Goodman & Gilman's

The Pharmacological Basis of Therapeutics

14TH EDITION

LAURENCE L. BRUNTON
BJÖRN C. KNOLLMANN

Mc Graw Hill

Goodman & Gilman's

THE PHARMACOLOGICAL BASIS OF THERAPEUTICS

FOURTEENTH EDITION

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Goodman & Gilman's THE PHARMACOLOGICAL BASIS OF THERAPEUTICS

FOURTEENTH EDITION

Preface

This is the 14th edition of book that began as a collaboration between two friends and professors at Yale, Louis Goodman and Alfred Gilman. Over the years, "G&G" has been acclaimed as the "blue bible" of pharmacology. Surely much of that acclaim reflects the book's purpose, delineated by the original authors and steadily adhered to over 81 years: to correlate pharmacology with related medical sciences, to reinterpret the actions and uses of drugs in light of advances in medicine and the basic biomedical sciences, to emphasize the application of pharmacodynamics to therapeutics, and to create a book that would be useful to students of pharmacology and to healthcare practitioners.

Following these principles is demanding: the sheer volume and unremitting growth of knowledge in the basic biomedical sciences and their clinical applications continue to amaze, challenging editors and contributors who are trying to produce a one-volume work, and surely challenging students. To create a book that reflects our times, we have updated all chapters and have added five new chapters: drug response and the gastrointestinal biome, pharmacovigilance, the blood-brain barrier (it is not simply a lipid sheath), cannabinoids, and immunotherapies for cancer, plus a novel appendix on drug-drug interactions. Advances in immunomodulation are presented in most sections. In addition, we have continued to reach out to younger contributors who are on the forefront of pharmacological investigation and clinical practice. As a result, we have, in this edition, 56 new contributors, drawn from diverse backgrounds, who will ensure the book's vigor into the future.

A multi-authored work such as *Goodman & Gilman* grows by accretion, deletion, addition, replacement, and repair. The current text reflects over eight decades of such activity, with wisdom, memorable pearls, new material, and flashes of wit, hopefully edited to meet the present and to be forward looking. End-of-chapter notes acknowledge retired contributors to the 13th edition, but I am happy to acknowledge that several generations of editors and contributors have helped to bring this 14th edition to its present form. As in the 13th edition, we have used a larger page size, no extract type, and more mechanistic figures as we attempt to explain the pharmacodynamics of new agents. Some readers have complained that the book is getting too complex. We believe that a thorough understanding of a drug's actions and interactions at multiple physiological sites and with other drugs is essential to modern therapeutics. However, we also prominently summarize the mechanisms of action, ADME, and clinical use of individual agents and drug classes. Not wanting to favor one manufacturer's product over that of another, we continue generally to avoid using trade names except as needed to distinguish multiple formulations of the same agent that have distinct pharmacokinetic or pharmacodynamic properties or that are known only by a trade name. The full text is available online at many medical, pharmacy, and nursing schools by institutional subscription to *AccessMedicine.com* and *AccessPharmacy.com*, where we publish regular updates. Feel free to contact the editors by email if you have comments on the book or the websites.

Editing this book brings to mind a number of larger issues, both positive and negative, relating to health care; among them: the remarkable explosion of molecular genetic techniques, the proliferation of therapeutic agents affecting the immune system, and the power of computer-aided drug design; antibiotic resistance promoted by the continuing misuse and overuse of antibiotics in healthcare and animal husbandry; the adverse environmental effects of human activity to life on Earth; the effects of global warming and the sheer size of the human population on global health and nutrition; the ease with which infectious diseases can spread around the world; the fragility of truth and fact, and the difficulty of promoting health based on science and data in the face of determined conspiracy theories and political ideology. A better world is possible.

A number of people have contributed to the preparation of this edition of *Goodman & Gilman*. Many thanks to: my co-editor, Bjorn Knollmann, and to the clinical pharmacology fellows at Vanderbilt whom he recruited to read the first drafts of chapters as they honed their editorial skills; our attentive publisher at McGraw Hill, Michael Weitz, and his colleagues Christina Thomas and Melinda Avelar; consulting pharmacist Nelda Murri; Nitesh Sharma at KnowledgeWorks Global Ltd, who tirelessly oversaw the transformation of Word documents into a printed book; Jason McAlexander of MPS North America, whose rapid-response artwork brightens the pages; and the eagle-eyed Becky Hainz-Baxter, who saw what the editors had missed.

My special thanks to Lynne Larson, a novelist, artist, and grants management specialist who managed this enterprise and kept the editors organized. Lynne managed the production of the 11th edition of *Goodman & Gilman* when I first became the editor, when everything was done with hard copy and Word files submitted by mail, when galley proofs were actual long sheets of paper on which corrections were handwritten and then transcribed to new Word files. I was delighted when Lynne agreed to manage this all-electronic project. We would not have this 14th edition without her.

Chapter 1

Drug Discovery: From Medicinal Plants to Computer-Aided Drug Design

Michael K. Gilson and Laurence L. Brunton

The first edition of *Goodman & Gilman*, published in 1941, helped to organize the field of pharmacology, giving it intellectual validity and an academic identity. That edition began: "The subject of pharmacology is a broad one and embraces the knowledge of the source, physical and chemical properties, compounding, physiological actions, absorption, fate, and excretion, and therapeutic uses of drugs. A *drug* may be broadly defined as any chemical agent that affects living protoplasm, and few substances would escape inclusion by this definition." In practice, of course, a chemical or biological agent is considered a legal drug only if it has been approved as such by a national regulatory agency, such as the U.S. Food and Drug Administration (FDA) or the European Medicines Agency; these approved compounds are the focus of this book.

This first nine chapters of this book, ***General Principles***, provide the underpinnings for these definitions of pharmacology and drugs by exploring the physiological, biochemical, and molecular mechanisms of drug action. This section covers drug invention, development, and regulation, as well as how drugs act in biological systems, i.e., *pharmacodynamics*, *pharmacokinetics* (including *drug transport* and *metabolism*), *the influence of the gastrointestinal microbiome*, and *pharmacogenetics*, with brief forays into *pharmacovigilance* and *drug toxicity and poisoning*. Subsequent sections deal with the use of specific classes of drugs as therapeutic agents in human subjects. The present chapter is an introduction to pharmaceuticals, their development, and the activities of the pharmaceutical industry and government surrounding the discovery, production, and use of therapeutic agents. The processes of discovery and invention of drugs have changed substantially with the general progress of biomedical sciences, the advent and improvement of computer-aided drug design, and technical advances in biochemistry and molecular biology. Some of these new capabilities are reviewed below.

From Medicinal Plants to Computer-Aided Drug Design

Early Experiences With Plants

The human fascination—and sometimes infatuation—with chemicals that alter biological function is ancient and begins with our long experience with and dependence on plants. Because most plants are rootbound, many produce defensive compounds that animals learn to avoid and humans to exploit or abuse. Thus, the prior of an Arabian convent came to appreciate coffee (caffeine) after noting the behavior of goats that gamboled and frisked through the night after eating the berries of the coffee plant; women sought to enhance their beauty by using an extract of the deadly nightshade plant, *Atropa belladonna* ("beautiful lady"), enriched in *atropine*, to produce pupillary dilation; the Chinese herb *ma huang* (*ephedrine*) was used as a stimulant; indigenous people of South American used curare to paralyze and kill animals hunted for food; and poppy juice (opium), containing *morphine* (from the Greek *Morpheus*, the god of dreams), has long been used for pain relief and control of diarrhea. *Morphine*, of course, has well-known addicting properties, as do other psychoactive natural products, such as nicotine, cocaine, and ethanol. Note that these drugs did not derive from a search for a druggable target or any knowledge of a target. Rather, drug discovery in the past often resulted from serendipitous observations of the effects of plant extracts or individual chemicals on animals or humans. Drugs were selected based on effect, with no understanding of mechanism as we use the term today. In the 20th century, the hunt for natural products broadened, driven in part by the discovery of antibiotics, such as *penicillin* and the cephalosporins, which fungi and microbes make to compete with each other.

Abbreviations

ADME: absorption, distribution, metabolism, and excretion
BLA: Biologics License Application
CADD: computer-aided drug discovery
DEL: DNA-encoded compound library
DHHS: U.S. Department of Health and Human Services

Drug Discovery or Drug Invention?

The conventional phrase *drug discovery* makes sense for therapeutic compounds obtained from plants and other organisms. Today, however, only a fraction of the new drugs introduced each year are discovered in nature. Instead, most drugs are not discovered, but are totally new compounds, painstakingly optimized against many criteria through an interplay of design and experimentation. In that sense, today's new drugs are more invented than discovered.

The current paradigm for drug development grew out of synthetic organic chemistry, which arose as the dye industry in the late 19th century and has continued to flourish. Dyes are colored compounds with selective affinity across various biological tissues. Study of these interactions stimulated Paul Ehrlich to postulate the existence of chemical receptors in tissues that interacted with and "fixed" the dyes. Similarly, Ehrlich thought that unique receptors on microorganisms or parasites might react specifically with certain dyes and that such selectivity could spare normal tissue. Ehrlich's work culminated in the invention of *arsphenamine* in 1907, which was patented as "salvarsan," suggestive of the hope that the chemical would be the salvation of humankind. This and other organic arsenicals were used to treat syphilis until the discovery of *penicillin*. Gerhard Domagk demonstrated that another dye, *prontosil* (the first clinically useful sulfonamide), was dramatically effective in treating streptococcal infections, thereby launching the era of antimicrobial chemotherapy. The collaboration of pharmacology with chemistry on the one hand and clinical medicine on the other has been a major contributor to the effective treatment of disease, especially since the middle of the 20th century.

Early on, new compounds could be tested for their activities only in whole organisms. This is how the nonsteroidal anti-inflammatory drug *indomethacin* was discovered, for example (Brune and Hinz, 2004). In the past 70 years, researchers have begun to understand in considerable detail the cellular and molecular mechanisms of disease. As a result of this basic biomedical research, it is possible to do initial testing of compounds *in vitro* ("in glass"), using cellular and molecular assays. For example, one could look for the cellular responses due to inhibition of a protein involved in a disease process. In this scenario, by testing enough appropriately chosen compounds, one could develop at least a partial understanding of which types of compounds are most likely to be active and then use this information to steer the program of chemical synthesis and testing toward increasingly potent compounds.

In the 1980s, it became practical to determine high-resolution three-dimensional structures of complex organic molecules and even larger molecules such as proteins, using and refining the techniques of X-ray crystallography pioneered by Hodgkin, Kendrew, and Perutz in the mid-20th century. It was already known that many drugs worked by binding tightly to a disease-related protein and thereby modulating (e.g., inhibiting or activating) its biological function, but the atomic details of these interactions had remained mysterious. As a consequence, the only way to advance a drug discovery project had been by synthesizing and testing one compound after another. Now, with the protein's three-dimensional structure in hand, one could finally hope to design a compound that would bind with high affinity by fitting snugly into a pocket in the protein, such as an enzyme's active site. Thus, protein crystallography enabled *structure-based drug design* (SBDD), where the three-dimensional structure of the drug target is used to guide creation of tight-binding compounds, often called *ligands*.

