physiologic modeling/remodeling that occurs in the ridge following tooth removal.

In a randomized controlled clinical study, parallel-walled and conical implants exhibiting modified medium rough surfaces were placed immediately into 93 extraction sockets of maxillary non-molar teeth (Sanz *et al*. 2010). Detailed clinical measurements taken at implant placement and 16 weeks thereafter assessed the changes in the relationship between the bone of the socket and the implant surface. A pronounced reduction of the buccal bone dimension occurred over this time period. A smaller reduction of external bone dimension was observed at the lingual aspect. No differences were found between the parallel-walled and conical implants with respect to reduction of the ridge contour. In contrast to the reduction of the external dimensions of the ridge, the gaps between the walls of the socket and the implant surface at the time of placement had partially been filled with newly formed bone at the 16-week follow-up examination (Huynh-Ba *et al*. 2010; Sanz *et al*. 2010).

In a subsequent paper analyzing the same patient groups, it was found that the bone fill of the gap between the implant and the bone walls of the socket as well as the maintenance of the buccal bone height were more favorable at premolar as compared with canine and incisor sites (Ferrus *et al*. 2010; Tomasi *et al*. 2010). Furthermore, the thickness of the buccal bone wall and the dimension of the gap described above favorably influenced the amount of bone fill during the 4-month healing period. A 3-year follow-up examination reported minimal implant failures and stable soft and hard tissue conditions in both groups of implants (Sanz *et al*. 2014).

In order to study the bone modeling/remodeling that occurs in the fresh extraction site following implant placement in more detail, Araújo and Lindhe (2005) used histologic means to determine the magnitude of the dimensional alterations that occurred in the alveolar process following the placement of implants in fresh extraction sockets in the Beagle dog. Buccal and lingual full-thickness flaps were elevated in both quadrants of the mandible. The distal roots of the third and fourth premolars were removed (Fig. 40-5a). In the right jaw quadrants, implants with a medium rough surface were placed in the sockets so that the marginal border of the rough surface was below the buccal and lingual bone margin (Fig. 40-5b). The flaps were replaced to allow a "semi-submerged" healing (Fig. 40-5c). In the left jaws, the corresponding sockets were left without implantation and the extraction sockets

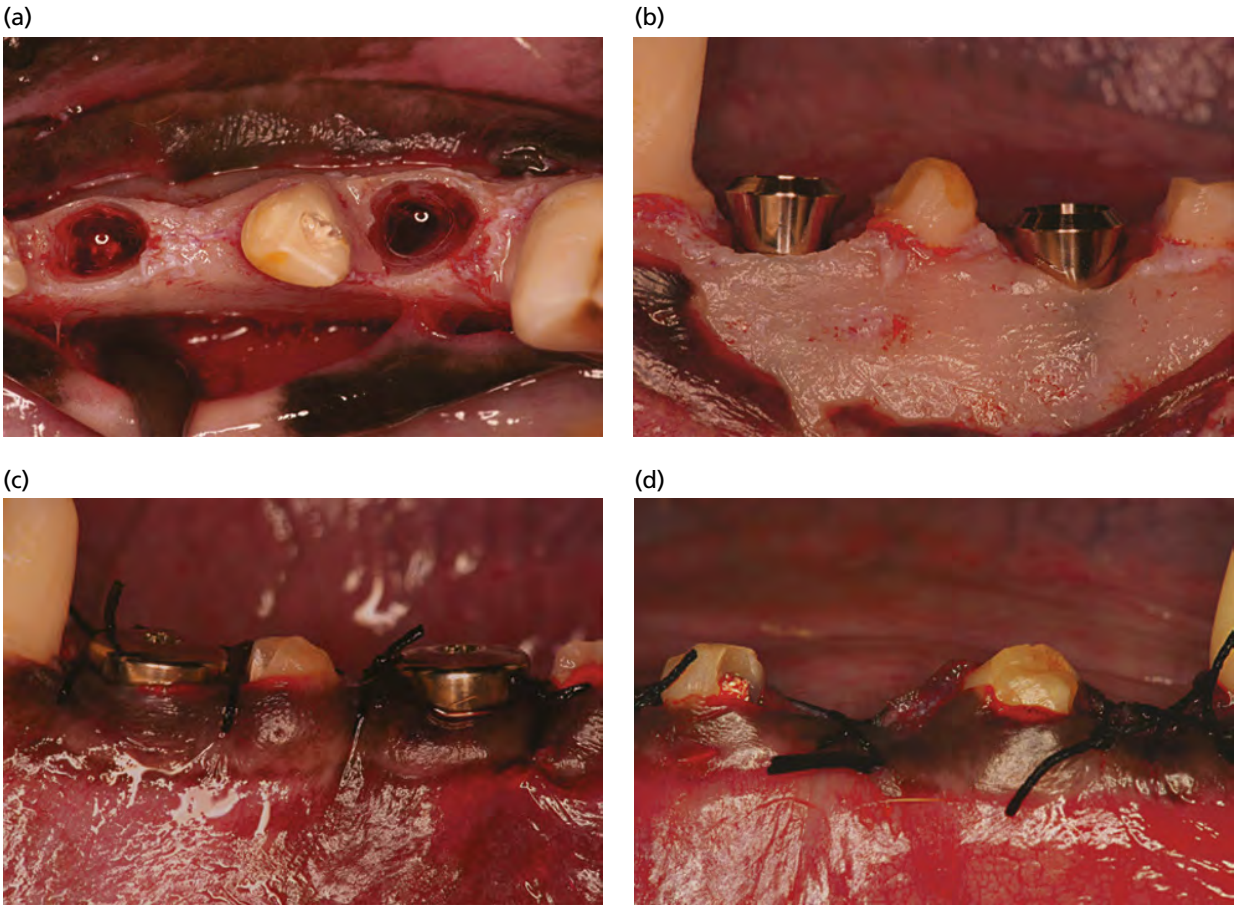

Fig. 40-5 (a) Mandibular premolar site (in a dog experiment) from which the distal root of the fourth premolar was removed. (b) In the test side of the mandible, the implant was placed in the socket in such a way that the rough surface marginal limit was flush with the bone crest. (c) Mucosal, full-thickness flaps were replaced and sutured to allow a "semi-submerged" healing. (d) On the contralateral side of the mandible, the sockets were left without implantation.

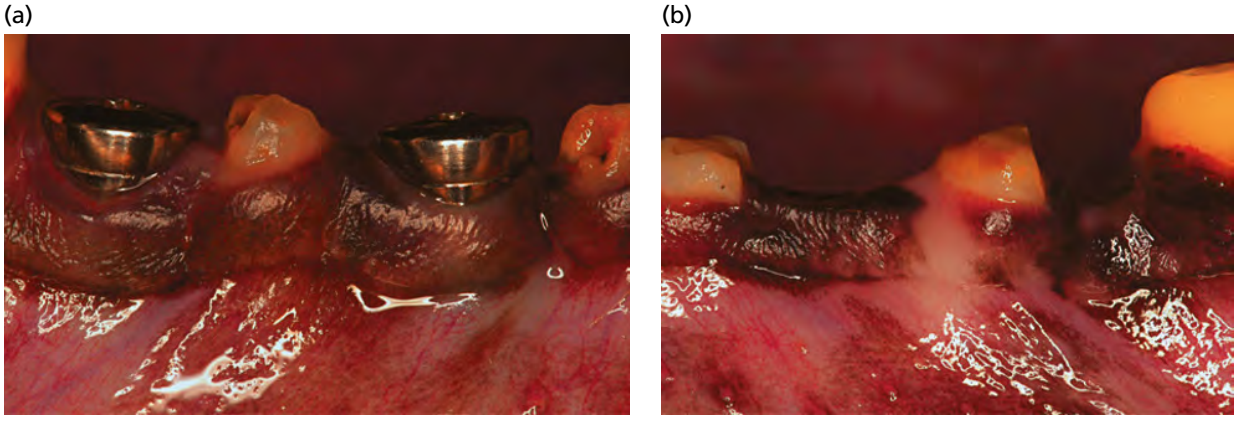

Fig. 40-6 (a) Implant and (b) edentulous sites after 6 months of healing.

were fully submerged under the mobilized flaps (Fig. 40-5d). After 3 months, the mucosa at the experimental sites in the right and left jaw quadrants appeared to be properly healed (Fig. 40-6). The animals were euthanized and tissue blocks containing the implant sites and the edentulous socket sites were dissected and prepared for histologic examination. Figure 40-7 shows a buccolingual section of one edentulous site after 3 months of healing. Newly formed bone covers the entrance of the socket. The lamellar bone of the buccal cortical plate is located about 2.2 mm apical to its lingual counterpart. Figure 40-8a presents a similar section from an implant site in the same dog. The marginal termination of the buccal bone plate is located about 2.4 mm apical to the lingual crest. In other words, the placement of an implant in the fresh extraction socket failed to influence the process of modeling that occurred in the hard tissue walls of the socket following tooth removal. Thus, after 3 months of

healing the amount of reduction of the height of the buccal bone wall (in comparison to the lingual bone alteration) was similar at the implant sites and the edentulous sites. At 3 months, the vertical discrepancy between the buccal and lingual bone margins was >2 mm in both categories of sites (edentulous sites 2.2 mm, implant sites 2.4 mm).

In a follow-up experiment in the dog, Araújo *et al*. (2006a) studied whether osseointegration, once established following implant placement in a fresh extraction socket, could be lost as a result of continued tissue modeling of the bone walls during healing. As was the case in their previous study (Araújo & Lindhe 2005), the distal roots of the third and fourth premolars in both quadrants of the mandible were removed following flap elevation. Implants were installed in the fresh extraction sockets, and initial stability of all implants was secured. The flaps were replaced and "semi-submerged" healing of the implant sites was allowed. Immediately following flap closure, biopsies were obtained from two dogs, while in five dogs healing periods of 1 month and 3 months were permitted prior to biopsy. Figure 40-9a shows a buccolingual aspect of an extraction site immediately after implant installation. Contact was established between the pitch on the surface of the implant body and the walls of the socket. A coagulum resided in the void between the contact regions (Fig. 40-9b) and also in the marginal gap. In sections taken after 4 weeks of healing, it was observed that this void had become filled with woven bone that made contact with the rough surface part of the implant (Fig. 40-10). In this 4-week interval, (1) the buccal and lingual bone walls

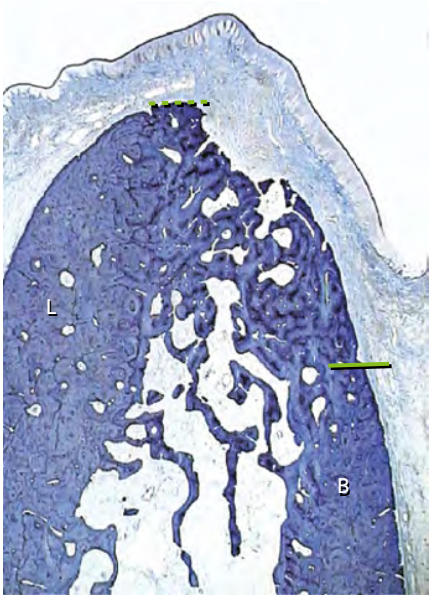

Fig. 40-7 Buccolingual section of the edentulous site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). B, buccal aspect; L, lingual aspect.

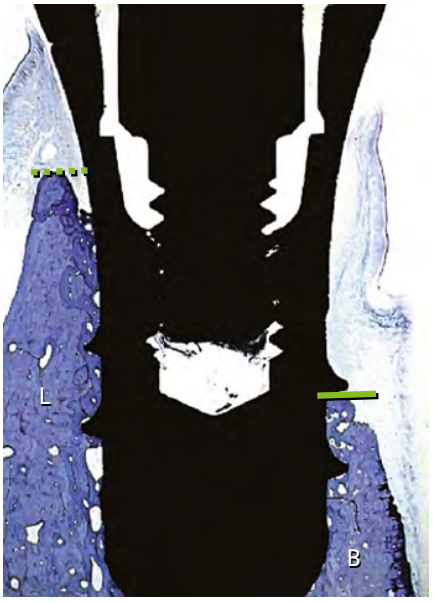

Fig. 40-8 Buccolingual section of the implant site. Note that the remaining buccal crest (continuous line) is located far below the lingual counterpart (dotted line). B, buccal aspect; L, lingual aspect.

had undergone marked surface resorption, and (2) the height of the thin buccal hard tissue wall had been reduced. In the interval between 4 weeks and 12 weeks of healing, the buccal bone crest shifted further in an apical direction (Fig. 40-11). The woven bone at the buccal aspect that in the 4-week sample made contact with the implant in the marginal gap region had modeled and only fragments of this bone remained (Fig. 40-11c). At the end of the study, the buccal bone crest was located >2 mm apical to the marginal border of the rough implant surface.

These findings demonstrate that the bone (woven bone)-to-implant contact that was established during the early phase of socket healing following implant installation was in part lost when the buccal bone wall underwent continued atrophy. It is obvious, therefore, that the alveolar process following tooth extraction (loss) will adapt to the altered functional demands by atrophy and that an implant, in this respect, is unable to substitute for the tooth. The clinical problem with type 1 placement is that the bone loss will frequently cause the buccal portion of the implant to gradually lose its hard tissue coverage, and that the metal surface may become visible through a thin peri-implant mucosa and cause esthetic concerns (Fig. 40-12).

The question now arises whether it is possible to overcome this problem. This issue was studied in a Beagle dog experiment by Araújo *et al*. (2006b). The

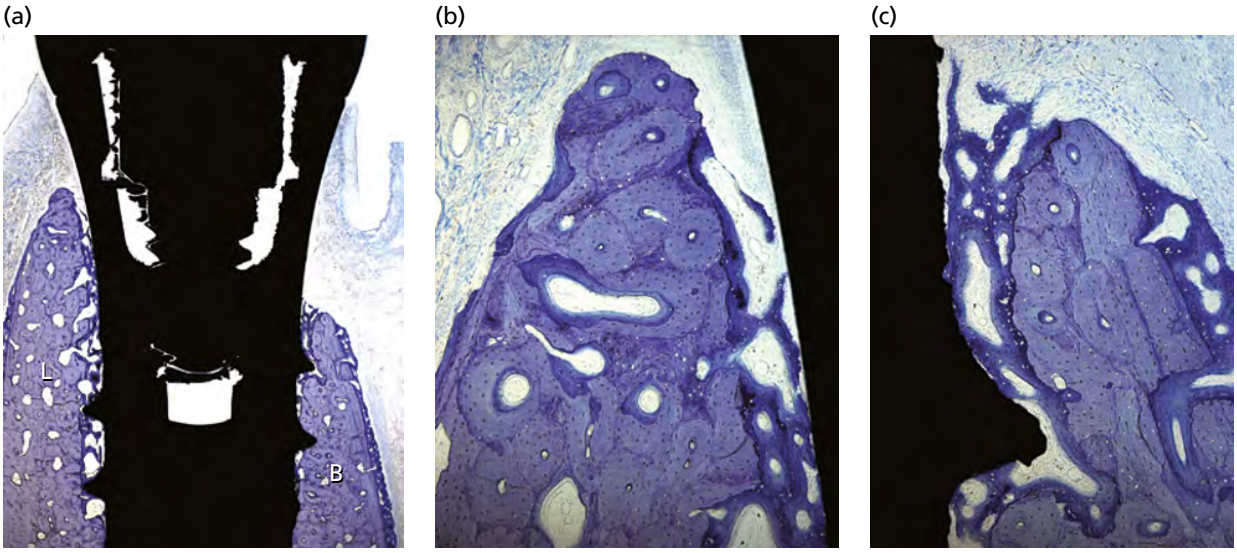

Fig. 40-10 (a) Buccolingual section 4 weeks after implant installation. The void between the implant surface and the bone wall was completely filled with newly formed bone in both lingual (b) and buccal (c) aspects. B, buccal aspect; L, lingual aspect.

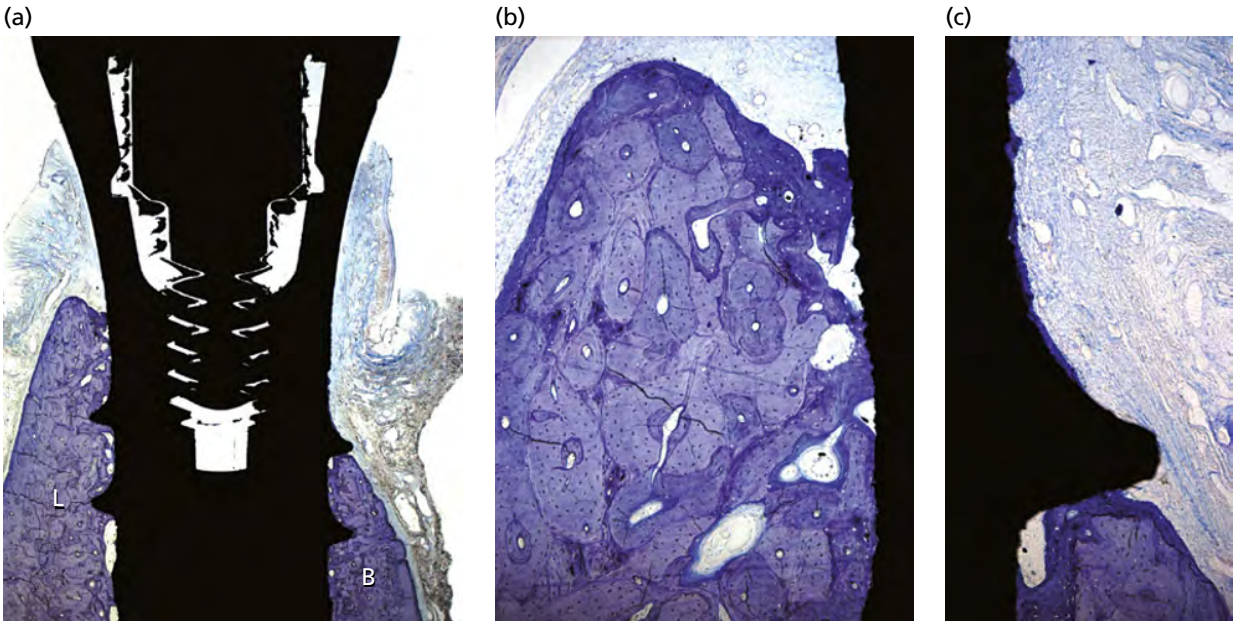

Fig. 40-11 (a) Buccolingual section 12 weeks after implant installation. Note that the buccal bone crest shifted in an apical direction and fragments of it can be seen on the denuded implant surface (c). The lingual bone crest, however, remained stable (b). B, buccal aspect; L, lingual aspect.

distal root of the third mandibular premolar and the distal root of the first mandibular molar were removed and implants placed in the fresh extraction sockets. The third premolar socket in this dog model is comparatively small, and hence the implant inserted exhibiting a diameter of 4.1 mm occupied most of the hard tissue wound (Fig. 40-13). During healing, resorption of the buccal bone wall occurred (Fig. 40-14) and >2 mm of the marginal portion of the implant became exposed to peri-implant mucosa.

The molar socket, on the other hand, is very large (Fig. 40-15) and hence after placement of an implant with a diameter of 4.1 mm, a >1-mm wide marginal gap occurred between the metal body and the bone walls (Fig. 40-16b). Primary stability of the implant was achieved through contacts between the metal body and the bone in the apical (periapical) portions of the socket. During the early phase of healing, this gap in the molar site became filled with woven bone. In the interval during which the buccal bone wall underwent programmed atrophy, the newly formed bone in the gap region maintained osseointegration and continued to cover all surfaces of the implant (Fig. 40-16a, b).

Conclusion: The data reported illustrate an important biologic principle. Atrophy of the edentulous ridge will occur following tooth loss. This contraction of the ridge cannot be prevented by placing an implant in the fresh extraction socket. The atrophy includes a marked reduction of the width and height of both the buccal and lingual bone plates; in particular, the buccal bone plate will undergo marked change. To some extent the problem with buccal bone resorption can be overcome by placing the implant deeper into the fresh socket and in the lingual/palatal portion of the socket.

As a consequence of the above-described healing, bone regeneration procedures may be required to improve or retain bone volume and the buccal contour at a fresh extraction site. Such bone augmentation is sometimes mandatory in the esthetic area.

Stability of implant

Another issue with type 1 (and also type 2) placement is the anchorage of the implant to obtain primary stability in a position in the jaw that will enable

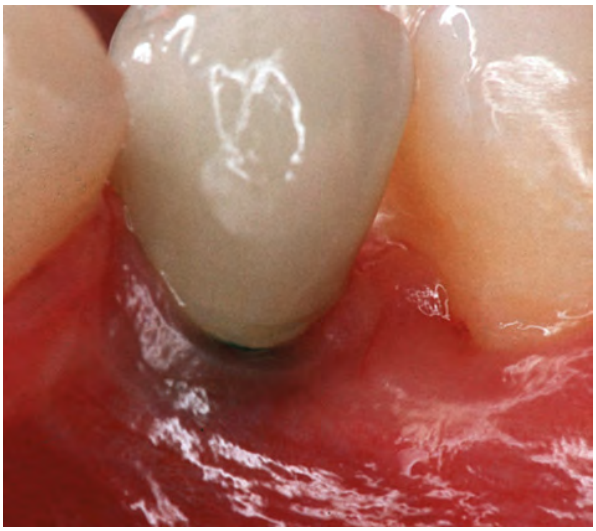

Fig. 40-12 An implant lacking the buccal bone. Note that the metal surface had become visible through the thin mucosa.

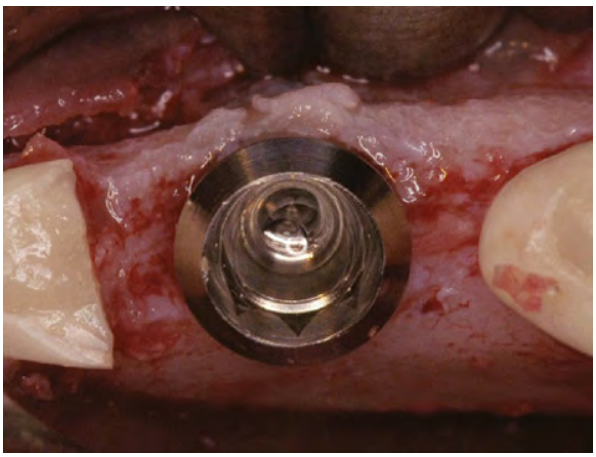

Fig. 40-13 Implant installation in the narrow, third premolar alveolar socket.

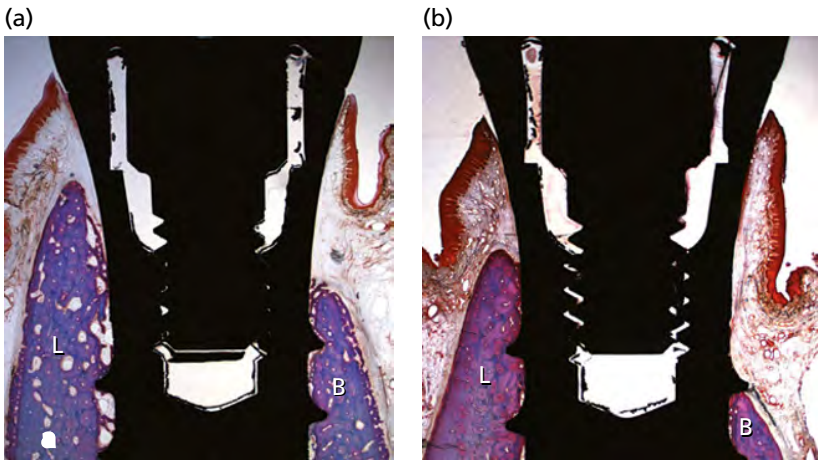

Fig. 40-14 Buccolingual section of the healed premolar sites (a) 4 and (b) 12 weeks after implant installation. B, buccal aspect; L, lingual aspect.

the subsequent restoration to meet high demands regarding esthetics and function. In most cases of type 1 placement, the implants are fixed in native bone apical to the alveolus (Fig. 40-17). Additional retention may be achieved by anchoring the implant in the bony structures of the alveolar walls or interradicular septa.

Another critical issue with type 1 placement is related to how to deal with the presence of periapical pathology at the tooth to be extracted. In a controlled clinical trial, it was observed that primary stability of some implants in a type 1 procedure could not be achieved (Siegenthaler *et al*. 2007). In this study, implants were inserted to replace teeth either exhibiting periapical pathology (test) or presenting healthy periapical conditions (control) (Siegenthaler *et al*. 2007). Apart from the finding that in four implant sites in the test group and one in the control group no implants could be placed due to an unfavorable bone morphology that precluded primary implant stability, no differences were found between the test and the control groups. At 5-year follow-up of the same group of patients, 100% implant survival was recorded in both groups (Jung *et al*. 2013). Furthermore, low levels of marginal bone loss and favorable clinical parameters with no statistically significant difference between the implants in the test and control groups were observed. Focusing on anterior and premolar sites in the maxilla similarly favorable outcomes were earlier reported (Lindeboom *et al*. 2006). In this study sites showing radiographic signs of periapical pathology were randomized into two groups of 25 each. These sites received implants placed either immediately or 3 months after tooth extraction. During the insertion procedure a minimum torque of 25 Nm was required as an inclusion criterion. In contrast to the above study the survival rate in the immediate group reached 92%, whereas it reached 100% in the control group at the 1-year follow-up examination. No differences were found in the other clinical and radiographic parameters assessed except for a more pronounced recession of the midfacial mucosa in the immediate placement group (Lindeboom *et al*. 2006).

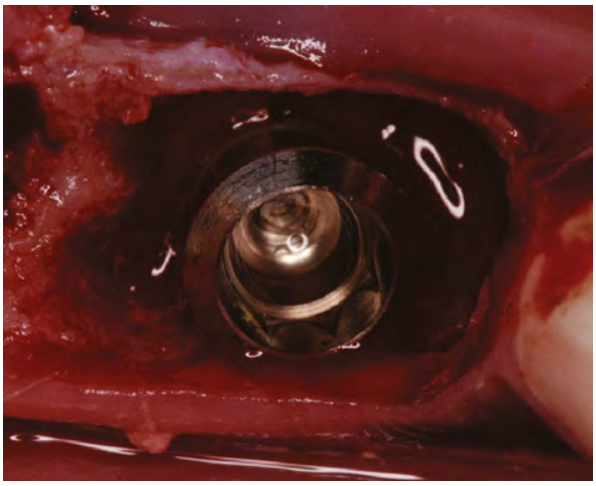

Fig. 40-15 Implant installation in the wide, first molar alveolar socket.

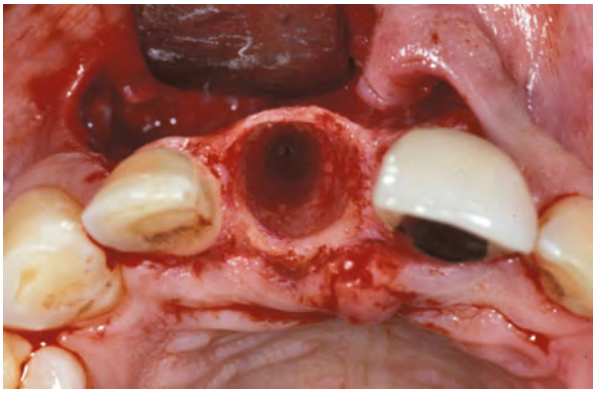

Fig. 40-17 Type 1 implant placement provides optimal availability of existing bone contours. Note the presence of a thin buccal bone plate. Anchorage of an implant can be achieved by engaging the bone apical to the apex of the extracted tooth and the palatal wall of the socket.

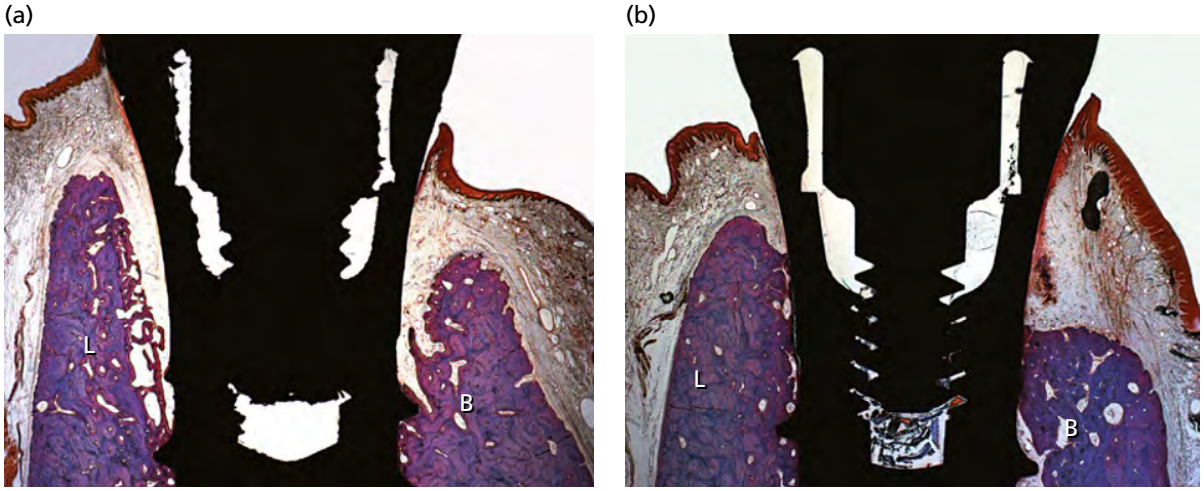

Fig. 40-16 Buccolingual section of the healed molars sites (a) 4 and (b) 12 weeks after implant installation. B, buccal aspect; L, lingual aspect.

Data from a recent study analyzing 418 sites where implants were immediately placed into extraction sockets with periapical pathology revealed 97.8% survival after a mean follow-up of >5 years (Fugazzotto 2012).

A systematic review analyzed data from eight human trials with implants immediately placed into extraction sockets in the presence of periapical pathology (Waasdorp *et al*. 2010). Treatment regimens consistently included thorough debridement of the site prior to implant placement. Bone defects present were normally treated with guided bone regeneration procedures. In the majority of cases, an antibiotic regimen was prescribed. Clinical and radiographic results revealed survival and success rates similar to those for implants placed in non-infected sites. In contrast, studies have reported a higher occurrence of periapical lesions at implants, when the tooth replaced by the implant had exhibited periapical pathology, or when the tooth next to the implant site exhibited periapical pathology (Lefever *et al*. 2013).

Hence, it appears that the presence of periapical pathology at the tooth to be extracted may represent a higher risk for periapical problems at implants immediately placed into the extraction socket. An important body of evidence, however, suggests that by applying a meticulous treatment regimen, implants placed into the site where teeth with periapical pathology have been extracted, can be maintained with high survival and success rates over time.

How to deal with teeth exhibiting marginal periodontal pathology is another important clinical question regarding type 1 implant placement. In a recent study, implants were immediately placed to replace two groups of teeth (Crespi *et al*. 2010). In one group, the marginal periodontium showed signs of infection, but in the other group the marginal periodontium was clinically healthy. Four years after implant placement, no significant differences between the two groups were found regarding implant survival, marginal bone levels, and peri-implant soft tissue parameters. Hence, properly performed immediate implant placement may lead to successful outcomes when replacing teeth affected by marginal periodontitis.

When compared with delayed implant placement in the context of controlled studies, immediate implant placement resulted in an implant survival rate reduced by 4% (94% versus 98%) as reported in a recent systematic review (Cosyn *et al*. 2019). In a recent multicenter, parallel armed, randomized study, implants were placed immediately after extraction of anterior and premolar teeth in 62 patients and 12 weeks after tooth extraction in another 62 patients (Tonetti *et al*. 2017). The results showed similar survival rates in both groups. In the immediate placement group the need for bone augmentation was higher than in the delayed placement group (72% versus 43.9%). In the immediate group probing depths were higher whereas marginal bone levels and esthetics scores were lower in the immediate group compared with the delayed group. Interestingly patient reported outcomes showed no difference between the groups. Collectively, these data indicate a higher probability for the desired treatment outcomes when placing implants in a delayed compared with an immediate placement protocol.

When focusing on posterior sites (molars and premolars) in both the maxilla and the mandible, a recent study reported no difference between implants placed immediately after tooth extraction or following a 4-month healing period (Cucchi *et al*. 2017). The investigators had randomized 92 patients into two groups and analyzed clinical and radiographic parameters for an average observation period of 2 years after initiation of prosthetic loading. No differences were reported between the two groups with respect to implant survival, marginal bone level changes, width of the buccal keratinized mucosa, and biologic or prosthetic complications. Overall, the study results indicated both procedures to be successful in posterior sites of both jaws.

Type 2 placement: completed soft tissue coverage of the tooth socket

There are several reasons why the type 2 approach is often recommended. At this stage of healing, the socket entrance is covered with a mucosa. The soft tissue is (1) comparatively mature, (2) has proper volume, and (3) can be easily managed during flap elevation and replacement procedures. Furthermore, the type 2 timing permits an assessment of the resolution of periapical lesions that may have been associated with the extracted tooth. The disadvantages inherent in the type 2 approach include (1) resorption of the socket walls and (2) an extended treatment time (see Table 40-1).

Following tooth extraction, the socket becomes filled with a coagulum that is then replaced with granulation tissue within a few weeks. In the normal case, it takes about 4–8 weeks before the soft tissue (granulation tissue, provisional connective tissue; see Chapter 3) fills the socket and its surface becomes covered with epithelium (Amler 1969; Zitzmann *et al*. 1999; Hammerle & Lang 2001; Nemcovsky & Artzi 2002). The maturation of the soft tissue (further deposition and orientation of collagen fibers) that can facilitate flap management may require an even longer healing time.

The larger amount of soft tissue that is present at the site of implant placement when the type 2 approach is used allows for precise management of the mucosal flap and hence optimal soft tissue healing (Fig. 40-18). This advantage with the type 2 timing must be matched against the hard tissue reduction and the change of the ridge contour that results from

Fig. 40-18 Soft tissues have completely healed over the extraction socket 8 weeks after tooth removal and a small loss of ridge contour is visible buccally (type 2).

the resorption of the socket walls and of the buccal bone plate. It must be noted that at some extraction sites the mucosa may remain adherent via scar tissue to the underlying bone or to the provisional connective tissue of the socket. In such cases, it may be difficult to separate the soft tissue from the bone and to mobilize the flap. In such a situation, the trauma caused in conjunction with flap elevation may rupture the soft tissue and compromise healing. This in turn may result in soft tissue dehiscence, local infection, and inflammation (Zitzmann *et al*. 1997).

As shown in Fig. 40-1, the initial gain in mucosa (area and volume) is later followed by an overall loss of soft tissue volume. This is evidenced by the fact that the volume of the alveolar process – including the bone as well as the mucosal compartments – markedly decreases during the first 12 months following tooth extraction (Schropp *et al*. 2003).

During the 4–8 weeks between tooth extraction and type 2 implant placement, only small amounts of new bone (woven bone) will form in the socket. This means that the risk of not achieving primary implant stability is similar in type 1 and type 2 approaches. Thus, in sites where the available bone height apical to the tip of the root is <3 mm, it is frequently impossible to obtain primary implant stability in the bone beyond the apex of the extracted tooth. When, in addition, a wide alveolus is precluding the engagement of its bony walls, the type 3 approach may be favored.

Whereas the potential clinical advantages of type 2 implant placement are listed above, there is a paucity of well-controlled clinical trials comparing type 2 placement to immediate or late implant placement with respect to these factors in anterior areas (for review see Graziani *et al*. 2019). There are, however, a few controlled studies and case series of up to 10-year duration demonstrating high survival rates, low biological complication rates, and pleasing esthetic outcomes (for review see Graziani *et al*. 2019).

Currently, the paucity of data from well-controlled clinical studies precludes clear statements regarding the effect of the different types of implant placement on the stability and the height of the soft tissues at the implant sites.

Type 3 placement: substantial bone fill has occurred in the extraction socket

The type 3 time frame is chosen for implant installation at sites where, for various reasons, bone fill is required within the extraction socket. Newly formed woven bone will occupy the socket area after healing periods extending from 10 to 16 weeks (Evian *et al*. 1982). In this period, however, the walls of the socket are frequently completely resorbed and replaced with woven bone. The entrance to the socket is closed with a cap of woven bone that is in the process of remodeling. The mucosa that covers the extraction site is (1) residing on a mineralized ridge, and (2) mature and easier to manage during surgical flap elevation and replacement procedures.

The type 3 approach often allows the clinician to place the implant in a position that facilitates the prosthetic phase of the treatment. The disadvantages with this approach encompass (1) a prolonged treatment time, (2) additional resorption and diminution of the ridge, including a substantial change of its contour, and (3) a concomitant loss of soft tissue volume.

Type 4 placement: alveolar process is healed following tooth loss

In the type 4 approach, the implant is placed in a fully healed ridge. Such a ridge can be found after 6–12 months of healing following tooth extraction (loss). The clinician may now find a ridge that is lined by a mature, often well-keratinized mucosa that resides on dense cortical bone. Beneath the cortical bone plate, cancellous bone occupies a varying portion of the alveolar process (see Chapter 3).

The advantage of type 4 installation is that healing is more or less complete and only minor additional change of the ridge may occur. It must be realized, however, that additional loss of ridge volume may at times occur and require bone augmentation procedures (Fig. 40-19).

Clinical concepts

When implants are to be placed in the edentulous portion of the ridge, factors in addition to the tissue

changes over time must be considered. Thus, in the treatment planning phase, aspects such as the (1) overall objective of the treatment, (2) location of the tooth within the oral cavity – in the esthetic or non-esthetic zone, and (3) anatomy of the bone and the soft tissue at the site(s) to be treated, must be evaluated.

Aim of therapy

Dental implants are most commonly used to restore health and function. During the surgical phase of therapy, therefore, ideal conditions must be established for successful bone and soft tissue integration with the implant. In a growing number of cases, however, treatment must also satisfy patient demands regarding the esthetic outcome. In such cases, the overall surgical and prosthetic treatment protocol may become more demanding, since factors other than osseointegration and soft tissue integration may play an important role.

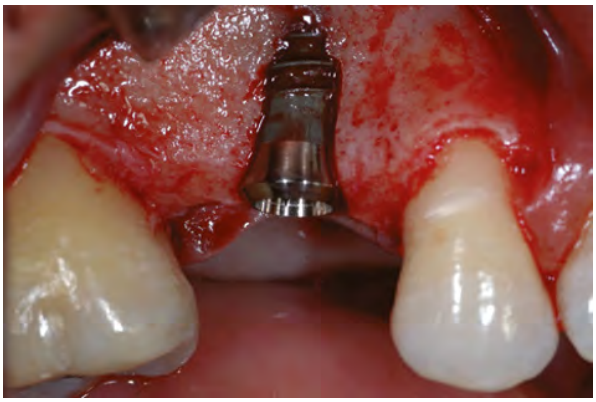

Fig. 40-19 Buccal dehiscence defect is present at an implant placed into a ridge, which has undergone substantial buccal bone resorption since tooth extraction several months ago (type 4).

Restoration of health and function

In cases where the restoration of health and function constitutes the primary goal of the treatment, the location and volume of available hard and soft tissues are the important factors to consider. In such cases, the type 1 approach is usually selected (Wichmann 1990).

The replacement of a single-rooted tooth with an implant in a fully healed ridge will, in most cases, ensure proper primary stability with the implant in a prosthetically correct position. In addition, the soft tissues are sufficient in volume and area. The mucosal flap can be adapted to the neck (or the healing cap) of the implant (one-stage protocol). When primary wound closure is intended (two-stage protocol), mobilization of the soft tissue will allow tension-free adaptation and connection of the flap margins.

When an implant is placed in the unhealed site of a multirooted tooth, the surgical procedure becomes more demanding. Often, the ideal position for the implant is in the area of the inter-radicular septum. If the septa are delicate, anchorage for primary implant stability may be difficult to achieve (Fig. 40-20). In addition, in molar sites there is often only a small amount of soft tissue present. This may create a problem with respect to wound closure with a mobilized, tension-free flap. In some molar sites, primary wound closure may not be possible following implant installation.

The presence of marginal defects (gaps) between the implant and the fully healed ridge following type 4 placement was regarded in the past as a significant problem that could compromise osseointegration. However, studies in humans and animals have demonstrated that in such a horizontal marginal defect (gap) of ≤2 mm, new bone formation as well as defect resolution and osseointegration of the implant (with a rough titanium surface) will occur (Wilson *et al*. 1998; Botticelli *et al*. 2004; Cornelini *et al*. 2005).

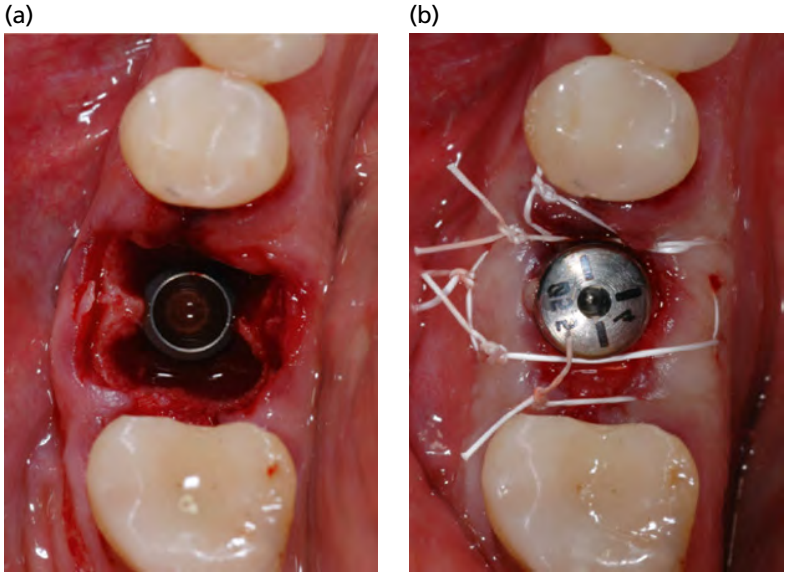

Fig. 40-20 (a) Immediate implant placement (type 1) in a mandibular premolar extraction socket. Note the buccal bone deficiency, where bone will be augmented by guided bone regeneration. (b) Same site as in (a) following adaptation of the flap around the neck of the implant, obtaining a transmucosal mode of healing.

Esthetic importance and tissue phenotype

The replacement of missing teeth with implants in the esthetic zone is a demanding procedure. Deficiencies in the bone architecture and in the soft tissue volume and architecture may compromise the esthetic outcome of treatment (Grunder 2000). Hence, when an implant is to be placed in the esthetic zone, not only the anatomy of the hard tissues but also the texture and the appearance of the soft tissues must be considered.

In a recent systematic review including patients with intact facial bone walls and a thick soft tissue phenotype, a limited risk for advanced mid-facial soft tissue recession was reported (Cosyn *et al*. 2012). Furthermore, it was stated that the literature was scarce regarding the effect of different parameters on mid-facial soft tissue recession, such as thin or thick tissue phenotype, flapless or flap surgery, and immediate or late provisionalization. In another study of a specific treatment protocol that included type 1 implant placement, flapless surgery, and immediate provisionalization, Cabello *et al*. (2013) reported good esthetic outcomes with only small changes in the height of the interproximal papillae and the level of the mid-facial mucosal margin.

Type 2 or 3 installations are often preferred when implants are placed in the esthetic zone (Fig. 40-21). The key advantage of type 2 (as opposed to type 1) installation is the increased amount of soft tissue that will have formed during the first weeks of healing following tooth extraction. Randomized controlled studies comparing the treatment outcomes in type 1 or type 3 placements have reported slightly higher implant survival rates and improved esthetic outcomes (Lindeboom *et al*. 2006; Cucchi *et al*. 2017; Tonetti *et al*. 2017). Non-controlled studies have reported high survival rates for type 2 placement of implants combined with early and conventional loading compared with type 1 placement (for review see Gallucci *et al*. 2018).

Apart from obtaining soft tissue coverage of the previous entrance to the alveolus, type 2 installation has also been claimed to reduce facial soft tissue recession compared with type 1 implant placement. In a comparative study assessing esthetic outcomes of immediate and conventional implant placement, no treatment was favored over any other with respect to overall esthetic results (Raes *et al*. 2011). Interestingly, conventional implant placement was associated with more mid-facial recession than immediate implant placement. In a clinical study of implants placed in fresh extraction sockets (Botticelli *et al*. 2004), during healing, they became clinically osseointegrated within the borders of the previous extraction socket. However, significant loss of buccal bone height (contour) also occurred. In esthetically critical situations, this loss of contour may lead to a compromised outcome. Hence, tissue augmentation procedures must frequently be performed in the esthetic zone.

In this context, it is important to realize that when a two-stage implant placement protocol is used, the labial mucosa will recede following abutment connection surgery. Mean values of recession between 0.5 mm and 1.5 mm, but with large variations, have been reported in several clinical studies (Grunder 2000; Oates *et al*. 2002; Ekfeldt *et al*. 2003). These findings additionally stress the necessity for a careful treatment approach when implants are placed in the esthetic zone. The phenotype (see Chapter 4) of the soft and hard tissues may play a role in the esthetic outcome of implant therapy. Characteristics of soft and hard tissues at teeth were described and classified into two phenotypes: the flat thick or the pronounced scalloped, thin phenotype (Olsson & Lindhe 1991; Olsson *et al*. 1993; Weisgold *et al*. 1997). The thin tissues in the latter type include a thin free gingiva, a narrow zone of attached mucosa, and a pronounced "scalloped" contour of the gingival margin. In addition, the scalloped thin phenotype is associated with a delicate bone housing. In a recent study it was found that buccal tissue recession at single-tooth

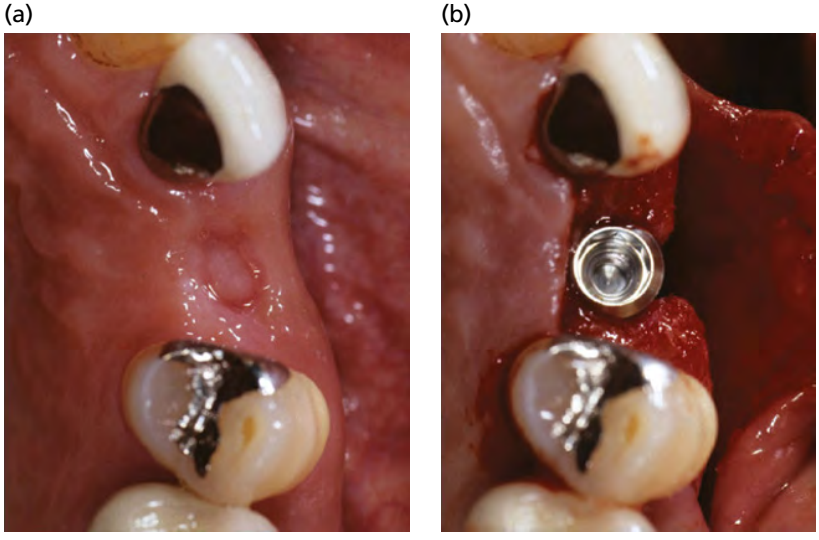

Fig. 40-21 (a) Single-tooth gap 8 weeks following tooth extraction. The soft tissues have completely healed over the extraction socket. (b) Same site as in (a). An implant has been placed in the edentulous gap. The resulting buccal dehiscence defect will be augmented with bone by applying guided bone regeneration.

Fig. 40-22 Patient exhibiting a thin tissue phenotype as characterized by a thin free gingiva, a narrow zone of keratinized and attached mucosa, shallow probing depths, and a pronounced "scalloped" contour of the gingival margin, including recessions at some maxillary anterior teeth. Tooth 11 is scheduled for extraction and replacement by an implant using a type 2 or 3 approach.

implants was more pronounced in patients exhibiting a thin phenotype compared with patients with a thick phenotype (Evans & Chen 2008). Based on these findings and on clinical experience, it was proposed that patients exhibiting a pronounced scalloped phenotype should be treated with a type 2, 3, or 4 rather than a type 1 implant installation approach (Fig. 40-22).

Success of treatment and long-term outcomes

Numerous clinical studies have demonstrated that type 1 implant placement is a successful and predictable clinical method (Lang *et al*. 1994; Schwartz-Arad & Chaushu 1997a; Hammerle *et al*. 1998; Covani *et al*. 2004). In addition, success and survival rates for type 1 implants have been reported to be of the same magnitude as those for implants placed in healed ridges (Gelb 1993; Grunder 2000; Gomez-Roman *et al*. 2001; Gotfredsen 2004; Schwartz-Arad *et al*. 2004). Histologic studies in animals confirmed the viability of type 1 placement. Unloaded titanium implants placed in extraction sockets showed a high degree of osseointegration (Anneroth *et al*. 1985) that is similar to that for implants placed in healed sites. Furthermore, a few studies analyzing survival rates for type 2 and 3 placements have shown survival rates similar to those reported for type 1 and 4 placements (Watzek *et al*. 1995; Nir-Hadar *et al*. 1998; Polizzi *et al*. 2000).

Conclusion

In situations where teeth are to be replaced with implants, various factors govern the decision regarding the optimal time point for implantation following tooth extraction. Of special importance are the overall objective of the treatment, the location of the tooth within the oral cavity, the anatomy of the bone and the soft tissue at the site, and the adaptive changes of the alveolar process following tooth extraction. The decision regarding the timing for implant placement needs to be based on a thorough understanding of the structural changes that occur in the alveolar process following tooth extraction, with and without implant placement, as presented in this chapter.

Introduction: principles of alveolar bone regeneration

The alveolar process is sensitive to a variety of environmental and physiologic factors that influence its ability to function and maintain its integrity. Before implant therapy became available, the physiology and healing patterns of the edentulous ridge after a tooth was extracted were often neglected or not dealt with properly (Amler *et al*. 1960; Amler 1969). Today, implant placement in severe cases of alveolar resorption is a well-understood and recognized challenge that significantly impacts the success of implant therapy. Although alveolar bone loss can be congenital, the result of chronic/acute infections, trauma, pathology, or the consequence of periodontitis, the loss of mechanical function following a tooth extraction is most often the cause of this clinical deficiency. In fact, after tooth extraction, approximately 25% of the bone volume is lost during the first year and over time, may progress to a 40–60% loss of alveolar volume after 3 years of the extraction. The resulting ridge deficiency is primarily the result of a rapid loss of bone height and gradual loss of the horizontal dimension (Carlsson *et al*. 1967). In light of these changes, clinicians have suggested protocols to minimize the resorption of the ridge or to correct these clinically unfavourable deficiencies (Tarnow & Eskow 1995; Sclar 2004; Seo *et al*. 2004) (Fig. 41-1).

Successful ridge augmentation procedures utilize bone biological and physical principles to

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

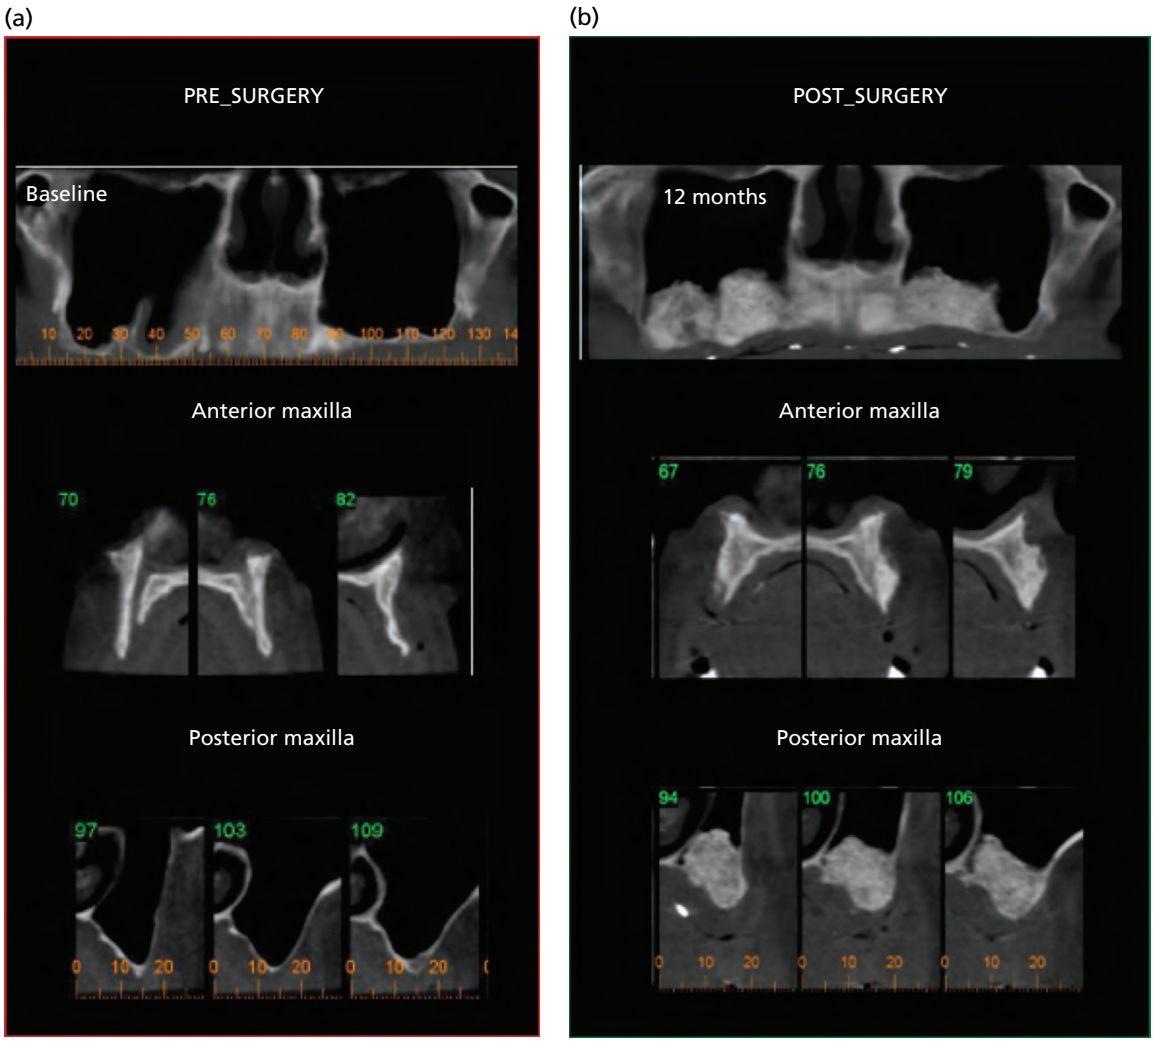

Fig. 41-1 (a) Preoperative and (b) postoperative cone-beam computer tomography images of an adequately corrected anterior and posterior ridge deficiency. Advanced bone grafting protocols have evolved to allow predictable implant placement in severe ridge deficiencies that would have otherwise prevented implant therapy.

enhance its regenerative potential. The placement of bone grafting materials to enhance the healing of osseous defects or to augment atrophic edentulous ridges has allowed the successful placement of dental implants. These regenerative interventions have become a standard procedure in implant dentistry and their efficacy has been evaluated in a number of experimental and clinical studies (Fig. 41-2).

The surgical principles that favour bone regenerative therapies should be based on sound biological factors that encourage adequate healing (Wang & Boyapati 2006). The molecular wound healing events following tooth extraction occur through an orderly sequence of expression of osteogenic factors associated with angiogenesis, cell survival, matrix synthesis, and maturation (Lin *et al*. 2011). These events require an appropriate environment, influenced by local as well as systemic factors, to maximize the osteogenic potential and the eventual reconstruction of the residual ridge. When these environmental conditions are not met (for example in the presence of bacterial contamination and local inflammation) the incorporation of the bone graft in the recipient site may be partially or completely impaired, resulting in bone resorption and bone loss associated with the donor grafting material. Some of the factors that are critical to attaining adequate wound management are discussed below.

Promoting primary wound closure

Primary closure is primordial for bone regeneration because it provides an undisturbed environment for healing (Gelb 1993; Becker & Becker 1996; Fugazzotto 1999; Goldstein *et al*. 2002). Ideal flap closure should be relatively passive and tension-free. In this way, the risk of exposure of the regenerative materials, wound contraction, ingrowth of connective tissue, re-epithelialization, and the associated patient morbidity are decreased. To assure primary closure, the presence of adequate soft tissue volume should be a pre-requisite before bone regenerative surgery. In cases of soft tissue deficiency, it may be advisable to augment the soft tissues prior to bone augmentation.

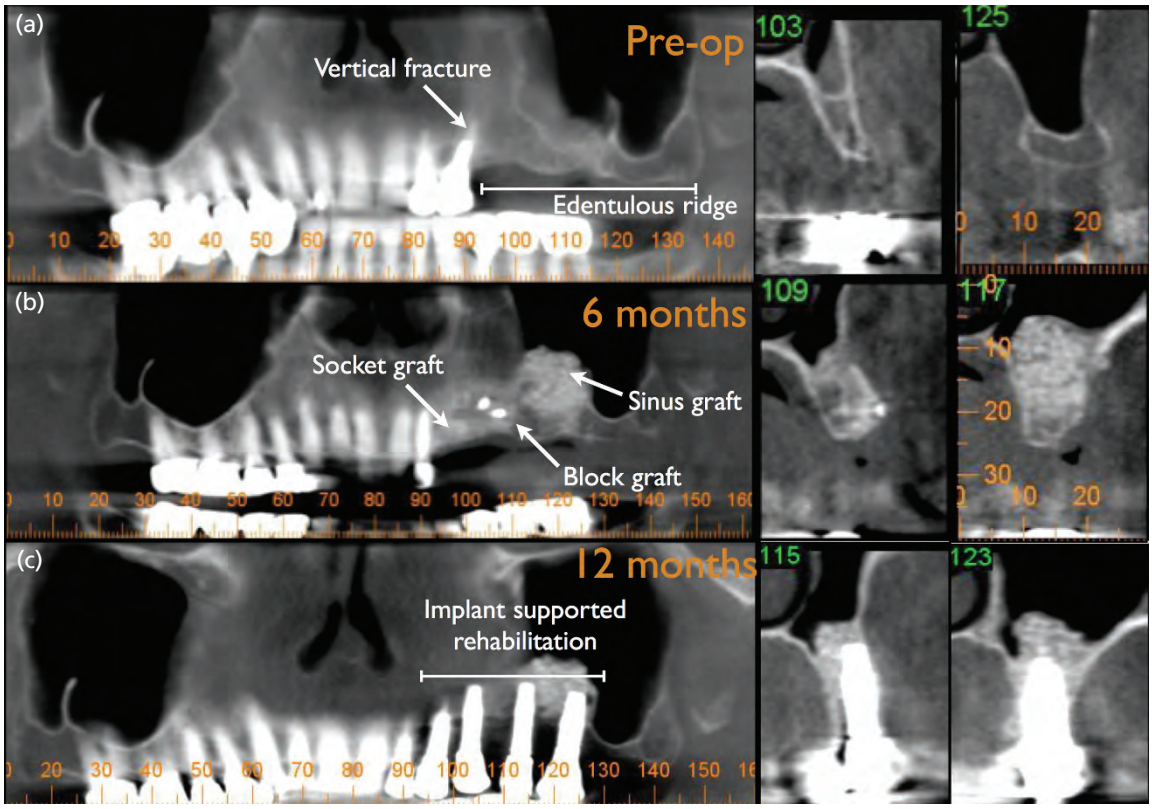

Fig. 41-2 Availability of diverse bone grafting materials. This has significantly contributed to the development of successful ridge augmentation techniques. (a) Baseline radiographic image highlights the edentulous deficient ridge. (b) Six months after the required grafting procedures. (c) Twelve months after surgery and implant supported rehabilitation.

Enhancing cell proliferation and differentiation

Proper enhancement of cell proliferation and differentiation not only provides angiogenic and osteogenic cells, but also acts as a source of blood, oxygen, and nutrients to the tissues. Sources of undifferentiated pluripotent mesenchymal cells and osteogenic cells include the periosteum and the endosteum (the walls of the defect). Bone marrow is an excellent source of mesenchymal cells, which will differentiate into osteoblasts with the appropriate molecular signalling. To increase the access of bone marrow to the healing site, perforations of the cortical plate have been recommended (Buser *et al*. 1995) because they act as a mechanical or non-infective stimulus that increases blood perfusion to the healing site and the release of growth factors that will improve the normal unperturbed regeneration process (Frost 1983; Shih & Norrdin 1985). This is a process referred to in the literature as the regional acceleratory phenomenon (RAP).

To enhance cell proliferation and differentiation, by increasing the bone anabolic signalling processes, a number of biologically active products are available and have been tested in preclinical and clinical investigations.

Protecting initial wound stability and integrity

One factor that affects wound healing is the stability of the blood clot (Wang *et al*. 2004). This is important because the clot contains a plethora of cytokines (e.g. interleukin [IL]-1, IL-8, tumor necrosis factor), growth factors (e.g. platelet-derived growth factor [PDGF], insulin-like growth factor 1 [IGF-1], fibroblast growth factor 2 [FGF-2]), and signalling molecules that aid in recruiting cells to promote neoangiogenesis and wound healing. Moreover, the blood clot is important, since it is eventually transformed into granulation tissue, which will be the framework of the subsequent bone formation (Schenk *et al*. 1994).

Since the jaw bones are usually convex or flat, they do not lend themselves for space provision, and therefore, a physical space is necessary to allow for the regenerative events leading to bone augmentation of the alveolar process (Oh *et al*. 2003). This is typically achieved through the use of bone replacement grafts that serve as a scaffold to allow the biological events leading to bone formation. Furthermore, the epithelial and connective tissue cells from the mucosa must be excluded from ingrowing into this space to allow for the osteogenic cells and the ensuing new bone formation. This is usually accomplished by the placement of barrier membranes, which usually serve a dual function of maintaining the soft tissues excluded from the healing of the bone defect and also supporting the stabilization of the blood clot. Different types of barrier membranes have been tested: those serving only as tissue barriers (bioabsorbable membranes) and others also providing space maintenance properties (titanium reinforced non-bioabsorbable membranes) (Jovanovic *et al*. 1995; Oh *et al*. 2003).

This chapter discusses the growing evidence in the area of bone augmentation procedures that are frequently employed by clinicians to augment the deficient residual ridges prior to implant therapy.

Treatment objectives

The rationale behind any crestal bone augmentation procedure is to establish sufficient bone availability for safe and predictable dental implant therapy, as well as for attaining adequate bone thickness around the installed implant. Spray *et al*. (2000) evaluated the influence of bone thickness on the marginal bone response at second-stage implant uncovering surgeries, and reported that as the bone thickness approached 1.8–2 mm, the occurrence of bone loss (i.e. implant dehiscence) decreased significantly. Although the "adequate" bone thickness may vary depending on the macroscopic and microscopic implant configurations, as well as the clinical indication, it is generally agreed that at least 2 mm of bone on the buccal side of the implant are recommended to increase the probability of long-term stability of peri-implant health and to attain good aesthetics.

This rationale is further justified by the growing bulk of evidence for biologic complications around functional implants. The prevalence of peri-implantitis, characterized by inflammation and implant-supporting bone loss was reported by Zitzmann and Lindhe ranging between 28% and 56% of patients and between 12% and 43% of implants (Zitzmann & Berglundh 2008). Most recently, a meta-analyses estimated weighted mean prevalence of peri-implant mucositis and peri-implantitis of 43% (CI [confidence interval]: 32–54%) and 22% (CI: 14–30%), respectively (Derks & Tomasi 2015). Among the potential risk factors for peri-implantitis, rough implant surfaces exposed to the oral environment are at a higher risk of accumulating bacterial plaque biofilms and hence the development of mucosal inflammation (Renvert *et al*. 2011). Schwarz *et al*. (2012) evaluated the influence of residual marginal dehiscence bone defects after guided bone regeneration (GBR) on the long-term stability of peri-implant health, and reported that implants exhibiting residual defect heights of >1 mm were at higher risk of presenting mucosal clinical attachment loss, marginal recession, and deepened probing pocket depths 4 years after treatment. Hence, any clinician placing dental implants should ensure that there is enough available bone covering the implant surface and in case there is limited availability, to carry out a bone augmentation procedure.

Diagnosis and treatment planning

Patient

In general, there are no specific contraindications for ridge augmentation procedures provided the patient can withstand a conventional oral surgical procedure. For bone augmentation procedures as well as for other types of oral implant operations, there are some relative contraindications that need to be taken into consideration, mainly medical conditions that might impair normal bone healing. For example, in patients with diabetes, there is evidence that implant success rates are similar to those in healthy patients, provided there is appropriate glycaemic control. Experimental studies, however, have provided histologic evidence of impaired healing in implants placed in diabetic animals when compared with healthy controls, although osseointegration was achieved in both groups (Colombo *et al*. 2011; Schlegel *et al*. 2013). The effect of experimental diabetes and metabolic control on the potential for *de novo* bone formation following GBR has been investigated in the rat mandible (Retzepi *et al*. 2010). These authors did not observe statistically significant differences in the amount of vertical bone regeneration when uncontrolled diabetic, insulin-controlled diabetic, and healthy animals were compared. The uncontrolled diabetes group, however, showed an increased rate of infectious complications and a less predictable outcome. When metabolic control of the systemic condition was achieved, the detrimental effects on healing were reversed.

Smoking has also been found to negatively affect the long-term prognosis of osseointegration (Bain & Moy 1993). Clinical studies have reported that smokers present not only higher rates of implant failure when compared with non-smokers (De Bruyn & Collaert 1994; Lambert *et al*. 2000), but also a greater number of complications around successfully integrated implants (Roos-Jansaker *et al*. 2006), such as a higher incidence of peri-implant mucositis and peri-implantitis (Heitz-Mayfield 2008). Although there is ample evidence on the negative effects of tobacco smoking on the clinical outcomes of periodontal regenerative therapies, such as guided tissue regeneration (GTR) (Patel *et al*. 2012), few studies have directly evaluated its effect on GBR. A meta-analysis, based on six studies, evaluated the effects of smoking on dental implants placed on augmented bone and reported an odds ratio (OR) of 3.61 (95% CI 2.26–5.77) for implant failures (Strietzel *et al*. 2007). In this systematic review, the impact of smoking on the outcomes of different bone regeneration techniques (lateral and/or vertical augmentation) was assessed in four retrospective studies: three studies reported more failures and complications in smokers compared with non-smokers. Moreover, the amount of bone augmentation in smokers was inferior when compared with that in non-smokers. Similarly, a clinical case series evaluated the outcomes of a GBR procedure combining autogenous bone and an expanded polytetrafluoroethylene (ePTFE) membrane (Lindfors *et al*. 2010). In the group of non-smokers, the augmentation procedure was successful in 95% of the cases, whereas in smokers it was successful in only 63% of the cases. Moreover, signs of soft tissue inflammation were present in 10 (37%) of the augmentation sites, and this occurred more often in smokers (75%) than in non-smokers (21%).

These patient-related factors are not absolute contraindications for bone augmentation procedures, but they should be taken into consideration during diagnosis and treatment planning. When a bone augmentation procedure is indicated, the patient's systemic status should be optimal.

Defect classification

Bone availability is the main prerequisite for safe and predictable implant placement. There are, however, many clinical situations where bone quantity is limited and therefore, bone augmentation procedures are indicated. In order to decide on the appropriate bone augmentation strategy, the available bone crest must be carefully evaluated with careful clinical examination and three-dimensional (3D) radiographical diagnosis (see Figs. 41-1, Fig 41-2).

According to Seibert (1983), alveolar crest defects are classified into three categories (Fig. 41-3):

- Class 1 defects: when the bone deficiency is predominantly in the horizontal dimension
- Class 2 defects: when the bone deficiency is predominantly in the vertical dimension
- Class 3 defects: when the bone deficiency affects both the vertical and horizontal dimensions.

Depending on the amount of available bone and the defect type, the treatment strategy may consider implant placement and a concomitant bone augmentation procedure (simultaneous implant-GBR procedure) or bone augmentation and delayed implant placement once the bone volume has been augmented (staged-GBR procedure). The simultaneous procedure is indicated in class 1 defects when there is enough vertical bone for placing an implant with appropriate primary stability and the bone regenerative procedure is intended for lateral bone augmentation. In class 2 and 3 defects, depending on the amount of vertical augmentation needed, the staged approach is usually indicated (Fig. 41-4).

Bone augmentation procedures could also be considered when placing implants in fresh extraction sockets. In most of these clinical situations, the morphology of the socket does not match the implant diameter and, depending on the resulting bone defect, a different bone augmentation procedure might be indicated.

Benić and Hämmerle (2014) (Fig. 41-3) have classified these defects as:

- Class 0 Site with a ridge contour deficit and sufficient bone volume for standard implant placement
- Class 1 Intra-alveolar defect between the implant surface and intact bone walls

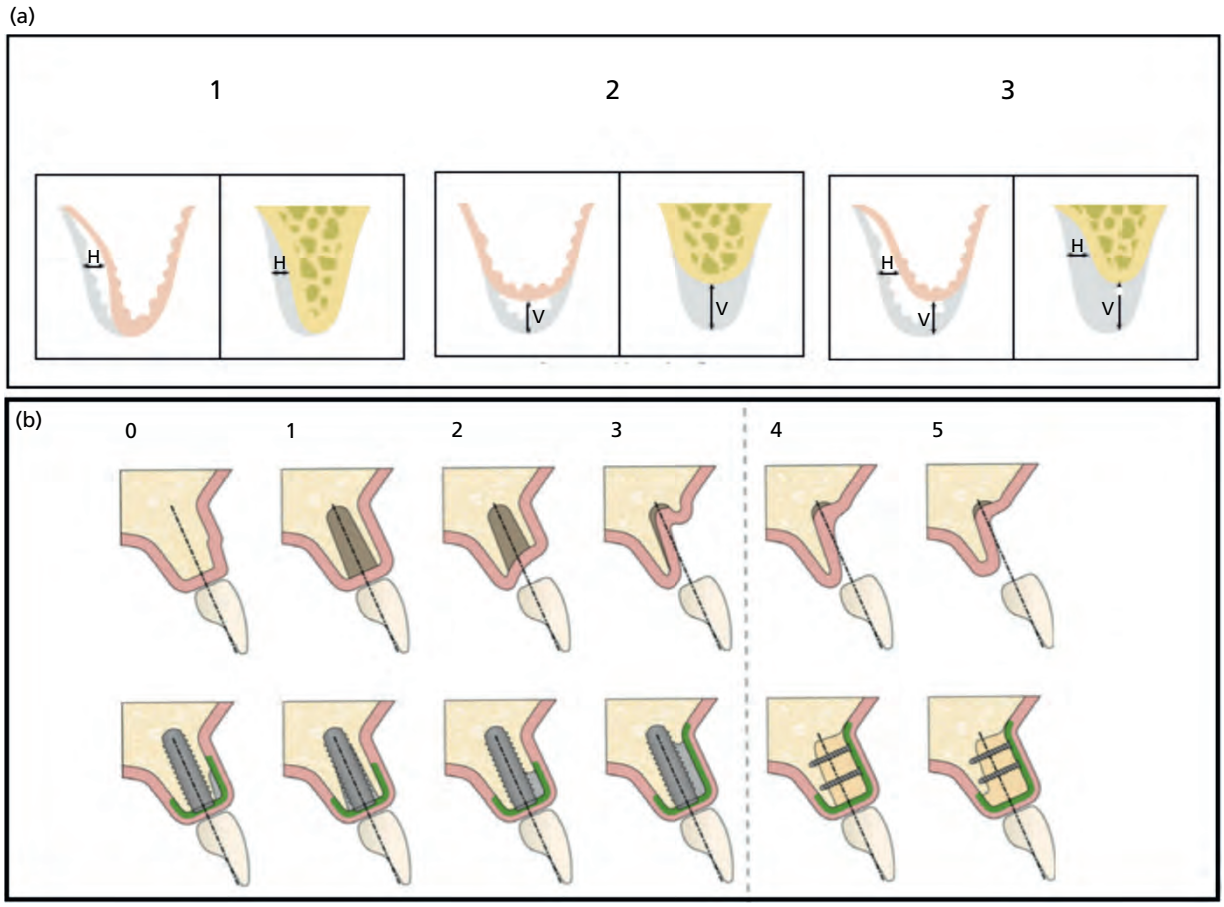

Fig. 41-3 (a) Alveolar crest defects, Seibert classification. (b) Extraction sockets defect, Benic and Hammerle classification.

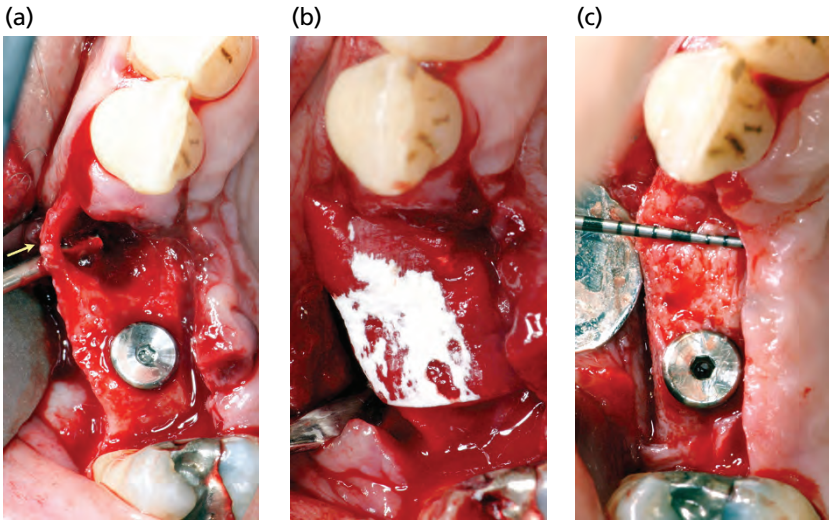

Fig. 41-4 (a, b) Socket preservation (deproteinized bovine bone mineral + non-cross-linked collagen membrane) in position 13 due to fenestration (arrow) of the buccal bone wall of the socket (class II defect, Hämmerle & Jung) and immediate implant (no graft) in position 14. (c) Re-entry surgery at 4 months. Outcome of the socket preservation procedure. Note the bone remodeling at the implant site.

- Class 2 Peri-implant dehiscence, in which the volume stability of the area to be augmented is provided by the adjacent bone walls
- Class 3 Peri-implant dehiscence, in which the volume stability of the area to be augmented is not provided by the adjacent bone walls
- Class 4 Horizontal ridge defect requiring bone augmentation before implant placement
- Class 5 Vertical ridge defect requiring bone augmentation before implant placement

A one-step GBR procedure is usually indicated for class 0–3 defects, while in larger horizontal and vertical bone defects the delayed approach should be indicated.

When placing implants in extraction sockets, timing of the bone augmentation procedure is also very important since, depending on the time elapsed from tooth extraction, different soft tissue conditions may be encountered. For details regarding the different implant treatment strategies in extraction sockets, see Chapter 40.

Bone augmentation therapies

In the mid-1980s, the GTR principle was applied in periodontal regeneration, based on the early studies of Melcher (1976), who developed the concept of using barrier membranes to "guide" the biologic process of wound healing. These early experimental studies demonstrated that the exclusion of soft tissue invasion of the defect by means of a barrier membrane, allowed the cells with regenerative potential to migrate to the site (derived from the periodontal ligament or bone marrow) and promoted periodontal regeneration (Nyman *et al*. 1982). Based on the same biologic principle, the GBR treatment concept aimed for mechanical exclusion of the soft tissues from filling the osseous defect, thus allowing the cells with osteogenic cells to colonize the wound (Dahlin *et al*. 1988). The key prognostic factor in GBR was to have enough space under the barrier membrane to allow for bone regeneration of the crestal defect. Depending on the morphology of the defect, this space can only be maintained with the use of a bone replacement graft, either particulated or as a block. Different biomaterials, natural and/or synthetic, have been used and investigated in their capacity to be used as bone replacement grafts in bone augmentation procedures of the jaws (Haugen et al. 2019).

The following sections describe the biologic principles of GBR and the efficacy of the biomaterials used as bone replacement grafts and barrier membranes.

Biologic principles of guided bone regeneration

Seibert and Nyman (1990) demonstrated successful reconstruction of surgically created, buccolingual defects in the edentulous ridge of dogs after 90 days of healing, with newly formed bone filling the space created beneath e-PTFE (Gore-Tex®) non-resorbable barrier membranes. Furthermore, Smukler *et al*. (1995) reported that the application of barrier membranes in class III ridge defects led to a mean vertical augmentation of 3.31 mm (Buser *et al*. 1995) and demonstrated that this regenerated bone could successfully integrate dental implants when these were placed 6 months after the GBR procedure.

The sequence and pattern of bone regeneration in GBR procedures has been investigated in experimental studies. Schenk *et al*. (1994) investigated surgically created, membrane-protected defects in the edentulous ridge in dogs. The sequence of events assessed histologically, started with the organization of a blood clot that filled the space protected under the membrane. Then a connective tissue matrix, rich in new vascular structures, replaced this blood clot and subsequently, woven bone started to deposit from the surrounding bony walls and concentrically filled the defect. This woven bone was later replaced by parallel-fibered lamellar

bone, resulting in a new cortical structure at the periphery of the defects. This pattern of intramembranous bone growth shown in GBR was described also in the healing of an alveolar sockets after tooth extraction (Cardaropoli *et al*. 2003). Dahlin *et al*. (1989) were the first to provide evidence to support the effectiveness of GBR around implants. e-PTFE membranes were applied around exposed implant threads inserted in rabbit tibiae and peri-implant bone formation was observed provided enough space was secured under the membrane. Becker *et al*. (1990) also assessed the potential of GBR in treating exposed threads of implants placed in dog mandibles. They reported a mean increase of 1.37 mm in bone height for the GBR-treated test sites, versus 0.23 mm for the sham-operated controls.

Vertical bone augmentation using this principle was also demonstrated by Jovanovic *et al*. (1995) who reported regeneration of the mandibular process when applying e-PTFE membranes around supracrestally placed implants in dogs. The new bone formed supracrestally amounted to 1.82 mm (SD 1.04) and 1.9 mm (SD 0.3) when using titanium-reinforced and standard e-PTFE membranes, respectively. GBR was also studied histologically in monkeys with e-PTFE membranes placed around dental implants inserted immediately into fresh extraction sockets (Warrer *et al*. 1991): bone regeneration was observed around the implant circumference in GBR-treated sites, compared with a lack of bone contact in non-GBR-treated control sites. Similar experimental studies in dogs also showed successful bone regeneration using e-PTFE membranes in implants immediately placed in fresh extraction sockets (Becker *et al*. 1991; Gotfredsen *et al*. 1993).

Regenerative materials

Barrier membranes

Different types of barrier membranes have been tested for GBR. These membranes must fulfil specific criteria for promoting bone regeneration of the edentulous ridge, such as biocompatibility, cell occlusion properties, integration by the host tissue, and space-making capacity. Their specific composition falls into two broad categories: non-resorbable (PTFE and e-PTFE) and resorbable. e-PTFE has been the most frequently investigated material for *non-resorbable membranes* in both periodontal and bone regeneration clinical applications. e-PTFE membranes are flexible with an external porous structure allowing for tissue integration and an internal occlusive layer providing the barrier mechanism. They are composed of a chemically stable and biologically inert polymer that resists microbiologic and enzymatic degradation and do not elicit any immunologic reactions. To enhance the space-making capacity of these devices, a titanium scaffold is applied between the two e-PTFE layers, adding stiffness and reinforcing the membrane structure. These non-degradable barrier membranes require a second surgical intervention to remove them. This disadvantage, together with the high occurrence of postoperative complications, mainly early membrane exposure, has limited their clinical use and has led to the development and broader use of resorbable membranes.

Bioresorbable membranes must ensure that the tissue reactions during the process of membrane resorption or biodegradation are minimal and do not affect the outcome of bone regeneration (Hardwick *et al*. 1995). Several bioresorbable materials have been tested with varying success in bone regeneration applications. Bioresorbable membranes are either natural (xenogeneic collagen type I or III) or made of synthetic polymers, including polyurethane, polyglactin 910, polylactic acid, polyglycolic acid, polyorthoester, polyethylene glycol, and different combinations of polylactic and polyglycolic acid (Sandberg *et al*. 1993; Zellin *et al*. 1995; Brunel *et al*. 1998; Jung *et al*. 2006). When inserted into an aqueous environment, such as a biologic system, the biodegradable polymers undergo enzymatic degradation by hydrolysis. The natural collagen membranes undergo resorption by enzymatic degradation. This membrane degradation process depends on many factors, such as membrane composition, pH, temperature, degree of polymer crystallization, cross-linking in collagen membranes, and membrane volume (Warrer *et al*. 1992; Hämmerle & Jung 2003). The duration of the barrier function is, therefore, variable and the resorption process may interfere with the wound healing and bone regenerative outcome.

Several experimental studies have compared the potential of these barrier membranes for promoting bone regeneration. When non-resorbable e-PTFE membranes were compared with synthetic bioresorbable membranes made of poly d,l-lactide-co-trimethylencarbonate, significantly more bone was formed around implants covered with e-PTFE membranes, although both test and control implants exhibited new direct bone-to-implant contact (Hurzeler *et al*. 1997). These differences are mainly due to the lack of stiffness and space-making capacity of bioresorbable membranes, which when placed directly over the implant threads, tend to collapse and occlude the space available for bone regeneration. This problem is usually overcome by using a scaffold or graft material under the membrane that provides the space for tissue ingrowth and subsequent bone formation. Experimental studies comparing non-resorbable and collagen resorbable membranes, with and without the use of a scaffold, have shown similar bone regenerative outcomes for the non-resorbable membranes and the collagen resorbable membranes used with a scaffold (Hurzeler *et al*. 1998).

For collagen membranes, the biodegradation and concomitant tissue integration depends on the degree of collagen cross-linking. A comparative study evaluated different collagen membranes: (1) BioGide

(BG) (non–cross-linked porcine type I and III collagens, bilayered) (Geistlich Biomaterials, Wolhusen, Switzerland); (2) BioMend (BM) (glutaraldehyde cross-linked bovine type I collagen) (Sulzer Medica, Colla-Tec Inc., Plainsboro, NJ, USA); (3) BioMendExtend (BME) (glutaraldehyde cross-linked bovine type I collagen) (Sulzer Medica); (4) Ossix (OS) (enzymatic cross-linked bovine type I collagen) (3i, Colbar R&D Ltd, Ramat Hush-aron, Israel); (5) TutoDents (TD) (non-cross-linked bovine type I collagen, bilayered) (Tutogen, Carlsbad, CA, USA); (6) VN(1); (7) VN(2); and (8) VN(3) (1, 3, 4 × chemical cross-linked porcine type I and III collagens, bilayered, respectively) (Geistlich Biomaterials) (Rothamel *et al*. 2004). The non-cross-linked porcine-derived collagen types I and III exhibited good tissue integration (without observable foreign body reactions), rapid neo-angiogenesis, and almost complete biodegradation 4 weeks after implantation. The vascularization and biodegradation of chemical and enzymatically cross-linked collagen membranes, however, were slower and the resorption rate was directly related to the degree of cross-linking.

The choice of membrane material usually depends on the amount of bone regeneration needed, mainly in the vertical dimension. e-PTFE barrier membranes have demonstrated more favourable results when compared with resorbable devices, mainly due to their better space-making capacity, longer barrier function, and lack of a resorption process that may negatively affect bone formation (Hämmerle & Jung 2003). Nevertheless, a high rate of soft tissue dehiscence was observed with the use of e-PTFE membranes. When this complication occurs, early contamination of the exposed membrane usually jeopardizes the regenerative outcome. A meta-analysis evaluating the influence of membrane exposure on the outcomes of regenerative procedures reported that new bone formation was six-fold greater when no soft tissue dehiscence occurred (Machtei 2001).

As already mentioned, these frequent complications and the need for a second surgery to remove the membrane with non-resorbable membranes make resorbable membranes the current gold standard, provided they are used with an adequate space-making graft material. The choice of non-cross-linked resorbable collagen membranes should be based on their advantages in terms of earlier neo-angiogenesis, lack of inflammatory response, and fast biodegradation/integration within the host tissue.

Bone grafts and bone and soft tissue substitutes

Bone grafts

Autogenous bone grafts (autografts) have historically been the gold standard in bone regeneration therapies since they have well-documented osteoinductive, osteoconductive, and osteogenic properties (Yukna 1993). In alveolar bone augmentation surgeries, autogenous bone is used either as a particulate or a block graft. Particulate bone grafts are normally harvested from intraoral sites and used in combination with barrier membranes following the principles of GBR. These bone chips have the disadvantages that their availability is limited within the oral cavity and, as they lack a rigid and supportive structure, they do not provide the space-making capacity necessary for the treatment of class II and III defects. In these cases, rigid titanium-reinforced ePTFE barrier membranes or other space maintenance strategies, such as tenting screws or micro-implants, have been used in conjunction with particulate bone autografts. Another drawback with the use of autografts is their fast resorption rate, which requires early implant placement to assure functional loading to the regenerated bone, thus preventing its resorption.

Monocortical block autografts may be harvested from intra- or extra-oral sites. Common intraoral donor sites are the mandibular chin or the ascending ramus area, whereas common extraoral donor sites are the iliac crest or the calvarial bone. They may be used in combination with barrier membranes or alone and they require fixation to the recipient crestal site with mini-screws to avoid micro-movements during healing. These grafts, due to their excellent space maintenance capacity, are indicated in large crestal defects in which there is a need for vertical bone augmentation. Their main disadvantage is the morbidity associated with their harvesting, mainly from the chin area. As with particulate autografts, their resorption rate is high, although when combined with a barrier membrane or with bone particulate xenografts, resorption is slowed.

Bone substitutes

In order to avoid the morbidity associated with the harvesting of autogenous bone grafts, allografts, xenografts, and alloplasts have been indicated and tested.

Allografts are bone grafts harvested from cadaver donors and processed by freezing or demineralizing and freezing. These grafts are then sterilized and supplied by specially licensed tissue banks as bone particles or large blocks. Demineralized freeze-dried bone allografts (DFDBA) have shown osteoconductive as well as osteoinductive properties due to the release of bone morphogenetic proteins (BMP) during the demineralization process. There is some concern, however, regarding their absolute non-infectivity, although there have been no reported cases of disease transmission from DFDBA used for dental purposes among over 1 million cases over 25 years (Yukna 1993). These allografts are usually used in combination with barrier membranes following the principles of GBR.

Xenografts are graft biomaterials of animal origin, mainly bovine and equine. These graft materials are deproteinized in order to completely remove the organic component and thus avoid any immunogenic reaction. This chemical or low heat process preserves the original bone architecture and the inorganic mineral composition, which assures the osteoconductive properties of the biomaterial. Inorganic bovine bone grafts are usually particulate and utilized according to the principles of GBR in combination with resorbable collagen membranes. Different preclinical and clinical studies have demonstrated their safety and efficacy as bone substitutes for both periodontal and peri-implant augmentation procedures (Baldini *et al*. 2011). Recently, highly purified porcine collagen type I has been added to xenografts to enhance their clinical handling by improving the cohesion between the mineral granules.

Alloplasts are synthetic bone substitutes that include different combinations of calcium phosphates fabricated under different sintering conditions, which yields different physical properties and resorption rates. The combination of hydroxyapatite and beta-tricalcium phosphate (β-TCP) provides a scaffolding function (hydroxyapatite) as well as osteoconductive properties (β-TCP). These biomaterials are usually resorbable and delivered as granules. They should be always used in combination with barrier membranes.

Soft tissue substitutes

Soft tissue substitutes have been introduced in periodontal plastic surgery as alternative materials to the use of soft tissue autografts. Their use in bone augmentation is limited to alveolar ridge preservation techniques and to bone augmentation at immediate implant sites. Based on their origin, these scaffold materials may be xenogeneic or allogeneic (for details see Chapter 39). The scaffolds tested so far in pre-clinical and clinical research are of xenogeneic porcine origin and aim at clot stabilization, cell invasion/guidance, and tissue integration.

Choice of the material

This choice should be based on the clinical indication. For small bone defects requiring mainly horizontal bone augmentation, the use of xenografts and alloplasts has demonstrated excellent results. When the objective is to preserve the socket walls after tooth extraction, experimental studies have evaluated the histologic healing when the sockets are filled with different graft materials. The use of autogenous bone chips alone does not counteract the physiologic process of bone remodeling that occurs at the socket bone walls after tooth extraction (Araújo & Lindhe 2011). Indeed, the healing process at these sites filled with autografts showed characteristics similar to those of the sockets without any filling. In contrast, the use of xenografts with a much slower resorption rate demonstrated significantly better preservation of the socket walls than the non-grafted sites. Histologically, these xenograft granules were integrated and fully surrounded by newly formed bone (Araújo & Lindhe 2009). In a similar experimental model, a β-TCP alloplast demonstrated limited bone promotion properties, with the graft particles being encapsulated with connective tissue (Araújo *et al*. 2010). In fresh extractions sockets, the use of collagen matrices of porcine origin has been introduced to seal the socket orifice (Jung *et al*. 2013) in alveolar ridge procedures or in combination with bone augmentation at immediate implant sites (Frizzera *et al*. 2019; Sanz-Martin *et al*. 2019).

In peri-implant dehiscence type defects, requiring simultaneous lateral augmentation, particulated bone grafts should be utilized in combination with barrier membranes. One experimental study testing different graft materials (biphasic hydroxyapatite + beta tricalcium phosphate β[β- TCP] [BCG]) or collagen-coated deproteinized bovine bone mineral (BOC) showed that both biomaterials increased bone fill and the percentage of osseointegrated bone–graft particles (Schwarz *et al*. 2007). Similarly, one experimental study testing (1) synthetic bone substitute covered by a cross-linked collagen membrane and (2) deproteinized bovine bone mineral covered by a natural collagen membrane, showed that both combinations of biomaterials increased horizontal bone augmentation compared with the control group. The synthetic bone substitute achieved better histological outcomes in terms of linear horizontal bone gain and tissue thickness (Jung *et al*. 2017). Therefore, it may be concluded that both synthetic and xenogeneic biomaterials may provide an osteoconductive scaffold to support GBR procedures at dehiscence-type defects.

For the treatment of horizontally deficient alveolar ridges that require a staged lateral bone augmentation, the GBR concept using a native collagen membrane with a combination of 1:1 ratio of particulate DBBM and autogenous bone has been tested, demonstrating the efficacy of this technique both in terms of average amount of horizontal bone gain and implant survival rates (Urban *et al*. 2013).

In large crestal defects for which the aim is both lateral and vertical bone augmentation, the GBR concept with titanium reinforced non-resorbable membranes, and a combination of particulate DBBM and autogenous bone (Urban *et al*. 2014), or the use of monocortical autogenous corticocancellous block grafts, may be recommended. In experimental studies comparing the use of these block grafts with and without a barrier membrane, a significant resorption and limited bone augmentation were demonstrated in the non-membrane protected group, thus demonstrating the clear indication for always protecting the block graft with a resorbable barrier device (von Arx *et al*. 2001).

Evidence-based results for ridge augmentation procedures

These procedures have been used in five main clinical applications: alveolar ridge preservation; bone regeneration in fresh extraction sockets; horizontal bone augmentation; ridge splitting/expansion; and vertical ridge augmentation.

Alveolar ridge preservation

Important structural changes of the edentulous ridge take place after tooth extraction and eventually lead to dimensional changes of the alveolar crest. A classic systematic review assessed the hard and soft tissue changes occurring 6 months after tooth extraction in humans and demonstrated a horizontal bone loss of 29–63% and vertical bone loss of 11–22% from the dimensions of the alveolar bone crest at the time of extraction (Tan *et al*. 2012). With the goal of preventing these physiologic hard and soft tissue changes, different bone augmentation techniques have been proposed to preserve the alveolar architecture after tooth extraction. In general, these ridge preservation techniques have been defined as: "Any therapeutic approach carried out immediately after tooth extraction aimed to preserve the alveolar socket architecture and to provide the maximum bone availability for implant placement" (Vignoletti *et al*. 2012).

These ridge preservation approaches have utilized GBR principles using the following regenerative technologies:

- Resorbable and non-resorbable barrier membranes alone
- Resorbable and non-resorbable barrier membranes in combination with bone substitutes
- Bone substitutes alone
- Bone substitutes in combination with soft tissue autografts
- Bone substitutes in combination with soft tissue substitutes.

From a surgical standpoint, either flapped and flapless approaches have been proposed. The flapped approach allows a primary intention healing due to coronal positioning of the buccal flap. Within the flapless approach, the "socket seal" technique has been introduced allowing a secondary soft tissue closure (Jung *et al*. 2004). The sealing of the socket orifice may be achieved by using either an autogenous or an exogenous barrier material. The purpose of both techniques is to protect the underlying bone compartment and assist soft tissue healing (Tonetti *et al*. 2019).

The efficacy of alveolar ridge preservation has been widely investigated through several systematic reviews and metanalyses (Avila-Ortiz *et al*. 2019). The effect of this procedure should be analyzed at the alveolar ridge dimension, implant, and patient level.

There is robust evidence that alveolar ridge procedures reduce the bone dimensional changes that occur after tooth extraction, although some degree of vertical and horizontal bone loss can still be expected (Ten Heggeler *et al*. 2011). Furthermore, all studies agree that the effect is more pronounced in the horizontal, rather than the vertical dimension. Results from a pooled quantitative analysis in a recent systematic review (Avila-Ortiz *et al*. 2019) demonstrated that alveolar ridge preservation prevented horizontal (M = 1.99 mm; 95% CI 1.54–2.44; P <0.00001), vertical mid-buccal (M = 1.72 mm; 95% CI 0.96–2.48; P <0.00001), and vertical mid-lingual (M = 1.16 mm; 95% CI 0.81–1.52; P <0.00001) bone resorption, as compared with spontaneous healing of the fresh extraction socket.

At the implant level, results from two systematic reviews highlighted less need of ancillary grafting at the time of implant placement (Mardas *et al*. 2015; Avila-Ortiz *et al*. 2019). Nevertheless, although the feasibility of implant placement was higher in sites that received alveolar ridge preservation, additional bone augmentation at the time of implant placement may still be required. Furthermore, when evaluating implant loss and implant success after a minimum of 12 months of functional loading with the final prosthesis, sites that received alveolar ridge procedures exhibited no differences compared with sites that underwent unassisted socket healing.

At the patient level, patient-related outcomes have been rarely reported. In two studies involving the use of autologous blood-derived products (Alissa *et al*. 2010; Temmerman *et al*. 2016), discomfort, perceived benefit, and quality-of-life scores were marginally in favor of alveolar ridge preservation therapies.

There are several factors that may influence the outcomes of therapy. These may be organized into three main categories: (1) the patient, (2) the fresh extraction socket, and (3) the surgical protocol. At the patient level, age, history of periodontal disease, systemic diseases, or smoking habits are all factors that may have an impact on the effect of therapy. Nevertheless, none of these systemic factors have been shown to be significant. When looking at the sites, reason for extraction, socket anatomy (single- or multi-rooted), integrity of extraction site, and buccal bone thickness have been explored as potential influencing factors. Buccal bone thickness has been highlighted as a crucial factor during the early spontaneous healing of the socket (Chappuis *et al*. 2015). In this 3D radiographic evaluation, the authors demonstrated that sockets presenting a thin (<1 mm) buccal bone at baseline demonstrated, after 8 weeks, seven times more mid-vertical buccal bone resorption as compared with sockets presenting a thick buccal bone wall. Taking this into consideration, when applying alveolar ridge preservation, no correlation between the initial thickness of the buccal bone and the final alveolar bone dimension was observed (Cardaropoli *et al*. 2014). This indicates that alveolar

ridge preservation masks the negative influence of a thin buccal bone. Indeed, the magnitude of effect of the application of alveolar ridge preservation-socket grafting is higher and more beneficial in sites exhibiting thin buccal bone (Avila-Ortiz *et al*. 2019).

When looking at the surgical protocol, several aspects have been explored, such as biomaterials utilized, modality of socket seal, flap elevation, primary or secondary closure, healing period. In an attempt to explore which of these factors mostly influenced the outcomes, a subgroup analysis with meta-regression was performed as part of a systematic review and meta-analysis (Vignoletti *et al*. 2012). The conclusions from the subgroup analysis demonstrated that: (1) the use of membranes; (2) primary intention healing; and (3) flapped surgical procedures were associated with less horizontal bone resorption. Similarly, the application of a xenogeneic or allogeneic bone grafting material and the necessity of sealing the socket orifice, has been strongly recommended in the consensus report of working group 3 on the management of the extraction socket of the XV European Workshop in Periodontology. This highlights the importance of achieving primary intention healing throughout the 3–4 months of recommended healing (Tonetti *et al*. 2019).

Bone regeneration at implants into fresh extraction sockets

According to the classification proposed at the Third ITI Consensus Conference (Hämmerle *et al*. 2004), immediate and early implant placement (type 1, 2) protocols have been indicated as the most suitable for implant placement following tooth extraction. The type 1 protocol (immediate implant placement) was first presented in 1976 by Schulte and Heimke (1976). The several advantages inherent to placing the implant immediately after tooth extraction have led to a growth in popularity of this protocol in the last decades and this has attracted the interest of clinicians and investigators (Fig. 41-5). Nevertheless, immediate implant placement has to be considered as a challenging procedure for the clinician. The osteotomy has to be performed in the palatal/lingual apical part of the socket to allow the ideal three-dimensional buccolingual and apicocoronal position together with adequate primary implant stability. It must also be kept in mind that most of the studies in the literature report on single unit, ideal, strictly selected cases with intact bony walls.

Based on preclinical and human studies, it is well accepted that implant placement into a fresh extraction socket does not counteract the physiologic bone modeling of the alveolar bone crest. Results from human trials have demonstrated that both vertical and horizontal dimensional changes of the alveolar crest may be expected. Botticelli *et al*. (2004) demonstrated a horizontal resorption of approximately 56% and 30% of the original dimension of the buccal and lingual bone walls of the sockets, respectively, when placing single-tooth immediate implants in the anterior region of the maxilla. These results are consistent with data from a similar study demonstrating 36% and 14% bone resorption at the buccal and palatal bone walls, respectively. Furthermore, the vertical bone resorption of the buccal bone crest was also investigated and amounted to a mean value of 1 mm (SD 2) (Sanz *et al*. 2010). These changes in the horizontal and vertical dimension were mainly influenced by the thickness of the buccal bone plate (>1 mm) and the gap that occurred between the implant surface and the buccal socket wall. Hence, implants placed into sockets with a ≤1-mm buccal thickness/gap are at higher risk of presenting a dehiscence defect that exposes the implant surface to the oral environment and a greater overall horizontal resorption of the alveolar crest.

To counteract these horizontal and vertical dimensional changes, the application of graft and/or barrier membranes and/or an autogenous or exogenous soft tissue graft (Fig. 41-6), in combination with either flapped or flapless surgery and the application of immediate provisionalization, have been proposed and investigated in combination with immediate implant placement.

It is widely accepted that the application of a graft material within the gap or in combination with a barrier membrane reduce in part the horizontal bone resorption that occurs after tooth extraction.

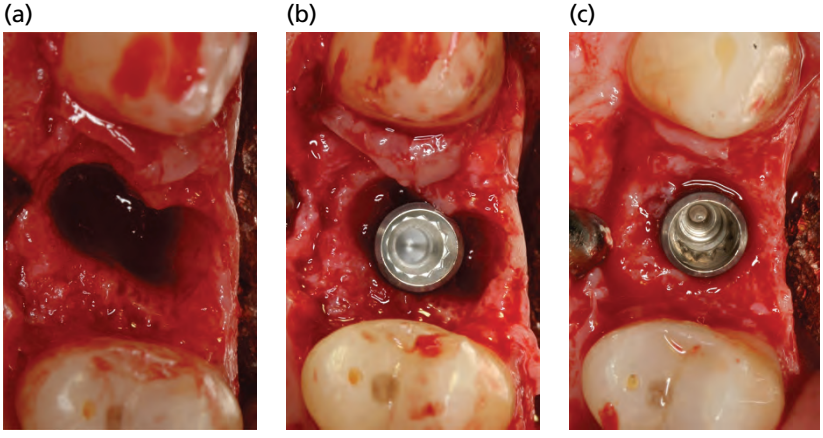

Fig. 41-5 (a) Class I defect (Hämmerle & Jung). Extraction of tooth 14. (b) Immediate implant placement and (c) re-entry procedure after 4 months of healing. Note the overall contraction of the maxillary ridge.

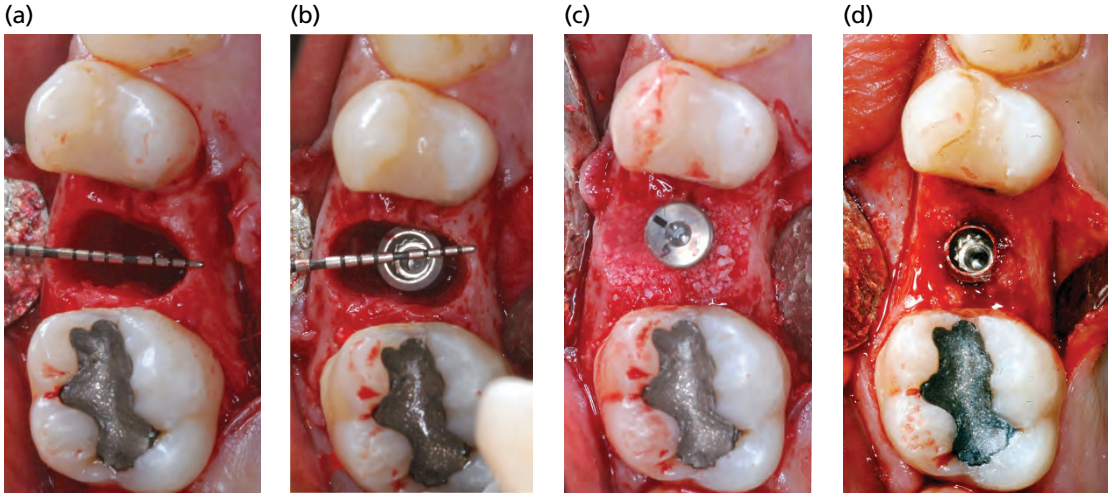

Fig. 41-6 (a) Class I defect (Hämmerle & Jung). Extraction of tooth 15. (b, c) Immediate implant placement with deproteinized bovine bone and porcine collagen fibers. (d) Re-entry surgery at 4 months. Outcome of the grafting procedure.

Several studies investigated the use of graft and/or barrier membranes in combination with immediate implants, assessing their effect on bone dimensional changes. Chen *et al*. (2007) compared three groups of treatment: (1) Immediate implants with a xenogeneic graft material alone, (2) immediate implants with a combination of graft material and a resorbable barrier membrane, and (3) immediate implants as control treatment. The horizontal bone resorption observed at the end of the study was 15%, 20%, and 48%, respectively. Differences were statistically significant between the two test treatments and the control group. Similarly, Sanz *et al*. (2016) observed 28.8% as compared with 37.8% buccal bone resorption, when using a xenogeneic bone graft within the gap as compared with immediate implant alone.

As this surgical protocol mostly applies to the maxillary highly aesthetic area, growing attention has been played to soft tissues. The introduction of volumetric analyses into clinical research allows for detailed evaluation of soft tissue vertical and horizontal changes that occur after immediate implant placement. Hence, a combination of hard tissue, soft tissue grafting and immediate provisionalization has been proposed recently.

Sanz-Martin *et al*. (2019) observed a mean 0.67 (SD 0.65) linear horizontal soft tissue reduction compared with baseline, after flapless immediate implant placement in combination with a buccally inserted xenogeneic bovine bone graft, a xenogeneic porcine collagen matrix, and immediate provisionalization (Fig. 41.7). Similarly, Van Nimwegen *et al*. (2018) observed a 0.68 mm (SD 0.59) linear horizontal reduction after flapless immediate implant placement in combination with a mixture of autologous bone and a xenogeneic bovine bone graft, a buccally inserted connective tissue graft, and immediate provisionalization. However, results from these combinations of treatment lack long-term follow-up data and definite conclusions cannot be drawn.

When evaluating survival and success rates, a systematic review estimated the prevalence of biologic, technical, and esthetic complications, and the magnitude of soft and hard tissue changes following implant placement immediately into fresh extraction sockets (Lang *et al*. 2012). On the basis of 46 included clinical trials, the 2-year survival rate of implants placed into extraction sockets was 98.4% (97.3–99%). Unfortunately, only limited long-term data were available for the occurrence of biologic complications. In terms of esthetic results, it was reported that about 20% of patients who underwent immediate implant placement suffered from suboptimal aesthetic outcomes due to buccal soft tissue dehiscence in studies with observation periods of 3 years or more. Important risk factors for unpredictable esthetic outcomes were the limited thickness of the buccal bone plate, thin gingival phenotype, and buccal positioning of the implant.

However, it must be taken into consideration that, although high survival rates for type 1 immediate implants have been reported in the literature, results from a recent systematic review and meta-analysis demonstrated higher early implant loss (94.9 % vs 98.9 %) compared with delayed implant placement, whereas similar outcomes were observed for marginal bone levels, probing pocket depths, and pink aesthetic scores (Cosyn et al. 2019).

To overcome some of these surgical/clinical limitations, the type 2 or early implant placement protocol has been advocated. This surgical protocol consists of performing the extraction and thoroughly cleaning the extraction socket, then waiting 4–6 weeks before placing the implant, which allows for soft tissue coverage and full healing of the extraction wound. The rationale for this surgical approach lies in the elimination of any infectious tissue, mostly in situations where the reason for the extraction was periapical or very deep periodontal pathology, and at the same time having enough soft tissue to allow

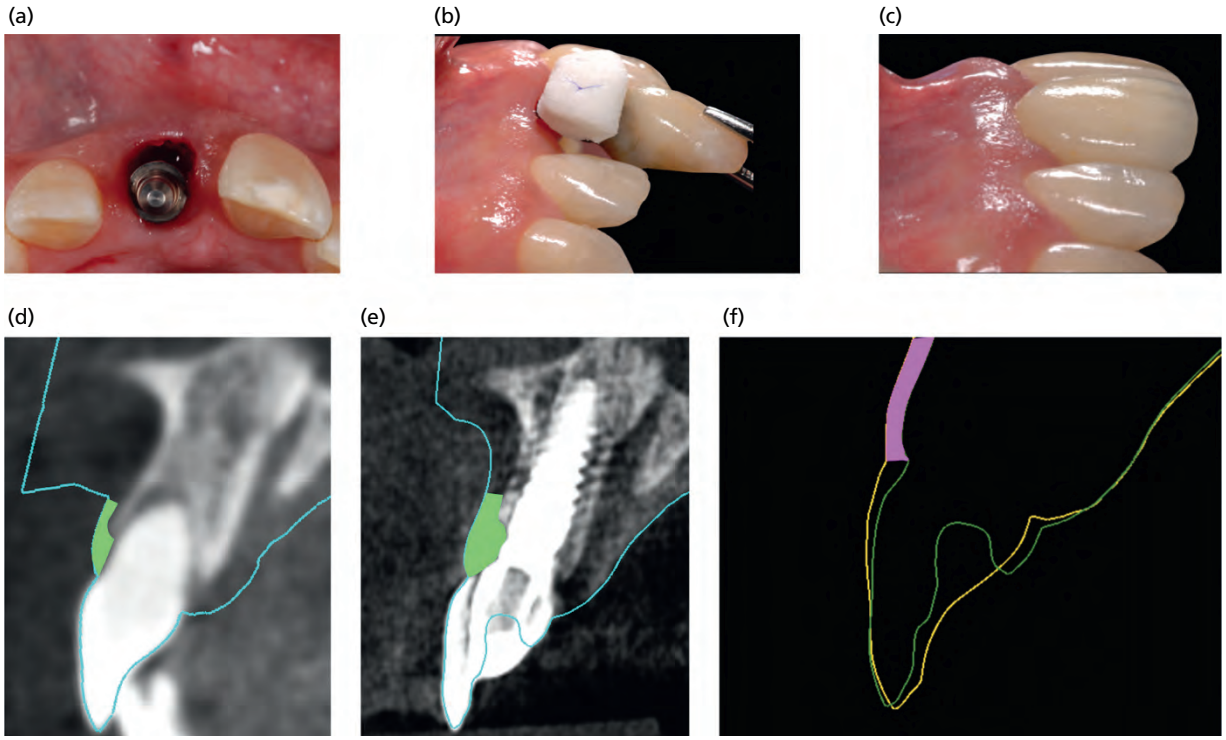

Fig. 41-7 (a) Immediate implant placement with a xenogeneic deproteinized bovine bone mineral. (b) Dimensions of the collagen matrix that is folded to increase its thickness. (c) Buccal view 6 months after surgery. (d, e) Baseline DICOM and STL files superimposed allowing for the evaluation of baseline soft tissue thickness (green area). An increase in soft tissue thickness may be appreciated between baseline and 6 months. for primary intention healing during the implant therapy through a tension-free flap closure without altering the mucogingival line. This is particularly important because, in many clinical situations, the cause of extraction is deep periodontal or periapical pathology where the availability of bone is limited, and bone augmentation will be required in conjunction with the implant placement. The importance of early implant placement lies in the availability of the socket walls architecture, facilitating the placement of the implant and the required bone augmentation. Moreover, the evidence for a usually very thin (<1 mm) maxillary buccal bone wall (Huynh-Ba *et al*. 2010; Januario *et al*. 2011) makes the requirement for bone augmentation almost the norm whenever implants are placed in critically esthetic areas in the anterior maxilla, in spite of having enough vertical bone availability. The type 2 implant placement protocol may be considered in this indication. Not only is the bone height and width of the ridge mostly preserved, but there is also enough keratinized mucosa to allow for a successful bone augmentation procedure during the implant placement (Buser *et al*. 2008).

The efficacy of this surgical protocol has been studied in a systematic review comparing it to the standard type 3 (implant placement at least 3 months after tooth extraction). This reported the pooled mean difference between the type 2 versus type 3 protocols to be a 13.11% reduction of defect bone height and a 19.85% of reduction of defect bone width in favor of the type 2 protocol (Sanz *et al*. 2012). In terms of esthetic outcomes, based on two studies (Schropp *et al*. 2004; Schropp & Isidor 2008), at 2-year follow-up, patients were significantly more satisfied with the early placement protocol, both in terms of the appearance of the restoration and the overall experience with treatment. These differences, however, were lost at the 5-year follow-up. Nevertheless, although it appears from the literature that this protocol shows good performance both short and long term (Graziani *et al*. 2019), it has to be kept in mind that the evidence on type 2 implants is restricted to a limited number of experienced surgeons and patients and thus it is unclear if these data may be generalized (Tonetti *et al*. 2019).

Horizontal ridge augmentation

Horizontal ridge augmentation can be performed simultaneously with implant placement (one-stage) or in a two-stage or delayed approach. The use of particulate or block grafts with or without barrier membranes have been widely used and documented in lateral augmentation procedures (Fig. 41-8).

As far as the bone width availability allows for an ideal implant three-dimensional position and adequate primary stability, usually in class I bone defects, a one-stage horizontal ridge augmentation procedure should be considered. The use of particulate bone grafts together with barrier membrane

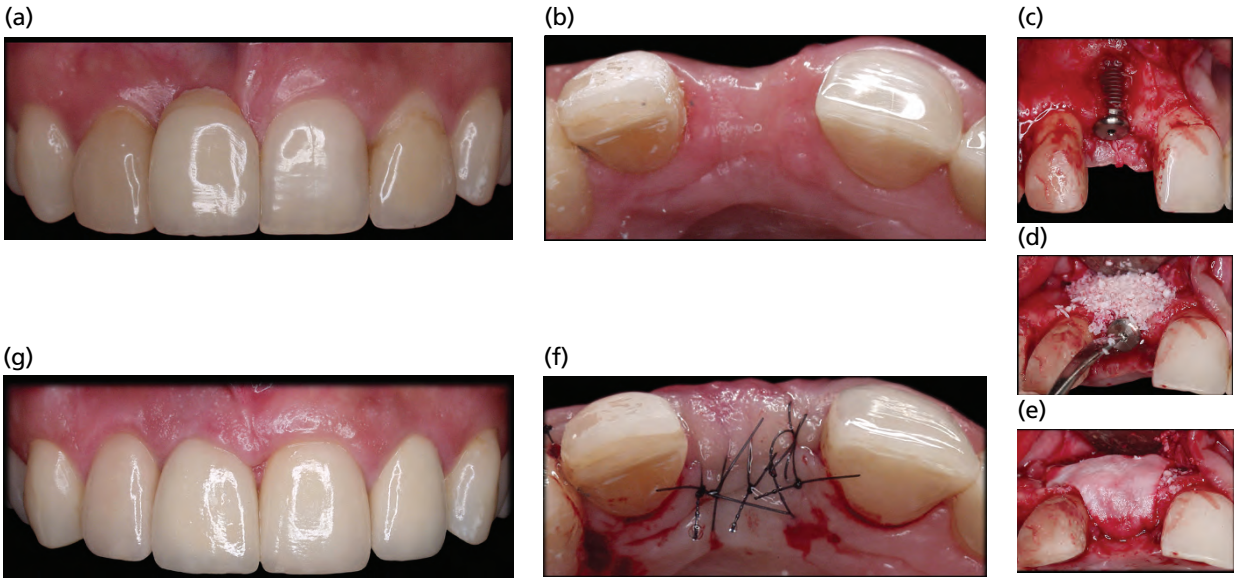

Fig. 41-8 (a, b) Class 2 defect (Seibert). (c–f) Implant placement and horizontal guided bone regeneration procedure with deproteinized bovine bone mineral + non-cross-linked collagen membrane. (g) Implant-supported prosthesis.

using the GBR principles is especially indicated in these types of clinical situations, being a well-established treatment modality. The efficacy of the procedure and the influence of various biomaterials on the outcomes have been recently investigated in a systematic review (Thoma *et al*. 2019). The most widely documented method for simultaneous lateral augmentation was the combination of a collagen membrane and a particulated xenogeneic grafting material. The overall mean vertical resolution of the defect was 81.3% (range 56.4–97.1) with a mean residual defect height of 0.9 mm (range 0.2–2.2) at re-entry. In terms of biomaterials, all barriers and biomaterial combinations yielded various degrees of defect resolution. Nevertheless, the bone augmentation was higher when a barrier membrane was used to cover the biomaterial (Thoma et al. 2019).

On the other hand, in severe class I defects, a delayed or staged ridge augmentation procedure is indicated. A block graft or a particulate bone graft in combination with a barrier membrane should be advocated to assure enough space maintenance to allow significant lateral augmentation. Both treatment strategies have been demonstrated to be successful and predictable treatment modalities to augment a horizontally deficient ridge and allow implant placement (Figs. 41-8, 41-9) (Fiorellini & Nevins 2003; Schwartz-Arad & Levin 2005; Schwartz-Arad *et al*. 2005; Sanz-Sanchez et al. 2015). Different authors have published several case series utilizing bone grafts for horizontal bone augmentation and have concluded that it is a reliable procedure. In 15 partially edentulous patients, 18 alveolar ridges were augmented with ramus or symphysis block grafts. The mean horizontal ridge augmentation was 6.5 ± 0.33 mm. At implant placement surgery, the graft had resorbed to 5.0 ± 0.23 mm, which is a reduction of 23.5%, but it was still sufficient for implant placement (Cordaro *et al*. 2002). Raghoebar *et al*. (2000) performed horizontal ridge augmentation on the edentulous mandibles of seven patients using autogenous block grafts. The bone width increased from 1.3 ± 0.3 mm to 5.6 ± 0.6 mm. Although after 3 months of healing, at implant placement, there had been a slight resorption of the bone width by 0.5 ± 0.3 mm, it was still sufficient for implant placement. In a controlled clinical study, 30 patients with inadequate bone width were assigned to two different groups: (1) GBR + e-PTFE + autograft and (2) autogenous onlay grafts only: 2.7 mm of horizontal bone gain was attained in the GBR group compared with 4.0 mm in the onlay graft group. The authors also found that the graft resorption was greater in the GBR group compared with the block graft group (40% vs 25%) (Chiapasco *et al*. 1999).

The use of autografts is currently somewhat limited due to the morbidity associated with their harvesting and their high resorption rate (mainly when used as bone chips). A recent systematic review reported an age dependent graft resorption. The authors indicated, based on the meta-analysis, that every additional year of age at the time of primary augmentation led to 0.05 mm more resorption of the augmented bone (Naenni *et al*. 2019). The use of bone substitutes, mainly of xenogeneic origin, together with resorbable membranes (collagen), has demonstrated good results in two-stage delayed horizontal bone augmentation techniques with minimal patient morbidity and few postoperative complications. Moreover, these xenogeneic grafts have a very slow resorption rate, which assure their long-term stability. A systematic review on the effectiveness of lateral bone augmentations indicated that the most frequently investigated therapy was the autologous block alone (Sanz-Sanchez *et al*. 2015). Results from the meta-analysis indicated that

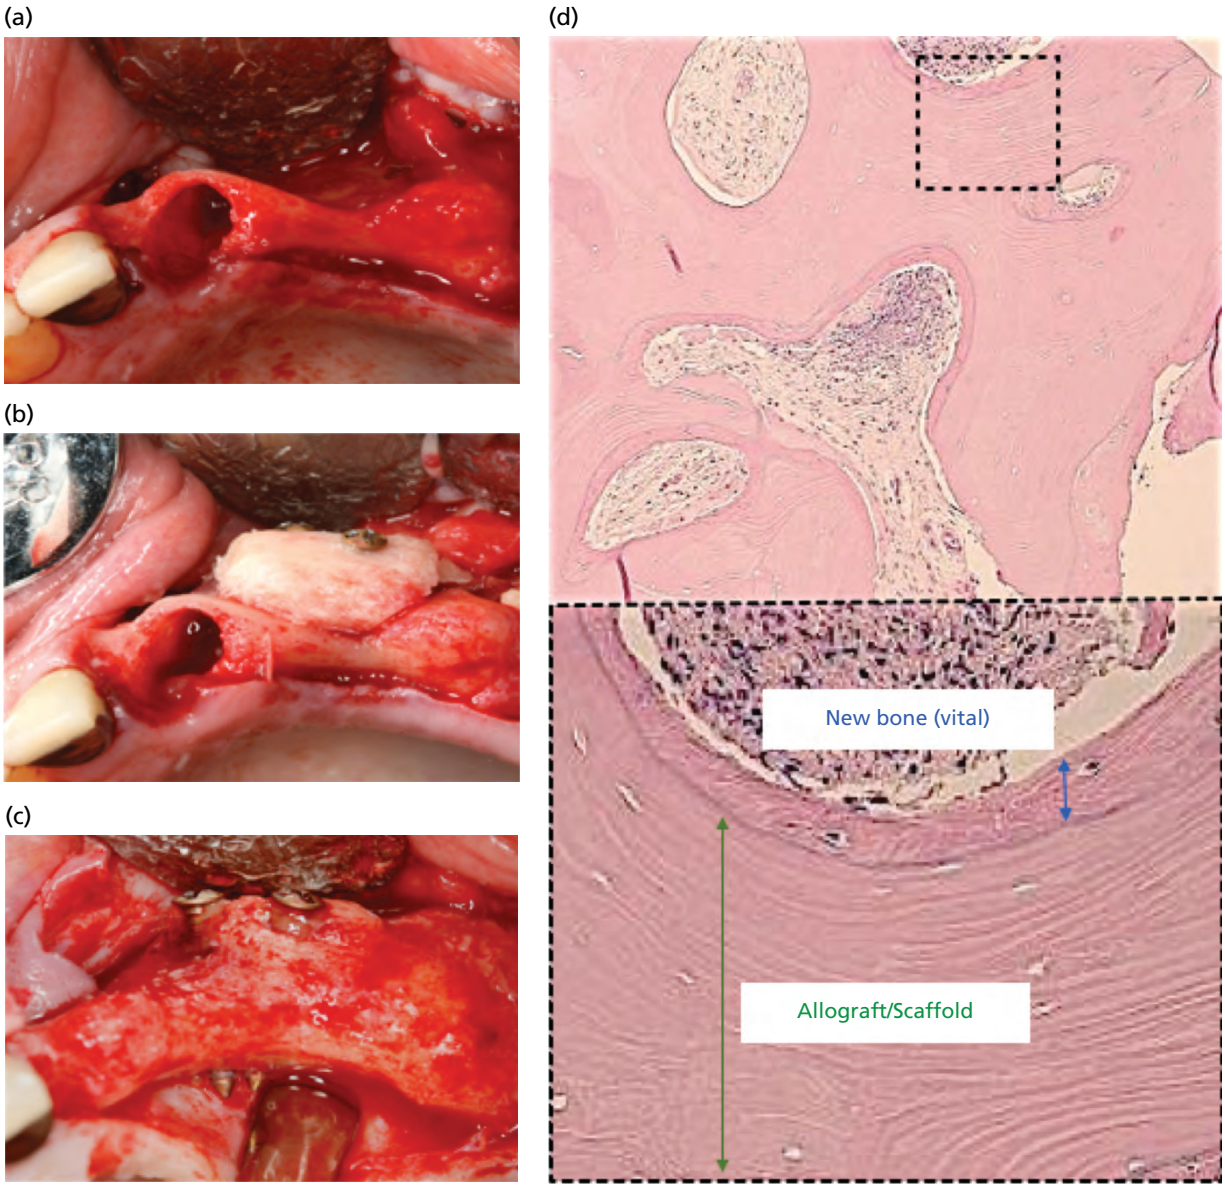

Fig. 41-9 (a, b) Use of an allograft block in the posterior maxilla. (c) Re-entry after 6 months. (d) Histologic evaluation of the regenerated bone shows significant osteoconductivity and incorporation of the allograft block particles with new/vital bone. Use of block grafts to overcome severe horizontal ridge deficiencies have proven very predictable.

the weighted mean gain for all studies on staged lateral augmentation was 3.90 mm (95% CI, 3.53, 4.28). The maximum bone width gain was reported for the combination of particulated xenograft plus autologous bone in combination with a resorbable membrane (5.68 mm; 95% CI, 5.00, 6.35), whereas the minimum was for the combination of particulated synthetic graft plus non-resorbable membrane (1.10; 95% CI, -0.33, 2.53).

According to Donos *et al*. (2008), the implant survival rate for staged GBR was 99–100%, while that for one-stage ridge augmentation was 87–95%, but this systematic review was hindered by a lack of randomized clinical controlled trials and heterogeneity of the available studies, thus restricting the number of studies included in the systematic review. These results are consistent with Sanz-Sanchez *et al*. (2015) who reported a mean high survival rate of 97.82% with a range in between 78.2% and 100%.

Ridge splitting/expansion

Another technique used in the maxilla to augment bone width through bone condensation is ridge splitting or ridge expansion osteotomy. Summers (1994a, b) first used this technique, osteocondensation, to augment bone width and elevate sinus floors in an attempt to avoid the lateral window sinus lift. This technique is preferably used in the maxilla because this bone is frequently type III or IV, which is more amendable to osteocondensation compared with type I or II bone. Chisels and osteotomes are used to produce longitudinal greenstick fractures in the bone and create osteotomy sites without the need for drilling. This preserves the compromised bone volume. The bone is compressed to the lateral surfaces with the use of osteotomes of increasing diameters, thus increasing its strength and density. The advantage of this technique is that it allows for the ideal

implant diameter to be placed in the restoratively driven position. In addition, the cancellous bone and marrow are exposed to grafting of the site, which improves revascularization and healing (Engelke *et al*. 1997). Summers (1994b) proposed the use of this technique if the alveolar bone is at least 3 mm wide on the basis of the assumption that this is the minimum width for cancellous bone found between the cortical plates. However, in a more recent study on cadavers, Katranji *et al*. (2007) found that the buccal plates in the edentulous maxilla and mandible had a mean cortical thickness of 1.0–2.1 mm. Therefore, it may be prudent to use this technique when the horizontal ridge width is 4–5 mm as at this width there is some cancellous bone between the cortical plates. This procedure is accompanied by simultaneous implant placement.

Ridge splitting and/or expansion are frequently described together because of their common treatment outcome: increase in horizontal bone width. Ridge splitting is essentially the fracture of the buccal cortical plate and its displacement laterally to accommodate implant placement. The spaces created between the cortical plates and the implants are subsequently filled with particulate bone graft materials (Scipioni *et al*. 1994; Engelke *et al*. 1997). Ridge expansion involves the creation of an osteotomy site with the initial implant drill and expansion of the site with osteotomes or the implant fixture. According to Chiapasco *et al*. (2006) and Kolerman *et al*. (2014), the reported bone widths gains were 3.5 mm (SD 0.93) and 3.9 mm (SD 0.8), respectively. In terms of implant survival rates, according to Donos *et al*. (2008), the implant survival rate ranged from 86.2% to 100%, while the success rate for the split osteotomy in achieving adequate ridge width for implant placement ranged from 87.5% to 97.8%.

Vertical ridge augmentation

In general, there is a lack of randomized controlled clinical trials evaluating the efficacy of these surgical techniques. Moreover, the available studies are very heterogeneous with relatively small sample sizes, which limits the ability to draw valid conclusions. From the limited information available, it appears that vertical augmentation is a highly technique-sensitive procedure which may give successful treatment outcomes, such as adequate gain in vertical bone height and successful implant placement (Fig. 41-10). Three treatment modalities have been proposed to treat vertical bone defects: GBR, onlay bone blocks, or distraction osteogenesis.

There are several published case series demonstrating the possibility of attaining a significant vertical bone augmentation, but also highlighting the technical difficulties and the high number of postoperative complications of this technique. In a small clinical study, six partially edentulous patients were recruited. Fourteen implants were placed, leaving the

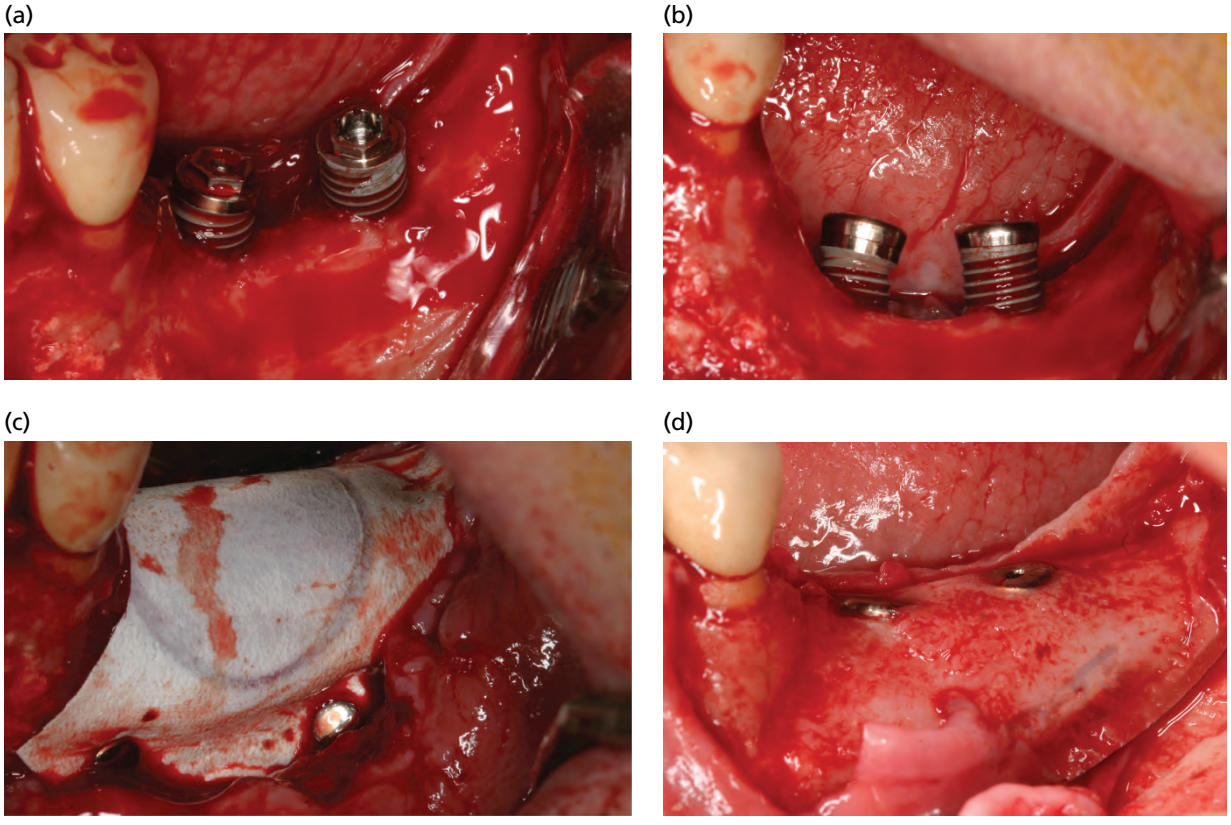

Fig. 41-10 (a–c) Class 3 defect (Seibert). Implant placement and vertical guided bone regeneration with an ePTFE membrane and autologous bone. (d) Re-entry surgery at 12 months. (Source: Courtesy of S. Morante.)

coronal third exposed circumferentially. Autogenous particulated bone grafts covered with titanium-reinforced e-PFTE membranes were used to cover the implants and the flaps were raised to allow for a submerged healing. An average of 4.95 mm of bone height was gained after 12 months in areas where the membranes were not exposed (Tinti *et al*. 1996). In a similar study, Simion *et al*. (1994) placed implants protruding 4–7 mm above the bone crest in five patients. e-PTFE membranes were used to cover the exposed implant threads. At 9 months, the histologic assessment showed bone formation up to 3–4 mm above the previous bone crest and the implant fixture was osseointegrated with the new bone. Most recently, a new titanium-reinforced non-resorbable membrane (high-density polytetrafluoroethylene), in combination with a mixture of anorganic bovine bone-derived mineral (ABBM) and autogenous particulated bone, was tested and used in vertical augmentation of deficient alveolar ridges, demonstrating successful results in terms of bone gain (Urban *et al*. 2014).

Onlay autologous bone blocks harvested from the chin or the mandibular retromolar area have been utilized for vertical ridge augmentation. Most recently, the split bone block technique has been introduced as a modification of the monocortical block autograft (Khoury & Hanser 2019) with the aim of accelerating bone regeneration and reducing graft resorption. The technique involves splitting the bone block into two bone laminae, which must then be reduced to a thickness of 1 mm each with a bone scraper. Once stabilized, the gap is filled with the autologous bone chips. In a case series with 146 treated patients, the authors demonstrated a mean vertical gain of 7.6 mm (SD 3.4). Similar results have been published by de Stavola and Tunkel (2013). In a 10 patient case series, the authors demonstrated a mean vertical gain of 6.50 mm (SD 1.43) with minimal bone graft resorption.

Distraction osteogenesis was initially used in orthopedics, and more recently adapted to augment deficient edentulous ridges. The technique involves three stages: (1) latency, (2) distraction, and (3) consolidation (Cano *et al*. 2006) (Fig. 41-11). In the latency phase, once the osteotomy has been performed, undisturbed healing takes place over 1 week. This is followed by the activation of the distractor, which is placed into the prepared site during surgery, with a daily controlled force that aims to separate the bone segments at a rate of 0.5–1 mm/day. Distraction is usually performed over a period of 30 days and significant bone gain can be attained (4–7 mm) (Gaggl *et al*. 2000). In the consolidation phase, a callus forms in the space between the bone segments and subsequently remodels into mature bone. This technique has the advantage of not requiring a donor site and the significant bone gain obtained can be in the vertical, horizontal, or both directions. However, distraction osteogenesis has frequent complications, sometimes of a severe nature, such as fracture of the mandible or the moveable segment. Increased patient discomfort during the activation of the device and the incorrect direction of the distractor leading to excessive bone on the lingual side are also frequent complications; the latter leads to inadequate bone formation (Saulacic *et al*. 2009).

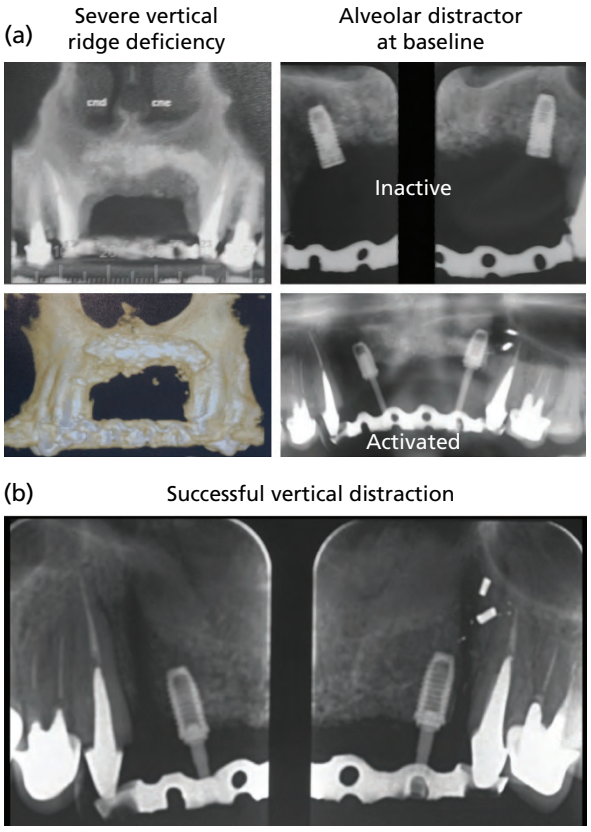

Fig. 41-11 Distraction osteogenesis. Stabilization of the ridge using a unidirectional vector distractor and successful vertical ridge compensation in the anterior maxilla. (Source: Courtesy of T. Valcanaia.)

According to a recent systematic review and meta-analysis (Urban *et al*. 2019), the most frequently investigated treatment modality was GBR. The weighted mean clinical vertical bone gain for all included studies was 4.16 (95% CI: 3.72–4.61 mm). Nevertheless, the clinical vertical bone gain varied among the different procedures. The weighted mean gains were 8.04 mm, 4.18 mm, and 3.46 mm for distraction osteogenesis (three studies), GBR (20 studies), and bone blocks (12 studies), respectively. The weighted mean complication rate was of 16.9% (95% CI: 12.5–21). This result is consistent with another systematic review (Rocchietta *et al*. 2008) that reported a broad range of technique-related complications. For GBR, the reported complication rates were 0–45.5% and complications were mainly related to membrane exposure. For distraction osteogenesis, complication rates were higher (10–75.7%), and complications included fractures or infection of the distractor, neurologic alterations, fractures of the distracted or basal bone, and lingual or palatal inclination of the distracted bone. Minor complications were reported after onlay block bone grafting and these were related to the morbidity from harvesting the block and graft shrinkage.

Taking into consideration the difficulties in performing these techniques, the common complications, and the heterogeneity and lack of quality of the available scientific evidence, their use should not be generalized, but rather limited to very experienced operators (Jepsen *et al*. 2019).

Emerging technologies

Growth factors

Tissue regeneration currently requires three main components: cells, scaffolds (matrices), and signaling molecules such as growth factors. Each of these components, together with sufficient vascularization, wound stability, and time, play an important role in regeneration. The introduction of growth factors has launched a new era in wound healing, and periodontal and bone regeneration in medicine and dentistry (Pilipchuk *et al*. 2018; Vaquette *et al*. 2018). The rationale behind the use of these natural biological mediators is to regulate crucial cellular events involved in tissue repair, including DNA synthesis, cell replication, chemotaxis, differentiation, matrix synthesis, and tissue vascularization (Larsson *et al*. 2016; Giannobile *et al*. 2019). Wound healing approaches using growth factors to increase bone volume have significantly advanced the fields of oral regenerative medicine reconstructive procedures. A major focus of oral regenerative research has been the impact of tissue growth factors on bone and tissue regeneration (Giannobile 1996; Anusaksathien & Giannobile 2002; Nakashima & Reddi 2003; Raja *et al*. 2009; Kaigler *et al*. 2011). Advances in molecular cloning have made available unlimited quantities of recombinant growth factors for applications in tissue engineering in the oral cavity. Recombinant growth factors known to promote skin and bone wound healing, such as PDGF (Rutherford *et al*. 1992; Giannobile *et al*. 1994; Camelo *et al*. 2003; Ojima *et al*. 2003; Nevins *et al*. 2005; Judith *et al*. 2010), IGF (Lynch *et al*. 1991; Giannobile *et al*. 1994, 1996; Howell *et al*. 1997), FGF (Murakami *et al*. 2003; Cochran *et al*. 2016; Aoki *et al*. 2021), and BMP (Sigurdsson *et al*. 1995; Giannobile *et al*. 1998; Wikesjo *et al*. 2004; Huang *et al*. 2005, Avila-Ortiz *et al*. 2016), have been used in preclinical and clinical trials for the treatment of large ridge and alveolar deficiencies (Jung *et al*. 2003; Fiorellini *et al*. 2005; Nevins *et al*. 2005; Nevins *et al*. 2013). Currently, there are two recombinant proteins clinically used to enhance and promote edentulous ridge augmentation and extraction socket healing, BMP-2 and PDGF-BB (Avila-Ortiz *et al*. 2016; Tavelli *et al*. 2020). Examples of studies using growth factors for regenerative approaches in teeth, implants, and alveolar ridge augmentation are shown in Table 41-1.

Biologic and clinical effects of PDGF for ridge augmentation

PDGF is a member of a multifunctional polypeptide family that binds to two cell membrane tyrosine kinase receptors (PDGF-Rα and PDGF-Rβ) and subsequently exerts its biologic effects on cell proliferation, migration, extracellular matrix synthesis, and antiapoptosis (Heldin *et al*. 1989; Rosenkranz & Kazlauskas 1999). PDGF-α and -β receptors are expressed in regenerating periodontal soft and hard tissues (Parkar *et al*. 2001). In addition, PDGF initiates cell chemotaxis (Nishimura & Terranova 1996), mitogenesis (Oates *et al*. 1993), matrix synthesis (Haase *et al*. 1998), and attachment (Zaman *et al*. 1999). More importantly, *in vivo;* application of PDGF alone or in combination with (IGF-1 enhances mineralized tissue repair (Lynch *et al*. 1991; Rutherford *et al*. 1992; Giannobile *et al*. 1996). PDGF has been shown to have a significant regenerative impact on periodontal ligament cells as well as on osteoblasts (Matsuda *et al*. 1992; Oates *et al*. 1993; Marcopoulou *et al*. 2003; Ojima *et al*. 2003). Based on the available data from 63 human clinical studies as reported by Tavelli *et al*. (2020), the following conclusions can be drawn: (1) the utilization of rhPDGF is safe when used in combination with a variety of bone matrices, including allografts, xenografts, or alloplasts for GBR and alveolar ridge preservation; (2) the outcomes are consistent for PDGF for GBR and sinus augmentation procedures: this evidence is based on randomized controlled trials, and also case reports and case series; (3) the outcomes are also positive for PDGF for alveolar ridge preservation using histologic outcomes for vital bone and future randomized clinical trials should focus on the effects of PDGF in alveolar ridge preservation, GBR, and sinus floor augmentation procedures. Moreover, it is important to determine whether GBR with PDGF can be used with or without a barrier because the material may reduce the chemotactic potential of the growth factor.

Biological and clinical effects of BMPs for ridge augmentation

BMPs are multifunctional polypeptides belonging to the TGF-β superfamily of proteins (Wozney *et al*. 1988). The human genome encodes at least 20 BMP (Reddi 1998). BMPs bind to type I and II receptors that function as serine–threonine kinases. The type I receptor protein kinase phosphorylates intracellular signaling substrates called Smads (*Sma* gene in *Caenorhabditis elegans* and *Mad* gene in *Drosophila*). The phosphorylated BMP-signaling Smads enter the nucleus and initiate the production of other bone-related matrix proteins, leading to bone morphogenesis. The most remarkable feature of BMPs is their ability to induce ectopic bone formation (Urist 1965). BMPs are not only powerful regulators of cartilage and bone formation during embryonic development and regeneration in postnatal life, but also participate in the development and repair of other organs such as the brain, kidney, and nerves (Reddi 2001).

Studies have demonstrated the expression of BMP during tooth development and periodontal repair, including alveolar bone (Aberg *et al*. 1997; Amar *et al*. 1997). Investigations in animal models have shown the potential repair of alveolar bony defects using rhBMP-12 (Wikesjo *et al*. 2004) or rhBMP-2 (Lutolf *et al*. 2003; Wikesjo *et al*. 2003). In a clinical trial, rhBMP-2 delivered by a bioresorbable collagen sponge revealed significant bone formation in a human buccal wall defect model following tooth extraction when compared with the collagen sponge alone (Fiorellini *et al*. 2005). Furthermore, BMP-7, also known as osteogenic protein-1, has demonstrated the ability to stimulate bone regeneration around teeth, around endosseous dental implants, and in maxillary sinus floor augmentation procedures (Rutherford *et al*. 1992; Giannobile *et al*. 1998; van den Bergh *et al*. 2000).

In published randomized clinical trials on ridge augmentation procedures, most studies favored the use of rhBMP-2 (Lin *et al*. 2016). Augmentation of extraction sockets with severe dehiscence was also included in the systematic review and it was demonstrated that BMP can assist in regenerating lost buccal bone for ridge augmentation. Between 3 and 6 months of follow-up, all studies used computed tomography (CT) to measure the clinical outcome in terms of bone height and alveolar ridge width.

In summary, clinical applications of rhBMP-2 on dental implant therapy-related bone augmentation procedures, including extraction socket grafting and alveolar ridge augmentation, are promising. Surface modification of dental implants to release BMP-2, enhanced delivery, or immobilization methods, are still under preclinical development (Haimov *et al*. 2017). Numerous randomized controlled clinical trials have proven that rhBMP-2 applications for ridge preservation or augmentation for implant therapy are effective and promising (Jung *et al*. 2003; Fiorellini *et al*. 2005).

Cell therapy

Cells are central to new tissue growth and differentiation. Cell-based therapy is a specific branch of tissue engineering in which a defined population of cells is transplanted into a defect site to promote accelerated and enhanced wound healing in that area (Moreno-Sancho *et al*. 2019). Cell delivery approaches are used to accelerate edentulous ridge regeneration through two primary mechanisms: (1) use of cells as carriers to deliver growth factors that promote tissue regeneration to host cells; and (2) provision of cells that are able to differentiate into multiple cell types directly involved in the regenerative response. For successful regenerative outcomes, this population of cells must integrate into the host tissues. Such therapies

can involve a wide variety of cell types, including somatic cells and stem cells. Due to the inherent challenges in reconstruction of large bone defects, identification and characterization of the cell populations being used is essential to clinical grafting success.

Stem cell research has soared in the past few years and the effects of these cells on healing and regenerative potential have been extensively studied. Cell therapy approaches involving mesenchymal stem cells (MSCs) are emerging as a potentially viable therapeutic modality undergoing preclinical and clinical investigation. MSCs are self-renewing cell populations originally identified in the bone marrow (Friedenstein *et al*. 1978; Caplan *et al*. 1991). First described as non-hematopoietic precursor cells with fibroblast morphology, they were initially characterized by their clonogenicity but later demonstrated to exhibit *in vivo* bone-forming potential and multipotency, having the capacity for their differentiation to be driven toward osteogenic, chondrogenic, and adipogenic phenotypes (Krebsbach *et al*. 1997; Kuznetsov *et al*. 1997; Pittenger *et al*. 1999). In addition to bone marrow, it has more recently been recognized that MSCs can be isolated from a variety of other tissues including adipose, muscle, alveolar bone, and tooth-related tissues (i.e. dental pulp, gingiva, periodontal ligament) (Gronthos *et al*. 2000; Zuk *et al*. 2001; Miura *et al*. 2003; Seo *et al*. 2004; Zhang *et al*. 2012; Mason *et al*. 2014). MSCs have tremendous potential in periodontal and alveolar bone regenerative procedures owing to their multipotency and capability to form a variety of tissues. In addition to tissue differentiation, their trophic and immunomodulatory properties are being investigated as factors influencing their capacity for bone regeneration indirectly through promoting tissue neovascularization and modulating inflammation during surgical wound healing. In periodontal and alveolar bone tissue engineering, both extraoral and intraoral derived stem cells can be harvested and then subjected to enrichment and expansion techniques to exponentially increase their numbers for transplantation. Within this context, multiple sources of stem cells have been evaluated for the treatment and regeneration of the edentulous ridge (Huang *et al*. 2009). There is strong potential for the use of MSC sources from outside the oral cavity for transplantation to the oral and craniofacial complex (Ward *et al*. 2010; Polymeri *et al*. 2016).

Bone marrow stromal cells have also been shown to promote bone healing and dental implant osseointegration (Bueno & Glowacki 2009). In a series of studies, Yamada *et al*. (2004) used a combination of platelet-rich plasma as an autologous scaffold with *in vitro*-expanded bone marrow stromal cells to increase osteogenesis in dental implant surgery. This "autogenous injectable bone treatment" (Fig. 41-12) resulted in higher marginal bone levels, better bone–implant contact, and increased bone density compared with controls. Recently, cells harvested from the bone marrow were driven down MSC pathways via an automated single-pass perfusion process to promote bone regeneration in a number of different clinical situations including tooth extraction socket defects, sinus floor augmentation, and large horizontal and vertical defects secondary to trauma and congenital cleft deformities (Kaigler *et al*. 2010, 2013, 2015; Rajan *et al*. 2014; Bajestan *et al*. 2017).

Scaffolding matrices to deliver genes, proteins, and cells

Scaffolding matrices are used in tissue engineering to provide an environment where space is created and maintained over a period of time for cellular growth and tissue in-growth. These matrices serve as 3D template structures to physically support and facilitate periodontal tissue regeneration when combined with cell- or gene-based tissue engineering. Over the

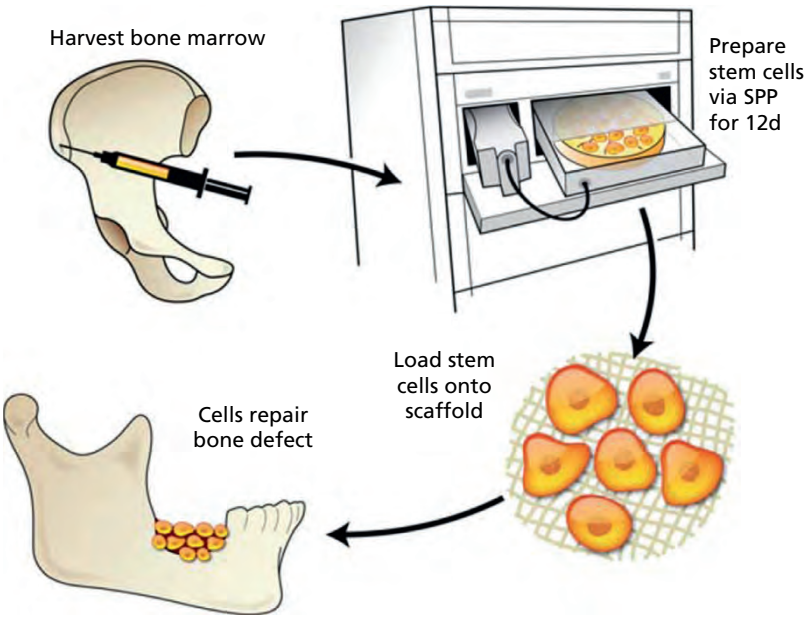

Fig. 41-12 Bone repair cell production. After harvest of bone marrow aspirates, cells are cultured using an automated, closed-system, single-pass perfusion (SPP) process. After 12 days of cell expansion in this bioreactor system, cells are packaged and delivered to the bone regenerative site on a biodegradable sponge. (Source: Kaigler *et al*. 2020.)

past two decades, scaffolds have been extensively developed, studied, and utilized. Regardless of the type and structure of the scaffold, there are a few key fundamental requirements of scaffold design that have served as the basis for scaffold development (Murphy & Mooney 1999). When applied to tissue engineering, scaffolds should: (1) provide a 3D architecture that supports a desired volume, shape, and mechanical strength; (2) have a high porosity and surface-to-volume ratio with a well-interconnected open pore structure to promote high seeding density and embrace bioactive molecules; (3) be biocompatible; and (4) degrade at a controlled rate and pattern that allows sufficient support until tissue defects are fully resolved.

Transplantation of cells for dental and craniofacial tissue engineering can be carried out via tissue-engineered scaffolds (Kaigler & Mooney 2001; Pagni *et al*. 2012) that provide adhesion and anchorage for interacting stem cells in order to control the presentation of adhesion sites, thereby improving cell survival and participation (Alsberg *et al*. 2003; Davis *et al*. 2005). Through similar cell therapy approaches, extensive reconstructions are becoming more predictable, as demonstrated by the regeneration of a mandible formed in a patient by using a metal and polymer scaffold seeded with stem cells and BMP (Warnke *et al*. 2004).

Bioactive molecules, such as growth factors, may also be encapsulated into nano-/micro-particles that are embedded in matrices to aid their sustained release, thereby enhancing stimuli for tissue formation. Other approaches using scaffolds include mimicking stem cell niches to regulate daughter cell proliferation, differentiation, and dispersion into surrounding tissue or attracting useful cells to a desired anatomic site (Discher *et al*. 2009).

Scaffold fabrication technologies as applied to periodontal tissue engineering include conventional prefabricated scaffolds, such as a particulated, solid form; injectable scaffolds that are adapted or administered into a periodontal defect; and novel image-based designs that result in a 3D-printed scaffold that is customized to fit into a defect.

Prefabricated scaffolding matrices

Personalized scaffolding technology utilizing 3D-imaging and 3D-printing has been very useful in the development of new prototype biomaterials for craniofacial reconstruction. Conventionally, dental and skeletal relationships are analyzed through wax-ups, 2D radiographs, photographs, and articulators, which is time consuming and cumbersome. In many complex cases, such as facial asymmetry, the analysis of skeletal movements using traditional 2D approaches is difficult (Janakiraman *et al*. 2015). In these cases, 3D-imaging builds a platform in which dental and skeletal features are documented accurately allowing a precise diagnostic system that increases the efficiency of treatment planning (Edwards 2010). Conventional scaffolds used to regenerate tissue *in vivo* are prefabricated, and many techniques have been described that produce both natural and synthetic polymeric scaffolds. Naturally derived scaffolds include autografts, allografts, and xenografts. Alloplasts and other polymers are synthetically engineered materials consisting of bioactive molecules that serve a similar purpose to natural scaffolds.

Naturally derived scaffolds

There are many naturally derived scaffolds used for tissue engineering applications. Freeze-dried bone allograft (FDBA) is a mineralized bone graft that has been suggested to promote osteoinductive and osteoconductive bone regeneration, although reports of its regenerative effectiveness have been mixed (Altiere *et al*. 1979; Dragoo & Kaldahl 1983; Goldberg & Stevenson 1987). Variability in preparations of the allograft, and its regenerative potential and osteoinductive ability, is seen between different bone banks (Shigeyama *et al*. 1995; Schwartz *et al*. 1996). Nonetheless, FDBA appears to be a practical material for regeneration of periodontal attachment apparatus. Xenogenic grafts show physical and chemical similarities to human bone matrix, and they have been successful in various periodontal and implant-related bone repair cell delivery applications (Nevins *et al*. 2006). Deproteinized bovine bone mineral has osteoconductive properties (Hämmerle *et al*. 1998).

Synthetic biomimetic polymer scaffolds

Synthetic polymers have been studied extensively as gene therapy delivery systems since it is easier to modify their properties, such as by controlling their macrostructure and degradation time, compared with naturally derived scaffolds (Jang *et al*. 2004). Furthermore, the release mechanism and exposure duration of bioactive molecules, such as growth factors, can be controlled (Ramseier *et al*. 2006). By acting as a localized gene depot, synthetic polymer scaffolds have the ability to maintain the therapeutic level of encoded proteins, which limits unwanted immune responses and potential side effects (Ghali *et al*. 2008).

Polymers such as the poly(lactic-co-glycolic acid) (PLGA) have drawn much attention for their excellent properties for encapsulation of genes (Mundargi *et al*. 2008). PLGA microspheres have been used to deliver antibiotics, as an occlusive membrane for GTR, as a growth factor carrier for periodontal regeneration, and for cementum and complex tooth structure engineering (Williams *et al*. 2001; Kurtis *et al*. 2002; Young *et al*. 2002; Jin *et al*. 2003; Cetiner *et al*. 2004; Moioli *et al*. 2006). However, while microsphere systems have demonstrated promising results, new microtechnology approaches today are focusing on nano-sized particles (Agarwal & Mallapragada 2008). Nanotechnology has been

attracting much attention for therapeutic agent and gene delivery and a number of studies and reviews have delineated its contribution and capability to meet challenges of current regeneration therapy (Agarwal & Mallapragada 2008; Mundargi *et al*. 2008; Sanvicens & Marco 2008).

The nanoscaled fibrillar structure of collagen shows promising effects on cellular biologic activities and suggests potential for a synthetic polymer scaffold that mimics the nanofibrous structure of collagen (Woo *et al*. 2007). Furthermore, a recent study has developed macroporous polymer scaffolds with varying pore wall architecture in order to enhance the environment for induction of cellular activity and provide guidance for 3D regeneration (Wei & Ma 2009). Therefore, a delivery scaffold can provide a suitable environment for targeted cells and tissues, as well as controlling the dynamic release of entrapped biologics. Periodontal therapy based on these systems, however, remains in its infancy.

The use of hyaluronic acid (HA) in the dental field has been demonstrated to restore periodontal defects and to carry and deliver growth factors such as BMP and FGF-2 (Wikesjo *et al*. 2003). An *in vitro* study has shown an HA and collagen (Col) combination scaffold to be a suitable environment for the growth of human periodontal ligament cells and therefore its potential in periodontal tissue engineering (Wang *et al*. 2009).

Inorganic calcium phosphate-based materials have also been used as delivery systems. Materials such as β-TCP are synthetic scaffolds that can be used to repair osseous defects around teeth or dental implants by acting as a bone substitute or as a carrier for growth factor delivery (Gille *et al*. 2002).

Hydrogels, formed by the cross-linking or self-assembly of a variety of natural or synthetic hydrophilic polymers to produce structures that contain >90% water, are obtained from natural materials such as collagen chitosan, dextran, alginate, or fibrin. They are favorable for tissue engineering due to their innate ability to interact with cells while undergoing controlled degradation (De Laporte & Shea 2007; Moioli *et al*. 2007; Agarwal & Mallapragada 2008). Vector release from hydrogels is dependent upon the physical structure and degradation of the hydrogel, and its interactions with the vector (De Laporte & Shea 2007).

Computer-based applications in scaffold design and fabrication

Computer-based and image-based scaffolding technology has been increasingly used in the alveolar ridge reconstruction for implant site development (Yu *et al*. 2019). 3D-printed diagnostic models and preoperative templates are widely applied for ridge augmentation in severe vertical and horizontal bony defects (Draenert *et al*. 2017; Al-Ardah *et al*. 2018). Despite the advanced applications of cone-beam computed tomography (CBCT) combined with computer aided design/manufacturing (CAD/CAM) fabrications, current 3D-printing for alveolar ridge augmentation is limited using printing templates, which might not directly induce bone regeneration as inert biomaterials. Considering its clinical potential in other specialties, future directions suggest applying 3D technology using osseoinductive and osseoconductive biomaterials will better enhance bone and tissue regeneration for vertical and horizontal ridge augmentation supporting implant placement.

In the rehabilitation of partially or fully edentulous patients with a lack of maxillary posterior bone support, sinus floor augmentation is required prior to dental implant placement. An anatomically sinus-specific block graft that can be fabricated via 3D technology for bone augmentation has recently been introduced in a clinical trial for lateral sinus augmentation (Mangano *et al*. 2013). Briefly, the scaffold manufacturing process applies a virtual plan and designs a custom-made scaffold. The 3D fabrication of the scaffold is performed using the CAM technique. The customized block graft is created from an original hydroxyapatite (HA) block using a cutting guide also made from 3D-image-based analysis and planning. The use of 3D-imaging and 3D-printing for fabrication of customized scaffolding technology to regenerate alveolar ridges is a rapidly growing research field. With continued advancement of novel 3D-imaging technologies, broader and more accurate clinical applications are anticipated combining printing with imaging to customized reconstructive scaffolds to repair large bone defects in the jaws (Yu *et al*. 2019). As bioprinting technology evolves to meet the scrupulous criteria that human tissues demand for their repair and regeneration, it can be expected that tissue engineering will become increasingly feasible and predictable. Continued development of precise and reproducible techniques will eventually facilitate translation into clinical practice.

Future perspectives

Tissue engineering is making an important impact on alveolar bone regeneration therapy. The use of cell and gene therapy to enhance and direct periodontal wound repair into a more predictable regenerative path is being exploited in bioengineering efforts aimed at developing a therapeutic system to promote bone repair (Yu *et al*. 2019). Various novel delivery scaffolding systems are being extensively studied and fabricated, and are demonstrating capabilities to meet the challenges of current regeneration therapy. However, numerous challenges remain. A major obstacle is how to maximize the utility of cells/genes delivered to a passive or permissive environment where there is context for the type of cell needed, but in which very few biologic signals are given to encourage normal cell function (Polymeri *et al*. 2016).

Other obstacles, such as identifying cell sources and clinically relevant cell numbers, the integration of new cells into existing tissue matrices, and the achievement of functional properties of tissue equivalents using an expanded repertoire of biomaterials, also need to be confronted in the field of tissue engineering. Practical and regulatory requirements will also need to be met before the technologies of cell and gene transfer can be applied in the clinical arena.

Collectively, the cell-based, scaffold, and gene therapy methods interface and complement each other to enhance the potential to restore tissue function and structure in a predictable manner (Figs. 41-13, 41-14, 41-15). It is expected that in the future that there will be greater usage of bioactive molecules such as growth factors or bone anabolic agents to accelerate and enhance the healing potential of the defects, bringing about faster, easier, and predictable treatment outcomes. The success and the future of alveolar bone regenerative medicine will need to be supported by the understanding of and the ability to recognize clinical scenarios that will benefit from one or an integration of these new emerging technologies for both horizontal and vertical ridge reconstruction.

Conclusion

In general, ridge augmentation procedures have become increasingly predictable. The correct selection and application of the available techniques and biomaterials are key determinants of implant survival/success rates. Currently, research in the field of advanced bone grafting is directed at overcoming the technical and biologic limitations that continue to challenge implant dentistry. The use of novel scaffolding biomaterials, bioactive molecules, and advanced surgical techniques offers potential in the creation of increased bone volume and predictability in the treatment of challenging bone defects. Only through further research and development in the area of scaffold fabrication, along with cell-based and gene therapy, can tissue engineering continue to advance.

Acknowledgments

The authors thank Dr. Hector Rios for valuable contributions to this chapter. The authors appreciate the assistance of Mr. Chris Jung with the figures.

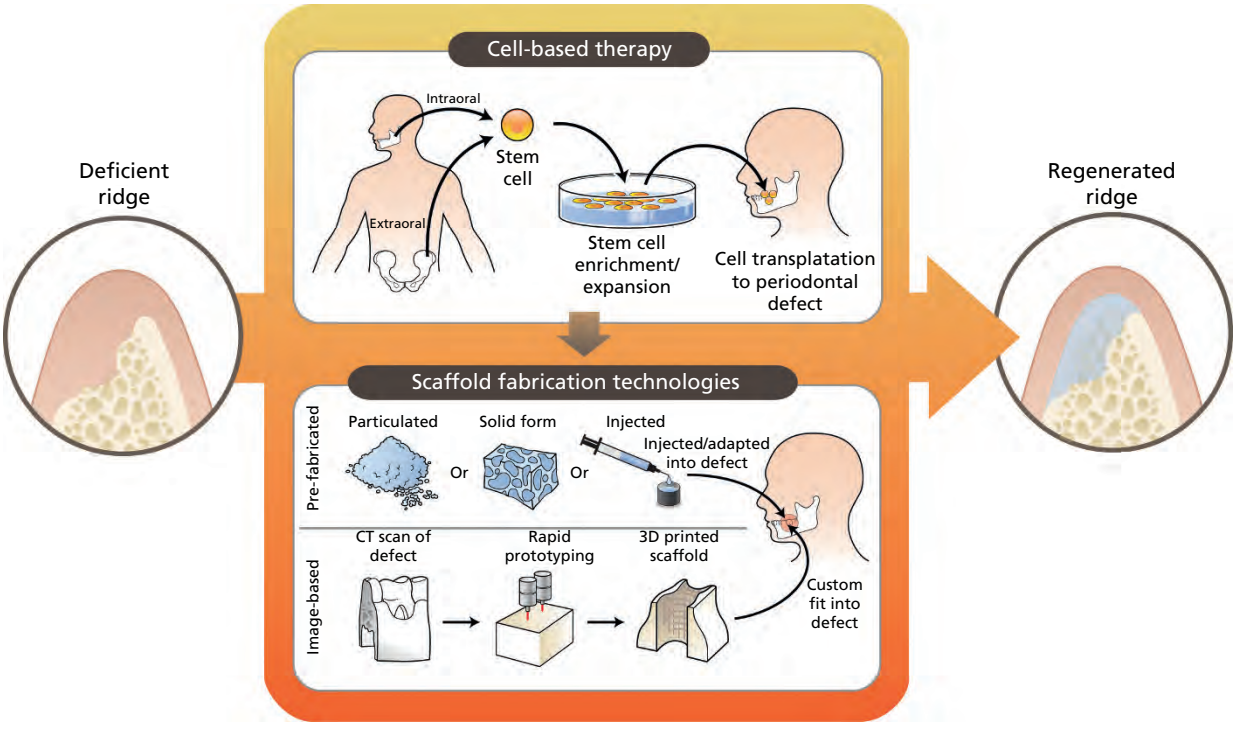

Fig. 41-13 New emerging technology for the treatment of edentulous ridge deficiencies. Research advances enable the integration of cell therapy and novel scaffold fabrication technologies. This promising modality could enhance predictable rapid tissue regeneration and ultimately the outcome of implant therapy. Extraoral and intraoral stem cells represent a viable and accessible source from which to harvest and expand multipotent colonies. Adequate cell density could be reached *in vitro* in a controlled environment and made readily available. Prefabricated and image-based scaffolds are becoming an essential component in regenerative medicine. A defined supporting structure allows the localization and guidance of the appropriate cells and proteins, and the establishment of a mechanically competent environment.

Chapter 42

Maxillary Sinus Floor Augmentation

Gustavo Avila-Ortiz[1], Bjarni E. Pjetursson[2], and Niklaus P. Lang[3]

The maxillary sinus

The maxilla is an osseous structure of enormous relevance in the craniofacial complex. The maxilla is formed by two bilateral maxillary bones, which are fused at the midline by the intermaxillary suture (Fig. 42-1).

Each maxillary bone has one body and four processes. These are the alveolar, frontal, zygomatic, and palatine processes. The alveolar process is a crested basal extension that houses the maxillary teeth and gives its curved shape to the upper dental arch. The frontal process is an anterior projection of the maxillary body that articulates with the frontal bone and contains the lacrimal groove. The zygomatic process extends laterally from the body of the maxilla to articulate with the zygomatic bone. The palatine process is a horizontal bony plate that extends medially; it provides support to the soft tissues that line the hard palate and articulates with the more posteriorly located palatine bone. The maxillary sinus is a hollow cavity contained within the body of the maxillary bone (Fig. 42-2).

The maxillary sinus is one of the four paranasal sinuses, which also include the frontal, ethmoid, and sphenoid sinuses. The paranasal sinuses are air cavities lined with a pseudo-stratified ciliated columnar respiratory epithelium that covers a connective tissue layer (Fig. 42-3).

The stratum immediately beneath the epithelium is comprised of highly vascular, loose connective tissue. Underneath, a fibrous and irregular connective tissue layer, which is in intimate contact with the surrounding bony walls, may be observed (Insua *et al*. 2017). These three structures (epithelium, loose connective tissue, and dense connective tissue) are collectively referred to as the Schneiderian or sinus membrane (Fig. 42-4).

The physiologic functions of the paranasal sinuses have been the subject of debate, but may include lightening the total weight of the head for functional advantage, provide a buffer against trauma, humidify and heat the inhaled air (which contributes to olfaction), provide resonance to the voice (sinus cavities are usually more voluminous in males), assist in the regulation of intranasal pressure (e.g. in response to sudden height changes, such as those that occur when flying), secrete mucus, and immunological defense (Cappello & Dublin 2019; Watelet & Van Cauwenberge 1999).

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Fig. 42-2 Different spatial views of a left maxillary bone. (a) Medial (note the maxillary sinus cavity upon partial removal of the nasal wall). (b) Frontal. (c) Inferior. (d) Lateral. (e) Dorsal. (f) Superior.

The maxillary sinus, also known as antrum of Highmore, is the largest of all the paranasal sinuses (Fig. 42-5). According to a cadaveric study, the average volume of this cavity is 12.5 cc (Gosau *et al*. 2009), but its dimensions and architecture may vary widely from individual to individual (Fig. 42-6) depending on factors such as age, dentate status, and history of pathosis in the area (Lovasova *et al*. 2018; Rani *et al*. 2017; Velasco-Torres *et al*. 2017). Maxillary sinuses widely vary in shape and size, but typically have a morphological configuration that resembles a pyramid (Fig. 42-7).

The base of the pyramid is at the medial wall, facing the lateral nasal wall, and its apex points laterally towards the zygomatic arch. The boundaries of the maxillary sinus are six bony walls: anterior, posterior, superior, inferior, medial, and lateral. The anterior wall typically consists of thin, compact bone extending from the orbital rim to approximately the position of the apex of the maxillary canine. The posterior wall separates the sinus cavity from the temporal fossa, which is located in the pterygomaxillary region. The superior wall of the sinus corresponds to the orbital floor. The configuration of the inferior wall, or sinus floor, varies widely from sinus to sinus and is determined by the position of the apices of the posterior maxillary teeth and patterns of bone remodeling after tooth loss, if one or multiple teeth are missing. The medial wall rises in an apical direction from the palatal aspect of the alveolar process and forms part of the lateral bony wall of the nasal cavity. The lateral wall of the maxillary sinus is part of the lateral aspect of the posterior maxilla and the zygomatic process.

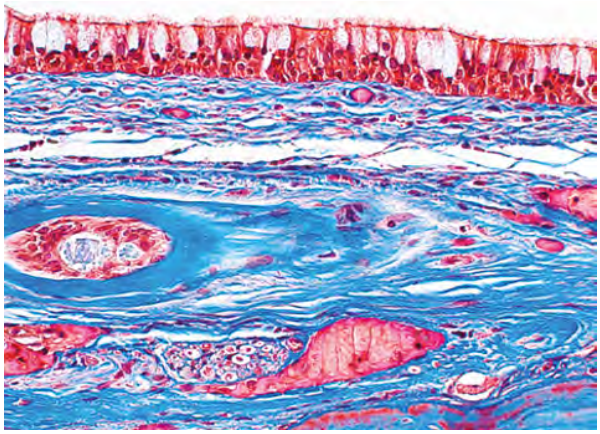

Fig. 42-3 High magnification histomicrophotograph illustrating the structural features of human pseudostratified ciliated columnar respiratory epithelium, predominantly stained in light red, and its relationship with the underlying connective tissue, which appears stained in blue (Masson's trichrome staining). (Source: Courtesy of Drs. Alberto Monje, Universitat Internacional de Catalunya, Barcelona, Spain and Ángel Insua, Private Practice, La Coruña, Spain.)

Each maxillary sinus has at least one non-physiologic drainage port, known as the maxillary ostium or maxillary hiatus, that is located on the medial wall and opens into the nasal cavity between the middle and lower nasal conchae (Fig. 42-8). Cadaveric studies have reported the occurrence of accessory ostia in approximately 20% of the specimens analyzed (Prasanna & Mamatha 2010; Yenigun *et al*. 2016).

The maxillary sinus produces mucus containing lysozymes and immunoglobulins, which have been linked to the defense against bacterial infections of the upper respiratory tract. Non-hemolytic and alpha-hemolytic *Streptococci* and *Neisseria* spp. are part of the normal commensal microbiota of the maxillary sinus. Diphtheroids, *Staphylococci*, *Hemophilus* spp., *Pneumococci*, *Mycoplasma* spp., and *Bacteroides* spp. may also be found in low amounts in health (Timmenga *et al*. 2003). The abundant vascularity of the Schneiderian membrane helps maintain a healthy status by allowing cellular and molecular diffusion to both the membrane and the sinus cavity. A healthy maxillary sinus is self-maintaining by postural drainage and the action of the ciliated epithelial lining, which propel fluids and microorganisms toward the ostium. The fact that the maxillary sinus opening to the nasal cavity is not in the lower part of the sinus, where a bone graft may be placed, is of high importance and provides an anatomic rationale for sinus floor augmentation, as the grafting procedure does not usually interfere with normal maxillary sinus functions.

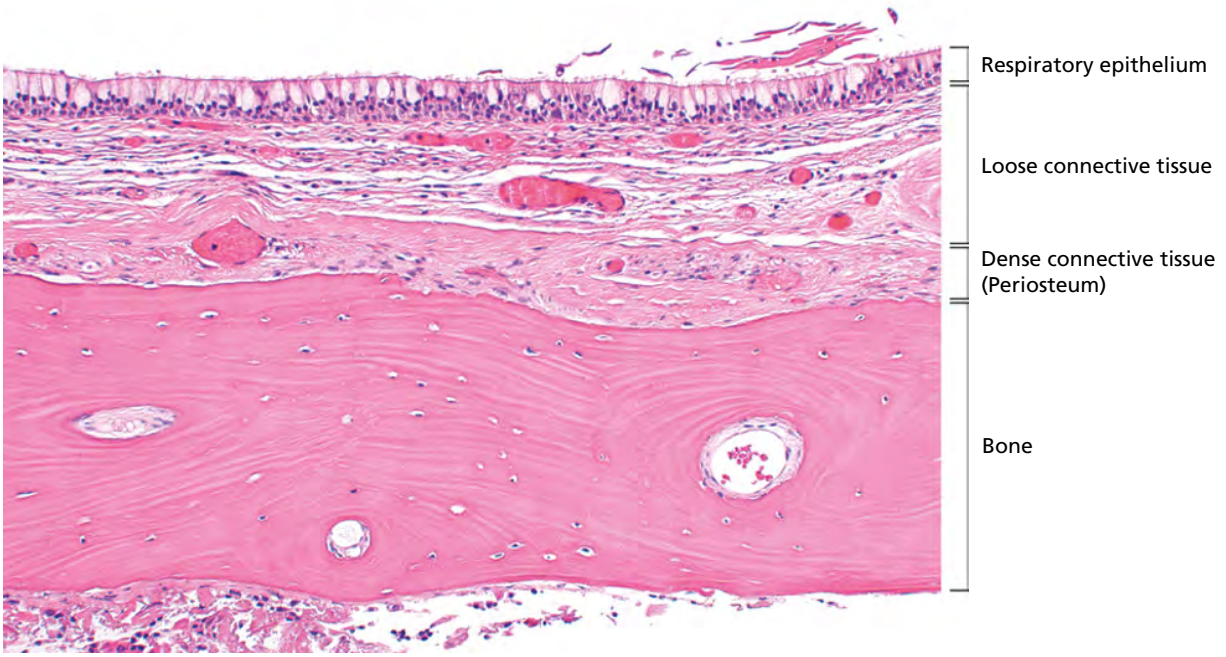

Fig. 42-4 Low magnification histomicrophotograph showing the three layers of the Schneiderian membrane and the underlying bone from a human specimen. Hematoxylin and eosin staining. (Source: Courtesy of Drs. Alberto Monje, Universitat Internacional de Catalunya, Barcelona, Spain and Ángel Insua, Private Practice, La Coruña, Spain.)

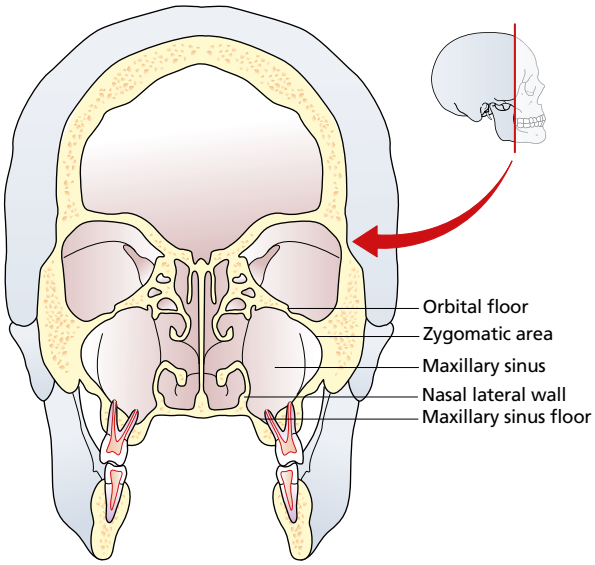

Fig. 42-5 Frontal section of the craniofacial complex. Note the anatomical boundaries of the maxillary sinus.

The blood supply to the maxillary sinus is primarily derived from branches of the internal maxillary artery (i.e. the posterior superior alveolar or alveolar antral artery, the infraorbital artery, and the posterior lateral nasal artery) and, to a lesser degree, from the greater palatine, anterior ethmoidal, and superior labial arteries. These vessels penetrate the bony plates and ramify within the medial, lateral, and inferior walls of the sinus (Fig. 42-9).

The posterior superior alveolar artery has tributary branches that primarily perfuse the posterior and lateral walls. The posterior superior alveolar and infraorbital arteries frequently anastomose at the bony lateral wall, forming a so-called *arterial arcade* (Solar *et al*. 1999). Venous drainage goes into the sphenopalatine vein and pterygomaxillary plexus. Innervation of the maxillary sinus is primarily provided by the anterior, middle, and posterior superior alveolar branches of the maxillary nerve, which is the second division of the fifth cranial pair (trigeminal nerve), as well as by branches

of the infraorbital nerve and the greater palatine nerve (Iwanaga *et al*. 2019).

Septa, or Underwood's septa, are intrasinusal bony walls of variable location, dimension, and morphology that may form during the development of the sinus cavity (i.e. primary septa) or as the result of functional adaptation or pathological processes (i.e. secondary septa). Some authors have pointed at a possible relationship between the presence of septa and maxillary exostoses, particularly in completely edentulous subjects (Naitoh *et al*. 2009). As reported in several studies, the prevalence of antral septa may range between 24% and 44.8% (Ulm *et al*. 1995; Velasquez-Plata *et al*. 2002; Sakhdari *et al*. 2016) and it appears to be significantly higher in edentulous patients (Kim *et al*. 2006). Septa are usually found in the inferior wall, or floor, of the sinus cavity (Fig. 42-10), although they can also be observed on the lateral, medial, or even superior wall (Fig. 42-11). In exceptional situations, a septum may completely divide the sinus cavity into several recesses (Fig. 42-12).

Conflicting information regarding the most common location of septa in the antero-posterior dimension has been reported. Although most studies have found them to be more commonly located in the middle or posterior regions of the sinus, in proximity to the typical location of maxillary molars, Krennmair and coworkers observed as many as 70% of septa in the anterior, more mesial, segment of the antral cavity (Krennmair *et al*. 1999).

Options for the rehabilitation of the posterior edentulous maxilla

Studies on patterns of tooth loss caused by periodontitis have reported that posterior teeth, particularly maxillary molars, are lost more frequently (Hirschfeld & Wasserman 1978; McFall 1982; Baelum & Fejerskov 1986). This trend can be attributed to different factors involved in the process of disease onset and progression, including difficult access to maintain adequate plaque control compared with anterior sites and the presence of inherent local anatomical features (e.g. multirooted configuration, cervical enamel projections, enamel pearls, and close root proximity between the first and the second molar).

Although it is well established that the total volume of the maxillary sinus cavity decreases with age (Rani *et al*. 2017; Velasco-Torres *et al*. 2017), the morphology of the sinus floor does not undergo major changes over time as long as the posterior teeth remain in function. Nonetheless, preclinical and clinical studies have demonstrated that the removal of a tooth from its alveolus triggers a cascade of biological events that results in an alteration of the structural configuration of the alveolar ridge and its surrounding structures (Araujo & Lindhe 2005; Chappuis *et al*. 2013). In fact, it has been shown that, following extraction of posterior teeth that are in close proximity to the maxillary sinus, the antral cavity expands both inferiorly and laterally in a phenomenon known as maxillary sinus pneumatization (Cavalcanti *et al*. 2018). This is accompanied by a process of alveolar bone atrophy which has been primarily attributed to the absence of stimulation from occlusal function as a result of posterior tooth loss (Schropp *et al*. 2003). A radiographic study using cone-beam computed tomography (CBCT) scans from 23 subjects who underwent extraction of maxillary molars revealed that bone remodeling between 2 and 60 months after tooth extraction is largely because of alveolar ridge resorption, whereas changes in maxillary sinus floor position contribute to a lesser extent (Hameed *et al*. 2019).

Clinicians may consider several options for the management of atrophic posterior edentulous maxillary segments (Fig. 42-13). However, in clinical scenarios in which posterior maxillary teeth planned for extraction are still present, the possibility of performing an alveolar ridge preservation procedure should be considered. Current evidence supports the effectiveness of alveolar ridge preservation via socket grafting and sealing performed immediately after tooth extraction as a means to minimize alveolar ridge remodeling and facilitate subsequent tooth replacement therapy (Avila-Ortiz *et al*. 2019; Tonetti *et al*. 2019). In fact, clinical studies focused on the posterior maxilla have demonstrated that alveolar ridge preservation via socket grafting directly contribute to attenuating alveolar ridge remodeling and sinus pneumatization, which may subsequently reduce the need for ancillary augmentation procedures (Rasperini *et al*. 2010; Levi *et al*. 2017; Park *et al*. 2019), as shown in Fig. 42-14.

However, there are situations in which alveolar ridge preservation does not render the expected outcomes or in which teeth are already missing, making it necessary to consider different therapeutic options.

Although a shortened dental arch compatible with adequate function (Fig. 42-15) may be a viable alternative to tooth replacement therapy (Kayser 1981; Wolfart *et al*. 2012), rehabilitation of the posterior edentulous maxilla is frequently requested by patients whose quality of life is affected by the absence of teeth (Gerritsen *et al*. 2010; Haag *et al*. 2017). Whether it is for the replacement of a single unit or multiple teeth, tooth replacement options may include removable and fixed dental prostheses. Removable dental prostheses can be supported by implants, remaining teeth (if any), and/or oral mucosa, whereas fixed dental prostheses can be implant- and/or tooth-supported. Given the scope of this chapter, the focus will be placed on the discussion of implant-based therapeutic alternatives for the management of posterior edentulous maxillary sectors exhibiting alveolar bone atrophy in the vertical dimension.

In clinical scenarios presenting limited bone height availability in the posterior maxilla, placement of standard-length implants often requires maxillary sinus floor augmentation (MSFA). MSFA can be defined as a surgical intervention aimed at gaining bone volume in the edentulous, atrophic posterior maxillary segments by displacing the existing sinus floor in an apical direction with the purpose of facilitating implant placement in a restoratively driven position. Analogous terms

to MSFA include maxillary sinus floor lift, maxillary sinus floor elevation, and maxillary sinus grafting, among others. MSFA involves entering the antral cavity with the purpose of elevating the Schneiderian membrane to displace the sinus floor. This can be accomplished with either a transalveolar, a lateral window, a crestal window, or a palatal window approach, with or without the use of a bone grafting material or space filler, and with or without simultaneous implant placement. These and other

specific aspects of MSFA will be discussed in depth in subsequent sections of this chapter.

Short or tilted/angled implants may be an alternative to MSFA in some scenarios. These approaches offer the advantage of minimizing or completely avoiding the need for ancillary bone augmentation procedures, which may potentially reduce morbidity, treatment time, and expense.

The threshold of length that defines a short implant is a subject of discussion in the scientific literature. Whereas some authors consider this value to be <10 mm, others draw the line at <8 mm, or even at ≤6 mm to define extra-short implants (Ravida *et al*. 2019). Earlier reports on the short-term (up to 5 years) survival rate of short implants were not particularly encouraging and linked implant failure with the so-called "poor bone quality" (i.e. lower mineral density) that is typically encountered in posterior maxillary segments (Friberg *et al*. 1991; Jemt & Lekholm 1995). A multicenter study conducted a few years later evaluated the outcomes of non-submerged, rough-surface dental implants. The investigators found that only one out of 208 short implants (6 mm) placed in the mandible was lost compared with six out of 45 short implants placed in the maxilla. The survival rates were 99.5% and 86.7%, respectively, after a follow-up of up to 7 years (ten Bruggenkate *et al*. 1998). Based on these and other studies, the clinical "dogma" that, generally, only long implants, regardless of the surface characteristics, should be inserted in type IV bone in the posterior maxilla gained popularity in the dental community (Jaffin & Berman 1991). Interestingly, two multicenter studies on rough-surface implants conducted in the 1990s evaluated the survival and success rates of implants of different lengths (Buser *et al*. 1997; Brocard *et al*. 2000). In these studies, no significant differences were found between 8-, 10-, and 12-mm implants after up to 8 years of follow-up. Further clinical studies on short implants with either machined or rough surfaces, reported survival rates of about 95% between 2 and 7 years after functional loading (Fugazzotto *et al*. 2004; Renouard & Nisand 2005), which is in congruence with the 5-year survival rate reported in different systematic reviews for standard implants (Berglundh *et al*. 2002; Jung *et al*. 2012). In contrast, a recent systematic review prepared for the Sixth ITI Consensus on the basis of 10 randomized controlled trials (RCTs) comparing long (>6 mm) and short (≤6 mm) implants, observed that short implants are associated with higher variability and lower predictability, in terms of survival rate, compared with longer implants after periods of 1–5 years in function (Papaspyridakos *et al*. 2018). Nevertheless, the reported mean survival rate was still high, at 96% (range: 86.7–100%) for short implants and 98% (range: 95–100%) for longer implants. It can be concluded that current evidence generally supports the efficacy of short implants as a viable treatment alternative in the rehabilitation of edentulous ridges, including the posterior maxilla (Fig. 42-16), as long as meticulous case selection, proper execution of surgical and restorative procedures, and an adequate maintenance program drive the delivery of care (Annibali *et al*. 2012; Monje *et al*. 2014b; Lorenz *et al*. 2019).

Another way to avoid maxillary sinus augmentation is to place tilted implants in a position mesial or distal to the sinus cavity, provided these areas have adequate bone (Fig. 42-17). Furthermore, extra-long zygomatic or pterygoid implants can be placed in the lateral aspect of the zygomatic bone or anchored in the pterygoid bone, respectively (Fig. 42-18).

Recent evidence supports the clinical performance of tilted, zygomatic, and pterygoid implants, as compared with standard, axially loaded implants, for the management of posterior edentulous maxillae, in terms of implant survival rate (Chrcanovic *et al*. 2015, 2016; Lin & Eckert 2018; Araujo *et al*. 2019). However, increased invasiveness, and surgical and prosthetic complexity associated with these procedures must be taken into consideration when presenting this option to potential candidates. Hence, the use of tilted or zygomatic implants should be primarily considered in sites thought unfavorable for placement of standard-length or short implants, such as those associated with extreme alveolar ridge

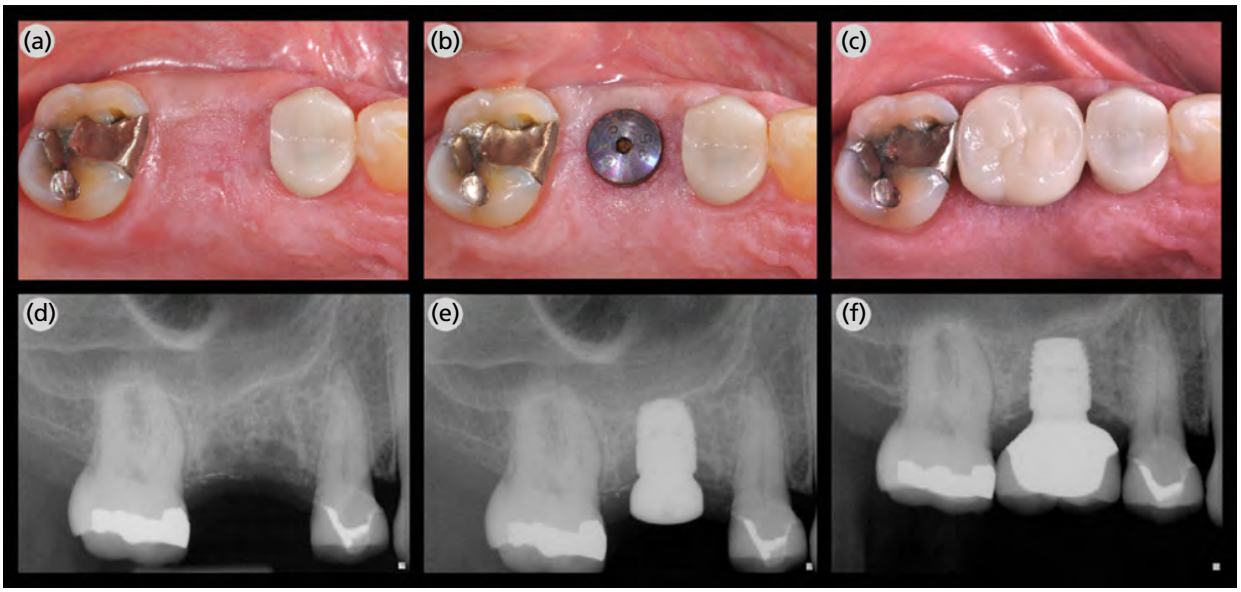

Fig. 42-16 Sequence of a case of tooth replacement therapy of a maxillary right first molar with an implant-supported prosthesis involving the use of a short implant to avoid MSFA. deficiencies (e.g. sites with a history of severe trauma or cancer resection) and/or in patients presenting absolute medical contraindications that preclude the performance of MSFA procedures.

Maxillary sinus floor augmentation techniques

Surgical modalities

The goal of MSFA in the context of contemporary dental practice is to gain bone volume in posterior maxillary segments presenting edentulism and vertical bone atrophy in order to facilitate tooth replacement therapy with implant-supported prostheses. The origin of this technique is controversial. Whereas some claim that MSFA was first described by Philip J. Boyne in lectures to postgraduate students in the 1960s as a preprosthetic surgical intervention to allow the delivery of removable appliances in areas of limited interocclusal space, others attribute the original idea to Hilt Tatum Jr. At any rate, a formal description of the technique was not published by Boyne and James until 1980 (Boyne & James 1980). In that original report the authors described a two-stage surgical procedure aimed at the elevation of the maxillary sinus floor in patients with large, pneumatized sinus cavities in preparation for the placement of intraosseous blade implants. According to the proposed technique, which was based on a procedure originally described in the field of otorhinolaryngology known as radical antrostomy or the Caldwell–Luc operation (Macbeth 1971), the maxillary sinus floor was grafted using autogenous particulate iliac bone, after gaining access through a lateral window and elevating the Schneiderian membrane. In the second surgical stage, approximately 3 months later, the site was surgically re-entered and implants were placed to later support fixed or removable dental prostheses. Other terms analogous to MSFA through a lateral window approach are direct MSFA, external MSFA, or lateral window osteotomy (LWO) sinus elevation.

Since the original description of the lateral window approach, other MSFA protocols and subsequent modifications have been proposed, namely transalveolar, crestal window, and palatal window approaches (Fig. 42-19).

The *transalveolar approach*, also referred to as transcrestal, internal, or indirect MSFA, was described by Hilt Tatum Jr. in 1986 as an alternative to the lateral window approach with the purpose of simplifying the bone augmentation technique and minimizing the occurrence of complications (Tatum 1986). According to the original description of this technique, a surgical instrument that was referred to as a "socket former" was used to prepare the implant site. A "green-stick fracture" of the sinus floor was manually accomplished by tapping the socket former with a mallet in a vertical direction. After preparation of the implant site, a cylindrical implant was placed in a submerged approach. In 1994, Robert B. Summers proposed a variation of this technique consisting of the use of a set of straight osteotomes of varying diameters (Fig. 42-20) to prepare the implant site without using drills with the purpose of achieving bone preservation and horizontal ridge expansion (Summers 1994).

This technique is also aimed at increasing the density of the maxillary bone surrounding the osteotomy to provide a higher chance to achieve implant primary stability. The Summers or BAOSFE (bone-added osteotome sinus floor elevation) technique is initiated by a small osteotomy that is made through the crest of the edentulous ridge, avoiding the perforation of the sinus floor. The pilot osteotomy creates a pathway for the insertion of osteotomes of increasing diameter to both compact the surrounding alveolar bone and elevate the sinus membrane, thus creating a "tent" and space for bone graft placement at the floor of the sinus, using the final osteotome to push it in a vertical direction. It should be noted that, in this technique, bone grafts are placed blindly into the space below the sinus membrane. Hence, one of the disadvantages of transalveolar MSFA is the possibility of inadvertent perforation of the sinus membrane. However, an endoscopic study has shown that, if the technique is carefully executed in the presence of favorable local anatomy, the sinus floor may be elevated by up to 5 mm without perforating the membrane (Engelke & Deckwer 1997). Although the essentials of the technique originally described by Summers still prevail, subsequent modifications of

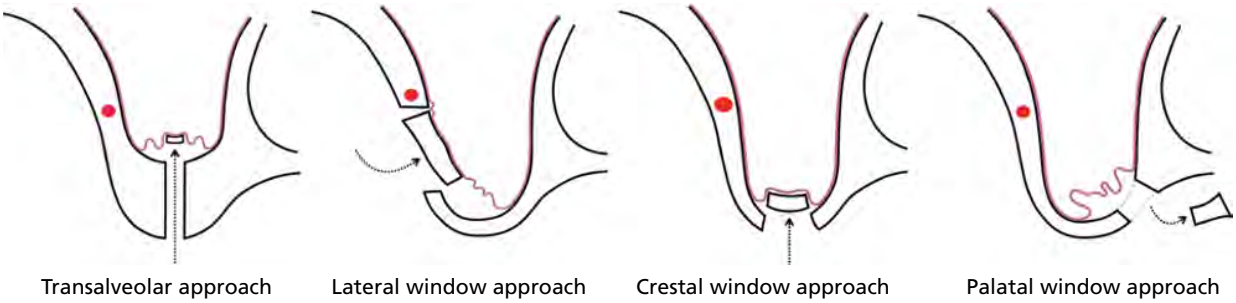

Fig. 42-19 Maxillary sinus floor augmentation modalities. Note the larger diameter of the posterior superior alveolar artery in the illustration representing the crestal window approach

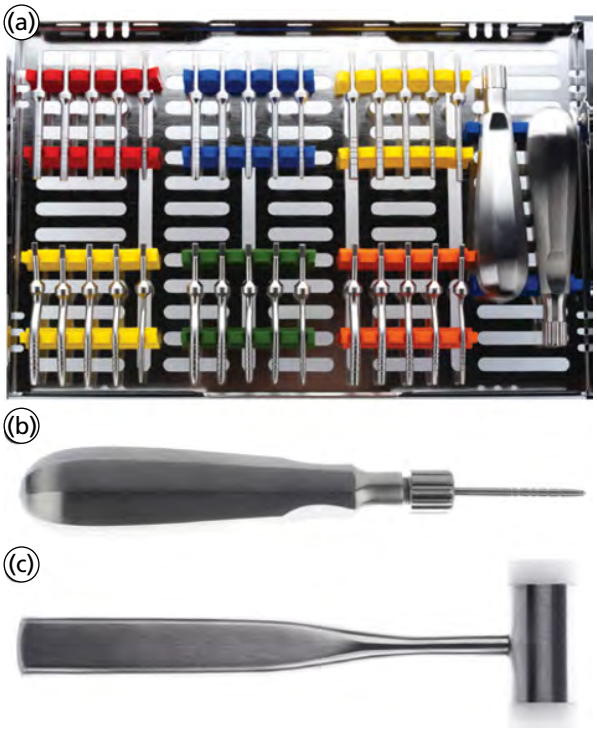

Fig. 42-20 (a) Contemporary osteotome kit. Note the variety of straight and angled tips of different diameters. (b) Osteotome handle assembled with a thin tapered blunt-ended tip. (c) Mallet composed of a surgical steel body and solid polytetrafluoroethylene working ends.

the transalveolar approach have been proposed over the past two decades involving the use of different devices, such as elastic balloons (Kfir *et al*. 2006), piezoelectric tips (Sohn *et al*. 2009), bone reamers (Ahn *et al*. 2012), and specially designed drills (Cosci & Luccioli 2000; Huwais *et al*. 2018).

The *crestal window approach* is a variation of the lateral window access. This approach was originally described by Alan A. Winter and collaborators in 2003 (Winter *et al*. 2003), and subsequently modified by Carlo Soardi and Hom-Lay Wang in 2012 (Soardi & Wang 2012). This technique may be useful to prevent a large perforation in clinical situations in which the oral mucosa and the Schneiderian membrane are fused at the level of the alveolar crest, which may result from inadequate healing after a complicated and/or traumatic extraction or because of a previous history of sinus pathosis (Block 2018). Although technically more demanding than accessing the antral cavity through a conventional lateral window, this approach may also serve as a viable alternative in cases in which avoiding the management a large posterior superior alveolar artery is desired. Given the nature of this approach, delayed implant placement is primarily indicated because of the difficulty of achieving primary stability.

The *palatal window approach* was originally described in 1992 in conjunction with a nasal approach, which can be a viable alternative in cases of extreme bone atrophy (Jensen *et al*. 1992). In these situations, the transverse dimension of the posterior maxilla can be reduced to an extent in which the alveolar process is in alignment with the lateral wall of the nasal cavity, making a lateral window approach inviable. Another possible indication for MSFA using a palatal window approach would be a scenario in which the lateral bony wall of the maxillary sinus is so thick, such as in cases of incomplete previous grafting, that accessing the maxillary sinus from the palate would be more time efficient and technically feasible (Ueno *et al*. 2015; Florio *et al*. 2017), as shown in Fig. 42-21.

Nevertheless, considering that these clinical situations are relatively infrequent, as well as other important technical implications (e.g. difficult access and proximity of major vascular structures), the palatal window approach should be reserved to very specific scenarios in which no other MSFA alternative is feasible.

In contemporary dental practice, two main MSFA approaches are commonly indicated: (1) the lateral window approach, which may involve simultaneous or delayed implant placement, or (2) the transalveolar approach, which usually involves simultaneous implant placement.

Residual bone height (RBH), also known as residual sub-antral bone, is considered a critical anatomic factor in the planning and execution of MSFA procedures. Although baseline RBH *per se* does not seem to play a critical role on implant integration (Fenner *et al*. 2009) or new bone formation after MSFA (Avila-Ortiz *et al*. 2012a), it has a direct influence on the likelihood of achieving implant primary stability. Hence, RBH is commonly utilized in clinical practice not only as the primary factor to determine the implant placement protocol (either simultaneous or delayed),

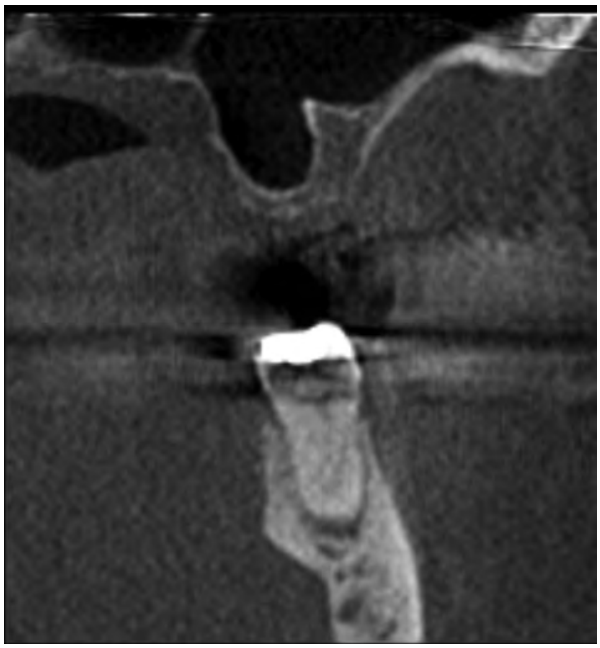

Fig. 42-21 Sagittal radiographic image showing a maxillary sinus presenting an unusually thick lateral wall. This scenario may be an indication for MSFA via a palatal window approach.

but also the MSFA approach (either transalveolar or lateral window). Since the publication of clinical guidelines originally proposed by Carl E. Misch in 1987 (Misch 1987), other RBH classifications have been developed to guide clinicians in the decision-making process that would lead to the indication of a specific MSFA modality, with or without simultaneous implant placement, or an alternative option (Wang &Katranji 2008; Wagner *et al*. 2017).

The following are general recommendations proposed by the authors of this chapter on the basis of contemporary evidence (Fig. 42-22):

- RBH >9 mm: standard implant (length ≥8 mm) placement.
- RBH of >5 to ≤9 mm: MSFA with a transalveolar approach and simultaneous standard implant placement or short implant (length <8 mm) placement with no bone augmentation.
- RBH of >3 to ≤5 mm: MSFA with a lateral window approach and simultaneous implant placement.
- RBH ≤3 mm: MSFA with a lateral window approach and delayed implant placement.

It is important to remark that these and other numeric thresholds proposed elsewhere must always be interpreted with caution prior to making treatment planning decisions, factoring in the skill and preferences of the surgeon, the characteristics of the implant system employed, the planned contour of the final prosthetic restoration relative to the vertical location of the implant restorative platform, the presence of concomitant pathosis (Manji *et al*. 2013; Friedland & Metson 2014) and additional anatomic variables that may play a role in the execution of the technique, such as configuration and cortication of the sinus floor (Niu *et al*. 2018; Choucroun *et al*. 2017), presence and morphology of septa (Wen *et al*. 2013), mediolateral sinus width (Teng *et al*. 2016), thickness of the lateral sinus wall (Monje *et al*. 2014a; Danesh-Sani *et al*. 2017b), size and location of the posterior superior alveolar artery (Anamali *et al*. 2015), and thickness of the Schneiderian membrane (Monje *et al*. 2016; Rapani *et al*. 2016). As a general surgical principle, the most predictable and conservative approach should always be indicated after consideration of relevant individual local and systemic factors.

Presurgical examination and care

Prior to executing any advanced intraoral surgical procedure, such as MSFA, a thorough preoperative examination should be conducted for adequate case selection and treatment planning (see Chapter 22). This includes a detailed review of the patient's medical, dental, and periodontal history. The dental and periodontal status should be evaluated according to clinical and radiographic examination methods aligned with current diagnostic standards. Prior to performing a MSFA procedure, all partially edentulous patients should have completed infection control therapy (see Part 11). Additionally, the vitality of teeth neighboring the edentulous space should be tested. It is also important to examine the keratinized mucosa width, vestibulum depth, and interocclusal space.

A complete anatomical analysis based on meticulous clinical and radiographic assessments of the maxillary sinus and parasinusal structures should be conducted prior to indicating MSFA procedures

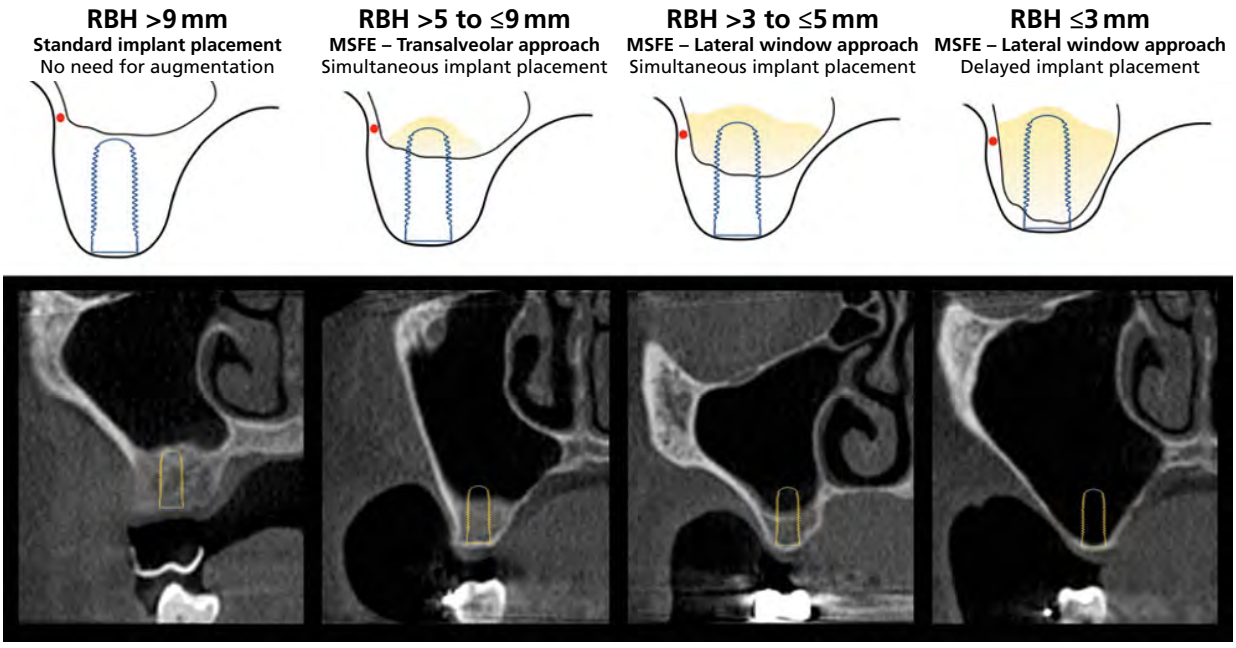

Fig. 42-22 Recommendations for the indication of different maxillary sinus floor augmentation (MSFA) and implant placement protocols in function of the residual bone height (RBH) with corresponding examples of sagittal CBCT sections. Note the increasing alveolar ridge atrophy and maxillary sinus pneumatization from the left to the right.

with the purpose of identifying and evaluating local factors that may influence the execution of the technique and the outcomes of therapy, such as unfavorable anatomic variations and/or presence of pathosis. The infraorbital, lateral nasal, and superior labial areas of the face should be examined extraorally for tenderness to palpation, abnormal swelling, or asymmetry. Likewise, the functional range of mouth opening should be assessed to confirm that surgical access will be favorable. Preoperative radiographic screening may include the analysis of periapical radiographs, orthopantomography, computed tomography (CT) or CBCT scans (see Chapter 23). Although some important information (e.g. remaining subantral bone height) may be obtained through the analysis of conventional 2D radiographs, critical diagnostic elements may go unnoticed if clinicians rely exclusively on these diagnostic tools. Therefore, the use of advanced imaging techniques, such as CBCT, is strongly recommended for the planning of MSFA (Benavides *et al*. 2012). CBCT imaging enables clinicians to perform a tridimensional assessment of the maxillary sinus and adjacent structures, detecting deviations from normal anatomy and the presence of pathosis. If pathosis that may interfere with the success of the surgical procedure is identified, appropriate medical consultations (e.g. otorhinolaryngological) and subsequent therapy (e.g. management of acute sinusitis, removal of polyps, or tumors) must be completed prior to MSFA in order to minimize the risk of intra- and postoperative complications (Chan & Wang 2011).

The prescription of prophylactic antibiotics to minimize the occurrence of an infection after MSFA is a controversial topic. A group of clinical experts that provided guidelines for the prevention and treatment of postoperative infections after MSFA advocated for the indication of presurgical antibiotic prophylaxis (Testori *et al*. 2012). However, it must be mentioned that, as recognized by the members of this expert panel, these recommendations are solely based on clinical experience and empirical observations. No clinical trial aimed at testing the need for antibiotic prophylaxis prior to the performance of MSFA procedures in order to reduce the incidence of postoperative complications has been conducted to date.

Healing dynamics

Progressive apposition of new bone in the subantral space intentionally created during the surgical intervention is expected in the course of a normal reparative response following MSFA procedures. This process consists of different healing phases (i.e. inflammatory, bone apposition, maturation, and remodeling), which partially overlap in time, in congruence with an intramembranous pattern of bone formation (Fuerst *et al*. 2004). In normal conditions of healing, if a bone grafting material and/or a dental implant are utilized to fill and/or maintain the space, new bone will be formed around the biomaterial and on the surface of the dental implant, followed by consolidation and maturation of the hybrid substrate, functional osseous remodeling, and a variable degree of resorption of the remaining bone grafting material (Watzek *et al*. 2006). Interestingly, preclinical and clinical studies on MSFA via a lateral window approach have demonstrated that the front, or gradient, of new bone formation primarily originates from the bony boundaries, on the periphery of the sinus cavity (Busenlechner *et al*. 2009; Scala *et al*. 2010; Kolerman *et al*. 2019), as shown in Fig. 42-23.

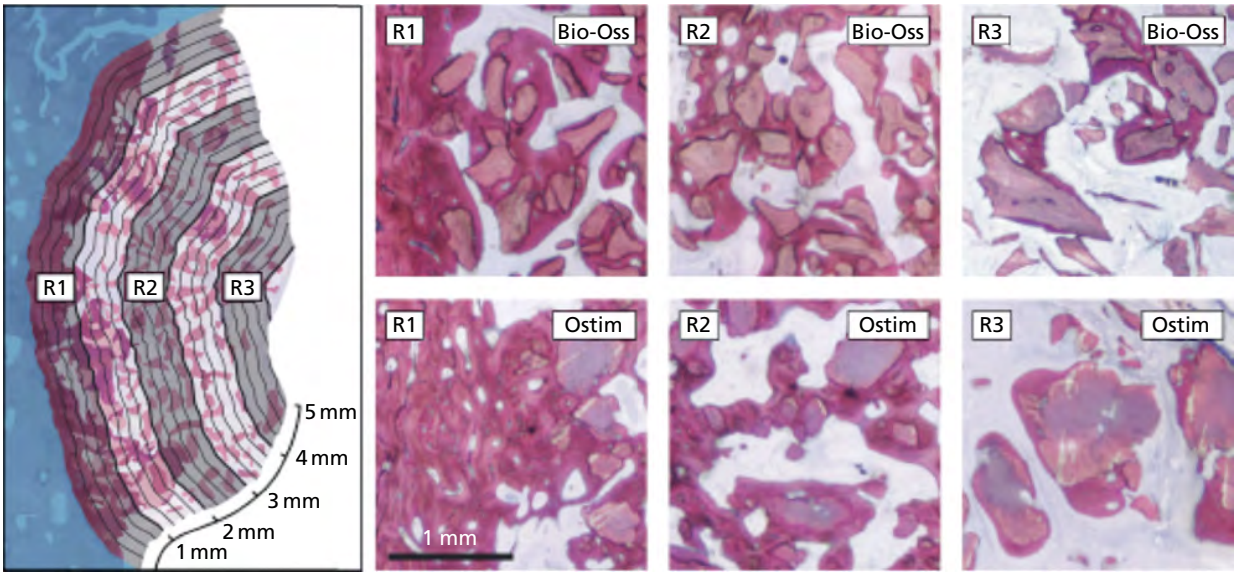

Fig. 42-23 Histologic sections illustrating the gradient of bone graft consolidation of two different biomaterials in different regions respective to the maxillary sinus bony boundaries in a minipig model. Source: This is Fig. 2 in the following publication: Busenlechner D, Huber CD, Vasak C, Dobsak A, Gruber R, Watzek G. 2009. Sinus augmentation analysis revised: the gradient of graft consolidation. Clin Oral Implants Res. 20(10):1078-1083. Reprinted with permission from Wiley and Sons.

Some authors have also commented on the osteogenic potential of the Schneiderian membrane, because it contains pluripotential mesenchymal cells that may differentiate into osteoblasts (Srouji *et al*. 2010; Graziano *et al*. 2012). However, the clinical significance of this concept is questionable. According to different preclinical studies the bone-forming capacity of the Schneiderian membrane seems to be modest, at best, and not critical in the success of MSFA procedures (Scala *et al*. 2012; Jungner *et al*. 2015; Caneva *et al*. 2017). This notion is supported by the findings of a recently published systematic review (Dragonas *et al*. 2020).

A normal process of bone formation and maturation requires a stable osteoconductive scaffold (e.g. blood clot and/or bone grafting material) in the early stages of healing, as well as adequate angiogenesis, migration, and attachment of cells involved in bone apposition and remodeling (i.e. osteoblasts and osteoclasts). Successful bone formation and graft consolidation depend on the inherent properties of the bone grafting material(s) employed and the osteogenic potential of the recipient bed. Delayed or insufficient bone maturation after MSFA may occur in patients with systemic conditions known to affect normal healing (e.g. uncontrolled diabetes), heavy smokers (Galindo-Moreno *et al*. 2012a), and in the presence of concomitant pathosis (Chan & Wang 2011) or unfavorable anatomical features, such as large sinus cavity dimensions (Avila *et al*. 2010; Stacchi *et al*. 2018). As with any other surgical intervention, careful assessment of local and systemic factors that may play a role in the healing process after MSFA is crucial for proper case selection and optimization of therapeutic outcomes.

Maxillary sinus floor augmentation: lateral window approach

Indications and contraindications

MSFA utilizing a lateral window approach is indicated for the prosthetic rehabilitation of edentulous spaces in the posterior maxilla presenting reduced RBH (≤5 mm), which may be incompatible with standard implant placement or transalveolar MSFA with simultaneous implant placement. In cases of reduced bone height caused by alveolar bone resorption and maxillary pneumatization combined with horizontal and/or vertical ridge deficiency, simultaneous MSFA and alveolar ridge augmentation (e.g. horizontal and/or vertical) may be indicated.

Contraindications for sinus floor augmentation may be relative (reversible) or absolute (irreversible) and can by divided into three groups: medical, behavioral, and local.

Medical contraindications

Medical contraindications include cancer treatment involving chemotherapy and/or radiotherapy of the head and neck area at the time of MSFA or in the preceding 6 months, immunocompromised patients, systemic diseases that affect the mucociliary function (e.g. cystic fibrosis), medical conditions known to affect bone metabolism, severe blood dyscrasias, uncontrolled diabetes, and psychological and/or psychiatric conditions that affect patient understanding or compliance. Additionally, drug regimens that may interfere with normal wound healing (e.g. bisphosphonates) should be carefully considered on an individual basis.