Around the same time, computer technology began to advance rapidly. This accelerated the data processing needed to go from X-ray diffraction patterns to protein structures (i.e., three-dimensional atomic coordinates) and enabled interactive visualization of complex protein structures comprising thousands of atoms. It also opened new vistas in *computer-aided drug discovery* (CADD), including the use of molecular simulations to model the physical interactions of compounds and proteins, and the development of tools to encode, archive, share, and analyze chemical and pharmacological data. In parallel, automation and miniaturization have dramatically increased experimental throughput, notably through robotic *high-throughput screening* (HTS), in which hundreds of thousands of compounds can be tested rapidly and at relatively low cost in cellular or molecular activity assays. Today, excitement about the power of artificial intelligence motivates wide-ranging efforts to apply these technologies to drug discovery.

The following section goes into more detail regarding the process of drug discovery, focusing on so-called *small-molecule* drugs, organic compounds with molecular weights typically less than 500 Da, which have traditionally been the most common type of drug. Subsequent sections introduce biological drugs, such as antibodies and other engineered biomolecules.

Target Identification

Today, most small-molecule drug discovery projects grow out of basic research that implicates a specific macromolecule, usually a protein, as a key player in a disease and, further, suggests that a small molecule which binds this macromolecule could be used to treat the disease. The macromolecule thus becomes a candidate *drug target*. Many small-molecule drugs are inhibitors (antagonists), which work by reducing the activity of their macromolecular target. Examples include the statins, which reduce cholesterol synthesis by binding and inhibiting the enzyme 3-hydroxy-3-methylglutaryl (HMG) coenzyme A (CoA) reductase, and β-lactam antibiotics, which kill bacteria by inhibiting enzymes involved in the synthesis of bacterial cell walls. However, some small molecules are activators (agonists) rather than inhibitors. Activators frequently target proteins whose normal role involves cell signaling, such as hormone receptors. For example, the asthma medication *albuterol* dilates bronchi by binding and activating β adrenergic receptors on bronchial smooth muscle, thereby mimicking the effect of adrenaline (epinephrine; see Chapter 10).

Candidate drug targets have been identified in many ways (Hughes et al., 2011). For example, the enzymes targeted by the β-lactam antibiotics were unknown in advance and were discovered precisely because they are bound by these naturally occurring antibiotics. In contrast, the target of the statins, HMG-CoA reductase, was identified by elucidation of the pathways of cholesterol synthesis (Tobert, 2003), and this information was used to help discover the first statins. Similarly, as researchers have determined the regulatory functions of human protein kinases—enzymes that change the activities of other proteins by covalently attaching phosphate groups to their hydroxyl-containing side

chains—specific kinases have been targeted for small-molecule drug discovery (Cohen et al., 2021). Many kinase inhibitors are anticancer agents that work by inhibiting protein kinases that accelerate cell proliferation. Some of these targeted kinases carry abnormal, cancer-associated mutations that make them hyperactive, so inhibiting them returns their regulatory activities toward normal. The pioneering example of this scenario is the drug *imatinib*, which inhibits a cancer-associated mutant protein kinase, the Bcr-Abl tyrosine kinase, and is used to treat chronic myelogenous leukemia (Buchdunger et al., 2002).

In recent years, technological advances enabling genome-wide experimentation (*omics*) have opened new approaches to identifying candidate targets (Lindsay, 2003; Paananen and Fortino, 2020). Fast, inexpensive genome sequencing facilitates genome-wide association studies, in which variations in the susceptibility to a disease across many people are correlated with variations in specific genes, leading to suggestions for gene products (i.e., proteins), that may be suitable drug targets. The growing availability of patient genomic data in the context of patients' electronic medical records will likely open new opportunities for data mining in support of target discovery in the coming years. It has also become routine to measure the quantities of messenger RNA (mRNA) transcribed from thousands of genes simultaneously (the *transcriptome*) and to quantify thousands of translated proteins (*proteomics*). By comparing such data between, for example, cancer cells and normal cells, one can identify proteins transcribed or present at elevated or depressed levels in the disease state. Mining data about these proteins from sources such as biomedical databases, scientific articles, and patents, and integrating it with the omics data, may suggest certain proteins as candidate drug targets.

A totally different approach starts with the use of high-throughput instrumentation and robotics to test a large collection of small molecules (a *chemical library*) for biological activity in a *phenotypic screen* (Swinney and Lee, 2020), which might use automated microscopy and image analysis to determine which compounds produce desired biological effects, such as the activation of a desired gene in cultured human cells or the death of a parasitic microorganism in culture. Various methods may then be used for *target deconvolution* (i.e., to determine how the active small molecules work). For example, candidate targets of compounds found to kill the malarial parasite *Plasmodium falciparum* were identified by cultivating these organisms in gradually increasing concentrations of the compound to select for resistant protozoa and then using omics methods to determine which genes had changed. The proteins encoded by these genes may then become candidate drug targets (Flannery et al., 2013).

Target Validation

After a candidate drug target has been identified, additional research is usually warranted to *validate* it by seeking stronger evidence that a small molecule that binds and modulates it will actually treat the disease (Jones, 2016; Lansdowne, 2018; see Box 1–1). For example, the fact that a protein is more abundant in cancer cells than normal cells by no means proves that it is a suitable drug target. Instead, this might be a correlate rather than a cause, so further research is needed to assess its role. Accordingly, *target validation* aims to "de-risk" a project by lowering the probability that a compound carefully developed to hit the targeted protein will fail in clinical trials, whether because hitting the target does not influence the disease as expected or because the compound generates unanticipated toxicity, termed *on-target* or *mechanism-based* toxicity.

There are no absolute criteria for target validation, nor is there a single method. One approach is to use a *chemical probe*, a small molecule that binds the target, and study its biological effects (Quinlan and Brennan, 2021). This approach requires that such a probe be available, and the fields of *chemical genetics* (Stockwell, 2000) and *chemogenomics* (Bredel and Jacoby, 2004) aim to create selective chemical probes for as many proteins in the human genome as possible. Alternatively, one may use gene silencing via small interfering RNA (siRNA) to block production of the target protein, thereby mimicking the effect of an inhibitor of the protein's activity. Additional insight into the biological role of a candidate drug target may sometimes be obtained by studying genetically modified mice, including *knockout mice,* in which the gene coding for the target has been disabled entirely, and *transgenic mice*, in which expression of the target's gene is placed under the control of a promoter that can be turned on by feeding the animals a specific compound, such as *tetracycline* (Lindsay, 2003).

BOX 1–1 ■ Target Validation: The Lesson of Leptin

Biological systems frequently contain redundant elements or can alter expression of drug-regulated elements to compensate for the effect of the drug. *In general, the more important the function, the greater the complexity of the system.* For example, many mechanisms control feeding and appetite, and drugs to control obesity have been notoriously difficult to find. The discovery of the hormone leptin, which suppresses appetite, was based on mutations in mice that cause loss of either leptin or its receptor; either kind of mutation results in enormous obesity in both mice and people. Leptin thus appeared to be a marvelous opportunity to treat obesity. However, on investigation, it was discovered that obese individuals have high circulating concentrations of leptin and appear insensitive to its action.

Target Druggability

It is important to know whether the candidate target is *druggable*, that is, whether it can, in principle, bind a small molecule with sufficient affinity. If the protein has been the target of a prior drug discovery effort, there may be informative small-molecule binding data in a public database, such as BindingDB (Gilson et al., 2016), PubChem (Kim et al., 2021), or ChEMBL (Gaulton et al., 2012), or in an article or patent not yet curated by one of these databases. One may also check the Protein Data Bank (Berman et al., 2000; Berman and Gierasch, 2021) for a crystal structure of the target, which may assist in locating a suitable binding pocket for the small molecule to be developed as a drug. This is frequently true for metabolic enzymes and receptors that have evolved to bind small substrate and transmitter molecules. Many proteins belong to families, such as the protein kinases, whose members have similar properties (e.g., an ATP binding pocket), so that if one member of a family is druggable, then the others probably are also. In contrast, receptors for proteins often have large, relatively flat binding surfaces, rather than small binding pockets suitable for a small-molecule drug, and are thus less likely to be druggable and influenced by small molecules. Efforts are under way to systematically search for all druggable targets encoded by the human genome (Nguyen et al., 2017; Finan et al., 2017; Hopkins and Groom, 2002) and to gain traction against targets hitherto considered *undruggable* (Dang et al., 2017).

The ultimate validation of a candidate target is the successful development of a novel drug that works by binding to it. Such a novel drug is termed *first-in-class*. A first-in-class drug is a true innovation and may represent a medical breakthrough, so one might expect first-in-class to be the goal of every drug discovery project. In fact, however, pharmaceutical companies often engage in less innovative, more predictable projects by developing *me-too drugs* against old targets that are already fully validated by a first-in-class drug. Such projects aim to improve on the first-in-class drug through, for example, greater potency, reduced side effects, or more convenient dosing (e.g., oral instead of intravenous), and ideally to produce a new drug considered *best-in-class*. For example, Merck's *lovastatin* broke ground as the first statin, the first in a class of drugs that lower cholesterol by inhibiting the enzyme HMG-CoA reductase (see Chapter 37); but other statins, such as *atorvastatin*, have also achieved enormous commercial success.

Beyond Single-Protein Drug Targets

A number of drugs, whether by accident or by design, hit multiple protein targets, a phenomenon termed *polypharmacology* (Peters, 2013). This phenomenon is particularly common when the target is a member of a family of proteins with similar binding sites. For example, the

full physiological effect of an adrenergic antagonist is determined by its actions across the family of adrenergic receptor types and subtypes. Similarly, many protein kinase inhibitors inhibit multiple kinases, each to a different degree. There are instances where hitting multiple targets is fruitful, such as inhibiting sequential reactions in a series. Modulating multiple proteins in a single biochemical pathway or signaling network overcomes the evolved redundancy of a robust biological system and hence leads to greater efficacy than modulating only one protein. A single compound may, alternatively, hit two entirely different targets in different pathways, although this is more challenging to achieve without going to larger compounds. The analysis of complex molecular systems in relation to drug action is termed *systems pharmacology*.

Polypharmacology is not always beneficial, and indeed, it can lead to toxicity. Some of the unintended effects of a drug will be termed side effects or even major adverse drug responses. For example, a number of initially promising compounds have proven to bind and inhibit hERG, the K^+ channel in the heart that mediates repolarization (the I_{Kr} current; see Chapter 34); inhibition of hERG can lead to potentially fatal arrhythmias. The hERG channel has, therefore, become a notorious *anti-target* that must be scrupulously avoided by drug discovery projects (Garrido et al., 2020).

Some small-molecule drugs do not bind to proteins at all. For example, platinum anticancer drugs, such as *carboplatin*, kill cancer cells by binding covalently to DNA; the aminoglycoside antibiotics block bacterial protein synthesis by binding to RNA within the bacterial ribosome; and antiviral nucleoside analogues are incorporated into viral DNA in place of normal nucleosides and then block DNA replication. The drug *sugammadex* has both an unusual purpose and an unusual mechanism. Surgical patients often receive not only general anesthesia but also the nondepolarizing neuromuscular blocking agent *rocuronium*, which prevents involuntary movements of skeletal muscle during surgical procedures (see Chapter 13). *Sugammadex*, a larger, cup-shaped molecule, binds and sequesters *rocuronium*. Thus, injection of *sugammadex* rapidly reduces the concentration of unbound *rocuronium* in the blood and promptly reverses paralysis when a procedure is complete.