Behavioral contraindications

Whether or not smoking is an absolute contraindication for MSFA remains controversial. A case series involving 52 patients who underwent MSFA via a lateral window approach linked smoking with an impaired healing response (Galindo-Moreno *et al*. 2012a). In this study, a histomorphometric assessment of core biopsies obtained at 6 months after bone augmentation revealed that smoking habits were associated with lower counts of osteoblasts and smaller proportions of new bone formation. In another case series study, the survival of implants placed in combination with bone augmentation (horizontal/vertical) and MSFA was evaluated (Mayfield *et al*. 2001). The survival rate of these implants was 100% for non-smokers compared with only 43% for smokers after a maximum of 6.5 years of functional loading. The detrimental impact of smoking on implant survival rate has also been corroborated in other studies (Bain & Moy 1993; Gruica *et al*. 2004). However, a large study evaluating 2132 implants after sinus floor augmentation with simultaneous implant placement reported conflicting results (Peleg *et al*. 2006a). Two hundred and twenty-six sinus floor augmentations involving the placement of 627 implants were performed on smokers, whereas 515 sinus floor augmentations for a total of 1515 implants were done on non-smokers. After a follow-up time of up to 9 years, the survival rate of the implants was 97.9%, and there were no statistically significant differences in terms of implant survival rate between smokers and non-smokers. A systematic review published in 2008 investigated the survival rate of implants inserted in combination with sinus floor augmentation utilizing the lateral window approach (Pjetursson *et al*. 2008). Five of the included studies reported on the influence of smoking status of the patients on implant survival after sinus floor augmentation. A group of non-smokers who received 2159 implants and a group of smokers who received 863 implants were analyzed. Although the smoking habits were not homogenously reported across studies, smoking was associated with a higher annual implant failure rate (3.54%) compared with non-smokers (1.86%). A recent systematic review aimed at evaluating the effect of smoking on the survival rate of dental implants placed in sites that underwent MSFA rendered similar results (Chambrone *et al*. 2014). The data from seven different studies that met the eligibility criteria were extracted and pooled in a

quantitative analysis that revealed a statistically significantly increased, but modest risk of implant failure in smokers (relative risk [RR] = 1.87; [95% CI: 1.35, 2.58], $P = 0.0001$). However, this effect was not statistically significant when only data from prospective studies ($n = 3$) was analyzed (RR = 1.55; [95% CI: 0.91, 2.65], $P = 0.11$). Excessive alcohol consumption and recreational drug abuse should also be considered as potential contraindications for MSFA.

Local contraindications

Alterations of the naso-maxillary complex that interfere with normal ventilation or mucociliary clearance of the maxillary sinus may be a contraindication for MSFA with a lateral window approach. It is important to keep in mind that patients with such abnormal conditions may be asymptomatic or only present mild clinical symptoms. These conditions include anatomical alterations (e.g. stenosis of maxillary ostium, concha bullosa of the middle turbinate, paradoxical curve of middle turbinate, enlarged agger nasi or infraorbital Haller cell, hypertrophic uncinate process, and aberrant septa), large mucous retention cysts, local aggressive benign (e.g. polyps) and malignant tumors, hypofunctional ciliary mucosae, viral, bacterial or mycotic rhinosinusitis, allergic rhinitis, allergic sinusitis, sinusitis caused by foreign bodies, odontogenic sinusitis, and acute, subacute, chronic, or recurrent bacterial sinusitis. Performing MSFA in the presence of any of the above conditions may disturb the fine mucociliary balance, resulting in mucus stasis, suprainfection, and subacute sinusitis.

Surgical technique

Since the original description of the lateral window approach by Boyne and James (Boyne & James 1980), numerous modifications of this modality of MSFA have been proposed in the literature to facilitate the performance of this surgical intervention, increase its predictability, and decrease the incidence of complications (Wallace *et al*. 2012). The generic protocol outlined below, proposed by the authors, is based on previous descriptions of this technique:

1. A presurgical rinse with an aqueous solution containing chlorhexidine (0.12% or 0.2%) is performed for a period of 1 minute.
2. Perioral cutaneous surfaces may be disinfected (e.g. wiping with iodine solution, unless contraindicated because of allergy).
3. Local infiltrative anesthesia is delivered buccal and palatal to the surgical area. In most cases, blocking the infraorbital, greater palatine, and posterior superior alveolar nerves is sufficient to obtain the necessary anesthesia to perform MSFA. Additional infiltrations along the mucogingival junction and the palatal mucosa using an anesthetic containing epinephrine may be administered to reduce intraoperative bleeding. Sedation should be considered in patients with a history of dental anxiety.
4. With the purpose of minimizing postoperative pain and discomfort for the patient, and to favor an uneventful postoperative period, MSFA procedures should be as minimally traumatic as possible. An initial mid-crestal or slightly palatal incision, if the amount of keratinized mucosa is limited, is made (Fig. 42-24c). This initial incision usually extends between the remaining teeth, in cases of partial edentulism, or from the canine or premolar area to the tuberosity, in cases of edentulous distal extension. In cases of partial edentulism, mesial and distal intrasulcular incisions may be done to increase the flap area. Then, vertical releasing incisions are made anteriorly and posteriorly, passing the mucogingival junction and extending into the buccal vestibulum for adequate surgical access after the reflection of a mucoperiosteal flap. It is important to place the incisions at a safe distance (a minimum of approximately 5 mm) from the boundaries of the planned lateral window in order to minimize the potential impact of a possible premature wound opening on the healing outcomes.
5. The trapezoid mucoperiosteal flap is raised slightly superior (2–3 mm) to the anticipated height of the lateral window. Precautions must be taken to avoid perforation of the flap. Unless simultaneous implant placement is planned, elevation of the palatal mucosa is not necessary in this surgical procedure (Fig. 42-24d). After the lateral sinus wall has been exposed, the window is outlined, which can be done using instruments such as a round diamond bur attached to a high-speed rotary handpiece, piezoelectric equipment, a bone scraper (Fig. 42-24e), which allows for the harvesting of autogenous bone, or a combination of them (Vercellotti *et al*. 2001; Peleg *et al*. 2004; Galindo-Moreno *et al*. 2007). In accordance with minimally invasive surgery principles and to maximize the amount of new mineralized tissue formation (Avila-Ortiz *et al*. 2012b), it is important to outline a lateral window that is as small as possible, but large enough to gain the necessary access to achieve the surgical goal (Fig. 42-24g). To aid in the elevation of the Schneiderian membrane, the most inferior boundary of the window should be delineated in proximity to the floor of the sinus. The position of the mesial and distal window boundaries within the edentulous segment is dictated by the location of the anterior and posterior maxillary sinus walls and by the presence of adjacent teeth. When adjacent teeth are present the window should be delineated at least 2 mm away from the root contours to avoid tooth damage. In cases of complete absence of posterior teeth, the mesial boundary should be outlined at approximately 2 mm distal from the anterior sinus wall and at a

variable distance from the posterior wall, because it is usually not necessary to augment all the way to the most posterior aspect of the antral cavity. The most apical boundary of the window should be placed at a distance that permits the placement of standard length implants (>8 mm), accounting for an approximate 10–25% of remodeling respective to the original grafted volume (Kirmeier *et al*. 2008; Mazzocco *et al*. 2014; Younes *et al*. 2019). The outline of the lateral window may require additional modifications to avoid septa (Fig. 42-25). Creating two or more separate windows is recommended to overcome tall septa (i.e. >2.5 mm) located on the sinus floor in order to minimize the risk of Schneiderian membrane perforation (Beretta *et al*. 2012).

Four methods for handling the lateral cortical bone plate have been proposed. A common approach is thinning of the buccal bone using a round bur or a piezoelectric tip and removing the overlying bone prior to maxillary sinus membrane elevation (Fig. 42-26).

Another method is to fracture the cortical bony plate like a trapdoor and use it as the superior border to the surgically created compartment, leaving it attached to the Schneiderian membrane. The third method is to remove the cortical bony plate during sinus floor elevation and replace it on the lateral aspect of the graft at the end of the grafting procedure. The rationale for this method is based on the notion that the lateral window would not completely heal without replacement of its cortical plate. However, healing of the lateral window by bone apposition without replacing the cortical bony plate has been demonstrated (Boyne 1993). The fourth method involves utilizing the lateral bone plate to harvest particulate autogenous bone that can be utilized in combination with a larger amount of a bone substitute (Fig. 42-24f). This can be accomplished by retrieving and processing the cortical bony plate using a bone mill or, as aforementioned, by using a bone scraper.

6. Once exposed, careful elevation of the Schneiderian membrane, which typically presents a bluish hue (Fig. 42-24g), may be performed using blunt piezoelectric tips and/or sinus membrane elevators (Fig. 42-27). Care should be taken not to perforate the membrane, reflecting it as much as necessary to create the compartment required for bone grafting and implant placement, but not overextending, to minimize the risk of complications (Fig. 42-24i). In order to avoid occlusion of the nasal meatus and a subsequent complication, the Schneiderian membrane should never be lifted

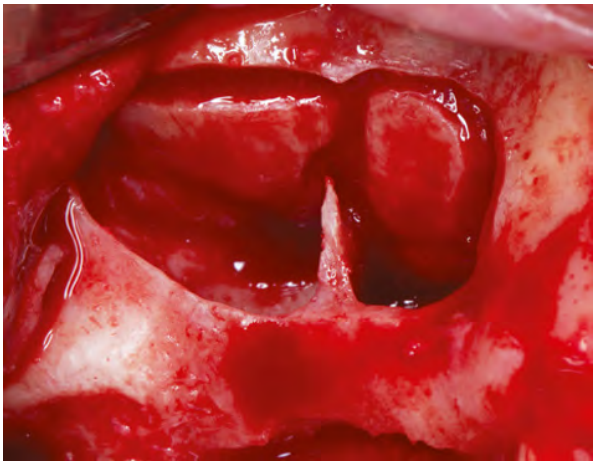

Fig. 42-25 Modified lateral access creating two separate windows to overcome the presence of a tall septum.

Fig. 42-27 Maxillary sinus membrane elevators with different tip designs.

beyond the ostium (Maksoud 2001). Care should be taken to reach the medial wall in order to allow for homogeneous graft distribution and avoid a medial void or recess (Fig. 42-28).

It is generally recommended to start releasing the areas of less tension and favorable access. Another useful tip is to apply careful and gentle pressure when the membrane elevators are used, feeling the underlying bony structures, to prevent the occurrence of a membrane perforation and/or damage to the posterior superior alveolar artery, which is crucial to avoid a significant hemorrhage if the artery is particularly large and has an intraosseous course (Fig. 42-29).

If a perforation occurs, a sealing material, such as an absorbable barrier membrane, can be placed over the perforation to prevent extravasation of the grafting material into the antral cavity, which may lead to severe complications (Fig. 42-24k). It is generally recommended to abort the bone grafting procedure if the perforation cannot be sealed intraoperatively (Vlassis & Fugazzotto 1999). Complete repair of the Schneiderian membrane after trauma may take up to 4 months (Huang *et al*. 2006), therefore surgical reentry to attempt a secondary procedure is not recommended before then.

Depending on anatomical variables, such as RBH, and the surgeon's preference, MSFA through a lateral window approach may be performed with delayed or simultaneous implant placement.

Fig. 42-28 Sagittal section of a posterior edentulous maxillary segment approximately 6 months after MSFA via a lateral window approach using bovine xenograft particles. Note the void medial to the grafted substrate resulting from an incomplete elevation of the Schneiderian membrane.

MSFA with a lateral window approach and delayed implant placement

1. Unless a graftless approach is followed, a bone grafting material is placed in the compartment created after the elevation of the sinus membrane (Fig. 42-24l). The total amount of grafting material required differs between cases depending on the dimensions and configuration of the maxillary sinus cavity. The grafting material should not be aggressively packed, because this may reduce the space needed for angiogenesis, cell migration, and in-growth of new bone. In addition, stretching a thin sinus membrane by exerting excessive pressure when packing the grafting material may result in a perforation.
2. The lateral window may be covered with an absorbable or a non-absorbable barrier membrane (Fig. 42-24m). Barrier membranes may aid in preventing soft tissue ingrowth into the grafted compartment. However, available evidence is equivocal regarding the effect of a barrier membrane to cover the lateral window. Although some studies have found a beneficial effect associated with use of a barrier in terms of new bone formation and increased implant survival (Froum *et al*. 1998; Tarnow *et al*. 2000; Tawil & Mawla 2001), others have reported no significant differences between sites that received a membrane and those which did not (Choi *et al*. 2009; Yu *et al*. 2017). A systematic review found that the cumulative

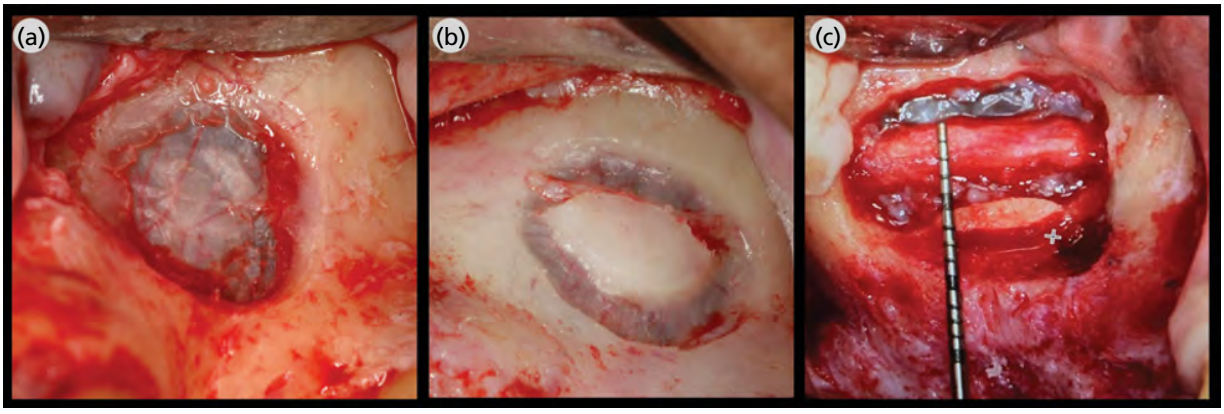

Fig. 42-29 Clinical images showing the presence of three right posterior superior alveolar arteries of different sizes when performing MSFA via a lateral window approach. (a) Small. (b) Medium. (c) Large. (Source: (c) is courtesy of Dr. Nikolaos Tatarakis, Queen Mary University and Private Practice, London, UK.)

3-year annual failure rate of dental implants placed in sites that underwent MSFA with a membrane covering the lateral access window was lower (0.79%) compared with those placed in sites that did not receive a membrane (4.04%) (Pjetursson *et al*. 2008). If a barrier membrane is used, it is generally recommended to use an absorbable membrane in order to avoid the need for elevating a larger flap for non-absorbable membrane retrieval at the time of delayed implant placement. Subsequently, the flap is repositioned and sutured to achieve primary closure (Fig. 42-24n). Periosteal releasing incisions are generally not necessary to achieve tension-free closure, unless simultaneous horizontal or vertical ridge augmentation is performed in combination with MSFA.

MSFA with a lateral window approach and simultaneous implant placement (Fig. 42-30)

1. After the sinus membrane has been elevated, the implant site(s) are prepared. The use of a surgical stent based on the prosthetic plan is recommended. If rotary instruments (e.g. drills) are used, the sinus membrane should be protected using a solid instrument, such as a large periosteal elevator. Alternatively, osteotomes of different diameters may be used to prepare the implant site. In these situations, the membrane can be protected by inserting sterile, lint-free gauze into the sinus compartment.
2. Unless a graftless approach is followed, the bone grafting material is inserted and gently packed towards the medial part of the sinus compartment, followed by implant placement and, finally, by grafting of the lateral aspect. This sequence allows for improved visibility and reduces the chance of leaving a void medial to the implant(s). The subsequent steps coincide with those described for the delayed implant placement approach, with the exception that, if adequate primary stability is achieved, a healing abutment may be delivered according to a non-submerged implant placement protocol.

Grafting material selection

There are differences of opinion regarding the need to employ bone grafting materials in MSFA procedures.

No grafting material: blood clot

An early preclinical study by Philip J. Boyne demonstrated that bone formation around osseointegrated implants protruding into the maxillary sinus after elevation of the Schneiderian membrane without the application of a bone grafting material is feasible (Boyne 1993). In the same study, it was also observed that implant design influenced the amount of spontaneous bone formation. New bone formation was insufficient around implants with open apices or deep-threaded configurations. On the other hand, implants with rounded apices that penetrated 2–3 mm into the maxillary sinus were associated with bone formation around their entire circumference. However, when the same implants penetrated 5 mm into the maxillary sinus, only a partial growth of new bone, up to approximately half of the total implant length, was achieved. A similar outcome was observed in a preclinical investigation in dogs (Kim *et al*. 2010).

This concept has also been demonstrated in human research models. Lundgren and co-workers conducted several studies in which, after removing the lateral bony wall, the sinus membrane was elevated and sutured against the lateral wall in an elevated position, in order to create and maintain a compartment for blood clot formation. Implants were placed simultaneously, which is a *sine qua non* for the graftless approach protocol. Comparisons of pre- and postoperative CT images obtained at 6 months after the surgical procedure clearly demonstrated the presence of new bone within the compartment created between the implants and the Schneiderian membrane (Lundgren *et al*. 2004; Hatano *et al*. 2007).

In another clinical study, 131 implants were placed simultaneously with MSFA via a lateral window approach. Implants were inserted with intentional protrusion into the sinus cavity, after Schneiderian membrane elevation. The sinus membrane was allowed to settle onto the apex of the implants, thus creating a space to be filled with a coagulum. After a mean follow-up of 5 years, the survival rate of these implants was 90% (Ellegaard *et al*. 2006).

A longitudinal study that monitored 84 patients who underwent a total of 96 sinus floor elevations procedures with simultaneous placement of 239 implants without using any bone grafting material, demonstrated an average vertical bone gain of 5.3 mm on intraoral radiographs after 6 months of healing. Implant survival was 98.7% at 3 years (Cricchio *et al*. 2011). Along the same lines, a systematic review aimed at analyzing the implant survival rates up to 5 years of follow up following MSFA using bone grafting materials or not. The survival rate of implants placed in grafted sites was 99.6%, whereas implants placed in sites that received no bone grafting exhibited a survival rate of 96.0% (Silva *et al*. 2016).

Hence, it may be concluded that graftless MSFA is a predictable and valid procedure associated with a low incidence of implant failure (Duan *et al*. 2017). It is also important to remark that simultaneous placement of implants protruding into the sinus cavity is required in this technique to tent the Schneiderian membrane and maintain an adequate space for blood clot stabilization. However, simultaneous implant placement is not always feasible when performing MSFA procedures, particularly in sites with limited RBH. In order to successfully manage a wide range of anatomical situations in the context of MSFA, it is

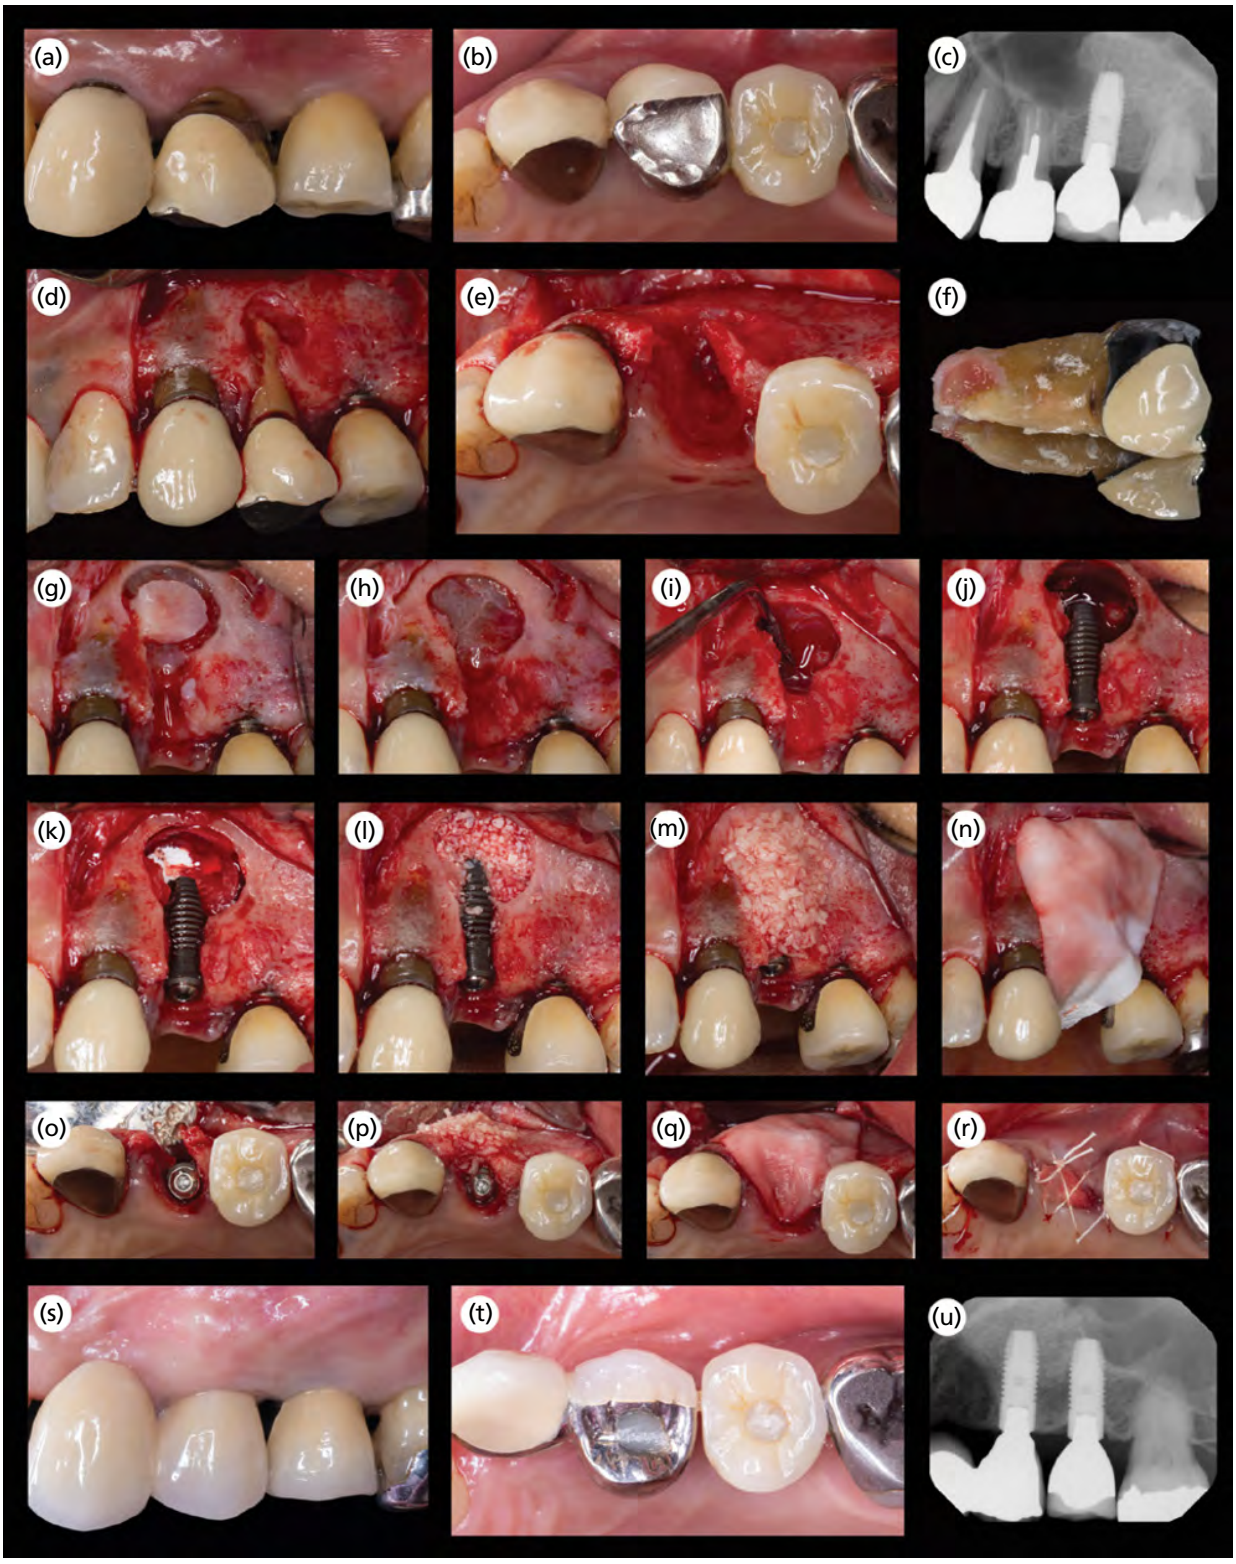

Fig. 42-30 Sequence of a case of MSFA via a lateral window approach with simultaneous implant placement to replace a hopeless maxillary left first premolar which exhibited a mid-buccal vertical root fracture. (a, b) Lateral and occlusal view of the site. (c) Periapical radiograph showing an apical radiolucency. Note that the second premolar was previously replaced with an implant-supported prosthesis and MSFA. (d) Complete absence of the buccal wall was verified upon elevation of a full-thickness flap. (e) Occlusal view immediately after tooth extraction and debridement. (f) Detail of the extracted tooth. (g) The lateral window was outlined using a piezosurgery unit. (h) The bony wall was carefully detached from the Schneiderian membrane. (i) A sinus membrane elevator was used. (j) An implant was placed after the osteotomy was completed. (k) Even though no perforation occurred, an absorbable porcine collagen membrane was used to facilitate the bone grafting procedure. (l) A bone graft mix consisting of bovine xenograft particles and milled autogenous bone from the lateral window was used to fill the subantral space. (m) The facial aspect of the ridge was grafted using cortical allograft particles. (n, p, q, r) Occlusal view of the site upon implant placement (o), grafting with the allograft material (p), covering with the porcine collagen membrane (q) and suturing (r). (s, t) Lateral and occlusal view of the site at the 5-year follow-up visit. The canine was eventually lost, also caused by a vertical root fracture. The prosthodontist (Dr. Galen Schneider, University of Iowa) opted for a mesial cantilever to replace the missing crown. (u) Periapical radiograph obtained at 5 years after implant placement.

therefore necessary to consider the indication of other surgical protocols involving the use of bone grafting materials.

Autogenous bone

Autogenous bone grafts have been considered historically as the gold standard for bone augmentation procedures because of their osteoconductive, osteoinductive, and osteogenic capacity. Autogenous grafts may be harvested intra- or extraorally. Common intraoral donor sites are the maxillary tuberosity, the zygomaticomaxillary buttress and the mandibular symphysis, body or ramus. Examples of extraoral donor sites are the anterior and posterior iliac crest, tibial plateau, fibula, rib, and calvaria. Bone may be harvested as a block or in particulate form. Aside from osteogenic cells, autologous bone grafts contain signaling molecules that play a crucial role in bone formation, such as growth factors and bone morphogenic proteins (BMPs).

Processing of autografts with grinding or morselizing devices does not seem to disturb the viability of the osteogenic cells (Springer *et al*. 2004). This was corroborated by a study aimed at evaluating the effect that different harvesting methods has on cell viability and release of growth factors of autogenous bone samples. Interestingly, this study found that bone mill and bone scraper samples revealed significantly higher expression of growth factors compared with bone obtained by drilling (bone slurry) or using a piezosurgery device (Miron *et al*. 2013).

Autogenous bone graft was the first documented material applied in MSFA (Boyne & James 1980). In early reports, autogenous bone was applied as a sole grafting material and was associated with successful outcomes. However, the use of autogenous bone in MSFA has two major disadvantages: (1) the need to harvest a large amount of bone that may range from 1 to 5 cm^3 (Arias-Irimia *et al*. 2012) from, at least, a second surgical site, which increases the surgical time and the risk of morbidity, and (2) the high resorption rate associated with particulate autogenous bone (Shanbhag *et al*. 2014), which may exceed the rate of new bone formation during the consolidation phase and render a suboptimal augmentation outcome.

Bone graft substitutes

With the purpose of overcoming the limitations of autogenous bone grafts, the use of readily available bone graft substitutes (i.e. alloplastic materials, allografts, and xenografts), alone or in combination with bone autografts (Fig. 42-24f), has become the most commonly indicated option for the performance of MSFA procedures in contemporary practice.

Over the past three decades, multiple preclinical and clinical studies in MSFA have demonstrated successful clinical and histomorphometric outcomes in association with the use of a wide range of bone graft substitutes. Histologic analyses of human biopsy specimens obtained at different time points from sinuses augmented with bone graft substitutes have demonstrated that the vast majority of these materials are biocompatible, osteoconductive, and present a low resorption rate. For example, several studies have documented the presence of bovine xenograft particles in biopsies obtained after 7, 9, or even 11 years from the time of grafting (Traini *et al*. 2007; Mordenfeld *et al*. 2010; Galindo-Moreno *et al*. 2013), demonstrating its long-term stability, biocompatibility, and clinical viability in MSFA procedures (Fig. 42-31).

Furthermore, a histologic study by Pablo Galindo-Moreno and colleagues found the presence of small capillaries, cells, and new bone formation within the existing Haversian canal of bovine xenograft particles in samples obtained at 6 months after MSFA using a combination of autogenous bone and bovine xenograft particles (Galindo-Moreno *et al*. 2010), as shown in Fig. 42-32.

Although some authors have suggested the use of particulate autogenous bone in combination with a larger proportion of a bone substitute, such as bovine xenograft or allograft particles (Froum *et al*. 1998; Mordenfeld *et al*. 2014), to maximize the therapeutic outcomes, several systematic reviews on this topic are coincidental in that no specific bone grafting material or combination thereof has been shown to be patently superior (Wallace &Froum 2003; Aghaloo & Moy 2007; Pjetursson *et al*. 2008; Corbella *et al*. 2016; Danesh-Sani *et al*. 2017a). Specifically, a recently published systematic review aimed at analyzing long-term (≥5 years) implant-therapy outcomes after MSFA with particulate autogenous bone graft compared to MSFA with a mix of particulate autogenous bone graft and bone graft substitutes or bone graft substitutes alone (Starch-Jensen *et al*. 2018). Of the nine included studies, eight exclusively reported data after MSFA with a lateral window approach. The 5-year implant survival after MSFA using solely autogenous bone or bovine xenograft particles was 97% and 95%, respectively.

Nevertheless, there is a need for targeted long-term studies evaluating the performance of different bone grafting materials in MSFA to collect information that may aid clinicians in discerning what protocol may render more favorable and predictable results in a wide range of clinical scenarios.

Tissue engineering approaches

The application of tissue engineering strategies to enhance the predictability and outcomes of bone augmentation procedures, such as MSFA, is a therapeutic option (Avila-Ortiz *et al*. 2016). Tissue engineering therapies may include the use of biologics, such as such as recombinant human bone morphogenic protein 2 (rhBMP-2) (Triplett *et al*. 2009; Lin *et al*. 2016) or recombinant human platelet-derived growth factor BB (rhPDGF-BB) (Nevins *et al*. 2009), autogenous blood-derived products (Dragonas *et al*. 2019a, b) and cell therapy (Kaigler *et al*. 2015). These strategies have

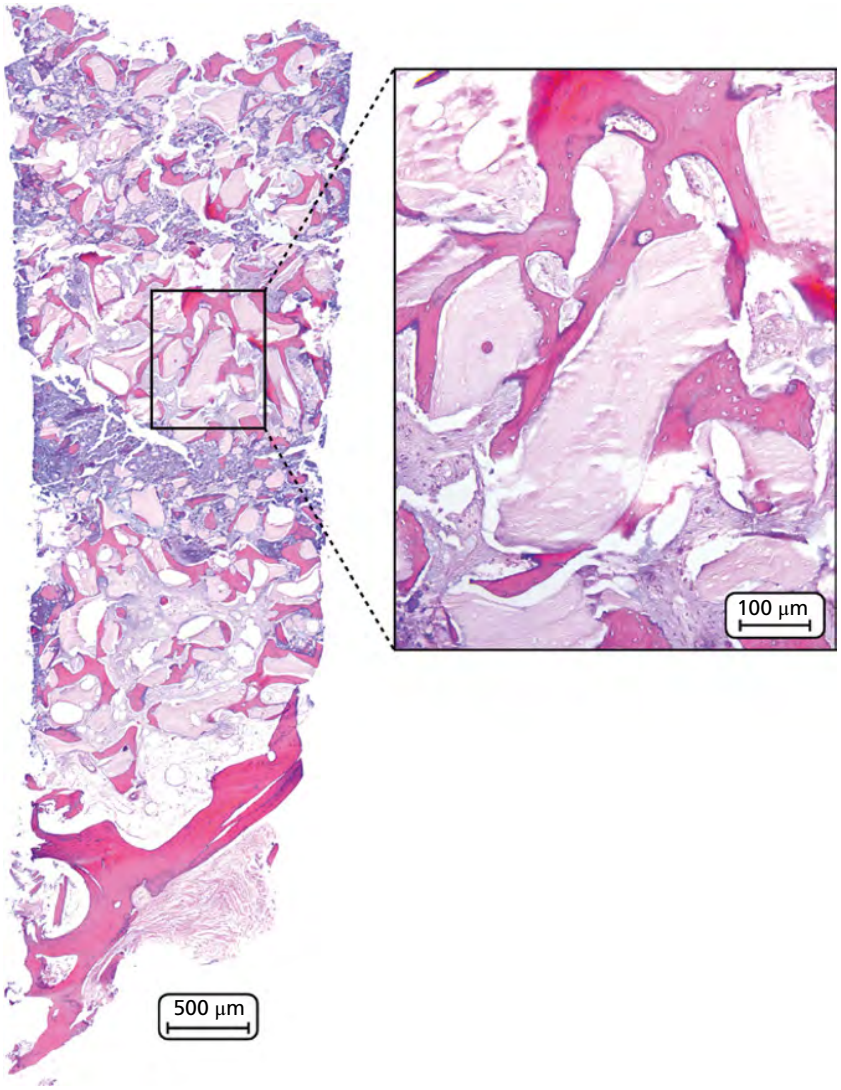

Fig. 42-31 Core biopsy obtained at the time of implant placement, approximately 6 months after MSFA using bovine xenograft particles. Hematoxylin and eosin staining. On the lower magnification image (left), note the presence of native bone at the bottom, corresponding with the residual bone height. On the higher magnification image (right), note the newly formed mineralized tissue in direct contact with remaining xenograft particles.

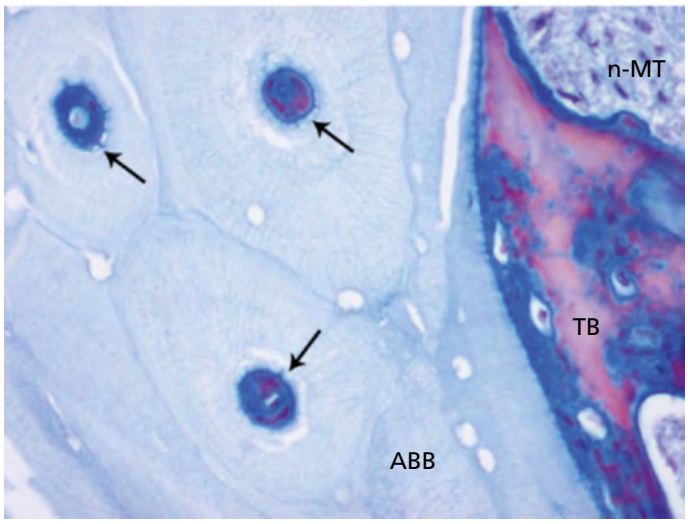

Fig. 42-32 Histomicrophotograph showing microvessels and newly formed mineralized tissue (n-MT) in intimate contact (TB) with and occupying the Haversian canals (arrows) of a bovine xenograft particle (ABB), illustrating the osteoconductivity of this material. Source: This was obtained from Fig. 1 in the following publication: Galindo-Moreno P, Padial-Molina M, Fernandez-Barbero JE, Mesa F, Rodriguez-Martinez D, O'Valle F. 2010. Optimal microvessel density from composite graft of autogenous maxillary cortical bone and anorganic bovine bone in sinus augmentation: Influence of clinical variables. Clin Oral Implants Res. 21(2):221-227. Reprinted with permission from Wiley and Sons.

shown promise and may be adopted to complement the osteoconductive properties of conventional bone graft substitutes or as monotherapy. However, their indication in MSFA is controversial because of the high degree of success and predictability associated with the use of conventional bone grafting materials, as well as the increased cost, preparation time, lack of structural integrity, and safety concerns associated with some of these strategies. Further studies to gather data on the most suitable indications and optimization of cost-effectiveness are required for tissue engineering therapies to be widely embraced in daily clinical practice.

Postoperative care

The level of postoperative pain experienced by patients undergoing MSFA procedures is generally mild and mostly limited to the first few days after surgery. Facial swelling and bruising are not uncommon and may extend from the inferior border of the orbit to the lower border of the mandible, or even to the neck. In order to reduce swelling, the local temperature of the treated area may be kept low by intermittent application of cooling pads on the face over the first 6–8 hours after surgery. A group of experts agreed that preoperative or postoperative corticosteroid therapy may be recommended to reduce the level of postsurgical swelling and discomfort. However, a consensus was not reached on the dosage because of the heterogeneity of the pharmacological regimens utilized by the members of the panel (Testori *et al*. 2012). Additionally, patients may be provided with prescriptions for non-steroidal anti-inflammatory drugs (NSAIDs), to control postoperative swelling and discomfort, and oral antibiotics, to reduce the risk of a postoperative infection, which is a controversial issue. Although there is no solid evidence supporting the therapeutic benefit of postoperative antibiotic regimens after MSFA, the same group of experts determined that there is a current trend in favor of the indication of such pharmacologic protocols and, therefore, recommended the indication of antibiotics prior to and/or after MSFA based on empirical experience (Testori *et al*. 2012). Patients should be instructed to avoid mechanical disturbance of the surgical area, such as direct, vigorous brushing. The use of antiseptic rinses (e.g. chlorhexidine 0.12 or 0.2%) twice daily may be indicated until suture removal for plaque control purposes. Occasionally, minor nasal bleeding (epistaxis) may occur within the first week. It is important to inform patients of this possibility in advance. If the patient needs to sneeze, the nostrils should not be blocked so that air pressure can be relieved, preventing early wound stability alterations.

Complications

According to a recent systematic review, intra- and postoperative complications after MSFA are typically minor and unrelated to the bone grafting material applied (Raghoebar *et al*. 2019). In this review, it was found that the most common intraoperative complication is perforation of the Schneiderian membrane, accounting for an approximate occurrence of 20% during MSFA procedures, which is coincidental with the findings of a previous systematic review on this topic (Pjetursson *et al*. 2008). Whether or not this complication influences implant survival rate has been debated. Although some studies have reported an association between membrane perforation and implant failure (Al-Moraissi *et al*. 2018), others found no correlation (Al-Dajani 2016; de Almeida Ferreira *et al*. 2017). However, Schneiderian membrane perforation, if not properly managed, appears to be associated with an increased risk of postoperative sinusitis and graft failure (Nolan *et al*. 2014). In the event of membrane perforation, it is recommended to elevate the membrane in the opposite direction to prevent further enlargement of the perforation. Smaller perforations (<5 mm) may be closed by using fibrin glue, suturing, or by covering them with an absorbable barrier, such as a collagen membrane, as shown in Fig. 42-33. In instances of larger perforations, where a stable seal cannot be achieved, aborting the grafting procedure should be considered.

According to the aforementioned systematic review, the second most common complication is abnormal postoperative bleeding (14.5%), whereas the occurrence of overall postoperative infections and subacute sinusitis was found to be very low, at 1.0% and 0.2%, respectively (Raghoebar *et al*. 2019). Sinusitis typically manifests at 3–7 days postsurgically and may lead to complete graft failure. A possible complication of sinusitis is a secondary infection that may spread to the orbita or even to the brain (Pereira *et al*. 2017). Therefore, infected sinus grafts must be treated immediately and effectively. Surgical re-entry and removal of the entire graft

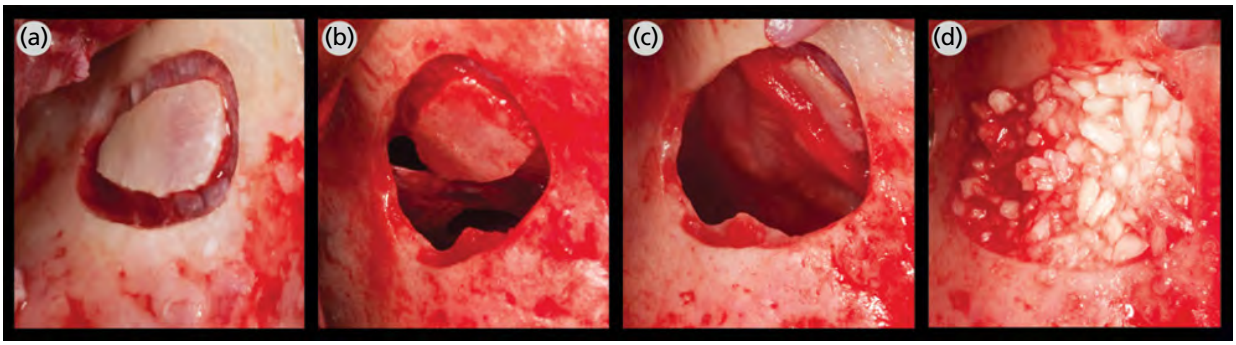

Fig. 42-33 (a) Lateral window outlined after using a piezosurgery instrument. (b) Two separate perforations occurred upon Schneiderian membrane elevation. The membrane was very thin in some areas. (c) An absorbable porcine collagen membrane was trimmed and carefully applied to seal the perforations. (d) Once the perforations were sealed, a particulate cortical allograft material was safely used to augment the maxillary sinus floor.

from the sinus cavity, plus administration of high doses of wide-spectrum antibiotics, are essential pillars of the clinical protocol.

Other reported causes of late MSFA failure include chronic infection (longer than 12 weeks), graft exposure and/or infection caused by premature wound dehiscence (Fig. 42-34a), idiopathic resorption of the entire bone graft, replacement of the bone graft with granulomatous tissue, ingrowth of soft tissue through the lateral window, oroantral fistula, and secondary sinus cysts. Rare iatrogenic complications after MSFA include adjacent tooth sensitivity or devitalization (Beck *et al*. 2018), implant migration into the sinus cavity (Galindo-Moreno *et al*. 2012b), severe antral hematoma (hemosinus) (Fig. 42-34b), injury to the infraorbital neurovascular bundle from deep flap dissection, or blunt trauma caused by the compression of the flap during retraction.

Outcomes

A wide variety of outcomes may be considered when assessing the short- and long-term success of MSFA. These may be categorized into clinical (e.g. wound healing patterns, incidence and type of surgical and prosthetic complications, implant survival and success), radiographic (e.g. linear or volumetric graft dimensional changes, marginal bone loss around implants), histologic/histomorphometric (e.g. structural features and proportion of different tissue compartments, cellularity and vascularity), molecular (e.g. expression of proteins of interest), and patient-reported outcome measures (e.g. perceived postoperative discomfort and quality of life). Nevertheless, MSFA is essentially an implant site development procedure. Hence, it can be argued that implant survival and success are the most relevant outcomes. Although the literature offers abundant information regarding implant survival after MSFA with a lateral window approach, there is limited data on implant success rates. Hence, this section will be focused on reviewing relevant information pertaining to implant survival in the context of MSFA via a lateral window approach from a historical perspective.

The findings from the 1996 Sinus Consensus Conference of the Academy of Osseointegration, which were based on retrospective data collection from 38 clinicians that collectively performed 1007 MSFA and placed 2997 implants over a 10-year period, revealed an overall survival rate of 90.0%. The majority of implants had been followed for at least 3 years. Of the 900 patient records that were screened, only 100 had radiographs of adequate quality for analysis of the effect of RBH on implant survival outcomes. In total, only 145 sinus grafts in 100 patients with 349 implants were analyzed. After a mean follow-up period of 3.2 years, 20 out of 349 implants were lost. Of the implants lost, 13 were placed in residual bone with a height of 4 mm and seven in residual bone with a height of 5–8 mm. None of the implants placed in sites presenting an RBH of >8 mm were lost. There was a statistically significant difference in implant loss when RBH was ≤4 mm as compared to ≥5 mm. However, data were so variable that no conclusions regarding the effect of bone grafting material, characteristics of the implants, and timing of implant placement could be drawn (Jensen *et al*. 1998).

As aforementioned, timing of implant placement (i.e. delayed or simultaneous with MSFA) is primarily dictated by the baseline RBH. Peleg and collaborators conducted a study to evaluate the survival rate after performing a one-stage sinus floor augmentation in sites presenting between 3 and 5 mm of RBH. Using the modified Caldwell–Luc technique, the maxillary sinus was elevated with composite grafts of symphyseal autograft and DFDBA in a 1:1 ratio. One hundred and sixty implants were placed in 63 elevated sinuses. A 100% survival rate of the implants was reported after 4 years (Peleg *et al*. 1999). In a follow-up study involving the placement of 2132 implants simultaneously with lateral MSFA in 731 patients presenting 1–5 mm of RBH, the same group reported an implant survival rate of 97.9% after 9 years of function (Peleg *et al*. 2006b).

In 2003, Stephen S. Wallace and Stuart J. Froum published a seminal systematic review on the survival rate of implants placed in areas that received MSFA (Wallace & Froum 2003). Clinical studies

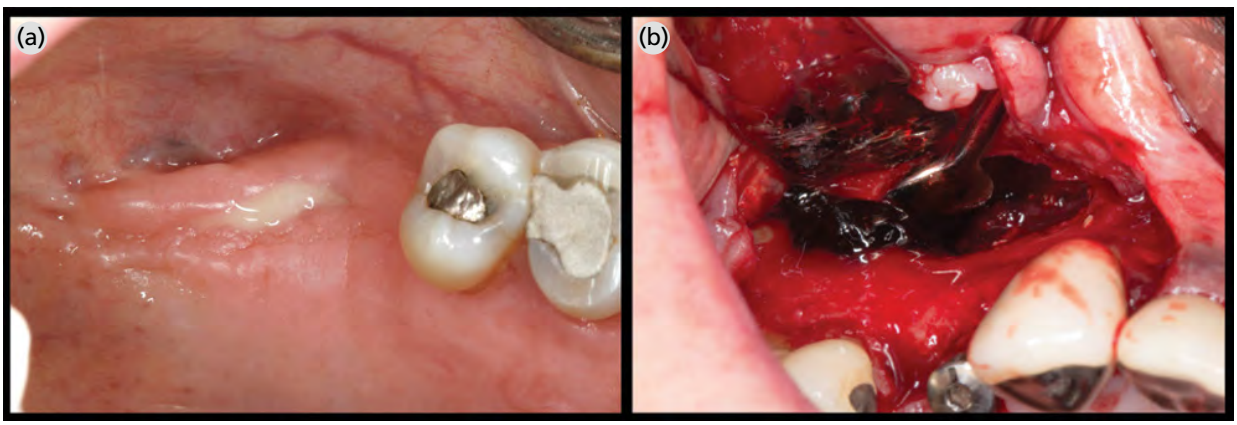

Fig. 42-34 (a) Premature wound dehiscence and acute infection. (b) Antral hematoma.

reporting a minimum of 20 MSFA interventions with a follow-up time of at least 1 year after functional loading were included. A total of 43 studies were selected, including three randomized controlled trials, five non-randomized controlled trials, 12 case series and 23 retrospective analyses. Thirty-four of the studies involved the performance of MSFA via a lateral window approach. The main findings were:

- Survival rate of implants placed in conjunction with MSFA via lateral window varied widely (61.7–100%), with an average of 91.8%.
- Survival rates of implants placed in sites that underwent MSFA compared favorably to those reported for implants placed in maxillary pristine bone that did not receive any bone grafting.
- Rough surface (textured) implants yielded higher survival rates than machined surface implants placed in conjunction with MSFA (91.6% vs. 84.0%, respectively).
- Implants placed into sinuses augmented with particulate autografts showed higher survival rates than those placed in sinuses that had been augmented with autogenous block grafts (92.3% vs. 83.3%, respectively).
- Implant survival rates were higher when barrier membranes were placed over the lateral window (93.6% vs. 88.7%, respectively).
- The utilization of grafts consisting of 100% autogenous bone or the inclusion of autogenous bone as a component of composite grafts did not affect implant survival.

Another systematic review published 5 years later included 48 prospective and retrospective studies reporting on 12 020 implants inserted in combination with MSFA using the lateral window approach (Pjetursson *et al*. 2008). Meta-analysis of data reported in the included studies indicated an estimated annual implant failure rate of 3.48%, translating into a 3-year implant survival rate of 90.1% (95% CI 86.4–92.8%). However, when data were analyzed at the subject level, the estimated annual implant failure rate was 6.04%, which translates to 16.6% of the subjects experiencing at least one implant loss over a period of 3 years. One of the main conclusions of the meta-analysis was that the implant surface significantly affected the outcome of the treatment. The annual failure rate of machined surface implants was 6.86%, which contrasts with the annual failure rate of 1.20% for rough surface implants. The overall 3-year survival rate for rough surface implants was 96.4% (95% CI 94.6–97.7%). The effect that delayed or simultaneous implant placement had on the survival rate was also assessed. Data from a total of 24 studies reporting the placement of 5672 simultaneous implants and 24 studies that involved the placement of 3560 delayed implants after MSFA was analyzed. The annual failure rates for the two methods were similar: 4.07% for the simultaneous approach and 3.19% for the delayed approach.

A recent systematic review including 11 prospective studies that reported the placement of 1517 implants with a minimum follow-up of 5 years after functional loading in 383 patients who underwent a total of 615 MSFA with a lateral window approach, reported an estimated annual implant loss of 0.43% (95% CI: 0.37–0.49) representing a 5-year implant survival rate of 97.8% (Raghoebar *et al*. 2019). Quantitative analyses showed no significant differences in terms of implant survival between edentulous or dentate patients and implants placed simultaneously or in a delayed approach. Likewise, the type of bone grafting material, whether it was autogenous, a substitute, or a combination, did not influence the survival rates. On the basis of contemporary evidence, it can be concluded that MSFA via a lateral window approach is a reliable procedure to facilitate the management of the partially and fully edentulous maxilla with implant-supported prostheses, and it is associated with high implant survival rates (Jepsen *et al*. 2019).

Maxillary sinus floor augmentation: transalveolar approach

Many of the principles and concepts already presented and discussed in regard to MSFA with a lateral window approach pertain to transalveolar MSFA. Hence, subsequent sections of this chapter will expand on distinctive aspects that specifically replace transalveolar MSFA.

Indications and contraindications

Transalveolar MSFA is indicated for the prosthetic rehabilitation of edentulous spaces in the posterior maxilla presenting >5 mm of RBH, a flat sinus floor, and adequate crestal bone width for simultaneous implant installation. Placement of short implants may be an alternative to transalveolar MSFA in some cases. Transalveolar MSFA is compatible with either single or multiple implant placement, although single implant placement is most commonly indicated. General contraindications for this technique are similar to those previously described for the lateral window approach. In addition, patients with a history of inner ear alterations and positional vertigo are not good candidates for a transalveolar MSFA involving the use of a mallet. In these patients, other alternatives should be explored. Regarding local contraindications, the presence of robust septa, a steep sinus floor (>45° inclination), and sites of close proximity between the lateral and the medial sinus walls may not be suitable for transalveolar MSFA, particularly when using osteotomes. In these situations, there is a high risk of perforating the sinus membrane.

Surgical technique

As previously acknowledged, several modifications of the original technique described by Summers have

been proposed since 1994. The following describes a contemporary surgical protocol to perform transalveolar MSFA, based on a previous publication (Pjetursson & Lang 2014):

1. A presurgical rinse with an aqueous solution containing chlorhexidine (0.12% or 0.2%) is performed for a period of 1 minute.
2. Perioral cutaneous surfaces may be disinfected (e.g. wiping with iodine solution, unless contraindicated because of allergy).
3. Local infiltrative anesthesia is delivered on the buccal and palatal mucosa adjacent to the surgical site. Different from the recommendations for MSFA with a lateral window approach, blocking the infraorbital, greater palatine, and posterior superior alveolar nerve is usually not required.
4. Either an open flap or a flapless approach can be followed. For an open flap approach, a minimally invasive mid-crestal incision, or slightly palatal incision if the amount of keratinized mucosa is limited, is made and a mucoperiosteal flap is raised (Fig. 42-34a). For a flapless approach, which should be only indicated in sites presenting sufficient keratinized mucosa, a circular scalpel (punch) of a diameter slightly larger than that of the planned implant is utilized to outline the overlying mucosa, which is subsequently excised using a small periosteal elevator.
5. Once the bone has been exposed, the implant positions are marked on the alveolar crest with a small round bur or a similar instrument (Fig. 42-35a). The use of a surgical stent based on the prosthetic plan is recommended.
6. After precisely marking the implant position(s), the implant osteotomy is prepared with drills of increasing size up to a diameter about 1–1.5 mm smaller than that of the planned implant and staying approximately 2 mm coronal to the maxillary sinus floor (i.e. estimated RBH minus 2 mm), to avoid perforating the Schneiderian membrane.
7. After radiographically confirming the distance to the sinus floor, an osteotome with the same or slightly wider diameter of the last drill utilized is inserted in the osteotomy towards the bony wall that separates the osteotomy space and the sinus floor (Fig. 42-35b). After manual resistance is encountered, the osteotome is progressively advanced in a vertical direction with light malleting in order to create a "greenstick" fracture on the bone and slightly push the Schneiderian membrane apically (Fig. 42-35c). An osteotome with a tapered tip may be used to minimize the force needed to fracture the compact bone (Fig. 42-36).

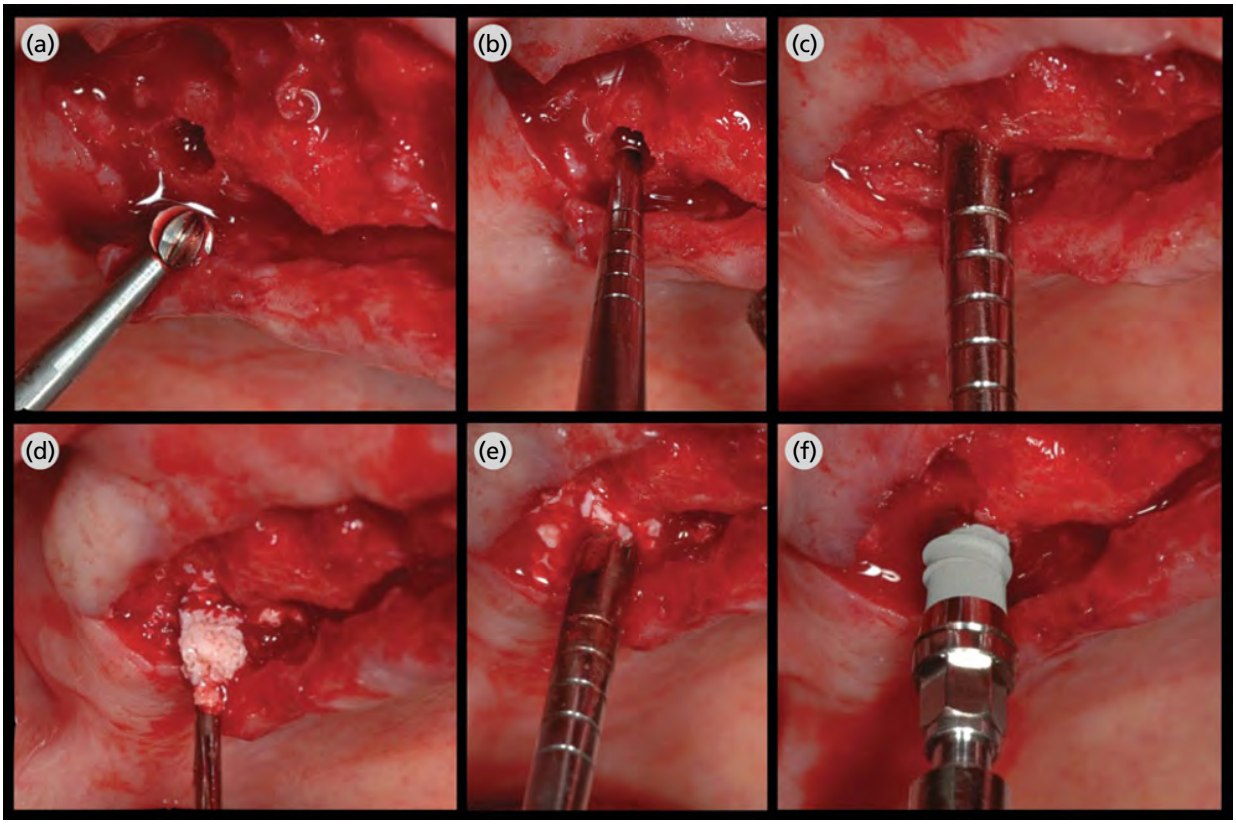

Fig. 42-35 Sequence showing the essential steps of a transalveolar MSFA procedure with simultaneous implant placement. (a) Upon elevation of a full-thickness flap, a round bur is used to mark the osteotomy site and facilitate the insertion of the first osteotome. (b) First osteotome is progressively inserted with gentle malleting to create a greenstick fracture of the sinus floor. (c) An osteotome of wider diameter is inserted to expand the osteotomy. (d) Bovine xenograft particles are placed into the site after the osteotomy is created. (e) The final osteotome is used to carefully push the bone grafting material in the subantral space. (f) The implant is inserted once the grafting procedure is completed.

Fig. 42-36 Osteotome tips of different design. From left to right: tapered rounded, tapered concave, and parallel flat.

Instead of using osteotomes to fracture the sinus floor, piezoelectric tips can be employed. The main advantage of the piezosurgery tips is that the risk of membrane perforation is reduced (Sohn *et al*. 2009). This could also reduce the risk of benign paroxysmal positional vertigo as a direct consequence from the malleting. A potential disadvantage, however, is that it is more time consuming than malleting, especially when the cortical bone at the sinus floor is thick and dense. Another emerging, although not fully validated, alternative to elevate the Schneiderian membrane through a transalveolar canal is the use of a balloon device (Asmael 2018).

From this point onwards, the subsequent steps are determined by whether the transalveolar MSFA procedure is completed by using a bone grafting material or not.

Implant placement without bone grafting material

1. An osteotome with a diameter about 0.5–1 mm narrower than that of the planned implant is progressively advanced into the sinus cavity by gentle malleting until it penetrates the sinus floor up to the desired length respective to the crestal bone. Extreme care should be taken to avoid increasing the diameter of the osteotomy excessively, which may compromise primary stability, or advancing the osteotome too deep, which may result in the perforation of the sinus membrane. Hence, the tip of the last osteotome to be used must have a shape and diameter that are suitable for the implant to be placed. For example, for a cylindrical implant with a diameter of 4.1 mm, the last osteotome should be a straight osteotome with a diameter that does not exceed 3.5 mm. It is also important that the last osteotome only enters the preparation site once. If several attempts have to be made in sites presenting soft bone, there is a high risk of increasing the diameter of the bone preparation, which, again, may jeopardize achieving primary stability. On the contrary, if the diameter of the last osteotome is too small compared with the implant diameter, too much force would be required to insert the implant, creating more trauma, which may be detrimental for successful osseointegration (Abrahamsson *et al*. 2004; Wang *et al*. 2017).
2. The final step before placing the implant is to check that the preparation is patent to the planned insertion depth. A narrower osteotome with a rounded tip or a depth gauge may be pushed to a depth that is congruent with the implant dimensions.

Implant placement with bone grafting materials

1. When performing transalveolar MSFA using bone grafting materials (Fig. 42-35d), the osteotomes are not supposed to enter the sinus cavity *per se*. As the bone graft is gently pushed vertically using an osteotome, the trapped fluid creates a hydraulic pressure effect that displaces both the fractured sinus floor and the Schneiderian membrane upwards (Fig. 42-35e). Prior to inserting the bone grafting material, it is very important to evaluate whether a perforation of the Schneiderian membrane occurred. This may be done by direct visualization using high magnification equipment and/or with the Valsalva maneuver (Farina *et al*. 2018). This maneuver is done by blocking the nostrils and asking the patient to blow air through the nose while looking at the implant osteotomy. If air leaks out, the sinus membrane is likely perforated, and no particulate grafting material should be placed or an attempt should be made to seal the perforation with a barrier material (e.g. collagen sponge or membrane), which may be technically challenging. However, it is important to keep in mind that the Valsalva maneuver may render a high number of false negatives, depending on the location and extent of the perforation. Hence, the validity of this assessment should be taken with caution when making clinical decisions.
2. As aforementioned in the graftless approach, the preparation should be checked for patency before implant placement (Fig. 42-35f).

If the procedure involved flap elevation, tension-free primary closure is necessary. Whether an open flap or a flapless approach was followed, if implant

primary stability is adequate, healing abutments may be delivered according to a non-submerged implant placement protocol.

Grafting material selection

As previously discussed in the section addressing the lateral window approach, the need to use bone grafting materials for adequate bone formation and implant survival is a controversial topic that has also been extensively debated in the context of transalveolar MSFA.

In the original publication describing the transalveolar approach, placement of harvested autogenous bone into the subantral space created after displacing the Schneiderian membrane was recommended to maintain the volume of the elevated area (Tatum 1986). Several years later, Summers introduced the BAOSFE technique, which was not restrictive regarding the type of bone grafting material to be employed (Summers 1994). Subsequently, a multicenter retrospective study involving nine clinicians, including Robert B. Summers, was carried out to determine the outcomes of the BAOSFE technique in function of the use of different bone grafting materials. A total of 174 implants placed in 101 patients was evaluated. Autogenous bone, allografts, and xenografts were employed as sole grafting materials or in different combinations. The authors concluded that the type of grafting material did not influence implant survival up to 66 months (Rosen *et al*. 1999).

In another retrospective study, sinus floor remodeling after implant insertion using a modified transalveolar technique without the use of a bone grafting material was assessed radiographically (Schmidlin *et al*. 2008). A total of 24 patients was included. Implant survival rate was 100% after a mean follow-up period of approximately 18 months. Bone fill around the apex of the implants in radiographs obtained at different time points was compared with baseline assessments. The reported mean bone height gain was 2.2 mm on the mesial and 2.5 mm on the distal. A later prospective clinical study reported the outcomes of 25 dental implants with a length of 10 mm placed using transalveolar MSFA without bone grafting material. The implants were protruded into the sinus cavity an average of 4.9 mm. After a 5-year follow-up, the implant protrusion was reduced to 1.5 mm. Hence, the authors reported that an average of 3.4 mm of the penetrating part of the implants was surrounded by new bone, which represented approximately 70% of bone gain from the time of implant placement (Nedir *et al*. 2010). Although these studies provide radiographic evidence of new bone formation in absence of a bone grafting material after transalveolar MSFA, the results must be taken with caution because of the relatively low sample size, short follow-up time and lack of standardization of the radiographic measurements.

The patterns of radiographic bone remodeling after placement of 25 implants in 19 patients using a transalveolar MSFA approach with a composite graft (i.e. mix of bovine xenograft particles and autogenous bone) were evaluated in another study. Periapical radiographs were obtained pre- and postsurgically at 3 and 12 months. The mean height of the bone contour apical and mesial to the implant body was 1.52 mm at the time of surgery, but this was significantly reduced to 1.24 mm at 3 months and 0.29 mm after 12 months. It was concluded that the grafted area apical to the implants underwent shrinkage and remodeling, and the original outline of the sinus was eventually consolidated and replaced by a new cortical plate (Bragger *et al*. 2004).

In a prospective comparative study, 252 implants were inserted using a transalveolar MSFA technique with or without grafting material (Pjetursson *et al*. 2009a). Bovine xenograft particles were used as the sole bone grafting material in the placement of 88 implants, whereas the remaining 164 implants were inserted in absence of a grafting material. Mean radiographic bone gain at 1 year measured in periapical radiographs was 4.1 ± 2.4 mm in the sites that received a bone grafting material, whereas the observed gain was 1.7 ± 2.0 mm in sites that did not receive bone grafting.

A recent systematic review aimed at analyzing the survival rate of implants placed using transalveolar MSFA with and without bone grafting (Shi *et al*. 2016). Thirty-four studies met the inclusion criteria. These studies reported the outcomes of a total of 3119 implants placed in 1977 patients. Most of the reported implant failures (84 of 102) occurred within 12 months of functional loading. Cumulative survival rates were higher in the sites that did not receive a bone grafting material (97.30% vs. 95.89%; $P = 0.05$). Although this comparison reached statistical significance, its clinical significance is questionable, particularly considering the relatively short follow-up period.

Postoperative care

Standards of postsurgical care after transalveolar MSFA with simultaneous implant insertion are similar to those after standard implant placement. Additionally, as aforementioned, patients should be instructed to avoid mechanical disturbance of the surgical area, especially if implants are placed in a non-submerged fashion. The use of antiseptic rinses (e.g. chlorhexidine 0.12 or 0.2%) twice daily may be indicated until suture removal for plaque control purposes. As with MSFA via a lateral window approach, minor nasal bleeding may occur within the first week. It is important to inform patients in advance. If the patient needs to sneeze, the nostrils should not be blocked so that air pressure can be adequately relieved, preventing early wound stability disturbance. Although there have been no studies comparing the outcomes associated with and without the intake of antibiotics after transalveolar MSFA, antibiotic prophylaxis for 10 days has been recommended by some authors (Wang *et al*. 2019).

Complications

As with the lateral window approach, the most common intraoperative complication in transalveolar MSFA is perforation of the Schneiderian membrane. The inevitable "blind" use of osteotomes and insertion of the bone grafting material increases the possibility of inadvertent sinus membrane perforation when performing these techniques. A systematic review aimed at assessing the outcomes of implants placed in sites that underwent transalveolar MSFA reported that the rate of perforation of the Schneiderian membrane varied between 0% and 21.4%, with a mean occurrence of 3.8%, out of a subsample of 1621 implants from eight of the 19 studies that met the eligibility criteria of this review (Tan *et al*. 2008). Small perforations (<1 mm) may be sealed through the transalveolar preparation using tissue fibrin glue or a collagen sponge. If a large perforation is identified before a particulate bone grafting material is inserted, aside from aborting the surgical procedure, clinicians may opt for: (1) using a bone grafting material with different properties (e.g. collagenated xenograft), (2) proceeding with no bone grafting material (graftless approach), and/or (3) the placement of a shorter implant.

Postoperative infections after transalveolar MSFA are rare, ranging from 0% to 2.5%, with a mean rate of 0.8% (Tan *et al*. 2008). Other possible complications may include abnormal postoperative hemorrhage, nasal bleeding, nasal obstruction, hematoma, and benign paroxysmal positional vertigo. Vertigo episodes are usually associated with aggressive malleting and may cause substantial stress to patients if not correctly identified and properly managed (Vernamonte *et al*. 2011).

Outcomes

As already stated regarding MSFA via a lateral window approach, a plethora of outcomes (i.e. clinical, radiographic, histologic/histomorphometric, molecular, and patient-reported) may also be assessed in the context of transalveolar MSFA. However, being a procedure primarily indicated for implant site development, the most relevant, and also most commonly reported, clinical outcome following transalveolar MSFA is implant survival (Fig. 42-37).

In the aforementioned multicenter retrospective study conducted by Paul S. Rosen and collaborators to evaluate the BAOSFE technique, implant survival rate up to 66 months was 96% if baseline RBH was at least 5 mm, but it dropped to 85.7% if RBH was ≤4 mm (Rosen *et al*. 1999). Similar results were reported in a prospective study in which 20% of the implants were placed in sites with a RBH of <5 mm, which tested the limits of the transalveolar MSFA technique (Pjetursson *et al*. 2009b). The survival rates were 91.3% for implants placed in sites with a baseline RBH ≤4 mm and 90% for implants placed in sites that exhibited a baseline RBH between 4 and 5 mm, which strongly contrasts with the 100% survival rate

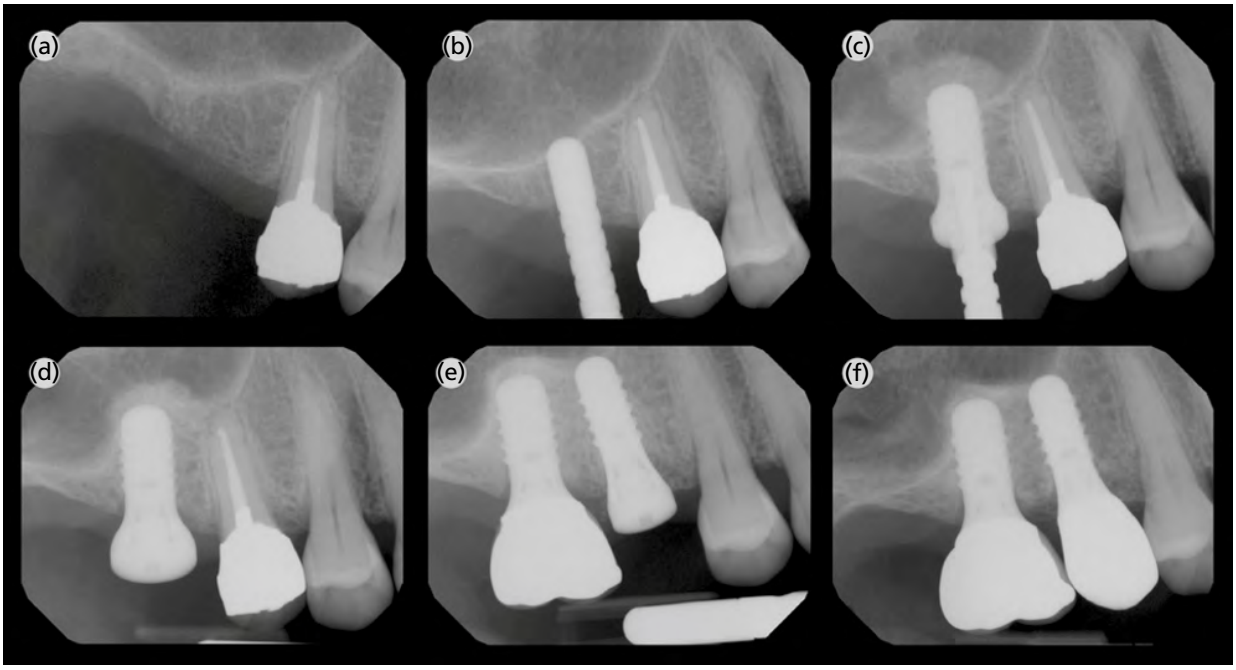

Fig. 42-37 Sequence showing the radiographic outcomes of transalveolar MSFA with simultaneous implant placement to replace a maxillary right first molar. (a) Baseline periapical radiograph. (b) Control radiograph using a radiographic pin after creating a greenstick fracture of the maxillary sinus floor with the final osteotome. (c) Radiograph obtained after grafting the sinus floor with bovine xenograft particles and inserting the implant. (d) Radiograph obtained 4 months later prior to sending the patient to the restorative clinician. (e) Four years after placement of the first implant, an implant was placed to replace the second premolar, which was extracted because of a vertical root fracture. (f) Radiograph obtained at 6 years after placement of the first implant in the molar position. Note the increased radiopacity and consolidation of the grafted area and the stable marginal bone levels around both implants.

of implants placed in sites that exhibited a baseline RBH >5 mm. Moreover, the survival rate of 6-mm implants was only 48%. This clearly demonstrates that the transalveolar MSFA technique was most predictable when placing implants with a length ≥8 mm in sites that presented a baseline RBH ≥5 mm, which is also supported by the findings of other studies, as discussed by Del Fabbro and collaborators in their systematic review on this topic (Del Fabbro *et al*. 2012)

Another systematic review primarily aimed at analyzing the survival rates of implants inserted in combination with transalveolar MSFA included a total of 19 studies reporting on 4338 implants (Tan *et al*. 2008). Meta-analyses of the data extracted from these studies revealed an estimated annual failure rate of 2.48%, which translated to an estimated 3-year survival rate of 92.8% (95% CI 87.4–96.0%). Furthermore, subject-level analyses revealed an annual failure of 3.71%, which translated to at least one implant loss in 10.5% of the subjects over a period of 3 years.

Patient-centered outcome measures (PROMs) have emerged in recent years as a relevant component of clinical research. A previously mentioned prospective comparative study (Pjetursson *et al*. 2009b), represents one of the earliest examples in the field of MSFA research in which PROMs were assessed. Of the 163 patients enrolled in this study, 23% found the surgical experience unpleasant. When asked about other postsurgical complications, 5% of the patients felt their head was tilted too far back during the surgery, and 5% experienced vertigo, nausea, and felt disoriented after the surgical procedure. Nonetheless, 90% of the patients expressed that they would be willing to undergo this treatment again, if necessary.

Summary

Multiple therapeutic options for the rehabilitation of completely or partially edentulous patients presenting posterior tooth loss are available. Maxillary sinus floor augmentation (MSFA) is an implant site development procedure that allows for the simultaneous or delayed insertion of standard-length implants in posterior edentulous segments presenting limited residual bone height (RBH). Different modalities of MSFA have been described in the literature. The most commonly indicated modalities are MSFA with a transcrestal or a lateral window approach. Each modality has different indications, primarily depending on the amount of RBH, horizontal ridge width, and the possibility of achieving implant primary stability, but both have been generally associated with high long-term implant survival rates regardless of the bone grafting material utilized (Jepsen *et al*. 2019). Besides the significance of MSFA as an effective implant site development procedure, it also represents an excellent research model for the study of the healing dynamics associated with different grafting materials or regenerative strategies for the treatment of craniofacial defects (Avila-Ortiz & Galindo-Moreno 2014).

Clinical symptoms of trauma from occlusion

Angular bony defects

It has been claimed that *angular bony defects* and *increased tooth mobility* are important symptoms of trauma from occlusion (Glickman 1965, 1967). The validity of this suggestion has, however, been questioned (see Chapter 13). Thus, angular bony defects have been found at teeth affected by *trauma from occlusion* as well as at teeth with normal occlusal function (Waerhaug 1979). This means that the presence of angular bony defects *cannot per se* be regarded as an exclusive symptom of trauma from occlusion.

Increased tooth mobility

Increased tooth mobility, determined clinically, is expressed in terms of amplitude of displacement of the crown of the tooth. Increased tooth mobility can, indeed, be observed in conjunction with *trauma from occlusion*. It may, however, also be the result of a reduction of the height of the alveolar bone with or without an accompanying angular bony defect caused by plaque-associated periodontal disease (see Chapter 13). Increased tooth mobility resulting from occlusal interferences may further indicate that the periodontal structures have adapted to an altered functional demand, that is a widened periodontal ligament with a normal tissue composition has become the end result of a previous phase of progressive tooth mobility (see Chapter 13) associated with trauma from occlusion.

Progressive (increasing) tooth mobility

In Chapter 13, it was concluded that the diagnosis of trauma from occlusion should be used solely in situations where a progressive mobility could be observed. Progressive tooth mobility can be identified only through a series of repeated tooth mobility measurements carried out over a period of several days or weeks.

Clinical assessment of tooth mobility (physiologic and pathologic tooth mobility)

If, in the traditional clinical measurement of tooth mobility, a comparatively large force is exerted on the crown of a tooth which is surrounded by a normal

*Deceased.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

periodontium, the tooth will tip within its alveolus until a closer contact has been established between the root and the marginal (or apical) bone tissue. The magnitude of this tipping movement, which is normally assessed using the tip of the crown as a reference point, is referred to as the "*physiologic*" tooth mobility. The term "*physiologic*" implies that "*pathologic*" tooth mobility may also occur. What, then, is "pathologic" tooth mobility?

1. If a similar force is applied to a tooth which is surrounded by a periodontal ligament with an increased width, the excursion of the crown in the horizontal direction will increase; the clinical measurement consequently demonstrates that the tooth has an increased mobility. Should this increased mobility be regarded as "pathologic"?
2. An increased tooth mobility, that is an increased displacement of the crown of the tooth after force application, can also be found in situations where the height of the alveolar bone has been reduced, but the remaining periodontal ligament has a normal width. At sites where this type of bone loss is extensive, the degree of tooth mobility (i.e. excursion of the crown) may be pronounced. Should this increased tooth mobility be regarded as "pathologic"?

   Figure 43-1b shows a tooth which is surrounded by alveolar bone of reduced height. The width of the remaining periodontal ligament, however, is within normal limits. A horizontally directed force applied to the crown of the tooth in this case will result in a larger excursion of the crown than if a similar force is applied to a tooth with normal height of the alveolar bone and normal width of the periodontal ligament (Fig. 43-4a). There are reasons to suggest that the so-called *increased mobility* measured in the case shown in Fig. 43-1b is, indeed, *physiologic*. The validity of this statement can easily be demonstrated if the displacement of the two teeth is assessed not from the crown, but from a point on the root at the level of the bone crest. If a horizontal force is directed to the teeth in Fig. 43-1, the reference points (*) on the root surfaces will be displaced a similar distance in both instances. Obviously, it is not the length of the excursive movement of the crown that is important from a biologic point of view, but the *displacement of the root* within its remaining periodontal ligament.

   In plaque-associated periodontal disease, bone loss is a prominent feature. Another so-called classical symptom of periodontitis is "increased tooth mobility". It is important to realize, however, that in many situations with even or "horizontal" bone loss patterns, the increased crown displacement (tooth mobility) assessed by clinical measurements should, according to the above discussion, also be regarded as physiologic; the movement of the root within the space of its remaining "normal" periodontal ligament is normal.
3. Increased crown displacement (tooth mobility) may also be detected by clinical measurement where a "horizontal" force is applied to teeth with angular bony defects and/or increased width of the periodontal ligament. If this mobility does not increase gradually – from one observation interval to the next – the root is surrounded by a periodontal ligament of increased width but normal composition. This mobility should also be considered *physiologic* since the movement is a function of the height of the alveolar bone and the width of the periodontal ligament.
4. Only *progressively increasing tooth mobility*, which may occur in conjunction with trauma from occlusion, is characterized by active bone resorption (see Chapter 13), and which indicates the presence of inflammatory alterations within the periodontal ligament tissue, may be considered *pathologic*.

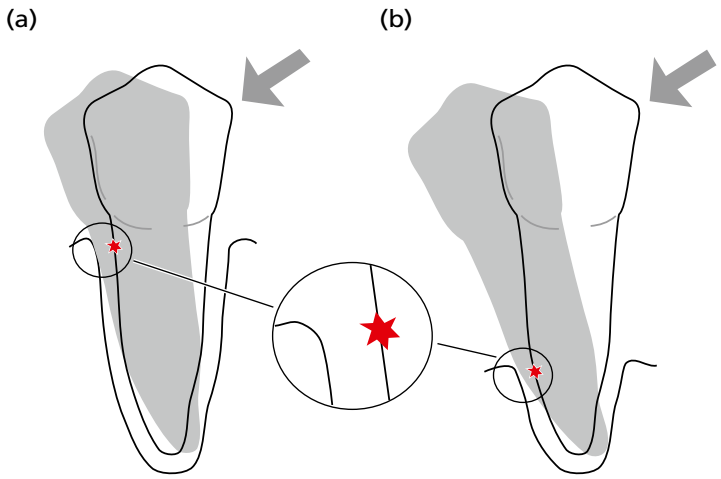

Fig. 43-1 (a) Normal "physiologic" mobility of a tooth with normal height of the alveolar bone and normal width of the periodontal ligament. (b) Mobility of a tooth with reduced height of the alveolar bone. The distance of the horizontal displacement of the reference point (*) on the roots is the same in the two situations (a, b).

Treatment of increased tooth mobility

A number of situations will be described which may call for treatment aimed at reducing an increased tooth mobility.

Situation 1

Increased mobility of a tooth with increased width of the periodontal ligament but normal height of the alveolar bone

If a tooth (e.g. a maxillary premolar) is fitted with an improper filling or crown restoration, occlusal interferences develop and the surrounding periodontal tissues become the seat of inflammatory reactions, that is trauma from occlusion (Fig. 43-2). If the restoration is designed such that the crown of the tooth in occlusion is subjected to undue forces directed in a buccal direction, bone resorption phenomena develop in the buccomarginal and linguoapical pressure zones with a resulting increase of the width of the periodontal ligament in these zones. The tooth becomes hypermobile or moves away from the "traumatizing" position. Since such traumatizing forces in teeth with normal periodontium or overt gingivitis cannot result in pocket formation or loss of connective tissue attachment, the resulting increased mobility of the tooth should be regarded as a physiologic adaptation of the periodontal tissues to the altered functional demands. A proper correction of the anatomy of the occlusal surface of such a tooth, that is occlusal adjustment, will normalize the relationship between the antagonizing teeth in occlusion, thereby eliminating the excessive forces. As a result, apposition of bone will occur in the zones previously exposed to resorption, the width of the periodontal ligament will become normalized, and the tooth stabilized, that is it reassumes its normal mobility (Fig. 43-2). In other words, resorption of alveolar bone which is caused by trauma from occlusion is a reversible process which can be treated by the elimination of occlusal interferences.

The capacity for bone regeneration after resorption following trauma from occlusion has been documented in a number of animal experiments (Waerhaug & Randers-Hansen 1966; Polson *et al*. 1976a; Karring *et al*. 1982; Nyman *et al*. 1982). In such experiments, the induced bone resorption not only involved the bone within the alveolus but also the alveolar bone crest. When the traumatizing forces were removed, bone tissue was deposited not only on the walls of the alveolus, thereby normalizing the width of the periodontal ligament, but also on the bone crest area, whereby the height of the alveolar bone was normalized (Fig. 43-3) (Polson *et al*. 1976a). In the presence of an untreated, plaque-associated lesion in the soft tissue, however, substantial bone regrowth did not always occur (Fig. 43-4) (Polson *et al*. 1976b).

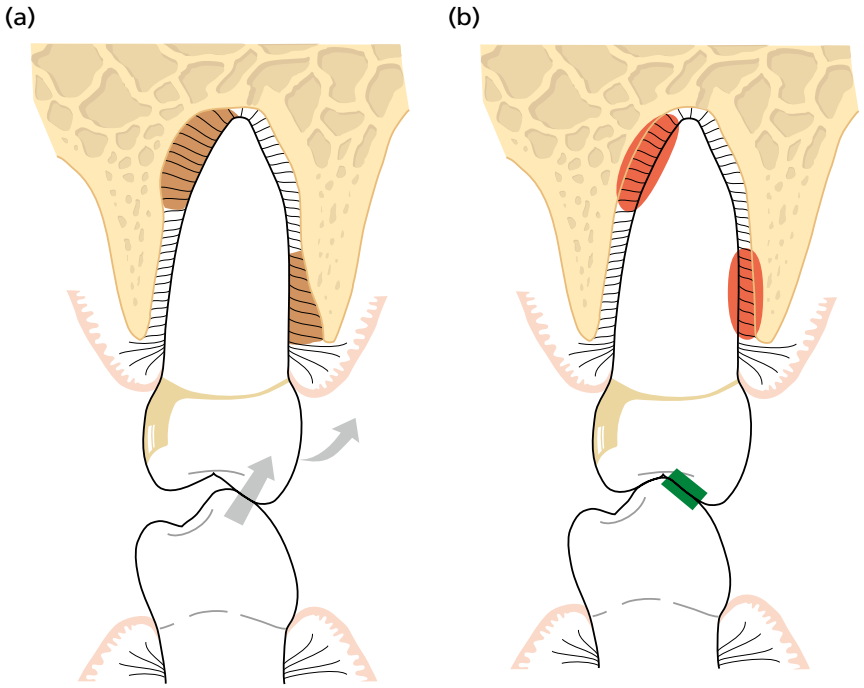

Fig. 43-2 (a) Contact relationship between a mandibular and a maxillary premolar in occlusion. The maxillary premolar is fitted with an artificial restoration with an improperly designed occlusal surface. Occlusion results in horizontally directed forces (arrows) which may produce an undue stress concentration within the "brown" areas of the periodontium of the maxillary tooth. Resorption of the alveolar bone occurs in these areas. A widening of the periodontal ligament can be detected as well as increased mobility of the tooth. (b) Following adjustment of the occlusion, the horizontal forces are reduced. This results in bone apposition ("red areas") and a normalization of the tooth mobility.

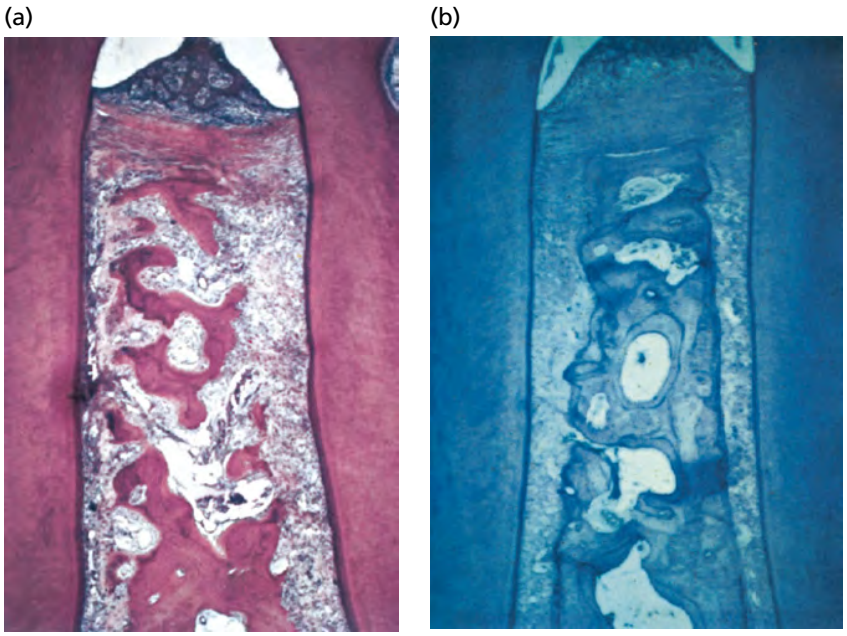

Fig. 43-3 Photomicrographs illustrating the interdental area between two mandibular premolars in the monkey. (a) Two premolars are exposed to jiggling forces. Note the reduction of alveolar bone in the area and the location of the bone crest. Ten weeks after the elimination of the jiggling forces, (b) a considerable regeneration of bone has occurred. Note the increase of the height of the interdental bone and the normalization of the width of the periodontal ligaments. The apical end of the junctional epithelium is located at the cementoenamel junction. (Source: Polson *et al*. 1976a. Reproduced with permission from John Wiley & Sons.)

Situation 2

Increased mobility of a tooth with increased width of the periodontal ligament and reduced height of the alveolar bone

When a dentition has been properly treated for moderate-to-advanced periodontal disease, gingival health is established in areas of the dentition where teeth are surrounded by periodontal structures of reduced height. If a tooth with a reduced periodontal tissue support is exposed to excessive horizontal forces (trauma from occlusion), inflammatory reactions develop in the pressure zones of the periodontal ligament with

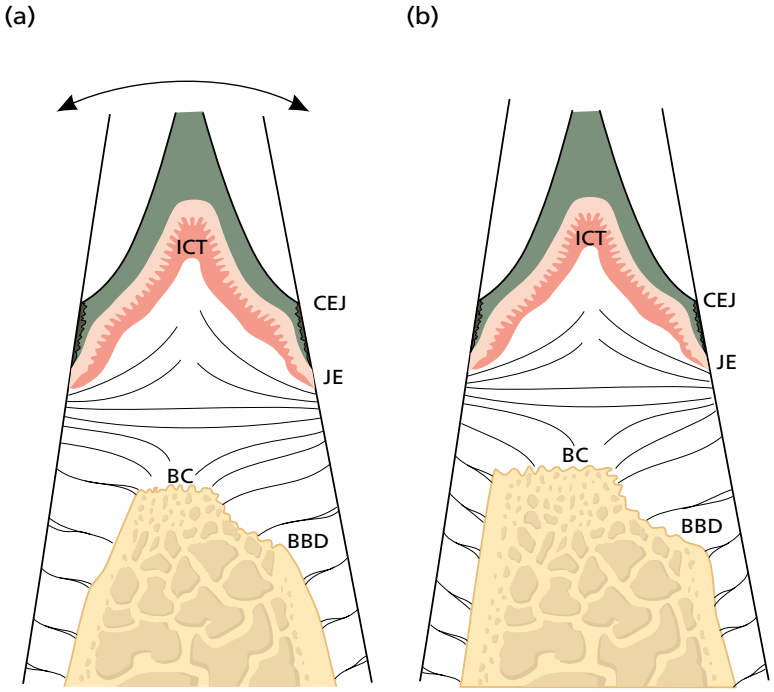

Fig. 43-4 In the presence of an existing marginal inflammation, alveolar bone lost by jiggling trauma (a), will not always regenerate following elimination of the traumatic forces (b). BBD, bottom of angular bony defect; BC, alveolar bone crest; CEJ, cementoenamel junction; ICT, infiltrated connective tissue; JE, apical end of junctional epithelium. (Source: Polson *et al*. 1976b. Reproduced with permission from John Wiley & Sons.)

accompanying bone resorption. These alterations are similar to those which occur around a tooth with supporting structures of a normal height; the alveolar bone is resorbed, the width of the periodontal ligament is increased in the pressure/tension zones, and the tooth becomes hypermobile (Fig. 43-5a). If the excessive forces are reduced or eliminated by occlusal adjustment, bone apposition to the "pre-trauma" level will occur, the periodontal ligament will regain its normal width, and the tooth will become stabilized (Fig. 43-5b).

Conclusion (situations 1 and 2): Occlusal adjustment is an effective therapy against increased tooth mobility when such mobility is caused by an *increased width* of the periodontal ligament.

Situation 3

Increased mobility of a tooth with reduced height of the alveolar bone and normal width of the periodontal ligament

The increased tooth mobility which is the result of a reduction in height of the alveolar bone without a concomitant increase in width of the periodontal membrane cannot be reduced or eliminated by occlusal adjustment. In teeth with normal width of the periodontal ligament, no further bone apposition on the walls of the alveoli can occur. If such an increased tooth mobility does not interfere with the patient's chewing function or comfort, no treatment is required. If the patient experiences the tooth mobility as disturbing, however, the mobility can only be reduced in this situation by splinting, that is by joining the mobile tooth/teeth together with other teeth in the jaw into a fixed unit – a splint.

A splint is "an appliance designed to stabilize mobile teeth" and may be fabricated in the form of joined composite fillings, fixed bridges, removable partial prostheses, etc.

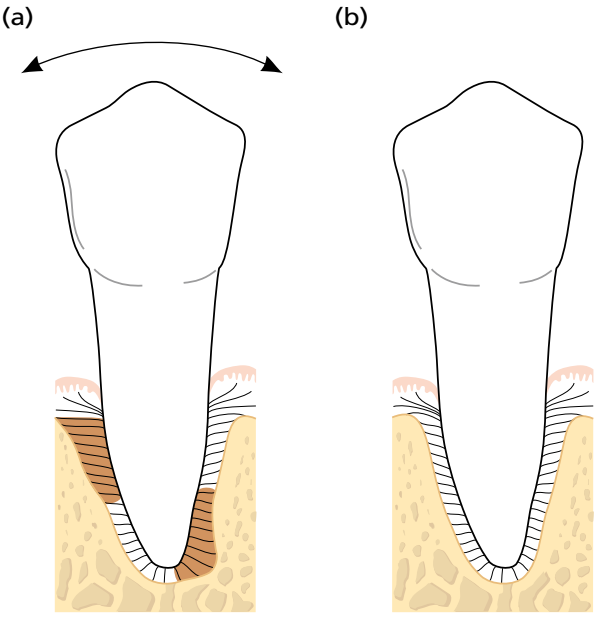

Fig. 43-5 If a tooth with reduced periodontal tissue support (a) has been exposed to excessive horizontal forces, a widened periodontal ligament space ("brown" areas) and increased mobility (arrow) result. (b) Following reduction or elimination of such forces, bone apposition will occur and the tooth will become stabilized.

Example: Case A, 64-year-old male

The periodontal condition of this patient is illustrated by the radiographs from the initial examination (Fig. 43-6). Periodontal disease has progressed to a level where, around the maxillary teeth, only the apical third or less of the roots is invested in supporting alveolar bone. The following discussion relates to the treatment of the maxillary dentition.

In the treatment planning of this case, it was decided that the first premolars (teeth 14 and 24) had to be extracted due to advanced periodontal disease and furcation involvement of degree III. For the same reasons, teeth 17 and 27 were scheduled for extraction. Teeth 16 and 26 were also found to have advanced loss of periodontal tissue support in combination with deep furcation involvements. The most likely *definitive* treatment should include periodontal and adjunctive therapy in the following parts of the dentition: 15 and 25, and 13, 12, 11, 21, 22, 23. For functional and esthetic reasons, teeth 14 and 24 obviously had to be replaced. The question now arose as to whether these two premolars should be replaced by two separate unilateral bridges, using 13, 15 and 23, 25 as abutment teeth, or if the increased mobility of these teeth and also of the anterior teeth (12, 11, 21, 22) (Fig. 43-6) called for a bridge of cross-arch design, with the extension 15–25, to obtain a splinting effect. If teeth 14 and 24 were replaced by two unilateral bridges, each one of these three-unit bridges would exhibit the same degree of mobility in a buccolingual direction as the individual abutment teeth (degree 2) (Fig. 43-6), since a unilateral straight bridge would not have a stabilizing effect on the abutment teeth in this force direction.

From the radiographs it can be seen that the increased mobility observed in the maxillary teeth of this patient is associated mainly with reduced height of the alveolar bone and not with increased width of the periodontal ligaments. This means that the mobility of the individual teeth should be regarded as normal or "physiologic" for teeth with such a reduced height of the supporting tissues. This in turn implies that the increased tooth mobility in the present case does not call for treatment unless it interferes with the chewing comfort or jeopardizes the position of the front teeth. This particular patient had not recognized any functional problems related to the increased mobility of his maxillary teeth. Consequently, there was no reason to install a cross-arch bridge in order to splint the teeth, that is to reduce tooth mobility.

Following proper treatment of the plaque-associated periodontal lesions, two separate

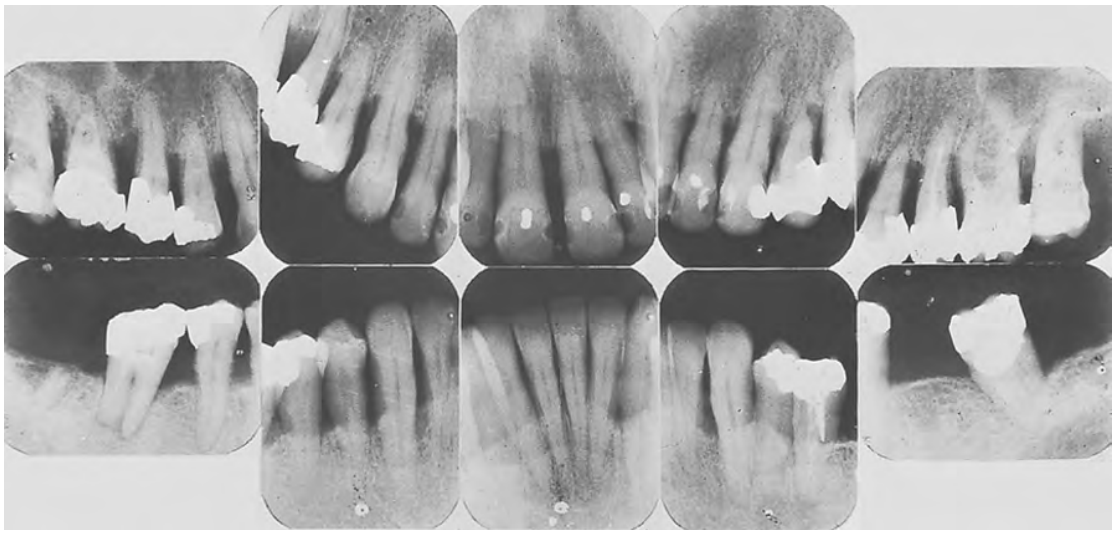

Fig. 43-6 Case A, 64-year-old male. (a) Periodontal chart. (b) Radiographs prior to therapy.

provisional bridges of unilateral design were produced (15, 14, 13; 23, 24, 25, 26 palatal root). The provisional acrylic bridges were used for 6 months during which time the occlusion, the mobility of the two bridges, and the position of the front teeth were all carefully monitored. After 6 months, no change of position of the lateral and central incisors and no increase of the mobility of the two provisional bridges had occurred, and the definitive restorative therapy was performed.

Figure 43-7 shows the radiographs obtained 10 years after initial therapy. The position of the front teeth and the mobility of the incisors and the two bridges had not changed during the course of the maintenance period. There had been no further loss of periodontal tissue support during the 10 years of observation, no further

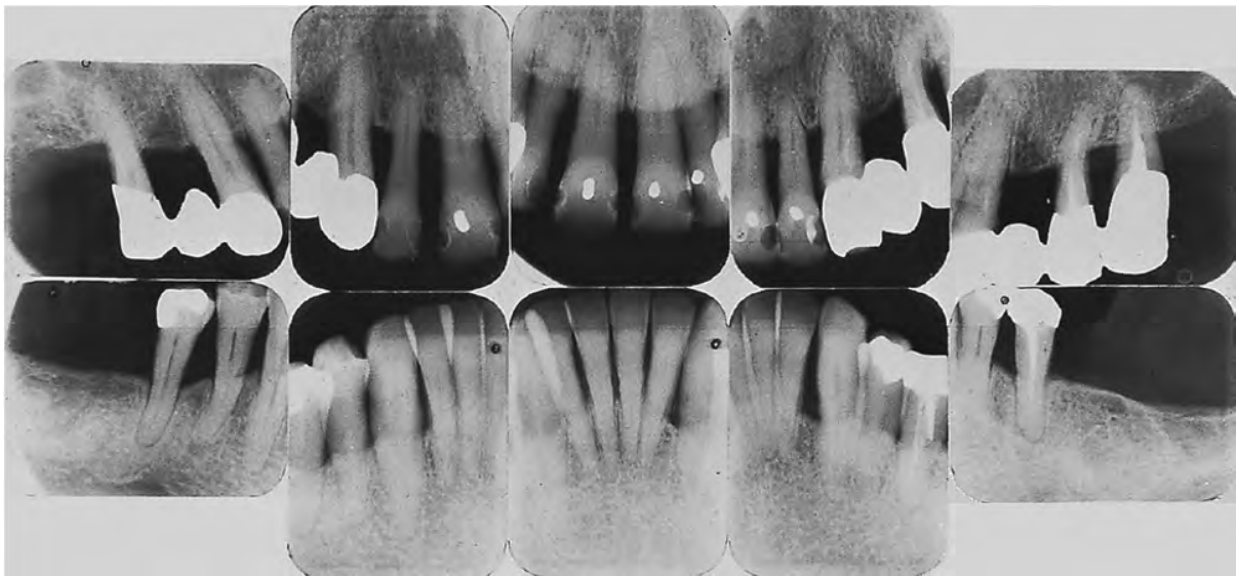

Fig. 43-7 Case A. Radiographs obtained 10 years after periodontal therapy and installation of two unilateral bridges in the maxilla.

spread of the front teeth, and no widening of the periodontal ligaments around the individual teeth, including the abutment teeth for the bridgework.

Conclusion: Increased tooth mobility (or bridge mobility) as a result of reduced height of the alveolar bone can be accepted and splinting avoided, provided the occlusion is stable (no further migration or increasing mobility of individual teeth) and the degree of existing mobility does not disturb the patient's chewing ability or comfort. Consequently, splinting is indicated when the mobility of a tooth or a group of teeth is so increased that chewing ability and/or comfort are disturbed.

Situation 4

Progressive (increasing) mobility of a tooth (teeth) as a result of gradually increasing width of the reduced periodontal ligament

Often in cases of advanced periodontal disease the tissue destruction may have reached a level where extraction of one or several teeth cannot be avoided. In such a dentition, teeth which are still available for periodontal treatment may, after therapy, exhibit such a high degree of mobility, or even signs of progressively increasing mobility, that there is an obvious risk that the forces elicited during function may mechanically disrupt the remaining periodontal ligament components and result in the loss of the teeth.

It will only be possible to maintain such teeth by means of a splint. In such cases, a fixed splint has two objectives: (1) to stabilize hypermobile teeth and (2) to replace missing teeth.

Example: Case B, 26-year-old male

Figure 43-8 shows the radiographs taken prior to therapy and Fig. 43-9 those obtained after periodontal treatment and preparation of the remaining teeth as abutments for two fixed splints. All teeth except 13, 12, and 33 have lost around 75% or more of the alveolar bone and widened periodontal ligaments are a frequent finding. The four distal abutments for the two splints are root-separated molars, the maintained roots being the following: the palatal root of tooth 17, the mesiobuccal root of tooth 26, and the mesial roots of teeth 36 and 47. It should be observed that tooth

Fig. 43-8 Case B, 26-year-old male. Radiographs showing the periodontal conditions prior to therapy.

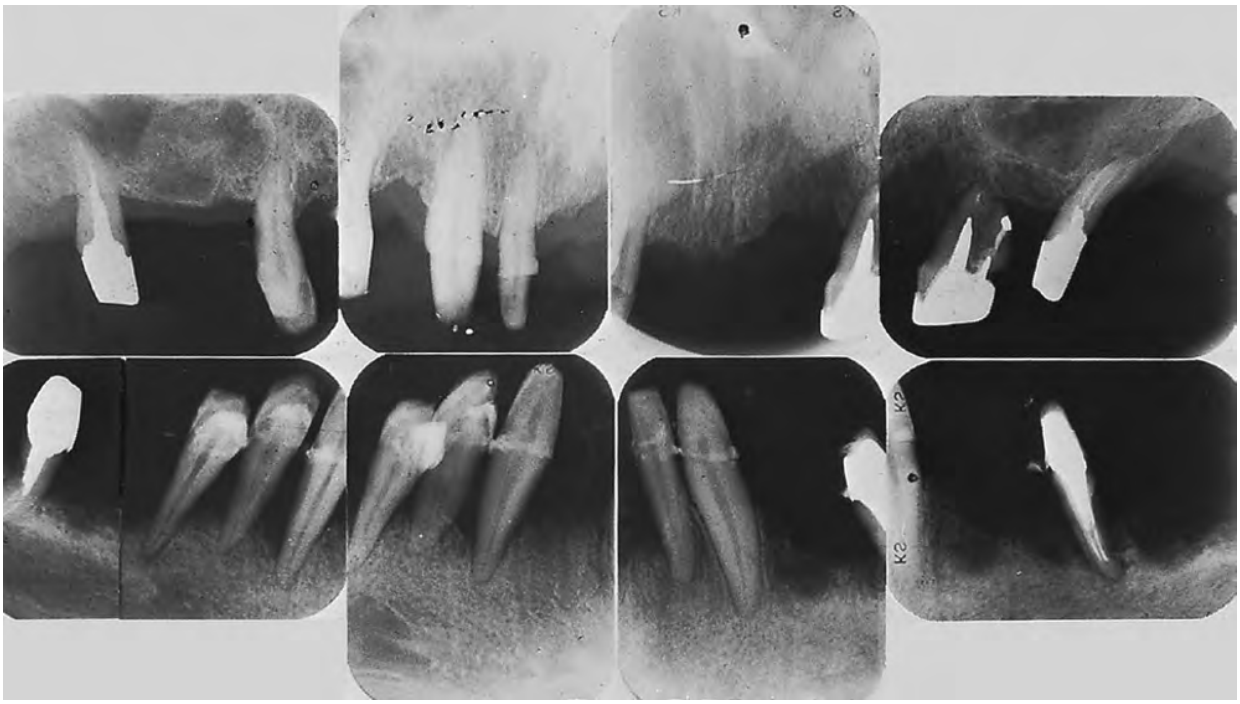

Fig. 43-9 Case B. Radiographs obtained after periodontal treatment and preparation of the abutment teeth for two fixed splints.

24 is root-separated and the palatal root maintained with only minute amounts of periodontium left.

Immediately prior to insertion of the two splints, all teeth except 13, 12, and 33 displayed a mobility varying between degrees 1 and 3. From the radiographs in Fig. 43-9 it can be noted that there is an obvious risk of loss of a number of teeth such as 24, 26, 47, 45, 44, 43, and 36 if the patient is allowed to bite with a normal chewing force without the splints in position.

Despite the high degree of mobility of the individual teeth, the splints were entirely stable after insertion, and maintained their stability during a maintenance period of >12 years. Figure 43-10 shows the clinical status and Fig. 43-11 the radiographs obtained 10 years after therapy. From these radiographs it can be observed (compare with Fig. 43-9) that during the maintenance period there had been no further loss of alveolar bone

Fig. 43-10 (a–c) Case B. Clinical status 9 years after therapy.