Protein-Drug Binding: Affinity and Allostery

A successful drug with a protein target must bind to its target with high affinity so that even a small dose of the drug will yield a blood concentration high enough to bind a large fraction of the targeted protein. If the affinity were low, then a high concentration of drug would be needed for a substantial fraction of the target sites to be occupied, and a large dose of drug would need to be administered, leading to inconvenience and an increased risk of side effects. The affinity of a small molecule for a protein is generally given as the dissociation constant, the concentration of free drug molecules in solution at which 50% of the targeted protein has bound drug; the lower this concentration, the higher the affinity (see Figure 3–3). Drug design projects typically aim for a dissociation constant on the order of 10^{-9} mol/L (1 nM); such a "nanomolar drug" is typically dosed in milligrams to grams per day. A successful drug should also exhibit a high degree of specificity for its target protein, meaning that the drug does not interact with other proteins that could lead to undesired side effects and toxicity. In some cases, the effectiveness of a drug may be influenced by not just the affinity but also the kinetic rate constants for drug-protein binding and dissociation, which determine the drug's residence time at its receptor (Copeland, 2016).

Most drugs bind their targeted proteins via attractive, intermolecular interactions that do not involve a covalent chemical bond. These *noncovalent interactions* typically include:

- Hydrogen bonding, in which an electronegative atom with a bound hydrogen atom, such as a hydroxyl group, partly shares its hydrogen with an electronegative atom on the other molecule
- Attractive electrostatic interactions between atoms of opposite charge, such as between a negatively charged carboxylic acid belonging to the drug and a positively charged arginine side chain of the protein
- The hydrophobic effect, in which nonpolar or "greasy" parts of the drug and protein associate with each other to reduce their energetically unfavorable exposure to water, much as oil droplets coalesce in salad dressing
- Dispersion forces—the attractive part of van der Waals interactions—short-ranged attractive interactions between the instantaneous electrical dipoles that result from the constant fluctuations of negatively charged atomic electron clouds around positively charged atomic nuclei

These attractive forces need to overcome the entropic tendency of the drug and protein to wander apart, due to thermal energy. There are also, inevitably, forces that oppose binding and that must be overcome by the attractive ones. For example, there is an energy penalty for stripping water from polar chemical groups of the ligand and protein as they come together to bind. Thus, the overall affinity of a drug-protein interaction reflects a delicate and hard-to-predict balance of attractive and repulsive interactions.

Small-molecule drugs do not bind to the relatively smooth, exterior surfaces of their protein targets, but instead are enfolded by binding pockets in the protein (see Figure 1–4). This structural arrangement makes it possible to form the extensive, short-ranged, physical interactions that are needed to hold the two molecules together tightly. Druggable binding pockets (i.e., ones that enable small-molecule binding) usually are available in enzymes whose substrates are small molecules and in receptors that bind small-molecule hormones and transmitters. However, many proteins lack a concave pocket and therefore are difficult or impossible to drug with a small molecule. In such cases, one may instead consider developing a protein therapeutic, such as an engineered antibody that targets the protein of interest. Because proteins are large, they can form extensive, short-ranged, physical interactions even with the relatively flat exterior surface of a targeted protein, and thus can achieve adequate binding affinity where a small-molecule drug cannot. These considerations also help explain why it is difficult to develop a small-molecule drug that will block a protein-protein interaction: protein-protein binding usually involves a large number of interactions on a relatively flat binding interface between the two proteins, and a small molecule cannot get sufficient purchase on such a flat surface.

Note that a drug must not only bind to its target but also have the desired effect upon it. If the goal is to inhibit an enzyme, then a drug that binds in the active site should easily accomplish this by simply blocking association of the enzyme with molecules of substrate. In contrast, when a cell-surface receptor is the target, a small molecule might interact at the agonist binding site but without inducing an activating conformational change and thus might function as an antagonist or inverse agonist (see Chapter 3). A drug may also inhibit the function of a protein by binding in a pocket outside the active site, and thereby modifying the three-dimensional conformation of the targeted protein; this is an allosteric effect. Such a drug must not only bind in a suitable pocket but also induce the desired conformational change. *Efavirenz* and *nevirapine*, used in treating HIV-AIDS, are nonnucleoside reverse transcriptase inhibitors that act allosterically to inhibit viral transcription of viral RNA to DNA (see Figure 65–5). Similarly, a number of ligands interact with allosteric sites on $GABA_A$ receptors (see Figure 16–11) and other Cys-loop receptors to modulate receptor/channel function. Allostery can also offer a sophisticated strategy to target a single enzyme from among a family of similar enzymes. Thus, in designing a drug, one might take advantage of the fact that, even within a family of related proteins with similar active sites, the members will likely have other regions of their structure that are more variable and possibly unique. Designing a small ligand that binds to such a site might produce an agent that is a quite selective allosteric modifier of enzyme function. This approach is being used to target selected protein phosphatases (Mullard, 2018).

A few small-molecule drugs react chemically with their protein targets to form *irreversible*, *covalent* bonds, rather than relying entirely on the noncovalent attractions discussed above. Such covalent drugs bond to a

specific chemical group of the protein target, often a relatively reactive amino acid side chain within an enzyme's catalytic site. In principle, covalent drugs should require smaller, less frequent dosing, because a covalently bound drug will not dissociate from the protein as the concentration of free drug dwindles over time following a dose (but note that some boron-containing compounds form *reversible* covalent bonds [Diaz and Yudin, 2017]). Drug developers have tended to avoid covalent drugs because they necessarily possess chemically reactive groups that risk reacting not only with the desired target but also with other proteins and biomolecules, with the potential for causing undesired biological effects. However, selectivity can be achieved by specific noncovalent interactions between the drug and the protein that pull the compound into a location and conformation where it is poised to form the desired covalent bond.

Covalent binding has been used to successfully target and inhibit a member of the RAS GTPase family, KRAS G12C, which had been viewed as virtually undruggable. As a result of such targeted positioning, the cancer drug *sotorasib* gains both potency and specificity by forming a covalent bond with a cysteine side chain present in an oncogenic mutant form of KRAS but not in normal KRAS (Lanman et al., 2020).

Experimental Approaches to Drug Discovery

Given a validated target, the next major milestone in a drug discovery project is arrival at a *clinical candidate*, a small molecule that binds the target with high affinity and specificity, has the desired effect on it, and meets a range of other criteria for a safe, efficacious drug (Hefti, 2008). Some of these criteria relate to *pharmacokinetics*: How well will the compound be absorbed if given orally? How well does it distribute to the targeted organs and tissues? How rapidly and by what mechanisms is it eliminated? Is it metabolized to an active metabolite? These properties are often lumped together as absorption, distribution, metabolism, and excretion (*ADME*) or drug metabolism and pharmacokinetics (*DMPK*).

It is also essential to confirm that the compound does not show evidence of toxicity. Both pharmacokinetics and toxicity can be initially studied *in vitro*. For example, there are *in vitro* methods that examine the ease with which the compound enters cells (see Chapter 4) and the likelihood that liver enzymes (see Chapter 5) will chemically modify the compound. Compounds also can be evaluated *in vitro* for evidence of toxicity and mutagenicity. However, *in vitro* studies cannot fully model the complexities of a living organism; animal studies are still required to minimize the chances that a compound will be problematic when first given to human subjects. For example, toxicity is usually assessed by long-term monitoring of the health of two species of animals, generally one rodent (usually mouse) and one nonrodent (often rabbit), when dosed with the compound. A good clinical candidate should also meet some nonbiological criteria. In particular, it must be amenable to large-scale synthesis and high-grade purification at acceptable cost, and it should be possible to create a formulation (e.g., a tablet or injection) that is sufficiently water soluble and stable.

Sophisticated technologies have been developed to speed the process of generating a clinical candidate. These mainly focus on the discovery or design of compounds that will bind the protein target with high affinity (*potent ligands*). Less progress has been made toward designing in safety and favorable pharmacokinetics. These properties pose more complex challenges, because they go far beyond how a small molecule and a protein interact with each other and instead involve the interactions of the small molecule with thousands of different biomolecules in a living system. The technologies for ligand discovery are both experimental and computational, and different methods are applicable in different settings. The following subsections touch on broad approaches but are not comprehensive. Note, too, that various approaches can be used in combination, so the distinctions made here are ultimately somewhat artificial.

Medicinal Chemistry

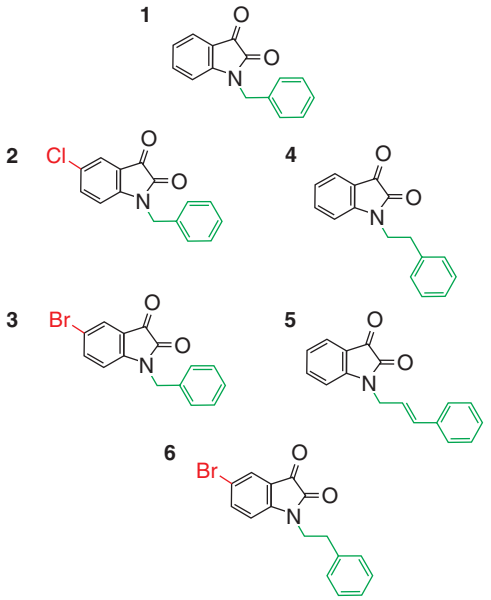
Synthetic organic chemistry remains at the heart of small molecule drug discovery, where it is specialized and known as medicinal chemistry. Medicinal chemists typically are part of a project team that includes, among others, biologists, assay specialists, and computational chemists; their role is to reduce chemical concepts to practice by synthesizing and purifying compounds that may ultimately lead to a new drug. In addition to providing the expertise needed to synthesize compounds of interest, they also help guide the design and selection of the compounds to be made. A key consideration is the complexity of a compound's synthesis, or "synthetic accessibility", which must be balanced against the level of interest in the compound. For example, it can be difficult to generate pure stereoisomers of compounds with multiple chiral carbon atoms, and certain chemical structures can by synthesized only via demanding, multi-step syntheses. A compound that is too difficult to make or purify will not only slow down the research effort but may also lead to a drug that is too costly to manufacture.

Medicinal chemists also inform the drug design process by providing insights into the properties of various chemical groups that might be incorporated into a drug, such as the attractive or repulsive interactions they may form with the targeted protein, their susceptibility to metabolic changes following administration, their potential to spontaneously form undesired covalent bonds with biomolecules, and their influence on the compound's ability to cross the blood-brain barrier (which may be desirable or undesirable, depending on the goal of the project). This expertise comes into play, for example, when a compound binds the target well but is rapidly metabolized by the liver into an inactive product. In this setting, the medicinal chemist may try substituting the part of the compound that is metabolized with a "bioisostere", a different chemical group with a similar shape and ability to interact with the protein but with reduced susceptibility to metabolic modification. More broadly, decades of experience have led to a number of rules of thumb for what makes a compound "drug-like", such as the "rule of five" (Lipinski, et al., 2001). These may be useful guides during drug discovery projects, but there are also many exceptions to the rules (Zhang et al., 2007).