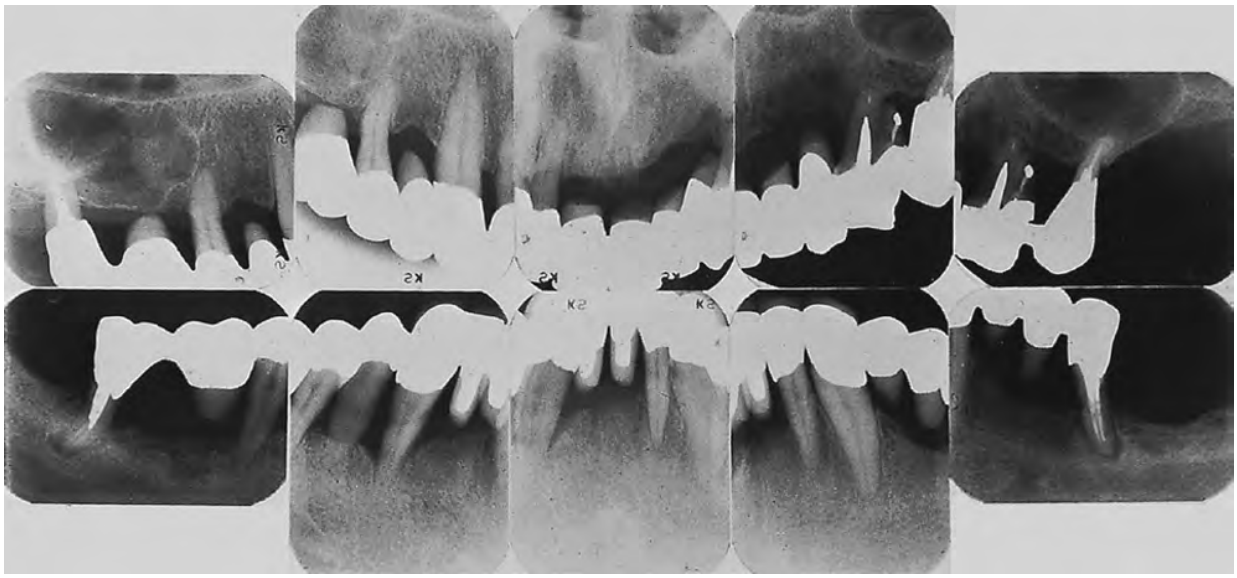

Fig. 43-11 Case B. Radiographs obtained 10 years after therapy.

or widening of the various periodontal ligament spaces.

Conclusion: Splinting is indicated when the periodontal support is so reduced that the mobility of the teeth is progressively increasing, that is when a tooth or a group of teeth are exposed to extraction forces during function.

Situation 5

Increased bridge mobility despite splinting

In patients with advanced periodontal disease, it can often be observed that the destruction of the periodontium has progressed to varying levels around different teeth and tooth surfaces in the dentition. Proper treatment of the plaque-associated lesions often includes multiple extractions. The remaining teeth may display an extreme reduction of the supporting tissues concomitant with increased or progressive tooth mobility. They may also be distributed in the jaw in such a way as to make it difficult, or impossible, to obtain a proper splinting effect even by means of a cross-arch bridge. The entire bridge/splint may exhibit mobility in frontal and/or lateral directions.

It was stated previously (situation 3) that a certain mobility of a tooth or a bridge of unilateral design can be accepted provided this mobility does not interfere with the patient's chewing ability or comfort. This is also valid for a cross-arch bridge/splint. From a biologic point of view, there is no difference between increased tooth mobility on the one hand and increased bridge mobility on the other. However, neither progressive tooth mobility nor progressive bridge mobility are acceptable. In cases of extremely advanced periodontal disease, a cross-arch splint with an increased mobility may be regarded as an acceptable result of rehabilitation. The maintenance of the status quo of the bridge/splint mobility and the prevention of tipping or orthodontic displacement of the total splint, however, requires particular attention regarding the design of the occlusion. Case C is an interesting illustration of this particular clinical problem.

Example: Case C, 52-year-old female

Figure 43-12 shows radiographs obtained at the initial examination. A 12-unit maxillary bridge was installed 10–15 years prior to the present examination using teeth 18, 15, 14, 13, 12, 11, 21, 22, 23, and 24 as abutments. After a detailed clinical examination it was obvious that teeth 15, 14, 22, and 24 could not be maintained because of severe symptoms of caries and periodontal disease. The remaining teeth were subjected to periodontal therapy and maintained as abutments for a new bridge/splint in the maxilla, extending from tooth 18 to the region of tooth 26, that is a cross-arch splint was installed which carried three cantilever units, namely 24, 25, and 26. The mobility of the individual abutment teeth immediately prior to insertion of the splint was the following: degree 1 (tooth 18), degree 0 (tooth 13), degree 2 (teeth 12 and 11), degree 3 (tooth 21), and degree 2 (tooth 23).

Radiographs obtained 5 years after therapy are shown in Fig. 43-13. The bridge/splint had a mobility of degree 1 immediately after its insertion and this mobility was unchanged 5 years later. The radiographs demonstrate that no further widening of the periodontal ligament had occurred around the individual teeth during the maintenance period.

When a cross-arch bridge/splint exhibits increased mobility, the center (fulcrum) of the movement must be identified. In order to prevent further increase in the mobility and/or to prevent displacement of the bridge, it is essential to design the occlusion in such a way that when the bridge/splint is in contact with the teeth of the opposing jaw, it is subjected to a balanced load, that is equal force on each side of the fulcrum.

Fig. 43-12 Case C, 52-year-old female. Radiographs obtained at the initial examination.

If this can be achieved, the force to which the bridge is exposed in occlusion can be used to retain the fixed prosthesis in proper balance (thereby preventing a further increase of mobility).

Balanced loading of a mobile bridge/splint has to be established not only in the intercuspal position (IP) and centric occlusion (CP), but also in frontal and lateral excursive movements of the mandible if the bridge shows mobility or a tendency for tipping in the direction of such movements. In other words, a force which tends to displace the bridge in a certain direction has to be counteracted by the introduction of a balancing force on the opposite side of the fulcrum of the movement. If, for instance, a cross-arch splint in the maxilla exhibits mobility in the frontal direction in conjunction with protrusive movements of the mandible, the load applied to the bridge in the frontal region has to be counterbalanced by a load in the distal portions of the splint; this means that there must be a simultaneous and equal contact relationship between the occluding teeth in both the frontal and the posterior regions of the splint. If the splint is mobile in a lateral direction, the force acting on the working side of the jaw must be counteracted by a force established by the introduction of balancing contacts in the non-working side of the jaw. The principle for establishing stability of a *mobile* cross-arch splint is consequently the same as that used to obtain stability in a complete denture. In situations where distal abutment teeth are missing in a cross-arch bridge/splint with increased mobility, balance and functional stability may be obtained by means of cantilever units. It is important in this context to point out that balancing contacts on the non-working side should not be introduced in a bridge/splint in which no increased mobility can be observed.

Fig. 43-13 Case C. Radiographs obtained 5 years after therapy.

Fig. 43-14 Case C. Cantilever section including teeth 24, 25, and 26.

The maxillary splint in Case C exhibited increased mobility in a frontal direction. Considering the small amount of periodontal support left around the anterior teeth, it is obvious that there would have been a risk of frontal displacement of the total bridge had the bridge terminated at the last abutment tooth (23) on the left side of the jaw. The installation of cantilever units in the 24 and 25 region prevented such a displacement of the bridge/splint by the introduction of a force counteracting the frontally directed forces during protrusive movements of the mandible (Fig. 43-14). In addition, the cantilever units provided bilateral contact relationship towards the mandibular teeth in the intercuspal position, that is bilateral stability of the bridge.

In cases similar to Case C, cantilever units can thus be used to prevent increasing mobility or displacement of a bridge/splint. It should, however, be pointed out that the insertion of cantilever units increases the risk of failures of a technical and biophysical character (fracture of the metal frame, fracture of abutment teeth, loss of retention, etc.).

In cases of severely advanced periodontal disease, it is often impossible to anticipate in the planning phase whether a bridge/splint will show signs of instability and increasing (progressive) mobility after insertion. In such cases, a provisional splint should always be inserted. Any alterations of the mobility of the bridge/splint can be observed over a prolonged period of time and the occlusion continuously adjusted until, after 4–6 months, it is known whether stability (i.e. no further increase of the mobility) can be achieved. The design of the occlusion of the provisional acrylic bridge is then reproduced in the permanent bridge construction. If, on the other hand, stability cannot be obtained, the rehabilitation of the case cannot be achieved with a fixed splint. The alternative treatment then is a complete denture or an implant-supported restoration.

Conclusion: An increased mobility of a cross-arch bridge/splint can be accepted provided the mobility does not disturb chewing ability or comfort and the mobility of the splint is not progressively increasing.

Introduction

The overall favorable long-term survival and success rates reported in the literature for osseointegrated implants in the treatment of various types of edentulism (Jung *et al*. 2012; Pjetursson *et al*. 2012; Zhang *et al*. 2019) permit consideration of dental implants as a very reliable therapeutic modality during the establishment of any prosthetic treatment plan. In numerous clinical situations, implants can clearly contribute to a notable simplification of therapy, frequently enabling removable prostheses to be avoided, keeping it less invasive with respect to the remaining tooth structure, or rendering the treatment more versatile (Belser *et al*. 2000).

Beyond any doubt, the advent of osseointegration has had a fundamental impact on the therapeutic approach and strategies implemented today in the field of prosthetic rehabilitation of the compromised posterior dentition. This treatment modality is increasingly applied worldwide, not only by specialists but also more and more by general practitioners, thus having a tremendous influence on traditional prosthodontic attitudes (Buser *et al*. 2017).

Because most of the established dental implant systems today comprise a wide range of mostly screw-type implants with different diameters, dimensions, and designs to replace missing premolars and molars, the versatility of implant therapy in the load-carrying part of the dentition of partially edentulous patients has been significantly enhanced. The use of implants may often significantly reduce the inherent risk of "borderline" conventional tooth-borne fixed dental prostheses (FDPs) (e.g. prostheses based on compromised abutment teeth, long-span FDPs, cantilevers) by implementing the principle of segmentation. It is currently widely accepted that – in comparison with extended splinted prosthetic segments – small units are preferable as they are easier to fabricate, generally provide improved "passive fit" and marginal fidelity, offer better access for the patient's oral hygiene, and ultimately are less complicated to handle where there is need for re-intervention.

In the past decade, various trends, innovations and scientific data shifted implant dentistry from specialists and referral-based clinicians to general dentists (Buser *et al*. 2017). This trend is based on improved

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

diagnostics tools (e.g. cone-beam computed tomographies, digitization), simplified treatment protocols, more options in terms of implant designs, lengths, and diameters as well as the availability of high-strength implant materials and components (Jung *et al*. 2012; Pjetursson *et al*. 2012; Thoma *et al*. 2015; Naenni *et al*. 2018; Roehling *et al*. 2018; Sailer *et al*. 2018b; Schiegnitz *et al*. 2018; Schneider *et al*. 2018; Tahmaseb *et al*. 2018; Avila-Ortiz *et al*. 2019; Cosyn *et al*. 2019).

It is the aim of this chapter to present clinically oriented guidelines and procedures for implant therapy of various types of edentulism in the posterior part of the dentition, addressing the partially dentate patient and focusing on implant-supported FDPs.

Indications for implants in the posterior dentition

Indications for implants in the posterior dentition are related to improve the subjective chewing comfort of partially edentulous patients (Gates *et al*. 2014), or to preserve sound mineralized tooth structure, or to avoid removable partial dentures (RPDs) and conventional FDPs. This includes situations with missing teeth, the distally shortened dental arch, extended edentulous segments, missing "strategic" tooth abutments, and structurally, endodontically, or periodontally compromised potential abutment teeth.

Numerous other indications have been added to the so-called classical indications for the use of implants including severely atrophied edentulous jaws, congenitally missing teeth, or the distally shortened dental arch (particularly when premolars are missing). Among these other indications, one should also mention that all the strategies aim at either reducing the prosthodontic risk in general or rendering the treatment simpler and more cost-effective. Virtually no limits on the placement of implants seem to exist any longer owing, for example, to well-documented bone augmentation (Jepsen *et al*. 2019) techniques comprising horizontal bone augmentation of buccal dehiscence/fenestration defects (Thoma *et al*. 2019), sinus floor elevation (Pjetursson *et al*. 2008; Raghoebar *et al*. 2019) as well as vertical bone augmentation (Rocchietta *et al*. 2008; Urban *et al*. 2019).

The rapid advances in terms of the broad utilization of dental implants are not exclusively based on the associated favorable long-term reports for this treatment modality. Other parameters such as purely "mechanical" advantages and the increasing use of digital technologies (Wismeijer *et al*. 2018) and components, which in turn contribute notably to the simplification of the treatment, also have had a significant impact on current concepts and strategies. Furthermore, clinical decision-making based on prosthetically oriented risk assessment frequently leads to the need for selective placement of dental implants. The objective is to reduce the overall risk (Box 44-1) associated with a given prosthetic solution on the one hand, and to implement the principle of segmenting on the other.

Box 44-1 "High-risk" conventional fixed partial dentures.

- Long-span fixed partial bridges
- Cantilever units (mainly distal extensions)
- Missing "strategic" tooth abutments
- Structurally-/periodontally-/endodontically-compromised tooth abutments

Therefore, the therapeutic strategy should be ideally planned in light of the current clinical evidence and according to the patient needs. In this context, for the posterior zone the following therapeutic concepts have become available in the respective jaws.

Therapeutic concepts at sites with sufficient bone quantity

When sufficient bone is available, placing dental implants in the posterior region of the jaws is a straightforward procedure. Primarily, posterior implants restore the function following the loss of a strategically important tooth. Treatment planning becomes highly involved and extensive reconstructions may result from the loss of such a tooth. Especially in dentitions that have received multiple reconstructions, the loss of one strategic abutment may lead to a time-consuming and costly therapy. By installing oral implants in the strategically correct locations, partial reconstruction of a dentition may become possible. Factors to be considered thereby include gap size, number, dimension (length, diameter) as well as distribution of implants.

Single-unit gap size

Premolar-size single-tooth restorations

In case of a gap size corresponding dimensionally to an average premolar, standard-size screw-form implants are well suited. The implant dimensions, either as a one-piece implant including both the intrabony part and the implant shoulder or as a two-piece implant with the intrabony part only, offer the additional advantage of being mostly compatible with a limited bone volume in an orofacial direction. Whenever feasible, a straightforward low-maintenance restorative design is advocated, normally consisting of a screw-retained porcelain-fused-to-metal (PFM) crown or a hybrid reconstruction with a CAD-CAM all-ceramic crown extraorally cemented to a titanium base, to provide adequate guidance for the cheek and tongue.

As one increasingly strives for the best possible biologic, functional, and esthetic integration of a given implant restoration in the pre-existing dentition, 3D preoperative site analysis is of paramount importance. It is not infrequent that this subsequently calls for a multidisciplinary approach, which may also include presurgical orthodontic therapy rendering a more optimal hard and soft tissue condition for implant therapy.

Optionally, in cases with a limited bucco-oral bone dimension, one might consider the placement of narrow-diameter implants (NDIs). Scientific evidence based on a randomized controlled trial provides favorable results up to 3 years with NDIs (Ioannidis *et al*. 2015). Surgically, NDIs reduce the need for simultaneous bone augmentation procedures and are preferred by clinicians (Benic *et al*. 2013; Jung *et al*. 2018). Nevertheless, from a prosthetic point of view, the reduced dimension of the implant shoulder limits the creation of the emergence profile and implants need to be placed with an increased sink depth.

Molar-size single-tooth restorations

If a given posterior single-tooth gap corresponds to the mesiodistal dimension of a molar, implant systems offer more options. The most often applied concept includes the placement of a standard-diameter implant. Optionally, a wide-diameter implant can be chosen. This approach, however, also requires the appropriate bone volume in an orofacial direction. If this is not the case, implant placement has to be combined with a lateral bone augmentation procedure using a simultaneous approach. This additional effort, risk, and ultimately also cost has to be discussed with the patient, but most often will not be chosen. Similarly, NDIs might be theoretically an option. Limitations apply, however, because of a lack of scientific evidence (in molar sites) and the large dimensional difference between the implant shoulder and the anticipated crown embrasure.

Two-unit gap size

Considering the dimensions of premolars (7 mm) and molars (8 mm) and adequate space for the interdental/interimplant space (4–5 mm), edentulous ridges between existing teeth may be reconstructed and chewing comfort increased without involving adjacent teeth. Obviously, risks can be minimized by reducing the length of bridge spans. Therefore, in combined molar and premolar reconstructions, the surgical positioning of the implants has to be calculated in detail and restoration-driven stents may have to be used in order to create adequate conditions for prosthetic reconstruction.

In the case of two missing occlusal units, one should try as a general rule to select the optimal implant diameter with respect to the total mesiodistal distance of the given edentulous segment. Decisive parameters are the interimplant distance and space between implants and adjacent teeth (if present), as well as the orofacial crest width at the two prospective implant sites. For a total gap diameter of about 14–15 mm (two premolars), two standard-size (Fig. 44-1), one standard-size, and one narrow-diameter or two NDIs are suitable. For an edentulous space of 17–18 mm options include two standard-diameter implants or the combination of one standard and one wide diameter/wide platform implant

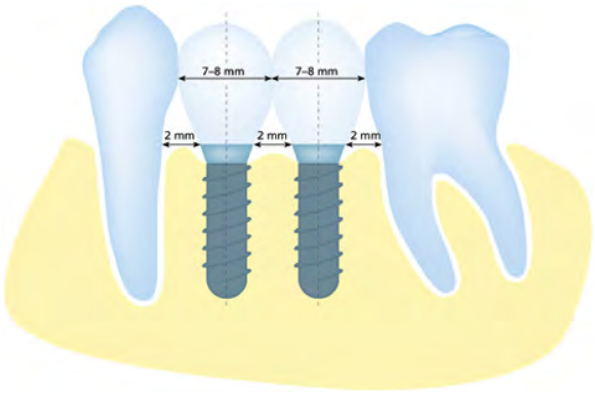

Fig. 44-1 If a given tooth-bound edentulous space only permits the insertion of two adjacent implants, a minimal interimplant distance of 2 mm and a minimal implant-to-tooth distance of 2 mm should be respected.

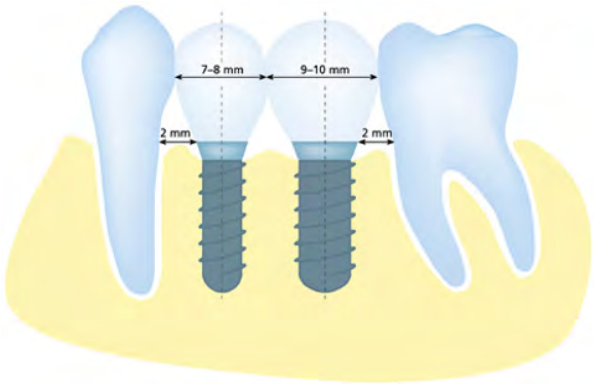

Fig. 44-2 In the presence of a mesiodistal gap width of approximately 17 mm, the combination of a standard and an increased-diameter implant may be considered. The same minimal interimplant and implant-to-tooth distances have to be respected.

(Fig. 44-2). The latter choice, as mentioned above, is rarely selected, mostly because of a reduced bucco-oral ridge width.

These are just the frequently encountered clinical examples, and for the function of other morphology and dimensions of edentulous tooth-bound segments, additional approaches and implant combinations may be envisioned (Fig. 44-3). Such a clinical situation is shown in Fig. 44-4. The gap diameter required the two adjacent implants to be spaced wider than the normally advocated interproximal 2 mm. The laboratory technician compensated for this excess of space with a root-imitation pontic, which in turn provided an excellent guide facilitating the use of an interdental brush (Fig. 44-4a).

Multiunit gap size (≥3 missing teeth to be replaced)

It is still unclear to date how many implants of which dimension and at which location are required to optimally rehabilitate a given edentulous segment in the load-carrying part of the dentition. Several different recommendations and related strategies are currently

in use, mostly derived from traditional prosthodontic experience and attitudes, and based on so-called clinical experience and common sense rather than on solid scientific evidence.

In cases of three or more posterior teeth to be replaced, dental implants are, therefore, strategically placed, and short-span bridges are the preferred treatment option (Fig. 44-3). This therapeutic option offers benefits in terms of costs, efforts to be undertaken, and ease of the surgical and prosthetic procedures compared with the installation of implants at every single-tooth position.

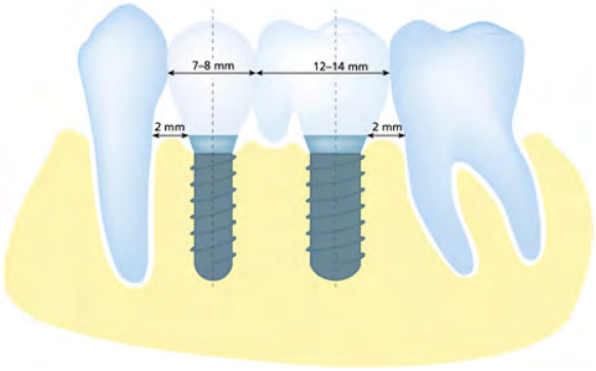

Fig. 44-3 If a posterior mesiodistal gap has a width of approximately 20 mm, a small central pontic should be considered to simplify the cleaning process.

Distribution and number of implants

In a situation where the canine is the most distal remaining tooth of a dental arch, at least five different options can be considered if it is planned that the missing teeth up to the first molar area are to be replaced: (1) replacement of each missing occlusal unit by one implant (Fig. 44-5a); (2) a mesial and a distal implant to support a three-unit FDP with a central pontic (Fig. 44-5b); (3) two distal implants to permit the insertion of a three-unit FDP with a mesial cantilever (Fig. 44-5c); (4) two mesial implants to sustain a three-unit FDP with a distal cantilever (44-5d); and (5) only one distally inserted implant in view of a four-unit FDP combining implant and natural tooth support (Fig. 44-5e).

As far as the recommendation to use premolar-size units for implant-borne posterior FDPs is concerned, it has proven its practical validity in >10 years of clinical experience (Buser *et al*. 1997;

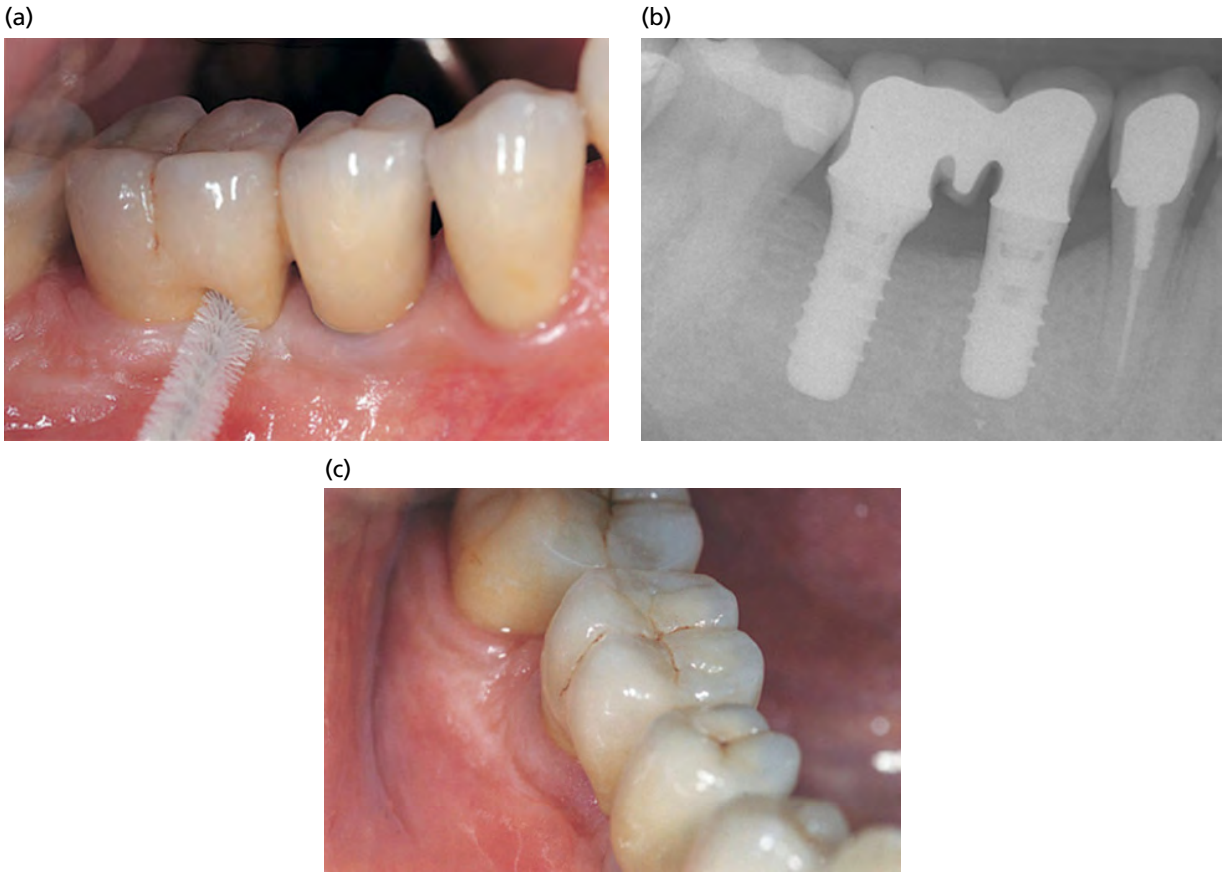

Fig. 44-4 (a) Vestibular aspect of a metal–ceramic restoration supported by two screw-type implants. Due to an excess of mesiodistal space, the implants have been separated by approximately 4 mm. Instead of a traditional pontic, a root imitation has been performed close to the distal implant, providing an adequate guide for an interdental brush in view of an efficient plaque control at the marginal area of the implant restoration. (b) With respect to cleanability, the prosthesis design is clearly visible on the postoperative radiograph. (c) On an oblique view, the vestibular axial profile of the implant restoration becomes visible. Soft tissue (cheek and tongue) support and harmony with adjacent teeth are of paramount importance.

Bernard & Belser 2002). In fact, a crown featuring a mesiodistal diameter of 7–8 mm at its occlusal surface allows the optimal generation of a harmonious axial profile, gradually emerging from the standard-implant shoulder (diameter 4–5 mm on average) to the maximum circumference. Furthermore, and because overloading appears to play little role in late implant failures (Lima *et al*. 2019), clinicians tend to replace molars with molar size reconstructions.

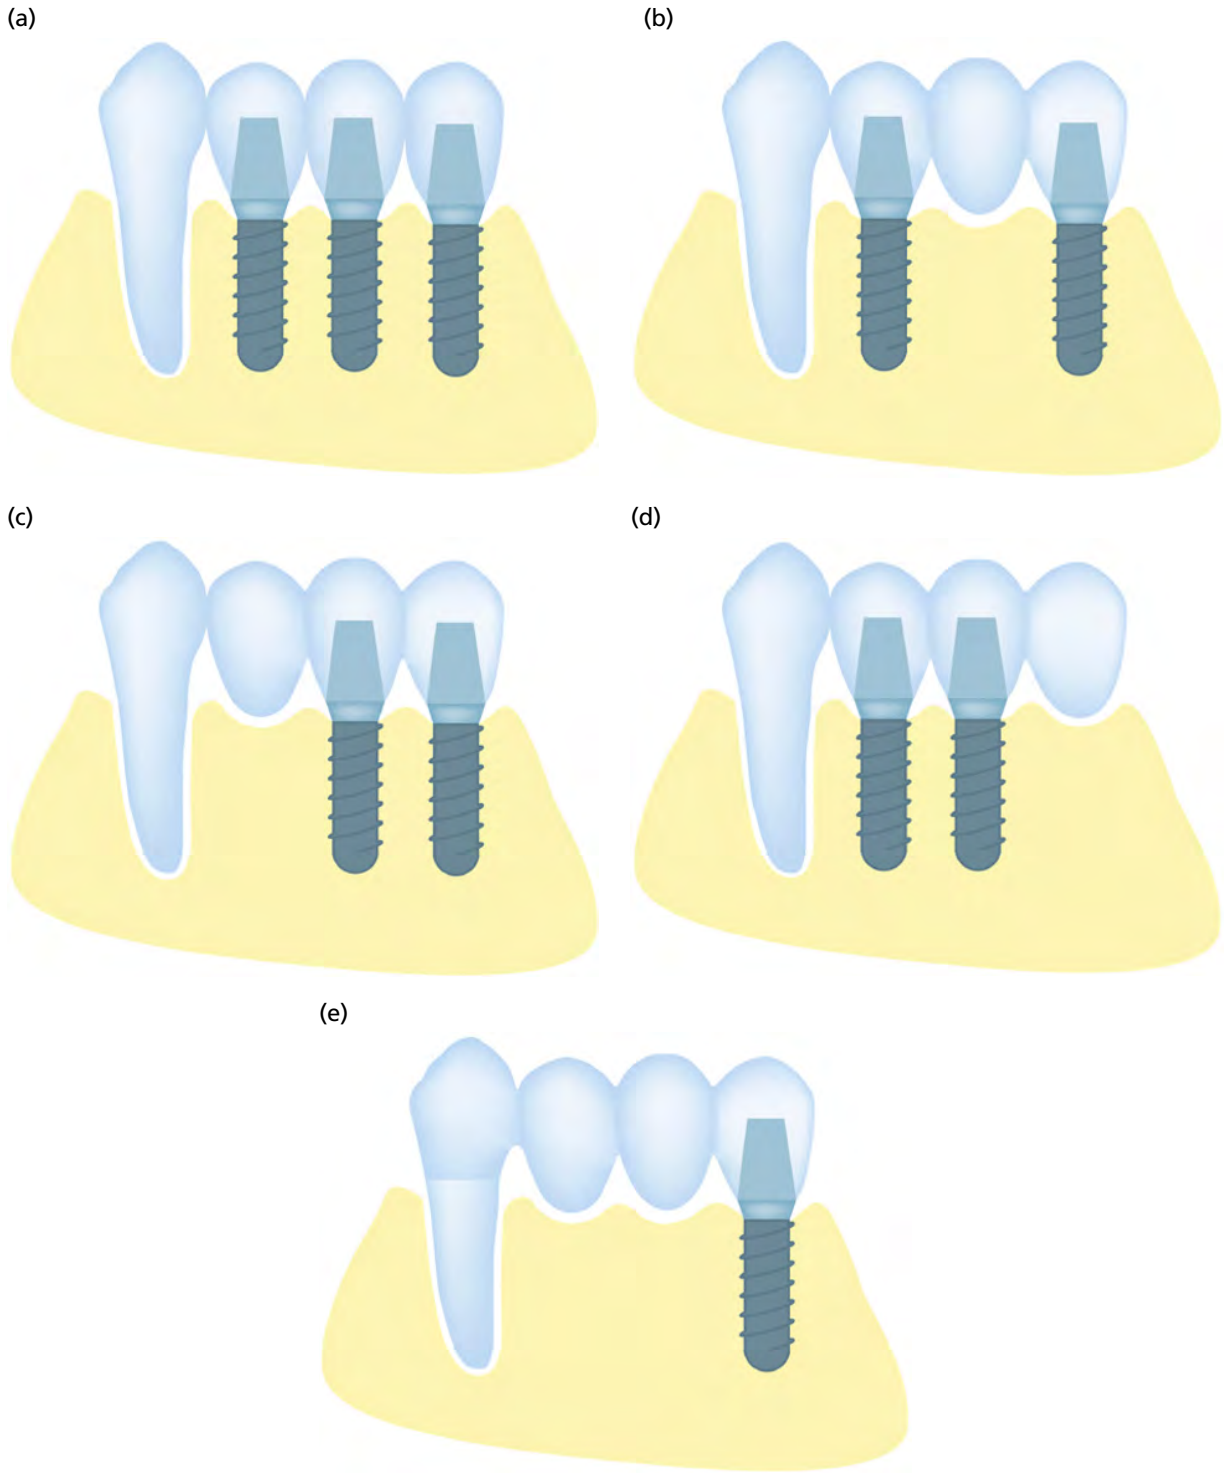

Fig. 44-5 The distally shortened dental arch. (a) One therapeutic option consists of replacing each missing occlusal unit up to the first molar area with an implant. (b) An alternative option would be the replacement of the three missing occlusal units with two implants to support a three-unit suprastructure with a central pontic. (c) In a case of an inadequate bone volume in the area of the missing first premolar, the placement of two distal implants may be considered, leading to a three-unit suprastructure with a mesial cantilever. (d) In a case of an inadequate bone volume in the area of the missing first molar, the placement of two mesial implants may be considered, leading to a three-unit suprastructure with a distal cantilever. (e) In a case of inadequate bone volume in the area of the two missing premolars, the placement of a distal implant may be considered, leading to a four-unit suprastructure with a mixed (tooth and implant) support.

Based on an increasing body of scientific evidence, most clinicians' first choice is the mesial and distal implant and the FDP with the central pontic (Fig. 44-6). Prospective mid- to long-term data (Ioannidis *et al*. 2015; Gamper *et al*. 2017) have confirmed the efficacy and predictability of this specific modality. In fact, it permits the defined treatment objective to be reached with a minimum number of implants and associated costs. Although formal evidence at the level of prospectively documented, randomized clinical trials is still lacking, it appears from clinical experience that the use of two implants to support a four-unit FDP with two central pontics (Fig. 44-7) may be adequate in certain clinical situations. Clinicians tend to use this approach in the presence of favorable bone conditions, permitting standard-size or less frequently wide diameter implants of appropriate length (i.e. ≥8 mm).

Therapeutic concepts at sites with insufficient bone quantity

It is quite common that distally shortened dental arches do not feature an adequate local bone volume at the prospective implant sites. This may refer to bone height, bone width, alveolar bone crest axis, or to the vicinity of noble structures such as the mandibular alveolar nerve canal or the anterior part of the maxillary sinus. Often, a combination of several of the mentioned limitations are encountered. Implant insertion is clearly a three-dimensional surgical and restorative procedure and a "restoration-driven" rather than "bone-driven" implant placement is widely recommended. Therefore, a meticulous presurgical site analysis – based on the envisioned treatment objective – is of primary importance. In order to keep the treatment as easy and cost-effective as possible, one should evaluate comprehensively all

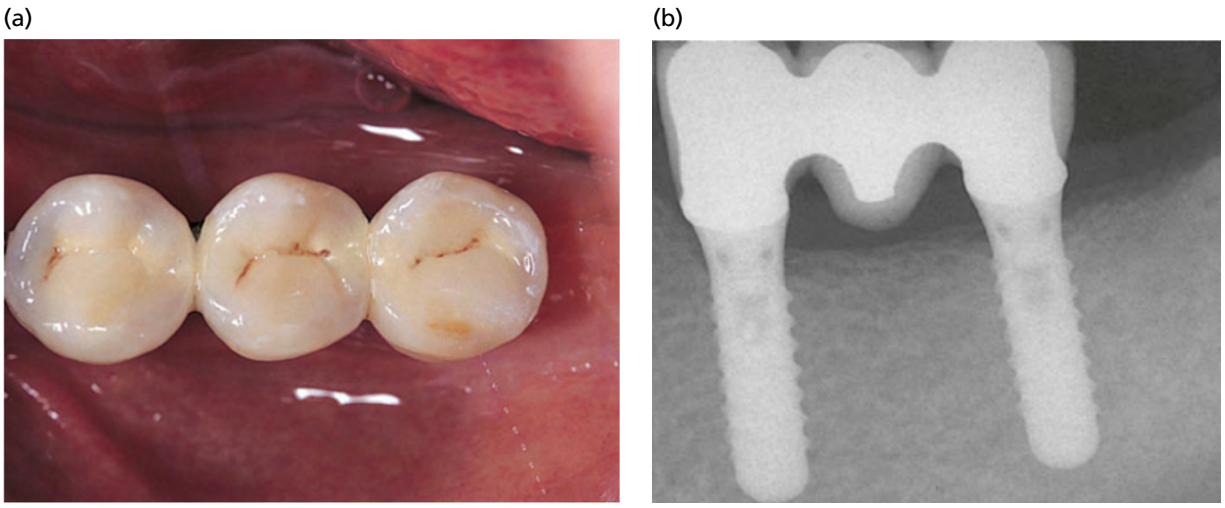

Fig. 44-6 (a) Occlusal view of a cemented three-unit metal–ceramic fixed dental prosthesis, supported by a mesial and a distal implant. (b) Corresponding 3-year follow-up radiograph confirms stable conditions at the implant–bone interface of the two 12-mm solid screw implants.

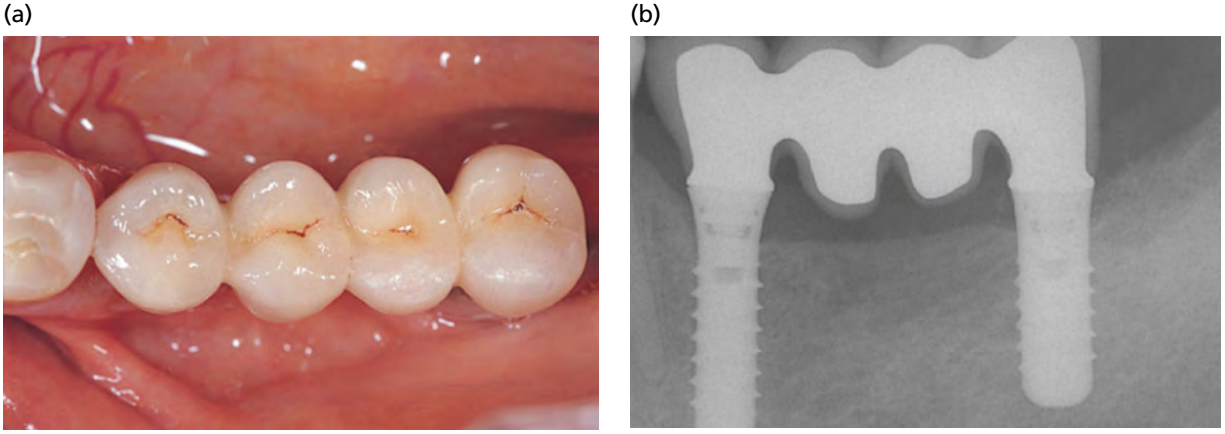

Fig. 44-7 (a) Occlusal view of a cemented four-unit metal–ceramic fixed dental prosthesis supported by a mesial and a distal implant. (b) Corresponding 2-year follow-up radiograph documents that at the distal site a 10-mm solid screw implant with an increased diameter ("wide-body implant") has been used.

available treatment options. Among the options to be considered are: (1) primary (Naenni *et al*. 2019) or simultaneous bone augmentation (Thoma *et al*. 2019) procedures in combination with standard-length implants; (2) use of shorter and NDIs and therefore avoiding extensive bone regenerative procedures (Nisand *et al*. 2015; Thoma *et al*. 2015; Jung *et al*. 2018); (3) insertion of an implant-supported crown with a cantilever (Aglietta *et al*. 2012); (4) the shortened dental arch concept (Kayser 1981); (5) combination of implant and natural tooth support; and (6) even a minor deviation from the ideal implant position (Lin & Eckert 2018) without accepting the risk that this treatment adversely affects predictability, longevity, and/or subjective comfort.

Therapeutic concepts to avoid larger bone augmentation procedures

Shorter dental implants

Clinicians are quite frequently confronted with posterior edentulous jaw segments that present all of the major prerequisites for successful implant, with the exception of a sufficient vertical bone height for the insertion of one or several implants featuring what is broadly accepted as an adequate length of the implants *per se* and also in relation to the prospective height of the suprastructures. The question that arises is whether there is a minimal implant length required in the context of posterior single-unit restorations and whether the ratio between implant length and suprastructure height has an influence on crestal bone resorption and ultimately on the longevity of the entire implant-suprastructure complex (Blanes *et al*. 2007; Quaranta *et al*. 2014; Hammerle *et al*. 2018; Meijer *et al*. 2018; Naenni *et al*. 2018).

Standard-length implants (>8 mm) have been universally recommended for many years, as it was widely accepted that this length was reasonable for a predictable success; the functional forces exerted on the implant were assumed to be distributed over a large surface area throughout the entire length of the implant. Later experimental studies concluded that this stress might not be minimized if the length of the implant is increased (Pierrisnard *et al*. 2003). Hence, it has been claimed that the generated interface stresses are, in fact, concentrated on the crestal bone and not redistributed over the entire length of the implant, and that shorter implants may even be more favorable in terms of peri-implant bone stimulation and resulting bone density (Renouard *et al*. 2006).

In the past 10 years, a high number of clinical studies and eventually systematic reviews broaden the evidence that shorter dental implants are not associated with a higher rate of biological complications (e.g. more marginal bone loss) (Esposito *et al*. 2019) or a lower implant survival rate (Tolentino da Rosa de Souza *et al*. 2018; Chen *et al*. 2019; Esposito *et al*. 2019). This in turn led to a decrease of the mean implant length used for daily clinical practice. At the Clinic of Reconstructive Dentistry at the University of Zürich, Switzerland the mean implant length has decreased by 3–4 mm within the last 10 years (Gamper *et al*. 2017; Ioannidis *et al*. 2019).

Currently, implants that are ≤8 mm long are broadly considered as "short implants". Short dental implants were engineered to avoid interferences with vital anatomic structures (e.g. mandibular nerve canal, maxillary sinus), to reduce surgical trauma and associated risks, to decrease the morbidity involved with advanced grafting/bone augmentation procedures, and to foster "prosthetically-driven" implant positioning (Papaspyridakos *et al*. 2018). As a result, these short dental implants may directly increase patient comfort and compliance (Jung *et al*. 2018), as well as minimize the amount of radiologic investigation and the number of visits, chair-side time, and costs involved.

Clinicians though, might still be afraid of placing shorter dental implants owing to particular limitations such as a slightly higher implant failure rate (Jung *et al*. 2018; Papaspyridakos *et al*. 2018) in direct comparison to standard length implants based on a recently published randomized controlled clinical trial (Naenni *et al*. 2018). Other parameters that have not been studied extensively include the influence of the implant surface and the appropriate implant design of shorter dental implants as well as the influence of the implant diameter. Shorter dental implants are therefore more often proposed in clinical situations where more advanced bone augmentation techniques require more surgical efforts to install the implants (Fig. 44-8) (Jung *et al*. 2018; Papaspyridakos *et al*. 2018).

Narrow-diameter implants

NDIs are recommended in clinical situations with a narrow ridge width or a reduced interdental gap width (Jung *et al*. 2018; Schiegnitz *et al*. 2018). The scientific literature describes various types and designs of NDI, generally with a diameter of ≤3.5 mm. The reported classification by the ITI Consensus Conference in 2018 proposed three categories (Jung *et al*. 2018): Category 1, implants with a diameter of <2.5 mm ("mini-implants"); Category 2, implants with a diameter of 2.5 mm to <3.3 mm; Category 3, implants with a diameter of 3.3–3.5 mm. Based on the current evidence, implants in category 3 are the only ones that can be recommended in posterior regions of the jaws, with a reported survival rate ranging between 91% and 100% after observation periods of 12–109 months (Jung *et al*. 2018). Potential advantages of NDIs include the maintenance of an adequate tooth–implant and interimplant distance in clinical situations with a reduced mesiodistal width, a decrease in the need and complexity of lateral bone augmentation procedures in clinical situations with a reduced bucco-oral ridge width, reduced treatment length by allowing a simultaneous rather

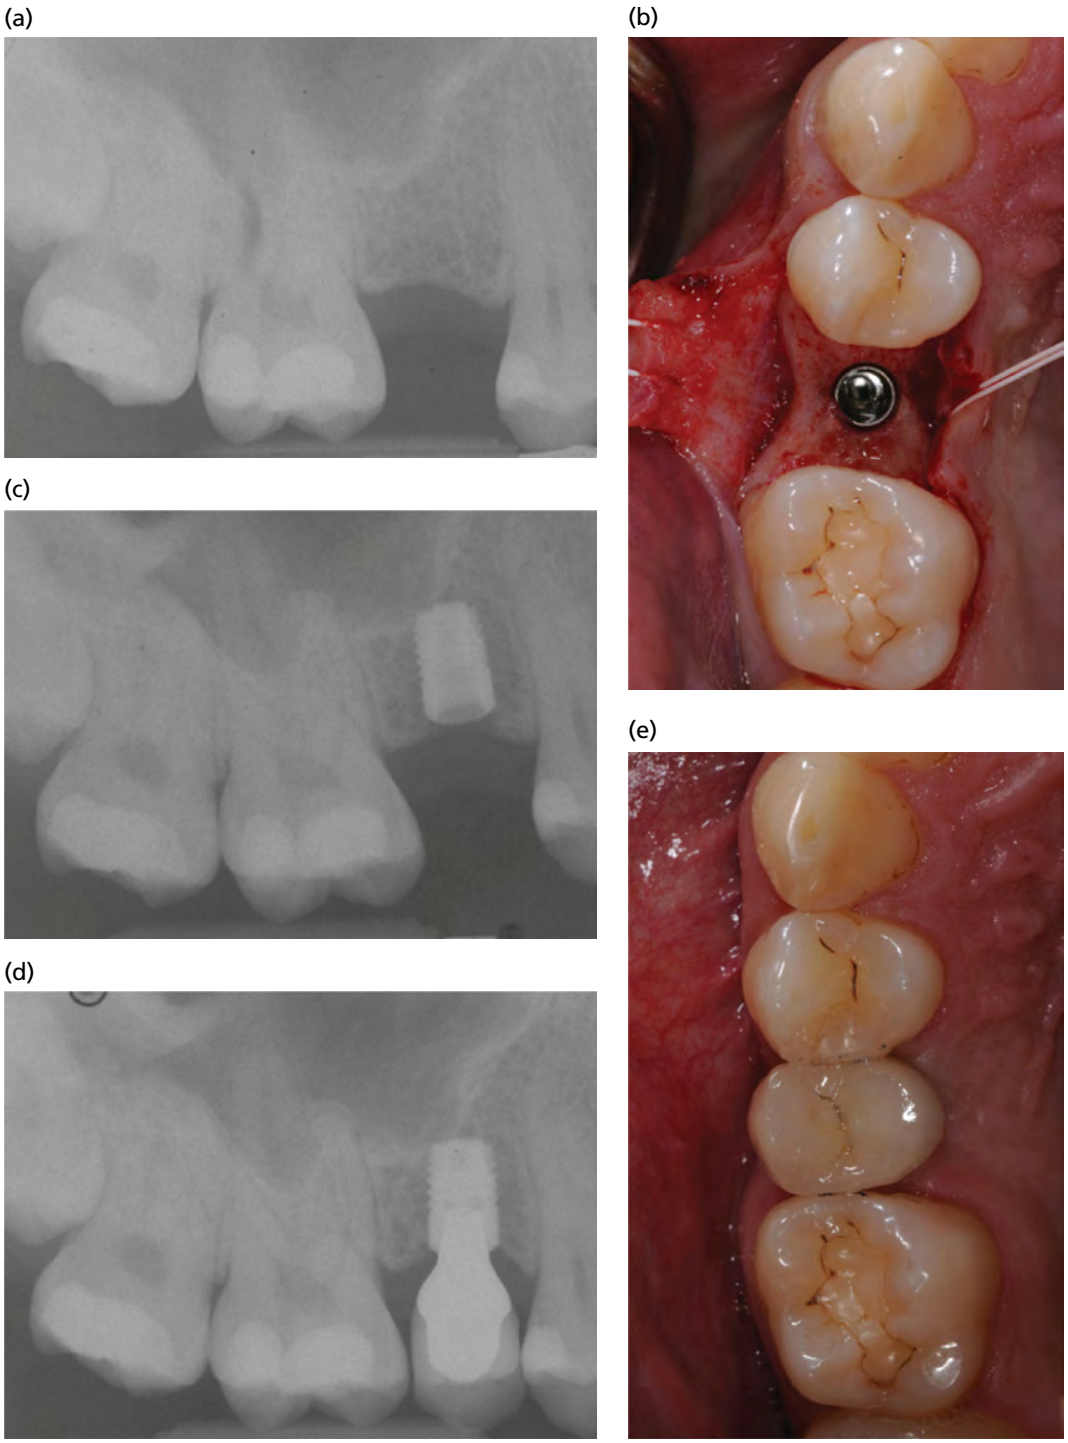

Fig. 44-8 (a) Preoperative radiograph demonstrates a reduced alveolar ridge height (6 mm) in region 15. (b) Occlusal view after implant installation without an additional sinus elevation procedure. (c) Radiograph after implant placement with a 6-mm short implant. (d) Periapical radiograph 1 year after insertion of the final reconstruction. (e) Occlusal view of the final porcelain-fused-to-metal crown after 1 year in function.

than a staged approach of implant placement, and an increased prosthetic flexibility (Benic *et al*. 2013; Jung *et al*. 2018). In an randomized controlled trial, comparing NDI to standard-diameter implants in the esthetic zone including premolars, 3-year data did not demonstrate significant differences in terms of survival and marginal bone level changes (Ioannidis *et al*. 2015). Moreover, at the time of implant placement, NDIs offered advantages by reducing the overall need for bone augmentation procedures and were the preferred choice by the clinicians (Ioannidis *et al*. 2015). Whether or not these results can be transferred to molar sites and short-span bridges (limited to molar sites) remains unclear and currently cannot be recommended.

Given anatomical limitations of the ridge and reduced interimplant/interdental distances, NDIs are a valid treatment option. However, clinicians are advised to consider that NDIs exhibit a lower mechanical stability and a suboptimal prosthetic design for the maintenance of peri-implant health.

Cantilever

The clinical situation with two adjacent missing teeth is often encountered in the posterior area of the jaws. One alternative is the insertion of an implant-supported crown with a cantilever (Fig. 44-9) Apart from being more economical than the placement of two implants, it provides an alternative in cases of unfavorable anatomical conditions of the residual ridge. It has been hypothesized that cantilevers may increase occlusal and functional forces onto the implant leading to a higher rate of biological complications expressed by an increased amount of marginal bone loss. This hypothesis has been investigated in clinical studies for short-span fixed dental prostheses with two implants with a cantilever. The results of these studies, nevertheless, failed to demonstrate a higher marginal bone loss in comparison with non-cantilever FDPs (Wennstrom *et al*. 2004; Halg *et al*. 2008; Aglietta *et al*. 2009). Recently, several studies on single implants with cantilevers have been published (Halg *et al*. 2008; Aglietta *et al*. 2012; Palmer *et al*. 2012; Roccuzzo *et al*. 2020). In these studies, the bone level changes were comparable to those observed at implants without cantilevers. Therefore, implant-supported cantilevers seem to be a viable alternative in cases where the local alveolar bone crest conditions do not allow the insertion of an implant at the most favorable location (Aglietta *et al*. 2009; Freitas da Silva *et al*. 2018). A recent systematic review compared implant-supported fixed prostheses, with and without cantilevers. The authors concluded that the presence of a cantilever does not interfere in the survival of the prosthesis or the marginal bone loss (Freitas da Silva *et al*. 2018). This is supported by other systematic reviews demonstrating a slightly increased rate of technical complications (Torrecillas-Martinez *et al*. 2014), but similar survival rates between implants with and without cantilevers (Van Nimwegen *et al*. 2017; Storelli *et al*. 2018). From a treatment planning point of view, these data may permit consideration of short-span implant-supported FDPs as a valid treatment option for the replacement of missing posterior teeth that avoids the more complex surgical bone augmentation procedures that are necessary for placement of an implant in a traditionally optimal position from a prosthodontic point of view. It has to be underlined in this context, however, that basic prosthodontic design principles, such as increased dimensions of the connectors, have to be respected to avoid mechanical complications.

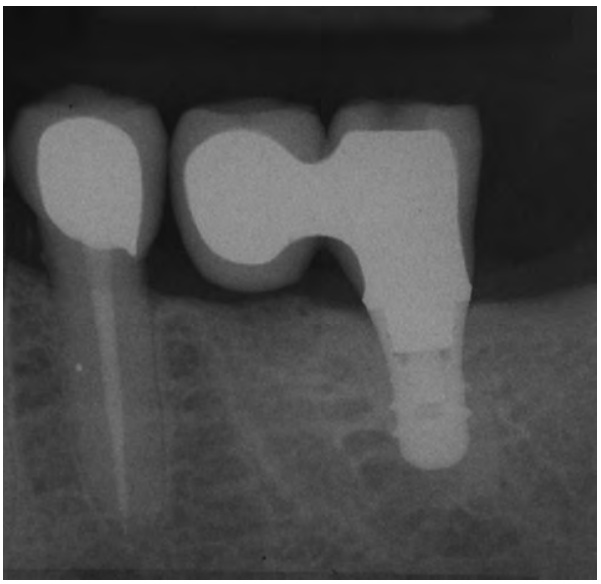

Fig. 44-9 Periapical radiograph of an implant with a mesial cantilever.

Shortened dental arch (SDA) concept

Generally, efforts are made to completely reconstruct a partially edentulous dentition. The question arises whether or not missing teeth have to be replaced at all and to the full extent. Usually, single teeth are replaced because of predominantly esthetic demands, while multiple missing teeth may also affect functionality and chewing capacity and hence, are replaced to improve these aspects. However, it is evident from cross-sectional and longitudinal studies (Kayser 1981; Reissmann *et al*. 2014; Reissmann *et al*. 2019; Walter *et al*. 2020) that not all lost teeth are replaced. The loss of one or more molars especially has been thoroughly studied. Studies on shortened dental arches (SDAs) have shown that dentitions comprising anterior and premolar teeth in general fulfill the requirements of a functional dentition, including patient-assessed oral comfort and chewing ability (Fig. 44-10). A review of the literature on SDAs concluded that the concept deserves serious consideration in treatment planning for partially edentulous patients. However, with ongoing

Fig. 44-10 Occlusal view of a patient rehabilitated with implant supported crowns according to the shortened dental arch (SDA) concept.

changes, for example in dental health and economy, the concept requires continuing research, evaluation, and discussion (Fueki & Baba 2017; Manola *et al*. 2017). Special attention has to be given to the patient's own needs and desires for increased chewing capacity when considering the SDA as a limited treatment goal. Clinical observations as well as research findings indicate that elderly patients can function at an acceptable level with a reduced dentition consisting of 10 or even fewer occluding pairs of teeth (Kayser 1981). This is further supported by a more recent review stating that 20 teeth throughout life will assure oral function (Gotfredsen & Walls 2007). The choice of implants as abutments to fulfill individual needs may, therefore, become a welcome treatment option within the concept of a shortened dental arch thereby avoiding additional bone augmentation procedures.

Combination of implant and natural tooth support

Combined tooth- and implant-supported FDPs are a treatment option in clinical situations where bone deficiencies only allow the placement of one implant (e.g. posterior sites) or for patients with limited finances. The potential advantages of combined FDPs are lower patient morbidity and lower treatment cost. Systematic reviews on combined FDPs reported a 5-year FDP survival rate of 90.1% (Lang *et al*. 2004) to 94.7% (Mamalis *et al*. 2012). Similarly, outcomes from a more recent systematic review reported a survival rate of 90.8% at 5 years (von Stein-Lausnitz *et al*. 2019). At 10 years, the survival rates ranged from 77.8% (Mamalis *et al*. 2012) to 82.1% (Lang *et al*. 2004), which are significantly lower than the 10-year survival rates of FDPs supported by implants only (Pjetursson *et al*. 2004). The indications for combined tooth- and implant-supported FDPs are therefore limited due to their relatively low survival rates.

Therapeutic concepts at sites requiring larger bone augmentation procedures

Maxilla–sinus floor elevation procedures

In the posterior regions of the maxilla, the clinician is often confronted with a reduced bone height because of a close relationship to the maxillary sinus. In these cases, different options exist: (1) primary sinus elevation and subsequent implant placement (Raghoebar *et al*. 2019); (2) implant placement with simultaneous sinus elevation (transalveolar approach or lateral window technique) (Pjetursson *et al*. 2008; Tan *et al*. 2008; Raghoebar *et al*. 2019); (3) use of shorter implants to avoid extensive bone augmentation procedures (Thoma *et al*. 2015; Jung *et al*. 2018); and (4) installation of angulated implants (Apaza Alccayhuaman *et al*. 2018) or zygomatic implants. The last of these options is mostly performed in edentulous cases by experienced maxillofacial surgeons (Davo & Pons 2015; Chrcanovic *et al*. 2016).

Sinus floor elevation Primary sinus augmentation procedures are indicated in cases with insufficient implant stability, which are often encountered when the vertical ridge height is <4 mm (Pjetursson *et al*. 2008; Raghoebar *et al*. 2019). This procedure is well documented, predictable, and can lead to high implant survival rates (Pjetursson *et al*. 2008; Jepsen *et al*. 2019; Raghoebar *et al*. 2019). However, the overall treatment time is increased since a healing time of several months (3–12 months depending on the graft material used) is required before implant placement can be performed. In some cases, primary implant stability can be achieved (ridge height 3–6 mm) when standard-length implants are placed simultaneously with either one of the two sinus elevation procedures (transalveolar or lateral window approach) (Pjetursson *et al*. 2009; Raghoebar *et al*. 2019). Simultaneous bone augmentation and implant placement can reduce the overall treatment time and costs and limit the number of surgical interventions. Implant survival rates are reported to be similar for all three sinus elevation procedures (transalveolar approach, lateral window one-stage or two-stage approach) with estimated implant survival rates over 3 years ranging between 88.5% and 98.3% (Pjetursson *et al*. 2008; Tan *et al*. 2008). In cases of the lateral window approach, the implant survival ranges between 88.6% and 100% at 5 years (Raghoebar *et al*. 2019). However, the transalveolar procedure offers benefits in being less invasive and less time-consuming (Tan *et al*. 2008).

Sinus floor elevation versus short implants Compared with standard-length implants in combination with extensive bone grafting procedures, the use of shorter implants potentially provides a variety of benefits: lower risk of damage to adjacent structures (roots, nerves, vessels, sinus), fewer complications, less invasiveness, fewer diagnostic procedures necessary, less diagnostic and surgical skill necessary, shorter treatment time, easier removal in case of failure, and less patient morbidity (Thoma *et al*. 2015; Jung *et al*. 2018).

In order to demonstrate that the use of short implants may result in similar survival rates to those for longer implants with sinus elevation procedures, various studies have been conducted and others are ongoing. In a recent randomized controlled clinical trial, short implants (6 mm) were compared with long implants (11 mm) placed in augmented sinuses (Thoma *et al*. 2018). At 5-years post loading, the results demonstrated similar survival rates for both implant lengths and treatments. However, the use of short implants was associated with a faster and cheaper treatment and less patient morbidity (Thoma *et al*. 2015). These data indicate that the use of short implants in the posterior maxilla may be considered a valuable treatment option (Jung *et al*. 2018) (Fig. 44-8).

Mandible–vertical ridge augmentation

In cases with a reduced ridge height in the mandible, three options exist: (1) primary vertical ridge

augmentation (Urban *et al*. 2019) and subsequent implant installation (Rocchietta *et al*. 2008; Esposito *et al*. 2019); (2) simultaneous implant placement with vertical ridge augmentation (Simion *et al*. 2007); and (3) the use of short implants (Jung *et al*. 2018; Papaspyridakos *et al*. 2018).

Vertical ridge augmentation Primary ridge augmentation procedures that allow the placement of standard-length implants have been proposed to result in smaller crown-to-implant ratios, better esthetics, and better cleanability of the prosthetic reconstruction. An array of different techniques (Urban *et al*. 2019) have been described for primary bone augmentation, including guided bone regeneration (GBR), distraction osteogenesis, and onlay bone grafting. The success rates of these techniques vary quite extensively. In addition, only a limited number of publications are available, and these are from a confined number of surgeons who are able to perform these treatments successfully. Their general use has therefore not been recommended (Rocchietta *et al*. 2008). The main reasons for this lack of recommendation included great variability in outcomes, a high rate of complications (extending up to 75%), and operator sensitivity (Rocchietta *et al*. 2008). However, a recent systematic review concluded that vertical ridge augmentation is a reasonable therapy for the reconstruction of deficient alveolar ridges. Although no technique is superior to others in terms of vertical augmentation (Urban *et al*. 2019), GBR using non-resorbable barrier membranes seems to be the preferable technique due to the low postoperative complication rates.

Vertical ridge augmentation versus short dental implants Similar to the maxilla, the use of shorter implants may avoid extensive bone regenerative procedures in cases with a ridge height exceeding 6 mm (Jung *et al*. 2018). Comparative clinical studies after 5 years of loading demonstrated fewer complications and less marginal bone loss with short implants compared with primary ridge augmentation and longer implants (Esposito *et al*. 2019). Hence, both patients and clinicians may benefit from the use of short implants. However, more comparative clinical studies with documented long-term data need to be provided (Nisand *et al*. 2015).

Diagnostics

Preoperative diagnostics in the posterior dentition

Dental implants are placed to support reconstructions (Esposito *et al*. 1998), and therefore, prosthetically driven implant placement is a prerequisite for the achievement of an ideal biomechanical, functional, and esthetic treatment outcome (Chiapasco & Casentini 2018). Together with anatomical site evaluation and risk assessment, the preoperative prosthetic diagnostics are essential for correct treatment planning in implant dentistry. The larger the span and the higher the complexity of the planned reconstruction, the more important are preoperative diagnostics.

Fig. 44-11 Conventional wax-up on a cast.

Fig. 44-12 Digital set-up as a screen view.

Prosthetic diagnostics are conventionally performed by means of a diagnostic set-up manufactured on plaster models (Fig. 44-11) as well as digitally using intraoral scans, digital set-ups (Fig. 44-12), and 3D-printed try-in mock-ups. More recently, even augmented reality came into play, allowing patients and professionals to mimic and visualize the final treatment outcome prior to any intervention (Joda *et al*. 2019).

The three-dimensional space available for the reconstruction will have a significant impact on the prosthetic and implant planning. In cases with reduced or excessive mesiodistal or vertical (distance from the prospective restorative margin to the opposing occlusion) space, adjunctive therapies might be necessary to adjust the space to that needed for the planned reconstruction (Fig. 44-13). This may involve orthodontic, surgical, reconstructive, or endodontic treatment procedures. Therefore, such clinical situations will result in an increased complexity of the treatment with dental implants.

Prior to the selection of implant design, length, and diameter, the following prosthetic elements have to be defined:

Fig. 44-13 Reduced vertical amount of space in the area of missing teeth 24, 25, and 26 due to elongation of antagonist teeth.

- Reconstruction design and material
- Prospective mucosal margin
- Type of retention
- Occlusal scheme.

Three-dimensional radiographic diagnostics and planning

The introduction of cone-beam computed tomography (CBCT) has allowed the acquisition of 3D images with an adequate quality for dentomaxillofacial examinations at reduced radiation doses compared with conventional multislice computed tomography (CT) (Loubele *et al*. 2009). The radiation burden of CBCT is, however, considerably higher in comparison to conventional two-dimensional (2D) radiography (Tyndall *et al*. 2012). Therefore, cross-sectional imaging should only be undertaken when it gives a justifiable benefit to the patient as a supplementary imaging technique where conventional radiography failed to answer the question for which imaging was required (Tyndall *et al*. 2012).

Computer-assisted implant planning and placement

Several software programs for computer-assisted implant planning based on the data from CBCT scans have been recently developed (Fokas *et al*. 2018; Joda *et al*. 2018; Schneider *et al*. 2018, 2019). A prerequisite for optimal implant planning when using such systems is the combination of the information on bone anatomy with the 3D image of the previously planned prosthetic reconstruction. This can be achieved by means of radio-opaque prosthetic templates or by superimposing a digital set-up on the CBCT image. To transfer the preoperatively planned implant position to the surgical site, intraoperative (static) guidance (Joda *et al*. 2018) or (dynamic) navigation (Aydemir & Arisan 2020) is required. Due to the limitation of computer-assisted implant planning and placement regarding accuracy (Tahmaseb *et al*. 2018; Schneider *et al*. 2019), the clinician should always allow an adequate safety margin for the relevant anatomic structures.

The following clinical situations may benefit from 3D radiographic diagnostics and planning as well as guided surgery (Dula *et al*. 2015; Wismeijer *et al*. 2018):

- In situations with limited vertical or horizontal dimension of the alveolar ridge in which, on the basis of the clinical examination, the two-dimensional X-ray images and the prosthetic diagnosis, a lateral bone augmentation (Fig. 44-14) or sinus elevation with lateral antrostomy is anticipated
- In situations where the two-dimensional X-ray images have failed to identify relevant anatomic structures (Fig. 44-15)
- In cases with unfavorable bone morphology and where there is low tolerance regarding the correct implant position
- If minimally invasive (e.g. flapless) surgery is intended
- When immediate implant restoration is planned, the use of CBCT in combination with guided surgery may be beneficial to obtain sufficient primary implant stability and to prepare the prosthetic reconstruction in advance.

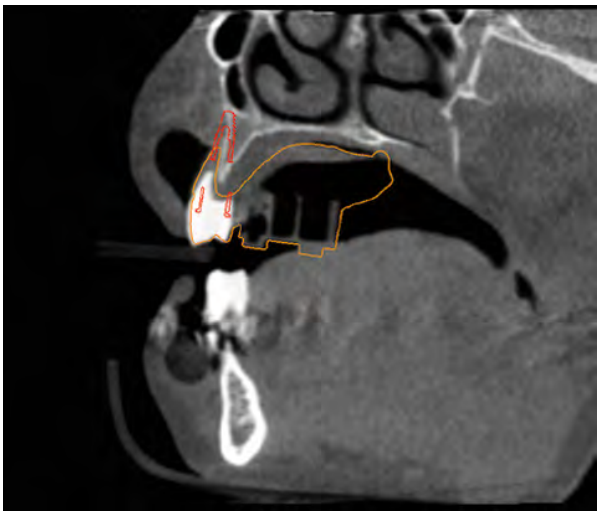

Fig. 44-14 Computer-assisted implant planning by superimposing the cone-beam computed tomography and the stereolithography data obtained from the diagnostic mock-up.

General considerations and decision-making for implants in the posterior dentition

Decision-making between implant-supported reconstruction and tooth-supported fixed dental prostheses

The decision-making process between implant-supported reconstruction and tooth-supported FDPs and the related decision criteria should be derived essentially from scientific evidence and objective prosthetically oriented risk assessments, as well as patient-related factors, including cost effectiveness and quality of life.

In the clinical situation of a hopeless tooth in the posterior dentition, the therapeutic options are a conventional bridge or an implant-supported single crown (Fig. 44-16). In terms of a hierarchy of decisions, the most important question is whether or not the prognosis of an implant-supported reconstruction is similar to that of a tooth-supported FDP. A systematic review of implant-supported single crowns reported an estimated survival rate of 96.3% after 5 years (Jung *et al*. 2012). These results were similar to the data reported for tooth-supported FDPs, revealing a survival rate of 94.4% after 5 years (Pjetursson *et al*. 2015). From a prognosis point of view, neither of the two treatment modalities appear to be superior to the other. However, it has to be considered that the type of complications seems to be different with each modality. Conventional tooth-supported bridges reveal more biologic complications like caries and loss of abutment vitality, whereas implant-supported single crowns show more technical complications like abutment or occlusal screw loosening. This has an impact on the severity and the invasiveness of the therapeutic intervention during the maintenance phase.

At the next level in the hierarchy for the decision-making process is the clinical and anatomical assessment and the patient's expectations. The clinical analysis comprises the comprehensive evaluation of the neighboring natural abutment teeth, including their structural, restorative, periodontal, and endodontic status. This objective evaluation is of primary importance and represents an ever-increasing challenge to the clinician. This is illustrated by a maxillary posterior segment where both the first premolar and the first molar were missing (Fig. 44-17). The insertion of a five-unit tooth-borne FDP was considered too invasive given the intact canine, and also not suitable because of a slightly questionable status of the endodontically treated second premolar in view of its eventual use as a so-called "peer-abutment". Finally, an implant had been placed at the site of the missing first premolar and subsequently restored with a single-unit restoration. As the proximity of the maxillary sinus at the location of the missing first molar would have required a grafting procedure to make an implant installation possible, a three-unit tooth-supported FDP was ultimately chosen, after having duly discussed the relevant advantages and shortcomings with the patient. Having attributed a "strategic value" to the moderately compromised second premolar by using it as an abutment for a short-span bridge, there was still a difficulty in consistently establishing clinical treatment plans that were fully based on scientific evidence.

Finally, the patient's expectations and requests are very important in the decision-making process. Besides the prognosis and the invasiveness of the reconstruction, the patient will want to know the cost difference and the treatment time difference between implant-supported reconstructions and tooth-supported FDPs. In a retrospective clinical study performed in private practice, 37 patients received 41 conventional FDPs and 52 patients received 59 implant-supported single crowns (Bragger *et al*. 2005). The aim was to assess and compare the economic aspects by recording the number of visits, chair-side time, treatment costs, and costs for implant components and laboratory work. It was reported that the implant treatment required more visits than FDP treatment; however, the total

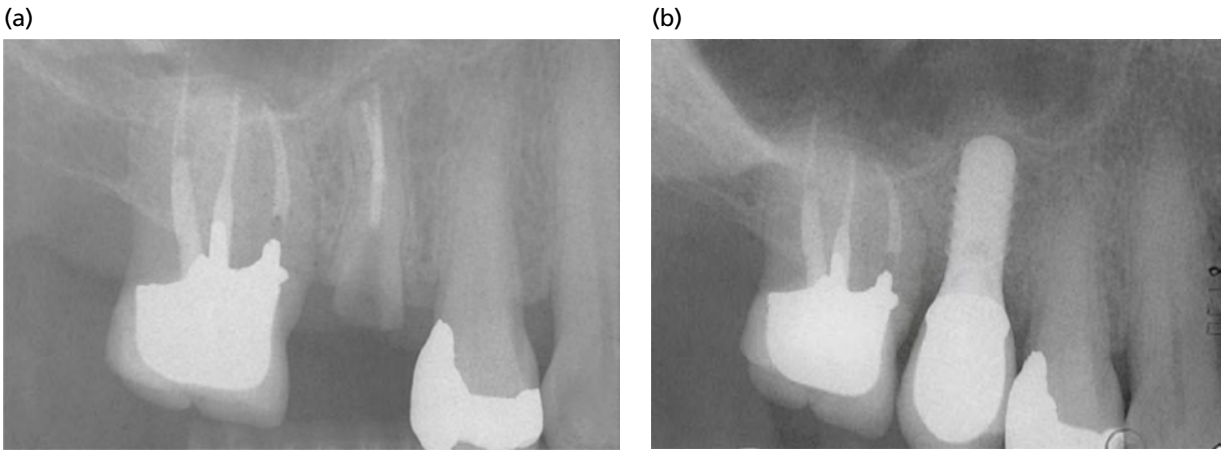

Fig. 44-16 (a) Ad hoc radiograph of the upper right posterior sextant. Note the presence of a structurally greatly compromised second premolar with a periapical pathology. Based on the clinical and radiographic assessment, tooth 15 was considered hopeless. (b) Postoperative radiograph shows that the root of the second premolar was replaced by a single-tooth implant restoration. In particular, the pre-existing metal–ceramic crown on the first molar could be maintained with this approach.

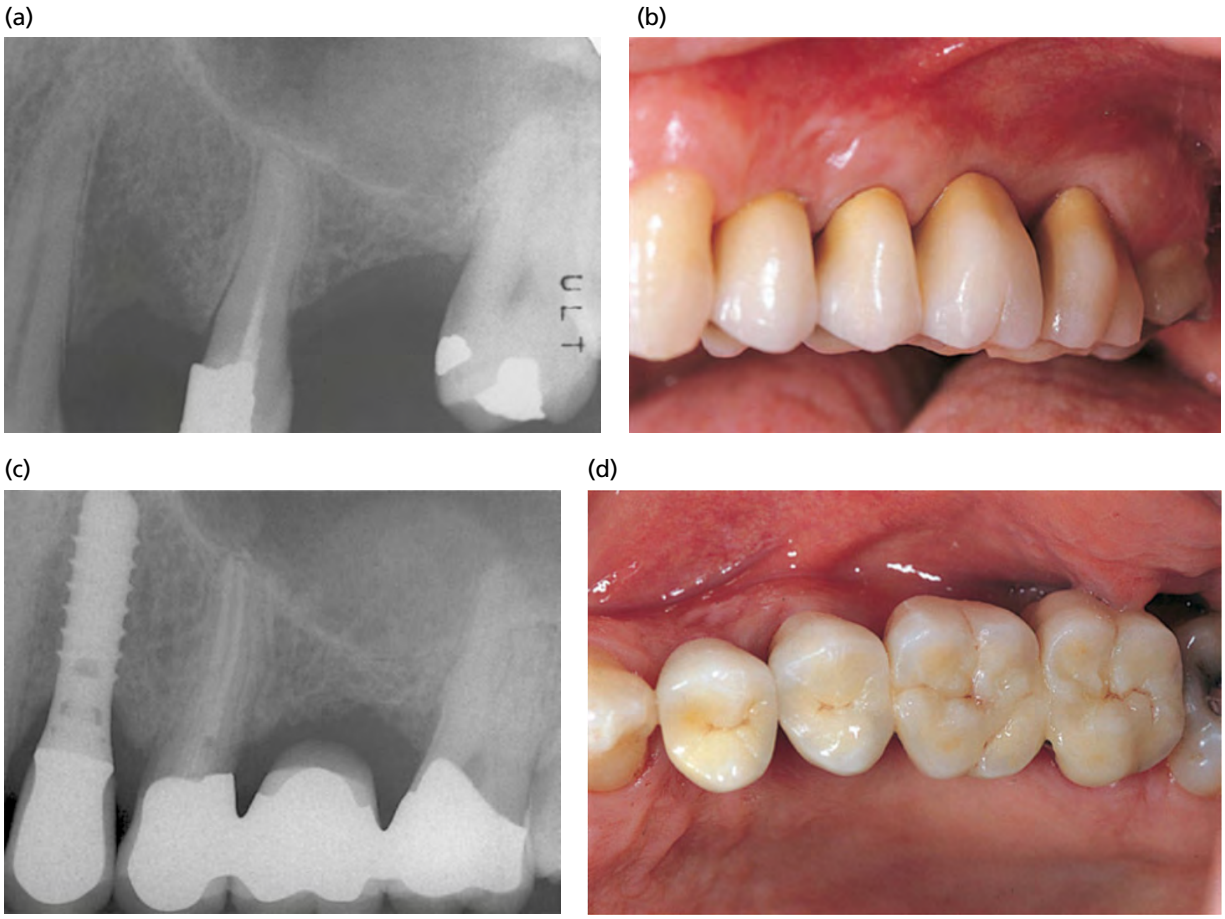

Fig. 44-17 (a) Preoperative radiograph of the left maxilla, revealing two missing dental elements. Note in particular an intact canine, a structurally reduced second premolar, and an extended recessus of the sinus in the area of the missing first molar. (b) Vestibular view of the prosthetic rehabilitation of the maxillary left quadrant: an implant-supported single-tooth restoration on the site of the first premolar, and a three-unit tooth-borne fixed dental prosthesis to replace the missing first molar. (c) Postoperative radiograph documents that an endodontic revision has been performed on the second premolar prior to its restoration with an adhesive carbon-fiber, post-based build-up and a metal–ceramic crown. (d) An identical prosthetic design has been applied for both the implant-supported and the tooth-supported restoration.

treatment time was similar. Regarding the costs, the laboratory costs and the total treatment costs were higher for FDPs than for implant-supported single crowns. Even when considering opportunity costs for each visit, the implant solution was less expensive. It was stated that over a short observation period of 1–4 years, the implant reconstruction demonstrated a more favorable cost-to-effectiveness ratio. Especially in clinical situations with either non- or minimally restored teeth and sufficient bone, the implant reconstruction can be recommended from an economic point of view (Bragger *et al*. 2005). These findings were further confirmed by a more recent systematic review indicating that implant-supported single crowns are more cost-effective than FDP (Beikler & Flemmig 2015).

Conclusion: The decision-making process between implant-supported reconstruction and tooth-supported FDPs should be based on the prognosis and the complication rate, the clinical assessment of the neighboring teeth and the anatomic condition of the edentulous area, and the patient's expectations.

Provisional reconstructions

The period of time between the beginning of therapy and implant loading in implant dentistry may amount to several months. Due to the functional, phonetic, and esthetic impairments during this period, it might be necessary to intermediately restore the edentulous region by means of a provisional reconstruction. Additionally, the provisional reconstruction may be indicated in order to test the ideal design of the final reconstruction, the patient's adaptation to the planned reconstruction, and it represents an important communication instrument between the patient, the dental technician, and the dentist.

The selection of the type of provisional has to be based on the patient's requirements, conditions of

Fig. 44-18 Provisional removable partial denture.

Fig. 44-19 Clear thermoplastic sheet containing pontics of the missing teeth.

the edentulous site, prosthetic requirements of the adjacent teeth, duration of the provisional phase, and financial considerations. The following types of temporary reconstruction are available:

- Removable partial denture (Fig. 44-18)
- Removable thermoplastic sheet containing pontics of missing teeth (Essix provisional) (Fig. 44-19)
- Provisional implant-borne fixed reconstruction with immediate (non-functional) loading
- Fixed partial denture (if full coverage of the adjacent teeth is required)
- Palatal implants (predominantly in patients undergoing simultaneous orthodontic treatment).

Resin-bonded partial dentures are generally unfavorable for the provisionalization of the posterior dentition due to the risk of debonding and fractures and significantly lower survival compared with resin-bonded bridges in the anterior zone (Thoma *et al*. 2017).

A correctly designed provisional should include the ability to accommodate changes of the underlying soft tissue and avoid uncontrolled pressure on healing implants and augmented regions.

Loading concepts

Loading concepts in implant dentistry have been widely discussed in the literature. Initially, healing phases of 3 months in the mandible and 6 months in the maxilla were recommended (Branemark *et al*. 1977). In order to meet the patients demands for earlier prosthetic rehabilitation, shortened healing periods between implant installation and loading were introduced. A variety of influencing factors, like initial implant stability, implant surface characteristics, bone quantity, bone healing, interim prosthesis design, and occlusal pattern during the healing phase, have been identified for successful osseointegration with modified loading protocols (Gallucci *et al*. 2018). Based on improvements primarily related to developments of the implant design (resulting in a higher primary stability) and surface modifications (resulting in an accelerated osseointegration), earlier time-points including immediate loading have been well documented (Gallucci *et al*. 2018).

Over time, the terminology for timing of loading has changed a few times. The most recent reference refers to the following terminology: "immediate loading or type A" is defined as a prosthesis in occlusion with the opposing arch within 7 days following implant placement; "immediate restoration or also type A" as a prosthesis held out of occlusion with the opposing arch within 7 days following implant placement; "early loading or type B" as a prosthesis being connected between 1 week and 2 months after implant placement; "conventional loading or type C" as a prostheses connected >2 months after implant placement allowing a longer healing period (Table 44.1) (Gallucci *et al*. 2018; Morton *et al*. 2018).

Concepts for partially edentulous patients

In patients with partially edentulous segments, various studies have confirmed high implant survival of immediately or early loaded compared with conventionally loaded implants. The respective mean survival rates range between 96% and 98.4% (Gallucci *et al*. 2018). These survival rates, however, do not take into account the considerable influence of the timing of implant placement as well as the fact that the majority of the studies on immediate and early loading were performed in the esthetic zone or using full-arch reconstructions. Thus, a more conservative approach combining late implant placement with early or delayed loading or immediate/early/

Table 44.1 Implant loading protocols. (Sources: Gallucci *et al*. 2018; Morton *et al*. 2018. Reproduced with permission of John Wiley & Sons.)

Loading protocol	
Type A	Immediate restoration/loading
Type B	Early loading
Type C	Conventional loading

late placement with conventional loading appears to be reasonable since these combinations are clinically well documented (Gallucci *et al*. 2018; Morton *et al*. 2018). Contributing factors in the posterior maxilla and mandible include cases of low implant stability including a complete lack of primary stability, extensive bone augmentation, or patient-related risk factors (e.g. parafunction, bruxism). In these cases, a conventional loading is recommended (Gallucci *et al*. 2018) (Table 44.1).

Loading concepts for single-tooth replacements

The load-bearing region of the maxilla and mandible present a higher risk and the decision on the timing of loading appears to be critical. The scientific evidence based on clinical studies applying immediate and early implant loading concepts for the posterior maxilla and mandible is increasing immensely, however (Ganeles *et al*. 2008; Nicolau *et al*. 2013). This is predominantly based on modifications of the implant design, surface, and the drilling protocol, ensuring a higher primary stability and a faster osseointegration.

Based on a clinical study, the comparison between immediate and early loading of implants in the posterior region did not demonstrate differences in terms of implant survival (Ganeles *et al*. 2008). Similar outcomes were reported for single implants in the posterior mandible with survival rates amounting to 97.4% (immediate) and to 96.7% (early) at 3 years post loading (Nicolau *et al*. 2013). Given this more recent clinical evidence, traditional loading concepts appear to be changing and at least the early loading concept might soon be considered as a standard of care.

It is important, however, to point out that the scientific documentation is almost exclusively based on studies with implants placed in sites with sufficient bone and without concomitant bone augmentation techniques. Therefore, little scientific documentation exists on outcomes of implants placed with simultaneous GBR procedures (Salvi *et al*. 2018). Depending on the size of the bone defect, it might be advisable to allow for longer healing periods after implant placement in conjunction with GBR (Jung *et al*. 2015) or sinus elevation procedures (Raghoebar *et al*. 2019). Human histologic data show a marked increase of bone in grafted sites between 6 and 8 months after augmentation (Cordaro *et al*. 2008). Clinical data for the augmented sinus recommend conventional loading protocols for dental implants placed with a lateral window or a transalveolar approach (Raghoebar *et al*. 2019). In clinical practice, loading of implants 3–6 months after placement together with GBR procedures has been documented to be a successful concept after 3–5 years of observation (Jung *et al*. 2015; Basler *et al*. 2018).

In general, immediate or early loading can be considered in patients with a high primary implant stability and without systemic risk factors or significant peri-implant bone defects. Splinted fixed reconstructions are favored over removable or single crown reconstructions in the posterior segments (Jung *et al*. 2018). Moreover, when considering immediate or early loading, reconstructions can be fabricated free from occlusal load as described earlier (Gallucci *et al*. 2018).

Splinted versus single-unit restorations of multiple adjacent posterior implants

In situations with multiple adjacent implants, the dentist faces the decision between fabricating either splinted or unsplinted implant crowns. The rationale for splinting implants is to evenly distribute loading forces on all the implants in order to minimize the stress on the marginal bone, implants, and prosthetic components. Dentists usually give the following reasons for splinting adjacent implants:

- Poor bone quality or major bone augmentation procedures (e.g. sinus floor elevation)
- Short implants or reduced diameter implants
- Anticipation of high occlusal forces (e.g. bruxism)
- Easier handling for the dentist (no adjustment of interproximal contacts is necessary).

The main arguments against splinting are:

- Perfect framework fit is more difficult to achieve with a multiunit FDP
- Interproximal hygiene is more demanding (if the use of interdental brushes or floss is hampered by the connector)
- Re-intervention is more complicated for multi- than single-unit FDPs (especially for cemented FDPs).

In the literature, the issue of splinting adjacent implants is controversial (Grossmann *et al*. 2005). Clinical studies directly addressing the issue reported no difference in survival rate or marginal bone loss between splinted and unsplinted implants (Clelland *et al*. 2016). Unsplinted implants nevertheless exhibited more technical complications such as screw loosening. More recently, a systematic review with meta-analysis assessed the marginal bone loss, implant survival rate, and prosthetic complications of splinted and unsplinted implant restorations. The study concluded that there were no differences in the marginal bone loss and prosthetic complications between splinted and unsplinted implant restorations. However, splinted restorations were associated with a decreased implant failure (de Souza Batista *et al*. 2019). The concept of splinting adjacent implants is also challenged by the evidence for high survival and success rates of unsplinted short implants particularly at the posterior region of the mandible (Ravida *et al*. 2019). It might be advisable, nonetheless, to splint restorations involving adjacent short implants (Jung *et al*. 2018). In general, there is no evidence that overloading of osseointegrated implants

is a phenomenon that occurs under standard clinical conditions (Lima *et al*. 2019). Thus, there is probably no need to distribute loading forces over several implants and no need to splint implants of standard diameter and length in sufficient bone quality and in patients without parafunctional habits.

Type of reconstruction(s)

When it comes to the prosthetic reconstruction of implants in the posterior region, the clinician has to decide on the type of retention and the material of the reconstruction. The decision is based on both general and clinical considerations:

- Does the implant angulation allow for screw-retention?
- How thick is the mucosa and how important are esthetics?
- What kind of reconstruction is planned: single unit/cantilever FDP/multiunit FDP (≥3 units).

Type of retention

The major advantages of screw-retained prostheses include retrievability and accessibility, facilitating replacement and maintenance of the reconstruction (Wittneben *et al*. 2017b). In addition, it is easier to shape the emergence profile with screw-retained implant provisionals and to transfer the contour to the master cast. Screw-retained restorations, nevertheless, usually involve more complex and more expensive laboratory procedures and can suffer from inherent mechanical complications such as screw loosening and fractures (Wittneben *et al*. 2017b). The presence of a screw access hole may impede the occlusal morphology and thus, interfere with the occlusion. Furthermore, the ceramic layer is thereby discontinued, which could have an impact on the stability of the ceramics in the long-term (Fig. 44-20).

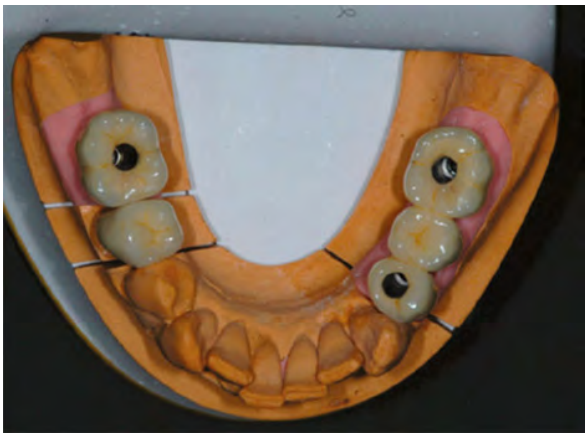
In contrast to the screw-retained restorations, where the ideal implant axis is a prerequisite, a cemented reconstruction offers the option to better compensate for a suboptimal implant position (Wittneben *et al*. 2017b). The restoration of inadequately positioned implants is facilitated through cementation and the esthetics of the restoration can be enhanced since the screw access hole is not visible (Wittneben *et al*. 2014). One of the major advantages of cement-retained restorations therefore is the absence of a screw opening (Fig. 44-21). As well as the abovementioned advantageous esthetics, an optimal occlusal morphology and a sound ceramic layer are enabled (Hebel *et al*. 1997). Nonetheless, a variety of disadvantages for cemented reconstructions have been reported, including the difficulty of removing cement and thereby a higher risk of peri-implant disease, a more complex retrievability of the reconstruction, and the possibility of crown loosening due to loss of retention (Wittneben *et al*. 2017b; Monje *et al*. 2019).

Clinically, the choice between using screw-retained or cemented reconstructions is controversial and mostly depends on the preference of the clinician (Sailer *et al*. 2012; Wittneben *et al*. 2017b).

With regard to the survival of implants and restorations, no differences were reported based on systematic reviews focusing on the comparison of the

Fig. 44-21 Cement-retained implant supported crown at site 36.

(a)



(b)

Fig. 44-20 Missing teeth (46, 34, 35, 36) in the posterior mandible. (a) The final screw-retained reconstruction on the master cast. (b) Screw-retained reconstruction with single implant crown (46) and screw-retained fixed dental prosthesis (35 × 37) after closing the screw-access holes.

two treatment modalities with survival rates being reported to range between 89.3% and 96.5% (single crowns) and between 96.9% and 98% for multiunit reconstructions (Sailer *et al*. 2012). Major differences, however, are reported in terms of the rate of complications. Screw-retained reconstructions predominantly suffer from technical complications, whereas cemented reconstructions are associated with a higher rate of major biological complications (Sailer *et al*. 2012).

Conclusion: On the basis of the existing scientific evidence, the decision to cement or screw-retain an implant restoration can rest on a clinician's personal preference when the implants are placed in a manner that allows both options (implant placement enabling optimal location of the screw access hole at screw-retained restorations). Ideally, the choice should depend on each particular patient situation, including anatomic, economic, and esthetic factors. However, from a clinical point and bearing in mind that technical rather than major biological is the "preferred" type of complications, screw-retention should be chosen whenever possible (Sailer *et al*. 2012; Wittneben *et al*. 2017b).

Selection criteria for choice of reconstruction materials

The posterior region of the jaw being the most load-bearing area mainly requires mechanically stable and biocompatible materials for the reconstructions. Today, a large variety of biocompatible materials is available due to the widespread use of CAD-CAM technology. Different factors are crucial to making the right decision between the optimal material and the reconstruction type for the posterior region (Muhlemann *et al*. 2018).

In general, a choice can be made between two kinds of abutments: prefabricated and customized. The decision-making process should be based on a variety of clinical, technical, and biologic factors. For implant reconstructions (irrespective of their location), an adequate emergence profile is a prerequisite for healthy soft (biologic width) (Sculean *et al*. 2014; Araujo & Lindhe 2018) and hard tissue integration, as well as ease of cleaning for the patient and a natural appearance. Prefabricated abutments have long been the treatment of choice due to the ease of use, decreased costs and a limited availability of individualized options. More esthetic concerns associated with a one-piece dental implant being placed deeper and an increased use of two-piece dental implants resulted in greater distances between the implant shoulder and the mucosal margin. This considerably increases the risk of cement excess (Monje *et al*. 2019). Therefore, the number of standardized abutments is decreasing and can only be proposed in clinical situations where the implant shoulder is close to the mucosal margin (Agar *et al*. 1997; Sancho-Puchades *et al*. 2017).

In addition, in molar areas, a large deviation between implant and crown diameters can often be found. In these situations, customized abutments in conjunction with the ideal emergence profile allow the crown margin to follow the present mucosal outline (Marchack 1996). Further conditions, like a limited vertical distance between the crown and the surrounding bone, a prosthetically inadequate implant position, and a thin highly scalloped mucosa, require customization of abutments even in posterior regions (Wittneben *et al*. 2017b).

A large variety of materials is available both for abutments (e.g. gold, titanium, alumina, and zirconia) and crowns (e.g. PFM) (Fenner *et al*. 2016), veneered zirconia (Heierle *et al*. 2019), veneered lithium-disilicate (Simeone & Gracis 2015), monolithic zirconia (Lerner *et al*. 2020), and lithium-disilicate (Joda *et al*. 2017). Metal abutments offer excellent material stability and exhibit superior clinical outcomes (Jung *et al*. 2012). For a long time they were considered to be the "gold standard" (Jung *et al*. 2008). Today, high strength ceramics are competing with the well-documented metal materials. Clinical mid- to long-term data are encouraging when used for single-tooth implants in the esthetic zone (Wittneben *et al*. 2017a; Heierle *et al*. 2019). However, it remains controversial whether or not use of the former in posterior regions is acceptable. Based on more recent systematic reviews, all-ceramic reconstructions based on one-piece abutments were associated with significantly higher fracture rates compared with metal-based treatment options (Pjetursson *et al*. 2018; Sailer *et al*. 2018c). Therefore, a more conservative approach applying metal-based reconstructions appears to be advisable in the posterior zone (Zarauz *et al*. 2020).

In order to overcome the abovementioned mechanical issues of one-piece zirconia abutments, so-called hybrid abutments were introduced. Hybrid abutments consist of a standardized titanium base. CAD-CAM-fabricated all-ceramic monolithic crowns can be extraorally cemented allowing these reconstructions to be screw-retained intraorally (Fig. 44-22) (Kurbad & Kurbad 2013). These reconstructions are widely used because of decreased costs, extensive availability for many implant systems, and the option of using various all-ceramic reconstruction materials. Based on *in vitro* experiments, hybrid abutments offer a strength comparable to that of metal abutments while still providing esthetic benefits of all-ceramic reconstructions (Sailer *et al*. 2018a). Unfortunately, clinical data exceeding 3 years and the lack of randomized controlled clinical trials limit to some extent a general recommendation for that kind of reconstruction (Joda *et al*. 2017; Asgeirsson *et al*. 2019). Scientific data on cantilever and multiunit FDPs using hybrid abutments and monolithic reconstructions are scarce but appear to offer the same benefits as single-unit hybrid abutments. Clinically, this type of reconstruction is increasingly being applied predominantly in the posterior region of the jaw.

Conclusion: Metal-based reconstructions are still considered to be the gold standard for the load-bearing zone of the jaw. Depending on the clinical situation, the anatomy and the position of the implant(s), screw-retained or cemented reconstruction are chosen. The

Fig. 44-22 All-ceramic zirconia crown cemented to a hybrid abutment with a titanium base.

use of monolithic hybrid reconstructions is increasing for single- and multiunit reconstructions offering two main advantages: decreased costs and high mechanical stability, thereby reducing the risk of chipping.

Decision tree

The clinical decision tree involves three steps:

1. Does the implant angulation allow for screw retention?
2. What kind of reconstruction is planned: single unit/cantilever FDP/multiunit FDP (≥3 units)
3. How thick is the mucosa and how important are esthetics?.

Figures 44-23 and 44-24 illustrate the decision tree for the selection of the type of retention, the type of reconstruction, and the type of material.

Applied clinical concepts

Therapeutic concepts at sites with sufficient bone quantity

Single-unit gap size

Premolar-size single-tooth restorations

All-ceramic tooth reconstruction on titanium implant A 65-year-old woman was referred from the endodontist because of a vertical root fracture on tooth 14. The patient requested a fixed reconstruction at site 14. The patient did not smoke and was without any underlying health conditions. After explaining and discussing the different treatment alternatives, the patient chose an implant-supported reconstruction to replace the missing tooth (Fig. 44-25).

All-ceramic reconstruction on a one-piece zirconia implant A 73-year-old woman was referred by her general dentist after endodontic failure of tooth 24. Tooth 24 was extracted 5 months prior to implant placement with a simultaneous ridge preservation procedure. The patient formerly smoked and was without any underlying health conditions. She requested a fixed reconstruction at position 24. Furthermore, the patient asked for a metal-free implant solution. After discussing the possible

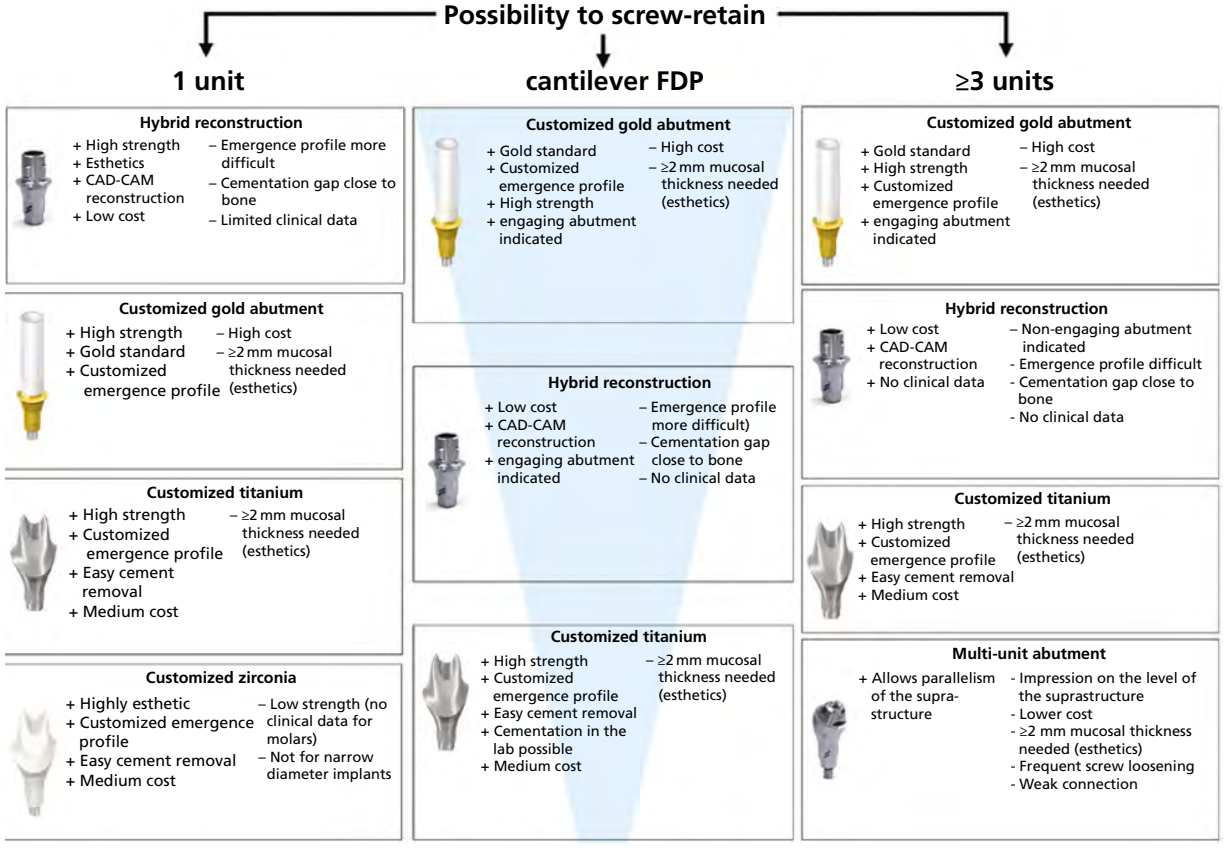


Fig. 44-23 Screw-retained decision tree.

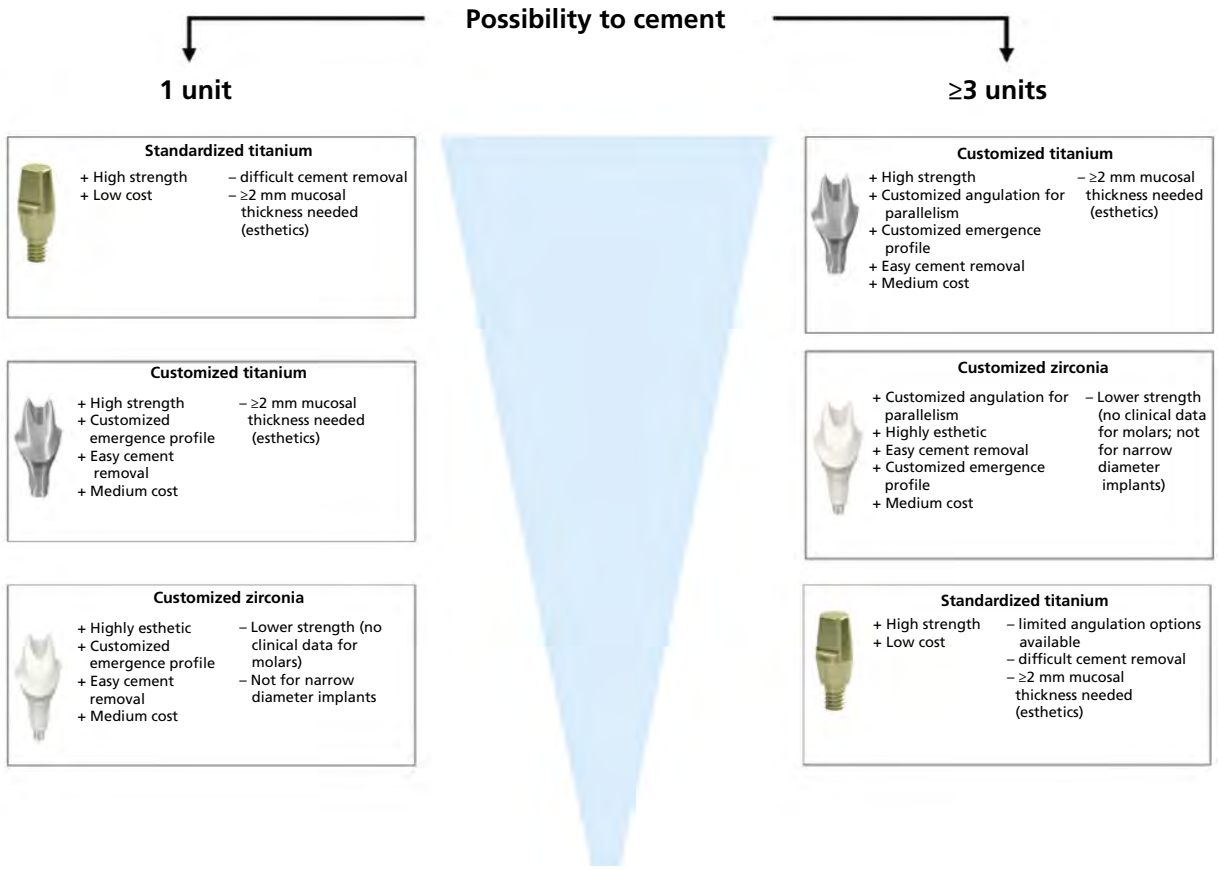

Fig. 44-24 Cement-retained decision tree.

treatment alternatives, an implant-supported crown using a zirconia implant was chosen. The patient was thoroughly informed about the advantages and disadvantages of zirconia implants in comparison with titanium implants. In addition, the patient was informed about the differences between one-piece and two-piece zirconia implants. Based on greater scientific evidence the patient chose a one-piece zirconia implant (Fig. 44-26).

Molar-size single-tooth restorations

A 69-year-old woman was referred by her general dentist for a restoration of a single-tooth gap at region 36. Tooth 36 was extracted due to a vertical fracture. The patient smoked fewer then 10 cigarettes a day and was systemically healthy. After having duly discussed the relevant advantages and shortcomings of implants with the patient, a standard titanium implant was chosen (Fig. 44-27).

Two-unit gap size

Two implants

A 73-year-old man was referred by his general dentist due to a vertical fracture of tooth 24 which supported a conventional tooth bridge (24–26). The patient did not smoke, was systemically healthy and requested a fixed and esthetic solution. After a thorough examination and discussion with the patient about the different treatment alternatives along with considering the good prognosis of the distal abutment tooth, it was decided to replace the two-unit gap size with two single implants (Fig. 44-28).

One implant with a cantilever

A 67-year-old woman was referred by her periodontist for a prosthetic rehabilitation at region 24–25. The patient, originally diagnosed with severe periodontitis, demonstrated a high standard of self-performed plaque control and all lesions in the periodontal tissues had been resolved. The patient wanted to increase her chewing comfort and therefore there was a need for a prosthetic rehabilitation in the posterior region of the maxilla. Furthermore, the patient, if possible, preferred to have fixed prosthetic reconstructions. After discussing the different alternatives with the patient along with considering her expectations, the morbidity, and particularly the costs, a single-tooth implant reconstruction with a mesial cantilever was chosen. The patient was informed that the treatment with a cantilever encounters a higher risk of technical complications compared with two implants with two single implant crowns (Halg *et al*. 2008) (Fig. 44-29).