High-Throughput Screening

If nothing is known about the structure of the target protein and what small molecules can bind it, it is common to turn to HTS, in which thousands or millions of compounds are tested using automation and robotics (Wildley et al., 2017). Tiny samples of each compound are drawn from a stored *chemical library* and deposited into multiwell plates for testing. Substantial effort often must be invested to devise an assay that works reliably in miniature and without user intervention. Most provide an optical readout, such as a change in luminescence, fluorescence, or color, as these can be efficiently measured with an optical plate reader. The compounds screened can range from part of the vast, in-house compound collection that a major pharmaceutical company has assembled over the years to a smaller set purchased from a commercial vendor. A screening library is often designed for the particular application. For example, one can purchase libraries tuned for activity against protein kinases, libraries with reactive groups that can form covalent bonds to the protein, and libraries designed to sample a wide range of compounds through high *chemical diversity*. A compound chosen at random from a screening library has a very low probability, typically 0.1% or less, of being active against a given target (Shun et al., 2011), and HTS measurements are subject to experimental error. Therefore, many of the compounds that appear active on an initial screen (*hit compounds*) are false positives, so careful data analysis and confirmatory testing are essential.

Even the confirmed hits from a high-throughput screen are far from being drugs. Their affinity for the target usually is orders of magnitude too weak, they may lack the desired specificity, and they do not meet DMPK or safety criteria. However, they offer an initial toehold on the challenge of finding a potent drug candidate. The next step is to purchase (*analogue by catalog*) and/or synthesize (*medicinal chemistry*) similar compounds that ultimately give a picture of how various changes in



Compound	ALDH1A1	ALDH2	ALDH3A1
1	0.02	82	7.7
2	0.06	2.1	16
3	0.58	2.1	69
4	0.07	3.5	0.45
5	0.07	>100	0.31
6	2.0	0.05	18

Figure 1–1 *Structure-activity relationship: scaffolds and substituents.* Five inhibitors of the aldhyde dehydrogenase family of enzymes have a common chemical scaffold (black) while having different chemical substituents at two positions (red, green). The table lists the IC_{50} (μM) of each compound for three members of the aldehyde dehydrogenase family of enzymes: ALDH1A1, ALDH2, and ALDH3A1; i.e., the concentration of compound needed to provide 50% inhibition of each enzyme. The lower the IC_{50}, the more potently the compound inhibits the enzyme. Focusing first on compounds **1**, **2**, and **3**, one can see that adding an increasingly bulky halogen atom (Cl, Br) on the six-membered ring tends to reduce the compound's potency against ALDH1A1 and ALDH3A1 but to increase it against ALDH2. Focusing next on compounds **1**, **4**, and **5**, one can see that adding increasingly bulky, nonpolar, aromatic substituents at the nitrogen modestly reduces the potency against ALDH1A1, initially improves but then destroys potency against ALDH2, and consistently improves potency against ALD3A1. Such patterns can guide the design of new compounds with desired potency and selectivity. For example, the substituents in compounds **3** and **4** each reduce potency against ALDH1A1 while increasing potency against ALDH2, so it is not surprising that compound **6**, which combines both substituents, has particularly low potency against ALDH1A1 and high potency against ALDH2. Note, however, that this kind of reasoning can only offer guidelines; its predictions are not always borne out by experiment. Data drawn from Kimble-Hill et al., 2014.

the chemical structure influence activity against the target (*structure-activity relationships, or SAR*) and other properties (Figure 1–1). This information is used to guide the synthesis of often hundreds of compounds with gradually improving properties. The most promising early molecules (*lead compounds*) serve as starting points for further improvement (*lead optimization*), ultimately generating, hopefully, a clinical candidate, potentially accompanied by several *backup compounds* in case the leading candidate fails.

Fragment-Based Drug Discovery

Even a large-scale screen can fail to provide useful hits (Keserü and Makara, 2009). This result becomes understandable when one recognizes that the number of stable, drug-sized, organic compounds is on the order of 10^{60} (Reymond et al., 2010), so a screen of even 10^6 compounds scarcely touches the vastness of *chemical space*. This vastness results from the combinatorial explosion of ways of connecting various chemical substructures, such as benzene rings, hydroxyl groups, and cycloalkanes. To be a good binder, a compound has to get multiple substructures positioned so they all form favorable interactions with complementary groups in the targeted binding pocket. If it has two chemical components suitable for binding the target but a third that is inappropriate or in the wrong place on the compound, it may fail to bind the target. This perspective motivates another method of discovering binders, *fragment-based drug discovery* (FBDD) (Erlanson, 2012; Lamoree and Hubbard, 2017). In FBDD, one conceptually breaks down drug-sized compounds into their substructures (*fragments*) and tests simple substructures against the target. Although such fragment-like molecules can bind only very weakly, such studies can, nonetheless, identify a small set of chemical substructures that are suitable for the target, and one can then buy or synthesize larger compounds assembled from these components. When either X-ray crystallography (Patel et al., 2014) or nuclear magnetic resonance spectroscopy (Shuker et al., 1996) is used to detect or analyze fragment binding, specific information is usually available about where each fragment binds to the protein. This information can be used to stitch together designed compounds that place the appropriate fragments at the right places in the protein's binding pocket (*fragment linking*) or to optimize and expand one selected fragment (*fragment growing*). In this way, FBDD avoids the combinatorial explosion of possible compounds made from various chemical components and allows researchers to focus quickly on compounds made from only a productive subset of chemical components. The drug *vemurafenib*, which targets an oncogenic mutation of B-Raf kinase and was developed with a fragment-growing strategy, is usually referenced as the first FBDD success story (Bollag et al., 2012).

Emerging Experimental Technologies

The difficulty and cost of drug discovery, coupled with the market and human need for new medications, have driven ongoing innovation in drug discovery technologies. For example, DNA-encoded compound libraries (DELs) dramatically expand the number of compounds that can be tested, relative to conventional HTS (Halford, 2017). Unlike a traditional HTS compound library, where each compound is kept in its own separate container or well, a DEL is a mixture of compounds in a single container and can include far more compounds—into the billions and even trillions. Each unique compound in the mixture is covalently bound to a corresponding unique short DNA molecule, which serves as an identification tag. Such libraries can be synthesized and tagged with the methods of *combinatorial chemistry*, where a mixture of compounds is split into multiple portions, each portion is modified with a different chemical step and its DNA tags modified accordingly, and the portions are mixed again. This process is iterated until the synthesis is complete. To screen the DEL for active compounds, one may immobilize the target of interest on a solid surface, expose the surface to the DEL mixture, and then wash the surface to remove all the DEL compounds that have not bound tightly to the target. The binders are then removed from the target by more aggressive washing, and the active compounds in the wash are identified by sequencing the DNA tags they carry.

Another emerging technology, sometimes termed *clinical trials in a dish* (Alpeeva et al., 2017; Fermini et al., 2018; Strauss and Blinova, 2017), aims to predict the effects of a compound in humans more accurately than is possible with standard cell culture or animal models. This approach involves creating specific cell types of interest from human pluripotent stem cells and using them to create three-dimensional organoids in culture (Fligor et al., 2018; Liu et al., 2021; Sato and Clevers, 2013) or artificial tissue architectures via three-dimensional bioprinting (Ferrer and Simeonov, 2017). These relatively intricate *in vitro* constructs promise to better recapitulate the properties of the corresponding *in vivo* tissues and may be used to test compounds for activity, DMPK properties, compound metabolism, and toxicity.

Computer-Aided Drug Discovery

The rise of information technology has enabled the research community to store and move large quantities of information, to write and maintain complex software, and to do calculations at unprecedented speed and scale. These continually improving capabilities are used in a variety of ways to support and accelerate drug discovery. Thus, chemical informatics enables compact databasing of information on hundreds of millions of compounds and rapid recovery of chemical data for a specific compound and/or chemically similar compounds (Willett et al., 1998), while the Internet makes chemical (Gaulton et al., 2012; Gilson et al., 2016; Kim et al., 2021), macromolecular (Benson et al., 1994; Berman et al., 2000; Berman and Gierasch, 2021; UniProt Consortium, 2015), biomolecular pathway (Croft et al., 2014; Ogata et al., 2000; Oughtred et al., 2021; Wishart et al., 2020), and other databases readily accessible to researchers worldwide. These data are useful in their own right and also support the development and evaluation of computer models used in drug discovery.

In parallel, exponential increases in computer speed, measured as the number of mathematical operations executed per second, have made more and more detailed molecular simulations feasible. Ideally, a computational chemist could design a compound, hand the design to a medicinal chemist to synthesize, and the compound would prove to bind the target with nanomolar affinity. When this level of accuracy becomes feasible, one might go further and compute the affinity of a candidate drug to all known human proteins in order to check for unwanted interactions. This level of accuracy is not possible today, but existing methods have predictive value, and growing computer power may make this vision achievable in the coming years.

Approaches to predicting the interactions of a small molecule with a protein may be broadly divided into *ligand-based* and *structure-based approaches*, as explained below.

Using Chemical Similarity to Discover Targeted Ligands

If the targeted protein is an enzyme with a small-molecule substrate or a receptor for a small-molecule transmitter (e.g., histamine), then compounds chemically similar to the substrate or transmitter may be active against the target and thus useful starting points for drug design (Figure 1–2). For some targets, more extensive information about ligands for the target may be available from prior drug discovery efforts and may be used to guide a new project. As noted above, even if a drug has already been developed against the target, there may still be room for a me-too drug with better properties, such as less frequent oral dosing or reduced side effects. Large quantities of data to support this ligand-based drug discovery approach are available in the scientific literature, patents, and public databases (Gaulton et al., 2012; Gilson et al., 2016; Kim et al., 2019).

Metrics of chemical similarity abstract the detailed chemical structures of compounds into characteristics that can be computed and compared across molecules. One approach computes a compound's molecular fingerprint, which indicates whether various molecular substructures are present (Muegge and Mukherjee, 2016). Other similarity metrics jettison such details and, instead, compute and compare the overall shapes of the two molecules and the electrical fields they generate (Bajorath, 2017). In a third approach, even molecular shape is set aside and one instead computes tens or hundreds of quantitative *descriptors* for each compound. Examples include simple descriptors, such as molecular weight or number of aromatic rings, and more complex descriptors such as electrical dipole and quadrupole moments. If one imagines descriptors as Cartesian coordinates in a multidimensional space, one can then quantify the similarity of two molecules in terms of how close they are in this *descriptor space* (Wale et al., 2008).

Similarity metrics such as these enable *virtual screening*, a fast, inexpensive, computational alternative to experimental HTS (Figure 1–3). In this approach, every compound in a chemical library—a large set of compounds that are available or synthesizable—is assessed for its similarity to one or more known ligands of the protein target. The most similar compounds are tested in an experimental assay, and confirmed hits become candidates for further chemical optimization. This approach is most relevant when the three-dimensional structure of the targeted protein has not been determined. When the structure is known, powerful structure-based methods become applicable.

Structure-Based Drug Design

The detailed three-dimensional structure of a targeted protein opens up a range of additional computational methods for designing a small molecule that binds the target with high affinity (Figure 1–4). The applicability of such SBDD methods has grown continually, due to rapid increases in computer power and the development of technologies that make determining protein structures easier and faster. One example is the use of synchrotrons (e.g., the Advanced Photon Source at Argonne National Laboratory) to generate high-quality X-ray beams for use in protein X-ray crystallography. Another is the development of methods to solve the structures of membrane-bound proteins, such as ion channels and cell-surface receptors. These can be high-quality drug targets because a drug does not need to enter the cell to access them and because they regulate many cellular processes. However, their structures were virtually impossible to solve until methods were developed in recent years to grow three-dimensional crystals of them. Since at least the 1980s, the promise of advances in SBDD methods has inspired the founding of multiple companies.