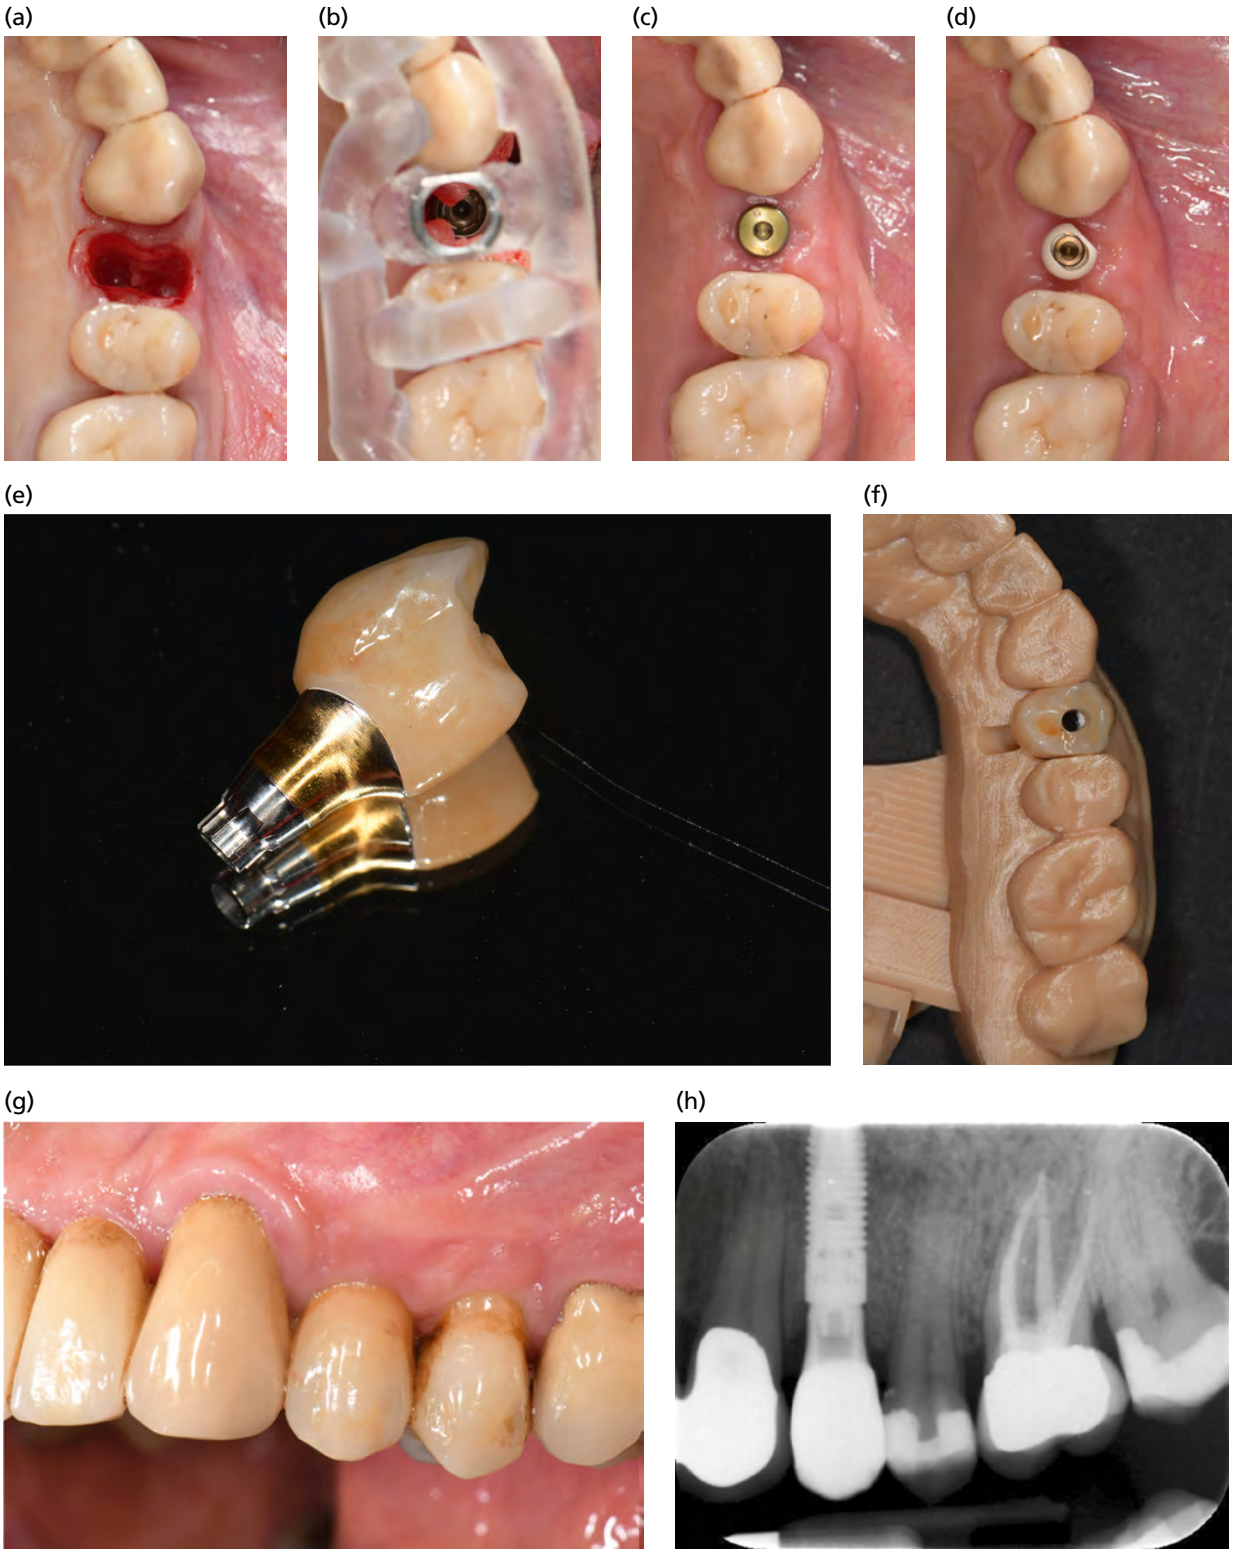

Fig. 44-25 (a) Clinical situation immediately after tooth extraction of tooth 24. The occlusal view reveals favorable soft and hard tissue conditions with an intact buccal bone plate. (b) Implant placement using a computer-assisted implant planning and placement (CAIPP) protocol. A 3D-printed surgical stent was placed to foster a prosthetically driven implant positioning. (c) Transmucosal healing 2 weeks after implant insertion with a healthy mucosa and a sufficient width of keratinized tissue. (d) Scan body mounted onto the implant serving as a digital reference for the digital impression by using an intraoral scanner. (e) For the screw-retained implant reconstruction a customized CAD-CAM-processed titanium abutment with an all-ceramic zirconia crown was fabricated. The veneered zirconia crown had been cemented to the titanium CAD-CAM abutment in the dental laboratory. (f) Screw-retained reconstruction fitted on the printed model. (g) Two weeks after all-ceramic crown delivery, showing healthy soft tissues and a sufficient amount of keratinized tissue. (h) Periapical radiograph reveals optimal osseointegration at the 1-year follow-up.

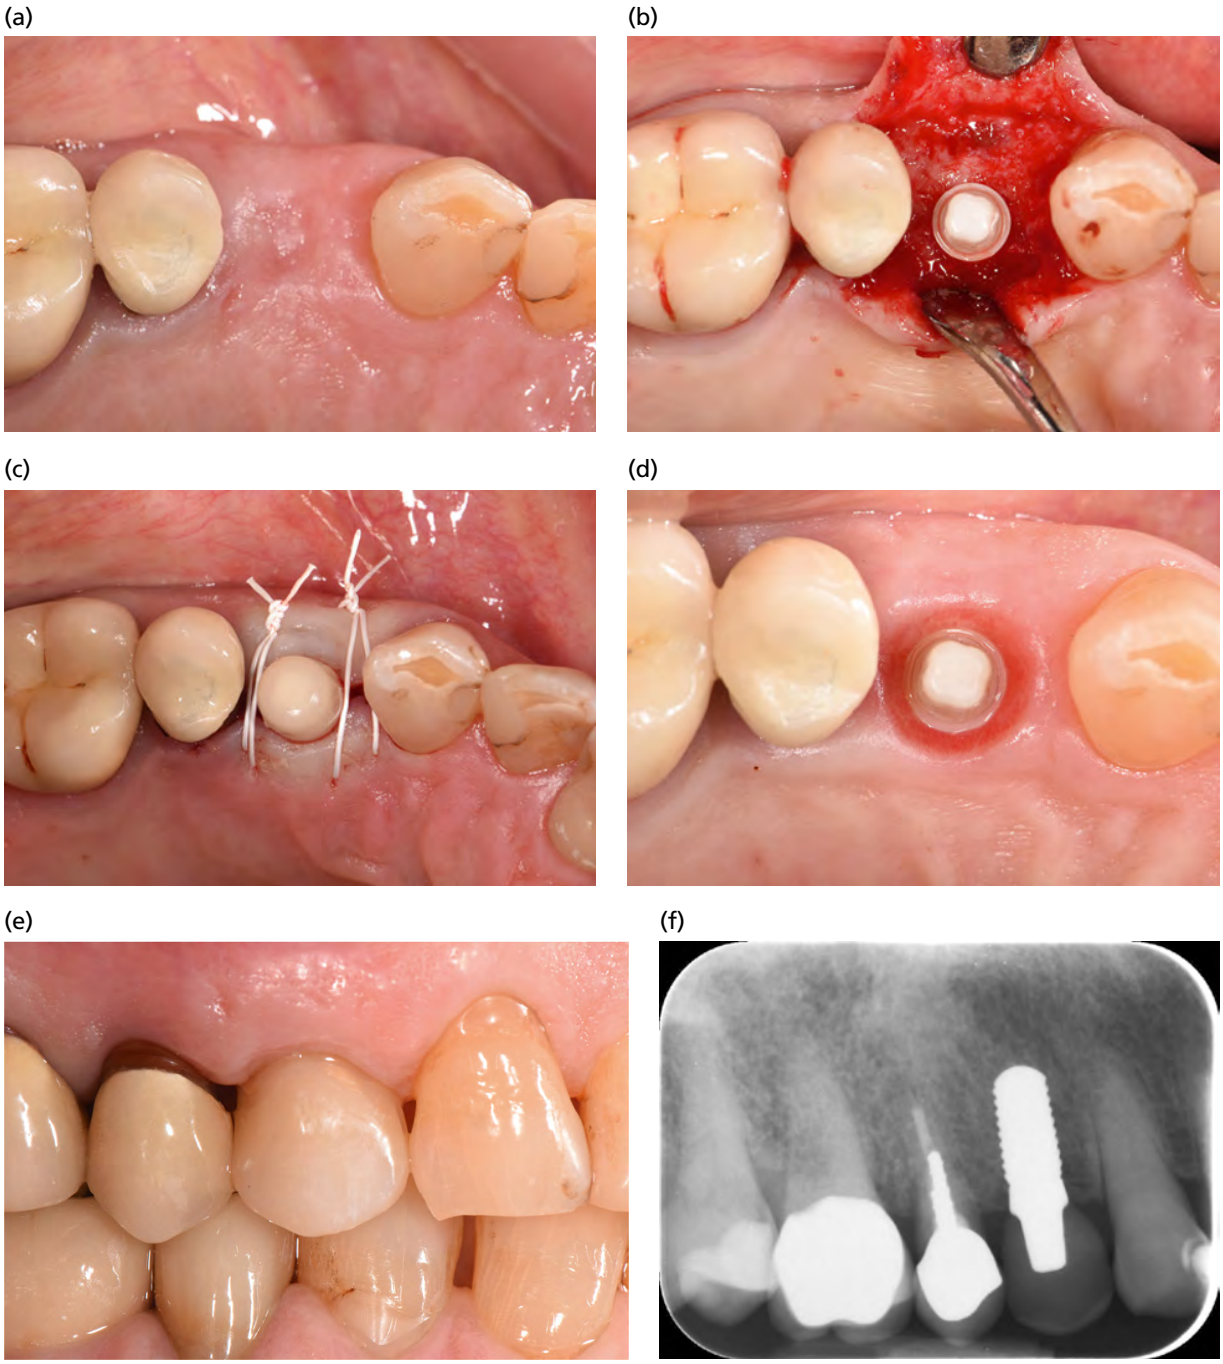

Fig. 44-26 (a) Preoperative single-tooth gap in the area of 14, with sufficient horizontal bone volume and sufficient keratinized mucosa. (b) Intraoperative situation after moderate flap elevation and the insertion of a one-piece zirconia implant. The implant shoulder was placed about 1.5 mm above the bone crest. (c) A temporary cap has been placed on the one-piece implant. Subsequently, the flap was adapted around the neck of the implant with two non-resorbable ePTFE sutures for transmucosal healing. (d) After 3 months of transmucosal healing, the zirconia implant is surrounded by healthy peri-implant tissues. At this time-point an implant impression was performed to initiate the prosthetic treatment. (e) Cemented zirconia implant crown at the 1-year follow-up with healthy and stable peri-implant soft and hard tissues. (f) Periapical radiograph reveals an optimal osseointegration of the one-piece zirconia implant with stable marginal bone levels after 5 years in function.

Multiunit gap size (≥3 missing teeth to be replaced)

Three-unit bridge

A 65-year-old patient was referred by her general dentist for a fixed reconstruction at region 35–37. Due to the presence of extensive caries and the poor prognosis of those teeth, a tooth-supported fixed dental prosthesis was not reasonable. After discussing the different alternatives with the patient along with considering her expectations and costs, a three-unit implant-supported bridge was chosen (Fig. 44-30).

Two implants with a cantilever

A 77-year-old woman presented to the dental clinic with a large edentulous area at region 13–17. The patient previously smoked, was systemically healthy,

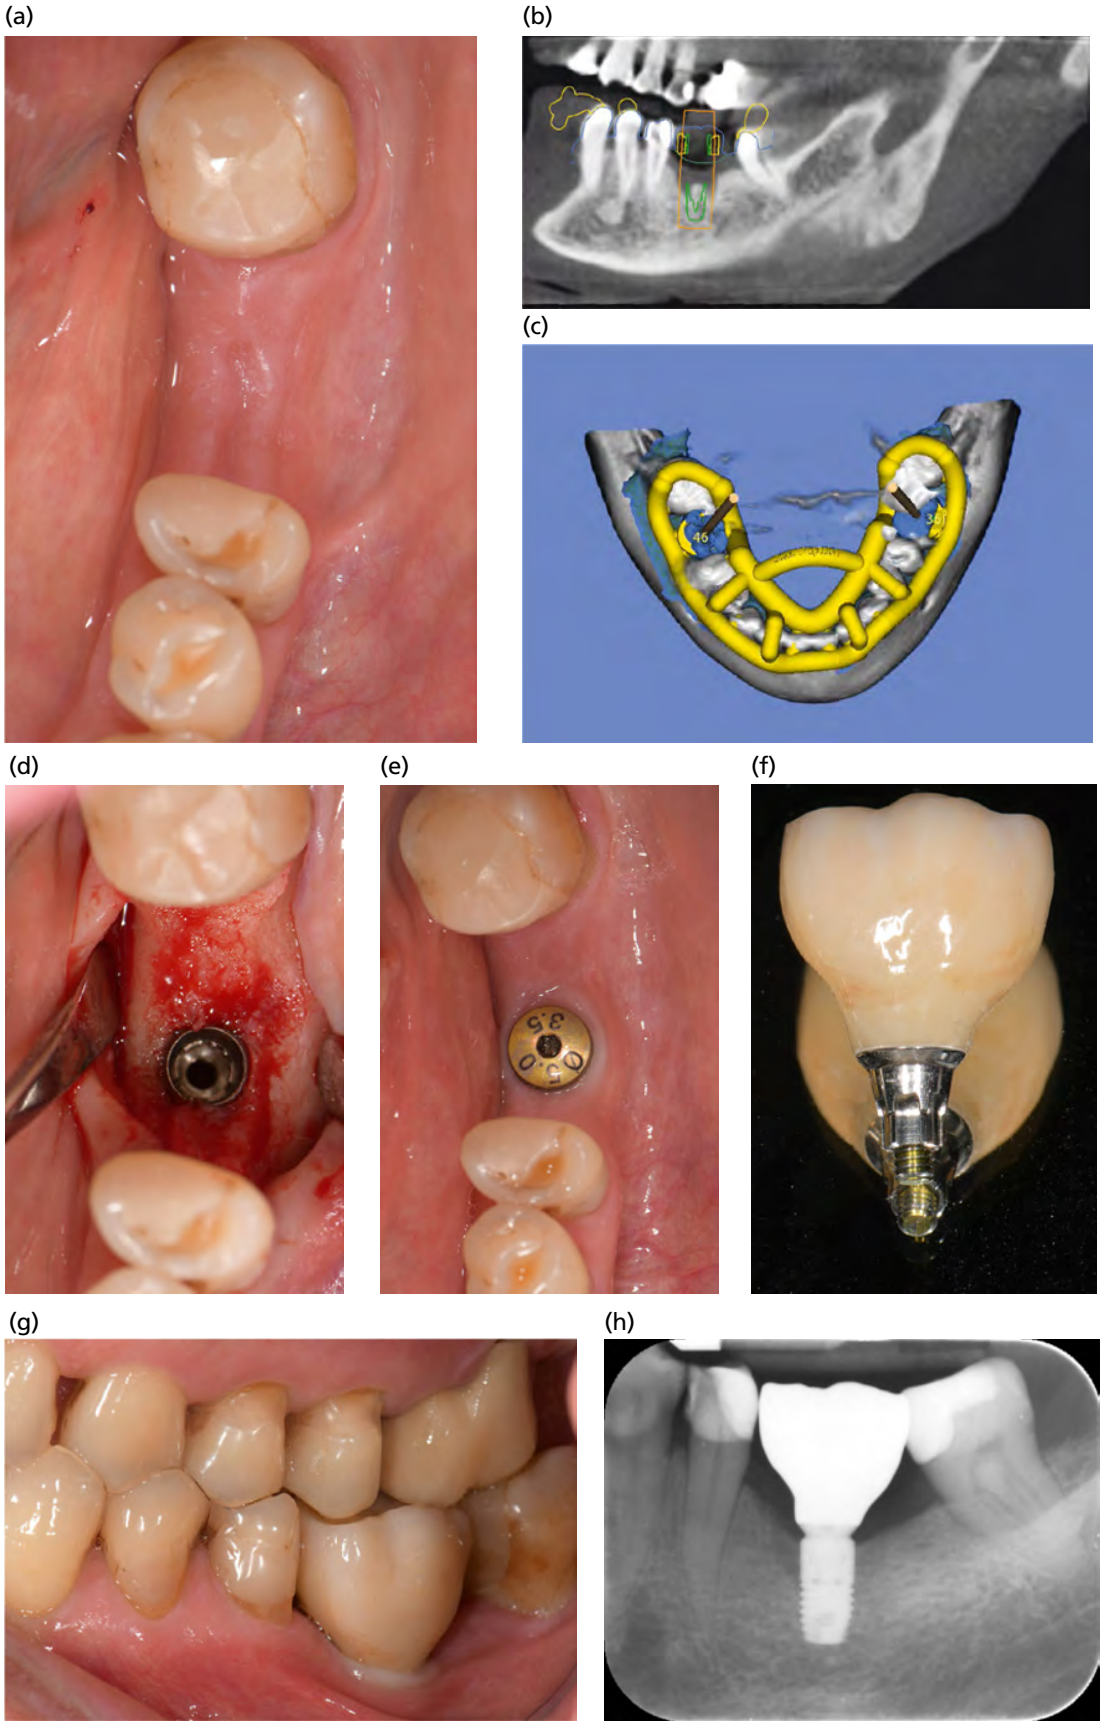

Fig. 44-27 (a) Preoperative single-tooth gap in the area of 36, with sufficient horizontal bone volume and sufficient keratinized mucosa. (b) Computer-assisted implant planning based on cone-beam tomography data. (c) 3D surgical guide based on the integration of the three-dimensional computer-tomography and the stereolithography data obtained from the diagnostic mock-up. The surgical 3D-printed guide allows for a prosthetically driven implant placement. (d) Intraoperative situation following flap elevation and implant insertion in a prosthetically driven position. (e) Clinical situation after 3 months of healing showing healthy peri-implant tissues and sufficient keratinized mucosa. (f) For the screw-retained CAD-CAM implant reconstruction a stock hybrid abutment with a titanium base was used. The CAD-CAM crown made out of zirconia had been cemented to the hybrid abutment in the dental laboratory. Alternatively, and in case a higher translucency is required, a monolithic lithium disilicate (LDS) crown can be fabricated (see Fig. 44.34h). (g) All-ceramic crown at region 36 right after crown insertion revealing an ischemic zone at the marginal gingiva. (h) Periapical radiograph showing the titanium implant with stable marginal bone levels at the 1-year follow-up.

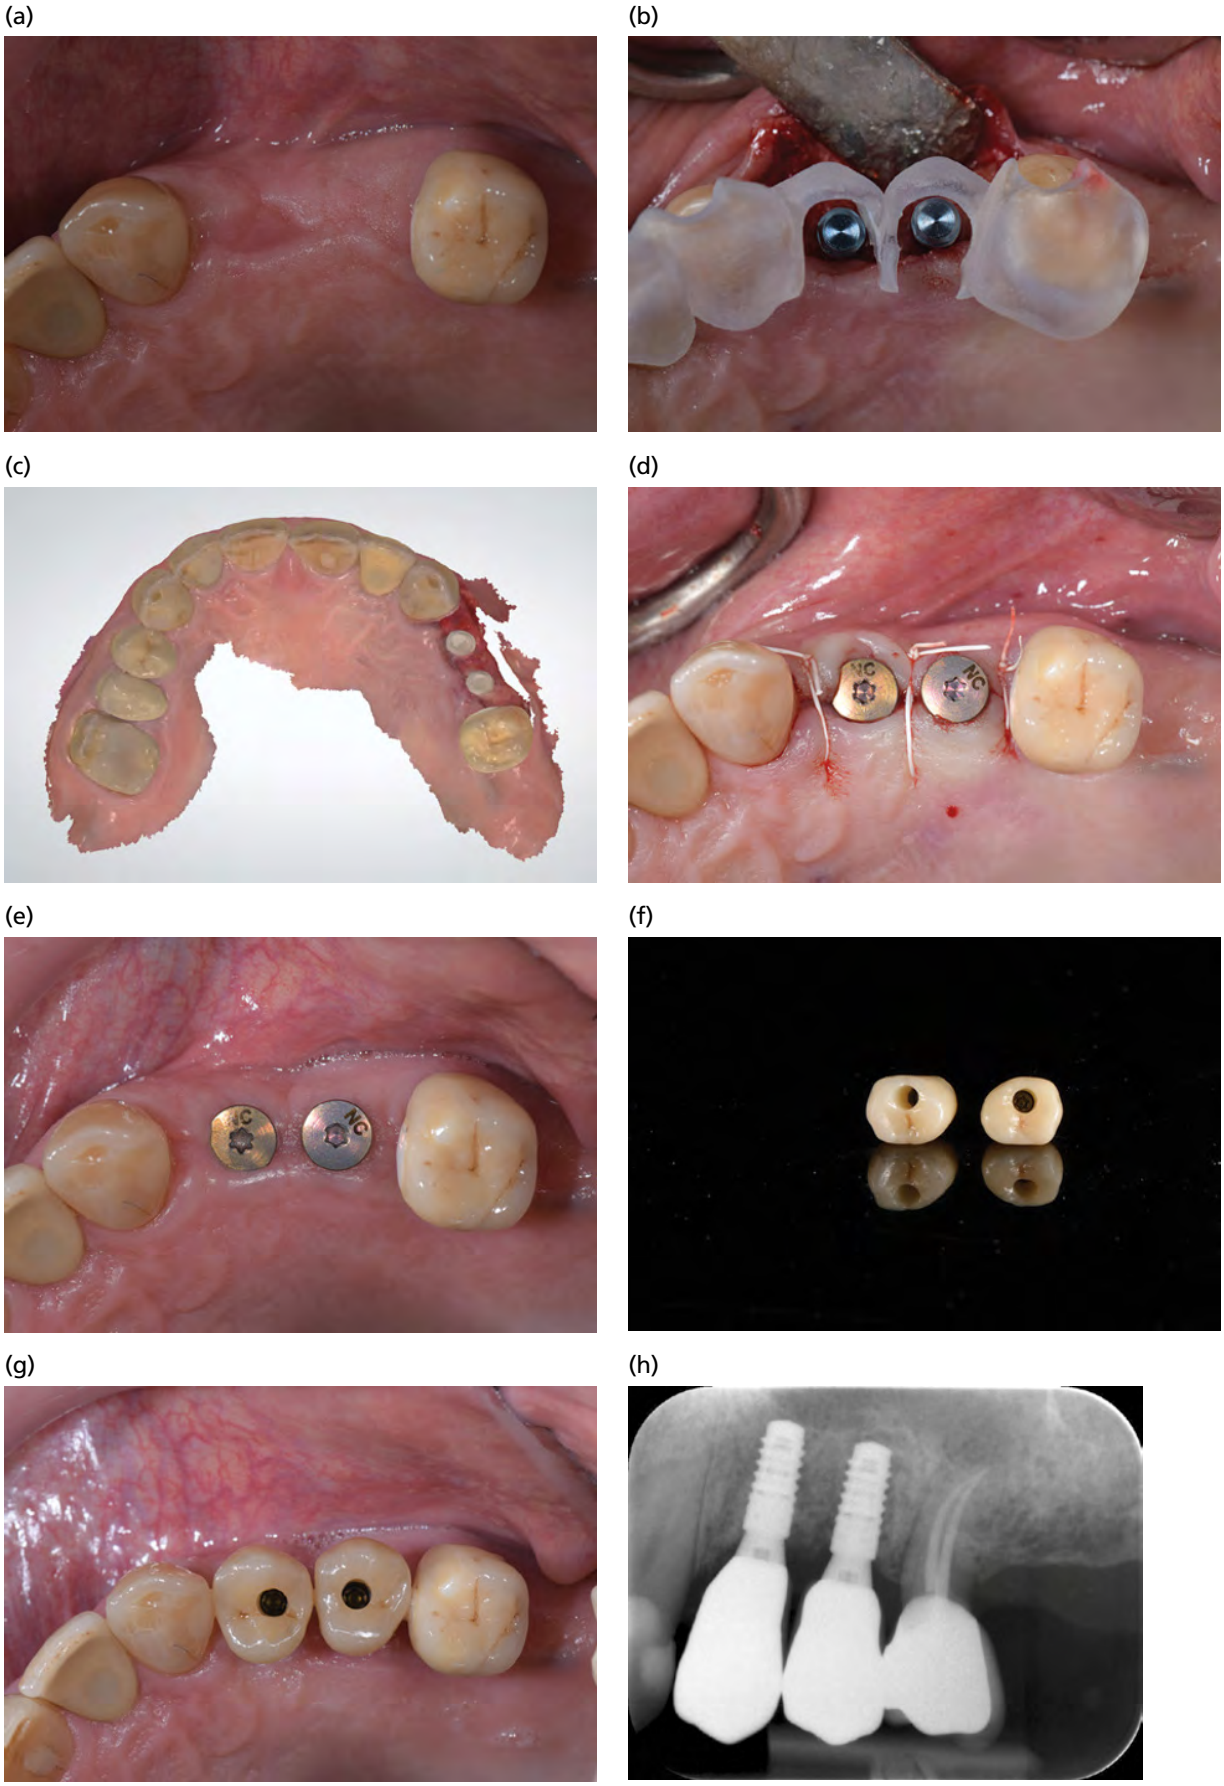

Fig. 44-28 (a) Preoperative two-unit gap size in the area of 24 and 25 showing sufficient horizontal bone volume and sufficient keratinized mucosa. (b) Intraoperative situation following flap elevation and implant insertion in a prosthetically driven position. (c) Digital impression taken with an intraoral scanner (IOS). The scan bodies had been mounted onto the implants serving as a digital reference. (d) Flap closure and adaptation around the healing abutment with two non-resorbable ePTFE sutures for transmucosal healing. (e) Clinical situation after 4 months of healing showing healthy peri-implant tissues and sufficient keratinized mucosa. (f) Screw-retained CAD-CAM implant reconstructions using a stock hybrid abutment with a titanium base. The CAD-CAM crowns were made out of monolithic zirconia and had been cemented to the hybrid abutment extraorally. (g) All-ceramic crowns at region 24 and 25 right after crown insertion. (h) Periapical radiograph revealing an optimal osseointegration of both implants at the crown delivery.

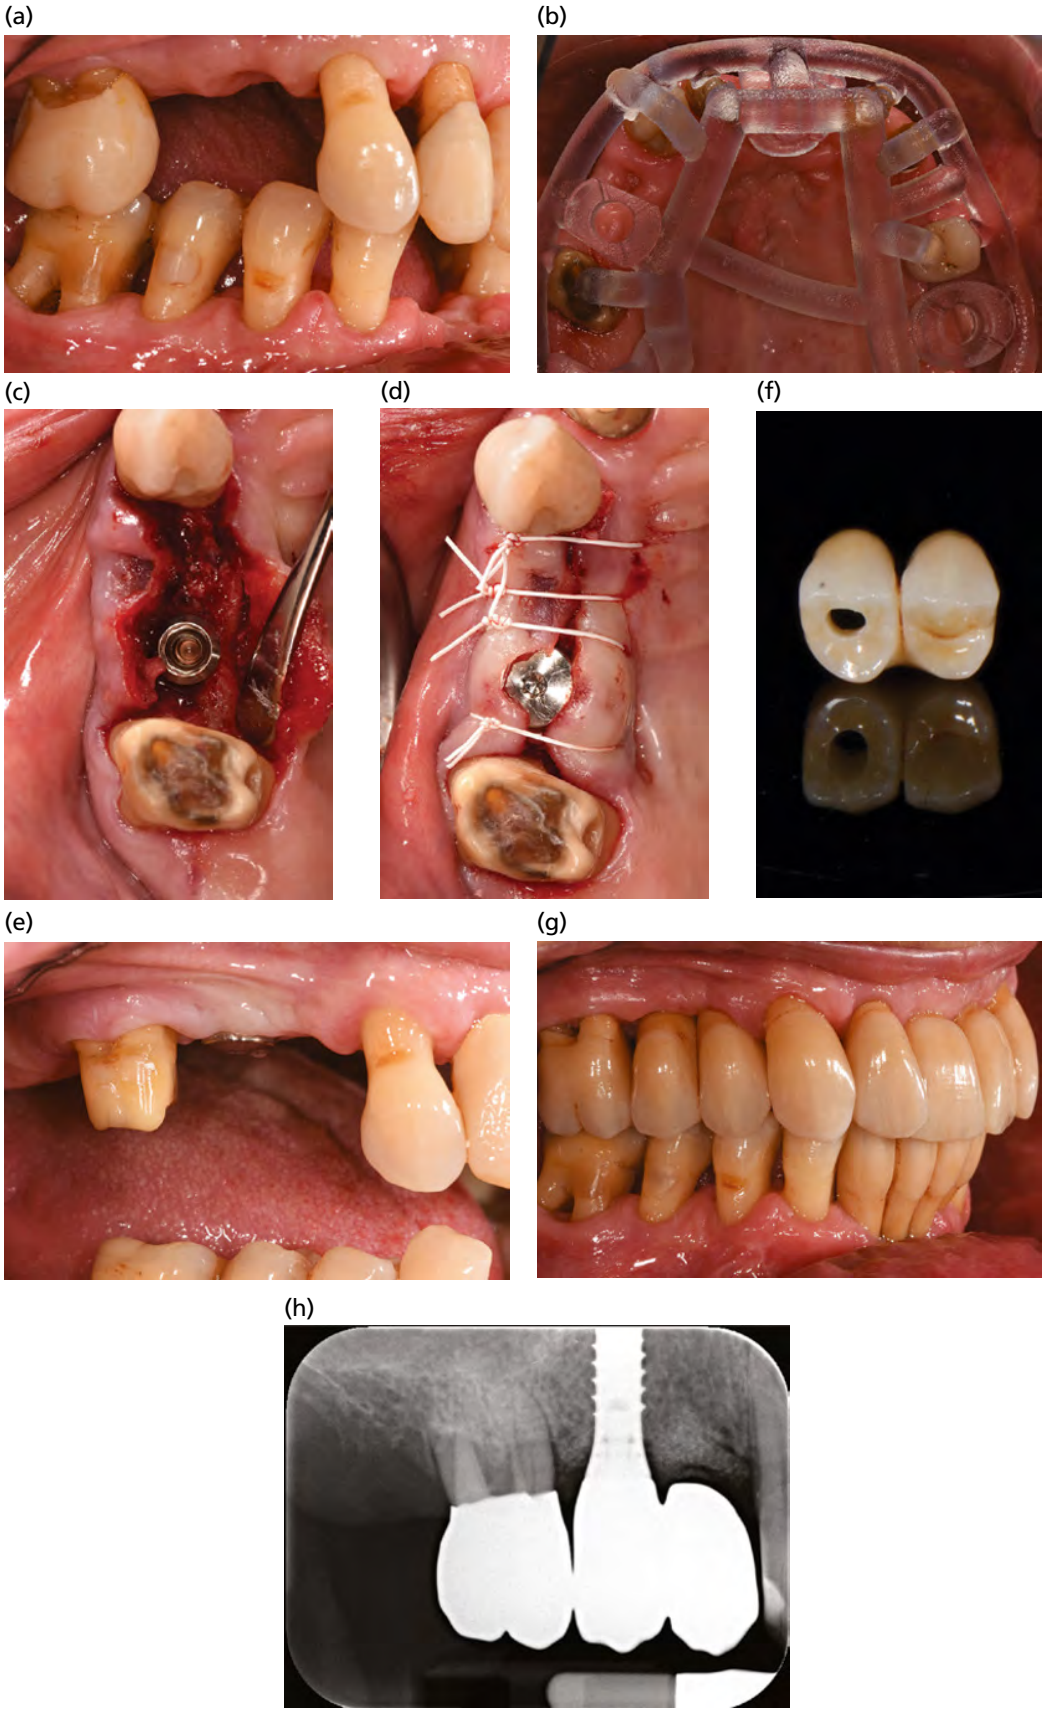

Fig. 44-29 (a) Preoperative clinical situation with a two-unit tooth gap in the area of 15 and 14 with sufficient horizontal bone volume and sufficient keratinized mucosa. (b) 3D-printed surgical stent based on the superimposition of the cone-beam computed tomography and the stereolithography data obtained from the diagnostic mock-up. (c) Intraoperative situation following flap elevation and implant insertion in a prosthetically driven position. In addition, an osteoplasty had been performed in order to level the alveolar ridge. (d) Flap closure and adaptation around the healing abutment with two non-resorbable ePTFE sutures for transmucosal healing. (e) Clinical situation after 3 months of healing exhibiting healthy conditions around the implant including a sufficient width of keratinized tissue. (f) For the screw-retained crown and the mesial cantilever a reconstruction made out of zirconia was chosen. The zirconia reconstruction was buccally veneered and was subsequently cemented extraorally to a stock hybrid abutment with a titanium base. (g) All-ceramic reconstruction delivery at region 15 with the mesial cantilever, showing healthy peri-implant tissue conditions along with sufficient keratinized tissue. (h) Periapical radiograph implant-supported reconstruction with the mesial cantilever revealing optimal osseointegration and stability of the marginal bone levels at 6-month follow-up.

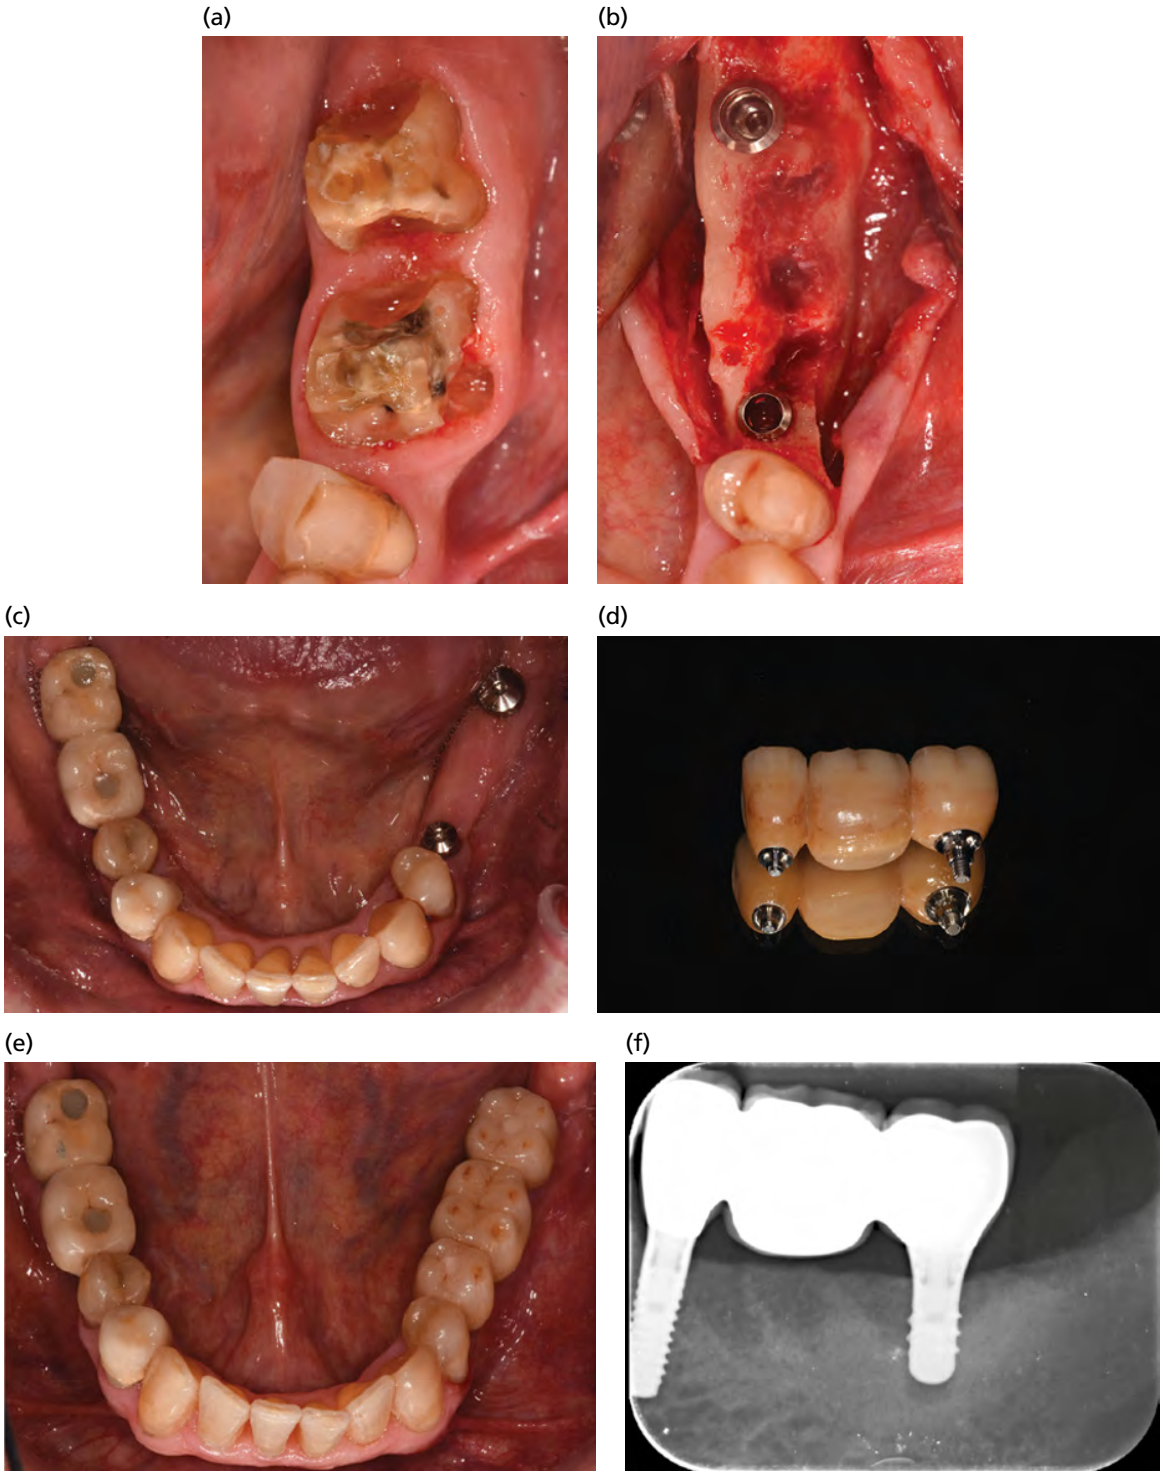

Fig. 44-30 (a) Clinical situation after the removal of metal–ceramic crowns and caries. The caries lesions surrounded the natural teeth abutments and extended into the root canal therefore the extraction of teeth 36 and 37 was indicated. (b) Intraoperative situation after the placement of two one-piece implants, one at region 35 and one at region 37. In addition, an osteoplasty was performed in order to level the alveolar ridge. The tooth extraction had been performed 2 months before implant placement. (c) Clinical situation after 3 months of transmucosal healing showing healthy peri-implant tissues and sufficient keratinized mucosa. (d) Screw-retained implant reconstruction made out of zirconia cemented extraorally to a titanium base. (e) All-ceramic 3-unit implant-supported bridge following insertion. (f) Periapical radiograph of the 3-unit implant-supported bridge at 6-month follow-up exhibiting stable marginal bone levels.

and her chief complaint was reduced chewing comfort. The patient also wanted to improve the esthetic appearance and, if it was possible, requested fixed prosthetic reconstruction. Furthermore, she stressed that she wanted as few surgeries as possible. After discussing the different alternatives with the patient, considering her expectations, the costs, and particularly the morbidity of the treatment, two single implants with a distal cantilever with a flapless approach was selected (Fig. 44-31).

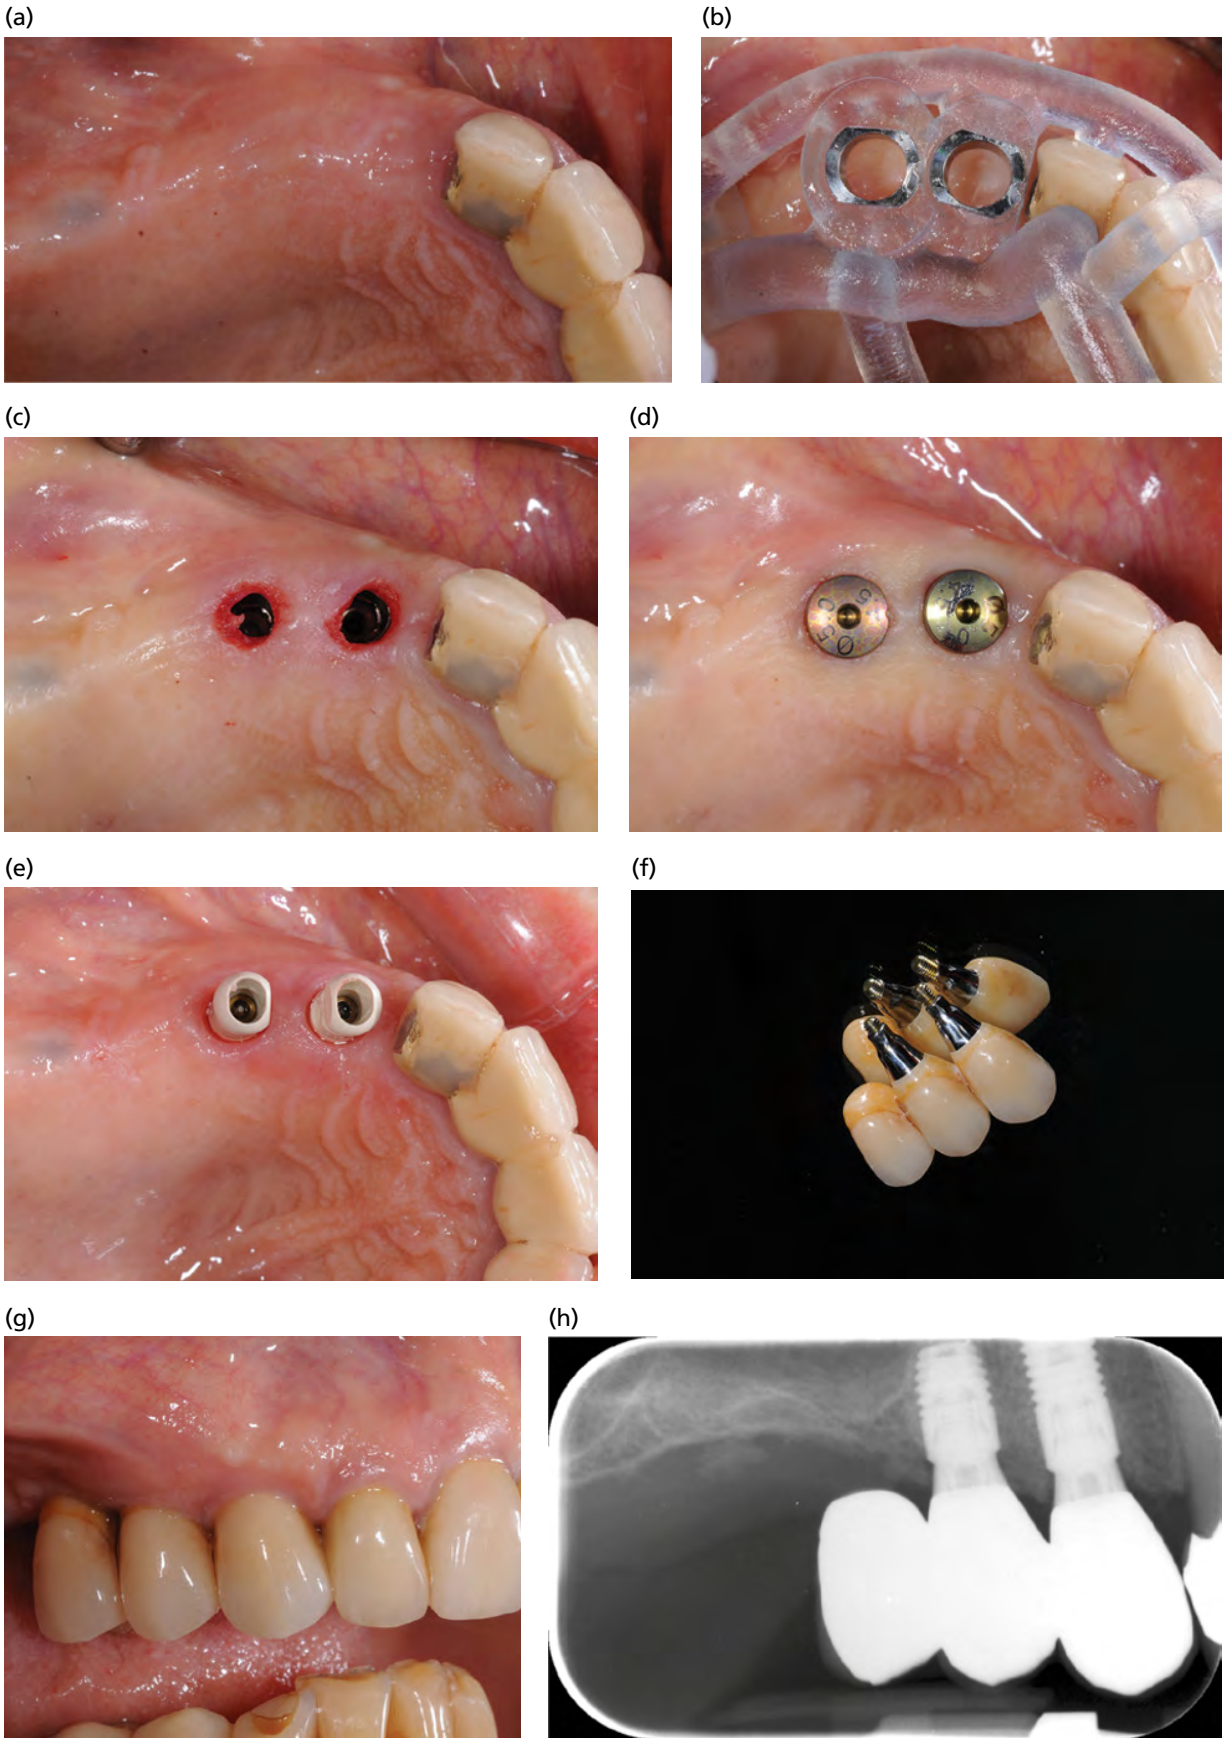

Fig. 44-31 (a) Preoperative clinical situation with a large edentulous area at region 13–17 with sufficient horizontal bone volume and sufficient keratinized mucosa. (b) Flapless implant surgery using a computer-assisted implant planning and placement (CAIPP) protocol. A 3D printed surgical stent was placed to foster a prosthetically driven implant positioning. (c) Clinical situation following implant placement. (d) Following implant placement, two healing abutments are placed for transmucosal healing. (e) After a healing period of 3 months, scan bodies are mounted onto the implants to serve as a digital reference for the digital impression with an intraoral scanner. (f) Splinted screw-retained implant crowns made out of zirconia cemented extraorally to a stock titanium abutment with titanium base. (g) All-ceramic reconstruction following insertion exhibiting healthy peri-implant soft tissues and satisfactory esthetics. (h) Periapical radiograph revealing optimal osseointegration following the insertion of the 3-unit final reconstruction.

Therapeutic concepts at sites with insufficient bone quantity

Short dental implants

A 50-year-old woman presented to the dental clinic with a single-tooth gap at region 16. The patient did not smoke and had no underlying health conditions. The chief complaint was the absence of tooth 16. The patient requested, if it was possible, a fixed reconstruction without many surgeries. Considering the patient's expectations, particularly regarding morbidity, and after discussing the different alternatives, a short single implant was finally chosen (Fig. 44-32).

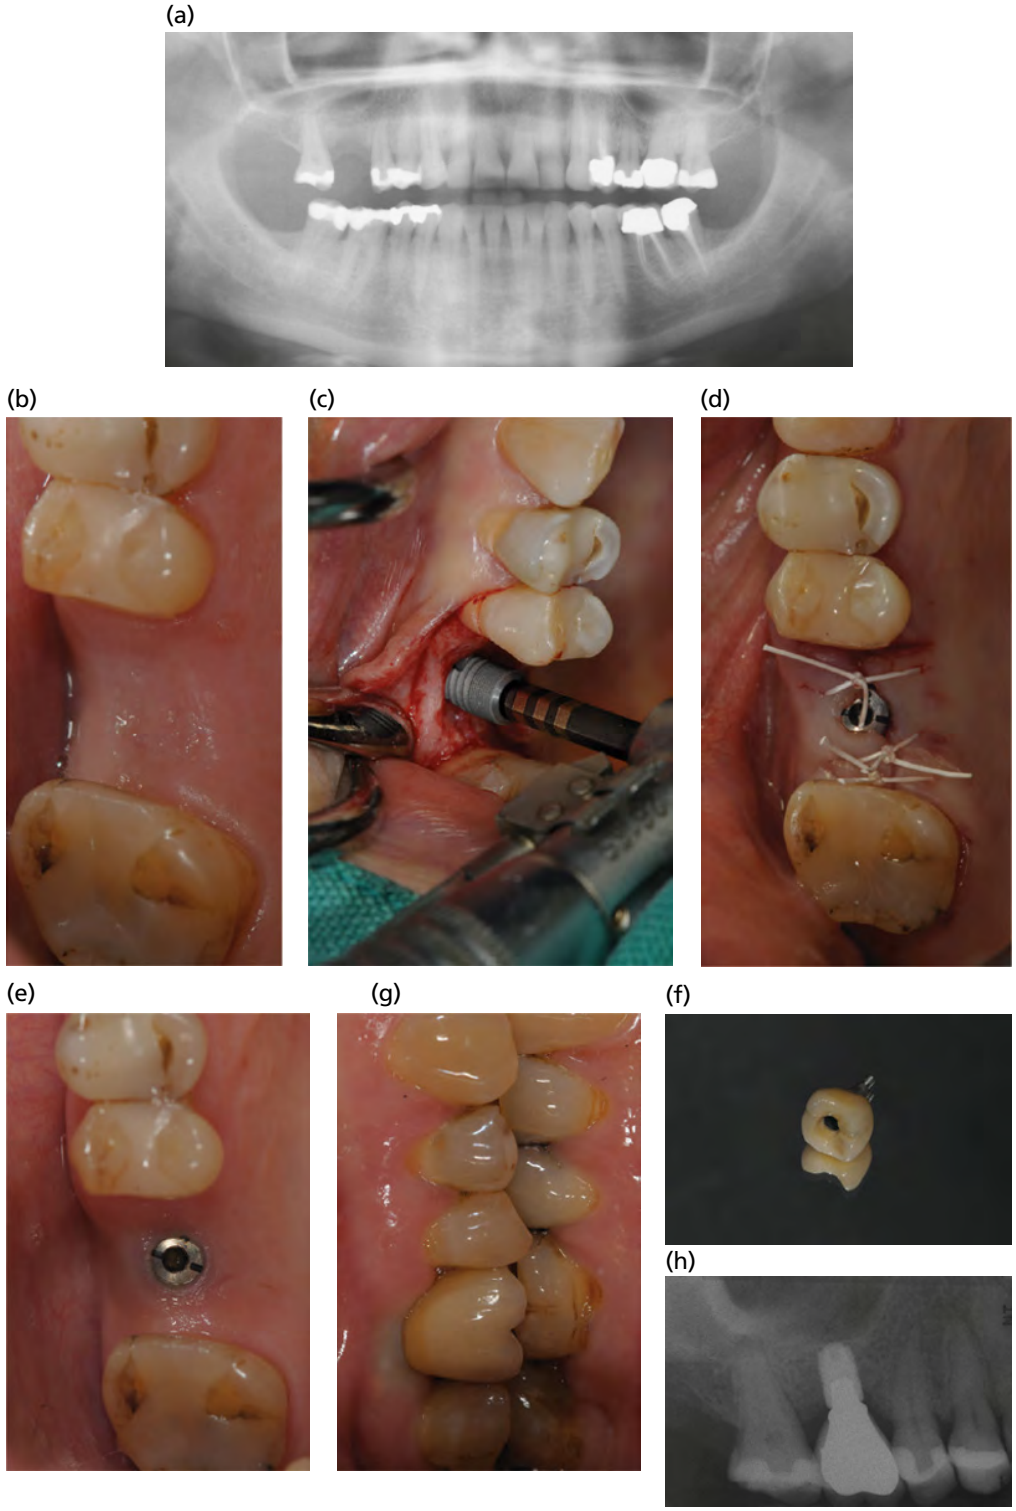

Fig. 44-32 (a) Panoramic radiograph evaluation revealing the proximity of site 16 to the sinus floor precluding implant placement of a regular length implant without sinus floor elevation. (b) Preoperative clinical situation of the single-tooth gap with sufficient keratinized tissue and an optimal amount of space for a single implant. (c) Implant insertion following flap elevation. (d) Flap closure and adaptation around the healing abutment with non-resorbable ePTFE sutures for transmucosal healing. (e) Three months after implant placement revealing healthy peri-implant tissues. (f) Screw-retained reconstruction based on a porcelain-fused-to-metal crown. (g) Clinical situation right after crown insertion showing an ischemic zone at the marginal gingiva. (h) Periapical radiograph at 6-year follow-up revealing an optimal osseointegration and stability of marginal bone level.

Narrow-diameter implants

A 56-year-old patient was referred by the orthodontist to replace the single-tooth gap at region 45. The orthodontist recommended distributing spaces, closing the diastemata, and uprighting the mesially tilted molars in order to create enough space for a fixed reconstruction at region 45. The patient was systemically healthy and did not smoke. Considering the healthy condition of the neighboring teeth, the site region (premolar area), the patient's expectations, and especially the limited mesiodistal amount of space, an implant-supported crown using NDIs made out of titanium-zirconium was chosen (Fig. 44-33).

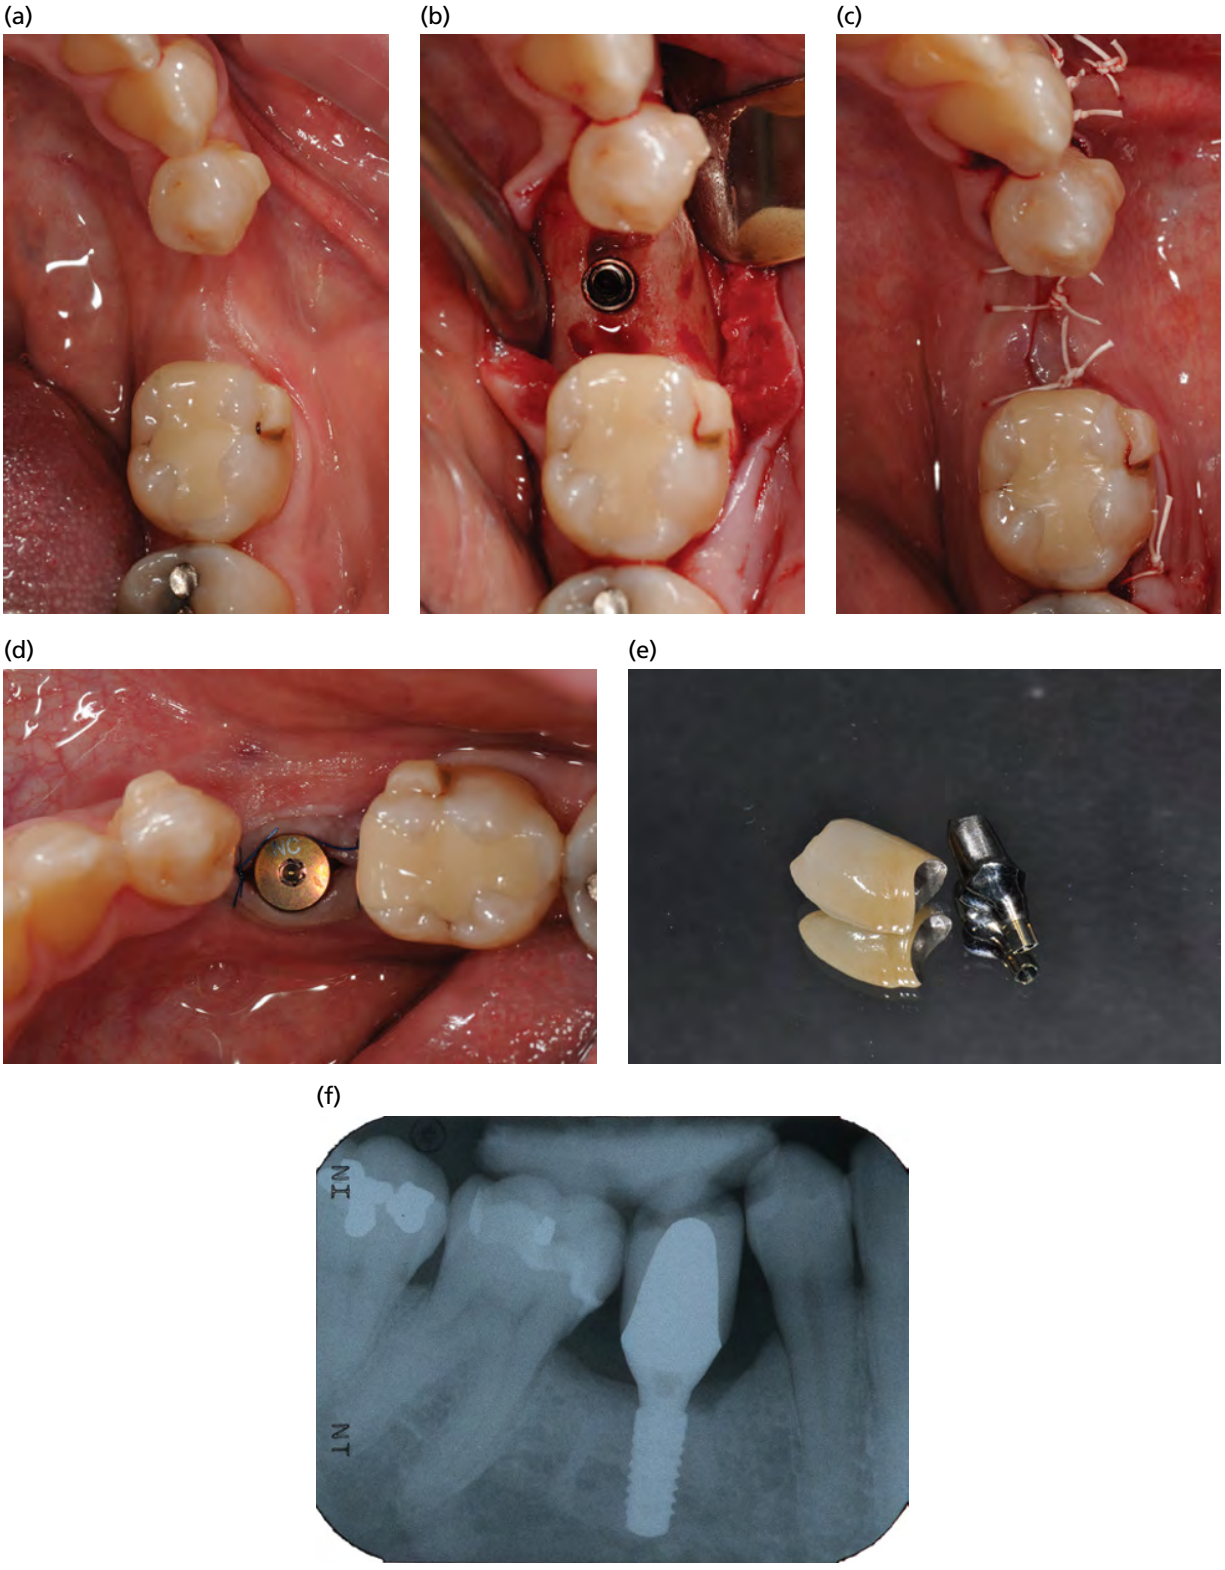

Fig. 44-33 (a) Preoperative clinical situation of a single tooth gap with reduced bucco-oral bone dimension and limited mesiodistal amount of space. (b) Intraoperative situation following flap elevation and insertion of a 3.3 mm titanium-zirconium implant in a prosthetically driven position. (c) Flap closure with ePTFE sutures for submerged healing. (d) Abutment connection after 3 months of submerged healing showing healthy peri-implant tissues and sufficient keratinized mucosa. (e) Screw-retained reconstruction made out of a porcelain-fused-to-metal crown. (f) Periapical radiograph of the one-piece narrow-diameter implant at 3-year follow-up revealing an optimal osseointegration and stability of the marginal bone level.

Maxilla–sinus floor elevation procedures

A 65-year-old patient was referred to replace the single-tooth gap at region 26. The patient wanted to increase his chewing comfort and if possible, preferred to have a fixed prosthetic reconstruction. The patient did not smoke and was systemically healthy. Considering the patient's expectations along with the healthy condition of the neighboring teeth an implant fixed reconstruction was chosen. In order to examine the bone height and volume at the implant region a CBCT was indicated. The results of the CBCT revealed insufficient bone height precluding a regular implant placement or an implant placement with minor sinus floor elevation using the osteotome technique. Therefore, a maxillary sinus floor elevation at region 26 using the lateral approach was chosen (Fig. 44-34).

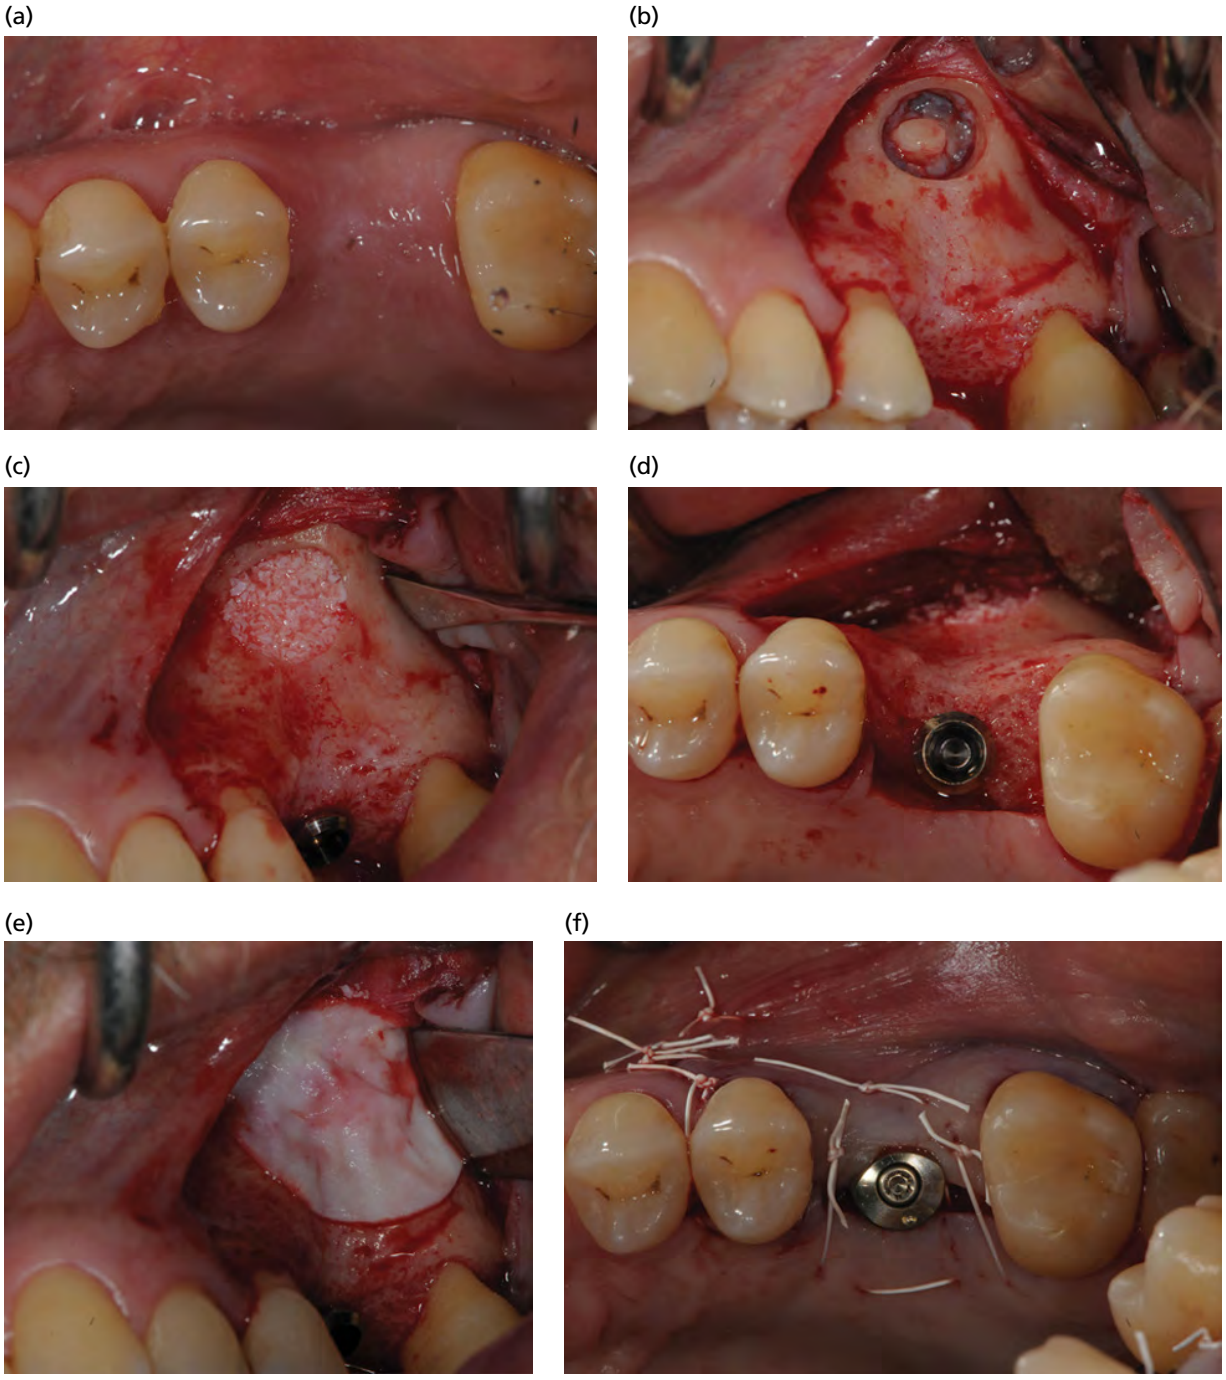

Fig. 44-34 (a) Preoperative clinical situation with a single-tooth gap with sufficient keratinized mucosa. (b) Outline of the small lateral window revealing the bluish hue of the sinus membrane. (c) After removing the buccal bone, the Schneiderian was carefully elevated to obtain access to the sinus floor. Thereafter, the implants were placed and subsequently the sinus compartment was filled with deproteinized bovine bone materials. (d) Intraoperative situation following sinus floor elevation and implant insertion of a one-piece implant in a prosthetically driven position. (e) Lateral window covered with a resorbable collagen membrane. (f) Flap closure and adaptation around the healing abutment with non-resorbable ePTFE sutures for transmucosal healing.

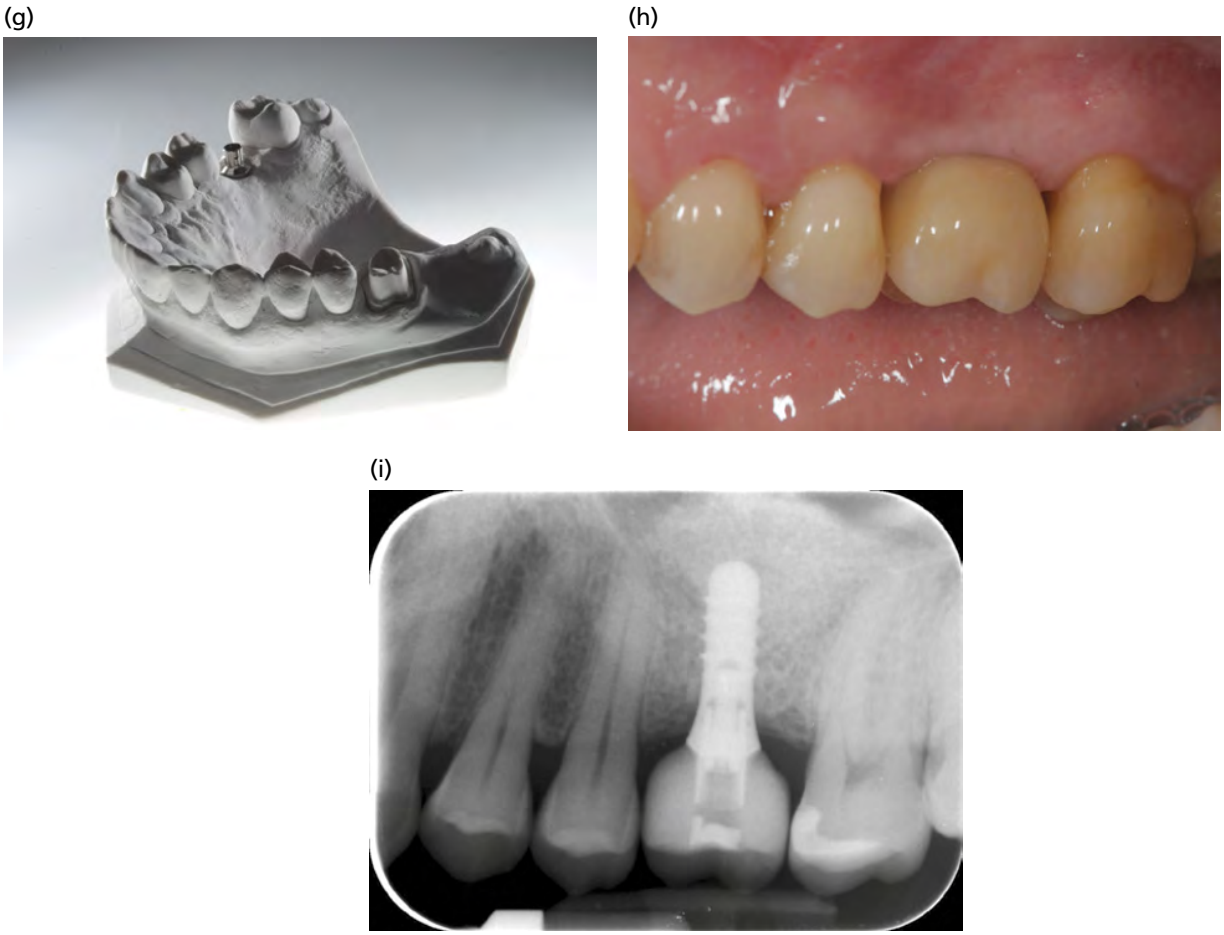

Fig. 44-34 (*Continued*) (g) For the screw-retained CAD-CAM implant reconstruction a stock hybrid abutment with titanium base was used. (h) Final implant supported crown made out of monolithic lithium disilicate (LDS) that was extraorally cemented to the hybrid abutment. (i) Periapical radiograph revealing an optimal osseointegration and a new inferior border of the maxillary sinus with a stable graft volume at the 2-year follow-up.

Acknowledgment

The authors gratefully acknowledge the help of the Drs. Ásgeir Ásgeirsson, Alexis Ioannidis, Roman Schellenberg, Lukas Stucki, and Prisca Walter (Clinic of Reconstructive Dentistry, University of Zurich, Switzerland) for their clinical contribution and their help in preparing the clinical cases for this chapter.

Chapter 45

Implants in the Zone of Esthetic Priority

Rino Burkhardt[1,2], Franz J. Strauss[2,3], and Ronald E. Jung[2]

Introduction

Today, in modern reconstructive dentistry, nobody would doubt the importance of esthetics as a primary outcome variable in the prosthetic rehabilitation of missing teeth. The loss of one or more teeth in the zone of esthetic priority may impair the esthetic appearance of the patient and, therefore, any treatment modality for reconstruction of the lost tissues must address both functional and esthetic outcomes.

In the last decade, much has been published concerning the promising esthetic results of prosthetic restorations supported by endosseous implants (Belser *et al*. 2009; Chen & Buser 2014; Hartlev *et al*. 2014; Slagter *et al*. 2014). Additionally, the main etiological factors for adverse outcomes have been described (Hammerle & Tarnow 2018). Despite scientific efforts to shed light on the causative aspects of esthetic failures, the many congresses and courses focusing on esthetics and implants, and publications aimed at educating clinicians, altered esthetic results

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

after placement of implant-supported reconstructions in the upper anterior area, with and without malpractice claims, still occur (Bordonaba-Leiva *et al*. 2019).

How can this chapter contribute to reducing errors in treatment planning and clinical execution so that performance and consistency is improved? The answer is complex and it seems naïve to believe that just summarizing the available scientific evidence in the specific subject area is enough to achieve the aforementioned goals. The chapter in the previous edition of this book on implant restorations in the zone of esthetic priority was written based on the principles of evidence-based dentistry (EBD) and the cited articles were strictly selected accordingly. However, despite the considerable benefits of EBD, it has since been realized that there have also been unintended consequences with an adverse impact on health care in general, and individual patient care in particular (Greenhalgh *et al*. 2014).

Implant dentistry is a part of oral health care that is influenced by several interconnected organizations such as oral health care-related industries, health authorities, universities, political organizations, and others. There is no doubt that the complex interactions between these players with individual interests have an effect on the quality of evidence informing person-centered health care. First discussed in the mid-1990s, EBM became central to research, teaching, writing, and administrative management in the majority of medical specialties and was described as "a new paradigm for medical practice". It quickly became an energetic intellectual community committed to making clinical practice more scientific and empirically grounded and thereby achieving safer, more consistent, and more cost-effective care (Pope 2003).

The first problem is that the evidence-based "quality mark" has been misappropriated and distorted by vested interests (Greenhalgh *et al*. 2014). In particular, the medical devices and biomedical products industries increasingly set the research agenda (Popelut *et al*. 2010; Probst *et al*. 2016). Secondly, many dentists did not learn how to interpret and use scientific evidence in their daily practice and how to amalgamate it with their clinical experience and expertise as a basis for good clinical decisions in each individual patient. Even if evidence does exist, very often patients and clinicians act according to their social roles, and not based on evidence. And last but not least, for many clinical problems there is simply not enough practice-related evidence available.

The fact that implant-supported restorations can give esthetically appealing results is documented by many cases in dental magazines and at implant congresses. However, the efficacy of the treatment and the quality of the decisions taken by the clinician cannot be determined from the result. Only too often, we assume that a decision that led to a good clinical result was a good decision. Rarely do we review whether the initial prognosis was correct.

It is the goal of this chapter to provide interested clinicians with an overview of the current knowledge in the specialty, to support them in clinical decision making, and thus help them to improve performance and to reduce errors. These goals cannot be achieved by simply summarizing the evidence-based literature concerning implant dentistry and related fields. Too many important questions would remain unanswered using this approach.

The operating room is a hugely complex environment that requires considerable interaction between various team members (Undre *et al*. 2007). An array of non-technical skills is required of a surgeon, which influences the quality of the surgical results. Although the importance of non-technical skills is being increasingly recognized, there is currently little integration of its teaching and assessment with technical skills training. To comply with these requirements, we have revised this chapter considering technical and non-technical skills, the latter consisting of cognitive (decision making) and social skills (communication, leadership, and teamwork) and the personal resource factors (personality traits, ability to cope with psychological stress).

Implant restorations in the zone of esthetic priority have developed and broadened considerably in recent years. It is now more than 20 years since this chapter first appeared; it has been extensively revised to include a section on non-technical skills, an analysis of the mechanisms of clinical decision making, and an examination of the clinician as a risk factor for esthetic implant failures. With reference to shared decision making in implant dentistry, we examine the relationship between patients and health professionals, viewed as one of the most complex interpersonal relationships, and attempt to identify ways of implementing shared decision making in daily practice in order to avoid unrealistic expectations by patients.

The sections on diagnostics and risk assessment have been updated. A description of the newly available digital technologies and software for planning and visualization of prospective prosthetic results has been included.

The main clinical sections describing the surgical and prosthetic concepts have been shortened, updated, and illustrated with new clinical cases. A new section concerning immediate implant placement has been added, including a discussion of the risks and benefits of such a treatment modality.

The final section, which describes the strategies for retreatment of esthetic failures, has been completely revised, based on recently available knowledge and scientific findings.

Patient safety first: how to protect patients from avoidable harm?

Understanding benefits and harms of implant treatments

In implantology and many other surgical specialties, patient safety and professional liability are

major concerns worldwide. Based on the results of the Harvard Medical Practice Studies (Brennan *et al*. 1991; Leape *et al*. 1991), including 30 121 reviews from randomly selected records from 51 randomly selected hospitals, the US Institute of Medicine (IOM) published a landmark report, entitled "To Err is Human: Building a Safer Health System" (Kohn *et al*. 2000). The report concluded that adverse events do occur, causing a substantial amount of injury to patients. Depending on the discipline, the prevalence of adverse events varied substantially, being highest for surgeries requiring fine motor skills. Of course, adverse events do not necessarily signal poor-quality care; nor does their absence necessarily indicate good-quality care. But interestingly, most of the adverse events resulted from substandard care, and, independent of the medical specialty, in all categories, negligence was the main causative factor. Regarding the type of error, performance errors ranked highest with 46.4%, followed by prevention errors (26.0%), diagnostic errors (17.5%), and drug treatment errors (10.1%).

The report brought the issues of medical error and patient safety to the forefront of international concern and as it described that errors were not rare or isolated, the WHO (World Health Organization) adopted a resolution that urged member states to pay the closest possible attention to the problem of patient safety and the systems of monitoring (WHO 2002).

An interim assessment, published by Harvard Medical Practice Studies (Leape *et al*. 2009), eight years after the IOM report, concluded that efforts to improve patient safety had been insufficient and progress toward improvement frustratingly slow. They claimed that medical education should be restructured to reduce its almost exclusive focus on the acquisition of scientific and clinical facts and to emphasize the development of skills, behaviors, and attitudes needed by practicing clinicians. These include the ability to manage information, understanding of the basic concepts of human interaction, patient safety, and health care quality.

A progress report was published by Gandhi *et al*. (2018), documenting that some existing gaps could be closed. Increasing volumes of data and information are collected from patient experience surveys at the service or clinician level and compelling evidence confirms that sharing data, successes, and failures can markedly accelerate learning and improvement (Lee 2017). However, the report also emphasized the many remaining challenges. There is still a lack of transparency between patients and clinicians regarding communication before treatment and in the aftermath of adverse events (McGaffigan *et al*. 2017; Wu *et al*. 2017) and current evidence documents that the prevalence and the severity of treatment errors do not primarily depend on the complexity of the medical problems but rather on the errors in diagnosis and improper performances of the clinicians (Graber 2013).

When considering implant treatments in the zone of esthetic priority, almost all procedures are scheduled, non-urgent surgical events. A review of malpractice claims in oral and maxillofacial surgery confirmed that 95% of patients were treated with implants as elective interventions (Bordonaba-Leiva *et al*. 2019). Because most cases did not involve a medical emergency, it is surprising that the most frequently claimed events in oral and maxillofacial surgery (30.5% of the total claims) were implant failures and diseases. In addition, a much higher risk for claims of malpractice was found when implants had to be placed in the anterior zone of the upper jaw, where the esthetic perception of the patient has the most impact.

When implant installations associated with an esthetic component lead to a higher risk of disappointed patients, compared with implant restorations in the posterior area, communication problems between the clinician and the patient may be the cause, with the latter having too high expectations regarding the esthetic appearance of the implant-supported prosthesis. On the other hand, considering that the majority of technical errors involve fully trained and experienced surgeons, operating within their area of expertise and in routine operations (Regenbogen *et al*. 2007), the causative origin of the adverse events might be based on the clinician's overconfidence, underestimating the technical sensitivity of the surgical procedure (Berner & Graber 2008). Whatever the cause, it is valuable to examine why esthetic treatment errors occur and how they can be prevented.

The patient

Efficient health care requires informed doctors and patients. After doctors and friends, the media such as television, magazines, or newspapers are the most frequented sources of health information in European countries. In a recent survey, 43% stated that they relied on TV reports frequently. However, when it came to understanding the benefits of the treatment, those patients who relied more on TV, radio, magazines, or daily newspapers were not better informed than those who did not consume information from the media (Gigerenzer *et al*. 2009).

In recent years, studies concerning the quality and accuracy of health and medical information available on the internet or from leaflets have shown that many sources provide inadequate information (Muhlhauser & Oser 2008). In implantology, a major cause of non-transparent risk communication is a conflict of interest concerning those communicating health statistics (Edelmayer *et al*. 2016). Websites and leaflets regarding oral implants, illustrated with decorative images, focus on the description of treatment and advantages with less information about risks of complications, adverse esthetic outcomes, and disadvantages (Ali *et al*. 2014; Barber *et al*. 2015). Additionally, a fundamental aspect of

patient information is the importance of making patients aware of the different treatment alternatives for missing single or multiple teeth in the zone of esthetic priority (Edelmayer *et al*. 2016). As each discipline and specialty in health care brings its own perspective to treatment and management, described as the specialty bias (Seshia *et al*. 2014), current evidence confirms an omission of information transfer between doctors and patients regarding alternative treatment options (Sherman *et al*. 2013).

In health care, non-transparent framing of information seems to be the rule rather than the exception, which is why patients have difficulties finding reliable information. The problem is aggravated when benefits and harms of treatment options must be evaluated (Gaissmaier & Gigerenzer 2011). To make informed health decisions, patients need to understand that in the first place, there is no such thing as certainty. The term "illusion of certainty" refers to an emotional need for certainty when none exists. This is true for both patients and doctors. However, although health care providers may not be sure about the probability of negative side effects of a particular treatment, studies indicate that they rarely communicate the uncertainties about risks and benefits of treatments to patients (Braddock *et al*. 1999). This might be a consequence of a conflict of interest for the clinician – and financial conflicts of interests are not the only source of conflicting interests for doctors – or caused by the fact that the results of studies were not correctly understood by the health professional.

The clinician

Gaissmaier and Gigerenzer (2011) suggested three basic competencies for health professionals in the twenty-first century. The first is health literacy, including basic knowledge about diseases, diagnostics, prevention, and treatment, as well as the ways to acquire reliable knowledge in further education. The World Health Organization recognized that social competencies and skills are essential additional components and defined health literacy as "cognitive and social skills which determine the motivation and ability of individuals to gain access to, understand, and use information in ways which promote and maintain good (oral) health" (Sorensen *et al*. 2012). The so-called critical health literacy originates from this new concept and contains competencies that enhance the autonomy of the consumer (doctor and patient), combining evidence-based medicine or dentistry, evidence-based health care, and health literacy (Steckelberg *et al*. 2009; Steckelberg *et al*. 2009). People who are health literate are able to request missing information and question the knowledge source and its bias. They are suspicious when a brochure specifies the benefit of, for example, implant restoration in the anterior area of the upper jaw, but neglects to list possible harms or the merits of alternative routes of action.

The second competency that was suggested is health system literacy, which is important not only for clinicians, to assist in making informed treatment decisions, but for all citizens. To know which medical treatment will be best in each individual case, clinicians must be aware of the organization of the system and the incentives within it, such as, for example, collective agreements or political prioritization of a prevention system. The inclusion of implant restorations in the service spectrum of compulsory health insurances, or the country-specific variabilities in quality and number of dental schools, which may produce a surplus of practitioners, illustrates the importance of knowledge concerning the interconnectedness of health systems and their effect on health care quality.

The third competency refers statistical literacy, that is, a basic understanding of numerical information in order to grasp benefits and harms of treatment options and understand test results (Fig. 45-1). It is commonly assumed that only patients have problems with health statistics. However, doctors themselves might not understand medical evidence (Reyna & Brainerd 2007; Smith 2011). Several studies investigating the statistical literacy of doctors in different specialties have shown that most clinicians do not understand medical statistics (Hoffrage *et al*. 2000; Welch *et al*. 2000; Young *et al*. 2002; Muhlhauser *et al*. 2006; Gigerenzer *et al*. 2007; Wegwarth *et al*. 2011). Such a lack of statistical literacy makes clinicians dependent on biased information contained in poor quality specialty journals or continuing education organized by the industry.

To understand benefits and harms of implant restorations in the zone of esthetic priority, it is crucial to understand the complexity of modern implantology, on the one hand offering unique and reliable treatment options, which are well investigated and scientifically proven. On the other hand, as complexity characterizes a system whose components interact in multiple ways and follow local rules, health care professionals and patients must be aware of the many incentives, the cognitive biases, conflicts of interest and ethical violations that are inherent in the system at individual and organization level, subverting the evidence that informs person-centered health care (Seshia *et al*. 2014). At this stage, it must be emphasized that a health system, branches of the industry, health professionals, or single doctors must be not be criticized, but the *whole system* should be analyzed which – by understanding the interconnectedness of its variables – helps us to improve the quality of clinical decision making when implant restorations in the anterior zone of the upper jaw are one of the options.

The gap between scientific evidence and what happens

Expertise in implantology requires mastery of a diversity of knowledge from different areas such as structural biology, material sciences, ethics, and

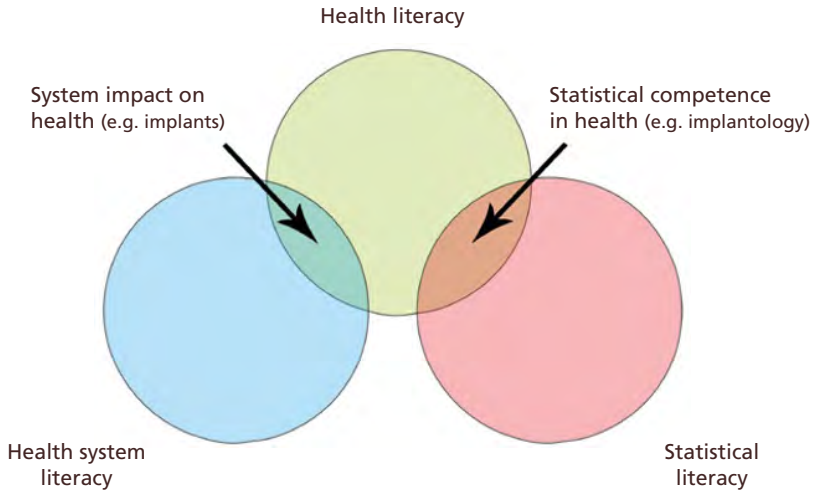

Fig. 45-1 Basic competencies for clinicians and patients for informed treatment decisions in implantology. Health system literacy entails basic knowledge about the organization of a system and the incentives within it. Health literacy comprises factual knowledge about diseases, diagnostics, prevention and treatment, and ways to acquire reliable knowledge. Statistical literacy involves the ability to understand uncertain evidence, including concepts such as false positive rates or differences between statistical significance and clinical relevance. (Source: Adapted from Gigerenzer & Gray.)

psychology. Clinical practice guidelines based on the principles of EBD build the foundations for teaching and implementing this knowledge into clinical workflows. In the last decade, much research has been performed in the specialty of oral implantology to increase patient safety and ensure that the esthetic outcome is more predictable and consistent. Critical voices and personal observations confirm that a significant gap exists between research recommendations, scientific evidence, and clinical practice guidelines, on the one hand, and actual clinical practice on the other (Cochrane *et al*. 2007). One of the major barriers to using current research evidence is the time, effort, and skill needed to access the right information from a considerable volume of research. For example, around 3000 new articles concerning the specialty of oral implantology are indexed each year in Medline.

A growing field of research on how to disseminate and implement scientific findings into clinical practice reveals the slow acceptance of practice guidelines by health care professionals in general, and doctors in particular (Bero *et al*. 1998; Wensing & Grol 2019; Wudrich *et al*. 2020). These transfer processes are summarized in the field of knowledge translation and aim to improve health care practice and make it more effective, thus leading to better care and outcomes for patients. Ultimately, research on knowledge implementation enhances the use and usefulness of all research efforts in medicine and dentistry.

Correctly applied, EBD aims to provide clinicians and patients with choices about the most effective treatment. These choices must be carefully considered, allowing for the specific circumstances, and the needs and expectations of the patient. For patients, this is a natural expectation, but studies document that practitioners rarely implement evidence in the decision-making process and they hardly ever change because of a change in evidence (Armstrong *et al*. 1996; Curran *et al*. 2011; Harding *et al*. 2014).

The lack of knowledge dissemination and implementation and the fact that clinicians do not apply the available evidence in their clinical treatment planning has also been documented for oral surgeons and dentists (van der Sanden *et al*. 2005). A study about the effectiveness of a dental clinical practice guideline on the management of asymptomatic impacted lower third molars clearly showed that the guidelines derived from systematic reviews only improved the dentist's knowledge but did not change their clinical performance by establishing a relevant improvement of their clinical decision-making skills.

Two pioneers of EBM provided a very helpful analysis to understand why there is a leakage of the possible efficiency in the pathway from research to practice (Glasziou & Haynes 2005). They argued that the translation of knowledge has to pass through several steps before it is implemented in everyday practice. By conservative estimation, in each step approximately 20% of evidence leaks and fails to proceed to the next step (Fig. 45-2). In the first three steps, clinicians are aware of evidence and that they should do something different from their daily routine. In general, they find it difficult to be aware of all the relevant, valid evidence. A central problem is that clinicians may be persuaded by many means other than unbiased evidence, such as the marketing techniques of advertising, authority, social validation (acceptance by peers), and friendship/personal relationships (Glasziou & Haynes 2005).

In the following two steps, the practitioner has internalized the evidence and now the patient must be brought into the discussion. Many patients may have their own ideas about treatment priorities and the restoration of their missing teeth. The opinions might deviate from the recommendations of their

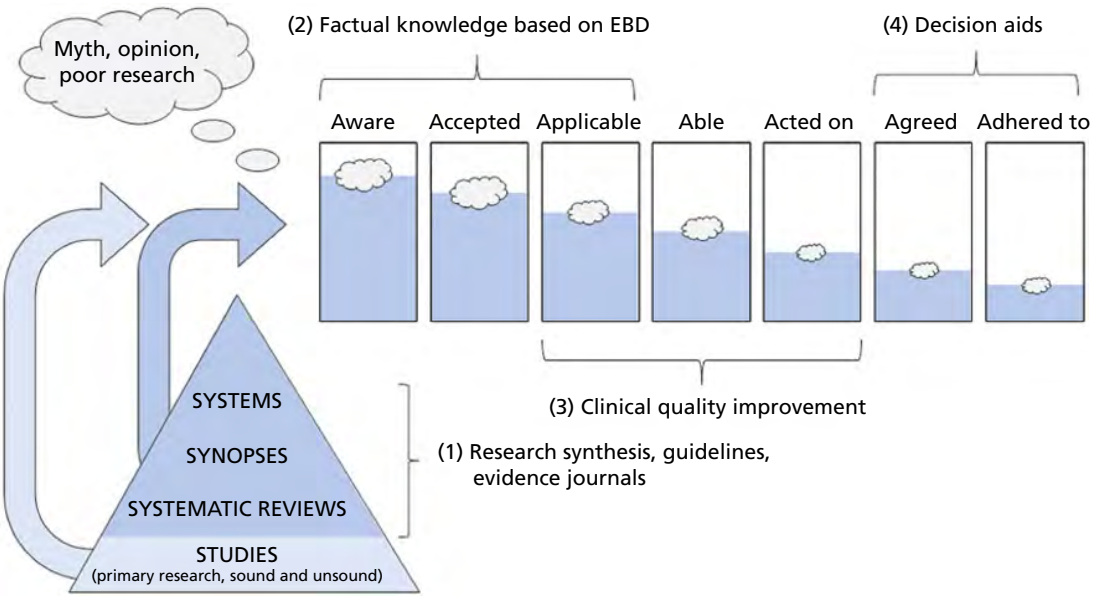

Fig. 45-2 Pathway from research to practice. At each step, approximately 20% of scientific evidence "leaks" and fails to proceed to the next step. This results in only 21% of scientific evidence being incorporated into patient care. EBD, evidence-based dentistry. (Source: Adapted from Glasziou & Haynes 2005.)

dentists. This failure to act is particularly common with preventive interventions such as oral hygiene programs prior to implant placement. Frequently, these important measures are not urgent for patients, and as a consequence, by respecting the patients' wishes, doctors skip the important steps to establish and maintain periodontal health. The gap between what we know and what we do is characterized by three different problems, namely misuse, overuse, and omission (National Academy of Medicine 2001), the latter perfectly describing the leakage of evidence in steps "able" and "acted on" and illustrated in the abovementioned example (Fig. 45-2).

The final two steps aim to match the values of the patients and of the clinicians, which might differ substantially. Patients may have their own interpretation of evidence and decline an intervention for reasons such as unwillingness to accept the pain or the inconvenience after a surgery. Even though clinicians prefer a certain therapy due to its evidence-based benefits, to successfully transfer evidence into clinical practice, patients must adhere to it, meaning that they must quit smoking, change their tooth brushing habits, or take their drugs as prescribed.

The reasons for the gap between scientific evidence and what is performed in clinical practice are manifold. Beyond the described loss of evidence in the knowledge transfer process, we must be aware that there is a bias already prevalent in many implant studies because much of the research in this field is of low quality and/or relevance (Masood *et al*. 2011; Tomasi & Derks 2012). The randomized trials that are published about implants and biomaterials might be biased in favor of the products owned by the company funding the trial (Popelut *et al*. 2010). Clinicians who do not interpret statistics correctly or only read low quality journals may have a very distorted view of the world.

Being aware of the described problems, which may have much more impact on the quality of esthetic outcomes of implant therapies than widely recognized, is a first step in engaging in an analytical process for critical self-reflection, in restructuring reasoning, and in changing ways of thinking (Croskerry *et al*. 2013a, b). Confidence in the procedure does not increase the suitability of the choice of therapy. The psychologic literature has well documented that, objectively, doctors are not good at assessing what they really know and generally tend to be overconfident in their judgments (Kruger & Dunning 1999; Saposnik *et al*. 2016; Burkhardt *et al*. 2019). Cognitive biases are specific systematic patterns of judgment or decision making that result in thoughts and behaviors deviating from what might generally be believed to be rational or optimal. They are hazardous because they are hardwired in our thinking, are strongly influenced by emotions, and are processed unconsciously. To counteract overconfidence and to detect the need for debiasing begins with becoming aware of the different types of cognitive errors which, mostly unconsciously, substantially influence clinical decision making and treatment planning (Croskerry & Norman 2008; Croskerry *et al*. 2013a, b). This means that those who are "unconsciously incompetent" do not even know how incompetent they are. One has to become consciously incompetent and ultimately unconsciously competent to take good clinical decisions and to provide the best benefit for each individual patient (Smith 2011).

Once the hurdles discussed above are cleared and the clinician has prepared a treatment plan to restore a missing central incisor with an implant, based on the

best available evidence, the idea has to be processed to the patient. However, the patient might have different expectations and be unwilling to accept the plan. In fact, the scenario that a clinician is processing the evidence unilaterally to the patient seems rather outdated. In a true clinician–patient partnership, the two will process the evidence together (Smith 2011).

Transparent risk communication and shared decision-making programs

The WHO defined oral health as a state of being free from any diseases and disorders that limit an individual's capacity in biting, chewing, smiling, speaking, and psychosocial well-being (WHO 2003). Considering the many site-specific variables which can affect the esthetic appearance of an implant restoration, it is obvious that an unfavorable result in the zone of esthetic priority may impair the smiling and psychosocial well-being of a patient and thus negatively affect his or her oral health. There are different scenarios which may lead to such an undesired result, but it is in almost all situations based on a discrepancy between expectations and outcome.

In one scenario, even if the clinician carefully communicated all possible benefits and harms of the therapy, it is probable that the patient did not or could not understand the explanations. A study on prosthodontic patients by Wolfart *et al*. (2006) evaluated general well-being with self-assessment of their dental appearance, and measured distinct esthetic concerns and psychosocial consequences of esthetic impairment. By using a psychometric test, the pretreatment mood of the patients, from euphoric to depressive, was diagnosed and placed in relation to the final satisfaction with prosthetic appearance. The patients in a depressive state were highly significantly more dissatisfied with their dental appearance than patients with normal well-being. Independent of the quality of the preoperative information, the psychological disposition of the patient may have an impact on the self-perceived esthetic appearance of the implant-supported crown or bridge.

In another scenario, the cause of the imbalance between expectations regarding esthetics and outcome may be based on the clinician not understanding the available evidence, not explaining it well, or being overconfident and providing the patient with a far too positive prognosis.

Whatever the reason, the communication between patient and clinician is essential and contributes substantially to mutual understanding and finally to a good overall clinical result.

Shared decision making is much more than the patient selecting one option from a given menu set. It was already part of the EBM movement of the 1980s and 1990s and has been defined as "involvement of both the patient and the doctor, a sharing of information by both parties, both parties taking steps to build a consensus about the preferred treatment, and reaching an agreement about which treatment to implement" (Charles *et al*. 1997). How much a patient needs to be involved in the process of decision making depends on their willingness and interest to participate. Many patients do not seek out information, feeling this is the doctor's job. More important than the dominance of the responsibility for the decision in the doctor–patient relationship is the patient's engagement in discussion about the nature of their problems (Bugge *et al*. 2006), the question about who defines the question set (Wirtz *et al*. 2006), and the facilitation of the patient's contribution to the delivery of the choice of therapy (Entwistle & Watt 2006). Independent of the benefits of task-related information, the feeling that patients are well cared for as individuals and respected as part of the team is crucial for a good patient–doctor relationship (Wright *et al*. 2004). Frequently, the underlying cause of the patient's unhappiness with the appearance of the restored teeth and the smile is not the medical problem itself but the lack of self-confidence and the pressure of a highly competitive society. Clinicians who believe that they can solve such psychological issues with medical technologies, without a detailed conversation with their patient, cannot genuinely be interested in the patient's well-being (Maio 2007). It is proven by systematic reviews that the involvement of patients in the decision-making process and a thorough presurgical conversation results in better quality of care, increased patient satisfaction, and improved self-esteem (Crawford *et al*. 2002).

The field of shared decision making has evolved in the last two decades and is closely related to concepts such as EBM, informed decision making, and patients' autonomy, in the medical context, describing patients making use of their right of self-determination when dealing with health subjects. In 2020 more than 10 000 related articles were indexed in Medline, but only a handful dealt with shared decision making in dentistry (Bauer & Chiappelli 2010) and implantology (Alzahrani & Gibson 2018). In general, the involvement, needs, and perceptions of dental patients have not yet been sufficiently assessed (Reissmann *et al*. 2019). The few available studies in dentistry are in accordance with those from the medical context and confirm that the majority of patients prefer to actively participate in the decision process (Singh *et al*. 2010). The preference for a more active role in decisions seems to correlate with the invasiveness of the intervention and the long-term effects (e.g. treatments concerning the various stages of tooth loss and the replacement of teeth).

In the whole process of shared decision making, the communication of risks and the manner of sharing uncertainty is an essential part, which is difficult to achieve but contributes substantially to the quality of shared informed decisions. Firstly, uncertainty exists on a professional collective level, which suggests that additional and better quality research is required. Secondly, uncertainty relates to the

individual clinician and depends on his or her professional education. Thirdly, effective risk communication about harms and benefits of different treatments or care options is important and is known as stochastic uncertainty (Edwards *et al*. 2002). Factors such as ensuring credibility of the source, competing interests, previous experiences, understanding patients' values and maximizing the clarity of the message are important to determine the quality of risk communication (Poortinga & Pidgeon 2004). Besides the cognitive aspects of risk perception and communication, the method and preferred format of information delivery, ensuring that the information has been understood by the patient, and monitoring the reactions triggered by the information are also important and contribute to make evidence part of the patient choices. Risk communication on the collective level and open declaration of one's own uncertainty (individual uncertainty), once it is realized by critical self-reflection ("does this work in my hands?"), should remind the patients that virtually all treatment options are associated with some possibility of risk. Practical strategies and helpful guidelines for clinicians have been described elsewhere (Paling 2003).

Compared with other medical domains, the role of shared decision making and risk communication in implantology is not yet well investigated and, in regular practice, contrasts between patient preferred and perceived roles in decision making may occur (Reissmann *et al*. 2019). On the other hand, it is documented by some scientific evidence from other surgical specialties that the application of the principles of shared decision making and the use of decision aids result in much higher patient satisfaction (Sepucha *et al*. 2019). In particular, when decisions have to be taken for elective surgeries and patients have been informed on the basis of shared decision-making programs, it is evident that the willingness to undergo the intervention decreases, but for the patients who, nevertheless, decided in favor of the surgery, the patient-reported outcome, the satisfaction, and overall happiness with the intervention, on short- and long-term evaluation, is much better (Bozic *et al*. 2013; Martinez-Gonzalez *et al*. 2019). It is hoped that shared decision-making programs will be implemented in oral implantology in the near future. This would help to reduce biological and esthetic adverse outcomes and provide patients with the best individual benefit from the chosen treatment.

Preoperative diagnostics

Clinical measurements

Preoperative diagnostics in the zone of esthetic priority do not differ fundamentally from those in other areas of the upper and lower jaw. The precise evaluation of the three-dimensional loss of tissue in the edentulous area and the periodontal condition of the neighboring teeth are the center of attention. From the latter, the periodontal attachment level at the tooth, adjacent to the site where an implant has to be placed, is of utmost importance as the complete embrasure fill between an implant restoration and the neighboring tooth is correlated with the integrity of the periodontal ligament (Roccuzzo *et al*. 2018). Preoperative interproximal probing on the adjacent teeth, combined with recordings of the gingival recessions, reduce the risks for adverse esthetic outcomes. Other parameters that reflect the oral hygiene status and compliance of the patients have to be evaluated routinely before starting treatment and while monitoring implant reconstructions over a lifetime (Mombelli *et al*. 1987). Besides the well-known negative effects of poor oral hygiene habits on implant complications and survival (Heitz-Mayfield & Salvi 2018; Schwarz *et al*. 2018), an inflamed mucosa cannot be manipulated with the same precision as a healthy one, and primary wound closures are more difficult to achieve as inflamed soft tissues are ambiguous and at higher risk for soft tissue dehiscences during the early healing phases.

Another factor that may influence the esthetic success of an implant reconstruction in the anterior area and, therefore, needs to be recorded presurgically, is the soft tissue phenotype (Cortellini & Bissada 2018) or according to the nomenclature, the phenotype (Caton *et al*. 2018). Even if numerous studies on humans show that a thin phenotype is more friable, less vascularized, and accompanied by thinner underlying bone and seems to be more susceptible to mucosal dehiscences (Linkevicius *et al*. 2009; Linkevicius *et al*. 2010), actual data confirm that thin mucosal phenotypes may be compensated by the use of connective tissue grafts, at least when implants are placed immediately after tooth extractions, and thus, level out the clinical differences between thick and thin phenotypes and the range of transitional categories in between (Tatum *et al*. 2020).

The extent of an edentulous space in the arch can best be described based on the number of missing teeth. The defects have been classified based on their morphologic characteristics (Wang & Al-Shammari 2002), dividing them into a horizontal and a vertical defect component. Depending on their extent, vertical hard and soft tissue defects show a much better prognosis for augmentation than horizontal ones. In the latter, the attachment level at the teeth neighboring the defect limits the prognosis and therefore the prospective esthetic result.

Based on a personal evaluation, it seems that sound preoperative clinical measurements are often neglected. By publishing a clinical picture and the corresponding X-ray on social media, dentists were asked to choose one of the options out of five listed treatment modalities. It was surprising that just a minority of the more than one hundred respondents opted for "I don't know" while the majority took a treatment decision based on the very limited available information (Fig. 45-3).

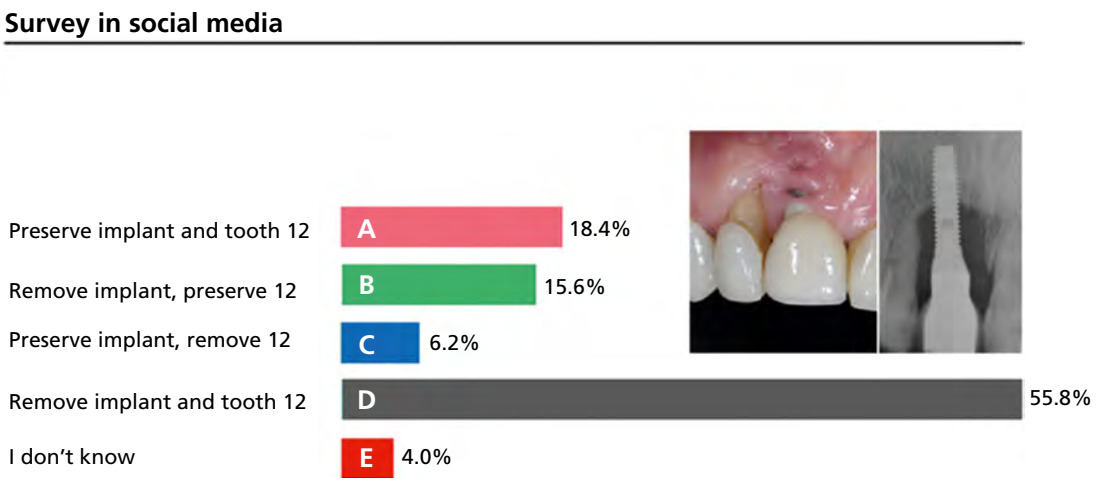

Fig. 45-3 A survey in social media confirmed the tendency that clinicians are ready to take a treatment decision without careful evaluation of important clinical parameters. Just based on a clinical picture and the corresponding X-ray, dentists were asked to choose one out of five treatment options. The graphic displays the distribution of the different answers and documents that just a minority of respondents was aware of the lack of information.

Image-guided diagnostics

To ensure proper planning of the implant position, which is a fundamental requirement in the zone of esthetic priority, the required information can be obtained from the aforementioned clinical examinations and additional appropriate image-guided diagnostics. To investigate an implant site in the anterior upper jaw, a clinician requires information on bone volume and quality, topography, and the relationship to important anatomic structures, such as the roots of neighboring teeth, nasal floor, vessels, and nerves. In the last decade, cone beam computed tomography (CBCT) has been rapidly adopted for implant planning. There is legitimate concern from experts in the clinical and radiology fields that these technical developments will lead to a significant increase in the radiation exposure of patients without a proper risk–benefit analysis. For this reason, guidelines for the use of diagnostic imaging in implant dentistry have been published, based on a consensus workshop of the European Association for Osseointegration (EAO) (Harris *et al*. 2012).