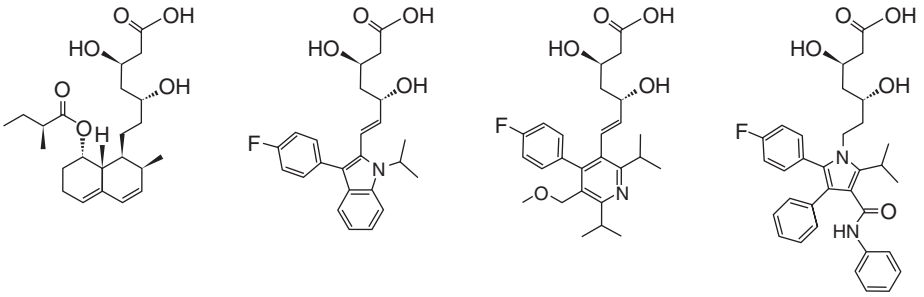
The field of physical chemistry tells us how to compute the binding affinity of two molecules in water (Gilson and Zhou, 2007). Ideally, one could use numerical solutions of Schrödinger's equation to obtain the electronic wave function for the compound, the target protein, and the aqueous solvent, for any given conformation of the system (i.e., given the Cartesian coordinates of all atoms). From the wave function, one could then compute the instantaneous force on every atom. Given this method of computing atomic forces, one could simulate the system at atomistic detail, computing the reversible work of gradually pulling the compound out of the protein binding site as all the atoms wiggled, jiggled, and shifted due to thermal motion (Feynman et al., 1963). This reversible work would equal the free energy of binding, ΔG^o, which is directly related to the dissociation constant, K_D:

$$\Delta G^o = RT \ln K_D \qquad \text{(Equation 1–1)}$$

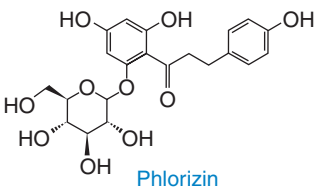
This would be a prohibitively massive calculation with existing computer technology. However, researchers have created fast approximations to such an ideal calculation, each with its own strengths and weaknesses in terms of accuracy, range of applicability, and the computer power required (Figure 1–5).

An important approximation used in molecular modeling is the force field or potential function, a mathematical model for the atomic forces that can be evaluated orders of magnitude faster than solving Schrödinger's equation (Dauber-Osguthorpe and Hagler, 2019). Force fields often contain adjustable parameters fitted to give agreement with reference solutions of Schrödinger's equation. With a force field in hand, it becomes practical to use molecular simulations to estimate protein-ligand binding free energies (Tembe and McCammon, 1984; Kollmann, 1993; Gilson et al., 1997; Simonson et al., 2002). Such *free energy methods* are among the most accurate approaches available to predict protein-ligand binding affinities (Schindler et al., 2020), and their use by the drug

A. Statins



B. SGLT Inhibitors



SGLT inhibitor	IC_{50} (nM) at SGLT1	IC_{50} (nM) at SGLT2	Relative selectivity for SGLT2 (col2/col3)
Phlorizin	290	21	~14
Canagliflozin	710	2.7	~260
Dapagliflozin	1400	1.2	~1200
Empagliflozin	8300	3.1	~2700
Ertugliflozin	2000	0.9	~2200

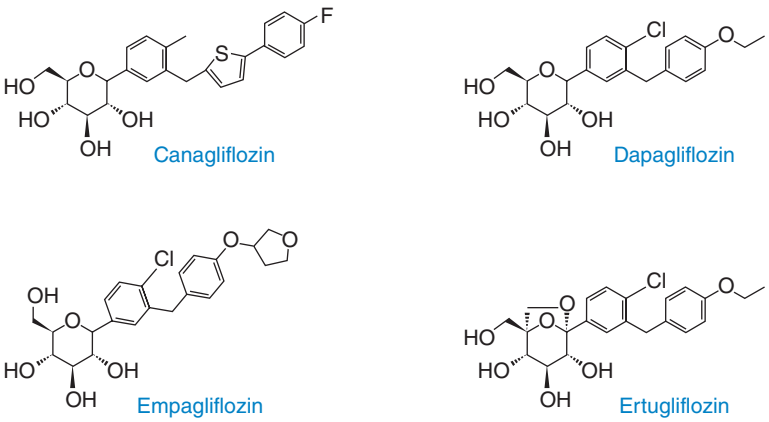


Figure 1–2 *Using chemical similarity to develop ligands.* **A.** *Statins.* Statins inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), the rate-limiting enzyme in cholesterol synthesis. These inhibitors are widely used to lower blood levels of cholesterol (see Chapter 37). Mevastatin is a natural product that inspired development of the three FDA-approved statins shown here. Each compound has a polycyclic lower part linked to a common hydroxyacid moiety, which can also exist as a cyclic lactone. **B.** *SGLT inhibitors.* Sodium-glucose cotransporters (SGLTs) facilitate glucose ingress in the gastrointestinal tract (SGLT1) and the kidney (SGLT2). The natural product phlorizin inhibits both SGLTs to varying extents. Modifications of the phlorizin structure led to the four FDA-approved relatively specific SGLT2 inhibitors, the gliflozins, shown here. Gliflozins reduce renal reabsorption of glucose, thereby lowering blood sugar concentrations, and thus are used to treat type 2 diabetes (see Chapter 51). Each compound has a glucose moiety (except *ertugliflozin*, which has a glucose-similar moiety), sensible for compounds that interact with transporters that bind glucose. Phenyl-containing moieties endow each inhibitor with varying activities against each of the two protein forms, as shown in the table. Activities are given as IC_{50}, the concentration of drug (nM) that reduces the transporter's activity by 50%. Data adapted from Fediuk et al. (2020) and Wright (2021).

discovery community has been enabled by the acceleration of molecular simulations on graphics processing units (GPUs) (Salomon-Ferrer R, et al., 2013). Even with GPUs, though, the simulations are too slow to replace an experimental high-throughput screen of millions of compounds. Instead, simulations are most commonly used to help medicinal chemists decide which chemical variations on a promising starting compound are worth synthesizing and testing. Fast molecular simulations also are used to explore the various conformations that a protein can adopt. For example, if a simulation shows that a new binding pocket could form as a result of thermal protein motions, it may be possible to design a drug that will bind this hitherto unrecognized site.

Another computational approach, *molecular docking* (Guedes et al., 2014; Huang, 2010; Meng, 2011), is fast enough to substitute for (or supplement) a large-scale experimental high-throughput screen. In docking, most or all of the protein is held rigid, and the software tries a vast number of different locations and conformations—*poses*—of a small molecule in the target's binding site, searching for the one that is lowest in energy and hence most stable. Because docking leaves out so many known contributions to the free energy of binding (e.g., protein flexibility and entropy), the energy model usually must be tuned against experimental binding data to make it more predictive. The resulting model is often called a docking *score*, to differentiate

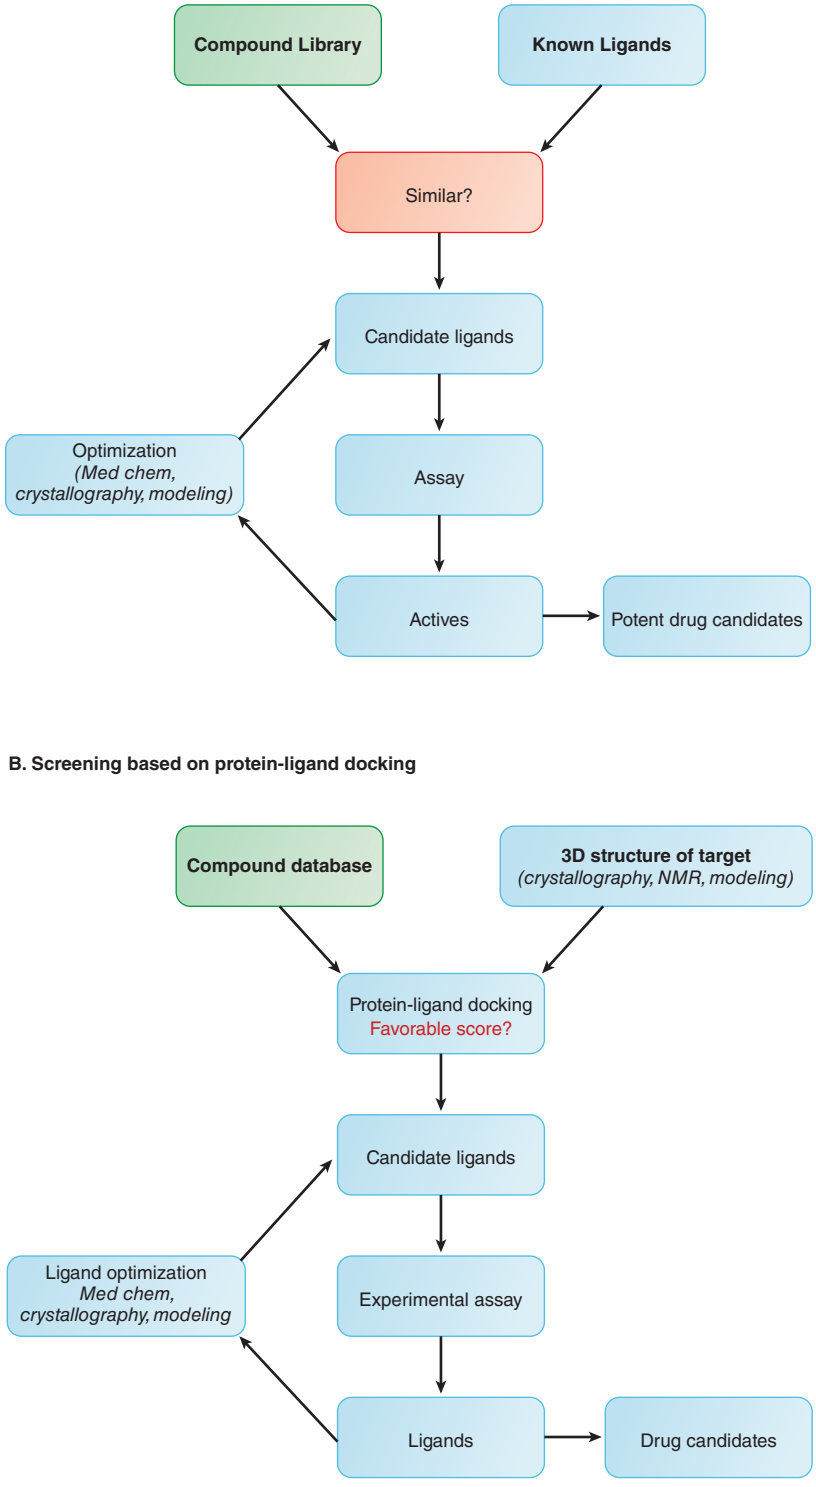

Figure 1–3 *Virtual screening.* **A.** *Virtual compound screening based on concepts of chemical similarity.* Using available similarity metrics, the compounds in a database (green) are computationally tested for chemical similarity to the known ligands (binders) of the targeted protein. Compounds that are above some threshold similarity are considered candidate ligands and so are experimentally assayed for binding to the protein target. Those found to be inactive are set aside, while "actives" are subjected to iterative rounds of ligand optimization where structure-activity relationships are defined and used to guide the design of new compounds by medicinal chemists. When sufficiently active compounds are found, these become early-stage drug candidates. **B.** *Virtual compound screening based on protein-ligand docking.* The compounds in a database (green) are computationally docked; i.e., optimally fitted into the binding site of a target protein of known three-dimensional structure. Compounds whose computed stabilizing interactions with the binding site are above a threshold similarity are considered candidate ligands and so are experimentally assayed for binding to the protein target. Those found to be inactive are set aside, while "actives" are subjected to iterative rounds of ligand optimization. This typically involves using the protein structure to design new compounds that can form better interactions with the binding site and solving crystal structures of the protein with selected compounds to determine whether the designed compounds bind as hoped and to guide further rounds of chemical design and synthesis. Advanced computational methods, such as simulation-based free energy calculations, may also be used at this stage. When sufficiently active compounds are found, these become early-stage drug candidates.

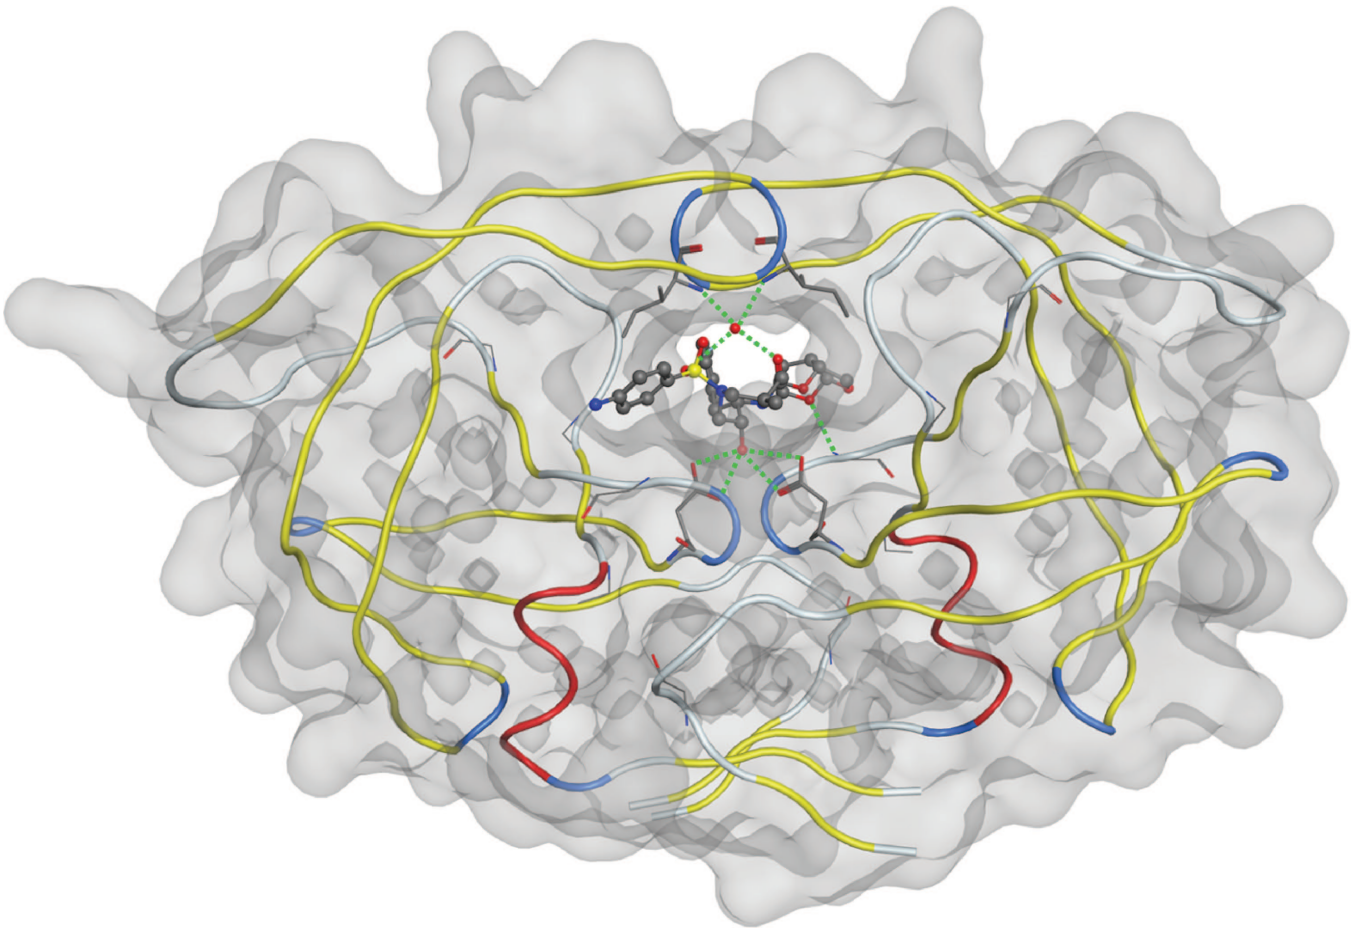

Figure 1–4 *Crystal structure of the human immunodeficiency virus 1 protease (HIV-1 protease) with the protease inhibitor darunavir bound in the active site.* Colored tubes: protein backbone of the enzyme, a symmetric dimer made up of two identical subunits, where color indicates secondary structure (yellow, β-sheet; red, α-helix; blue, turn; white, none). Translucent gray: overall surface of the protein, including both side-chain and backbone atoms. Ball and stick: *darunavir* in the tunnel-shaped active site, with atoms colored by element (gray, carbon; red, oxygen; blue, nitrogen), with hydrogen atoms omitted for simplicity. Key hydrogen bonds are shown as dashed green lines, and the oxygen of a water molecule that bridges between the drug and the protein is shown as a red ball. Atomic coordinates from Protein Data Bank (Wang et al., 2011).

it from a true force field. Docking calculations are typically used for *virtual HTS* (see Figure 1–3), in which thousands or millions of compounds in a chemical library are rapidly fitted into the binding site of the targeted protein. Tens or hundreds of the top-scoring compounds may then be subjected to more detailed calculations or tested experimentally. Although not all of the top-scoring compounds will be good binders, the fraction of binders will normally be enriched relative to the chemical library as a whole. In addition, the predicted binding poses may provide mechanistic insight and serve as starting points for molecular simulations (Guest et al., 2022; Heinzelmann and Gilson, 2021). The empirically tuned scoring functions used in docking can also be used to guide manual chemical editing of a known binder with graphical molecular modeling software. For example, one may manually edit an existing compound in the context of a three-dimensional rendering of the binding pocket to design a new compound that reaches into a neighboring subpocket and forms stabilizing hydrophobic and hydrogen-bonding interactions with the protein. This interactive work may be aided by immersive visualization and manipulation technologies, such as virtual reality.

Artificial Intelligence in Drug Discovery

Deep neural networks have proven their power in wide-ranging artificial intelligence tasks such as image recognition and language translation, and researchers are now exploring their use in drug discovery. These methods may be *trained* on existing data, such as on existing collections of protein–small-molecule binding data, the results of DELs, and protein structures, to enable direct prediction of protein–small-molecule binding and automated design of ligands for a targeted protein. They may also support drug discovery in other ways, such as by predicting the three-dimensional structures of proteins (AlQuraishi, 2021; Baek et al., 2021; Jumper et al., 2021), the energies of molecules as a function of conformation (Smith et al., 2017), and molecular properties such as whether a compound is water soluble (Francoeur and Koes, 2021). Artificial intelligence and machine learning will undoubtedly play an expanding role in drug discovery in the coming years.

Designing Large Molecules as Drugs: The Rise of Biopharmaceuticals

Large molecules are increasingly important as therapeutic agents. For example, antisense oligonucleotides are used to block gene transcription or translation, as are siRNAs and modified mRNAs (as in several vaccines for SARS-CoV-2 [severe acute respiratory syndrome coronavirus 2]). Important proteins used therapeutically include monoclonal antibodies, enzymes, and peptide hormones. Protein therapeutics were uncommon before the advent of recombinant DNA technology except for the few peptide hormones that could be isolated and purified in bulk. Insulin was

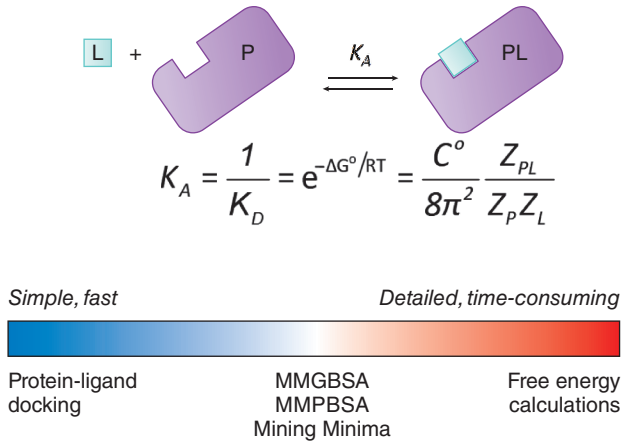

Figure 1–5 *Physics-based computational methods for estimating protein-ligand binding affinities.* These methods provide an estimate of the association constant, K_A, for binding of a ligand, L, to a protein of known three-dimensional structure, P, to form a protein-ligand complex, PL, held together typically by noncovalent interactions such as hydrogen bonding and the hydrophobic effect. The equation relates K_A to the standard free energy of binding ΔG^o, the gas constant R, and the absolute temperature T, and further relates the binding free energy to the standard concentration C^o, and the configuration integrals of the protein-ligand complex (Z_{PL}), the unbound protein (Z_P), and the unbound ligand (Z_L). As more low-energy conformations are accessible to each molecular species (PL, P, L), the corresponding value of Z increases. Therefore, if the protein-ligand complex can access more low-energy conformations than the separate protein and ligand, the equilibrium constant will be large, favoring binding. Direct calculation of these configuration integrals is a computational challenge; however, researchers have created a spectrum of computational methods, ranging from fast, approximate methods that are expected to be less accurate, to more detailed, more computationally demanding methods that are typically more accurate (Gilson and Zhou, 2007). Docking, discussed in the text, is at the fast end of the spectrum; it treats the protein as mainly rigid, along with other approximations. Free energy calculations, also discussed in the text, are at the slow end of the spectrum; they treat the protein and ligand as fully flexible. In the middle of the spectrum are the molecular mechanics generalized Born/surface area (MMGBSA) (Srinivasan et al., 1998), molecular mechanics Poisson-Boltzmann/surface area (MMPBSA) (Gouda et al., 2003), and Mining Minima methods (Chen et al., 2010). These use various approaches to directly estimate the configuration integrals, Z_{PL}, Z_P, and Z_L. For example, Mining Minima searches for low-energy conformations of the protein, the ligand, and the complex; estimates their individual contributions to Z; and sums these contributions to provide an overall estimate of the configuration integral.

introduced into clinical medicine for the treatment of diabetes following the experiments of Banting and Best in 1921. Insulins purified from porcine or bovine pancreas are active in humans, although antibodies to the foreign proteins are occasionally problematic. Growth hormone, used to treat pituitary dwarfism, exhibits more stringent species specificity. Only the human hormone could be used after purification from pituitary glands harvested during autopsy, and such use had its dangers—some patients who received the human hormone developed Creutzfeldt-Jakob disease (the human equivalent of mad cow disease), a fatal degenerative neurological disease caused by prion proteins that contaminated the drug preparation.