In the upper anterior maxilla, the recommended standard radiographic technique in sites with sufficient bone consists of an intraoral radiograph before replacing a missing single tooth, and an additional panoramic image in partially dentate and edentulous patients. The need for cross-sectional imaging has to be carefully evaluated for a sufficient net benefit, weighing the total potential diagnostic or therapeutic benefit against the detrimental effects the exposure might cause the individual.

In the zone of esthetic priority, a cross-sectional image (CBCT) can be indicated in clinical situations where clinical examinations or conventional radiography have failed to adequately identify the relevant anatomic boundaries or the absence of pathology. Specific challenges which justify a CBCT include (1) borderline cases with inadequate bone morphology and volume, (2) specific presurgical planning which helps to translate the information from radiographic evaluation into the clinical procedure (surgical guides) and (3) the virtual patient, a digital record that is used to plan the ideal implant position with respect to esthetic, prosthetic, and surgical requirements (Jacobs *et al*. 2018).

Visualization of prospective results for diagnostics and patient information

When treating the anterior zone of a patient's upper jaw, the wishes and expectations of each individual patient concerning the esthetic result have to be respected. Very often the patient's and the clinician's views of what constitutes an ideal esthetic outcome widely differ (Langlois *et al*. 2000). While the patient is influenced by his/her self-perception, the social environment, the media, his/her own dental history, and many other factors, the clinician bases his/her choice of a certain clinical strategy on the current dental knowledge, the empirical experience, and, possibly, on available medical checklists. The latter especially carries a risk of standardizing the prospective results and disregarding the individuality and personality of each patient. To address this, the contact and communication with the patient in the diagnostic phase, but also during the following treatment stages, requires special attention as patients are often unable to articulate their wishes and concerns (see Transparent risk communication and shared decision-making programs, previously).

By means of computer software, digital smile design programs offer new possibilities to capture facial, dentogingival, and dental esthetics and process the data into prospective esthetic treatment goals (for review see Omar & Duarte 2017). To close the gap between the true and the artificial environment, so called mixed reality digital applications (virtual reality, augmented reality) are available for different

simulations in implantology, showing huge potential and stimulating increased attention. Until now, these technologies are predominantly used for motor skills education, clinical analyses of maxillofacial surgical protocols, and investigating human anatomy (Joda *et al*. 2019).

New technologies, based on augmented reality principles, are currently under development for visualization of the esthetic results and improving the patient–doctor communication. Such software enables the patient to see within seconds the esthetic result of the dental reconstruction. A live video is taken of the patient's own teeth, on which a virtual model of the new set of teeth is superimposed. By just a mouse click, patients can try out several alternatives and adjust tooth length, width, shape, and color shade. Thanks to "virtual fitting", communication between the clinician, the patient, and the laboratory technician seems to be facilitated and expectations from all parties can be managed more easily.

Despite the many promises of innovations, we have to be aware that much of the policy rhetoric on new technologies rests not on what they have been shown to achieve in practice but on optimistic guesses about what they would, could, or may achieve if their ongoing development goes as planned, if the technologies are implemented as intended (Greenhalgh 2013). Additionally, a personal relationship cannot be replaced by digital technologies and the translation of a digital analysis with the help of computer imaging software may idealize the prospective results, which may not reflect the actual situation.

Especially in edentulous areas where a considerable amount of vertical tissue volume is missing, it can be difficult to reconstruct the tissue loss with surgical interventions alone, and clinicians must take care with what they promise patients regarding outcomes. Against this background, each treatment plan for a reconstruction in the zone of esthetic importance should be based on the interaction between all participating persons and must include the patient's opinions and desires.

All the rules that have been learned about tooth form, geometry, and harmony to recreate an esthetically pleasing smile can only be viewed as a general guide. Otherwise, all treatment goals would be the same for all patients and the facial physiognomy and uniqueness of each individual would be neglected.

Checklists can be helpful to clinicians in identifying problems, but they have a tendency to overlook patient individuality and usually follow a set pattern that ends with a standardization of the procedure.

Key factors for success when planning implant restorations in the zone of esthetic priority are taking the time to deal with the patient's esthetic problem, the communication within the treatment team, and the notes on each individual step in the development of the prospective esthetic outcome.

Preoperative risk assessment

Evaluation of alternative treatments and checklists

Prior to selecting an implant-based solution, one should carefully review all possible treatment alternatives that have the potential to solve a given problem. Additionally, the advantages and disadvantages of the solutions should be comprehensively pondered, not only in light of long-term survival but also with respect to the esthetic outcome and its stability over time. The therapeutic modalities that can be used to replace a tooth in the zone of esthetic priority, without placing implants, are listed in Table 45-1. In cases with unrestored neighboring teeth, adhesive, resin-bonded zirconia bridges have been shown to reliably replace single missing teeth in the anterior upper jaw with almost no preparations needed at the anchor teeth (Shahdad *et al*. 2018). In cases with minor incisal clearance, conventional porcelain-fused-to-metal-crowns will still render good service with promising long-term results, in some situations even without esthetic restrictions (Fig. 45-4) (Pjetursson *et al*. 2008).

In comprehensive esthetic treatment planning, attention should be directed not only to implant alternatives but also to strategies aimed at improving the implant sites prior to placing the implant or even at improving a tooth's prognosis such that implant reconstruction can be postponed or even avoided (Fig. 45-5). Based on our personal experience, orthodontic pretreatments especially can improve the clinical situation in many cases and provide a better esthetic prognosis for therapy. These pretreatments include forced eruptions (Giachetti *et al*. 2010) to increase the retention for placement of a conventional crown or to condition the site for later implant placement (Amato *et al*. 2012).

Another orthodontic treatment option consists of changing the distribution pattern of the edentulous spaces by turning a neighboring two-unit space into two one-unit spaces (Fig. 45-6). As previously mentioned, the latter situation has a much better predictability regarding the development of papillary-like structures, an important issue for a natural appearance. A palatally placed implant offers an absolute anchorage for orthodontic tooth movements without risk of negatively influencing the present occlusion. Additionally, the temporary implant may serve as an ideal anchor in many situations to firmly fix a provisional without

Table 45-1 Therapeutic modalities for tooth replacement in the zone of esthetic priority.

- Conventional fixed partial dentures, comprising cantilever units
- Adhesive, resin-bonded (cantilever) bridges
- Conventional removable partial dentures
- Tooth-supported overdentures
- Orthodontic therapy (closure of edentulous spaces)
- Implant-supported prostheses (fixed, retrievable, or removable suprastructures)
- Combinations of the above

Fig. 45-4 (a) Preoperative view: left central incisor with root resorption has to be removed and replaced. (b) Situation after tooth extraction, alveolar ridge preservation procedure, and coverage with a connective tissue graft. (c) Uneventful healing of the site 8 days postsurgically, overcontouring of the lateral ridge to compensate for shrinkage of the buccal bone. (d) Final restoration with a resin-bonded adhesive bridge (metal framework), 8 months after tooth extraction.

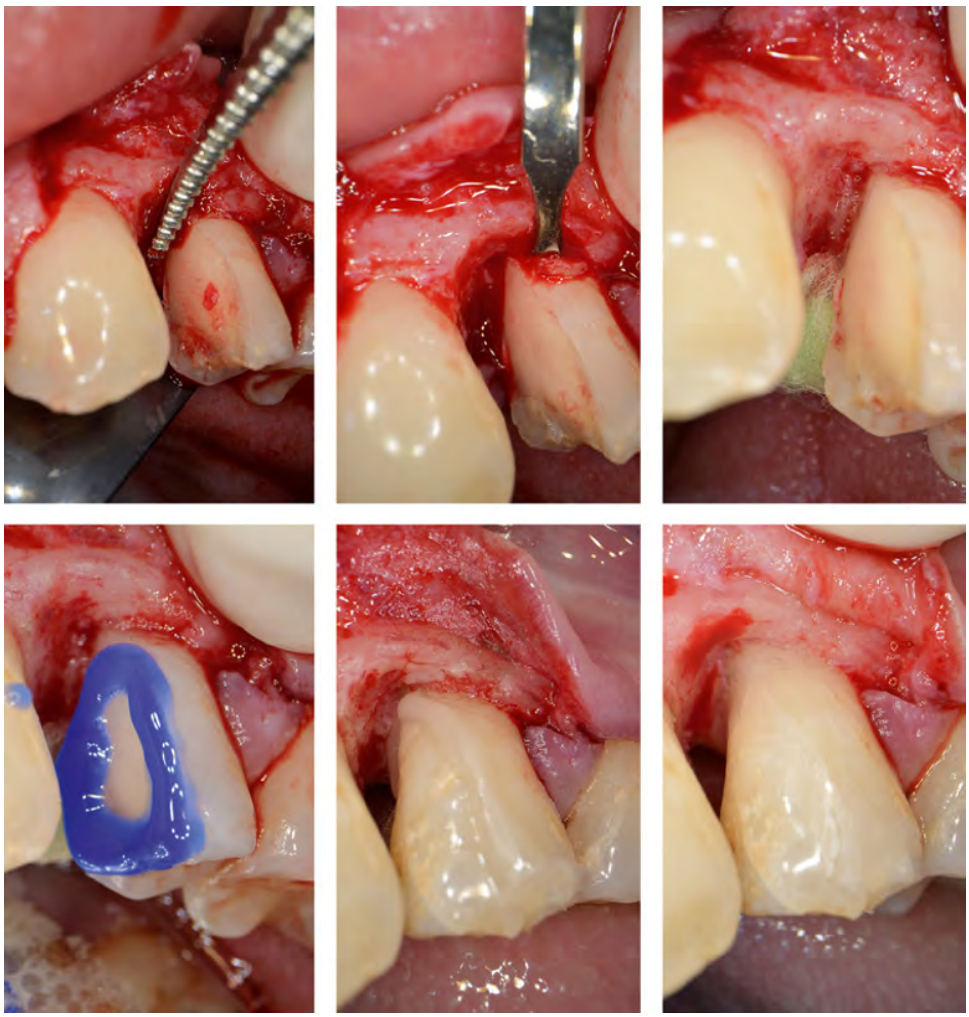

Fig. 45-5 Clinical situation after accident with infrabony fractured first premolar. Instead of extracting the tooth and replacing it with an implant, the tooth is saved using minimally invasive flap surgery and ostectomy. The broken piece can be fixed adhesively and tooth vitality is kept intact. Even if no scientific evidence exists for such treatment, for the individual patient it might perform well and preserves tissue.

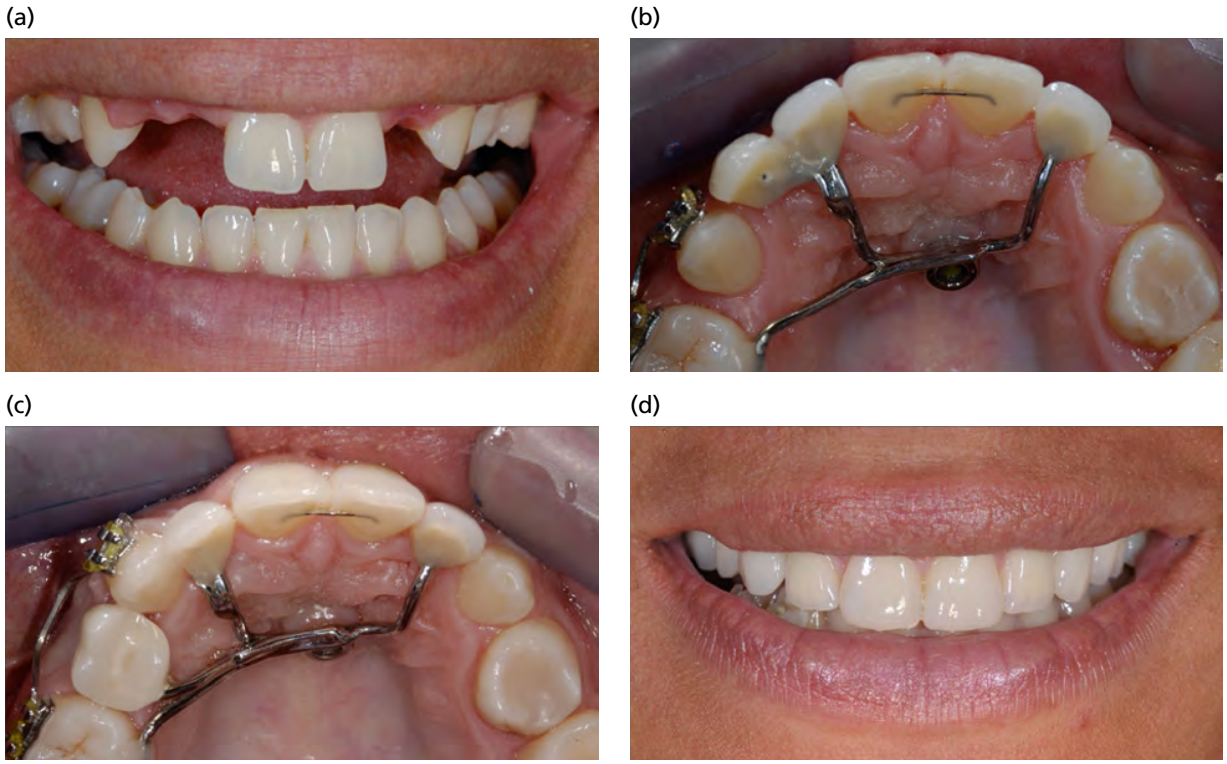

Fig. 45-6 (a) Patient with missing teeth in zone of esthetic priority. An edentulous single-unit gap is present in area 22 and a two-unit gap in area 12, 13. (b) Palatal implant for absolute anchorage and mesial movement of right upper canine. Additionally, the palatal implant serves as an ideal screw fixation for the provisional restoration which is shortened stepwise while moving the canine. (c) The orthodontic treatment is finished and the provisional has been adapted to the new situation. The palatal implant supports the provisional until the end of the implant treatment. As the patient is restored with a fixed provisional, the definitive restoration is not urgently required, which might be important in some cases to comply with the healing times. (d) Final prosthetic restoration with three single implants in the areas 14, 12, and 22.

any visible attachments on the anterior incisors and canines until the implants can be loaded with provisional crowns. Even if not documented by prospective studies, the long-term restoration supported by palatal implants seems to be a true alternative when esthetics are important and site-specific variables prevent the insertion of a conventional implant.

In patients with open interdental spaces and one or more missing teeth to be replaced, a conventional fixed approach will be critical as a single diastema cannot be closed for symmetry reasons and thus, an implant-supported reconstruction becomes the treatment of choice. Besides diastemata, other situations which favor the inclusion of implants in the treatment plan are: (1) unrestored, healthy neighboring teeth; (2) compromised, risky abutments; (3) extended edentulous areas; and (4) missing strategically important abutment teeth. The fulfilment of one or more of these criteria does not necessarily mean that the inclusion of implants in the treatment strategy is a given. Other risk factors related to the bone, soft tissue, and tooth (clinical crown) level have to be carefully evaluated and considered in the decision-making process (Table 45-2).

Surgeon-related risk factors

Because all implant interventions in the zone of esthetic priority are elective surgeries, there is enough time for detailed treatment planning, decision making, and communication of benefits and harms to the patient. As a result of this, coupled with available scientific evidence, adverse esthetic results in implantology should not routinely occur. Unfortunately, this is wishful thinking and corresponds well with elective surgeries in other fields. In the last decade, psychologists and behavioral scientists have addressed this problem and analyzed its origins (Ballard 2014). A dual-system framework has been introduced to explain human decision making and cognitive biases (Tversky & Kahneman 1974). System 1 refers to an unconscious, fast, and intuitive mechanism to take decisions, while system 2 is conscious, slow, and effortful to make deliberate decisions. It is suggested that cognitive biases are likely due to the overuse of system 1 or when system 1 overrides system 2. Despite the efforts in other fields, such as aviation or factory production (Dhillon 1989; Ballard 2014), to shed light on the influence of cognitive biases on the sequences of operations, little is known about the influence of such biases and personality traits on decision making in medicine and implantology. Evidence confirms that medical personnel are generally prone to show cognitive biases, but it is still unclear how these biases relate to the number of treatment errors (Blumenthal-Barby & Krieger 2015).

Table 45-2 Risk factors for implant placement in the zone of esthetic importance.

	Low risk	Medium risk	High risk
Patient factors			
General health	Systemically healthy		Reduced defense
Smoking conditions	Non smoker	Occasional smoker	Smoker, heavy smoker
Compliance	Good		Poor
Esthetic expectations	Within normal limits		Very high
Lip line	Low	Medium	High
Dental/facial symmetries	Symmetric		Visible asymmetries
Interarch relationship	Normal situation		Deep bite situation
Hard and soft tissue factors			
Attachment level of neighboring teeth	Intact		Reduced
Periodontal and endodontic health	Healthy		Compromised
Distance contact area –bone level at neighboring teeth	<5 mm	5 mm	>5 mm
Ridge deficiencies	Intact alveolus	Lateral defect	Vertical or combined defect
Mesio-distal gap distance	1 tooth (>7 mm)	1 tooth (<7 mm)	2 neighboring units
Mucosal phenotype	Low scalloped, thick	Medium	High scalloped thin
Soft tissue surfaces	Intact		Texture irregularities, scar formations
Mucosal scalloping	Regular		Irregular
Tooth factors			
Crown forms	Squared shape		Triangular shape
Structural integrity	Intact, healthy	Sufficiently restored	Decayed, insufficiently restored
Line of incisal edges	Following lower lip		Irregular

A recent systematic review (Saposnik *et al*. 2016) found that 50–100% of physicians were affected by at least one cognitive bias. The most commonly studied personality trait was tolerance to risk or ambiguity which might also have an impact when it comes to decide between implants in the zone of esthetic priority and the treatment alternatives. The most common cognitive biases were overconfidence and framing, the latter describing the fact that different wordings of a message, by expressing exactly the same content, affects the behavior and reaction of the recipient.

One may assume that a doctor's personality traits such as tolerance to uncertainty or cognitive biases do not equally influence patient outcomes in all disciplines. Time-urgency of the therapeutic decision may be a relevant characteristic. Even if implant placements in the zone of esthetic priority are elective interventions, it is hoped that future research will elucidate how the many described cognitive biases in medicine such as premature closure, ego bias, overconfidence, confirmation bias, and others (Croskerry 2005) affect decision making in implantology and how they are related to the reduction of errors and more realistic patient expectations.

Provisional restorations and timing of the treatment sequences

In the anterior zone, provisional restorations have a variety of important functions. Provisional restorations should be used to evaluate esthetic, phonetic, and occlusal function prior to delivery of the final implant restorations, while preserving and/or enhancing the condition of the peri-implant and mucosa tissues (Furze *et al*. 2019). An implant treatment approach in the edentulous anterior zone has three provisional phases: (1) the first phase, from tooth extraction to implant placement including immediate provisionalization after tooth extraction: (2) the second phase, after implant placement and prior to loading; and (3) the third phase, a loaded fixed implant-supported provisional and the ensuing emergence profile.

From tooth extraction to implant placement

After tooth extraction in the esthetic zone, several options are available to immediately replace the missing teeth with provisional restorations. These

provisional restorations can be in the form of removable or fixed prostheses. It is of great importance for the patient to discuss the options as well as the advantages and disadvantages prior to the therapy. When a patient is going to lose one or more teeth in the anterior area, an adequate provisional restoration will give the patient the confidence back after losing his/her own teeth.

Removable partial acrylic dentures have commonly been used after tooth extraction and maybe also throughout the entire implant therapy (Fig. 45-7). They are simple to construct, relatively inexpensive, and easy to adjust and fit. They can be easily modified in cases with additional extractions by adding provisional teeth to the existing removable dentures with minimal cost. Care must be taken with the mucosal portion supporting the provisional partial denture in order not to apply too much pressure to the healing site. Immediately after tooth extraction the provisional restoration can be placed with ovate pontics extending into the extraction sockets to partially preserve the pre-extraction soft tissue morphology. These removable partial acrylic dentures are not particularly comfortable because they have a certain resilience and cover part of the palate. Hence, there are alternatives to these tissue-borne provisional restorations. An Essix provisional (Fig. 45-8) may be used as a removable prosthesis in these cases, as well as in limited interocclusal space or deep anterior overbite (Santosa 2007; Siadat *et al*. 2017). This prosthesis is made from an acrylic tooth bonded to a clear vacuform material on a cast of the diagnostic wax up. The prosthesis provides protection to the underlying soft tissue and implant during the healing phase. Limitations of this provisional restoration include its inability to mold the surrounding soft tissue, and lack of patient compliance can cause rapid occlusal wear through the vacuform material (Santosa 2007). However, some patients may not like to wear, or are unable to tolerate, a removable provisional prosthesis; thus, fixed provisional prosthesis are sometimes necessary.

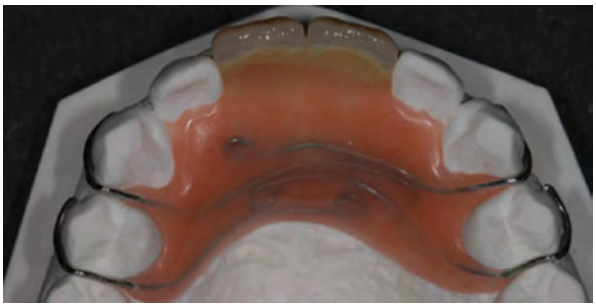

Fig. 45-7 Occlusal view of a removable partial acrylic denture on the cast with wires retained to the teeth 14, 13, 23, and 24.

(a)

(b)

(c)

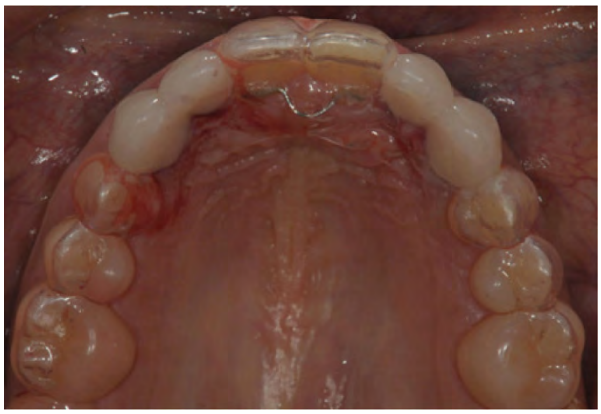

Fig. 45-8 (a) Occlusal view of an Essix provisional made from acrylic teeth bonded to a clear vacuform material. (b) Clinical occlusal view immediately after tooth extraction of the remaining deciduous teeth and before inserting the provisional restoration. (c) Clinical occlusal view of an Essix provisional after teeth extractions in the upper jaw.

Fixed tooth supported provisional restorations in the anterior region mainly include resin-bonded pontics or bridges (Siadat *et al*. 2017). The pontic can be in the form of an acrylic tooth, porcelain, or decoronated extracted tooth. The resin-bonded acrylic or natural tooth may be reinforced with composite resin and/or fiberglass. These types of provisional restorations are much more comfortable from a functional, phonic, and esthetic point of view. However, their removal and rebonding after the surgical intervention requires more time and work for the dentist. If a provisional restoration is needed for a longer time and more stability is required, a resin-bonded, cast metal framework prosthesis such as a Maryland Bridge is indicated (Grizas *et al*. 2018). These prostheses are cemented to the neighboring teeth by means of acid etching and the use of composites (Fig. 45-9). They can be detached by removing the composite within the palatal perforations and by using forceps interdentally and a hammer. This type of fixed provisional restoration also allows more than one missing tooth to be replaced. However, the relatively high laboratory costs of these resin-bonded, cast metal framework prostheses must be taken into consideration.

At implant placement with immediate provisionalization

Immediate provisionalization is a common procedure in daily practice that was initially developed for the esthetic regions in order to benefit patients during the implant treatment and prior to crown delivery (Donos *et al*. 2018). It is of outmost importance, however, that each case for immediate provisionalization undergoes a thorough risk assessment. The risk of soft tissue recession after insertion of the provisional reconstruction should be carefully considered. Upon the insertion of a provisional crown, the surrounding peri-implant soft tissue reacts and creates the so-called emergence profile. The aim of this structure is to allow a pleasing natural esthetic appearance through a smooth transition between the round and narrow shape of the implant connection and the oval and wider shape at the marginal area. This smooth transition is usually obtained after a few appointments by modifying the provisionals. Previous studies suggested, nevertheless, that the frequent exchange or dis/reconnections of abutments may disturb the surrounding tissues, resulting in marginal bone loss (Rodriguez *et al*. 2013; Bressan *et al*. 2017). The detrimental effect of this frequent manipulation has been documented preclinically (Rodriguez *et al*. 2013) as well as clinically (Bressan *et al*. 2017). In this context, a recent randomized controlled trial compared the radiographic, clinical, and esthetic outcomes of immediately provisionalized and conventionally restored implants for up to 24 months (Donos *et al*. 2018). The study revealed a significantly mean difference in bone loss in favor of conventionally restored implants but no differences in terms of clinical and esthetic outcomes (Donos *et al*. 2018).

Likewise, and based on a similar notion, the "one abutment–one time" protocol was introduced. This protocol proposes a definitive abutment instead of a provisional abutment at the time of implant placement in order to minimize the trauma to the surrounding tissues. A recent systematic review on this concept concluded that although definitive abutments minimized the changes in peri-implant marginal bone levels statistically, the clinical significance of this finding is still uncertain (Atieh *et al*. 2017). Moreover, the same review revealed no differences in terms of periodontal and esthetic outcomes (Atieh *et al*. 2017).

Digital technologies in implant dentistry are increasingly applied and are continuously replacing conventional provisional reconstructions. Intraoral scanning (IOS) and computer-aided design and manufacturing (CAD-CAM) have become common tools to fabricate these provisionals (Muhlemann *et al*. 2018). The fabrication process can either be executed via the dental laboratory (lab side) or directly by the dentist (chairside). The latter may simplify the fabrication of an implant-borne provisional reconstruction immediately after implant placement, resulting in fewer appointments and thereby improving patient comfort (Malo *et al*. 2007;

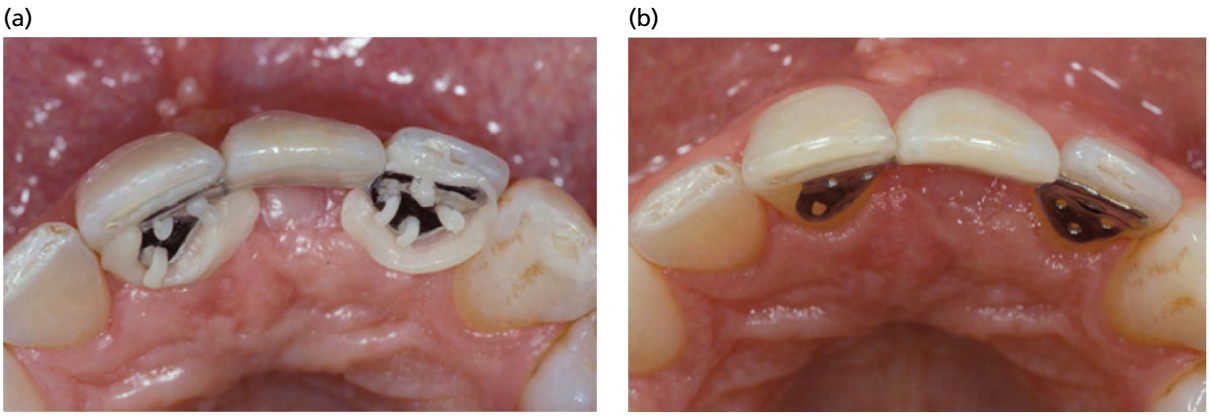

Fig. 45-9 (a) Placing of the provisional adhesive bridge with filling composite before removing the excess material. (b) Provisional adhesive bridge replacing the missing tooth 21 after cementing.

Arisan *et al*. 2010; Muhlemann *et al*. 2018). Consequently, digital workflows have been proposed as more efficient and less time-consuming compared with traditional approaches (Sailer *et al*. 2017; Muhlemann *et al*. 2019).

From implant placement to abutment connection

During the period from implant placement to abutment connection the same options of provisional restorations are available as after tooth extraction (Siadat *et al*. 2017). However, after implant placement, especially with the use of guided bone regeneration techniques, a significant swelling of the tissues must be anticipated during the first few postoperative days. Soft tissue-borne prostheses used during this healing period may cause uncontrolled soft tissue pressure defined as "transmucosal loading", leading to implant exposure, marginal bone loss, and/or failed integration (Santosa 2007). In order to avoid too much contact to the soft tissue and the healing implants the provisional dentures are adjusted to have a distance of approximately 2–3 mm to the tissue after surgical interventions. In this context, Essix provisionals have advantages because they are vertically stabilized through the neighboring teeth and, therefore, cause less pressure to the tissue in cases of swelling.

From abutment connection to final crown/bridge placement

According to the preoperative risk assessment, it has to be decided whether an implant will heal best with a submucosal or a transmucosal approach. In highly demanding situations with high lip line, thin phenotype, and tissue deficiency, a submucosal approach is generally chosen in order to create soft tissue extra volume. In less demanding situations with thick phenotypes, sufficient tissue, and possible soft tissue excess, a transmucosal approach with healing abutments or provisional reconstructions can be selected. Hence, the preoperative risk assessment and the intraoperative information (i.e. primary implant stability, bone defects, soft tissue quantity and quality) will determine the timing of the treatment sequences. In cases with lower risks and sufficient tissue, a more straightforward approach without abutment connection can be chosen (Fig. 45-10). In contrast, higher risk cases require another treatment sequence with a more complex approach, including abutment connections with or without soft tissue management (Fig. 45-11).

A recent randomized clinical trial compared the esthetic outcomes of implant-supported crowns with and without provisionals in the anterior region. The results after 3 years revealed better esthetic outcomes in the group with provisionals (Furze *et al*. 2019).

Hence, implant-retained provisional reconstructions are not only beneficial for the diagnostic phase but also for the treatment outcomes. Furthermore, they can serve as a communication tool between clinicians, laboratory technicians, and the patients. One of the most important functions of an implant-retained provisional restoration is to develop the desired soft tissue emergence profile. Dental implants differ from teeth in size and shape at the crestal bone level and at the mucosa level. After the healing period, the geometry of the tissue profile tends to be circular and

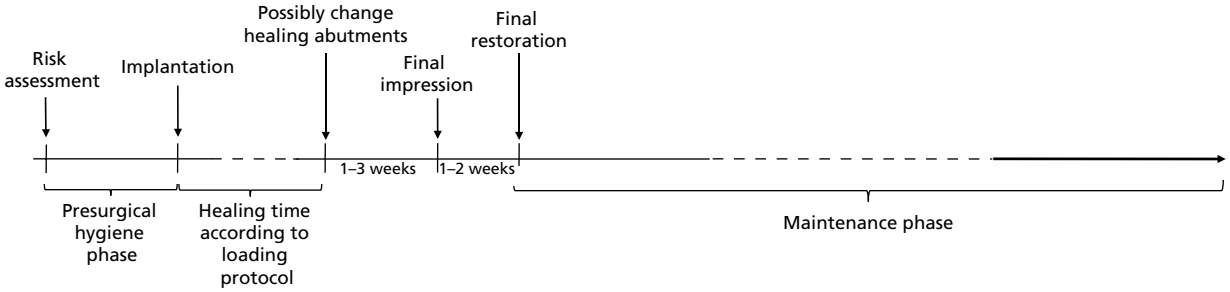

Fig. 45-10 Time sequence of a straightforward case without abutment connection and provisional implant retained restorations.

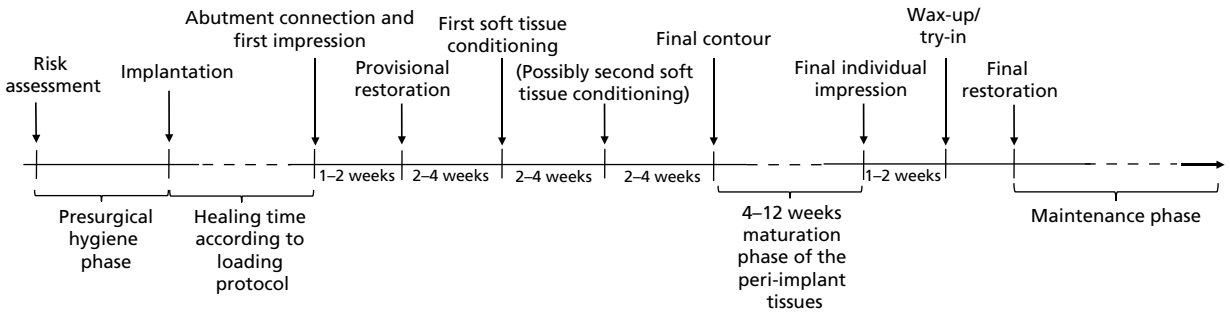

Fig. 45-11 Time sequence of an advanced/complex case with abutment connection and provisional implant retained restorations in order to condition the soft tissues.

does not match the corresponding one around teeth (Fig. 45-12). The tissue profile created by the emergence profile and form of the teeth has a more triangular shape, especially for incisors. Therefore, the peri-implant soft tissue profile has to be converted into a tissue profile that is in harmony with the neighboring dentition (Wittneben *et al*. 2013). This transition can either be performed through individualized healing abutments or implant-retained provisional restorations (Fig. 45-13). These implant-retained provisional restorations can either be fabricated in an ideal contour or with a reduced emergence profile (Fig. 45-14). For the provisional with an ideal profile, the clinician needs to work in a subtractive way by selectively reducing the diameter before being able to place the provisional restoration. In contrast, for the provisional with a reduced emergence profile the clinician is working in an additive way by selectively adding resin material before inserting the provisional (Fig. 45-14).

Provisional restorations can either be cemented or screw-retained. Chapter 44 provides a detailed discussion about the two types of reconstructions along with a decision tree (Fig. 44-23, Fig. 44-24). Overall, the decision whether to cement or screw retain a provisional or a final implant restoration depends on the clinical situation (i.e. angulation of the implant and implant position) and the clinician's preference regarding the method of fixation (Wittneben *et al*. 2017). For proper soft tissue conditioning, a screw-retained provisional is preferred due to the retrievability and the easy conditioning of the soft tissue in the desired direction. Fixed implant-supported provisionals can be fabricated either in the laboratory or chair-side. In order to improve the soft tissue contour, the provisional reconstruction is inserted thereby creating a slight pressure on the mucosa. The applied pressure generates an ischemic reaction, a so-called "blanching" of the peri-implant soft tissue, which should only be moderate and disappear within 15 minutes after placement of the provisional (Cooper 2008). By customizing the shape and the contour of the provisional restoration, the peri-implant contour is improved and the emergence profile formed. This soft tissue conditioning process is performed over a period of 8–12 weeks by selectively adding flowable composite material or light-cured acrylic resin to the provisional reconstruction (Wittneben *et al*. 2013). After achieving the final emergence profile it is important to transfer the created soft tissue profile (Fig. 45-15) to the final master cast. This can be attained by an individualized impression coping that has the same tissue profile as the clinically approved provisional restoration

Fig. 45-12 Peri-implant soft tissue profile after a healing period of 3 months, revealing the lack of emergence profile.

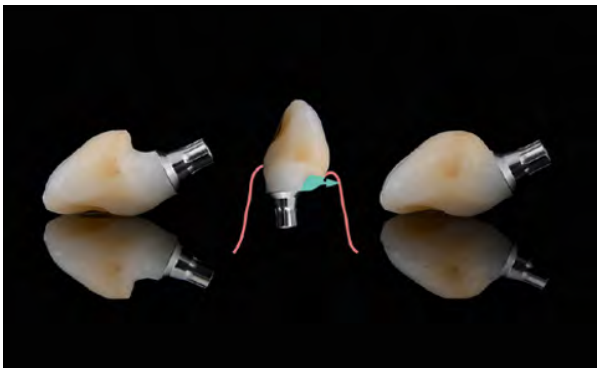

Fig. 45-14 Provisional screw-retained reconstruction with a reduced emergence profile which needs to be individually adjusted by adding resin material before insertion.

Fig. 45-13 Emergence profile after 2 months of soft tissue conditioning with a screw-retained provisional.

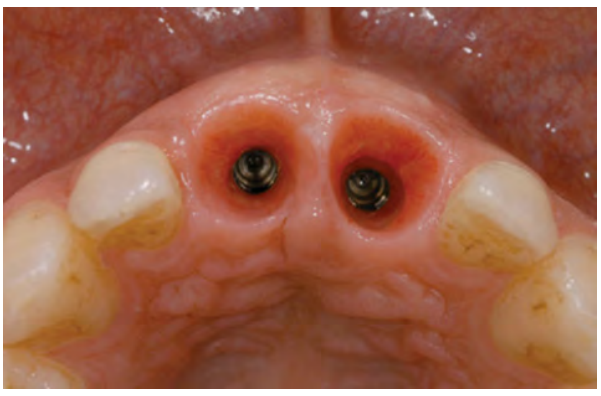

Fig. 45-15 Occlusal view after reaching the final emergence profile of the missing central incisors 11 and 21.

(Furze *et al*. 2019) (Fig. 45-16). As most of soft tissue recessions take place within the first 3–6 months (Oates *et al*. 2002), it has been assumed that the soft tissue margin after the conditioning process stays stable and therefore a final reconstruction can be fabricated. A recent long-term prospective study on immediately restored single tooth implants revealed that a provisionalization phase of 2 months was adequate to provide stability of the soft tissue margins at 8 years follow-up (Raes *et al*. 2018).

New manufacturing techniques (CAD-CAM and 3D printing)

With the advent of digital technologies in implant dentistry, conventional surgical and prosthetic approaches have been increasingly replaced by digital workflows (Schneider *et al*. 2018). Conventional approaches have demonstrated predictable long-term outcomes but they are not free of limitations. These limitations include a higher number of visits and an increased treatment time, which may result in higher costs for the patient. To overcome these limitations, digital workflows through IOS and computer-aided design (CAD) as well as computer-aided manufacturing (CAM) have been introduced (Muhlemann *et al*. 2018). Under a digital workflow, IOS replaces the impression taking and the traditional cast fabrication (Muhlemann *et al*. 2018). The digital impression obtained is then exported to a standard data file. Subsequently, the data file is digitally transferred to the dental laboratory, where the dental technician uses an associated system to design (CAD) and fabricate (CAM) the implant-supported prosthesis utilizing different materials (Pyo *et al*. 2020) (Fig. 45-17). The fabrication process of the different CAD-CAM materials relies on two methods: (1) subtractive or (2) additive manufacturing (Pyo *et al*. 2020). Subtractive manufacturing usually involves a milling process of a disc-shaped manufacturing material to obtain a provisional or a definitive prosthesis (Revilla-Leon *et al*. 2019). These protheses are mainly made out of ceramics including zirconia and lithium disilicate because excess material waste limits the use of metals. On the other hand, additive manufacturing, commonly referred to as 3D printing, is the joining of material layer by layer by means of a 3D printer (Jockusch & Ozcan 2020). This type of manufacturing is advantageous in material waste and reproducibility of complex structures (Galante *et al*. 2019). However, additive manufacturing is still under investigation and, therefore, has not yet been established in daily practice.

Fig. 45-16 Individualized impression copings in place before impression taking.

Surgical considerations when dealing with implants in the zone of esthetic priority

Surgical aspects for undisturbed wound healing

In general, denuded bone and exposed root surfaces as a result of the surgical intervention must be covered by the soft tissue flap if optimal outcomes are to be achieved. However, in implant surgery, inherent challenges may complicate the procedures. When

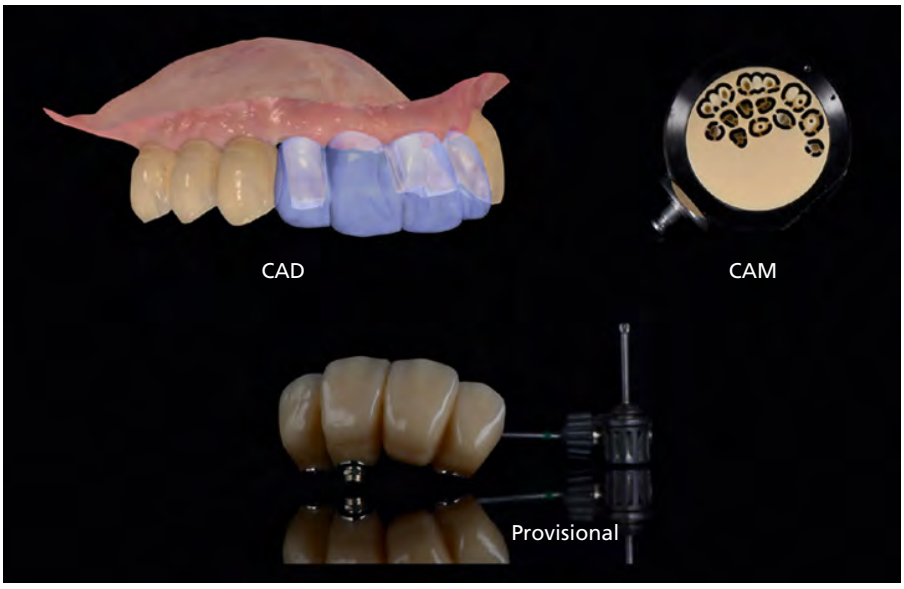

Fig. 45-17 Digital workflow. CAD, computer-aided design. CAM, computer-aided manufacturing.

dealing with implants in the zone of esthetic priority, clinicians are confronted with a variety of anatomic structures, such as hard and soft tissues adjacent to each other, resulting in wounds which are constituted of several interfaces of tissues that fundamentally differ in composition. Furthermore, flap stability and healing outcomes may be hampered during the postoperative phase as the oral cavity is an aqueous environment in which biofilm forms on non-shedding surfaces like teeth and implants and their prosthetic components. Consequently, bacterial colonization may jeopardize uneventful healing (Bartold *et al*. 1992). Also, the negative effect on wound stability and healing outcomes of mechanical influences of continuous masticatory and other functions of the dentition should not be underestimated.

Wound healing primarily depends on early formation and organization of the blood clot and the establishment of an attachment of the clot that is resistant to mechanical forces acting on the flap and opposing surfaces participating in the wound closure (Wikesjo *et al*. 1991). Impaired clot adhesion may weaken the tensile strength of the wound during early healing events and leave the implant–mucosal flap interface susceptible to tearing, compared with physiologic tensile forces on wound margins (Wikesjo & Nilveus 1990). Tensile forces vary depending on the stability of the blood clot and subsequently on the biochemical and mechanical properties of the wound bed (Burkhardt *et al*. 2016). The mechanical weakness of the interface between a debrided, non-shedding root surface, comparable to an implant surface, and the mucoperiosteal flap has been shown to be compensated by the interposition of a connective tissue graft or a collagen matrix, firmly affixed to the denuded root surface. Particularly, connective tissue grafts in thin layers substantially improved the wound healing strength and can be recommended to increase flap stability on non-shedding surfaces (Burkhardt *et al*. 2016), as healing of peri-implant defects following flap surgery involves conceptually more complex processes than wound healing in most other sites of the body.

Most models investigating the tensile forces on wound margins have considered the interfaces in recession coverages (Pini Prato *et al*. 2000). In only one study has the role of flap tension in primary wound closure been investigated in humans (Burkhardt & Lang 2010). In that study, 60 patients scheduled for single implant installation were recruited. Before suturing, the tensile forces on the flaps were recorded with an electronic device. After 1 week the wounds were inspected with regards to complete closure. While flaps with minimal tension of 0.01–0.1 N resulted in only a few (10%) wound dehiscences, flaps with higher closing forces (>0.1 N) yielded significantly increased percentages of wound dehiscences (>40%). This study also revealed that flaps with a thickness of >1 mm demonstrated significantly lower proportions of flap dehiscences at higher closing forces (>15 g) than thinner flaps (≤1 mm). The results of this study indicated a need to control the closing forces at the wound margins. In order to minimize tissue trauma, finer suture diameters may be helpful owing to the fact that thinner sutures (6-0, 7-0) lead to thread breakage rather than tissue tear and breakage (Burkhardt *et al*. 2008).

It is evident that flap design, flap advancement, and suturing should receive greater attention in situations where mucoperiosteal and/or mucosal flaps are positioned to cover large peri-implant defects. Owing to the fact that the peri-implant wound is constituted of the connective tissue surface of the flap and an avascular surface such as titanium, ceramics, or another alloplastic material, peri-implant defects require careful tissue management and stable flap adaptation, especially in the anterior zone of the upper jaw where the mucosal morphology and topography play an important role in the esthetic result.

Incisions and flap design

Flaps can be classified according to their form (e.g. semilunar, triangular), the direction of the intraoperative advancement (e.g. rotating, apically, or coronally advanced) or the composition of the contributing tissues (e.g. full thickness, split thickness). In contrast to connective tissue grafts, which receive their early nutrition by plasmatic diffusion, flaps are characterized by a still functioning network of vessels which provide the injured tissues with blood. Thus, it is evident that when planning the flap outline, attention should focus on the importance of maintaining a good blood supply from vessels entering at the base of a pedicle. To assure a good blood supply, it was recommended that two aspects are noted before starting with the first incision: (1) a broad flap base which allows many nutrient vessels to enter the flap and (2) a flap length-to-width ratio that should not exceed 2:1. These principles seemed to make sense because increasing the flap's width at its base increases the blood supply and supports a greater flap length. However, with a deeper insight into the biologic contexts and processes (Kleinheinz *et al*. 2005), these recommendations now appear rather too simplistic. It cannot be assumed that major vessels enter the base of mucosal flaps at regular intervals. Additionally, most conclusions from studies focusing on vascular impairment are based on histologic examination of specimens after vascular perfusion and suggest that blood vessels remain intact and patent following surgery. Alternative techniques like fluorescein angiography (Mörmann *et al*. 1975; Mörmann & Ciancio 1977) and laser-Doppler flowmetry (Retzepi *et al*. 2007a, b) are more reliable in qualitatively and quantitatively evaluating the vascularity and blood supply of an injured mucosal area.

An important difference between the blood supply of periodontal and peri-implant soft tissues

after wounding is the presence of the periodontal ligament around teeth. The dense capillary network has been shown to contribute to the early nutrition of the adjacent mucosa and to be a major source for sprouting capillaries in the angiogenetic process (Schröder 1986). Following horizontal incisions along the mucogingival junction, the blood supply of the gingiva was displayed with a fluorescent dye (Mörmann & Ciancio 1977). One day after the injury, the gingiva coronal to the incision line showed a severe anemia, which was more pronounced in the interdental and papillary area than in the tooth prominences. The authors explained the differences as the result of the influence of the collateral vessels coming from the ligament and contributing to the marginal tissue perfusion. It might have a minor influence on wound healing but the vascularity of the periodontal ligament around teeth increases gradually from the incisors to the molars, being least at lateral incisors of the upper jaw. In all single-rooted teeth, the mesial and distal surfaces are usually better perfused than oral and buccal ones (Schröder 1986).

These results have been confirmed in another angiographic dog study (McLean *et al*. 1995) which showed that the sole act of flap elevation initiates substantial and significant vascular trauma. Significant reduction in flap circulation in relation to the presurgical baseline lasts for at least 3 days in the mid-buccal sites, but persists for 7 days at the interproximal sites, independent of the applied suture techniques. This is an important finding and might have an impact on the decision regarding an ideal flap outline when dealing with implant placements or retreatments in the upper anterior zone where there is no collateral vascularity from the periodontal ligament.

Another critical factor influencing the vascularity of a flap is its length, especially when the flap is replaced on an avascular surface like a root or the alloplastic material of an implant or its components. Several studies confirm a decrease of the flap vascularity with increasing flap length (Mörmann & Ciancio 1977; McLean *et al*. 1995). Interestingly, in studies of the early healing stages, significantly greater portions of the flaps took up fluorescence from extravascular diffusion compared with from intracapillary circulation. While it is certainly prudent to avoid long pedicle flaps in implant surgery, other flap properties like thickness and alternate vascular sources deserve recognition.

Based on reliable knowledge of the distribution pattern and architecture of the arterial vascular system of the human oral mucosa, recommendations for ideal flap preparation and releasing incisions can be given (Kleinheinz *et al*. 2005): (1) avoid releasing incisions in the zone of esthetic priority; (2) place mid-crestal incisions in edentulous areas; (3) incise in the sulcular area around teeth and avoid marginal and paramarginal incisions; (4) if a releasing incision is required, cut the flap as short as possible and carry it out at the anterior border of the incision line. The releasing incisions should not be placed on the buccal root prominences as there the mucosa is thicker between two teeth (Müller *et al*. 2000). Incision lines in the concavity between two teeth facilitates a firm flap adaptation and provides a better vascular network within the pedicle flap.

Implant placement in the zone of esthetic priority is often combined with guided bone regeneration procedures and soft tissue augmentations to compensate for the lost tissue volumes and to restore the morphology of the implant housing in all three dimensions. To achieve a healing on primary intention, the soft tissue flaps must be mobilized to completely cover the augmented sites. Such flap advancement is limited and also has some adverse effects. The common method of flap lengthening consists of a periosteal incision at the base of the buccal flap to reduce its resistance. The extent of flap lengthening depends on the outline of the flap and has been evaluated in a cohort study on patients (Park *et al*. 2012). Simply by placing one vertical releasing incision and pulling with a tension of 5 g, the flap could be mobilized by 1.1 ± 0.6 mm, which corresponds to 113.4% of its original length. These values increased to 1.9 ± 1.0 mm (124.2%) when a second vertical incision was made at the opposite end of the horizontal incision and became statistically highly significant after combining the two vertical releasing incisions with a periosteal releasing incision, yielding a flap advancement of 5.5 ± 1.5 mm (171.3%).

The abovementioned surgical technique facilitates primary wound closure but shows distinct disadvantages as the coronal mobilization of the masticatory mucosa might decrease the amount of masticatory mucosa lateral to the implant-supported crown. Additionally, the irregularity of the mucogingival junction can cause an esthetic problem in high lip line cases when a broad zone of soft tissues is displayed apical of the mucosal margin. A variety of advanced flap techniques have been described to achieve primary wound closure and overcome the abovementioned drawbacks (Tinti & Parma-Benfenati 1995; Nemcovsky *et al*. 1999; Triaca *et al*. 2001; Penarrocha *et al*. 2005; Stimmelmayr *et al*. 2010). Even if a certain approach shows promising clinical results, some of them should be applied with caution as they are technically highly sensitive and hold pronounced risks for adverse outcomes. Successful implant treatments in the zone of esthetic priority include many variables of flap management that are interconnected and which have to be carefully evaluated and assessed in relation to the patient's expectation and the expertise and psychomotor skills of the individual clinician.

In order to maintain the original tissue morphology for esthetic reasons and to shorten the treatment duration, an increasing number of publications favor the placement of the implants immediately after tooth extraction (Slagter *et al*. 2014; Cosyn *et al*. 2016; Buser *et al*. 2017; Noelken *et al*. 2018). Most of them are in combination with free connective tissue grafts,

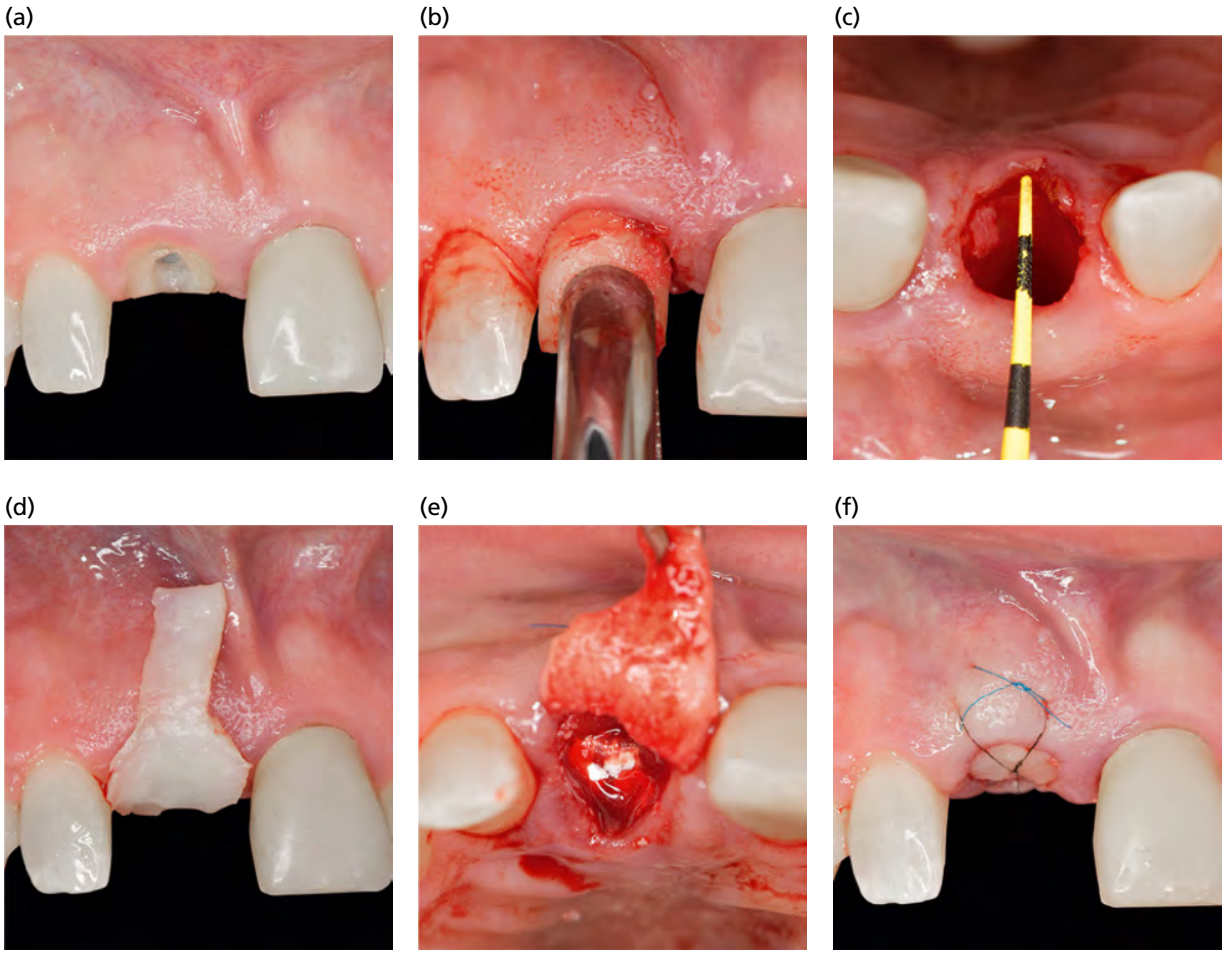

Fig. 45-18 (a) Preoperative view from above: central incisor with root resorptions that have to be removed and replaced. (b) Tooth extraction after careful circumferential dissection of the supracrestal connective tissue fibers. This treatment step can only be performed under visual control when the clinical crown has been removed presurgically. (c) The dimension of the tooth cross-section at the level of the gingival border defines the size of the connective tissue graft ensuring sufficient coverage buccal and orally and by the adjacent mucosa of the col areas. (d) Connective tissue graft harvested from the palatal lamina propria and trimmed to the appropriate dimension. (e) Graft fixation after implant placement and covering the socket with a resorbable membrane. (f) Lateral view of postsurgical site. The socket is primarily closed by the connective tissue graft, secured by only three fine sutures.

either to compensate for postoperative buccal tissue shrinkage or to achieve primary wound closure (Fig. 45-18). Overall, short- and long-term results seem to be comparable to the ones with immediate-delayed and delayed implant insertions (Chen & Buser 2014), but factors such as mucosal phenotype, thickness of the facial bone, and vertical level of the facial bone crest need more careful attention to avoid the increased risks of adverse esthetic outcomes compared with implants placed using a delayed approach. Additionally, other aspects should be noted in the decision-making process for immediate implant placement in the anterior zone of the upper jaw. Firstly, several of the described implant insertion and flap procedures are highly technically sensitive (Baumer *et al*. 2017; Mosea 2018; Zuhr *et al*. 2018) and there are no commonly accepted meaningful measures to assess technical expertise of implant surgeons. A recent study confirmed the findings from other surgical specialties (Eva & Regehr 2005; Saposnik *et al*. 2016) that the self-assessed expertise of clinicians does not correspond with objectively collected data and surgeons tend to be overly self-confident (Burkhardt *et al*. 2019). Secondly, it should be noted that in a majority of studies reporting about the positive esthetic results with immediate implants, no detailed information is available about the reasons for tooth loss and about the periodontal, endodontic, and prosthetic aspects that led to the decision for tooth extraction and which might have an impact on the final esthetic result.

Clinical concepts for replacement of a single missing tooth

Before any implant placement in the anterior region, a comprehensive presurgical risk analysis of the single-tooth gap is of utmost importance. An increasing body of evidence indicates that the most determinant parameter for achieving esthetic results in the anterior region is the interproximal bone height at the neighboring teeth confining the edentulous gap

(Jung *et al*. 2018; Roccuzzo *et al*. 2018). The related bone should be within a physiologic distance (i.e. approximately 2 mm) of the cementoenamel junction (CEJ), thereby providing the essential support for the overlaying soft tissue compartments. Consequently, the preoperative diagnosis will include interproximal radiographic bone height assessment and periodontal probing of the soft tissue attachment level. If a case presents missing interproximal bone, alternative conventional prosthetic solutions need to be taken into consideration. In this particular case of a 38-year-old woman, a zirconia adhesive bridge was inserted after alveolar ridge augmentation procedures (Fig. 45-19).

Sites with no or minor tissue deficiencies

If the risk analysis confirms a favorable vertical level of both soft tissue and underlying alveolar bone at the interproximal aspect of the two adjacent teeth on the one hand, and no major vestibular bone deficiencies on the other hand along with a normal to thick phenotype, the site can be considered compatible with a straightforward implant surgical protocol including immediate implant placement. In order to ensure the best probability of a successful and long-lasting esthetic treatment outcome, the actual implant placement has to be carried out meticulously, including key parameters such as low-trauma surgical principles in general and precise three-dimensional ("restoration-driven") implant positioning in particular.

A 51-year-old man was referred to the dental clinic due to a tooth fracture at tooth 11 (Fig. 45-20). The patient formerly smoked and had no underlying health conditions. Apart from a thick gingival phenotype, the patient had a low smile line and according to the CBCT, tooth 11 exhibited a thick facial bone (>1 mm). Based on these findings and the latest Consensus Report of the European Workshop in Periodontology (Tonetti *et al*. 2019) where the current evidence regarding the implant placement protocols were appraised, this patient was a suitable candidate for an immediate implant placement protocol (type 1) (Gallucci *et al*. 2018; Cosyn *et al*. 2019). It should be emphasized that the patient was thoroughly informed about the slightly higher risk of early implant loss that immediate implant carries compared with delayed implant placement (4% excess implant loss). This protocol, however, tends to be preferred by the patients because it may involve tangible shorter treatment time and cost-efficiency (Tonetti *et al*. 2019).

Sites with extended tissue deficiencies

The risk analysis of a 23-year-old female patient revealed a demanding clinical situation with missing buccal bone and a buccal probing pocket depth of 11 mm at the left central incisor (Fig. 45-21). The radiographic analysis demonstrated intact mesial and distal crestal bone levels (Fig. 45-22). This is an important prerequisite in order to be able to maintain the interdental soft tissue level. Based on the clinical and radiographic findings the diagnosis was a vertical root fracture of tooth 21. After patient information and discussion of the therapeutic options it was decided to extract the tooth and to replace it by an implant supported single crown. Due to the extended buccal bone defect it was decided to perform a socket preservation technique to improve the soft tissue quality and quantity before implant placement and bone augmentation procedure. In this case of extended horizontal alveolar bone crest deficiencies, a simultaneous implant placement and lateral bone augmentation procedure becomes technically more difficult and less predictable, as the ultimate goal remains an optimal "restoration-driven" implant positioning. Therefore, the feasibility of combining implant placement with simultaneous bone regeneration procedure was evaluated by performing preoperative diagnostics and a CBCT scan. The CBCT scan revealed an extended buccal bone defect with a minimal amount of apical bone to stabilize the implant (Fig. 45-23). After three-dimensional computer-assisted implant planning a computer-guided template was fabricated within the dental laboratory. After a healing period of 6 weeks following tooth extraction a mucoperiostal flap was elevated. This was advocated by a palatal crestal

incision followed by sulcular incisions and a vertical releasing incision distal 22. With the help of the computer-guided stent it was possible to ideally place the implant in the proper prosthetic position (Fig. 45-24). Because of the complete loss of the buccal bone a volume stable non-resorbable membrane was chosen. After grafting the site with autogenous bone particles and demineralized bovine bone mineral (DBBM)

Fig. 45-21 Preoperative view of a 23-year-old woman. Left central incisor shows slight discoloration and apical migration of the gingival margin.

Fig. 45-22 Radiographic analysis revealed an endodontically treated incisor and an apical radiolucency. Mesial and distal bone levels were intact.

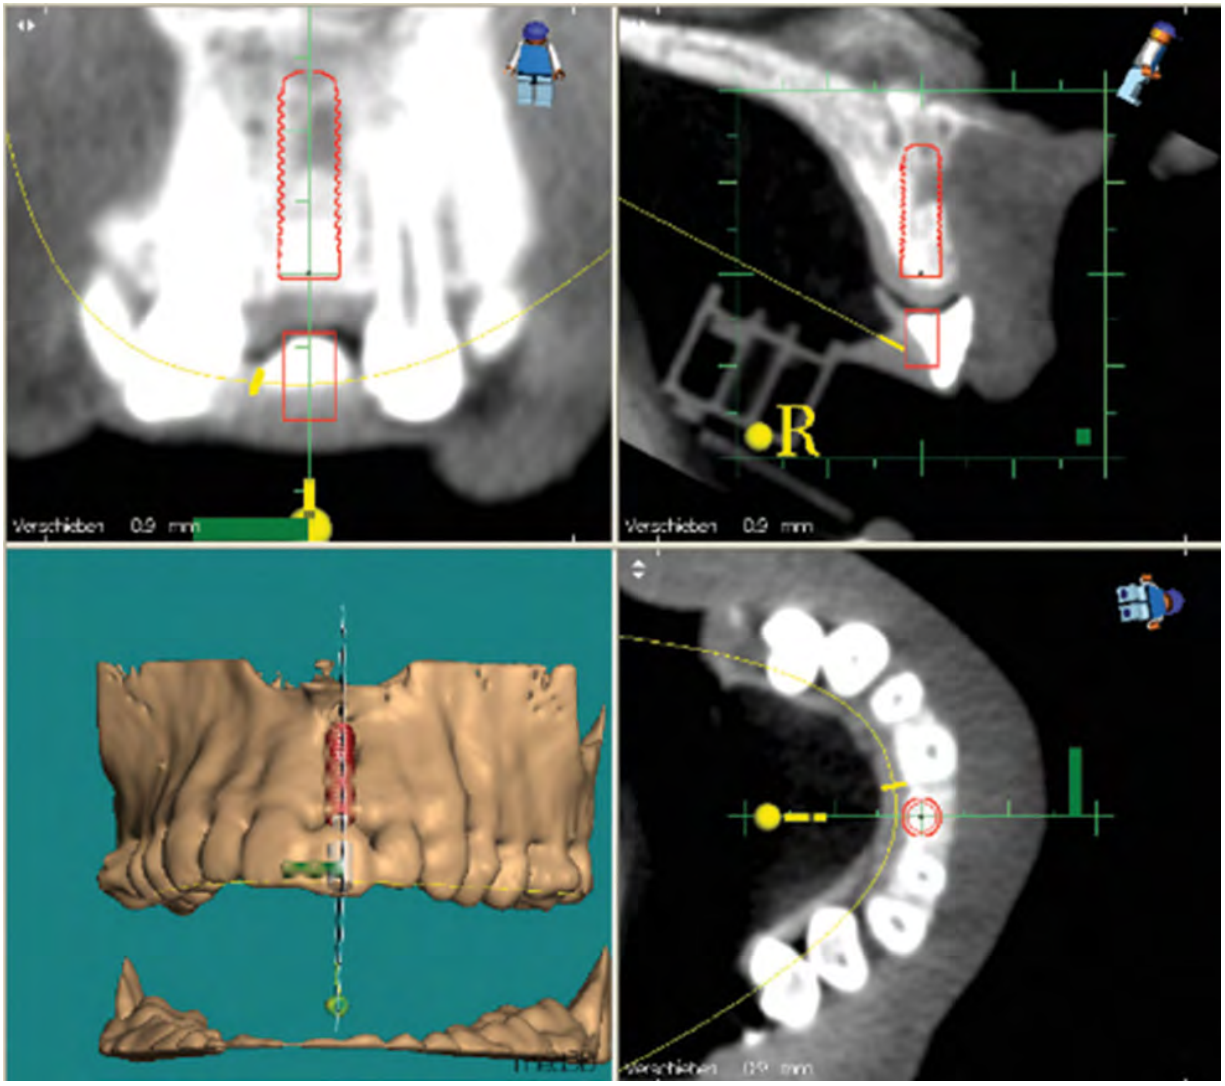

Fig. 45-23 CBCT was obtained using a scanning template with barium sulfate (BaSO4) teeth according to the previously performed wax-up. The ideal implant position was established using 3D planning software and a surgical guide was fabricated.

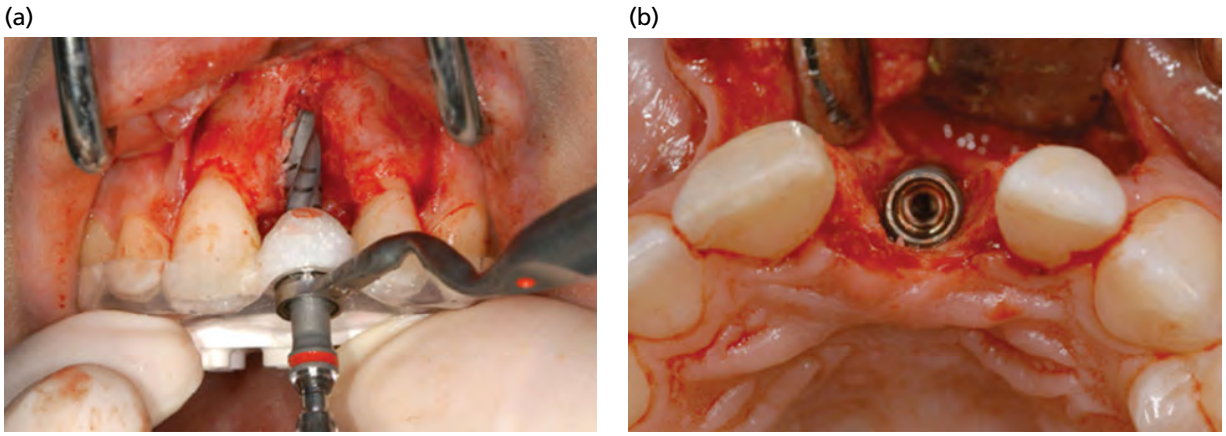

Fig. 45-24 (a) Guided implant drilling was performed based on the CBCT and implant planning software helped to stabilize the drills during the preparation process. (b) Occlusal view of the implant in place. Note the non-self-containing buccal osseous defect, which limits the guided bone regeneration options.

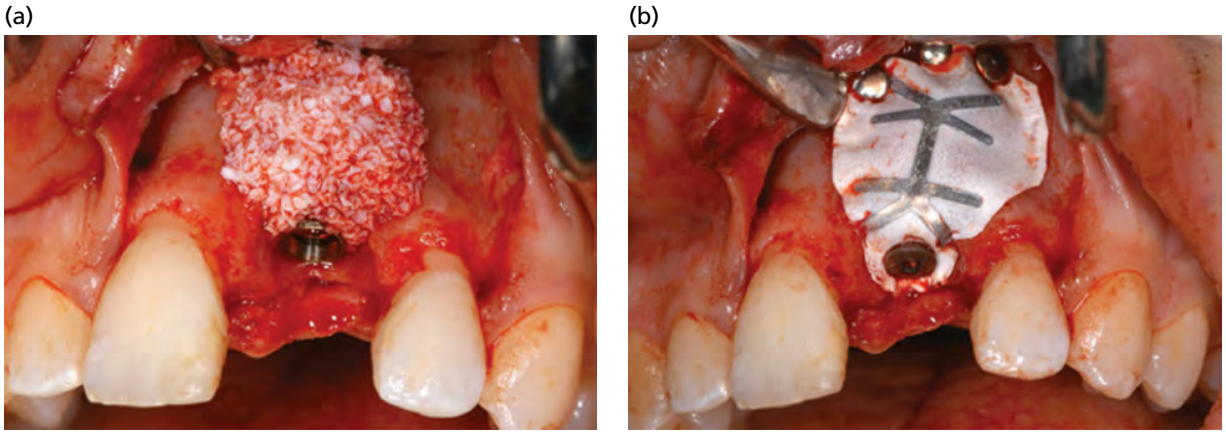

Fig. 45-25 (a) After placement of autogenous bone particles, harvested from the neighboring area, an additional layer of deproteinized bovine bone mineral (DBBM) was added on top of the implant in order to recreate the missing contour. (b) Due to the non-self-containing osseous defect, a volume of stable non-bioresorbable titanium-reinforced e-PTFE membrane was used in combination with titanium fixation pins. Additionally, the implant cover screw was used to stabilize the membrane.

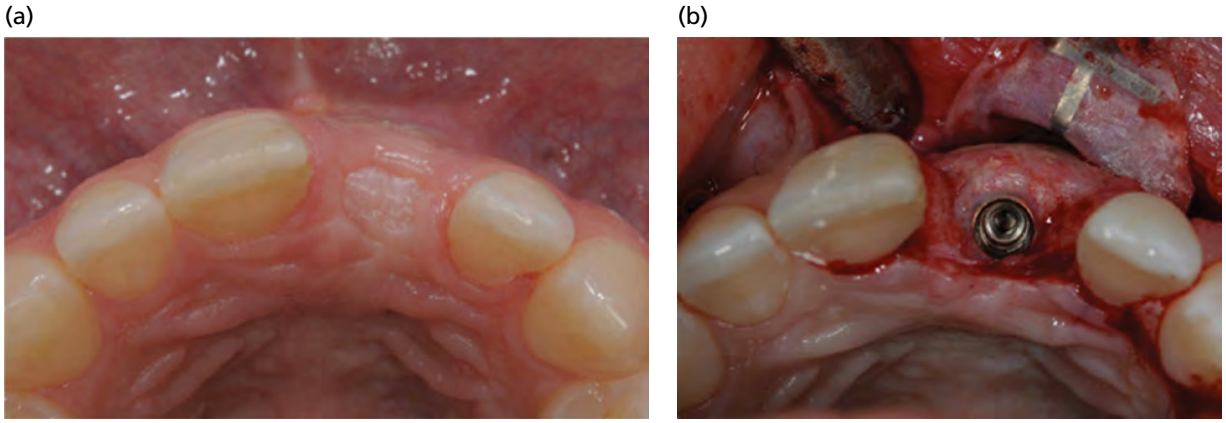

Fig. 45-26 (a) Occlusal and buccal views after a healing period of 6 months. Note the maintained buccal ridge contour. (b) Full thickness flap was raised in order to remove the volume of stable e-PTFE non-bioresorbable membrane. The implant was completely covered by bone and the buccal contour was recreated.

a titanium reinforced ePTFE membrane was applied to the defect morphology and adapted with titanium pins (Fig. 45-25). Subsequently, the periosteum was released in order to facilitate a completely flapless soft tissue closure. After a healing period of 6 months a full thickness flap was elevated again in order to remove the non-resorbable membrane and the titanium pins (Fig. 45-26). In addition, a connective tissue graft harvested from the palate was placed underneath the flap in order to increase the soft

tissue volume (Fig. 45-27). Six weeks later, a minimally invasive abutment connection was performed by using a u-form incision and rotation of this flap to the buccal. Simultaneously to the abutment connection an impression was taken on the level of the implant shoulder. The screw-retained implant-borne provisional crown was used for diagnostic purposes and to form the emergence profile. After reaching the final soft tissue contour (Fig. 45-28) a definitive individual impression was taken in order to capture the information from the temporary restoration. In this way, the clinical situation is transferred to the master model, which contains a replica (analogue) of the implant. This master model was subsequently scanned in order to produce an individual zirconia abutment by means of a CAD-CAM procedure. By directly veneering this zirconia abutment it was possible to provide the patient with a very natural-looking screw-retained all ceramic crown (Fig. 45-29).

Clinical concepts for replacement of multiple missing teeth

The normal consequence following the loss of two or more adjacent upper anterior teeth comprises a flattening of the edentulous segment (Tan *et al*. 2012). In particular, the disappearance, in an apical direction, of the crestal bone originally located between the incisor teeth can be observed (Tan *et al*. 2012). This phenomenon is not, or only minimally, present at the interproximal aspect of the remaining anterior teeth and thus explains the fundamental difference between a maxillary anterior single-tooth gap and a multiunit edentulous segment.

If two standard screw-type titanium implants are inserted to replace two missing maxillary central incisors (Fig. 45-30), an additional peri-implant bone remodeling process will take place. In the frontal plane, two different characteristic processes, one between the tooth and the implant and the other between the two implants, can be distinguished. At the site between tooth and implant, the tooth-sided interproximal bone height should theoretically remain at its original location, i.e. within 2 mm from the CEJ, from where the implant-sided interproximal bone height drops in an oblique manner towards the first implant-to-bone contact, normally located approximately 2 mm apically of the junction ("microgap") between the implant shoulder and the abutment or suprastructure. This phenomenon has been referred to in the literature as the establishment

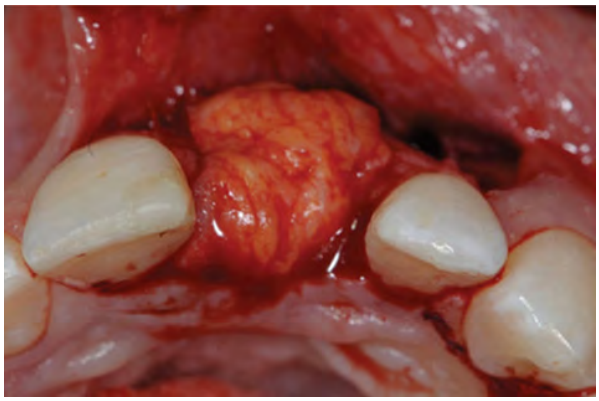

Fig. 45-27 Additionally, a connective tissue graft, harvested from the palate, was placed to augment both the occlusal and buccal aspects of the ridge. It was first sutured to the palate and then mobilized to the buccal site.

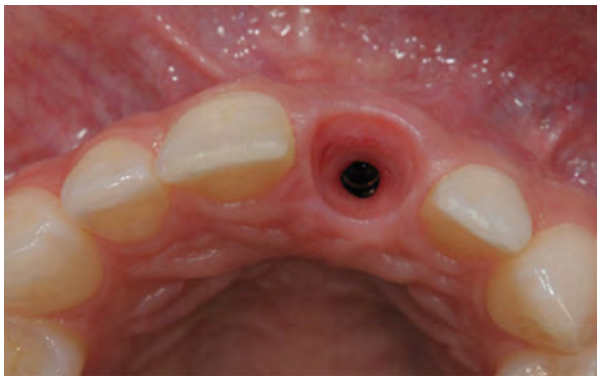

Fig. 45-28 Simultaneously, an impression was taken at the level of the implant shoulder and sent to the laboratory to fabricate a screw-retained acrylic provisional.

(a) (b)

(b) Final restoration was fabricated by direct ceramic veneering of the zirconia abutment. Note the symmetry between the soft tissue margin and contour compared with the right central incisor.

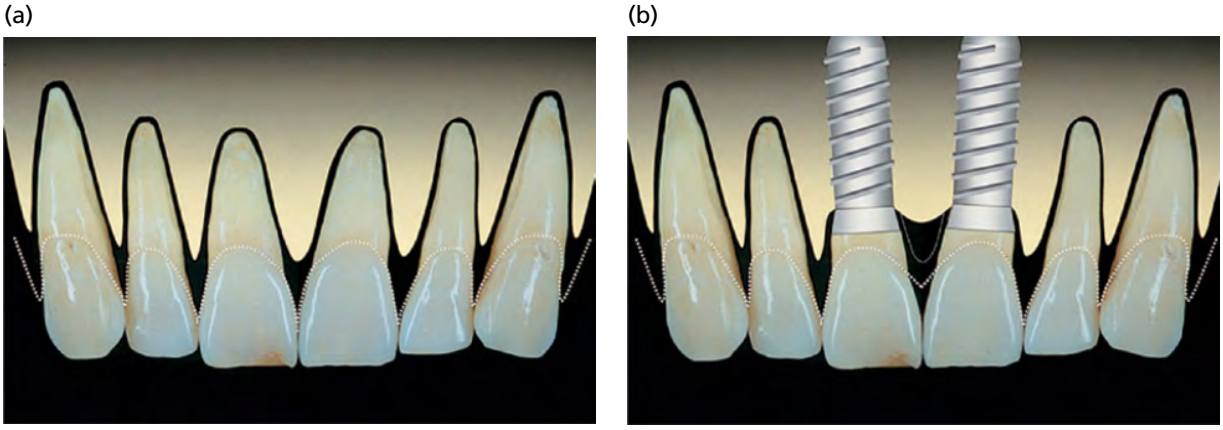

Fig. 45-30 (a) The six maxillary anterior teeth, including their bony support and the course of the marginal soft tissue, corresponding ideally approximately to the cementoenamel junction (dotted line). (b) Loss of the two central incisors and their subsequent replacement by implant restorations normally leads to well-defined bone loss ("micro-gap", establishment of a "biologic width") around the implant sites. The main consequence from an esthetic point of view is vertical soft tissue deficiencies, namely between the adjacent implants (dotted lines).

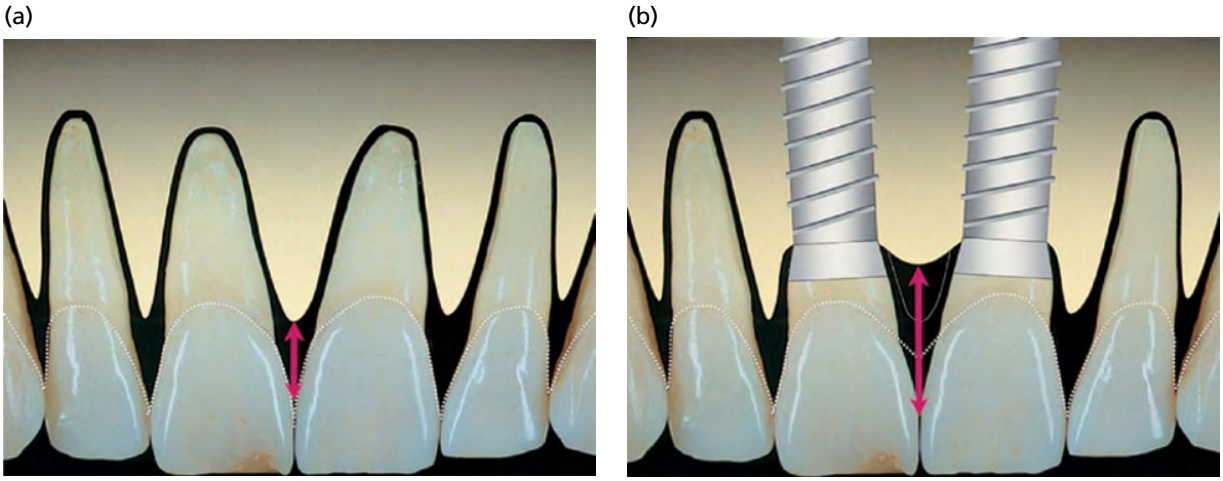

Fig. 45-31 (a) Close-up view of the relationship between the cementoenamel junction, alveolar bone, and gingiva in the maxillary incisor area. (b) Same area after implant therapy. The arrow represents the distance between the interimplant bone crest and the interdental contact point. The lack of bony support for the interdental soft tissue often causes the appearance of black triangles, compromising the esthetic treatment outcome.

of a "biologic width" (Sculean *et al*. 2014; Araujo & Lindhe 2018). In contrast, the interimplant bone height normally decreases further in an apical direction, once the respective abutments or suprastructures are connected to the implant shoulder (Caricasulo *et al*. 2018). This process is mostly accompanied by a loss of interimplant soft tissue height and hence may lead to unsightly, so-called "black interdental triangles". The schematic close-up views comparing the original dentate situation with the status after integration of two adjacent implant restorations, clearly demonstrate the negative consequences on the course of the marginal soft tissue line in a case of multiple adjacent maxillary anterior implants (Fig. 45-31).

For all the abovementioned reasons the implant position and distribution in cases with multiple missing teeth in the esthetic area are of great importance. With two missing central incisors, two implants are placed with sufficient distance between them (Fig. 45-32). In cases of a missing central and a missing lateral incisor, it is preferable that only one implant at the position of the central incisor is placed, with a cantilever replacing the lateral incisor (Fig. 45-33). Because of the small diameter of a lateral incisor the mesiodistal dimension often does not allow two implants to be placed with sufficient interimplant distances. In a clinical situation with three missing incisors including teeth 11, 21 and 22, it is recommended that two implants are placed. One option is to place two implants at positions 11 and 22 in order to have sufficient space between the implants (Fig 45-34). The drawback of this option is the difficulty with creating a similar appearance of the emergence profile of an implant restoration (implant 11) and a pontic at postion 21 with a prosthesis. Alternatively, if there is a sufficient mesiodistal dimension in the area of the two missing central incisors, one implant can be placed at position 11 and the other at position 21, with a cantilever to replace 22 (Fig 45-35). With this second option, two identical emergence profiles

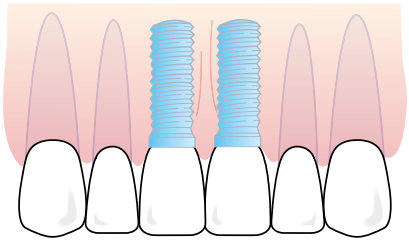

Fig. 45-32 Replacement of both central incisors with non-splinted implant-supported crowns.

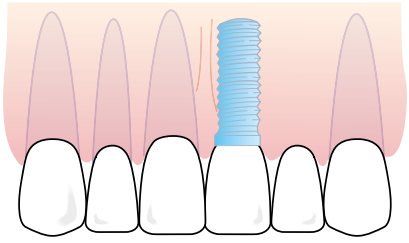

Fig. 45-33 Replacement of a central incisor with an implant and the lateral incisor with a distal cantilever.

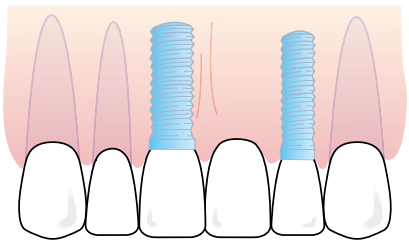

Fig. 45-34 Replacement of 3 missing incisors with an implant supported bridge with the pontic at position 21.

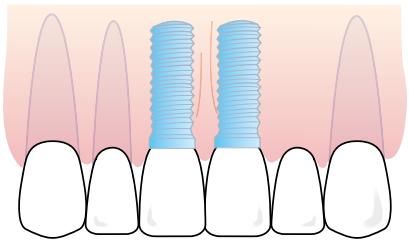

Fig. 45-35 Replacement of 3 missing incisors with 2 implants at position 11 and 21, and 21 with a distal cantilever.

can be created, but has the drawback of having two implants next to each other. When all four incisors are lost, generally two implants are placed at the position of the two lateral incisors (Fig 45-36). This concept has also been proven with the use of reduced diameter implants at positions 12 and 22 over an observation period of 5 years (Moraguez *et al*. 2017).

Sites with minor tissue deficiencies

In cases with minor tissue deficiencies, the previously described shortcomings are also inherent in multiple adjacent implant restorations. Therefore, some restorative "tricks", including peri-implant soft tissue conditioning and a

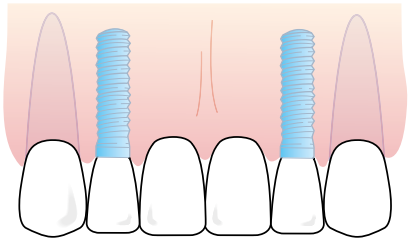

Fig. 45-36 Replacement of all four incisors with two implants and two pontics in between.

particular interproximal crown design, need to be implemented to predictably achieve an acceptable esthetic compromise. The initial prosthetic planning, the implant surgery, and the prosthetic reconstruction for a 54-year-old man who in an accident had lost three incisors and one pontic at the position of 21 are shown in Fig. 45-37.

Sites with severe tissue deficiencies

A 24-year-old patient, because of a riding accident, lost teeth 11, 12, 13, 14, and 15, resulting in severe soft and hard tissue deficiencies. Apart from the severe tissue deficiencies, the clinical examination revealed a high smile line along with a thin phenotype. In this context, a complex surgical reconstruction of the region was unavoidable. The risk analysis and treatment plan were presented to and discussed with the patient. Key factors in favor of the procedure were the good general conditions, young age, and willingness to undergo orthodontic treatment. The clinical steps are shown in Fig. 45-38.

Prosthetic reconstruction in the zone of esthetic priority

As high implant survival and success rates have been reported, the esthetic outcome of the reconstruction has become the main focus of interest in these sensitive areas. The prosthetic reconstruction should imitate the appearance of the healthy teeth as closely as possible. When deciding the final prosthetic reconstruction, the dentist and the dental laboratory technician should assess and consider the following aspects.

Decision-making process: standardized versus customized abutments

Each clinical situation should be individually analyzed in order to decide whether to use a standardized prefabricated abutment or a customized abutment in the esthetic area. In order to facilitate the decision-making process, a decision tree has been provided in Chapter 44. A thorough assessment should include the following factors so that the right choice can be made: (1) soft tissue morphology including soft tissue scalloping and vertical implant position,

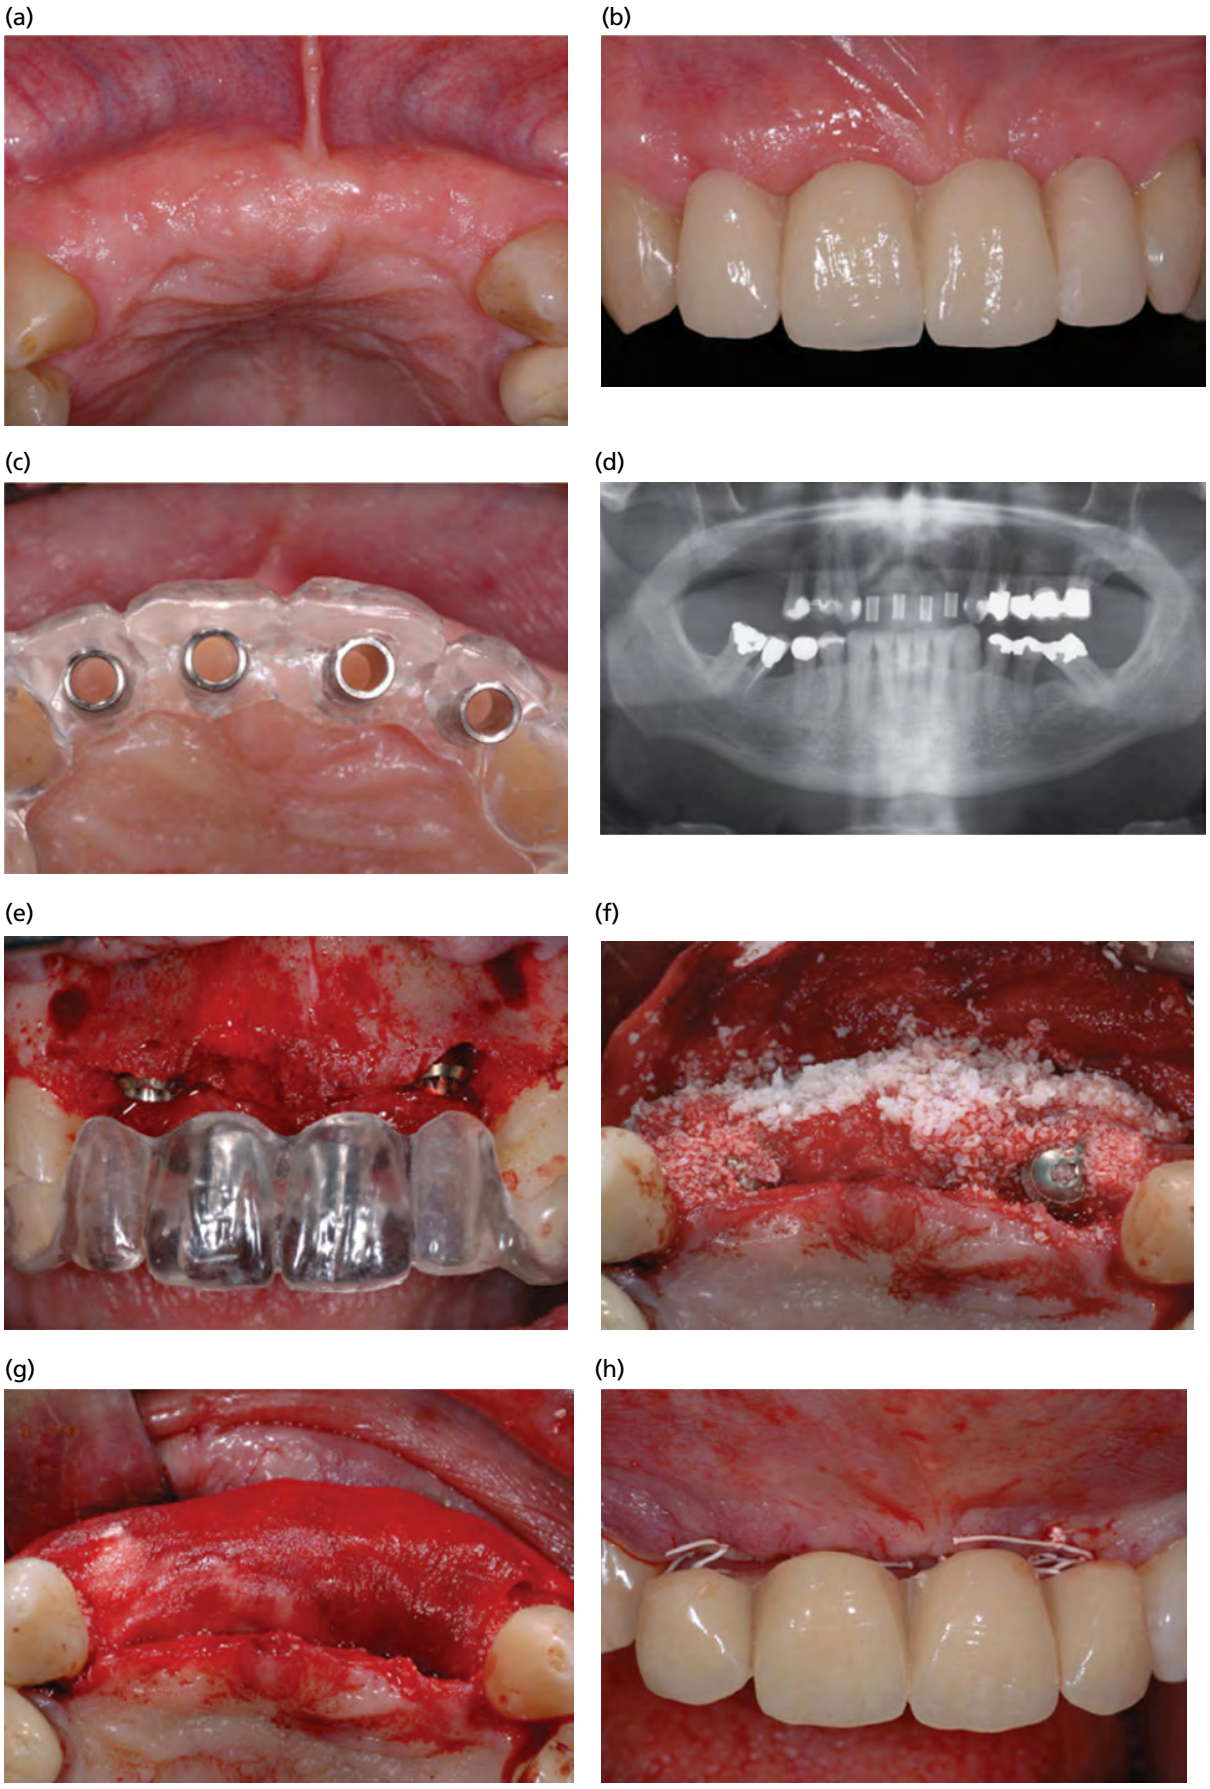

Fig. 45-37 (a) Initial occlusal view of four missing incisors revealing minor contour deficiencies. The 54-year-old male patient was referred after an accident, to restore these four missing teeth with a fixed dental prosthesis. (b) After placing the set-up within the patient's mouth, the functional, phonetic, and esthetic outcomes were assessed. Note the long contact areas in between the teeth that compensate for the lack of scalloping. (c) Occlusal view of the radiographic and surgical template with four titanium cylinders indicating the four possible implant positions. (d) Initial panoramic X-ray with the radiographic template in place. According to the available bone and the ideal implant distribution, two implants at positions 12 and 22 were planned. (e) The surgical template indicated the proper vertical implant position to be approximately 2 mm apical to the future implant crown margin with this type of soft tissue level implant. (f) A slowly resorbing bovine graft material was chosen to fill the gap between the implant and the buccal bone plate and to further augment the buccal bone contour. (g) A collagen membrane was used to cover the grafted area before soft tissue closure. (h) The removable temporary reconstruction was released to give a distance of 2–3 mm to the mucosa in order to compensate for the postsurgical swelling.

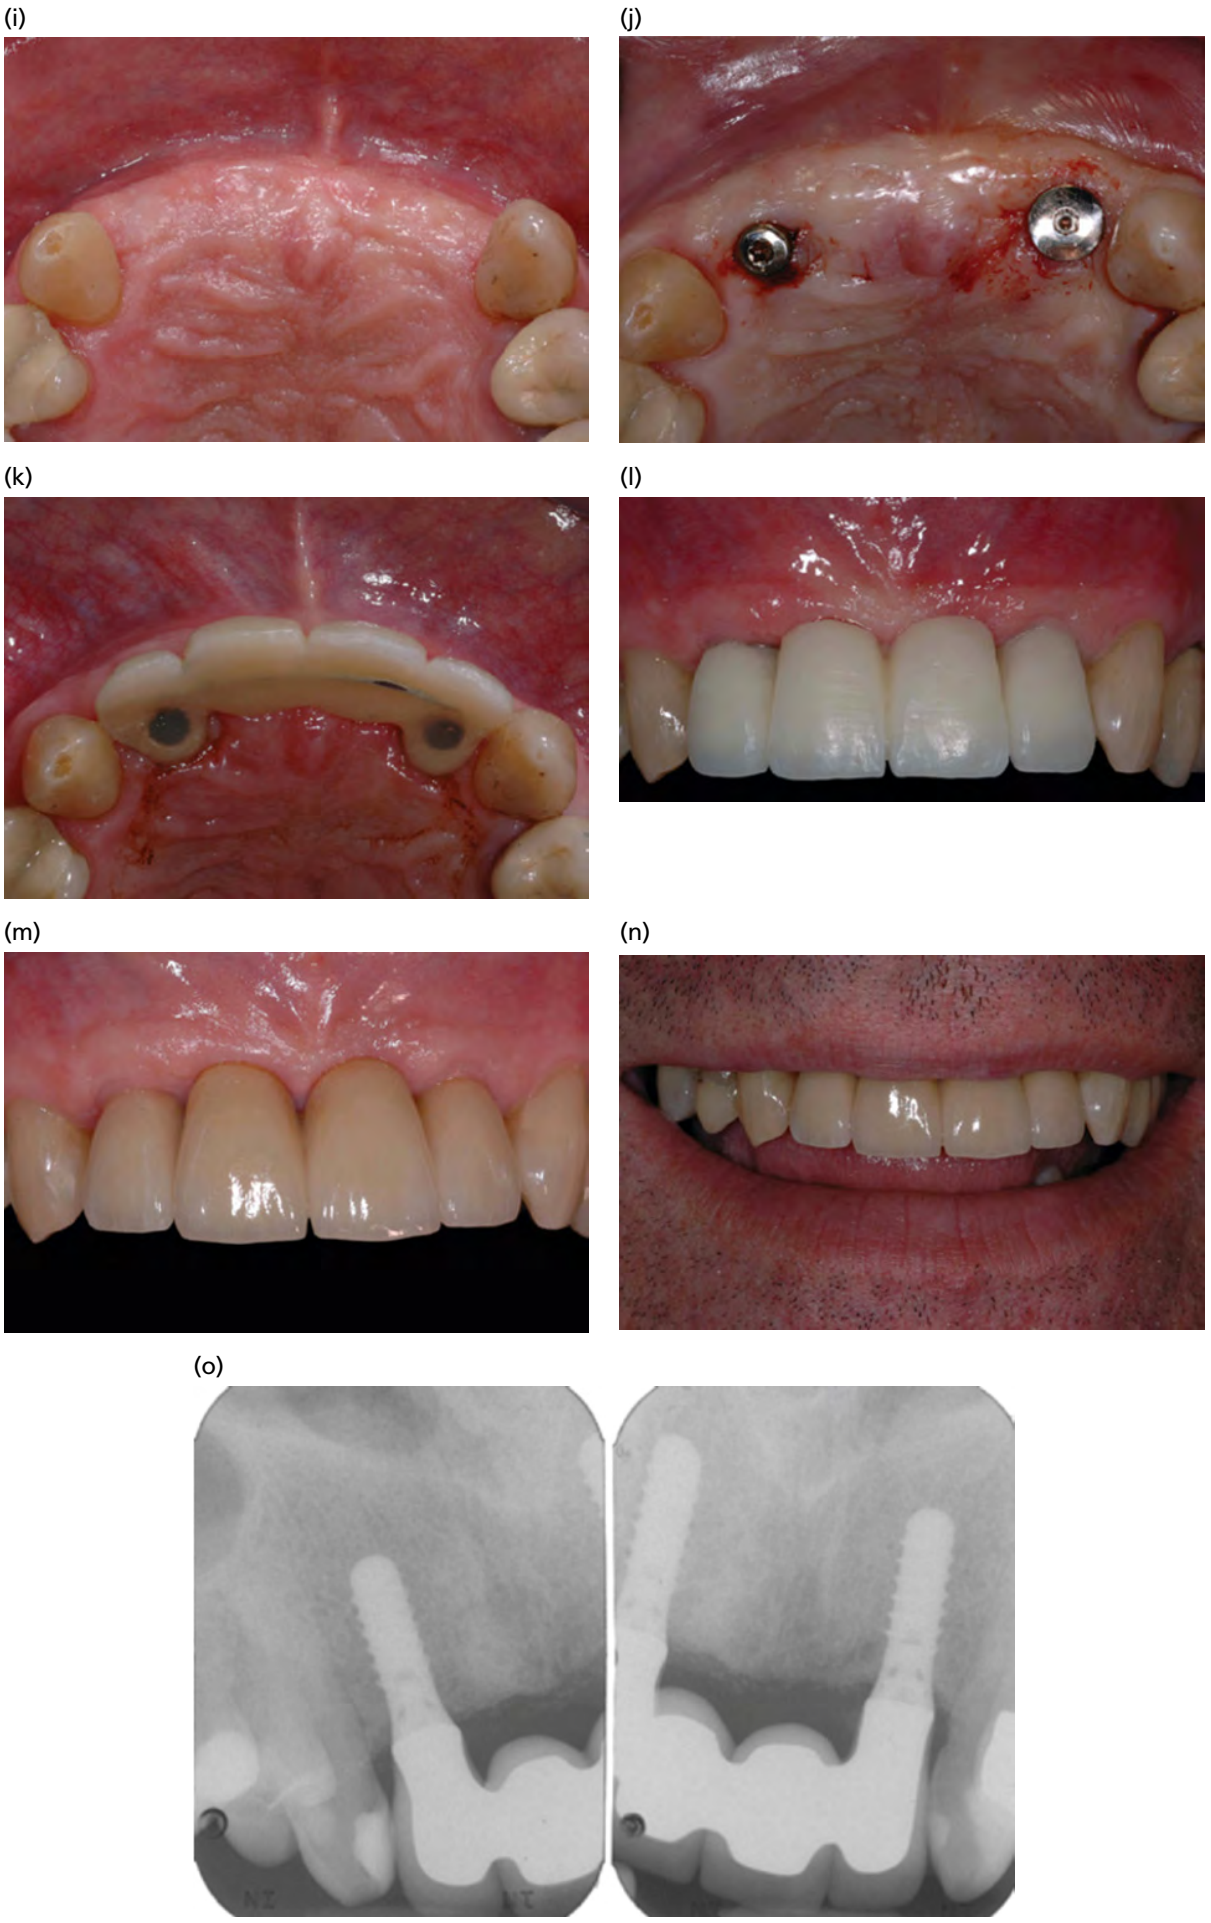

Fig. 45-37 *(Continued).* (i) After soft tissue grafting, an ideal bucco-oral contour was achieved. (j) Titanium healing abutments were chosen and placed in such a way as to avoid overlap with the level of the neighboring soft tissue. (k) Occlusal view of the screw-retained temporary reconstruction. (l) Wax-up within the patient's mouth, checking again for function, phonetics, and esthetics. (m) Buccal view of the final reconstruction in place. Note the slight papilla in between the two central incisors, but almost no papilla between the implant sites and the central incisors. (n) Final lip line of the patient without visible mucosal aspects apical to the implant-supported crowns and pontics. (o) Periapical X-rays 2 years after insertion of the final reconstruction, showing stable bone levels.

(2) discrepancy of the cross-sections of implant and tooth, (3) clinical and dental technical handling, and (4) costs.

Anterior implant sites are often characterized by a high scalloped mucosa margin (Fig 45-39). Implant shoulders, which are positioned 2–3 mm apical to the buccal mucosal margin have proximal depths of up to 7–8 mm depending on the individual scalloping of the soft tissue. Using a standardized abutment not following the soft tissue margin would lead to a difficult removal of the excess cement especially in the mesial and distal areas (Linkevicius *et al*. 2011). Outcomes from a recent systematic review identified cement remnants as possible risk indicators for peri-implant diseases (Staubli *et al*. 2017). Therefore, the emergence profile may play a pivotal role in terms of cement remnants. A recent *in vitro* study tested whether a concave or a convex emergence profile design was superior in terms of remaining cement following the cementation of reconstructions on customized abutments. The results revealed that a concave emergence profile, along with a deep

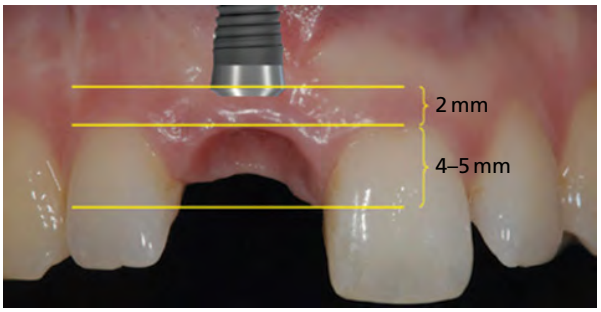

Fig. 45-39 Depth of an implant shoulder in a normally scalloped anterior site.

crown–abutment margin position, increases the risk of cement excess (Sancho-Puchades *et al*. 2017). Nevertheless, the clinical evidence linking the presence of submucosal cement and peri-implantitis is still limited (Berglundh *et al*. 2018).

In clinical situations with high scalloped soft tissue morphologies and deep vertical implant positions, customized abutments have been recommended (Fig. 45-40). Hence, the crown margin can be located not more than 1.5 mm below the soft tissue margin and following the scalloping of the mucosa (Fig. 45-41). However, a 3-year randomized multicenter trial comparing prefabricated and CAD-CAM customized abutments for implant-supported crowns in the esthetic region, showed no significant differences in terms of clinical and esthetic outcomes (Wittneben *et al*. 2020). These findings, nevertheless, should be interpreted cautiously since studies comparing stock and CAD-CAM customized abutments are scarce (Schepke *et al*. 2017).

Customized abutments can be fabricated either by copy-milling techniques or by means of computer-aided (CAD-CAM) systems. For CAM, these abutments can be scanned, digitized, and the data is thereafter sent to a central production facility via the internet (Joda *et al*. 2017; Pyo *et al*. 2020). In the future, more and more customized CAD-CAM abutments will be virtually designed without the need of prefabricated abutments. This procedure allows multiple options in terms of individualizing the abutment to the clinical situations. However, from a clinical and technical handling perspective, it is more time consuming and slightly more expensive compared with standardized prefabricated abutments. Therefore, in clinical situations with flat gingival morphologies, shallow-placed implants, and minor discrepancy between the cross-sections of implant and tooth, standardized prefabricated abutments can still be used. Once the decision has been made to use either prefabricated or customized abutments, it is important to choose the material for the abutment and the reconstruction.