Thanks to gene cloning, expression of the cloned gene in bacteria or eukaryotic cells, and large-scale production techniques, protein therapeutics now use highly purified preparations of human (or humanized) proteins. Rare proteins can be produced in quantity, and immunological reactions are minimized. Proteins can be designed, customized, and optimized using genetic engineering techniques.

Proteins used therapeutically include hormones, growth factors (e.g., erythropoietin, granulocyte colony-stimulating factor), cytokines, and a number of monoclonal antibodies used in the treatment of cancer and autoimmune diseases (see Chapters 38–40, 45, and 72). Murine monoclonal antibodies can be "humanized" (by substituting human for mouse amino acid sequences). Alternatively, mice have been engineered by replacement of critical mouse genes with their human equivalents, such that they make completely human antibodies. Protein therapeutics are administered parenterally, and their receptors or targets must be accessible extracellularly.

Using some of the strategies outlined above, nonantibody therapeutic proteins and peptides can now be optimized for stability, activity, and targeting to particular cell types. Peptides are being developed as therapeutics, especially in the area of interrupting protein-protein interactions where the large contact surfaces may defy small-molecule action. Computational methods are proving very useful in the design of peptide therapeutics (Belvisi et al., 2021). Therapeutic proteins are usually close copies of naturally occurring proteins that are optimized for high stability (both during manufacture and after administration) and optimized to avoid rapid degradation, to have low immunogenicity, and to have high potency when administered to a patient. Strategies include optimizing expression of a protein's gene sequence in multiple hosts, exploring close relatives of the protein of interest and mutations (random and rational), introduction of posttranslational modifications, and exploring biological modifications such as fusion with macromolecules (Dellas et al., 2021). Conjugation strategies (e.g., PEGylation) can be used to improve pharmacokinetic properties of therapeutic proteins (Moncalvo et al., 2020). The roster of recently engineered proteins that are not antibodies includes agents for cancers, gout, clotting disorders and hemophilia, inherited metabolic diseases, lysosomal storage disorders, pancreatic exocrine deficiency, insufficiencies of hormones and growth factors, and macular degeneration, among others. The number of nonantibody FDA-approved therapeutic proteins and peptides is growing rapidly (see a database of FDA-approved proteins and peptides at https://webs.iiitd.edu.in/raghava/thpdb/index.html; Usmani et al., 2017). A few protein therapeutics are administered topically or orally, but most are administered by injection. However, this is changing with the development of liposomal drug delivery systems, which are administered parenterally but are proving amenable to inhalation, ocular, and topical routes.

The Investigational New Drug Application

Before the drug candidate can be administered to human subjects in a clinical trial, the sponsor must file an Investigational New Drug (IND) application, a request to the FDA for permission to use the drug for human research (see Clinical Trials, below). The IND describes the rationale and preliminary evidence for efficacy in experimental systems, as well as pharmacology, toxicology, chemistry, manufacturing, and so forth. It also describes the plan (protocol) for investigating the drug in human subjects. The FDA has 30 days to review the IND application, by which time the agency may disapprove it, ask for more data, or allow initial clinical testing to proceed.

Clinical Trials

Role of the FDA

The FDA, a federal regulatory agency within the U.S. Department of Health and Human Services (DHHS), is responsible for protecting the public health by ensuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation's food supply, cosmetics, and products that emit radiation (FDA, 2018). The FDA also is responsible for advancing public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable and by helping people obtain the accurate, science-based information they need to use medicines and foods to improve their health.

The first drug-related legislation in the U.S., the Federal Pure Food and Drugs Act of 1906, was concerned only with the interstate transport of adulterated or misbranded foods and drugs. Motivations for federal regulation included the prominence of "patent medicines" and

their adulteration, the journalism of S. H. Adams (via articles in *Colliers Weekly*), and Upton Sinclair's novel *The Jungle* (Law, 2004). In the 1906 act, there were no obligations to establish drug efficacy or safety. This act was amended in 1938 after the deaths of over 100 children from "elixir sulfanilamide," a solution of *sulfanilamide* in *diethylene glycol*, an excellent but highly toxic solvent and an ingredient in antifreeze. The enforcement of the amended act was entrusted to the FDA, which began requiring toxicity studies as well as approval of a New Drug Application (NDA) (see The Conduct of Clinical Trials, below) before a drug could be promoted and distributed. Although a new drug's safety had to be demonstrated, no proof of efficacy was required.

In the 1960s, *thalidomide*, a hypnotic drug with no obvious advantages over others, was introduced in Europe. Epidemiological research eventually established that this drug, taken early in pregnancy, was responsible for an epidemic of what otherwise is a relatively rare and severe birth defect, phocomelia, in which limbs are malformed. In reaction to this catastrophe, the U.S. Congress passed the Harris-Kefauver amendments to the Food, Drug, and Cosmetic Act in 1962. These amendments established the requirement for proof of efficacy as well as documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated (the more serious the disease, the greater the acceptable risk). Today, the FDA faces an enormous challenge, especially in view of the widely held belief that its mission cannot possibly be accomplished with the resources allocated by Congress. Moreover, harm from drugs that cause unanticipated adverse effects is not the only risk of an imperfect system; harm also occurs when the approval process delays the approval of a new drug with important beneficial effects.

The Conduct of Clinical Trials

Clinical trials of drugs are designed to acquire information about the pharmacokinetic and pharmacodynamic properties of a candidate drug in humans and to establish the efficacy and safety of the drug prior to its sale in the U.S. The U.S. National Institutes of Health (NIH) identifies seven ethical principles that must be satisfied before a clinical trial can begin (NIH, 2021):

1. Social and clinical value
2. Scientific validity
3. Fair selection of subjects
4. Informed consent
5. Favorable risk-benefit ratio
6. Independent review
7. Respect for potential and enrolled subjects

The FDA-regulated clinical trials typically are conducted in four phases. Phases I to III are designed to establish safety and efficacy. Phase IV postmarketing trials and surveys gather additional data from larger populations and increasing numbers of administered doses. This phase provides information regarding new indications, risks, and optimal doses and schedules, as presented in Chapter 8. Table 1–1 and Figure 1–6 summarize the important features of each phase of clinical trials; note the attrition at each successive stage over a relatively long and costly process. When initial phase III trials are complete, the sponsor (usually a pharmaceutical company) applies to the FDA for approval to market the drug; this application is called either an NDA or a BLA (Biologics License Application). These applications contain comprehensive information, including individual case report forms from the hundreds or thousands of individuals who have received the drug during its phase III testing. Applications are reviewed by teams of specialists, and the FDA may call on the help of panels of external experts in complex cases.

Under the provisions of the Prescription Drug User Fee Act (PDUFA; enacted in 1992 and renewed every 5 years, most recently in 2017), pharmaceutical companies now provide a significant portion of the FDA budget via user fees, a legislative effort to expedite the drug approval review process by providing increased resources. The PDUFA also broadened the FDA's drug safety program and increased resources for review of television drug advertising. Under PDUFA, review typically takes 6 to 10 months after an NDA is submitted to the FDA. During this time, numerous review functions are usually performed, including advisory committee meetings, amendments, manufacturing facility inspections, and proprietary name reviews (FDA, 2013). Before a drug is approved for marketing, the company and the FDA must agree on the content of the "label" (package insert)—the official prescribing information. This label describes the approved indications for use of the drug and clinical pharmacological information, including dosage, adverse reactions, and special warnings and precautions (sometimes posted in a "black box"). Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. Importantly, the physician is not bound by the package insert; a physician in the U.S. may legally prescribe a drug for any purpose that he or she deems reasonable. However, third-party payers (insurance companies, Medicare, and so on) generally will not reimburse a patient for the cost of a drug used for an "off-label" indication unless the new use is supported by a statutorily named compendium (e.g., the American Hospital Formulary Service–Drug Information [AHFS-DI]). Furthermore, a physician may be vulnerable to litigation if untoward effects result from an unapproved use of a drug.

TABLE 1–1 ■ TYPICAL CHARACTERISTICS OF THE PHASES OF CLINICAL TRIALS REQUIRED BY THE FDA BEFORE THE MARKETING OF NEW DRUGS*

PHASE I FIRST IN HUMAN	PHASE II FIRST IN PATIENT	PHASE III MULTISITE TRIAL	PHASE IV POSTMARKETING
10–100 participants	50–500 participants	A few hundred to a few thousand participants	Many thousands of participants
Usually healthy volunteers; occasionally patients with advanced or rare disease	Patient-subjects receiving experimental drug	Patient-subjects receiving experimental drug	Patients in treatment with approved drug
Open label	Randomized and controlled (can be placebo controlled); may be blinded	Randomized and controlled (can be placebo controlled) or uncontrolled; may be blinded	Open label
Safety and tolerability	Efficacy and dose ranging	Confirm efficacy in larger population	Adverse events, compliance, drug-drug interactions
1–2 years	2–3 years	3–5 years	No fixed duration
U.S. $10 to 15 million	U.S. $20 to 40 million	U.S. $50–150 million	Variable
Success rate: 50%	Success rate: 30%	Success rate: 25%–50%	—

*Costs of clinical trial phases vary widely with a drug's therapeutic area, size and complexcity of trial, whether trial must prove non-inferiority to existing agents, etc. Overall cost to develop a new molecular entity (NME) from laboratory to FDA approval is estimated at $1 billion to $4 billion.

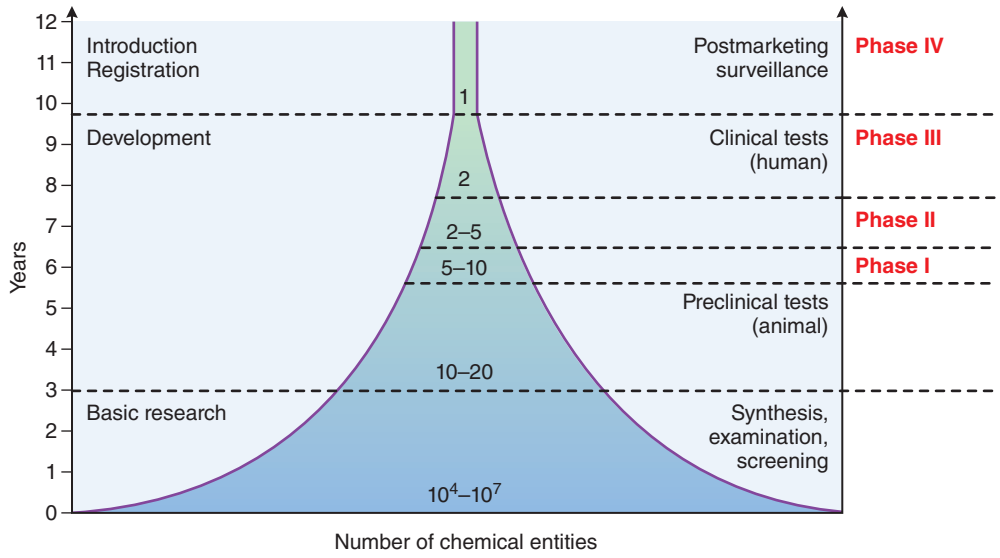

Figure 1–6 *The phases, timelines, and attrition that characterize the development of new drugs.* See also Table 1–1.