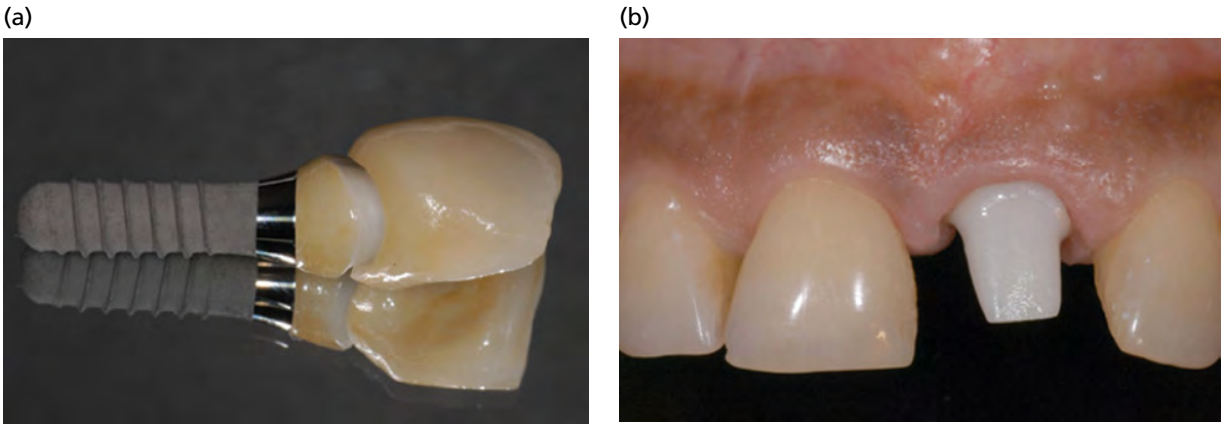

Fig. 45-40 (a) Individualizing the CAD-CAM abutment in order to better match the color of the all-ceramic crown. (b) Customized zirconia abutment following the gingival morphology before cementing the all-ceramic crown.

Decision-making process: all-ceramic versus porcelain-fused-to-metal reconstructions

In the esthetic zone, the choice of the reconstructive material is mainly influenced by the soft tissue architecture, the esthetic expectations of the patient, and the esthetic goal to be achieved with the reconstruction (i.e. the value and color of the neighboring teeth). The gray color of titanium abutments needs to be masked by means of metal–ceramic reconstructions. Because of refinements in veneering ceramics for metallic frameworks, excellent esthetic results can be achieved with this kind of reconstruction. However, many studies, including systematic reviews (Linkevicius & Vaitelis 2015), indicate that the grayish color of the abutments can impair the esthetic result due to a discoloration of the peri-implant soft tissues. In this context, several studies have suggested that ceramic abutments may be more advantageous and esthetically pleasing because of their tooth-resembling color (Linkevicius & Vaitelis 2015). In order to prove these claims, different clinical and preclinical studies evaluated the color change effect of all-ceramic versus porcelain-fused-to-metal (PFM) restorations on the marginal peri-implant soft tissue. For example, it was demonstrated that all-ceramic restorations exhibit a significantly better color match to the unrestored neighboring teeth compared with PFM restorations (Jung *et al*. 2008). Furthermore, the same study revealed that the increase of soft tissue thickness by connective tissue grafts, reduces the risk for soft tissue discoloration regardless of the reconstruction material (Jung *et al*. 2008). These observations were further validated by another study in pig jaws demonstrating that the soft tissue discoloration is reduced by the increase of soft tissue thickness (Jung *et al*. 2007) (Fig. 45-42). The same study showed that titanium induced the most pronounced color change of all tested materials. Zirconia, however, did not induce a visible color change at mucosa thicknesses of 2 and 3 mm, irrespective of whether it was veneered or not. According to these findings, the authors concluded that 2 mm was the critical mucosa thickness and came up with the following clinical recommendations: (1) with a mucosa thickness of more than 2–3 mm PFM or all-ceramic reconstructions can be recommended and (2) with a thin gingiva of 2 mm or less either a soft tissue graft should be performed or an all-ceramic reconstruction is indicated (Jung *et al*. 2007).

In addition to the esthetic evaluation, the decision whether or not to use an all-ceramic or a metal–ceramic reconstruction should also be based on the clinical performance and the mechanical properties. Metal–ceramic reconstructions were considered to be

the "gold standard" (Jung *et al*. 2008), but since the introduction of high strength ceramics, these new materials are competing with the well-documented metal–ceramic materials. So far, mid-term clinical data are encouraging in the esthetic zone (Wittneben *et al*. 2017; Heierle *et al*. 2019). A recent systematic review evaluated the survival and complication rates of zirconia–ceramic and metal–ceramic single implant-supported crowns (Pjetursson *et al*. 2018). Based on 36 studies, the review revealed similar survival rates between zirconia–ceramic (97.6%) and metal–ceramic (98.3%) implant-supported single crowns at 5 years follow-up. Furthermore, the biological and technical complication rates were similar between both reconstructions. Although zirconia showed fewer esthetic complications, it also exhibited more catastrophic core fractures (Morton *et al*. 2018; Pjetursson *et al*. 2018). In this sense, and in order to overcome the mechanical issues of one-piece zirconia abutments, the so-called hybrid abutments have been introduced. Hybrid abutments consist of a standardized titanium base extraorally cemented to a CAD-CAM all-ceramic reconstruction (Kurbad & Kurbad 2013). These reconstructions have been increasingly used in clinical practice mainly because of the possibility to be cemented to various all-ceramic materials, along with the low costs. *In vitro*, these abutments have shown a comparable strength to metal abutments while still providing esthetic benefits of all-ceramic reconstructions (Sailer *et al*. 2018). However, it needs to be emphasized that there is a lack of long-term clinical data, which limits to some extent this type of reconstruction (Joda *et al*. 2017; Asgeirsson *et al*. 2019). In addition, the biological impact of the cement gap close to the marginal bone needs to be further investigated.

Adverse esthetic outcomes

Origin, causes, and prevalence of adverse esthetic outcomes

All treatment modalities in any dentoalveolar segment that are visible upon full smile and which include the placement of one or more implants, must be classified as advanced or even complex procedure. For that reason, esthetic failures do occur, most often due to the lack of proper preoperative diagnostics and planning or the previously described cognitive biases such as overconfidence, or personality traits such as tolerance to risk.

In general, implant-supported clinical crowns have been evaluated to be longer than the non-restored contralateral teeth, and factors such as topography of the surrounding soft tissues, form of the crown, and contact point position were found to have a statistically significant influence on the clinician's determination of the overall satisfaction with appearance (Chang *et al*. 1999). Data on the prevalence of adverse esthetic outcomes at implants are scarce and difficult to estimate, but peri-implant mucosal dehiscences seem to be the most frequent reason for esthetic complaints (Sculean *et al*. 2017). Taking into account the many influencing variables and, correspondingly, the paucity of data, it is estimated that at least 25% of the implants immediately placed in the zone of esthetic priority exhibit mucosal dehiscences (Cosyn *et al*. 2012) and that, generally, mucosal dehiscences at implant sites can be judged as a common finding (Mazzotti *et al*. 2018). Follow-up studies document that most of the soft tissue changes happen within the first 6 months after prosthetic loading (Bengazi *et al*. 1996; Schropp *et al*. 2003; Cosyn *et al*. 2012; Pieri *et al*. 2013).

The site-specific etiological factors for peri-implant dehiscences may be related to various elements such as the mucosal phenotype (thick versus thin bordering mucosa), the presence of an insufficient width of keratinized and/or attached mucosa, the height and thickness of the facial bone wall, an orofacial malposition of the implant, the inclination of the implant body, the implant–abutment connection, and the contour of the prosthetic crown (Evans & Chen 2008; Chen & Buser 2014).

Another frequently observed esthetic impairment is the lack of papillary-like structures between tooth and implant or between two implants (Schropp *et al*. 2005; Chow & Wang 2010; Perez *et al*. 2012; Chang & Wennström 2013). Regarding this aspect, the esthetic appearance seems to improve over time, mainly dependent on the attachment level of the adjacent teeth (Finne *et al*. 2012). The lack of papillae may not only influence the patient's satisfaction with the esthetic appearance, but also his/her phonetic speech, especially when multiple teeth are replaced by implants (Suphanantachat *et al*. 2012).

Clinical findings and classification of esthetic adverse outcomes

The new classification system of gingival recessions has shown to reliably fulfil the requirements of a classification, namely to allow a distinct assignment of each particular lesion into its own class and to enable clinicians to make a reliable prognosis regarding treatment outcome of each single recession type (Cairo *et al*. 2011). As there are no naturally grown reference points around implants such as the CEJ around teeth, the definition of peri-implant mucosal dehiscences seems to be more vague and therefore difficult to verbalize in unequivocal terms. Peri-implant mucosal dehiscences can best be defined as an apical shift of the soft-tissue margin of the implant-supported crown with respect to the homologous natural tooth, with or without exposure of the metallic part of the implant (Burkhardt *et al*. 2008; Mazzotti *et al*. 2018). By trying to classify peri-implant dehiscences and opt for a surgical treatment with the best possible prognosis we should always keep in mind that each treatment of such lesions should be guided by patients' esthetic

demands and that the final outcome is not only a complete dehiscence coverage but a satisfactory esthetic result based on patient-related outcome measures.

To date, there is no reliable classification system that guides clinicians to make a treatment decision for peri-implant mucosal dehiscences based on scientific evidence. Only a few authors have proposed classification systems for peri-implant mucosal lesions but most of them did not provide reliable clinical recommendations for surgical treatment of the mucosal problems or the options were mainly based on the clinical experience of the authors (Decker *et al*. 2017; Mesquita De Carvalho *et al*. 2019).

A recently published classification system for peri-implant mucosal dehiscences at single implants, based on the amount and specificity of the labial bordering soft tissues, the bucco-oral position of the implant, and the interproximal papillae dimension, relates each individual type of mucosal lesion with a treatment recommendation (Zucchelli *et al*. 2019). Four different classes reflect the bucco-oral position of the implant and the quality and location of the buccal soft tissues while the three subgroups in classes II to IV refer to the interproximal soft tissue level (Fig. 45-43). The management of the cases is divided into two categories, namely surgical and combined surgical–prosthetic approaches, including crown removal. The combined approaches are the preferred treatment modality when implants are located buccal to the tangent of the neighboring teeth and the interproximal tissues receded compared to the unrestored contralateral teeth. In severe cases with far too buccal implant positioning and substantial interproximal tissue loss, the soft tissue augmentation with submerged healing or the removal of the implant following new prosthetic rehabilitation are the only options to improve the esthetic appearance (for detailed information regarding the classification system and treatment recommendations, see Zucchelli *et al*. 2019).

Fig. 45-43 Buccal peri-implant mucosal dehiscence in area 21 (class IIIb) with thin bordering tissues. The implant is buccally positioned and mucosal margin is apical to the gingival margin of the contralateral tooth. As the interproximal tissues distally of the implant are receded, a combined surgical–prosthetic approach has to be considered.

Strategies for retreatment of esthetic adverse outcomes and clinical results

Given the variety of influencing factors (e.g. site-, patient- and surgeon-related), and the biocomplexity of the problem, it becomes obvious that reliable prognoses of surgical retreatments of peri-implant mucosal dehiscences might be difficult to achieve and the importance of proper diagnosis and decision making prior to the surgical intervention must be emphasized.

A literature research revealed that a variety of surgical and restorative techniques have been proposed, most of them in case reports (Hidaka & Ueno 2012; Cosyn *et al*. 2013; Happe *et al*. 2013; Fickl 2015), three prospective studies (Burkhardt *et al*. 2008; Zucchelli *et al*. 2013; Roccuzzo *et al*. 2014), and only one randomized controlled trial (Zucchelli *et al*. 2018). The results of the prospective cohort studies varied from 66% to 75% mean and no complete coverages (Burkhardt *et al*. 2008) to 89.6% mean, and complete implant soft tissue coverage in 56.3% of cases (Roccuzzo *et al*. 2014). As the outcome variables in the two studies are incongruent, the former taking the mucosal margin of the unrestored contralateral tooth as a reference, the latter just aiming at covering the denuded metal part of the implant abutment, the results of the two cohort studies cannot be compared. The best results in absolute numbers, with a mean coverage of 96.3% and complete coverage of 75% after 1 year, was achieved with a combined surgical–prosthetic–surgical approach (Zucchelli *et al*. 2013). The difference in the treatment modalities, again, did not allow comparison of the results of the different studies and conclusions could not be drawn regarding the preferred approach.

Almost all of the published studies reported positive results but long-term data regarding the maintenance of the 1-year results after surgical peri-implant dehiscence coverage are scarce. Zucchelli *et al*. (2018) published data on 5 years follow-up after peri-implant mucosal dehiscence coverage which confirmed stable successful esthetic results, with 99.2% mean and 79% complete dehiscence coverages.

Despite the abovementioned articles differing regarding the chosen clinical approach for peri-implant mucosal dehiscence coverage and the invasiveness of the execution, most used a combined approach which created a tunnel or flap and interpositioned a connective tissue graft. This observation might confirm previous findings that (1) connective tissue grafts, well sutured to the immobile neighboring tissues, have the capacity to increase wound stability in the early healing phases (Burkhardt *et al*. 2016) and (2) that the thickness of the labial mucosa might be a key factor in preventing future dehiscences after successful coverage.

Beyond the cases with severely malpositioned implants, which have to be removed and restored by a completely new prosthetic rehabilitation, the surgical approaches to cover peri-implant mucosal dehiscences can be classified as (1) coronally-advanced

flaps with or without releasing incisions and with or without connective tissue grafts or its replacements, (2) laterally-positioned flaps with connective tissue grafts (Fig. 45-44), (3) envelope flap/pouch/tunnel techniques with connective tissue grafts, and (4) submerged techniques with connective tissue grafts (for overview see Zucchelli *et al*. 2019) (Fig. 45-45).

The treatment guidelines given in the literature are mainly based on expert opinions and must be considered in the light of the little available scientific evidence. As previously mentioned, most of the approaches to improve peri-implant esthetics belong to a high complexity level in periodontal and peri-implant mucosal surgery and success does not only depend on the required advanced psychomotor skills but even more on diagnostic and prognostic skills and the expertise of the clinician.

As the ultimate goal of those surgical interventions is to alter the self-perception of the patients regarding their esthetic appearance and to improve their satisfaction with the dental restoration, and as many of these patients already have been exposed to a treatment error, a shared decision making approach, with communication of all the inherent risks, is fundamental.

Concluding remarks and perspectives

Since the last edition, much has been published that has substantially contributed to the content of this revised chapter. We thank the many authors for their contribution and for their help in increasing patient safety in this specialty.

There is no doubt that esthetics affect the self-perception of patients, impacting their psycho-social well-being and their oral health. However, restoration in the zone of esthetic priority means more than satisfying patient demands regarding the esthetic appearance of the prosthetic restoration. There is also a responsibility to deliver treatment that provides each individual patient with the best possible benefit, which requires empathy and social skills to capture the needs of the patient and health literacy to amalgamate them with the available scientific evidence. Healthy, critical self-reflection by the clinician guarantees a treatment plan that is within his or her circle of competence, and consequently a reliable prognosis. Keeping in mind that implant placements are non-reversible and most adverse esthetic outcomes are treatment errors rather than esthetic complications, the time dedicated to key issues such as diagnostics and treatment planning and the effort to openly communicate benefits and harms of implant therapy with alternatives options, is vital.

This, in turn, means that beyond the available scientific evidence in the specialty of implantology, clinicians must develop an awareness of cognitive biases and become familiar with the many non-technical skills such a decision making, debiasing, and communication of risks and uncertainties to patients.

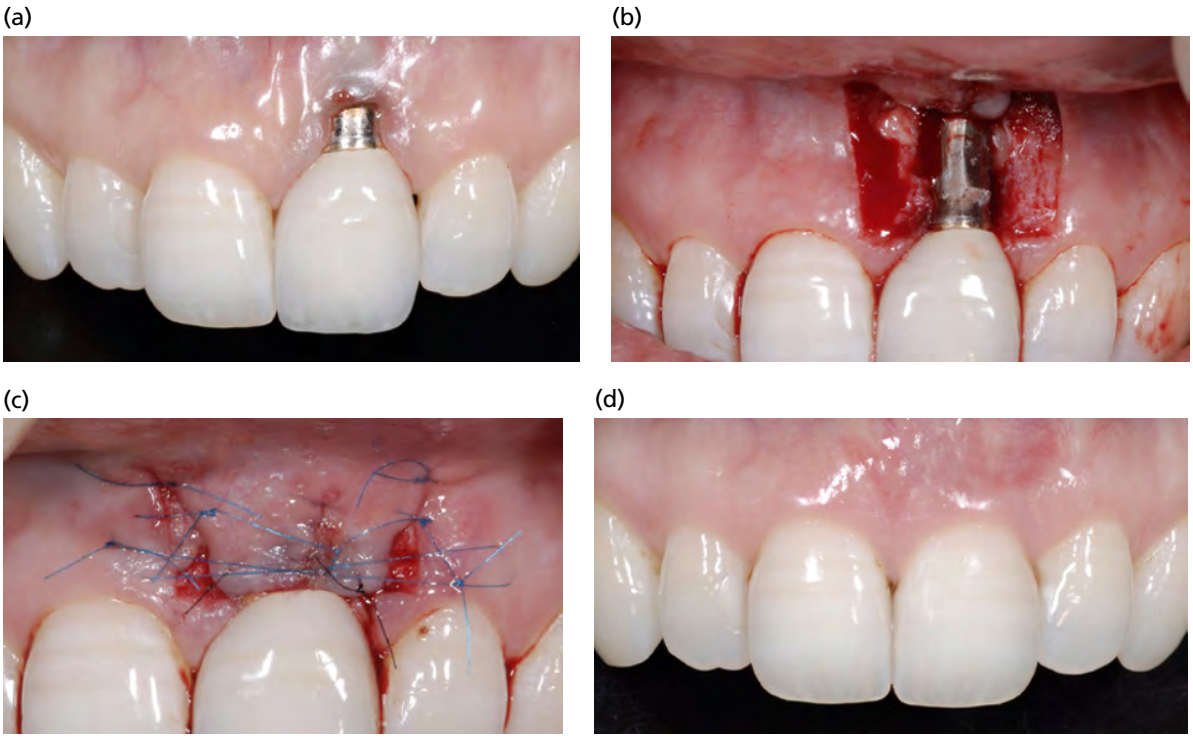

Fig. 45-44 (a) Buccal peri-implant dehiscence in area 21 (dehiscence class IIa). (b) Frontal view after flap elevation (double pedicled and laterally positioned flaps) and site preparation. (c) Postsurgical situation after flap closure and interposition of a connective tissue graft, firmly sutured to the underlying periosteum. (d) Healed situation 6 months postsurgically. Even if the primary outcome in this particular case was the increase of the buccal masticatory mucosa and thickening of the soft tissues, a complete coverage of the mucosal dehiscence could be achieved.

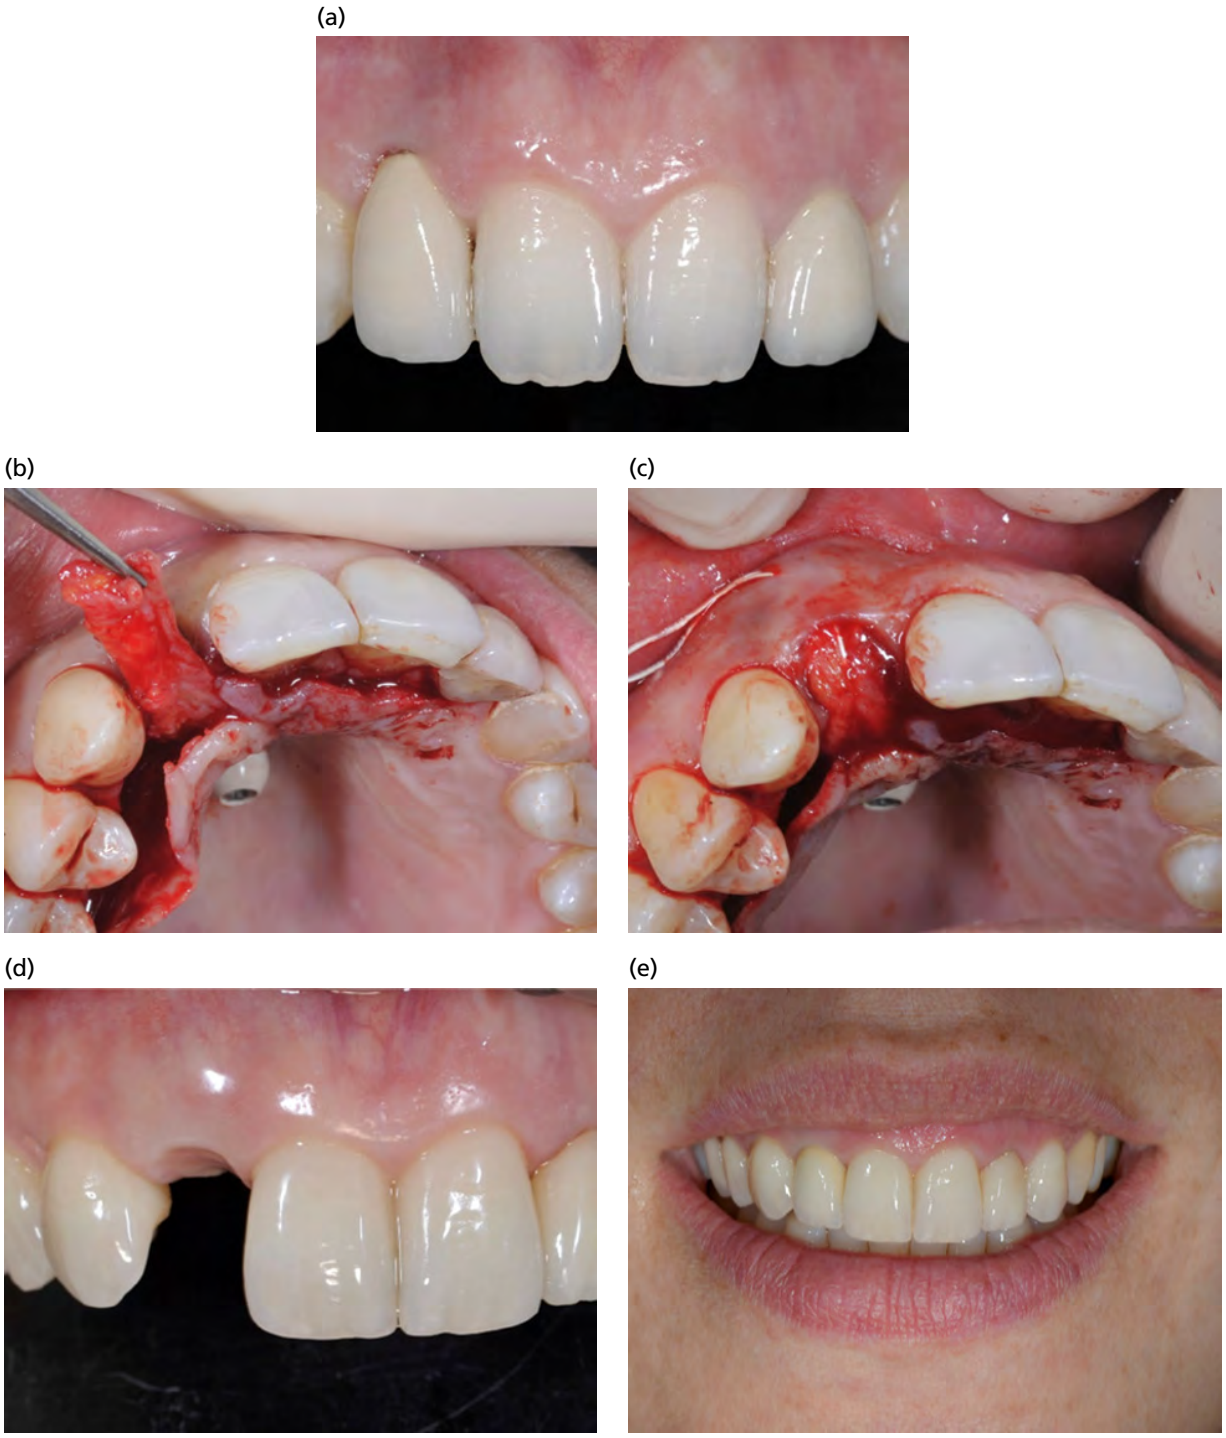

Fig. 45-45 (a) Frontal view of peri-implant mucosal dehiscence in area 12 (class IVb). (b) Intrasurgical situation after palatal flap preparation in the gingival area (connective tissue from the lamina propria). (c) Flap positioning in the buccal pouch for vertical and horizontal site augmentation. (d) Healed interdental area, 6 months postsurgically. (e) Final restoration with newly fixed implant-supported crown.

Acknowledgments

The authors gratefully acknowledge the help of the Drs. Alfonso Gil and Thomas J.W. Gasser as well as the Dental Technician Thomas Barandun (Clinic of Reconstructive Dentistry, University of Zurich, Switzerland) for their clinical contribution and their help in preparing the clinical cases for this chapter.

Chapter 46

Technical Complications in Implant Dentistry

Clark M. Stanford and Lyndon F. Cooper

University of Illinois at Chicago, College of Dentistry, Chicago, IL, USA

Introduction

Technical complications are a part of dental implant therapy. Complications and expected wear (maintenance) should be differentiated, although both can be considered "technical" complications. Complications are unexpected technical issues such as fracture, misfit, unusual wear and abrasion, or compromised hygiene access due to prosthetic contours created to satisfy esthetic demands. Maintenance is a measure of the expected service life of the prosthetic restoration and is an anticipated part of informed consent. The goal with maximal service life is a restoration providing a functional, phonetic, and esthetic prosthesis fulfilling patient desires and matches the functional capacities of the patient to manage the daily preventive needs to reduce the risk factors associated with biological complications. Systematic reviews indicate incidence(s) of technical complications exceed biologic complications (Zembic *et al*. 2014). Thus, understanding the potential technical complications affecting implant prosthesis is an essential part of the lifelong management of the implant patient. The components and restorative materials used to provide implant prostheses are all subject to loading and wear in an environment challenged by various antagonists including changes in lubrication, abrasives, forces (their magnitude, direction and velocity) and pH or chemistry of the environment (e.g. plaque fluid or saliva). While long-term success is certainly feasible, the reality of continuous implant supported dental prosthesis use is that wear, fatigue, and potential mechanical failure is inevitable (Dhima *et al*. 2014). The impact of technical complications though will shorten the expected service life of the prosthesis.

Dental implant treatment is growing worldwide. For example, a recent study of the prevalence of implant use in the USA indicates there is currently a 5% prevalence of dental implant use that will expand to 17% in the next decade (Elani *et al*. 2018). It can be extrapolated that, without significant advances in materials and techniques, there will be a parallel increase in the numbers of technical complications associated with implant prostheses. With increasing duration of use, the absolute number of technical complications presenting for resolution may increase. Importantly, given that technical complications of implants increase with time, we may see a non-linear increase in implant-related complications in the coming decade. Are we prepared?

Technical complications in implant therapy can have significant impacts. Technical complications encouraging plaque accumulation can influence peri-implant mucositis and peri-implantitis. Technical complications can cause pain, social discomfort, and psychological distress. Complications typically are accompanied by time and direct and indirect financial impacts influencing patient-reported outcome measures, and when left

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

unattended, these complications do create functional and esthetic limitations. Technical complications have a significant impact on the patient's perception of implant therapy (Adler *et al*. 2016).

The aim of this chapter is to identify the technical complications affecting dental implant therapy and to implicate potential risk factors influencing these complications as well as to suggest possible solutions. We focus on and summarize the current knowledge regarding technical complications relating to implants, implant components, and implant prostheses.

Implant fractures

Postloading implant fractures occur infrequently and account for less than 1% of all complications (Gealh *et al*. 2011). Both horizontal and vertical fractures present and require implant removal/replacement (Fig. 46-1). The fracture of an implant may, however, result in the loss of an entire prosthesis. Five factors were identified to be significantly associated with implant fracture. They included (1) the grade of titanium, (2) bruxism, (3) implants adjacent to cantilevers, (4) increased implant length, and (5) decreased implant diameter (Chrcanovic *et al*. 2018). A recent systematic review of implant fractures that included 12 studies reporting on 594 subjects (868 implants) demonstrated a 2% incidence of implant fracture. In this study, narrow implants demonstrated a higher incidence of fracture. Fractures occurred more frequently in the maxilla than the mandible. Fractures were reported to occur from before loading to 17 years follow-up (Goiato *et al*. 2019). This implies that fatigue and overload are not the only factors influencing implant fracture. One must question the significance of high insertion torque in contributing to implant fracture (Fig. 46-1).

There exist several potential factors predisposing an implant to fracture (Box 46-1). Among the most often discussed factors is the role of implant design. In an *in vitro* study, narrow diameter implants with three implant-abutment connection designs were loaded at 75 N and 200 N: external hexagon, internal hexagon, and internal conical connected to a titanium abutment. The results indicated narrow implants with external or internal hexagon connections presented the lowest reliability at high loads compared with internal conical connections (Bordin *et al*. 2018). Although this report suggests implant design can influence fracture of narrow implant, other clinical factors must be considered more widely. The vast majority of factors influencing implant fracture are within the clinician's control.

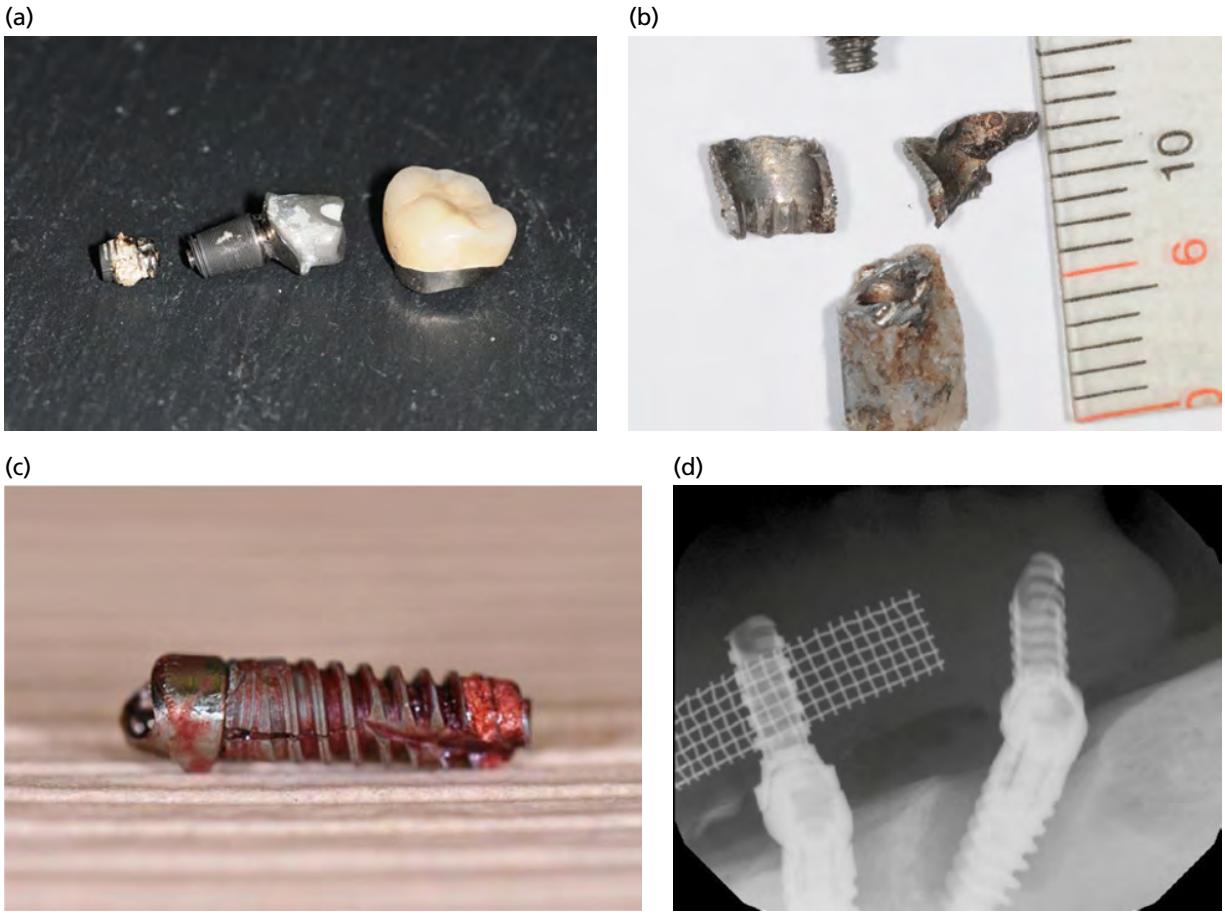

Fig. 46-1 Implant fractures are an uncommon but irreversible technical complication. (a) Horizontal fracture of implant that resulted in removal of the molar implant abutment and crown. (b) Vertical fracture of implant that is observed for internal implant/abutment connections. (c) Remarkable vertical implant fracture that may be caused by stress incurred because of high insertion torque. (d) Radiographic image of bone loss associated with vertical implant fracture (not observed radiographically)

Box 46-1 Factors predisposing implants to fracture.

1. Low grade titanium implant
2. Inappropriate diameter for the functional loads expected at the site
3. Bruxism (and/or loss of anterior guidance creating shear fractures on posterior restorations)
4. Large bending moment (cantilever or excessive crown/implant ratio) affecting adjacent implants
5. High insertion torque resulting in implant damage and/or stress

(Source: Adapted from Chrcanovic *et al*. 2018. With permission from John Wiley & Sons.)

There are several clinical signs of potential vertical implant fractures affecting internal conical or internal parallel connection implants. First, repeated and frequent abutment loosening is one sign that the implant is fractured or the internal aspect of the implant has been deformed. Vertical fractures are also associated with vertical bone loss adjacent to the implant fracture. This bone loss will appear circumferentially around the implant (e.g. Figure 46-1d).

Unfortunately, there are few solutions for vertical or horizontal implant fractures. The implant may be buried or removed. The implant may be maintained by altering the prosthesis to connect with the residual portion of the implant. In many multi-implant scenarios, the prosthesis may be modified or an alternative prosthesis provided (e.g. an overdenture) to account for implant fracture without additional implant replacement.

Implant complications

Iatrogenic damage to an implant occurs and has not been well documented. However, attempts to remove overtightened cover screws or abutments or to remove broken abutment screws may lead to inadvertent damage to the internal aspects of the implant. Damage to the threads or the internal interface can result in inability to replace the fractured abutment screw or abutment. Iatrogenic damage to an implant is the result of using rotary instrumentation to loosen fractured components within the implant; attempts to remove broken abutment screws should apply hand instrumentation, careful isolation, and high-power magnification where the fractured component may be visualized.

Iatrogenic damage to the implant may occur upon implant insertion. Improper engagement of implant drivers can lead to deformation of external or internal abutment interfaces. Application of non-axial forces to internal connection implants may result in fracture of the thinner wall of the implant. High torque upon insertion can also deform the implant/implant driver interface. For example, in an experimental model of implant insertion, three different implant/implant drivers were shown to be deformed by insertion in simulated dense bone (high torque) versus insertion in simulated lower density bone (low insertion torque) (Romanos *et al*. 2019). This suggests that high torque protocols may increase the risk of implant damage upon insertion.

Implant complications include situations where an intact, osseointegrated implant is non-restorable. Three situations are typically encountered (Fig. 46-2). The first is where the implant is placed too shallowly (or deeply) to permit three-dimensional space

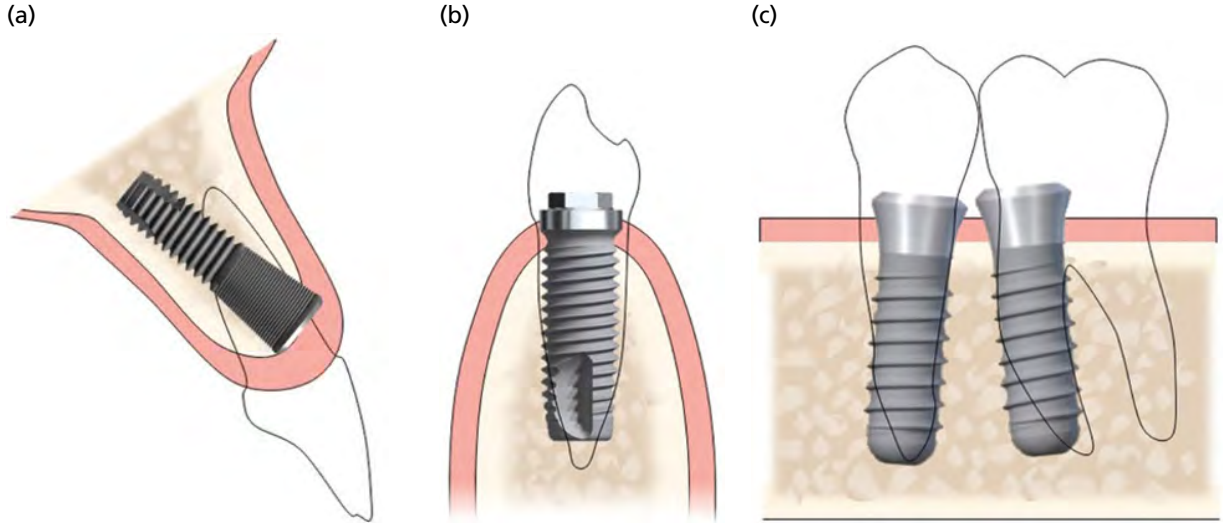

Fig. 46-2 Iatrogenic implant placement causing technical challenges. The installation of implants in non-restorable positions lead to unesthetic, unhygienic, or mechanically inferior abutments and restorations. (a) Excessive rotation of the implant axis in the sagittal plane creates conditions where an abutment cannot resolve the position, leading to an unesthetic and unhygienic restoration. (b) Shallow implant placement creates a situation where a ridgelap restoration is required to resolve the esthetic limitation. (c) Implants erroneously placed in non-parallel and proximal positions can preclude fixture-level impression making, restoration, and hygiene.

to create an abutment transition zone compromising hygiene contours and esthetic restoration. The second is when the implant is placed too facially or lingually to permit restoration. The third situation is that the implant is oriented too close to an adjacent tooth for restoration, proximal tilting or rotation has occurred, or two implants are too closely approximated to permit restoration (or eventual hygiene). These iatrogenic complications require careful consideration of potential implant removal and the management of what may be a compromised restoration.

Abutment and abutment screw complications

Abutment fracture is not common. However, when abutments do fracture, the prosthesis is at risk of complete replacement. The connection of teeth to implants is often mediated by an intermediary component or abutment. The abutment is typically attached to the implant by means of a central screw. The connecting interfaces of abutments vary appreciably and have evolved dramatically since the introduction of the external hex implant. They are generally represented by close sliding interfaces and conus interfaces. Relative to external hex systems, a conus interface may offer mechanical advantages by reducing or eliminating micromotion and more favorable distribution of forces along the implant and to bone (Gracis *et al*. 2012; Yamanishi *et al*. 2012). One interesting potential complication observed for conus interfaces is the 'settling' of the abutment and related screw loosening (Lee & Lee 2012). It has been speculated that the implant itself is deformed, permitting conus interfaces to seat deeper within the implant and resulting in loss of preload. Alternatively, novice clinicians may not realize the abutment is not completely seated; the device becomes wedged into the internal indexing slots or grooves and the abutment screw torques into place. Within a short period of time the abutment comes loose (because the lateral conical walls are not engaged between the abutment and the intaglio of the implant, or the apical portion of the abutment fractures). This is a suspected cause of screw loosening and infraocclusion. Although not universally observed and perhaps related to material selection (Jo *et al*. 2014), it suggests that internal conical implants and abutments must be sufficiently robust to support the conical abutment-derived forces.

In a recent review by Pjetursson *et al*. (2018), at 5 years, the estimated incidence of technical complications with fixed prostheses was approximately 5%. Regarding implant abutment material effects on the incidence of complications, the 5-year failure rates were 2.4% for ceramic versus 1.5% for metal abutments. There were no significant differences among the reported low 1.4–1.9% incidence of abutment failures for cement- versus screw-retained restorations. Regarding implant position effects on abutment complications, the 5-year abutment failure rate was significantly higher in the anterior than the posterior regions (2.5% versus 0.5%). Suggested reasons for improved performance of internal connection versus external hex connection abutment and abutment screws was that the load on the screw is reduced in internal implant-abutment connections. The authors concluded that "the implant-abutment connection appears to have an influence on the incidence of biological and technical complications". Yet, this complication is observed and may be related to abutment material (Fig. 46-3). Externally connected abutments encountered more technical problems such as abutment or screw loosening, whereas internally connected abutments were more associated with biologic problems" (Pjetursson *et al*. 2018). This recent review indicated that abutment failure rates at single crowns were low and were reported to be 2.3% and 1.3% at internal and external connection rates, respectively.

In a 2009 systematic review, abutment screw loosening was the most frequently reported technical complication. While not statistically significant,

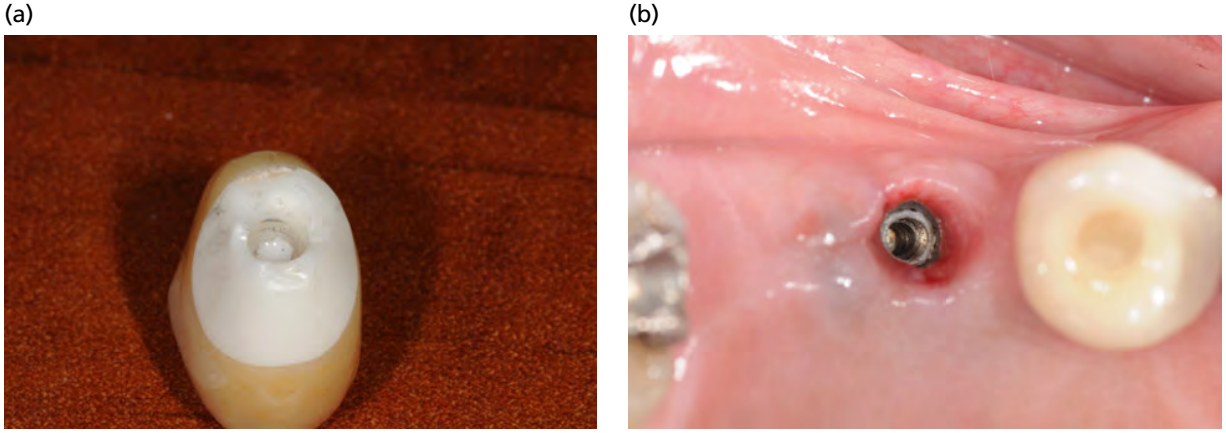

Fig. 46-3 Abutment fracture. (a) Catastrophic fracture of a zirconia abutment. This typically occurs along the conical portion at the junction of the internal or external hex of abutments. (b) The residual fractured fragment of a zirconia abutment is retained within the internal aspect of the implant. This is a challenging clinical scenario that requires removal of the fragment without marring or damaging the internal aspect of the implant.

Box 46-2 Factors influencing abutment screw loosening.

1. The lack or inappropriate use of a torque control device
2. Abutment binding to cortical bone at initial seating
3. Internal versus external connections
4. Cast abutment vs. CAD-CAM abutment
5. Anterior/posterior location of restoration
6. Single versus multiunit reconstruction
7. Excess inciso-gingivial crown dimension or cantilever

there was a trend for a lower incidence of problems at internal connection abutments (Sailer *et al*. 2009). There was significantly more screw loosening at external implant-abutment connections. Higher complication rates were experienced for fixed dental prostheses; there were 9.4% and 12.2% total technical complications recorded for internal versus external connection abutments. The incidence of abutment screw or occlusal screw fracture was significant (P = 0.01). This may reflect the clinical challenge of obtaining a passive fit of complex prostheses at multi-implant prostheses. There are numerous factors that contribute to abutment screw loosening (Box 46-2) and several of these factors were the subject of a recent review (Huang & Yang 2019). Abutment screw loosening can be the result of clinician error. A torque wrench is required for proper tightening of abutment screws (Goheen *et al*. 1994). Because abutment diameters are often greater than the implant osteotomy or mucosal contours, abutments may be bound by bone or dense collagenous mucosa that precludes complete seating of the abutment, even when sufficient torque has been achieved. Additionally, clinicians may place the abutment with incorrect timing in the implant. Such binding of an abutment with an implant may preclude its seating as further torqueing can damage the implant interface. These human errors can be avoided by use of a seating guide and evaluation using a periapical radiograph.

Abutment screws can loosen from a preloaded state. This is due to inelastic deformation of the screw itself reducing the initial clamping force of the screw. Subsequent micromotion leads to greater loosening and greater movement (and ultimately fatigue of the metal screw and fracture). One potential cause is excessive torque that can permanently deform the screw. It is also possible that upon torqueing to establish preload, there is minor deformation of the screw/implant thread interfaces that causes reduction in preload or settling. Retorqueing of the abutment screw following a 10 minute period is suggested by some clinicians. However, laboratory studies suggest that retightening does not enhance the clamping preload (Cardoso *et al*. 2012).

The nature of the implant abutment interface may influence abutment screw behavior. Several studies have shown that internal connection (particularly internal conus/morse taper interfaces) demonstrate less abutment screw loosening than external hex implants (Gracis *et al*. 2012; Bidra & Rungruanganunt 2013). In a more recent review, Pjetursson *et al*. (2018) identified superior abutment survival for metal versus ceramic abutments. Abutment or occlusal screw loosening was more prevalent at external versus internal connections. Importantly, the abutment complication rates for fixed dental prostheses were greater than for single crowns. The authors also noted greater abutment failure rates for anterior versus posterior implants, albeit at low levels (2.5% vs 0.5%). The review affirms laboratory studies that demonstrate higher strength and resistance to bending of internal abutment constructions. It was concluded that abutments exhibit high survival rates but the implant abutment connection and abutment materials influence the incidence of technical complications. Despite these conclusions, several prospective clinical studies have demonstrated that zirconia abutments provide for high success when used for single tooth, anterior implant restorations (Cooper *et al*. 2016; Meijndert *et al*. 2020).

The reason for using a zirconia abutment is largely one of esthetics. Dental implant esthetics is influenced by both abutment-related discoloration of the crown and the abutment. In a comparative study involving 98 implants, both implant crowns and surrounding mucosa was compared with that of natural teeth. The comparison of zirconia, titanium, gold hue titanium, and zirconia abutments revealed that the gold or gold hue abutment with a zirconia coping was the best for the esthetic crown and the zirconia abutment was best for peri-implant soft tissue coloration (Peng *et al*. 2017). In a study using the mini pig maxillae, spectrophotometric measurements were used to examine the impact of mucosal thickness and various zirconia, gold, gold anodized titanium, pink anodized titanium, and titanium abutment materials. When the color differences (ΔE) were measured, the use of fluorescent zirconia or a gold alloy resulted in the least discoloration. Importantly, discoloration was reduced with increasing mucosal thickness (1–3 mm) (Ioannidis *et al*. 2017). When compared with titanium, zirconia has minimal effect on mucosal color difference when placed beneath 1.5 mm of mucosa in the pig maxillae model (Happe *et al*. 2013). This technical complication is one that requires consideration of the biologic foundation for implant therapy; management by enhancing the soft tissue thickness on the facial aspect of the abutment is a valid alternative to managing this discoloration.

Prosthetic (bridge) screw loosening increases with the complexity of the prostheses. The reported incidence of screw loosening has been reported to be higher for full arch and multi-implant prostheses than for single tooth implant restorations.

A suggested cause for this is the role that passive fit of the prostheses has on preload behavior of the abutment screws. Recurrent screw loosening of a multi-implant prosthesis requires evaluation of the prosthesis fit as a root cause affecting recurrent screw loosening. Another factor that has been suggested to influence abutment screw loosening, particularly for single tooth implants, is the crown to implant ratio. However, a recent systematic review concluded that crown-to-implant ratios of 1–2 did not demonstrate significant technical complications (Meijer *et al*. 2018).

Attempts to restore implants at the fixture level have included use of milled or cast prosthesis frameworks with direct to implant interfaces. When these frameworks are designed to engage tilted implants, the internal connections of the abutment are removed to enable insertion (path of draw). This leaves the bridge screw as the sole mechanical agent to resist lateral loading (Fig. 46-4). Imposed loads can then exceed established abutment screw preload, which ultimately results in loosening and possible fracture. Subsequent prosthesis retrieval at the implant level versus the abutment levels creates relatively greater effort and challenges to replace or tighten a screw. At least two prospective comparative clinical studies have recently demonstrated that fixture level restorations are associated with greater inflammation and marginal bone loss than abutment level restorations (Gothberg *et al*. 2018; Tola *et al*. 2019). The authors concluded that restoration at the abutment level may be a safer procedure than at the implant level with regard to peri-implant tissue health. Abutment-level restorations should be selected and treatment planning must include consideration of the necessary restorative dimension required to accommodate the approximately 2-3 mm of additional transmucosal dimension needed for successful abutment level restoration.

Residual cement as a technical problem

The relative advantages and risks of cement versus screw-retained implant restorations were revealed by a systematic review (Sailer *et al*. 2012). For example, ceramic chipping is greater for screw-retained versus cement-retained restorations. There are fewer reported biologic complications for screw-retained versus cement-retained implant restorations. There are advantages and risks associated with both forms of implant restoration retention. Pragmatically, esthetic considerations often drive the selection of a cement retained implant restoration. The use of angled screw access channels to position screw access to the lingual of anterior implant restorations offers a direct alternative to esthetic anterior implant restorations (Fig. 46-5). Posterior restorations can be placed using screw retention to achieve a positive esthetic outcome when steps are taken to fill the access channel (e.g. opaque resins or ceramic plugs).

Although it is not the intent of this chapter on technical complications to discuss the long-known association of residual cement and peri-implant inflammation (Pauletto *et al*. 1999; Wilson 2009), the control of residual cement is a restorative matter of consequence. There is a reported high incidence of undetected residual cement on abutments (up to75%) (Wasiluk *et al*. 2017). Despite concerns for residual cement and peri-implantitis, cement-retained restorations can be used with appropriate caution. Three points can be made with regard to proper cementation:

1. Patient-specific abutments (CAD-CAM) should be designed with shallow crown margin locations circumferentially (<1.0 mm). Laboratory studies have shown that cement is not accessible for removal from abutments when the crown margin is located further than 1 mm from the mucosal margin (Linkevicius *et al*. 2013).

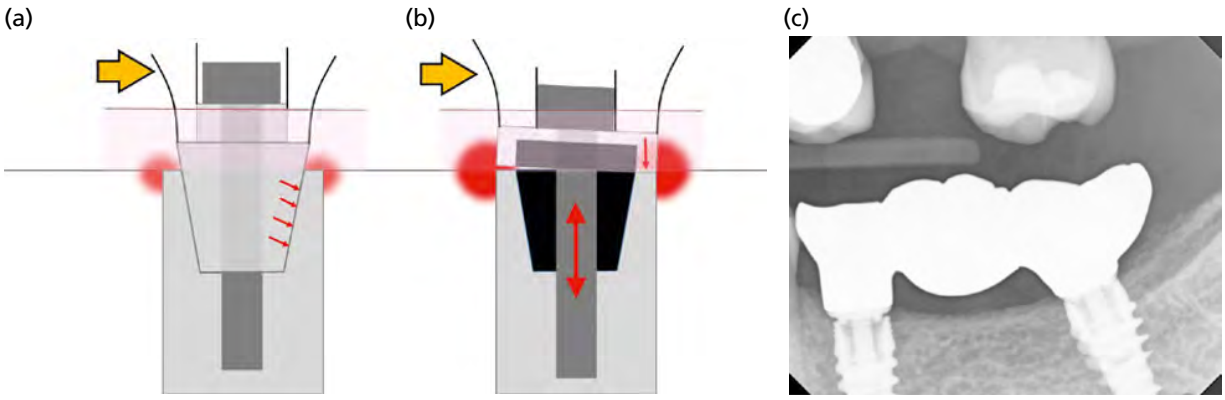

Fig. 46-4 Construction of implant prostheses at the implant level is contraindicated. (a) Construction of the prosthesis at the abutment level results in (1) force transmission from the prosthesis to the implant abutment interface, thereby reducing effects on the abutment screw, and (2) places the restorative margin at a distance from the implant/bone interface. It is suggested that this reduces inflammation at the implant/abutment interface. (b) Construction at the implant level often results in the absence of internal engagement with the implant. Upon loading, the forces are directed to the abutment screw. If these forces exceed the elastic limit of the screw, the screw is permanently deformed and loosening or fracture occurs. The micromotion and bacterial leakage contribute to greater inflammation at this implant/prosthesis interface. (c) Example of an implant prosthesis constructed at the implant level without engagement of the internal aspects of the prosthesis. The mesial abutment screw has fractured.

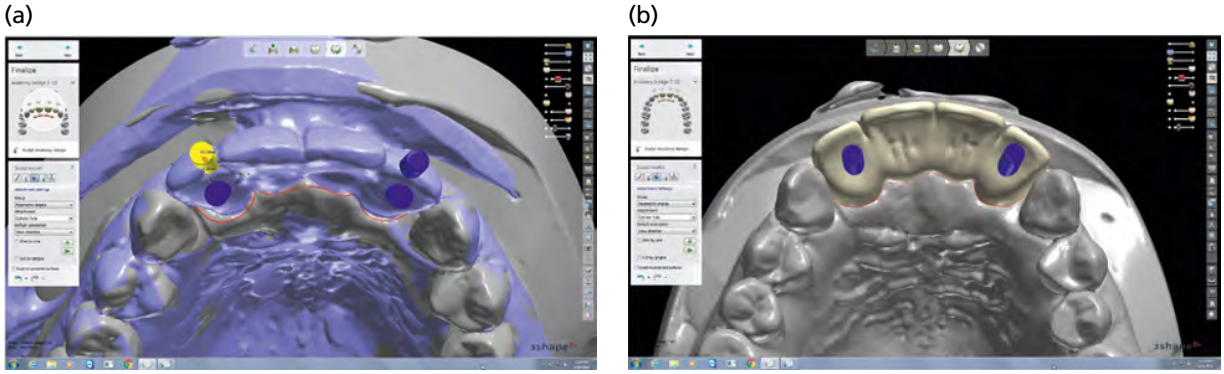

Fig. 46-5 Advantages of angled screw access. (a) Digital design of implant prosthesis demonstrating interference of screw channels with esthetics. (b) The use of angled screw access permits screw access to be in an esthetically acceptable position, in a position that favors robust prosthesis design, and one that is readily accessible.

2. Cementation techniques to reduce residual cement have been broadly advocated and include precementation on abutment replicas, venting of crowns, and applying cement as a monolayer using a brush (Wadhwani & Piñeyro 2009).
3. Where peri-implant mucositis is observed, the primary suggestion for the cause must be the presence of residual cement.

Recent studies have suggested additional risk factors influencing increased residual cement and include the shape of the abutment, the degree of undercut, and implant position in the arch (Vindasiute *et al*. 2015). The type of cement may influence the occurrence of peri-implantitis. In a series of studies, the relative absence of purulence and bleeding on probing was noted around implant crowns cemented with zinc oxide eugenol cements versus resin-based cements (Korsch & Walther 2015). When resin-based cements were replaced with a zinc oxide eugenol cement, peri-implant inflammatory signs were significantly reduced (Korsch *et al*. 2017). These findings that suggest cement type for implant prostheses influences peri-implantitis merits further investigation.

Prosthesis attrition and fracture

Full arch implant restorations, originally restored according to the Branëmark protocol, involved the use of metal frameworks with acrylic denture teeth or "hybrid" prostheses attached by bridge screws to abutments. These prostheses demonstrated high implant and bridge survival (Adell *et al*. 1981). Over the past 20 years, published data has demonstrated time-dependent increasing complications with implant supported or retained full arch prostheses. In a detailed review, Bozini *et al*. (2011) demonstrated an accumulating and increasing number of complications involving wear, tooth, veneer fracture, and to a lesser degree, framework and screw fracture, and the frequency of prosthesis complications increasing over time (Fig. 46-6). Since then, other retrospective cohort studies have affirmed that complications are commonplace and part of the patient experience, requiring management during the maintenance phase of therapy. A cohort study with a mean follow up of 35 months suggest that complications occur in over 15% of cases within the first few years of use. In a 29-year study of implant-retained metal acrylic prostheses, the majority (89%) of prostheses demonstrated complications by 20 years (Dhima *et al*. 2014). Another cohort study also demonstrated a time-dependent reduction in prosthesis survival, thus demonstrating that these prostheses require maintenance, repair, and likely replacement over time (McGlumphy *et al*. 2019). Given the high level of occlusal function, lack of proprioception, and use of a low strength denture tooth, wear often occurs on the posterior aspect leading to anterior tooth fracture. In extreme cases, this can result in multiple acrylic tooth fractures and the need to (re)establish the vertical dimension of occlusion and stabilize the posterior occlusal stability (Fig. 46-7).

When considering risk factors, framework design was predominant and other prosthesis factors such as acrylic thickness, occlusal contacts, or bruxism were not statistically associated with the reported complications (Coltro *et al*. 2018). Regarding the evidence that there is increasing risk of technical complications associated with implant prostheses over time, a more recent review indicated a reduction in the prevalence of minor technical implant prosthesis complications (Pjetursson *et al*. 2014).

A comprehensive assessment of the performance of full arch metal acrylic implant prosthesis has focused on the cantilever length and its relationship to anterioposterior spread of the implants (Drago 2018). When evaluating 193 full arch prostheses over a 48-month period, a very low acrylic fracture rate was recorded (<1%). The average cantilever length was approximately 15 mm and the average anterioposterior spread was approximately 18 mm. The calculated cantilever length/anterioposterior ratios were not associated with the frequency or type of prosthetic repairs. However, in a related report of this same cohort the author

Fig. 46-6 Veneer fracture is a common complication with metal acrylic hybrid prostheses. (a) Fracture of teeth, (b) tooth loss, (c) acrylic fracture/debonding, (d) wear, and (e) framework fracture. It is essential to provide sufficient restorative dimension to enable the construction of a framework that will resist fracture. (f) Panoramic radiograph demonstrating framework design and cast in gold alloy to support hybrid prosthesis prior to fracture illustrated in (e). (g) Panoramic radiograph demonstrating new framework with greater restorative dimension (enabled by increased vertical dimension of occlusion) and cast in cobalt/chrome alloy.

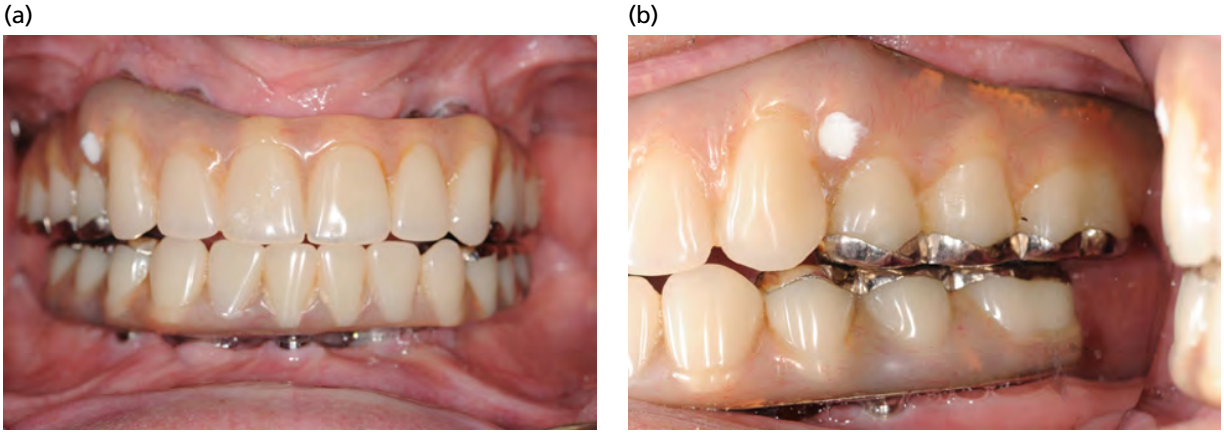

Fig. 46-7 Restorative solutions to wear include use of gold occlusal tooth surfaces. (a) Intraoral facial view demonstrating the absence of anterior tooth wear after years of metal acrylic hybrid prosthesis with gold occlusal surfaces. (b) Intraoral lateral view illustrating the cast gold occlusing surfaces of the maxillary and mandibular prostheses. Today this can be accomplished using milled ceramic materials or selective laser sintered materials in lieu of cast gold materials.

demonstrated interim acrylic prostheses were associated with significant technical complications including fracture of the prostheses (Drago 2017). These reports indicate that planning may significantly reduce the near term technical complications for metal acrylic full arch implant prostheses, yet the interim prostheses used (often via conversion of dentures) present technical complications (17% of patients treated) that challenge the clinical management of these patients.

Alternatives to the metal acrylic (hybrid) prosthesis include porcelain-fused-to-metal, unit constructions, and monolithic zirconia prostheses. There exists less data regarding the outcomes of such restorations. However, porcelain-fused-to-metal restorations have been reported to possess a relatively high porcelain chipping complication rate of 20% (Kinsel & Lin 2009). In 11 studies with at least a 5-year follow-up, there was a relatively low incidence of technical complications when compared with metal acrylic prosthesis. However, veneer fractures were common. The 5- and 10-year complication rates for metal ceramic restorations were 22.1% and 39.3% (Wong *et al*. 2019). A retrospective cohort evaluation of 55 metal ceramic full arch prostheses also reported high technical complications including porcelain wear and chipping; at 5 and 10 years there were 56.4% and 9.8% prostheses free of technical complications (Papaspyridakos *et al*. 2019). In a similar retrospective analyses involving both metal ceramic and acrylic metal full arch prostheses, with a mean observation period of 5.2 years, increased risk of chipping was greater for (× 4.6) for ceramic versus metal acrylic type prostheses. Bruxism and the absence of nightguard use were associated with increased ceramic chipping (Papaspyridakos *et al*. 2020). The use of metal ceramic prostheses is also not without significant, time-dependent technical complications that often require repair.

In a systematic review by Millen *et al*. (2015), comparing outcomes for screw- versus cement-retained full arch prostheses, the authors concluded that there were no differences in the reported incidence of complications, but higher rates of mechanical (and biologic) complications were observed for cement-retained prostheses. In a recent retrospective study including 71 prostheses in 53 subjects with an observation period of 1–12 years (mean = 5.2 years), the most common minor and major complications included wear of the veneering material and fracture of the prosthetic material. Similar to the study of Dhima *et al*. (2014), largely considering metal acrylic prostheses, they demonstrated a time-dependent increase in the incidence of prosthesis complications (85.5% versus 30.1% complication-free restorations at 5 and 10 years respectively) (Papaspyridakos *et al*. 2020). These studies infer that porcelain-fused-to-metal restorations do not represent a universal solution for technical complications associated with full arch implant restorations (Millen *et al*. 2015).

The development of monolithic zirconia restorations for full arch restorations have met with early success. Initial studies and systematic reviews imply few complications (Abdulmajeed *et al*. 2016; Bidra *et al*. 2018; Tischler *et al*. 2018). Veneered zirconia frameworks are not immune from chipping complications (Spies *et al*. 2018) and have been largely replaced in the market by monolithic zirconia prostheses. A recent comparative clinical study demonstrated veneered zirconia prostheses were associated with a higher incidence of technical complications when compared with the monolithic zirconia prostheses (Caramês *et al*. 2019). In a limited study involving bruxing patients, comparison of veneered and monolithic zirconia prostheses demonstrated the absence of minor chipping complications compared to high rates of chipping in the veneered zirconia prostheses (Levartovsky *et al*. 2019). These various reports suggest that monolithic zirconia prostheses may reduce technical complications that plague full arch implant restoration.

Fig. 46-8 Zirconia bridge fracture. While recent studies indicate no or only rare fracture of monolithic zirconia implant supported prostheses, fractures are non-repairable and require replacement of the entire prosthesis. Fortunately, if the digital files have been retained, a duplicate can be constructed with minimal clinical effort.

When monolithic zirconia prostheses fail, failure may be catastrophic in nature (Fig. 46-8). This phenomenon has not been widely reported in the literature and may reflect a low rate of major technical failures. The possible causes of catastrophic monolithic zirconia failures may include: ceramic flaws caused by improper handling following sintering, use of higher cubic ZrO content in more translucent ceramic systems, improper sintering, post sintering adjustments, hydrolytic aging and inadequate three-dimensional framework designs. High translucency zirconia materials possess lower biaxial flexural strength and are differentially influenced by mechanical cycling or aging *in vitro* (Muñoz *et al*. 2017). Regarding dimensional requirements for full arch zirconia implant prostheses, prosthesis height should permit 10 mm of vertical dimension and connectors should be as large (and especially tall) as feasible (> 25 mm^2). The thickness of zirconia surrounding the titanium cylinders should be greater than 3 mm circumferentially (Rojas Vizcaya 2018). Thus, screw access must be directed through the body of crowns and their location interproximally should be avoided. Additional detailed attention should be paid to the connector and embrasure design of these prostheses as laboratory studies indicate that blunt embrasures and large interproximal separations decrease the measured load to fracture (Bakitian *et al*. 2019). Meeting the expectations for reduced technical complications with monolithic zirconia implant prostheses requires careful attention to details of design and manufacture.

Prevention of technical complications

The current data suggests that technical complications will be frequently encountered in implant dental practice. The more common problems appear to include abutment screw loosening and prosthesis veneer fracture. More rarely, catastrophic technical complications requiring prosthesis replacement are encountered. When considering early complications, they may represent inadequate implant placement planning and/or prosthesis design.

To assure robust prosthesis function over time, two important features must be considered at the time of implant planning. One is the assurance of an adequate restorative dimension that is determined by both proper management of the vertical dimension of occlusion and recognition that the depth of implant placement may require alveolectomy. Related is the biomechanical approach to reduce the bending moments by reduction of cantilever length through tilted implant positioning. Together, these features of planning can ensure that a prosthesis of sufficient bulk is provided and will avoid being loading by excessive forces.

A third aspect of planning to reduce potential technical complications is to utilize components of "optimal" dimension. This includes avoiding the use of narrow implants for posterior implants or use of narrow abutment platforms for posterior implants. Related is the use of implant components with precise interface connections; today's dental technology largely avoids casting of components due to the precision of CAD-CAM manufacture. The selection of abutment dimension for strength is dependent on implant selection. Thus, surgical planning is the phase in treatment when many decisions must be made to reduce potential technical limitations (Box 46-3).

Technical complications may also be associated with procedural errors in implant restoration. These errors accumulate in two areas. One is in the management of the implant abutment interface. As reviewed, it is strongly recommended that all multiple implant restorations be restored at the abutment level and not the implant level. Abutment connection to the

Box 46-3 Implant planning steps to reduce technical complications.

1. Plan implant number to account for imposed loading
2. Select implant dimensions (and materials) to oppose these loads
3. Plan implant location vertically to allow sufficient restorative dimension
4. Reduce cantilevers to minimize anticipated bending moments
5. Design 'shallow' occlusion to reduce lateral loading

implant must be performed with fidelity; the components must be correctly assembled, be free of tissue interferences, and be tightened appropriately using torque control to achieve the manufacturer's recommended torque level. The prosthesis to abutment interface must also be connected with high fidelity and there must be absolute passivity to reduce potential high stresses in bridge screws or – in extreme cases – the prosthesis. Careful attention must be paid to each step in the prosthetic process, including abutment selection, abutment insertion, impression, verification of master cast accuracy and/or digital image recording, framework design, framework assessment, and esthetic veneer designation and assessment. Stepwise assurances help to limit potential risks leading to technical complications or failure.

Conclusion

Currently available data indicates technical complications are commonly encountered in implant dental therapy and shorten the service life of the restoration. These complications span the range of implant, abutment, and prostheses complications. Minor complications typically do not require replacement of abutments or prostheses. However, they impact practice and patient perceptions of implant treatment. Major complications require major modification or replacement of the prosthesis and have a significant impact on the practice of implant dentistry. The root causes of complications must be identified when possible and these causes should be addressed to prevent recurrent complications. Understanding the factors that lead to technical complications enable clinicians to improve the planning of implant surgery and prosthesis fabrication to anticipate risk and limit complications that lead to therapeutic dissatisfaction.

Part 17: Orthodontics and Periodontics

Chapter 47

Tooth Movement in the Periodontally Compromised Patient

Mariano Sanz[1] and Conchita Martin[2]

[1]Faculty of Odontology, ETEP (Etiology and Therapy of Periodontal and Peri-Implant Diseases) Research Group, Complutense University of Madrid, Madrid, Spain and Department of Periodontology, Faculty of Dentistry, Institute of Clinical Dentistry, University of Oslo, Oslo, Norway
[2]Faculty of Odontology, Complutense University of Madrid, Madrid, Spain

Introduction: biologic principles of orthodontic tooth movement

The objective of orthodontic therapy is to correct altered tooth positions and the resulting malocclusions by the application of orthodontic appliances and techniques that once applied to the tooth surface exert the appropriate pressure and tension forces (Dolce *et al*. 2002; Meikle 2006; Wise & King 2008). This therapy presents distinctive characteristics when it is applied to dentitions when the bone is still growing, such as in children and adolescents, in comparison with adult dentitions where the bone has finished its growth. In the first case, orthodontic therapy aims both to elicit tooth movements within the alveolar bone housing and to guide the growth of the jaws to attain adequate intermaxillary relationships. In adults, orthodontic therapy is limited to dentoalveolar tooth movements and in many instances these movements need to be applied in teeth with a healthy but reduced periodontal ligament (PDL) as a consequence of a history of periodontitis. Moreover, cellular activity in adults is reduced in comparison with younger patients, which may reduce the rate of orthodontic tooth movement (Verna et al. 2000; Ren *et al*. 2002). With the increasing esthetic demands of modern society, a growing number of adult patients are seeking orthodontic treatment for correcting common conditions as anterior tooth diastemas, crowding, uneven gingival margins, or loss of interdental papillae. Furthermore, in patients suffering from severe periodontitis, the combination of attachment and bone loss with tooth loss results in a series of events leading to secondary occlusal trauma, pathological tooth migration, and frequent severe malocclusions and malpositions that severely compromise the patient's masticatory function. In the recent classification of periodontal and peri-implant diseases, stage IV periodontitis defines this clinical situation where severe periodontitis is accompanied by extensive tooth loss and the sequelae of tooth drifting and altered masticatory function. This stage of periodontitis will usually need not only the appropriate treatment of the periodontal condition but also a multidisciplinary rehabilitation including orthodontic tooth movements to restore the patient's functional dentition (Papapanou *et al*. 2018). The

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

multidisciplinary treatment of these patients requires close coordination and collaboration between the orthodontist, the periodontist, and the restorative dentist in order to optimize the treatment outcomes. This chapter specifically reviews how orthodontic therapy can be implemented in adults with periodontally affected dentitions.

Physiological tooth movements are those undertaken by a tooth to attain and maintain its functional position. They take place during the processes of tooth growth, eruption, or when the tooth movement is a consequence of the application of an external force, such as the push from an inclined erupting third molar. Orthodontic tooth movements are those generated by external forces when applied in a controlled manner with the purpose of achieving a predetermined tooth movement. In both types of movements, the basic biological processes are similar; the transmission of a mechanical force from the root to the PDL affecting the homeostasis between the cells and the extracellular matrix, and leading to a series of biological events characterized by the modeling and remodeling processes of the alveolar bone housing, which results in changes in tooth position. The orthodontic forces applied to the tooth crown elicit a series of cell–matrix interactions within the PDL that convert physical distortion into changes in the extracellular, cell membrane, and nuclear transduction mechanisms that alter cell behavior through a chain of biochemical cascades (Masella & Meister 2006). These highly sophisticated biological pathways transforming mechanical forces into controlled active cellular processes represent a controlled inflammatory response (aseptic inflammation), which is regulated by neurotransmitters, growth factors, cytokines, and molecular mediators (Meikle 2006).

Depending on the amount and direction of the mechanical force applied to the tooth, the resulting tooth movement will be different. A mechanical force perpendicular to the longitudinal axis of a tooth will elicit wide areas of pressure on certain parts of the root and corresponding areas of tension on others. In general terms, the tension areas will widen the PDL space by stretching the periodontal fibres, which will distend the blood vessels and increase the fibroblasts orientated in the direction of the applied force. This phenotypic alteration of the fibroblast will induce the differentiation of the osteoblast precursors into functional osteoblasts that will form osteoid leading to bone apposition and reformation of the Sharpey's fibres within the new calcified formation. On the contrary, on the pressure zones, there will be compression of the PDL space, with partial obliteration of the blood vessels and collagen tissue remodeling, leading to a proinflammatory biological cascade with differentiation of bone resorbing cells (osteoclasts), resulting in bone resorption and change of the tooth position towards the force direction. Once the tooth has been displaced and escaped from the physical force, homeostasis will return with new vessel formation, osteoblast recruitment, and reformation of the periodontal fiber attachment to the newly formed bone.

If the mechanical force was located near the center of resistance of the root, there will be an even distribution of pressure and tension areas on both sides of the root, resulting in a horizontal translation of the tooth, also called bodily movement. This movement, however, is impossible in most clinical situations because the root is invested in its alveolar housing and the only available surface to apply the orthodontic force is the crown. Orthodontic forces are, therefore, applied to the tooth crown via some kind of appliance that ensures a two-point contact enabling the necessary couple that transfers the applied force to the tooth center of rotation. The dimensions of such a movement will depend on the site of the force application, the shape of the tooth, and the architecture of the tooth supporting apparatus. Under these circumstances, the ensuing tooth displacement will be a combination of bodily and tilting movements where pressure and tension forces are located everywhere around the root, leading to diverse stress distribution within the PDL (Fig. 47-1).

Because the socket housing is a three-dimensional structure, pressure/tension areas are not clearly defined and will occur simultaneously around the root, usually following a biphasic process with two concomitant sequential phases occurring in the alveolar bone. First, there is a catabolic phase during which osteoclasts resorb bone to adapt to the orthodontic force, followed by an anabolic phase, where bone formation and reorganization of the periodontal fibers will restore homeostasis within the PDL once the tooth has been displaced. Depending on the orthodontic force there will be specific cellular and molecular events establishing the limits for each phase (Alikhani *et al*. 2018).

Application of light mechanical forces (approximately 50–100 g/tooth) on the pressure side is associated with "direct bone resorption". In these situations, the vessels are patent, and the physiology of the cells and tissues is preserved. In contrast, stronger mechanical forces will cause a crushing injury to PDL tissues, with cell death, hyalinization, and the formation of cell-free areas between the PDL and the adjacent alveolar bone, which will interfere with the tooth movement and will slow the biologic processes. Patient variability in the response to similar mechanical forces is common in orthodontic practice and there are many possible reasons for this heterogeneity, such as differences in alveolar bone mineral density, in vascularity, in the number of available bone cells, and in the many inherent cellular and metabolic responses due to differences in the patient's genome that dictate differences in cell recruitment, differentiation, and function, as well as in the expression of the many proteins and regulatory molecules that intervene in bone metabolism.

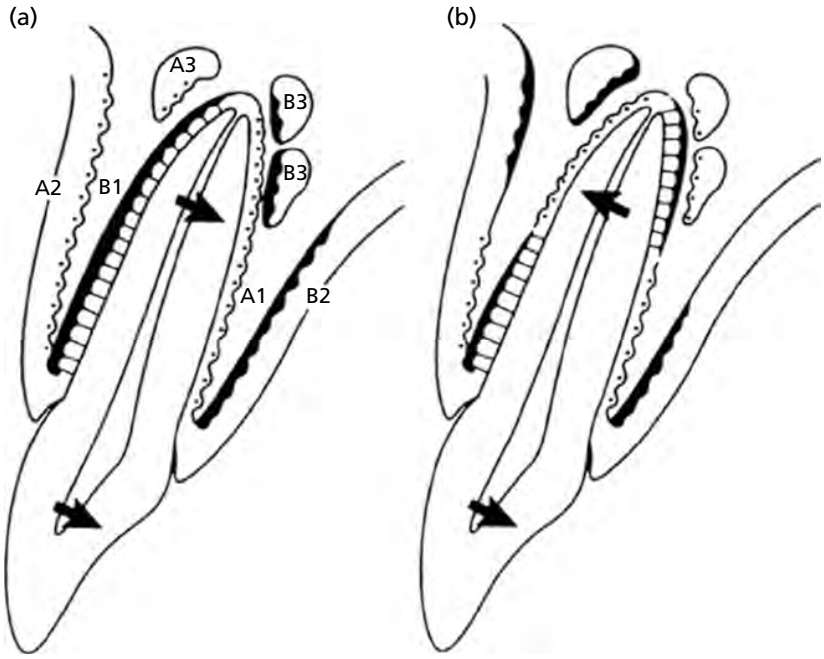

Fig. 47-1 (a) Mechanical force perpendicular to the longitudinal axis of a tooth produces wide areas of pressure on one side of the root and corresponding areas of tension on the other. (b) Direction of the force varies depending on the site of the force application, shape of the tooth, and architecture of the tooth-supporting system. The resulting movement will be a combination of bodily and tilting movements, leading to pressure and tension forces on either side of the root and a varying distribution of the stress along the periodontal ligament.

Periodontal and orthodontic diagnosis

Periodontal health is a prerequisite for any orthodontic tooth movement, and this particularly applies to adult orthodontics. Any adult patient seeking orthodontic therapy must have a comprehensive periodontal diagnosis, including oral examination, periodontal charting, and a complete periapical radiographic series before the start of orthodontic therapy. Periodontal charting should include registration of full mouth probing pocket depths, gingival recessions, bleeding on probing and plaque indexes in 4–6 sites per tooth. Furthermore, presence of tooth mobility, furcation involvements, and mucogingival defects should be evaluated. In conjunction with the periodontal examination, it is important to evaluate carefully the status of the remaining dentition with close attention to the presence of undiagnosed caries or presence of periapical pathology that may interfere with orthodontic therapy. If these pathologies are present, appropriate restorative and/or endodontic therapy should also be performed before the start of orthodontic therapy.

In the diagnosis of the patient's malocclusion, the appropriate intraoral and extraoral examination should be conducted in close collaboration between the orthodontist and the periodontist. The extraoral examination should include a full smile analysis, including the evaluation of the shape and form of the lips, the tooth and gingival exposure in open smiling, as well as the exposure of the posterior corridors. The intraoral examination should also include assessment of the static and dynamic occlusion to detect the presence of prematurities in maximum intercuspidation, or interferences in the protrusive and lateral disclusive movements. The intermaxillar relationships should be studied with the appropriate intraoral and extraoral records. Intraoral models appropriately mounted should reveal the shape of both arches, presence of diastemas, tooth crowding, tooth rotations, anomalies in the size, shape and number of teeth, and their interocclusal relationships. Classically, the combination of orthopantomography (OPG) and cranium lateral radiography will allow a cephalometric analysis leading to the appropriate diagnosis of the patient's malocclusion. The advent of cone-beam computed tomography (CBCT) has improved the diagnostic accuracy for examining the craniofacial complex, including the assessment of buccal alveolar bone height and thickness, transverse dimensions, the presence of impacted, ectopic, supernumerary teeth, as well as the presence of root resorptions. Three-dimensional imaging also allows the assessment of the position of the soft tissues in relation to the bone envelope (Fig. 47-2).

In the treatment of adult patients it is also important to take a detailed medical and drug history because adults may suffer from medical conditions or take regular medications that might interfere with periodontal and/or orthodontic therapy. To assure the appropriate response to periodontal therapy, patients who smoke should be advised to cease and patients who are diabetic or prediabetic should achieve appropriate glycemic control. For orthodontic therapy, the medical history should include details of regular drug-consumption because the use of non-steroidal anti-inflammatory drugs (NSAIDs) may alter the behavior of those cells targeted by the orthodontic forces during tooth movement. These NSAIDs not only effectively reduce inflammation and pain, but also affect the sequence of tooth movement by inhibiting, or at least reducing, the controlled inflammatory and bone resorptive processes. New generation anti-inflammatory drugs such as nabumetone, on the contrary, have been shown to reduce the amount of root resorption in intrusive orthodontic forces, without

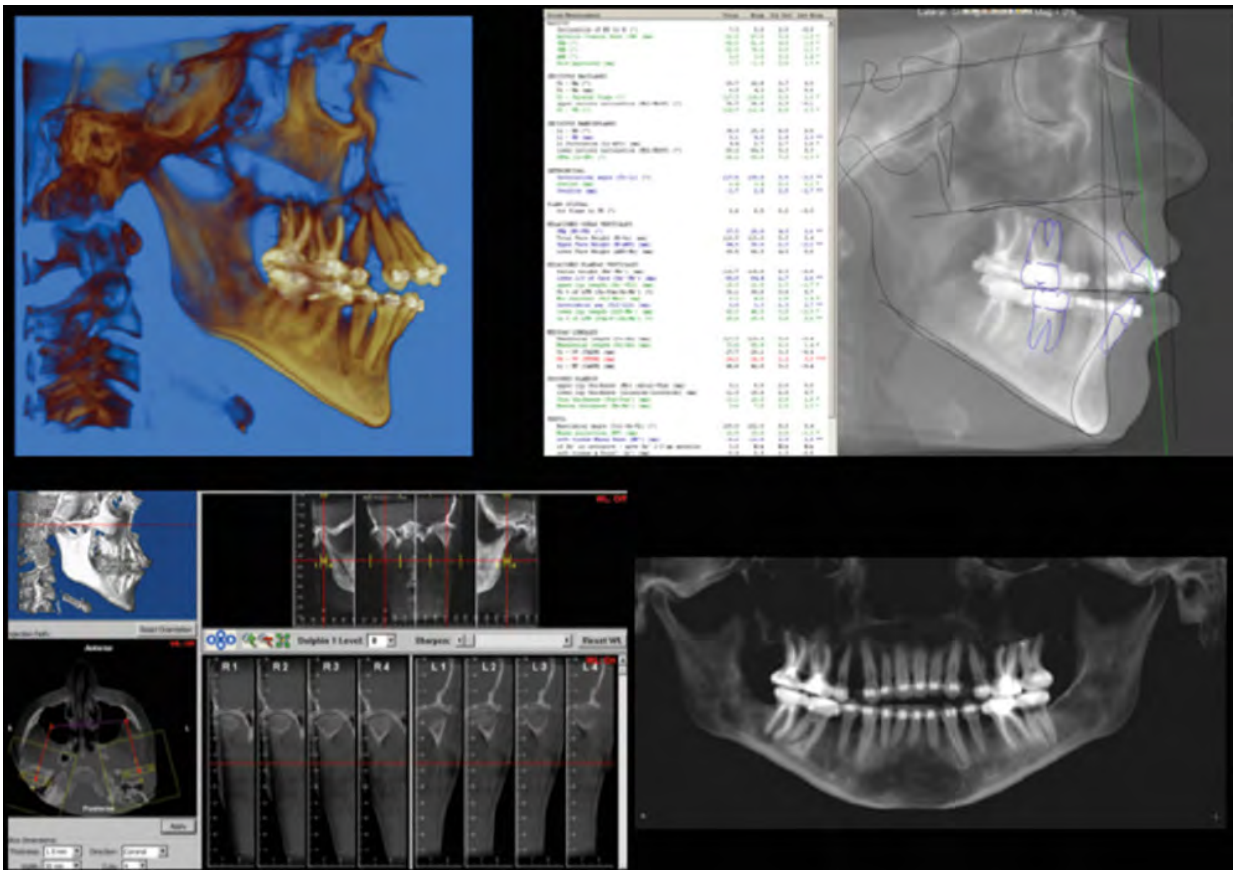

Fig. 47-2 Diagnostic information used in orthodontic treatment planning can now be obtained with cone-bean computed tomography (CBCT) allowing the combination of classical orthopantomography and cranium lateral radiography with 3D information of the craniofacial complex.

affecting the pace of tooth movement (Krishnan & Davidovitch 2006). Another group of drugs that may affect adult patients under orthodontic care are muscle relaxants, such as cyclobenzaprine, and tricyclic antidepressants, such as amitriptyline and benzodiazepines. The main side effect of the latter is xerostomia, which can negatively affect the proper maintenance of oral hygiene, and hence proper periodontal health during orthodontic therapy. Similarly, in patients requiring chronic use of inhalers with steroids, such as those suffering from asthma, oral candidiasis and xerostomia may result. Appropriate measures should be implemented in these patients, such as the use of topical antifungal agents and salivary substitutes before and during orthodontic treatment.

A condition that frequently affects women in adulthood is osteoporosis and most of the current therapies for this disease are antiresorptive (bisphosphonates, selective estrogen receptor modulators, and calcitonin), which may slow the remodeling phase of bone turnover and potentially interfere with orthodontic therapies. Similarly, in patients suffering from rheumatoid arthritis or other chronic inflammatory conditions, therapy aims to block the catabolic cytokine production responsible for the damage to soft tissues and bones (TNF or interleukin antagonists). These immune-modulatory agents might also interfere with orthodontic tooth movement.

Another group of drugs that need special consideration are those associated with gingival hyperplasia, such as phenytoin used for seizure disorders, calcium blockers used as antihypertensive drugs, or cyclosporine-A used in organ transplant patients. These drugs induce gingival hyperplasia, which might prevent the application of certain orthodontic mechanics, as well as interfering with the maintenance of proper oral hygiene and periodontal health.

Tooth movement might also be affected in patients who have recently received chemotherapy with busulfan/cyclophosphamide (<2 years of disease-free life), because these drugs are known to produce damage to the precursor cells involved in the bone remodeling processes.

Treatment planning

Once the patient has completed the required dental and periodontal treatments leading to oral and periodontal health, the multidisciplinary treatment, including orthodontic tooth movements, should be planned, always taking into consideration the patient's main concerns and expectations, and the foreseen realistic functional and aesthetic objectives. The sequence of planned interventions must be customized to the patient's pattern of bone loss, type of malocclusion, and periodontal disease severity

(Geisinger *et al*. 2014). One important complication during the orthodontic treatment of periodontal patients is the occurrence of root resorption, which may be associated with the presence of periodontal inflammation, the dimension of the orthodontic forces, or the individual relative expression of inflammatory/osteoclast marker genes (Kirshneck *et al*. 2017).

Periodontal considerations

Although the effects of orthodontic forces on the periodontium have been studied extensively, there are contradictory findings in the scientific literature on the impact of orthodontic therapy on periodontal health. A recent systematic review assessing the effect of orthodontic treatment on periodontal outcomes concluded that orthodontic treatment with fixed appliances has little to no clinically relevant effect on periodontal clinical attachment levels (Papageorgiou *et al*. 2018a). In fact, many clinical studies have clearly shown that with adequate plaque control, orthodontic treatment in patients with a reduced but healthy periodontium achieves the orthodontic objectives without aggravating their periodontal condition and the risk of periodontal recurrence in these patients is not increased during orthodontic therapy (Re *et al*. 2000). When periodontal inflammation is not fully controlled during orthodontic treatment, however, these inflammatory processes may accelerate the progression of periodontal destruction leading to further loss of attachment (Fig. 47-3).

In some clinical studies, a mean increase in probing depth of about 0.5 mm during orthodontic treatment has been reported, and this increase has been interpreted as caused by marginal inflammatory changes rather than by periodontal attachment loss (Ristic *et al*. 2007; van Gastel *et al*. 2008). Clinical trials comparing molars with bands versus brackets have shown that bands exhibit greater gingival inflammation and loss of attachment (Boyd & Baumrind 1992). Other studies, however, have reported the presence of gingival inflammation as a result of accumulation of subgingival plaque around the bands, but without loss of attachment (Diamanti-Kipioti *et al*. 1987; Huser *et al*. 1990) or without demonstrating significant differences in other clinical periodontal parameters when comparing banding and bonding procedures (Sinclair *et al*. 1987; van Gastel *et al*. 2008).

It is, therefore, critical that accumulation of dental biofilm during orthodontic treatment is prevented and closely monitored. This is particularly relevant when using fixed orthodontic appliances that may facilitate plaque accumulation and hinder a patient's oral hygiene practices. Although changes in the subgingival microbiota after the insertion of orthodontic appliances have been reported, they appear to be a transient and usually revert to a healthy microbiota in the first months after appliance removal (Papageorgiou *et al*. 2018b).

Patients preparing for orthodontic therapy must demonstrate not only gingival and periodontal health but also excellent oral hygiene. Patients should be informed that the lack of adequate oral hygiene poses a significant risk of periodontal breakdown that will entail the discontinuation of orthodontic treatment until low plaque scores have been re-established.

In some patients with poor oral hygiene, the fixed orthodontic appliances may promote gingival enlargement, which further enhances plaque accumulation. In these situations, orthodontic therapy should be stopped, and the orthodontic appliance removed until the inflammation is resolved, and efficient oral hygiene practices are reinstated (Davis *et al*. 2014). Sometimes the marginal tissues do not revert to their appropriate position with only subgingival instrumentation and surgical removal of the excessive gingival tissue is needed (Graber & Vanarsdall 1994; Sanders 1999).

The timing of initiating orthodontic treatment after periodontal therapy is still controversial. A recent clinical trial compared starting orthodontic therapy immediately after basic periodontal therapy versus 3–6 months after the surgical therapy and showed no differences in attachment levels (Zasciurinskiene *et al*. 2018). However, there is no consensus on the optimal timing for initiating orthodontic tooth movements after periodontal surgery, although it is mandatory to start orthodontic therapy once periodontal health has been achieved. In consideration of the previously described biological bases of orthodontic tooth movements, once proper infection control has been implemented and the endpoints of periodontal therapy achieved (no pockets of ≥6 mm and no probing pocket depth >4 mm with bleeding on probing), it is advisable to start the orthodontic treatment as soon as possible in order to benefit from the high bone turnover secondary to the healing of the periodontal interventions, which may accelerate orthodontic tooth movements (Frost 1989).

During orthodontic therapy, the periodontal condition and oral hygiene compliance of patients should be closely monitored. It is advisable that during the monthly orthodontic appointment, the periodontal status is verified and professional plaque removal should be implemented if required.

Orthodontic considerations

Orthodontic tooth movements *per se* do not cause periodontal attachment loss and/or gingival recession (Wennstrom 1996). However, in areas of thin buccal cortical bone, labial or proinclination orthodontic tooth movements can result in bone dehiscence defects, which when accompanied by a thin gingival phenotype in conjunction with presence of plaque derived gingival inflammation and/or toothbrush trauma may lead to attachment loss and the development of localized gingival recessions (Coatoam *et al*. 1981; Artun & Krogstad 1987; Maynard 1987;

Fig. 47-3 Patient with severe chronic periodontitis, together with pathologic tooth migration, secondary occlusal trauma, and severe esthetic and functional impairment. (a) Intraoral initial clinical pictures. (b) Initial orthopantomogram (OPG), lateral cephalogram, and periapical series.

Wennstrom 1996). In the presence of thick gingival tissues, gingival marginal tissue recessions will not occur, even when labial or expansive tooth movements are carried out (Coatoam *et al*. 1981; Artun & Krogstad 1987; Maynard 1987; Wennstrom 1996).

In children and adolescents, prospective and retrospective clinical studies have not found a correlation between orthodontic labial inclination of mandibular central incisors with the development of gingival recessions (Ruf *et al*. 1998; Artun & Grobety 2001; Djeu *et al*. 2002). In adults, however, a prospective study showed a significant correlation between the incidence and the severity of recession lesions with excessive proinclination (>10°) of the mandibular incisors (Artun & Krogstad 1987). However, other studies in patients with mandibular prognathism subjected to orthognathic surgery reported that in spite of extensive labial tipping the mandibular incisors, there were no negative outcomes in the periodontal tissues (Ari-Demirkaya & Ilhan 2008). It is the combination of the final tooth inclination and the thickness of the marginal gingival tissues (<1 mm) that has been associated with the occurrence of recessions in mandibular central incisors after orthodontic treatment (Yared

Fig. 47-3 *(Continued).* (c) Orthodontic treatment progress, lower arch appliances first and preventive root canal treatment prior to upper arch appliances. (d) Orthodontic treatment progress. (e) Follow-up periapical series and OPG.

et al. 2006) and, therefore, the main risk factors associated with the development or the aggravation of gingival recession lesions after adult orthodontic therapy is the presence of a thin gingival phenotype combined with an insufficient width of keratinized gingiva, and/or presence of gingival inflammation (Melsen & Allais 2005). In these risk situations, the orthodontist should consult with the periodontist and consider a gingival augmentation or root coverage procedure before attempting to move the affected tooth or root labially (Pini-Prato *et al*. 2014). On the contrary, if a labially positioned tooth is orthodontically moved lingually, the bone dehiscence may disappear and the gingival thickness increase (Steiner *et al*. 1981; Karring *et al*. 1982; Wennstrom *et al*. 1987). In these situations, the mucogingival conditions should be closely monitored during the orthodontic therapy and the possible indication of a mucogingival surgical procedure should be evaluated during and after orthodontic treatment (Fig. 47-4).

Some authors have also reported the risk of gingival recessions in the area of maxillary premolars and molars when rapid maxillary expansion movements are carried out after mid-palatine suture fusion (after 20 years of age) (Graber & Vanarsdall 1994). Similarly, the movement of teeth into edentulous spaces (areas of reduced buccolingual bone dimension) is often possible with slow, light orthodontic forces, depending on the tooth-to-bone width ratio, although in spite of these measures, loss of alveolar bone and presence of dehiscence defects have been reported in these clinical situations (Stepovich 1979; Hom & Turley 1984; Pontoriero *et al*. 1987; Goldberg & Turley 1989; Fuhrmann *et al*. 1995; Wehrbein *et al*. 1995). This complication may be even more frequent when orthodontic tooth movements are aimed through atrophic and narrow alveolar ridges (Ramos *et al*. 2019). In these situations, the orthodontist, together with the periodontist, should consider a lateral bone augmentation procedure to increase the width of the ridge prior to the orthodontic treatment (Kaminishi *et al*. 1986).

Goldberg and Turley (1989) studied the periodontal changes associated with orthodontic space closure of edentulous maxillary first molar areas in adults. With a space closure averaging 5.3 mm, the resulting vertical bone loss averaged 1.2 mm in the second molar and 0.6 mm in the second premolar, with 60% of the teeth showing ≤1.5 mm of bone loss. Although space closure can be considered a potential solution in the absence of the first permanent molar, attachment loss and space reopening can be common complications.

Orthodontic treatment

Once orthodontic therapy starts; periodontal patients should be closely monitored for any signs of recurrence of their previous periodontal pathology and they should be frequently recalled for professional infection control. These recall visits should be customized according to the severity of the reduced periodontium and the associated patient risk factors (smoking, diabetes, etc.). At these visits, probing pocket depths and gingival bleeding scores should be monitored and when present, appropriate professional plaque removal or subgingival root instrumentation, together with other adjunctive therapies (adjunctive antiseptics, such as chlorhexidine, cetyl pyridinium chloride, or phenolic compounds) should be implemented.

In patients with a reduced periodontium, the total surface of the PDL that receives the orthodontic forces is significantly less and the tooth's center of resistance is displaced apically, which results in the expression of greater moments of force. In these cases, orthodontic treatment should be carefully planned and monitored to achieve as much as possible bodily, instead of tipping, tooth movements (Melsen 1988). In terms of orthodontic appliances, it is always advisable to use the simplest orthodontic system with the goal of facilitating oral hygiene practices and thus reducing plaque accumulation. It has been shown, although in the short term, that the design of the bracket may influence significantly bacterial accumulation and gingival inflammation (van Gastel *et al*. 2007). In this context, self-ligating brackets or wire ligatures are considered better than elastomeric ligatures (Turkkahraman *et al*. 2005; Alves de Souza *et al*. 2008). Although the use of clear aligners in the treatment of periodontal patients has shown no differences in terms of plaque levels or gingival scores, when compared with fixed orthodontic appliances, patients in the group with fixed appliances had significantly shallower pockets and the duration of the treatment was shorter (Han 2015). When using aligners, the placement of attachments on tooth surfaces with a reduced bone support should be avoided, because these teeth may be traumatized when inserting the appliances.

Reduced periodontal support also implies a reduction in the anchorage required to undertake orthodontic tooth movements and in patients with severe periodontal destruction, the use of skeletal anchorage devices, such as orthodontic mini-screws, mini-plates, or conventional dental implants is recommended to assure better control of three-dimensional tooth movements (Fig. 47-5).

Once orthodontic treatment is finished after achieving the desired tooth position, a permanent retention is recommended in patients with a reduced periodontium. Retainers bonded to both canines and incisors are usually the preferred retention method, although in some studies these lingually fixed retainers have resulted in negative periodontal outcomes (Pandis *et al*. 2007; Levin *et al*. 2008), whereas in others no significant long-term periodontal changes were shown (Reitan 1969). In some severe cases, a two-retainer approach is chosen, combining a conventional lingual retainer and a segmented retainer inserted within the crowns of two adjacent teeth and covered with composite resin. Removable retainers should be avoided to prevent jiggling movements on the periodontally compromised teeth.

Fig. 47-4 Patient with localized gingival recession and absence of keratinized tissue in a central incisor prior to orthodontic therapy. (a) Orthodontic therapy was initiated by rapid palatal expansion. (b) Prior to expansion and retraction of upper central incisors, an autogenous gingival graft was placed. The final intraoral images demonstrate the root coverage of the recession by a combination of grafting and lingual tooth movements.

Specific orthodontic tooth movements

Extrusion movements

Tooth extrusion is a predictable tooth movement to level bone margins or to lengthen the clinical crown in cases of tooth fracture or when indicated for restorative purposes. Mainly in situations of compromised periodontal support, orthodontic eruption is a valuable alternative to surgical crown lengthening, because in these surgical interventions, resective osseous surgery will further compromise the attachment apparatus. When malocclusion or malalignment affects the aesthetic areas, tooth extrusion movements can also be considered to align gingival margins and correct incisor edges, thus

Fig. 47-5 Patient with severe chronic periodontitis, together with pathologic tooth migration, open anterior bite, and posterior bite collapse. (a) Intraoral images before periodontal and orthodontic therapy. (b) Radiographic images demonstrating the severe bone loss and posterior bite collapse.

reducing the need for periodontal and/or restorative therapy (Majzoub *et al*. 2014).

When extruding teeth with a healthy periodontium, a concomitant displacement of the gingival margin and the mucogingival junction occurs in 80% and 52.5% of cases, respectively (Pikdoken *et al*. 2009). Similar results have been reported in experimental studies where the free and attached gingiva followed the tooth movement in 90% and 80% of cases, respectively, while the mucogingival junction remained in the same position (Berglundh *et al*. 1991; Kajiyama *et al*. 1993). In the presence of intrabony

Fig. 47-5 *(Continued)*. (c) Orthodontic therapy accomplished by using microimplants as anchorage. Posterior dentition was restored by dental implants. (d) Final retention and esthetic treatment was accomplished with composite veneers. Posterior function was restored with implant-supported restorations. (e) Patient before treatment, after restorative therapy, and 3 years post retention.

defects, orthodontic extrusive movements will predictably eliminate the angular bony defect, but the periodontal attachment levels will remain unaltered. This treatment option is particularly indicated in the presence of one-wall intrabony defects because in these lesions periodontal regenerative techniques do not have a favorable prognosis and once the extrusive orthodontic movement has been completed the unaltered connective-tissue attachment will be positioned in a more coronal position (Ingber 1974).

Orthodontic extrusion of "hopeless" teeth for alveolar site preparation prior to implant placement has been proposed with the objective of displacing the bone crest coronally and thus facilitating implant placement levelled with the rest of the bone crest, what may reduce the need for complex bone augmentation procedures. The efficacy of this intervention has been evaluated in a systematic review, which reported improvements in alveolar bone availability with varied qualitative and quantitative gains in hard and soft tissues, although most of the identified studies were case reports or case series (Korayem *et al*. 2008). In spite of this heterogeneity and the different orthodontic methods reported in the different studies, the authors recommended: (1) the use of light, constant, extrusive forces of 15 g for the anterior teeth to 50 g for the posterior teeth; (2) the rate of extrusion should be maintained at a slow and steady rate of no more than 2.0 mm per month; (3) a buccal root torque component may be applied concomitantly to increase the buccolingual bulk of alveolar bone; (4) a retention and stabilization period of no less than 1 month for every month of active extrusion is recommended prior to extraction; and (5) overlay wires (anchorage wires) are recommended to reinforce anchorage and avoid tipping of adjacent teeth toward the tooth undergoing active extrusion (Fig. 47-6).

Depending on the amount of periodontal attachment, there will be either coronal displacement of the gingival margin when extruding the affected teeth or in cases of teeth affected with deep periodontal pockets, the marginal tissue will not move coronally until there is complete elimination of the pocket (Hochman *et al*. 2014)

Limited orthodontic extrusion has also shown an additional benefit in the correction of infrabony defects when combined with periodontal regenerative interventions. The addition of orthodontic extrusive forces attained significantly higher attachment level gains at 6 months, when compared with the same regenerative interventions without the orthodontic movements (Ogihara & Wang 2010)

Molar up-righting

The orthodontic up-righting of mesially tilted molars is particularly indicated when an angular bony defect is formed in the mesial aspect of the affected molar. This orthodontic movement will level the bone crest and eliminate the bone defect, although the periodontal attachment level will be unaltered. In these clinical situations, the recommended movement is to displace the tooth away from the defect in a disto-occlusal direction, which may increase the tension in the collagen fibers of the PDL, thus stimulating new bone formation and levelling the alveolar crest contours (Diedrich 1996). Even though the level of the connective tissue attachment remains unchanged, the new anatomical position of the molar usually translates into an improvement in probing depth levels and the crown–root ratio (Brown 1973) (Fig. 47-7).

When the mesially tilted molar has a furcation involvement, the orthodontic tooth movement may exacerbate the periodontal lesion, unless strict infection control measures prevent the development of inflammation (Burch *et al*. 1992). A valid alternative in these clinical situations is to treat the furcation lesion with either regenerative or resective approaches and then carry out the orthodontic movement subsequently in order to attain the ideal tooth position before the final restorative therapy (Muller *et al*. 1995).

Orthodontic tooth movements through cortical bone

Alveolar ridge contraction is the physiologic consequence of tooth extraction. In fact. most of the buccolingual crest reduction will occur within the first 3 months after tooth extraction (Schropp *et al*. 2003), although the resorptive process will continue, albeit at a slower pace (Carlsson *et al*. 1967). When the alveolar bone housing is thin and there is minimum trabecular bone between the buccal and lingual cortical plates, the orthodontic tooth movement may be slowed or result in bone dehiscence defects in these areas. To avoid these unwanted consequences, surgical interventions aimed at bone augmentation width have been suggested before the orthodontic movement (Diedrich 1996). Other authors have recommended undertaking orthodontic tooth movement immediately after tooth extraction to counteract this resorptive process and thus develop an appropriately sized alveolar ridge. A prospective case series in a sample of 20 patients demonstrated that orthodontic tooth movement through fresh extraction sockets maintained the profile of the ridge with less than 1% of bone contraction at 4 years (Ostler & Kokich 1994). Similar results were reported in an experimental study on dogs where the pressure side (towards the socket) showed increased bone height, while in the tension side the bone level remained unaltered (Lindskog-Stokland *et al*. 1993).

The orthodontic movement of teeth with a reduced but healthy periodontium through edentulous areas is usually possible with minimal loss of bone, provided the movement is parallel to the ridge and slight orthodontic forces are used (Hom & Turley 1984). However, experimental studies have shown that

Fig. 47-6 Patient with severe chronic periodontitis, presence of diastemata, and pathologic tooth migration, together with a hopeless prognosis for tooth 12. when bodily movements are carried out through cortical bone in a labial direction there is no bone formation in the buccal aspect of the tooth and a dehiscence defect occurs (Steiner *et al*. 1981). The orthodontic movement *per se* will not cause attachment loss and gingival recession, but the resulting bone dehiscence in combination with thin soft tissues will be a predisposing factor for attachment loss in presence of inflammation and/or trauma (Wennstrom 1996). On the contrary, lingual movements of labially displaced teeth showing dehiscence defects will result in new bone formation in the buccal aspect of the root, with concomitant soft tissue augmentation (Karring *et al*. 1982; Wennstrom *et al*. 1987). Wennstrom (1996) recommended the treatment of localized gingival recessions with orthodontic movements, whenever the affected tooth was labially displaced and lingual orthodontic movements were possible. Pini-Prato *et al*. (2000), however, recommended the placement of a gingival autograft prior to orthodontic therapy in these situations in order to prevent periodontal attachment loss and the occurrence of recession defects, because pure lingual root movements through cortical bone are difficult and in most cases crown tipping or rotation components will occur, hence moving the root buccally and causing further bone dehiscence and soft tissue loss (Fig. 47-8).

Intrusive tooth movements

Intrusive tooth movements can be attempted even in situations of reduced periodontal support provided the periodontal tissues do not have inflammation and plaque control is excellent. Melsen *et al*. (1989) recommended the use of light forces during these intrusive movements (5–15 g per tooth) to prevent root resorption, mainly in teeth with an increased crown–root ratio due to reduced periodontal support. There is controversy whether this orthodontic tooth movement should be recommended in the presence of angular bony lesions and intrabony defects. In experimental studies, when intrusive movements have been carried out in the presence of plaque, formation of periodontal pockets and infrabony defects has occurred (Ericsson *et al*. 1977; Polson *et al*. 1984). On the contrary, in the absence of inflammation, other experimental studies have shown the resolution of the intrabony defect when teeth are moved bodily into bone, although the periodontal attachment levels did not change and the healing was reparative, mainly through the formation of a long junctional epithelium. These results were contradicted by Melsen *et al*.(1988), who demonstrated in monkeys the resolution of bone defects by intrusive movement, but healing occurred through the formation of a new connective tissue attachment and periodontal regeneration. In humans, several clinical studies have also shown gains in clinical attachment levels with intrusive tooth movements in absence of periodontal inflammation (Melsen *et al*. 1989; Cardaropoli *et al*. 2001). Corrente *et al*. (2003) recommended the treatment of infrabony defects in anterior teeth by combining surgical periodontal therapy (access flaps) with intrusive orthodontic movements and reported significant attachment gains and radiographic bone fill. Similarly, Re *et al*. (2004) showed a 50% reduction in recession after intrusion of periodontally comprised teeth. These movements, however, are not always predictable and some authors have recommended that intrabony defects are first treated with surgical periodontal regenerative procedures, followed by intrusive tooth movement (Diedrich 1996; Re *et al*. 2002a). In the presence of shallow circumferential bony lesions, orthodontic intrusive movements may resolve the defect, but if these defects are deep they should be treated first with periodontal regenerative procedures. When these defects are too wide, orthodontic intrusive movements have been

recommended to improve the defect anatomy before carrying out the regenerative procedure (Rabie *et al*. 2001; Passanezi *et al*. 2007) (Fig. 47-9).

Orthodontic intrusion movements have also been recommended for leveling gingival margins with the adjacent teeth when treating extruded and misaligned teeth, since the gingival margin will move apically together with the tooth (Erkan *et al*. 2007).

Orthodontic tooth movements and periodontal regeneration

Periodontal regenerative procedures are frequent in the treatment of chronic periodontitis, particularly in the presence of infrabony defects and furcation lesions. These surgical techniques aim for the establishment of a new periodontal attachment apparatus to a root surface previously affected by periodontitis. Histologically, periodontal regeneration requires the formation of new cementum on the affected root and the establishment of new connective tissue attachment between newly formed cementum and the alveolar bone. Several regenerative technologies have demonstrated these regenerative outcomes in experimental studies, such as guided tissue regeneration (GTR), use of bone graft materials, and application of enamel matrix derivatives (EMDs). They have also evidenced clinical efficacy, as reported in several systematic reviews (for details see Chapter 38). In clinical situations where orthodontic tooth movements were planned in patients where periodontal regenerative surgeries were part of the periodontal treatment plan, there has been controversy whether these orthodontic tooth movements might be different when applied through regenerated periodontium or whether these movements might create unwanted effects (root resorption, bone loss, ankylosis, etc.). There has also been controversy on the optimum timing for starting the orthodontic therapy after the regenerative procedure, as well as the necessary stability once the teeth have been moved into regenerated areas.

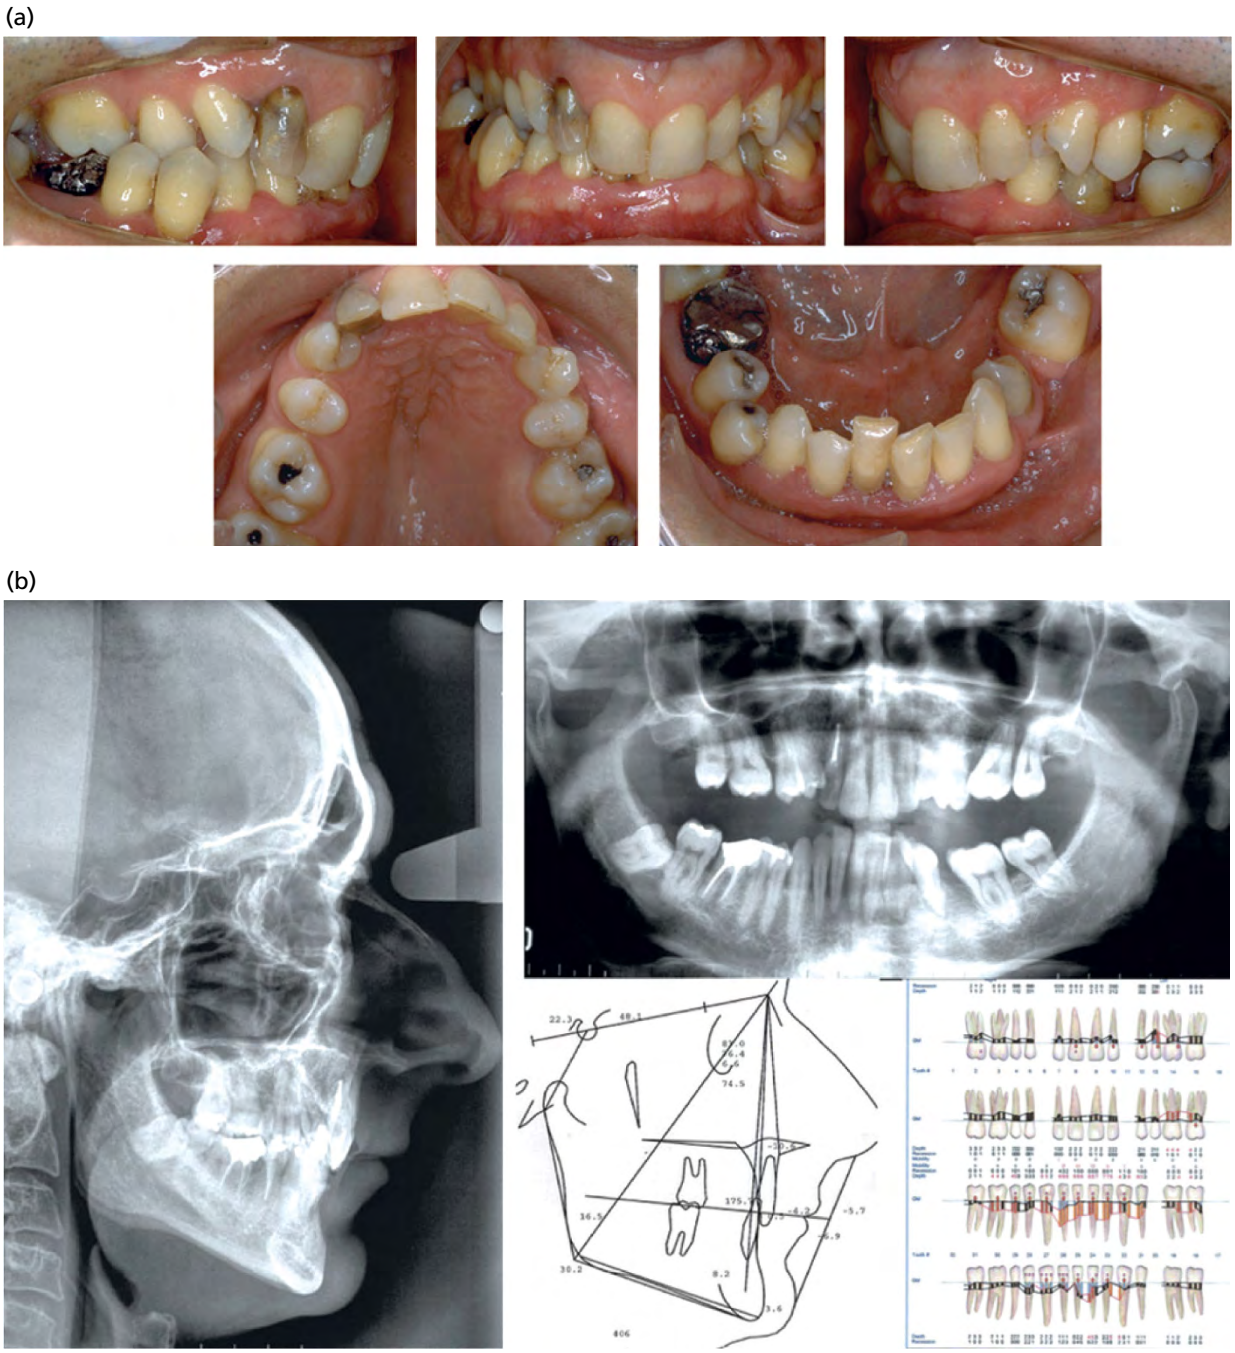

Fig. 47-9 Patient with severe chronic periodontitis and severe overbite. (a) Intraoral images before orthodontic therapy. Note the posterior bite collapse and severe overbite. (b) Initial panoramic and lateral cephalogram depicting the bone loss. The periodontal charting after therapy shows lack of periodontal pockets except in the lower anterior region, with tooth 41 having a hopeless prognosis.

Diedrich (1996) conducted a series of experimental studies evaluating the impact of orthodontic treatment on regenerated tissue after GTR procedures and demonstrated that the newly regenerated tissue was not negatively affected by the orthodontic treatment. Several case reports in humans have corroborated these experimental results, demonstrating the long-term stability of these regenerated periodontal structures subjected to orthodontic therapy (Stelzel & Flores-de-Jacoby 1995, 1998; Efeoglu *et al*. 1997).

Barrier membranes have also been utilized on fresh extraction sockets aiming to preserve the alveolar ridge and when teeth subsequently moved into these regenerated areas, the orthodontic therapy was uneventful and without complications (Tiefengraber *et al*. 2002). Also, membranes have been used to protect bone replacement grafts in corticotomy surgical procedures in combination with orthodontic therapy. Even though the membrane did not show a significant added value in the amount of tipping and new

Fig. 47-9 *(Continued)*. (c) Orthodontic therapy was aimed at aligning the teeth by intrusion of maxillary teeth. (d) End of orthodontic therapy with proper alignment of the upper incisors and re-establishment of an occlusal plane. Note the resolution of the deep overbite by orthodontic tooth intrusion.

bone formation in the buccal wall, the use of membranes promoted the augmentation of the buccal contour (Lee *et al*. 2014).

The regenerative periodontal treatment of non-contained infrabony defects usually combines bioabsorbable barrier membranes with bone grafts. These bone replacement grafts can be autologous, allogeneic, xenogeneic, and synthetic with similar outcomes, although with lesser morbidity and complications when using xenogeneic or allogenic

grafts. Orthodontic tooth movements through regenerated bone after using xenografts of bovine origin has been investigated in animal studies (Araújo *et al*. 2001; Kawamoto *et al*. 2002, 2003; da Silva *et al*. 2006; Zhang *et al*. 2006). Araújo *et al*. (2001) showed that these orthodontic tooth movements were possible without any complication. The xenogeneic deproteinized bovine bone material (DBBM) was partially resorbed on the pressure side, whereas there was no sign of resorption in the tension side. These findings are explained by the enhanced osteoclastic activity during tooth movement. Similar observations were made when implanting xenogeneic grafts into furcation defects (da Silva *et al*. 2006). When comparing the healing after the application of orthodontic tooth movements in regenerated defects with xenogeneic bone substitutes versus in non-regenerated teeth, they found no differences in the amount of newly developed bone and no signs of root resorption. Similar results were reported with the use of synthetic biomaterials and bioglasses in rats (Hossain *et al*. 1996; Kawamoto *et al*. 2002; Zhang *et al*. 2006). When comparing the behavior of different biomaterials used as bone replacement grafts after orthodontic tooth movements, the rate and amount of movement depended on the biomaterial bioabsorbability (Ru *et al*. 2016). For example, when comparing synthetic bone grafts made of hydroxyapatite and ß-tricalcium phosphate (ß-TCP) with DBBM in experimental studies, the slower rate of bioabsorbability of DBBM resulted in a slower and lesser amount of tooth movement, although the resulting orthodontic outcomes were similar (Machibya *et al*. 2018; Klein *et al*. 2019; Klein *et al*. 2020)

The results from these experimental studies have been corroborated with several clinical case series in humans where orthodontic movements were carried out in teeth previously treated with allogeneic and xenogeneic grafts in combination with collagen barrier membranes. These cases showed stable bone levels 12–18 months after the end of the orthodontic therapy, without evidence of any unwanted side effects (Yilmaz *et al*. 2000; Ogihara & Marks 2002, 2006; Re *et al*. 2002b; Naaman *et al*. 2004; Maeda *et al*. 2005; Cardaropoli *et al*. 2006; Pinheiro *et al*. 2006). There are, however, no clinical trials comparing the outcome of orthodontic therapy in teeth with and without previous regenerative therapy (Fig. 47-10).

The application of biological agents in periodontal regeneration, such as enamel matrix proteins (EMDs), has also been evaluated in relation to orthodontic tooth movements demonstrating uneventful results in both experimental studies (Diedrich 1996) and human clinical case reports (Juzanx & Giovannoli 2007). However, the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) for bone regeneration has shown complications, mainly root resorption on the pressure side (Kawamoto *et al*. 2003)

With regard to the timing of orthodontic tooth movements in relation to regenerative interventions, Ahn *et al*. (2014) evaluated the outcome of alveolar osteotomies and orthodontic tooth movements with grafting with DBBM immediately, 2 weeks, or 12 weeks after bone surgery. They concluded that application of immediate orthodontic forces accelerated the orthodontic tooth movement with favorable periodontal regeneration, and fewer complications. The effect of low-level laser therapy on orthodontic tooth movement into bone-grafted alveolar defects also demonstrated enhanced defect healing and maturation, with a decreased rate of orthodontic tooth movements, mainly when these were delayed (Kim *et al*. 2015).

Pathologic tooth migration

Pathologic tooth migration (PTM) is a common complication of periodontitis and is often the motivation for patients to seek orthodontic therapy. It is characterized by significant changes in tooth position as a consequence of the severe attachment loss and the subsequent disruption of the forces that maintain teeth in position. Its clinical presentation is characterized by extrusion and drifting out of the anterior maxillary teeth, resulting in diastemas and increased overbite. Prevalence of PTM among periodontal patients has been reported to range between 30% and 55%. The etiology of PTM appears to be multifactorial, although the destruction of periodontal supporting tissues seems to be the major factor, because in these teeth with reduced periodontal support, application of non-axial occlusive forces contributes to the abnormal migration of teeth. The soft tissue forces of the tongue, cheeks, and lips can also play a role in these unwanted tooth migrations, mostly resulting in the extrusion and flaring of the anterior teeth.

When posterior teeth are lost and there is lack of arch integrity, PTM is usually combined with posterior bite collapse and loss of vertical dimension. Treatment of this complex anatomical and functional condition will require a multidisciplinary approach with complete periodontal therapy to eliminate the infection and fully arrest inflammation, followed by orthodontic therapy and restoration of the lost dentition with dental implants and/or prosthetic restorations (Fig. 47-11).

Multidisciplinary treatment of esthetic problems

During the course of orthodontic therapy in periodontally affected dentitions the advent of unesthetic complications are relatively frequent, mainly related to loss of interdental papillae, gingival margin discrepancies, or excessive gingival exposure (Kokich 1996; Gkantidis *et al*. 2010). Kurth and Kokich

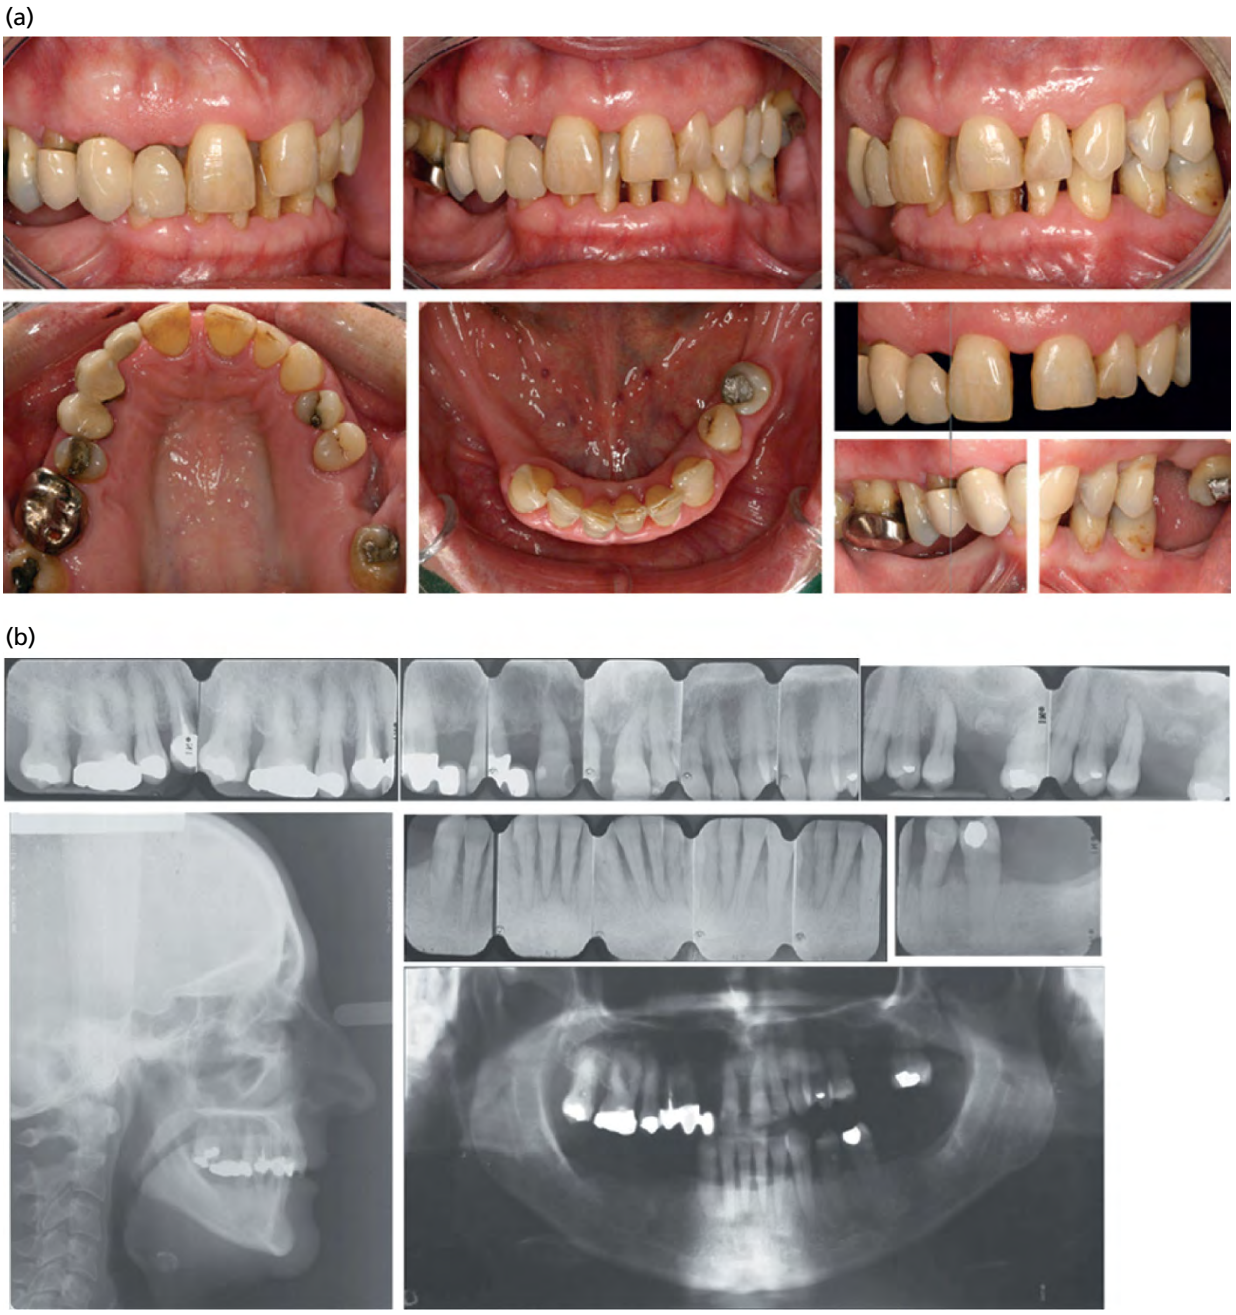

Fig. 47-10 Patient with severe chronic periodontitis, presence of deep intrabony defects in maxillary teeth, and severe malocclusion. (a) Intraoral images before orthodontic therapy. Note the anterior diastema, severe extrusion of maxillary right posterior teeth, and presence of edentulous spaces. (b) Initial panoramic, lateral cephalogram, and periapical radiographic series depicting the bone loss and presence of deep intrabony defects in the upper incisors and the upper and lower left premolars.

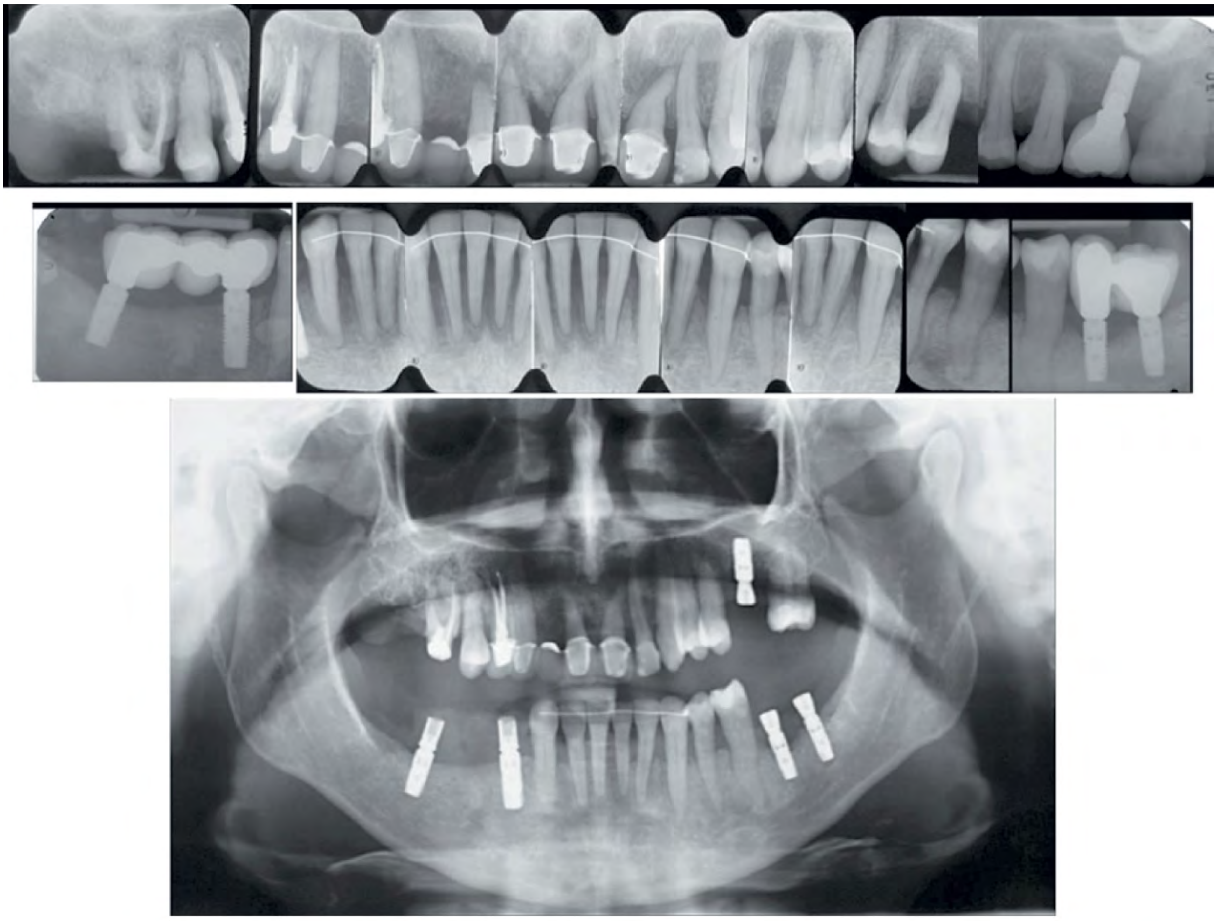
(2001) reported a 38% prevalence of open gingival embrasures in the region of the maxillary incisors after adult orthodontics.

Improper root angulation, divergent or triangular-shaped crown forms, and periodontal bone loss are factors associated with this unwanted effect. Burke *et al*. (1994) correlated the incidence and size of pretreatment tooth crowding with the post-treatment gingival embrasure space between maxillary central incisors in adult orthodontic patients. Another important factor in the loss of the interdental papilla is bone loss. Tarnow *et al*. (1992) correlated the distance from the contact point to the crest of bone with the presence or absence of the interproximal dental papilla. When this distance was 5 mm or less, the papilla was present in almost 100% of cases, when the distance was 6 mm, it was present in 56%, and when the distance was 7 mm or more, only in 27%. In the clinical situations where there is a combination of severe anterior crowding and periodontal bone loss, orthodontic therapy should be aimed not only at attaining the proper tooth alignment, but also at reducing the interdental space in order to compress the interdental soft tissues to force the formation of a new papilla. In these situations, orthodontic tooth movement should be combined with restorative

Fig. 47-10 *(Continued)*. (c) Regenerative surgical procedure using guided tissue regeneration with a xenogeneic bone graft and a collagen resorbable membrane to treat the deep one-two wall defect in tooth 21. Dental implants were placed in the posterior mandible for anchorage during orthodontic therapy. Similarly, microscrews were placed in the maxillary right posterior tooth for anchorage for the intrusive movements. (d) Orthodontic therapy was aimed at intruding the upper posterior right segment, aligning the teeth, closing the diastema, and distributing the spaces prior to final implant therapy in the posterior maxilla. The orthodontic tooth movements in the maxilla were carried out 9 months after the periodontal regenerative procedure.

(e)



(f)

Fig. 47-10 *(Continued).* (e) Final radiographs depicting stable bone levels and resolution of the intrabony defects. (f) End of orthodontic therapy with proper alignment of the upper incisors and re-establishment of an occlusal plane. Final restorations were performed using full ceramic crowns.

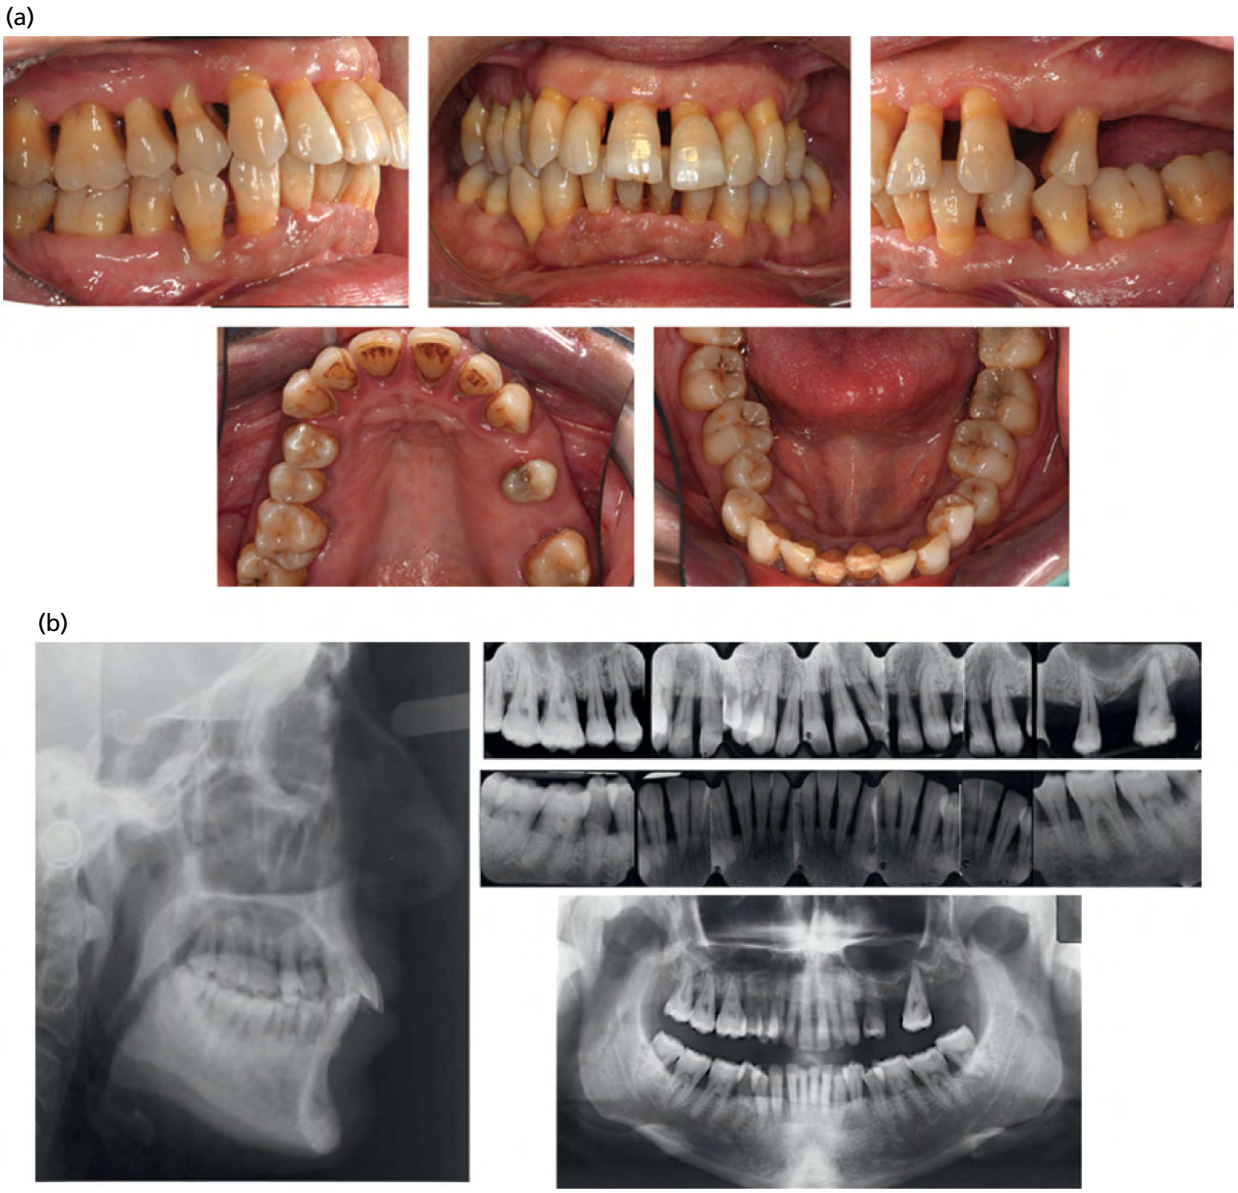


Fig. 47-11 Patient with severe chronic periodontitis, together with pathologic tooth migration, posterior right cross-bite, and posterior bite collapse. (a) Intraoral images after periodontal and before orthodontic therapy. (b) Radiographic images demonstrating the severe bone loss. Note the hopeless prognosis of tooth 26.

procedures aimed at raising the contact point, thus creating the illusion of a healthy interdental papilla.

The gingival marginal relationships of the upper anterior teeth play an important role in the aesthetic appearance of the smile. These gingival marginal contours should mimic the natural anatomy of the tooth cementoenamel junction (CEJ), providing an adequate scalloping with thin marginal tissues and papillae filling the interdental space. When orthodontic therapy is applied to periodontally affected dentitions, the occurrence of gingival marginal discrepancies is frequent and should be treated orthodontically with minor intrusive or extrusive tooth movements until the correct marginal alignment is reached. In situations with localized gingival recessions, the appropriate mucogingival surgical techniques for root coverage should be implemented before the orthodontic tooth movement (see Figs. 47-3, 47-5, 47-11).

During treatment planning it is very important to evaluate the length of the clinical crowns, the patient's gingival exposure, and the presence of gingival marginal discrepancies during smiling (Kokich 1996). Depending on these factors, different combinations of periodontal plastic surgical techniques and orthodontic tooth movements will be indicated. In some situations, the indication will be the extrusion of the longer tooth and subsequent grinding of its incisal edge, whereas in others, it will be intrusion and treatment of the resulting shorter tooth reconstruction of the incisal edge.

Fig. 47-11 *(Continued).* (c) Orthodontic therapy was aimed at intruding the upper anterior segment, aligning the teeth, and distributing the spaces prior to final implant therapy in the posterior left maxilla. (d) Final retention and esthetic treatment was accomplished with composite veneers. Note the improvement in the esthetic result and the lack of interdental papillae following the restorative work.

The problem of excessive gingival exposure (a gummy smile) can also be found frequently in adults requiring adult orthodontics. This condition may be caused by: excessive maxillary growth, tooth extrusion in deep anterior overbites, and delayed apical migration of the gingival margin over the maxillary anterior teeth. Its esthetic correction largely depends on its etiology.

If the cause of the gummy smile is the extrusion of the upper anterior teeth, orthodontic intrusion will solve the excessive gingival display. In contrast, the retardation of the physiological apical migration of gingival margins will require a mucogingival excisional surgical correction. In situations with a clear skeletal cause, an orthognathic surgical approach is the only corrective solution.

Introduction

Clinical trials on the long-term effects of the treatment of periodontitis have clearly demonstrated that post-therapeutic professional maintenance care is an integral part of this treatment. This also constitutes the only means of assuring the maintenance of long-term beneficial therapeutic effects. Re-infection could be prevented or kept to a minimum in most patients, mainly through rigid surveillance involving visits to professionals at regular intervals. However, the maintenance systems presented in the various studies do not give a clear concept with general validity for the frequency of maintenance visits to professionals and the mode of maintenance therapy. In some patients there may be a danger that re-infection and recurrent disease are neglected, while in others there may be a tendency to overtreat.

Objective criteria for assessing the patient's individual risk for recurrent disease have been the focus of attention in recent years. However, this evaluation still has to be based on a probability estimate derived from the assessment of the patient, tooth, or tooth-site risks.

The purpose of this chapter is to discuss the basics of continuous patient monitoring following active periodontal and implant therapy in order to prevent re-infection and progression of periodontal disease following therapy. The mode and extent of interceptive therapeutic measures needed to achieve this goal will also be evaluated.

Lindhe's Clinical Periodontology and Implant Dentistry, Seventh Edition. Edited by Tord Berglundh, William V. Giannobile, Niklaus P. Lang, and Mariano Sanz.

Definition

Periodontal treatment includes:

1. Systemic evaluation of the patient's health
2. Cause-related therapeutic phase
3. Corrective phase involving periodontal surgical procedures, and
4. Maintenance phase.

The 3rd World Workshop of the American Academy of Periodontology (1989) renamed the collective periodontal treatment procedures to supportive periodontal therapy (SPT). This term expresses the essential need for therapeutic measures to support the patient's own efforts to control periodontal infections and to avoid re-infection. Regular visits to the therapist should serve as a positive feedback mechanism between the patient and the therapist with the purpose of ensuring that patients can maintain their dentitions in a healthy status for the longest possible time. An integral part of SPT is the continuous diagnostic monitoring of the patient in order to intercept with adequate therapy and to optimize the therapeutic interventions tailored to the patient's needs.

Basic paradigms for the prevention of periodontal disease

Periodontal maintenance care, or SPT, follows the paradigms of the etiology and pathogenesis of periodontal and peri-implant diseases and must consider the fact that these diseases represent opportunistic infections.

Almost 60 years ago, a cause–effect relationship between the accumulation of bacterial biofilm on teeth and the development of gingivitis was proven (Löe *et al*. 1965). This relationship was also documented by the restoration of gingival health following biofilm removal. The same cause–effect relationship has been demonstrated for the peri-implant tissues between the biofilm and the development of mucositis (Salvi *et al*. 2012). This causal relationship was further characterized when loss of connective tissue attachment and resorption of alveolar bone with biofilm accumulation and the development of periodontal disease was shown in laboratory animals (Lindhe *et al*. 1975). Because some of these animals did not develop periodontal disease despite a persistent biofilm accumulation for 48 months, it must be considered that the composition of the microbiota or the host's defense mechanisms or susceptibility to disease may vary from individual to individual. Nevertheless, in the study mentioned, the initiation of periodontal disease was always preceded by obvious signs of gingivitis. Hence, it seems reasonable to predict that the elimination of gingival inflammation and the maintenance of healthy gingival tissues will prevent both the initiation and the recurrence of periodontal and peri-implant disease. In fact, as early as 1746, Fauchard stated that "little or no care as to the cleaning of teeth is ordinarily the cause of all diseases that destroy them".

From the clinical point of view, the abovementioned results must be translated into the necessity for proper and regular personal biofilm removal, at least in patients treated for or susceptible to periodontal disease. This simple principle may be difficult to implement in all patients; however, interceptive professional SPT at regular intervals may, to a certain extent, compensate for the lack of personal compliance with regard to oral hygiene standards.

These aspects have been imitated in a Beagle dog model with naturally occurring periodontal disease (Morrison *et al*. 1979). Two groups of animals were used. The test group was subjected to initial scaling and root planing and, subsequently, biofilm was eliminated by daily toothbrushing and biweekly polishing with rubber cups for a period of 3 years. In the control group, no initial scaling and no oral hygiene practices were performed during the same period of time. Every 6 months, however, the teeth in two diagonally opposed jaw quadrants in both test and control animals were scaled and root planed. The results showed that the reduction of probing pocket depth (PPD) and the gain of probing attachment obtained after the initial scaling and root planing in the test animals were maintained throughout the entire course of the study irrespective of whether or not repeated scaling and root planing had been performed. The control animals, on the other hand, continued to show increasing PPD and loss of attachment in all quadrants irrespective of whether or not repeated scaling and root planing had been performed. However, in the jaw quadrants where the teeth were repeatedly instrumented every 6 months, the progression of the periodontal destruction was significantly less pronounced (Fig. 48-1). These results indicate that professional SPT, performed at regular intervals, may, to a certain extent, compensate for a "suboptimal" personal oral hygiene standard. In this respect, it has been demonstrated that following root instrumentation, the subgingival microbiota is significantly altered in quantity and quality (Listgarten *et al*. 1978), and that the re-establishment of a disease-associated, subgingival microbiota may take several months (Listgarten *et al*. 1978; Slots *et al*. 1979; Mousquès *et al*. 1980; Caton *et al*. 1982; Magnusson *et al*. 1984).

In a number of longitudinal clinical studies on the outcome of periodontal therapy, the crucial role of SPT in maintaining successful results has been documented (Ramfjord *et al*. 1968; Lindhe & Nyman 1975; Ramfjord *et al*. 1975; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981, Hill *et al*. 1981; Lindhe *et al*. 1982a, b; Pihlström *et al*. 1983; Westfelt *et al*. 1983a; Lindhe & Nyman 1984; Westfelt *et al*. 1985; Isidor & Karring 1986; Badersten

et al. 1987; Kaldahl *et al*. 1988). In all these studies, PPD and clinical attachment levels were maintained as a result of a well-organized professional maintenance care program (SPT intervals varying between 3 and 6 months), irrespective of the initial treatment modality performed.

In one of the studies (Nyman *et al*. 1977), an alarming result was that patients treated for advanced periodontal disease involving surgical techniques, but not enrolled in a supervised maintenance care program, exhibited recurrent periodontitis, including loss of attachment, at a rate three to five times higher than documented for natural progression of periodontal disease in population groups with high disease susceptibility (Löe *et al*. 1978, 1986). Within this area, the effect of negligence in providing adequate SPT following periodontal treatment was studied over a 6-year period by Axelsson and Lindhe (1981a). Following presurgical root instrumentation and instruction in oral hygiene practices, all study patients were subjected to modified Widman flap procedures. During a 2-month healing period, professional tooth cleaning was performed every 2 weeks. Following this time period, baseline clinical data were obtained and one in every three patients was dismissed from the clinic, while the other two were enrolled in a professionally conducted maintenance program with an SPT visit once every 3 months.

These patients maintained excellent oral hygiene and consequently yielded a very low frequency of bleeding sites. In addition, PPD and probing attachment levels were maintained unchanged over the 6-year period. In contrast, the non-recalled patients demonstrated obvious signs of recurrent periodontitis at the 3-year and 6-year re-examinations. Further evidence for the likelihood of recurrent disease in patients not subjected to professional maintenance care was presented by Kerr (1981). Five years after successful treatment, 45% of the patients presented with periodontal conditions similar to their status before treatment. SPT had only been provided at intervals varying between 9 and 18 months. Similar results were obtained from a systematic review by Farooqi *et al*. (2015). Their analysis revealed that shorter intervals were positively associated with reduced tooth loss while available evidence for the indication of specific intervals (e.g. 3 months) remains scarce (Farooqi *et al*. 2015).

Even though the number of well-controlled longitudinal clinical trials is rather limited for patients who, in addition to periodontal treatment, have undergone extensive reconstructive therapy, it should be realized that the concept of professional maintenance care has unrestricted validity. In a longitudinal study of combined periodontal and prosthetic treatment of patients with advanced periodontal disease, periodontal health could be maintained over a study period of 5–8 years with regular SPT appointments scheduled every 3–6 months (Nyman & Lindhe 1979). Similar results have been presented by Valderhaug and Birkeland (1976) and by Valderhaug (1980) for periods of up to 15 years. Another study of 36 patients who received extensive poly-unit cantilevered bridgework following periodontal therapy, confirmed the maintenance of periodontal health over 5–12 years (Laurell *et al*. 1991). More recent studies on the long-term maintenance of periodontal patients who, following successful treatment of periodontitis, were reconstructed with extensive fixed reconstructions, revealed that regularly performed SPT resulted in periodontal stability. Only 1.3% (Hämmerle *et al*. 2000) and 2.0% (Moser *et al*. 2002) of the abutments showed some minor attachment loss during these long periods of observation (10 and 11 years, respectively). In contrast, a report of insurance cases who were not regularly maintained by SPT yielded a recurrence rate for periodontitis of almost 10% after an observation of 6.5 years (Randow *et al*. 1986).

Summary: The etiology of gingivitis and periodontitis is fairly well understood. However, the causative factor, that is the microbial challenge which induces and maintains the inflammatory response, may not be completely eliminated from the dentogingival and peri-implant environment for any length of time. This requires the professional removal of all microbial deposits in the supragingival and subgingival areas at regular intervals, because recolonization will occur following the debridement procedures, leading to a re-infection of the ecologic niche and, hence, further progression of the disease process. Numerous well-controlled clinical trials, however, have documented that such a development can be prevented over very long periods of time only by regular interference with the subgingival environment aimed at removal of the subgingival bacteria.

Patients at risk for periodontitis without regular supportive periodontal therapy

The effect of omission of SPT in patients with periodontitis may best be studied either in untreated populations or patient groups with poor compliance.

One of the few studies documenting untreated periodontitis-susceptible patients reported on the continuous loss of periodontal attachment as well as teeth in Sri Lankan tea plantation workers receiving no dental therapy (Löe *et al*. 1986; Ramseier *et al*. 2017). In this – for the Western world – rather unique model situation, an average loss of 0.3 mm per tooth surface and per year was encountered. Also, the laborers lost between 0.1 and 0.3 teeth per year as a result of periodontitis. In another untreated group in the USA, 0.61 teeth were lost per year during an observation period of 4 years (Becker *et al*. 1979). This is in dramatic contrast to reports on tooth loss in well-maintained patients treated for periodontitis (e.g. Hirschfeld & Wasserman 1978; McFall 1982; Becker *et al*. 1984; Wilson *et al*. 1987, Ng *et al*. 2011; Costa *et al*. 2012, 2014). Such patients were either completely stable and lost no teeth during maintenance periods ranging up to 22 years or lost only very little periodontal attachment and only 0.03 teeth (Hirschfeld & Wasserman 1978) or 0.06 teeth (Wilson *et al*. 1987).

Non-complying but periodontitis-susceptible patients receiving no SPT following periodontal surgical interventions continued to lose periodontal attachment at a rate of approximately 1 mm per year regardless of the type of surgery chosen (Nyman *et al*. 1977). This is almost three times greater than would be expected as a result of the "natural" course of periodontal disease progression (Löe *et al*. 1978, 1986; Ramseier *et al*. 2017).

In a British study of a private practice situation (Kerr 1981) where the patients were referred back to the general dentist after periodontal therapy, 45% of the patients showed complete re-infection after 5 years.

Similar results have been described for private practice patients who decided not to participate in an organized maintenance care program following active periodontal therapy (Becker *et al*. 1984). Subsequent examinations revealed clear signs of recurrent periodontal disease, including increased PPD and involvement of furcations of multirooted teeth concomitant with tooth loss. Also, loss of alveolar bone observed on radiographs and tooth loss have been reported for a group of patients in whom

SPT was provided less frequently than once every 12 months (De Vore *et al*. 1986).

From all these studies, it is evident that periodontal treatment is ineffective in maintaining periodontal health if SPT is neglected, denied, or omitted.

The most impressive documentation of the lack of SPT in disease-susceptible individuals is probably that from a clinical trial in which one-third of the patients had been sent back to the referring general practitioner for maintenance, while two-thirds of the patients received SPT in a well-organized maintenance system (Axelsson & Lindhe 1981a). The 77 patients were examined before treatment, 2 months after the last surgical procedure, and 3 and 6 years later. The 52 patients on the carefully designed SPT system visited the program every 2 months for the first 2 years and every 3 months for the remaining 4 years of the observation period. The results obtained from the second examination (2 months after the last surgery) showed that the effect of the initial treatment was good in both groups. Subsequently, the patients on SPT were able to maintain proper oral hygiene and unaltered attachment levels. In the non-SPT group, plaque-index scores increased markedly from the baseline values, as did the number of inflamed gingival units (Fig. 48-2a). Concomitantly, there were obvious signs of recurrent periodontitis. The mean values for pocket depth and attachment levels at the 3-year and 6-year examinations were higher than at baseline (Fig. 48-2b). In the SPT group, approximately 99% of the tooth surfaces showed either improvement, no change or <1 mm loss of attachment, compared with 45% in the non-SPT group (Table 48-1). In the latter patients, 55% of the sites showed a further loss of attachment of 2–5 mm at the 6-year examination, and 20% of the pockets were 4 mm deep or more (Tables 48-1, 48-2).

Summary: Patients susceptible to periodontal disease are at high risk for re-infection and progression of periodontal lesions without meticulously organized and performed SPT. Since all patients who are treated for periodontal disease belong

Table 48-1 Percentage of sites showing various changes in probing attachment level between baseline examination, 2 months after completion of active periodontal therapy, and at follow-up examination 6 years later.

Site level	Periodontal probing depths (mm)	
	SPT	Non-SPT
Attachment level improved	17	1
No change	72	10
Attachment level worse by:		
≥1 mm	10	34
2–5 mm	1	55

to this risk category by virtue of their past history, an adequate maintenance care program is of utmost importance for a beneficial long-term treatment outcome. SPT has to be aimed at the regular removal of the subgingival microbiota and must be supplemented by the patient's efforts for optimal supragingival biofilm control.

Supportive periodontal therapy for patients with gingivitis

Several studies, predominantly in children, have documented that periodic professional prophylactic visits in conjunction with reinforcement of personal oral hygiene are effective in controlling gingivitis (Badersten *et al*. 1975; Poulsen *et al*. 1976; Axelsson & Lindhe 1981a, b; Bellini *et al*. 1981). This, however, does not imply that maintenance visits in childhood preclude the development of more severe disease later in life. It is obvious, therefore, that SPT must be a lifelong commitment of both patients and oral health professionals.

Adults whose effective oral hygiene was combined with periodic professional prophylaxis were clearly healthier periodontally than patients who did not participate in such programs (Lövdal *et al*. 1961; Suomi *et al*. 1971). One particular study of historical significance was performed on 1428 adults from an industrial company in Oslo, Norway (Lövdal *et al*. 1961). Over a 5-year observation period, the subjects were recalled two to four times per year for instruction in oral hygiene and supragingival and subgingival scaling. Gingival conditions improved by approximately 60% and tooth loss was reduced by about 50% of what would be expected without these efforts.

In another study (Suomi *et al*. 1971), loss of periodontal tissue support in young individuals with gingivitis or only loss of small amounts of attachment was followed over 3 years. An experimental group receiving scaling and instruction in oral hygiene every 3 months yielded significantly less biofilm and gingival inflammation than the control group in which no special efforts had been made. The mean loss of probing attachment was only 0.08 mm per surface in the experimental as opposed to 0.3 mm in the control group.

When adult patients with gingivitis were treated with scaling and root planing, but did not improve their oral hygiene procedures, the gingival condition did not improve compared with individuals receiving prophylaxis at 6-month intervals (Listgarten & Schifter 1982).

Summary: The available information indicates that the prevention of gingival inflammation and early loss of attachment in patients with gingivitis depends primarily on the level of personal biofilm control, but also on further measures to reduce the accumulation of supragingival and subgingival biofilm.

Supportive periodontal therapy for patients with periodontitis

As mentioned previously, a series of longitudinal studies on periodontal therapeutic modalities has been performed, first at the University of Michigan, USA, later at the University of Gothenburg, Sweden, and also at the Universities of Minnesota, Nebraska, and Loma Linda, USA. These studies always enrolled patients into a well-organized maintenance care system with SPT visits at regular intervals (generally 3–4 months). Although the patients performed biofilm control with various degrees of efficacy, the SPT resulted in excellent maintenance of postoperative attachment levels in most patients (Knowles 1973; Ramfjord *et al*. 1982).

On average, excellent treatment results with maintained reduced PPD and maintained gains of probing attachment were documented for most of the patients in the longitudinal studies irrespective of the treatment modality chosen (Ramfjord *et al*. 1975; Lindhe & Nyman 1975; Rosling *et al*. 1976; Nyman *et al*. 1977; Knowles *et al*. 1979, 1980; Badersten *et al*. 1981; Hill *et al*. 1981; Lindhe *et al*. 1982a; Pihlström *et al*. 1983; Westfelt *et al*. 1983a, b, 1985; Isidor & Karring 1986; Badersten *et al*. 1987).

In a study on 75 patients with extremely advanced periodontitis, who had been successfully treated for the disease with cause-related therapy and modified Widman flap procedures (Lindhe & Nyman 1984), recurrent infection occurred in only very few sites during a 14-year period of effective SPT. However,

it has to be realized that recurrent periodontitis was noted at completely unpredictable time intervals but was concentrated in about 25% of the patient population (15 of 61). This suggests that, in a periodontitis-susceptible risk population, the majority of patients can be "cured" provided an optimally organized SPT is performed, while a relatively small proportion of patients (20–25%) will suffer from occasional episodes of recurrent periodontal re-infection. It is obviously a challenge for the therapist to identify such patients with very high disease susceptibility and to monitor the dentitions for recurrent periodontitis on a long-term basis.

Two decades later, the effect of a 30-year biofilm control-based maintenance program in a private dental office on tooth mortality, caries, and periodontal disease progression was presented (Axelsson *et al*. 2004). This prospective controlled cohort study initially included 375 test and 180 control patients who received traditional maintenance care (by the referring dentist once or twice a year). After 6 years, the control group was discontinued. The test group was subjected to prophylactic visits every second month for the first 2 years and every 3–12 months (according to their individual needs) over 3–30 years. The prophylactic visits to the dental hygienist included biofilm disclosure and professional mechanical tooth cleaning, including the use of a fluoride-containing dentifrice. During the 30 years of maintenance, very few teeth were lost (0.4–1.8), and rare teeth loss was predominately the result of root fractures. Over the 30 years of maintenance, 1.2–2.1 new carious lesions (>80% secondary caries) were found. During this period, only 2–4% of all sites exhibited periodontal attachment loss of ≥2 mm. This unique study clearly demonstrated that SPT based on biofilm control tailored to the individual needs of the patient will result in very low tooth mortality, minimal recurrent caries, and almost complete periodontal stability.

Summary: SPT is an absolute prerequisite to guarantee beneficial treatment outcomes with maintained levels of clinical attachment over long periods of time. For the majority of patients, the maintenance of treatment results has been documented for up to 14 years, and in a private practice situation even up to 30 years, but it has to be realized that a small proportion of patients will experience recurrent infections with progression of periodontal lesions in a few sites in a completely unpredictable mode. The continuous risk assessment at subject, tooth, and tooth-site levels, therefore, represents a challenge for the SPT concept.

Continuous multilevel risk assessment

As opposed to an initial periodontal diagnosis which considers the sequelae of the disease process, in other words documents the net loss of periodontal attachment, the concomitant formation of periodontal pockets, and the existence of inflammation, clinical diagnosis during SPT has to be based on the variations of the health status following successful active periodontal treatment. This, in turn, means that a new baseline has to be established once the treatment goals of active periodontal therapy (i.e. phases 1–3) are reached and periodontal health is restored (Claffey 1991). This baseline includes the level of clinical attachment achieved while the inflammatory parameters are supposed to be under control. Under optimal circumstances, SPT would maintain the clinical attachment levels obtained after active therapy for many years. However, if re-infection occurs, the loss of clinical attachment will progress. The relevant question is, therefore, which clinical parameters serve as early indicators for a new onset or recurrence of the periodontal disease process, that is re-infection and progression of periodontal breakdown of a previously treated periodontal site? It is also very important to achieve consistency in the definition of a "progressive" case in order to be able to interpret the results of clinical studies evaluating risk factors/indicators for the disease progression. Such a definition was proposed during the 5th European Workshop in Periodontology (Tonetti & Claffey 2005): presence of two or more teeth with longitudinal loss of proximal attachment of ≥3 mm. Where serial proximal attachment level measurements are not available, longitudinal radiographic bone loss of ≥2 mm at two or more teeth may be used as a substitute.

From a clinical point of view, the stability of periodontal conditions reflects a dynamic equilibrium between bacterial aggression and effective host response. As such, this homeostasis is prone to sudden changes whenever one of the two factors prevails. Hence, it is evident that the diagnostic process must be based on continuous monitoring of the multilevel risk profile. The intervals between diagnostic assessments must also be chosen based on the overall risk profile and the expected benefit. To schedule patients for SPT on the basis of an individual risk evaluation for recurrence of disease has been demonstrated to be cost-effective (Axelsson & Lindhe 1981a, b; Axelsson *et al*. 1991).

Subject periodontal risk assessment

The patient's risk for recurrence of periodontitis may be evaluated on the basis of a number of clinical conditions whereby no single parameter displays a paramount role. The entire spectrum of risk factors and risk indicators should be evaluated simultaneously. For this purpose, a functional diagram has been constructed (Fig. 48-3) (Lang & Tonetti 2003) including the following aspects:

- Patient-level percentage of bleeding on probing (BoP)
- Prevalence (number) of residual pockets ≥4 mm following active periodontal therapy
- Loss of teeth from a total of 28 teeth

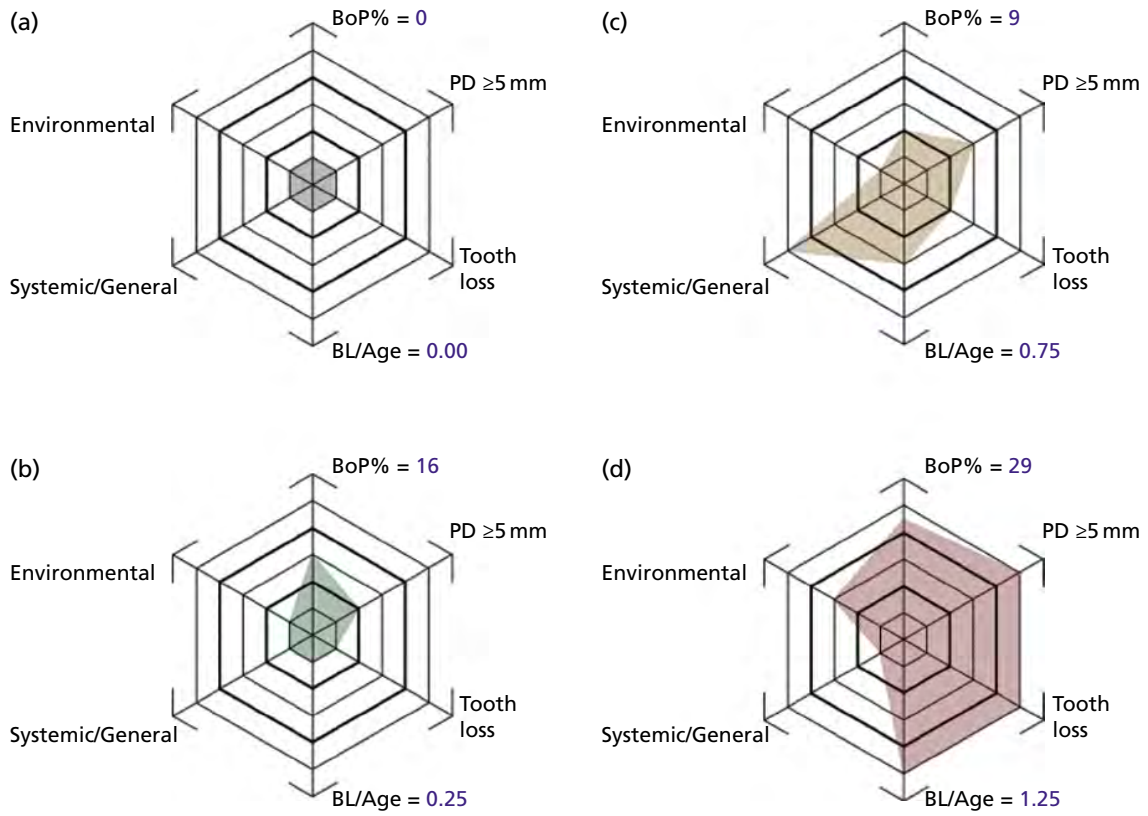

Fig. 48-3 (a) Functional diagram to evaluate the patient's risk for recurrence of periodontitis. Each vector represents one risk factor or indicator with an area of relatively low risk, an area of medium risk, and an area of high risk for disease progression. All factors have to be evaluated together and hence, the area of relatively low risk is found within the center circle of the polygon, while the area of high risk is found outside the periphery of the second polygon in bold. Between the two rings in bold, there is the area of moderate risk. Source: From: www.perio-tools.com/pra. (b) Functional diagram of a low-risk maintenance patient. Bleeding on probing (BoP) is 15%, four residual pockets of ≥5 mm are diagnosed, two teeth have been lost, the bone factor in relation to the patient's age is 0.25, no systemic factor is known, and the patient is a non-smoker. (c) Functional diagram of a medium-risk maintenance patient. BoP is 9%, six residual pockets of ≥5 mm are diagnosed, four teeth have been lost, the bone factor in relation to the patient's age is 0.75, the patient has type I diabetes, but is a non-smoker. (d) Functional diagram of a high-risk maintenance patient. BoP is 32%, 10 residual pockets of ≥5 mm are diagnosed, 10 teeth have been lost, the bone factor in relation to the patient's age is 1.25, no systemic factors are known, and the patient is an occasional smoker. BL, bone loss; PPD, probing pocket depth. (Source: Lang & Tonetti 2003. Reproduced with permission from John Wiley & Sons.)

- Loss of periodontal support in relation to the patient's age
- Systemic and genetic conditions
- Environmental factors such as cigarette smoking.

Each parameter has its own scale for low, medium, and high-risk profiles. A comprehensive evaluation of these factors after active periodontal therapy will provide an individualized total risk profile and help in determining the frequency and complexity of SPT visits. Modifications may be made to the functional diagram if additional factors become important in the future. The validity of the periodontal risk assessment (PRA) in identifying various patient-based risk levels for disease progression following active periodontal treatment has been tested in several cohort studies around the world (Lang *et al*. 2015).

The assessment of the risk parameters for the subject-based risk assessment may be repeated after a number of years, preferably 5 years. In the meantime, more detailed assessment of the residual periodontal pocket profiles and BoP may be additionally helpful to decide on the specific interval of 3 to a maximum of 12 months (see Determination of personalized supportive periodontal therapy intervals).

The PRA tool may easily be used online at www.perio-tools.com/pra.

Compliance with the SPT system

Several investigations have indicated that only a minority of periodontal patients comply with the prescribed SPT (Wilson *et al*. 1984; Mendoza *et al*. 1991; Checchi *et al*. 1994; Demetriou *et al*. 1995). In a more recent study it was confirmed that approximately 25% of patients no longer returned for SPT despite a recommendation being made (Ramseier *et al*. 2014). Because it has been clearly established that treated periodontal patients who comply with regular periodontal maintenance appointments have a better prognosis than patients who do not comply (Axelsson & Lindhe 1981a; Becker *et al*. 1984; Cortellini *et al*. 1994, 1996), non-compliant or poorly compliant patients should be considered at higher risk for periodontal

disease progression. A report that investigated the personality differences of patients participating in a regular SPT program following periodontal therapy as compared with patients who did not, revealed that the latter patients had higher incidences of stressful life events and less stable personal relationships (Becker *et al*. 1988). Moreover, it is convincingly demonstrated that smokers yielded a significantly lower compliance rate than did non-smokers or former smokers (Ramseier *et al*. 2014).

Oral hygiene

Since bacterial biofilms are by far the most important etiologic agent for the occurrence of periodontal diseases (for review see Kornman & Löe 1993), it is evident that full-mouth assessment of the bacterial load must have a pivotal role in the determination of the risk for disease recurrence. It has to be realized, however, that regular interference with the microbial ecosystem during periodontal maintenance will eventually obscure such obvious associations. In patients treated with various surgical and non-surgical modalities, it has been clearly established that biofilm-infected dentitions will yield recurrence of periodontal disease in multiple locations, while dentitions under biofilm control and regular SPT maintain periodontal stability for many years (Rosling *et al*. 1976; Axelsson & Lindhe 1981a, b). Studies have thus far not identified a level of biofilm infection compatible with maintenance of periodontal health. However, in a clinical set-up, a biofilm control record of at most 20% will be tolerated in most patients. It is important to realize that the full-mouth biofilm score has to be related to the host response of the patient, in other words compared with inflammatory parameters.

Percentage of sites with bleeding on probing

Bleeding on gentle probing represents an objective inflammatory parameter which has been incorporated into index systems for the evaluation of periodontal conditions (Löe & Silness 1963; Mühlemann & Son 1971) and is also used as a parameter alone (Lang *et al*. 1986, 1991). In a patient's risk assessment for recurrence of periodontitis, BoP reflects, at least in part, the patient's compliance and standards of oral hygiene performance. No acceptable level of prevalence of BoP in the dentition above which there is a higher risk for disease recurrence has been established. However, a BoP prevalence of 20% was the cut-off point between patients with maintained periodontal stability for 5 years and patients with recurrent disease in the same timeframe in a retrospective study (Ramseier *et al*. 2015) (Fig. 48-4). Further evidence of BoP percentages between 20% and 30% determining a higher risk for disease progression originates from studies by Claffey *et al*. (1990), Badersten *et al*. (1990), and Joss *et al*. (1994).

In assessing the patient's risk for disease progression, BoP percentages reflect a summary of the patient's ability to perform proper biofilm control, his/her host response to the bacterial challenge, and his/her compliance. The percentage of BoP, therefore, is used as the first risk factor in the functional diagram of risk assessment (see Fig. 48-3). The scale runs in a quadratic mode with 4, 9, 16, 25, 36, and >49% being the divisions on the vector.

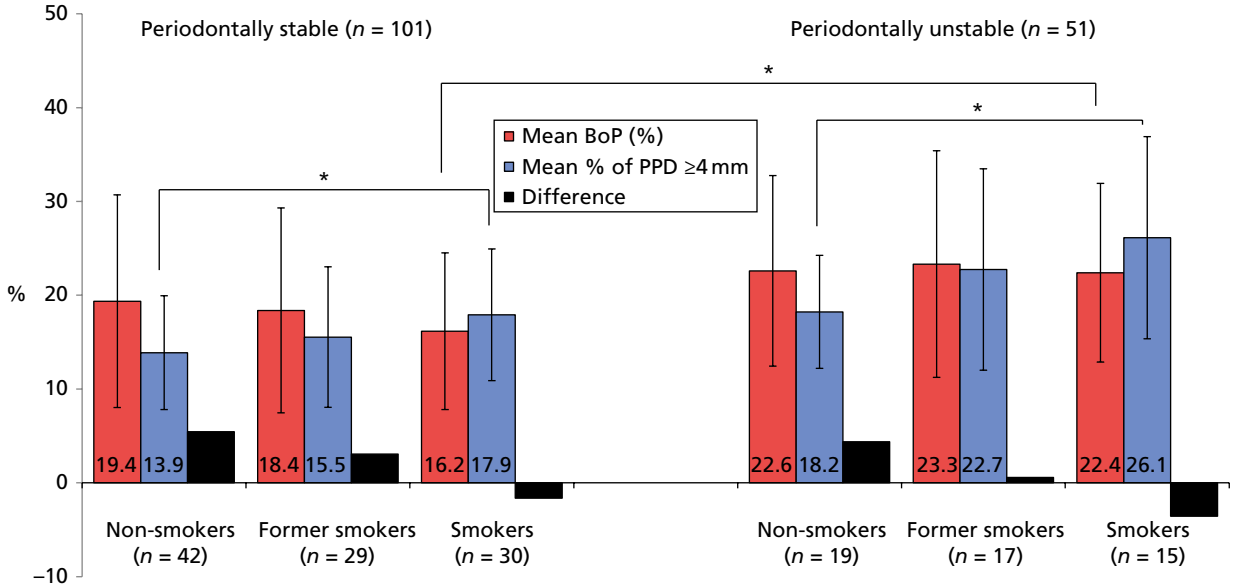

Fig. 48-4 Mean bleeding on probing (BoP), mean percentage of periodontal probing depths (PPD) ≥4 mm and calculated difference per smoking status over 5 years of supportive periodontal therapy in 101 periodontally stable and 51 periodontally unstable patients initially categorized with periodontitis stage III. Error indicators specify the standard deviation (SD). Calculated negative differences in both periodontally stable and unstable smokers represent a higher mean percentage of PPD ≥4 mm compared with a lower mean BoP. *Statistically significant difference at $P < 0.05$. (Source: Data from Ramseier *et al*. 2015. Reproduced with permission from John Wiley & Sons.)

Individuals with low mean BoP percentages (<10% of the surfaces) may be regarded as patients with a low risk for recurrent disease (Lang *et al*. 1990), whereas patients with mean BoP percentages of >25% should be considered to be at high risk for re-infection.

Prevalence of residual pockets of ≥5 mm

The enumeration of the residual pockets with a PPD of ≥5 mm represents, to a certain extent, the degree of success of the periodontal treatment rendered. Although this depth *per se* does not make much sense when considered as a sole parameter, the evaluation in conjunction with other parameters, such as BoP and/or suppuration, will reflect existing ecologic niches from and in which re-infection might occur. It is, therefore, conceivable that periodontal stability in a dentition is reflected by a minimal number of residual pockets. At a site level, the presence of deep residual pockets after initial periodontal therapy and deepening of pockets during SPT has been associated with high risk for disease progression (Badersten *et al*. 1990; Claffey *et al*. 1990; Matuliene et al. 2008). At the patient level, however, this evidence is evolving. In one study of 16 patients suffering from advanced periodontitis (Claffey & Egelberg 1995), the presence of high proportions of residual PPD of ≥6 mm after initial periodontal therapy indicated patient susceptibility for further attachment loss over a 42-month period. In a retrospective study of mean duration of 11.3 years, SPT was provided for 172 patients treated for periodontitis (Matuliene *et al*. 2008). Analysis of the data at the patient level demonstrated that, besides heavy smoking (≥20 cigarettes/day), SPT duration exceeding 10 years, initial diagnosis of periodontitis stage III and IV (Tonetti & Claffey 2005), and the presence of at least one site with PPD of ≥6 mm or nine or more sites with PPD of ≥5 mm contribute significantly to the risk of periodontitis progression (Matuliene *et al*. 2008).

On the other hand, it has to be realized that an increased number of residual pockets does not necessarily imply an increased risk for re-infection or disease progression, because a number of longitudinal studies have established that, depending on the individual SPT provided, even deeper pockets may be stable without further disease progression for years (e.g. Knowles *et al*. 1979; Lindhe & Nyman 1984; Ramseier *et al*. 2019).

Nevertheless, in assessing the patient's risk for disease progression, the number of residual pockets with a PPD of ≥5 mm is assessed as the second risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 48-3). The scale runs in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector. Individuals with up to four residual pockets may be regarded as at a relatively low risk, while patients with more than eight residual pockets may be regarded as at high risk for recurrent disease.

Loss of teeth from a total of 28 teeth

Although the reason for tooth loss may not be known, the number of remaining teeth in a dentition reflects the functionality of the dentition. Mandibular stability and individual optimal function may be assured even with a shortened dental arch of premolar to premolar occlusion, that is 20 teeth. The shortened dental arch does not seem to predispose the individual to mandibular dysfunction (Witter *et al*. 1990, 1994). However, if more than eight teeth from a total of 28 teeth are lost, oral function is usually impaired (Käyser 1981, 1994, 1996). Since tooth loss also represents a true end-point outcome variable reflecting the patient's history of oral diseases and trauma, it is logical to incorporate this risk indicator as the third parameter in the functional diagram of risk assessment (see Fig. 48-3). The number of teeth lost from the dentition without the third molars (28 teeth) is counted, irrespective of their replacement being pontics or implants. The scale runs also in a linear mode with 2, 4, 6, 8, 10, and ≥12% being the divisions on the vector.

Individuals with up to four teeth lost may be regarded as patients at low risk, while patients with more than eight teeth lost may be considered as being at high risk.

Loss of periodontal support in relation to the patient's age

The extent and prevalence of periodontal attachment loss (i.e. previous disease experience and susceptibility), as evaluated by the height of the alveolar bone on radiographs, may represent the most obvious indicator of subject risk when related to the patient's age. In light of the present understanding of periodontal disease progression, and the evidence that both onset and rate of progression of periodontitis might vary among individuals and over different timeframes (van der Velden 1991; Ramseier *et al*. 2017), it has to be realized that previous attachment loss in relation to the patient's age does not rule out the possibility of rapidly progressing lesions. Therefore, the actual risk for further disease progression in a given individual may occasionally be underestimated. Hopefully, the rate of progression of disease has been positively affected by the treatment rendered and, hence, previous attachment loss in relation to the patient's age may be a more accurate indicator during SPT than before active periodontal treatment. Given the hypothesis that a dentition may be functional for the most likely life expectancy of the subject in the presence of a reduced height of periodontal support (i.e. 25–50% of the root length), the risk assessment in treated periodontal patients may represent a reliable prognostic indicator for the stability of the overall treatment goal of keeping a functional dentition for a lifetime (Papapanou *et al*. 1988).

The estimation of the loss of alveolar bone is performed in the posterior region on either periapical

radiographs, in which the worst site affected is estimated grossly as a percentage of the root length, or on bitewing radiographs in which the worst site affected is estimated in millimeters. One millimeter equates to 10% bone loss. The percentage is then divided by the patient's age. This results in a factor. As an example, a 40-year-old patient with 20% bone loss (BL) at the worst posterior site affected would be scored BL/Age = 0.5. Another 40-year-old patient with 50% BL at the worst posterior site scores BL/Age = 1.25.

In assessing the patient's risk for disease progression, the extent of alveolar bone loss in relation to his/her age is estimated as the fourth risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 48-3). The scale runs in increments of 0.25 of the factor BL/Age, with 0.5 being the division between low and moderate risk, and 1.0 being the division between moderate and high risk for disease progression. This, in turn, means that a patient who has lost a higher percentage of posterior alveolar bone than expected for his/her own age is at high risk regarding this vector in a multifactorial assessment of risk.

Systemic conditions

The most substantiated evidence for modification of disease susceptibility and/or progression of periodontal disease arises from studies on type I and type II (insulin-dependent and non-insulin-dependent) diabetes mellitus populations (Gusberti *et al*. 1983; Emrich *et al*. 1991; Genco & Löe 1993).

It has to be realized that the impact of diabetes on periodontal diseases has been documented in patients with untreated periodontal disease. It is reasonable to assume that the influence of systemic conditions may also affect recurrence of disease.

In recent years, genetic markers have become available to determine various genotypes of patients regarding their susceptibility for periodontal diseases. Initial research on the interleukin-1 (IL-1) polymorphisms has indicated that *IL-1* genotype-positive patients show more advanced periodontitis lesions than *IL-1* genotype-negative patients of the same age group (Kornman *et al*. 1997). Also, there is a trend to higher tooth loss in the *IL-1* genotype-positive subjects (McGuire & Nunn 1999). In a retrospective analysis of over 300 well-maintained periodontal patients, the *IL-1* genotype-positive patients showed significantly higher BoP percentages, and a higher proportion of these patients yielded higher BoP percentages during a 1-year SPT period than the *IL-1* genotype-negative control patients (Lang *et al*. 2000). Also, the latter group had twice as many patients with improved BoP percentages during the same maintenance period, indicating that *IL-1* genotype-positive subjects do indeed represent a group of hyperreactive subjects even if they are regularly maintained by effective SPT (Lang *et al*. 2000). In a prospective study over 5 years on Australian white and blue collar workers at a university campus, the *IL-1* genotype-positive group aged above 50 years showed significantly deeper PPD than their *IL-1* genotype-negative counterparts, especially when they were non-smokers (Cullinan *et al*. 2001). Moreover, tooth loss was assessed in 5117 adults categorized as either low or high risk as determined by the quantitative presence of risk factors such as cigarette smoking, diabetes, and *IL-1* genotype, respectively. Specifically, in adults at high risk, two annual dental visits were positively associated with reduced tooth loss when compared with high-risk individuals attending fewer annual dental visits (Giannobile *et al*. 2013).

In assessing the patient's risk for disease progression, systemic factors are only considered, if known, as the fifth risk indicator for recurrent disease in the functional diagram of risk assessment (see Fig. 48-3). In this case, the area of high risk is marked for this vector. If not known or absent, systemic factors are not taken into account in the overall evaluation of risk.

Research on the association and/or modifying influence on susceptibility and progression of periodontitis of physical or psychological stress is sparse (Cohen-Cole *et al*. 1981; Green *et al*. 1986; Freeman & Goss 1993). The hormonal changes associated with this condition, however, are well documented (Selye 1950).

Cigarette smoking

Consumption of tobacco, predominantly in the form of smoking or chewing, affects the susceptibility and the treatment outcome of patients with adult periodontitis. Classic explanations for these observations have included the association between smoking habits and poor oral hygiene, as well as lack of awareness of general health issues (Pindborg 1949; Rivera-Hidalgo 1986). More recent evidence, however, has established that smoking *per se* represents a true risk factor for periodontitis (Ismail *et al*. 1983; Bergström 1989; Bergström *et al*. 1991; Haber *et al*. 1993). In a young population (19–30 years of age), 51–56% of periodontitis was associated with cigarette smoking (Haber *et al*. 1993). The association of smoking and periodontitis has been shown to be dose-dependent (Haber *et al*. 1993). It has also been shown that smoking affects the treatment outcome after scaling and root planing (Preber & Bergström 1985), modified Widman flap surgery (Preber & Bergström 1990), and regenerative periodontal therapy (Tonetti *et al*. 1995). Furthermore, a high proportion of so-called refractory patients have been identified as smokers (Bergström & Blomlöf 1992). The impact of cigarette smoking on the long-term effects of periodontal therapy in a population undergoing SPT has been reported. Smokers displayed less favorable healing responses both at re-evaluation and during a 6-year period of SPT (Baumert-Ah *et al*. 1994). This was confirmed in another study in which higher percentages

of heavy smokers experienced more multiple (≥9) residual pockets (≥5 mm) than non-smokers both after active periodontal therapy (31.2% versus 7.3%, respectively) and after 11 years of SPT (52.4% versus 14.8%, respectively) (Matuliene *et al*. 2008). In this study, heavy smoking was found to be a significant risk factor for periodontitis progression. Moreover, smoking was the main statistically significant risk factor for the recurrence of periodontitis after 10.5 years of SPT in the 84 patients with periodontitis stage IV, grade C. More than half of the current smokers in this study showed a recurrence of disease at re-examination and had a ten-fold increased risk for a relapse compared with non-smokers (Bäumer *et al*. 2011). In a systematic review of 13 observational studies of long-term periodontal maintenance, smoking was found to be associated with tooth loss, which could be interpreted as the end-point event of periodontitis progression (Chambrone *et al*. 2010).

In conclusion, today there is enough evidence relating cigarette smoking to impaired outcomes during SPT. Therefore, it seems reasonable to include heavy smokers (>20 cigarettes/day) in a higher risk group during SPT.

In assessing the patient's risk for disease progression, environmental factors such as smoking must be considered as the sixth risk factor for recurrent disease in the functional diagram of risk assessment (see Fig. 48-3). While non-smokers (NS) and former smokers (FS) (>5 years since cessation) have a relatively low risk for recurrence of periodontitis, heavy smokers (HS), as defined by smoking more than one pack per day, are definitely at high risk. Occasional (OS; <10 cigarettes/day) and moderate smokers (MS; 11–19 cigarettes/day) may be considered at moderate risk for disease progression.

Conducting the patient's individual periodontal risk assessment

Based on the six parameters specified above, a multifunctional diagram is constructed for the PRA. In this diagram, the vectors have been constructed on the basis of the scientific evidence available. It is obvious that ongoing validation may result in slight modifications.

- *Low periodontal risk (PR) patient*: all parameters within the low-risk categories or at the most one parameter in the moderate-risk category (Fig. 48-3b)
- *Moderate PR patient*: at least two parameters in the moderate category, but at most only one parameter in the high-risk category (Fig. 48-3c)
- *High PR patient*: at least two parameters in the high-risk category (Fig. 48-3d).

The application of the multifunctional diagram for the subject-based PRA was validated in several studies. A 4-year prospective cohort study (Persson *et al*. 2003) yielded complete periodontal stability after individually tailored SPT intervals for all patients with a negative *IL-1* gene polymorphism. For the *IL-1* genotype-positive patients, however, the PRA resulted only in periodontal stability for 90% of the patients. On the other hand, two recently published studies of 100 and 160 patients evaluating the results of SPT of mean duration of >10 years demonstrated that patients with a high-risk profile after active periodontal therapy were more prone to recurrence of periodontitis (Matuliene *et al*. 2010) and to tooth loss (Eickholz *et al*. 2008; Matuliene *et al*. 2010) than the patients with a moderate- or a low-risk profile.

Summary: The subject risk assessment may estimate the risk for susceptibility to progression of periodontal disease. It consists of an assessment of the level of infection (full-mouth BoP), the prevalence of residual periodontal pockets, tooth loss, an estimation of the loss of periodontal support in relation to the patient's age, an evaluation of the systemic conditions of the patient, and finally, an evaluation of environmental and behavioral factors such as smoking and stress. All these factors should be contemplated and evaluated together. A functional diagram (see Fig. 48-3) may help the clinician in determining the risk for disease progression at the subject level. A tool to compute patient-level periodontal risk profile is found online at www.perio-tools.com/pra. This may be useful in customizing the frequency and content of SPT visits.

Tooth risk assessment

It has to be realized that the subject-based risk assessment may be supplemented by the individual tooth risk assessment which encompasses an estimation of the residual periodontal support, an evaluation of tooth positioning, furcation involvements, presence of iatrogenic factors, and a determination of tooth mobility to evaluate functional stability. A risk assessment at tooth level may be useful in evaluating the prognosis and function of an individual tooth and may indicate the need for specific therapeutic measures during SPT visits.

Site risk assessment

It is suggested that patients are evaluated at *three different levels*. At the *patient-level*, loss of support in relation to patient age, full-mouth biofilm and/or BoP scores, and prevalence of residual pockets are evaluated, together with the presence of systemic conditions or environmental factors, such as smoking, which can influence the prognosis. The clinical utility of this first level of risk assessment influences primarily the determination of the SPT frequency and time requirements of maintenance. It should also provide a perspective for the evaluation of the risk assessment conducted at the tooth and tooth-site levels.

At the *tooth- and tooth-site levels*, residual periodontal support, inflammatory parameters and their persistence, presence of difficult to access ecologic niches, such as furcations, and presence of iatrogenic factors have to be put into perspective with the patient's overall risk profile. The clinical utility of tooth and tooth-site risk assessment relates to the rational allocation of the time available for therapeutic intervention to the sites with higher risk, and possibly to the selection of different forms of therapeutic intervention.

Objectives for supportive periodontal therapy

The objective of maintenance care must be the continued preservation of gingival and periodontal health, obtained as a result of the active periodontal treatment. Irrespective of whether or not additional treatment such as prosthetic reconstructions or placement of implants has been rendered, the regular and adequate removal of supragingival biofilm by the patient is, therefore, a prerequisite for a good long-term prognosis. In order to achieve these goals, regular clinical re-evaluations with appropriate interceptive treatment, continued psychological support and encouragement of the patient, and a lifelong commitment by the therapists are required.

General rules regarding frequency of maintenance care visits are difficult to define. However, there are a few aspects to consider in this respect: the patient's individual oral hygiene standard, the prevalence of sites exhibiting BoP, and the pretherapeutic attachment level and alveolar bone height. This in turn means that patients with suboptimal biofilm control and/or concomitant high prevalence of bleeding sites should be recalled more frequently than patients exhibiting excellent biofilm control and healthy gingival tissues. Nevertheless, patients with healthy gingival conditions, but with a severely reduced height of periodontal support, should also be recalled at short time intervals (not exceeding 3–4 months) in order to exclude or at least reduce the risk of additional tooth loss. In most of the longitudinal studies referred to above, positive treatment results were maintained with regular maintenance care provided at 3–6-month intervals. It seems reasonable to commence post-therapeutic maintenance with SPT visits once every 3–4 months and then shorten or prolong these intervals in accordance with the aspects discussed above.

Since clinical attachment levels are usually stable 6 months following active periodontal therapy, it has been suggested that the first 6 months after completion of therapy be considered a healing phase (Westfelt *et al*. 1983b) during which frequent professional tooth cleaning has been recommended. Following this healing phase, it is generally agreed to recall SPT patients treated for periodontal disease at intervals of 3–4 months in a well-organized system of SPT. It has to be realized that tissue contours may be subjected to remodeling processes despite stable clinical attachment levels and, hence, morphologic changes may still improve the accessibility of all tooth surfaces to oral hygiene practices for months and even years. Proper oral hygiene practices appear to be the most important patient factor that can guarantee long-term stability of treatment results (Knowles *et al*. 1979; Ramfjord *et al*. 1982; Lindhe & Nyman 1984; Ramfjord *et al*. 1987). This, in turn, necessitates optimization of the patient's skills and continuous motivation and reinforcement to perform adequate mechanical oral hygiene practices. It is obvious that regular visits for SPT should be scheduled soon after completion of cause-related therapy, even if periodontal surgical procedures are still to be performed following a careful re-evaluation of the tissue response. To postpone the organization of a maintenance care program until corrective procedures such as surgery, endodontic, implant, operative or reconstructive therapy have been performed may reinforce a possible misconception by the patient that the professional visits to a therapist or hygienist guarantee positive treatment outcomes and optimal long-term prognosis rather than the patient's own regular performance of individually optimal and adequate oral hygiene practices.

Determination of personalized supportive periodontal therapy intervals

As the PRA is applied after periodontal therapy and then at intervals of approximately 5–10 years, it is desirable to develop an algorithm for fine-tuning the interval between SPT visits to be applied at every visit. The basis for such an effort comes from a recently published study (Ramseier *et al*. 2019). In this study, a total of 445 patients were followed over a period of at least 5 years resulting in a total 8741 SPT visits evaluated. Special attention had been given to the profile of residual pockets of various depths and the longitudinal performance of the patients depending on their SPT interval. An algorithm was constructed in which the interval between SPT visits was tailored to the residual pocket profile of a given patient. Generally, the pocket probing depths tended to decrease with shorter intervals, whereas, with longer SPT intervals, the number of residual pockets increased between two subsequent visits. The intersection of the numbers of residual pockets that were increasing or decreasing, respectively, resulted in a number of thresholds determining the interval which maintained periodontal stability (Fig. 48-5).

In Fig. 48-5 it is evident that, for example, a patient, following an SPT interval of 3 months, may yield periodontal stability with 30% of 4 mm or more, 20% of at least 5 mm, and even 4% of 6 mm PPD. However, if the SPT interval is higher (4 months) the respective percentages for residual pockets tolerated for periodontal stability are 20% for ≥4 mm, 10% for

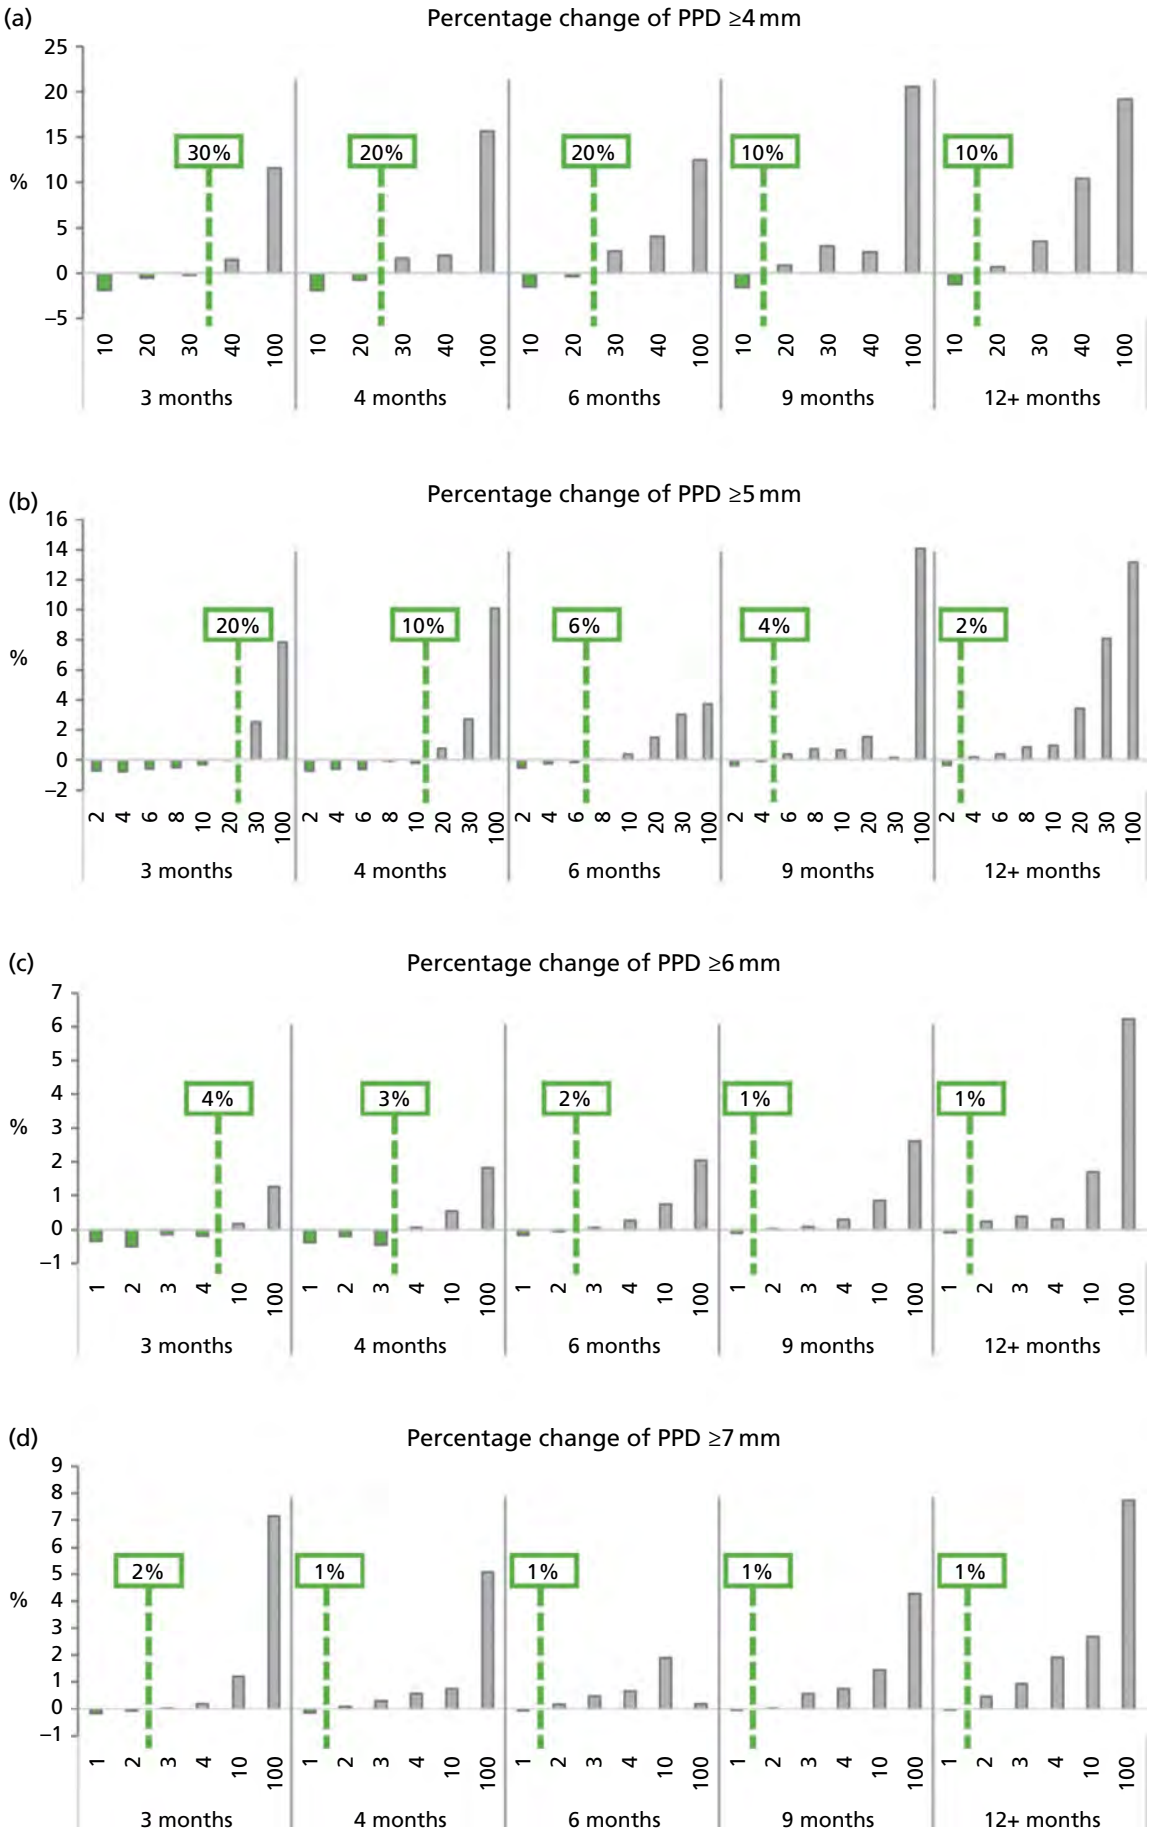

Fig. 48-5 Percentage change increase (+) and decrease (-) of residual periodontal probing depths (PPD) from 11 842 supportive periodontal therapy (SPT) visits and 883 patients in relation to the length of SPT intervals (3, 4, 6, 9, and 12+ months) and the category of residual PPD recorded at the previous SPT visit. Empirically determined thresholds of no change of PPD are labelled and indicated by dashed lines in (a) for PPD% ≥4 mm (-5–25%), (b) for PPD% ≥5 mm (-2–16%), (c) for PPD% ≥6 mm (-1–7%), and (d) for PPD% ≥7 mm (-1–9%). (Source: Data from Ramseier *et al*. 2019. Reproduced with permission from John Wiley & Sons.)

≥5 mm, and 3% for ≥6 mm. Moreover, if the SPT interval was 6 months, periodontal stability was achieved with <20% of 4 mm pockets, 6% of 5 mm, and 2% of 6 mm pockets. This clearly indicates that only very few residual pockets are compatible with periodontal stability.

Such an analysis of the profile of residual pockets may be calculated on www.perio-tools.com/spt.

Supportive periodontal therapy in daily practice

The SPT visit should be planned to meet the patient's individual needs. It basically consists of four different sections which may require various amounts of time during a regularly scheduled visit:

- Examination, re-evaluation, and diagnosis (ERD)
- Motivation, re-instruction, and instrumentation (MRI)
- Treatment of re-infected sites (TRS)
- Polishing of the entire dentition, application of fluorides, and determination of future SPT (PFD).

The SPT visit (Fig. 48-6) generally consists of 10–15 minutes of diagnostic procedures (ERD) followed by 30–40 minutes of motivation, re-instruction, and instrumentation (MRI), with the instrumentation concentrated on the sites diagnosed with persistent inflammation. Treatment of re-infected sites (TRS) may include small surgical corrections, applications of local drug delivery devices or just intensive instrumentation under local anesthesia. Such procedures, if judged necessary, may require an additional appointment. The SPT visit is normally concluded with polishing of the entire dentition, application of fluorides, and another assessment of the situation, including the determination of future SPT visits (PFD). Approximately 5–10 minutes must be reserved for this section.

Examination, re-evaluation, and diagnosis

Since patients on SPT may experience significant changes in their health status and the use of medications, an update of the information on general health issues is appropriate. Changes in health status and medications should be noted. In middle-aged to elderly patients especially, these aspects might influence the future management of the patient. An extraoral and intraoral soft tissue examination should be performed at any SPT visit to detect any abnormalities and to act as a screening for oral cancer. The lateral borders of the tongue and the floor of the mouth should be inspected in particular. An evaluation of the patient's risk factors will also influence the choice of future SPT and the determination of the SPT interval at the end of the maintenance visit. Following the assessment of the subject's risk factors, the tooth site-related risk factors are evaluated.

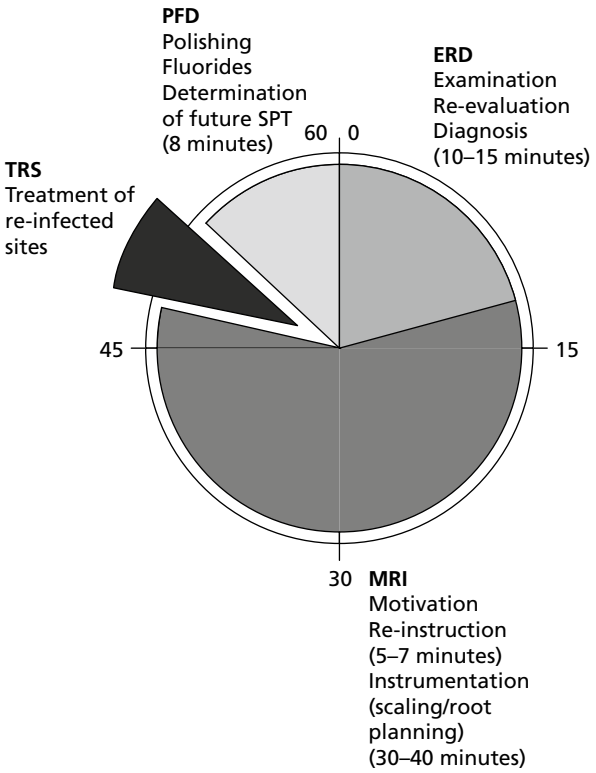

Fig. 48-6 An supportive periodontal therapy (SPT) visit is divided into four sections. (1) Examination, re-evaluation, and diagnosis (ERD) providing information on stable and inflamed sites. This segment uses 10–15 minutes. (2) Motivation, re-instruction of oral hygiene where indicated, and instrumentation (MRI) use the bulk of the visit (30–40 minutes). Sites diagnosed as not stable are instrumented. (3) Treatment of re-infected sites (TRS) may require a second appointment. (4) Polishing all tooth surfaces, application of fluorides, and determination of the future SPT interval (PFD) conclude the visit (5–10 minutes).

As indicated above, the diagnostic procedure usually includes an assessment of the following:

- Oral hygiene
- Determination of sites with BoP, indicating persistent inflammation
- Scoring of clinical probing depths and clinical attachment levels. The latter is quite time-consuming and requires the assessment of the location of the cementoenamel junction as a reference mark on all (six) sites of each root. Therefore, an SPT evaluation usually only includes scoring of clinical probing depths
- Inspection of re-infected sites with pus formation
- Evaluation of existing reconstructions, including vitality checks for abutment teeth
- Exploration for carious lesions.

All these evaluations are performed for both teeth and oral implants. Occasionally, conventional dental radiographs should be obtained at SPT visits. Especially for devitalized teeth, abutment teeth, and oral implants, single periapical films exposed with a parallel and preferably standardized technique are

of great value. Bitewing radiographs are of special interest for caries diagnostic purposes. They also reveal biofilm-retentive areas such as overhanging fillings and ill-fitting crown margins. Since only approximately 10–15 minutes are available for this section, these assessments have to be performed in a well-organized fashion. It is preferable to have a dental assistant available to note all the results of the diagnostic tests unless a voice-activated computer-assisted recording system is used.

Motivation, re-instruction, and instrumentation

This aspect uses most of the available time of the SPT visit. When informed about the results of the diagnostic procedures, for example the total percentage BoP score or the number of pockets exceeding 4 mm, the patient may be motivated either in a confirmatory way in the case of low scores or in a challenging fashion in the case of high scores. Since encouragement usually has a greater impact on future positive developments than negative criticism, every effort should be made to acknowledge the patient's performance.

Patients who have experienced a relapse in their adequate oral hygiene practices need to be further motivated. Positive encouragement is especially appropriate if a patient's personal life situation has influenced his/her performance. Standard "lecturing" should be replaced by an individual approach.

Occasionally, patients present with hard tissue lesions (wedge-shaped dental defects) which suggest overzealous and/or faulty mechanical tooth cleaning (Fig. 48-7). Such habits should be broken, and the patient re-instructed in toothbrushing techniques which emphasize vibratory rather than scrubbing movements.

Because it appears impossible to instrument 168 tooth sites in a complete dentition in the time allocated, only those sites which exhibit signs of inflammation and/or active disease progression will be re-instrumented during SPT visits. Trauma from repeated instrumentation of healthy sites will inevitably result in continued loss of attachment (Lindhe *et al*. 1982a). In contrast, residual pockets of ≥6 mm may lead to periodontitis progression and tooth loss (Badersten *et al*. 1990; Claffey *et al*. 1990, Matuliene *et al*. 2008). Interestingly, the association of the residual PPD with tooth loss over a mean of 11.3 years of maintenance was calculated at the site and at the tooth level (Table 48-3). Starting from a residual PPD of 4 mm, the increase of the PPD by 1 mm was highly statistically significantly associated with tooth loss (Matuliene *et al*. 2008). Hence, all the BoP-positive sites and all pockets with a PPD exceeding 4 mm are carefully rescaled and root planed as instrumenting healthy sites repeatedly will inevitably result in mechanically induced loss of attachment (Lindhe *et al*. 1982a).

Similar observations were made in clinical studies by Claffey *et al*. (1988): loss of clinical attachment levels immediately following instrumentation was

Fig. 48-7 Wedge-shaped defects apical to the cementoenamel junction following recession of the gingival tissues resulting from overzealous or faulty toothbrushing.

Table 48-3 Results from multilevel logistic regression models for the association of site probing pocket depth (PPD) and deepest PPD of a tooth at the end of therapy with tooth loss during supportive periodontal therapy of mean duration of 11.3 years (not accounting for bleeding on probing).

PPD (mm)	Site level			Tooth level		
	OR	95% CI	*P* value	OR	95% CI	*P* value
≤3	1.0					
4	2.6	2.2–3.1	<0.0001	2.5	1.8–3.6	<0.0001
5	5.8	4.3–7.9	<0.0001	7.7	4.8–12.3	<0.0001
6	9.3	6.2–13.9	<0.0001	11.0	6.1–20.1	<0.0001
≥7	37.9	17.9–80.2	<0.0001	64.2	24.9–165.1	<0.0001

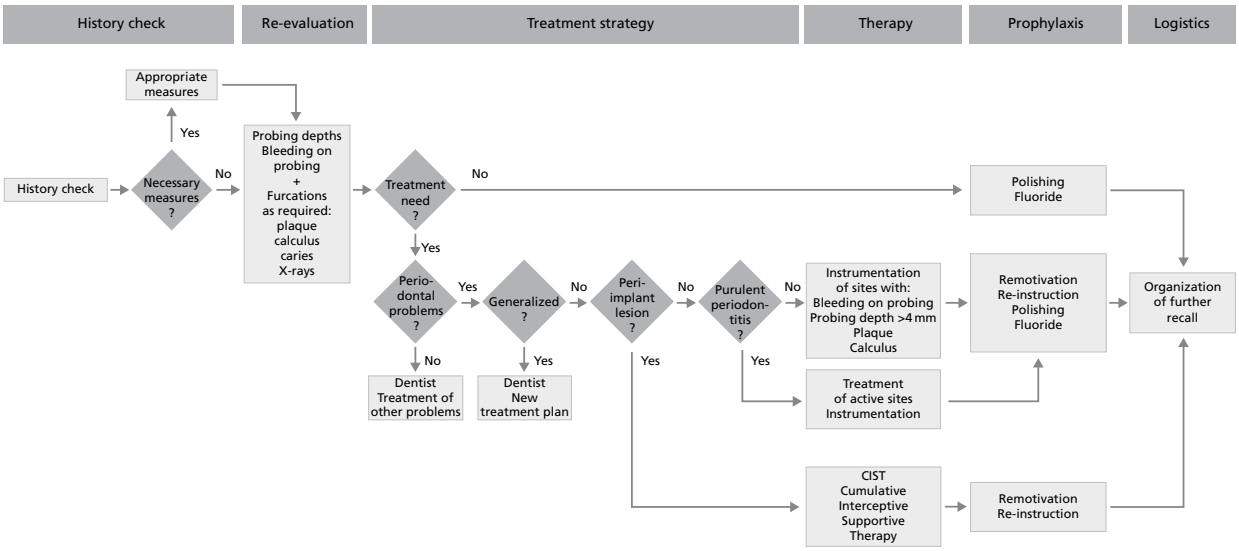

Fig. 48-8 Flow diagram of supportive periodontal therapy (SPT) with strategic decision tree for the SPT visit.

observed in 24% of the sites. It is also known from regression analyses of several longitudinal studies (e.g. Lindhe *et al*. 1982b) that probing attachment may be lost following instrumentation of pockets below a "critical probing depth" of approximately 2.9 mm. Instrumentation of shallow sulci is, therefore, not recommended. As it has been shown in several studies that sites that do not bleed on probing represent stable sites (Lang *et al*. 1986, 1990; Joss *et al*. 1994), it appears reasonable to leave non-bleeding sites for polishing only and to concentrate on periodontal sites with a positive BoP test or PPD of >5 mm. To protect the hard tissues, root planing should be performed with great caution. The deliberate removal of "contaminated" cementum during SPT is no longer justified (Nyman *et al*. 1986, 1988; Mombelli *et al*. 1995). During SPT visits, root surface instrumentation should be aimed especially at the removal of subgingival biofilm rather than "diseased" cementum. This may require a more differentiated approach than hitherto recommended. In this respect, the use of ultrasonics may have to be re-evaluated.

Treatment of re-infected sites

Single sites, especially furcation sites or sites that are difficult to access, may occasionally be re-infected and demonstrate suppuration. Such sites require a thorough instrumentation under anesthesia, the local application of antibiotics in controlled-release devices, or even open debridement with surgical access. It is evident that such therapeutic procedures may be too time-consuming to be performed during the routine SPT visit, and hence, it may be necessary to reschedule the patient for another appointment. Omission of thorough retreatment of such sites or only performing incomplete root instrumentation during SPT may result in continued loss of probing attachment (Kaldahl *et al*. 1988; Kalkwarf *et al*. 1989).

Treatment choices for re-infected sites should be based on an analysis of the most likely causes for the re-infection. Generalized re-infections are usually the result of inadequate SPT. Although not all sites positive for BoP may further progress and lose attachment, high BoP percentages call for more intensive care and more frequent SPT visits. Sometimes, a second visit 2–3 weeks after the SPT visit may be indicated to check the patient's performance in oral home care. It is particularly important to supervise patients closely for advanced periodontitis if they have a high subject risk assessment (Westfelt *et al*. 1983b; Ramfjord 1987). Local re-infections may either be the result of inadequate biofilm control in a local area or the formation of ecologic niches conducive to periodontal pathogens. The risk assessment at the tooth level may identify such niches which are inaccessible for regular oral hygiene practices. Furcation involvements often represent special periodontal risk factors which may require additional therapy to be performed following diagnosis in the regular SPT visit.

Polishing, fluorides, and determination of supportive periodontal therapy interval

The SPT visit is concluded with polishing the entire dentition to remove all remaining soft deposits and stains. This may give the patient a feeling of freshness and facilitates the diagnosis of early carious lesions. Following polishing, fluorides should be applied in high concentration in order to replace the fluorides which may have been removed by instrumentation from the superficial layers of the teeth. Fluoride or chlorhexidine varnishes may also be applied to prevent root surface caries, especially in areas with gingival recession. The determination of future SPT visits must be based on the patient's risk assessment.

Summary: Figure 48-8 provides a flowchart for SPT. The SPT visit is divided into four sections. Whereas the first 10–15 minutes are reserved for examination, re-evaluation, and diagnosis, the second and most time-consuming section of 30–40 minutes is devoted to re-instruction and instrumentation of sites identified to be at risk in the diagnostic process. Some re-infected sites may require further treatment, and hence, the patient may have to be rescheduled for an additional appointment. The SPT visit is concluded by polishing the dentition, applying fluorides, and determining the frequency of future SPT visits.