Determining "Safe" and "Effective"

Demonstrating efficacy to the FDA requires performing "adequate and well-controlled investigations," generally interpreted to mean two replicate clinical trials that are usually, but not always, randomized, double-blind, and placebo (or otherwise) controlled. Is a placebo the proper control? The World Medical Association's Declaration of Helsinki (World Medical Association, 2013) discourages use of placebo controls when an alternative treatment is available for comparison because of the concern that study participants randomized to placebo in such a circumstance would, in effect, be denied treatment during the conduct of the trial. What must be measured in the trials? In a straightforward trial, a readily quantifiable parameter (a secondary or surrogate end point), thought to be predictive of relevant clinical outcomes, is measured in matched drug- and placebo-treated groups. Examples of surrogate end points include low-density lipoprotein (LDL) cholesterol as a predictor of myocardial infarction, elevated high-density lipoprotein (HDL) cholesterol as a predictor of reduced risk of myocardial infarction (see Box 1–2), bone mineral density as a predictor of fractures, or hemoglobin A_{1c} as a predictor of the complications of diabetes mellitus. More stringent trials would require demonstration of reduction of the incidence of myocardial infarction in patients taking a candidate drug in comparison with those taking an HMG-CoA reductase inhibitor (statin) or other LDL cholesterol–lowering agent or reduction in the incidence of fractures in comparison with those taking a bisphosphonate. Use of surrogate end points significantly reduces cost and time required to complete trials, but there are many mitigating factors, including the significance of the surrogate end point to the disease that the candidate drug is intended to treat.

Some of the difficulties are well illustrated by experiences with *ezetimibe*, a drug that inhibits absorption of cholesterol from the gastrointestinal tract and lowers LDL cholesterol concentrations in blood, especially when used in combination with a statin. Lowering of LDL cholesterol was assumed to be an appropriate surrogate end point for the effectiveness of *ezetimibe* to reduce myocardial infarction and stroke, and the drug was approved based on such data. Surprisingly, a subsequent clinical trial (ENHANCE) demonstrated that the combination of *ezetimibe* and a statin did not reduce intima media thickness of carotid arteries (a more direct measure of subendothelial cholesterol accumulation) compared with the statin alone, despite the fact that the drug combination lowered LDL cholesterol concentrations substantially more than did either drug alone (Kastelein et al., 2008). Critics of ENHANCE argued that the patients in the study had familial hypercholesterolemia, had been treated with statins for years, and did not have carotid artery thickening at the initiation of the study. Should *ezetimibe* have been approved? Must we return to measurement of true clinical end points (e.g., myocardial infarction) before approval of drugs that lower cholesterol by novel mechanisms? The costs involved in such extensive and expensive trials must be borne somehow (see below). A follow-up 7-year study involving over 18,000 patients (IMPROVE-IT) vindicated the decision to approve *ezetimibe* (Jarcho and Keaney, 2015). Taken in conjunction with a statin, the drug significantly reduced the incidence of myocardial infarction and stroke in high-risk patients.

No drug is totally safe; all drugs produce unwanted effects in at least some people at some dose. Many unwanted and serious effects of drugs occur so infrequently, perhaps only once in several thousand patients, that they go undetected in the relatively small populations (a few thousand) in the standard phase III clinical trial (see Table 1–1). To detect and verify that such comparatively rare effects are, in fact, drug-related would require administration of the drug to tens or hundreds of thousands of people during clinical trials, adding enormous expense and time to drug development and delaying access to potentially beneficial therapies. In general, the true spectrum and incidence of untoward effects become known only after a drug is released to the broader market and used by a large number of people (phase IV, postmarketing surveillance). Drug development costs and drug prices could be reduced substantially if the public were willing to accept more risk. This would require changing the way we think about a pharmaceutical company's liability for damages from an unwanted effect of a drug that was not detected in clinical trials deemed adequate by the FDA. Would the public accept a drug with extremely severe unwanted effects, including death, if its therapeutic effect were sufficiently unique and valuable? Such dilemmas are not simple and can become issues for great debate.

Several strategies exist to detect adverse reactions after marketing of a drug. Formal approaches for estimation of the magnitude of an adverse drug response include the follow-up or cohort study of patients who

BOX 1–2 ■ A Late Surprise in the Search for a Blockbuster

Torcetrapib elevates HDL cholesterol (the "good cholesterol"). Higher levels of HDL cholesterol are statistically associated with (are a surrogate end point for) a lower incidence of myocardial infarction. Surprisingly, clinical administration of *torcetrapib* caused a significant *increase* in mortality from cardiovascular events, ending a development path of 15 years and $800 million. In this case, approval of the drug based on this secondary end point would have been a mistake (Cutler, 2007). A computational systems analysis suggested a mechanistic explanation of this failure (Xie et al., 2009).

are receiving a particular drug; the case-control study, in which the frequency of drug use in cases of adverse responses is compared to controls; and meta-analysis of pre- and postmarketing studies. Voluntary reporting of adverse events has proven to be an effective way to generate an early signal that a drug may be causing an adverse reaction (Aagard and Hansen, 2009). The primary sources for the reports are responsible, alert physicians and third-party payers (pharmacy benefit managers, insurance companies); consumers also play important roles. Other useful sources are nurses, pharmacists, and students in these disciplines. In addition, hospital-based pharmacy and therapeutics committees and quality assurance committees frequently are charged with monitoring adverse drug reactions in hospitalized patients. In the U.S., the FDA sponsors MedWatch, a drug safety information and adverse event reporting program. The website for MedWatch (http://www.fda.gov/Safety/MedWatch/default.htm) provides simple forms for reporting and lists recent safety alerts about specific medications. In addition to online access, the service may be reached by calling 800-FDA-1088. Health professionals also may contact the pharmaceutical manufacturer, who is legally obligated to file reports with the FDA.

Personalized (Individualized, Precision) Medicine

Drug inventors strive to "fit" the drug to the individual patient. To realize the full potential of this approach, however, requires intimate knowledge of the considerable heterogeneity of both the patient population and the targeted disease process. Why does one antidepressant appear to ameliorate depression in a given patient, while another drug with the same or very similar presumed mechanism of action does not? Is this a difference in the patient's response to the drug; in patient susceptibility to the drug's unwanted effects; in the drug's ADME; or in the etiology of the depression? How much of this variability is attributable to environmental factors and possibly their interactions with patient-specific genetic variability? Recent advances, especially in genetics and genomics, provide powerful tools for understanding this heterogeneity. The single most powerful tool for unraveling these myriad mysteries is the ability to sequence DNA rapidly and economically. The cost of sequencing a human's genome is now less than $1000, about six orders of magnitude lower than at the start of the 21st century (National Human Genome Research Institute, 2021). The current focus is on the extraordinarily complex analysis of the enormous amounts of data now being obtained from many thousands of individuals, ideally in conjunction with deep knowledge of their phenotypic characteristics, especially including their medical histories. Readily measured biomarkers of disease are powerful adjuncts to DNA sequence information. Simple blood or other tests can be developed to monitor real-time progress or failure of treatment; many such examples already exist. Similarly, chemical, radiological, and genetic tests may be useful not only to monitor therapy but also to predict success or failure, anticipate unwanted effects of treatment, or appreciate pharmacokinetic variables that may require adjustments of dosage or choice of drugs. Such tests already play a significant role in the choice of drugs for cancer chemotherapy, and the list of drugs specifically designed to "hit" a mutated target in a specific cancer is growing. Such information is also becoming increasingly useful in the choice of patients for clinical trials of specific agents, thereby reducing the time required for such trials and their cost, to say nothing of better defining the patient population who may benefit from the drug. These important subjects are discussed in detail in Chapter 7, Pharmacogenetics, and in Chapter 8, Postmarketing Drug Safety.

Public Policy Considerations

The Pharmaceutical Industry Operates in a Capitalist Economy

Drugs can save lives, prolong lives, and improve the quality of people's lives. However, in a free-market economy, access to drugs is not equitable. Not surprisingly, there is tension between those who treat drugs as entitlements and those who view drugs as high-tech products of a capitalistic society. Supporters of the entitlement position argue that a constitutional right to healthcare should guarantee access to drugs, and they are critical of pharmaceutical companies and others who profit from the business of making and selling drugs. Free-marketeers point out that, without a profit motive, it would be difficult to generate the resources and innovation required for new drug development. Clearly, drug development is both a scientific process and a political one, and also a process about which attitudes can change quickly. Critics of the pharmaceutical industry frequently begin from the position that people (and animals) need to be protected from greedy and unscrupulous companies and scientists (Angell, 2015; Kassirer, 2005; Ryan and DeSanctis, 2005). In the absence of a government-controlled drug development enterprise, our current system relies predominantly on investor-owned pharmaceutical companies that, like other companies, have a profit motive and an obligation to shareholders. The price of prescription drugs causes great consternation among consumers, especially as many health insurers seek to control costs by choosing not to cover certain "brand-name" products (see below). Further, a few drugs (especially for treatment of cancer) have been introduced to the market in recent years at prices that greatly exceeded the costs of development, manufacture, and marketing of the product. Many of these products were discovered in government laboratories or in university laboratories supported by federal grants. The U.S. is the only large country that places no controls on drug prices and where price plays no role in the drug approval process. Many U.S. drugs cost much more in the U.S. than overseas; thus, U.S. consumers subsidize drug costs for the rest of the world, and they are irritated by that fact. The example of newer agents for the treatment of hepatitis C infection brings many conflicting priorities into perspective (Box 1–3).

BOX 1–3 ■ The Cost of Treating Hepatitis C

Infection with hepatitis C virus (HCV) is a chronic disease afflicting millions of people. Some suffer little from this condition; many others eventually develop cirrhosis or hepatocellular carcinoma. Who should be treated? The answer is unknown. Until recently, the treatment of choice for people with genotype 1 HCV involved year-long administration of an interferon (by injection) in combination with *ribavirin* and a protease inhibitor. Unwanted effects of this regimen are frequent and severe (some say worse than the disease); cure rates range from 50% to 75%. A newer treatment involves an oral tablet containing a combination of *sofosbuvir* and *ledipasvir* (see Chapter 63). Treatment usually requires daily ingestion of one tablet for 8 to 12 weeks; cure rates exceed 95%, and side effects are minimal.

Controversy surrounds the price of the treatment, about $1000/day. Some insurers refused to reimburse this high cost, relegating many patients to less effective, more toxic, but less expensive treatment. However, these third-party payers have negotiated substantial discounts of the price, based on the availability of a competing product. Is the cost exorbitant? Should insurers, rather than patients and their physicians, be making such important decisions?

Continued and excessive escalation of drug and other healthcare costs will bankrupt the healthcare system. The question of appropriate cost involves complex pharmacoeconomic considerations. What are the relative costs of the two treatment regimens? What are the savings from elimination of the serious sequelae of chronic HCV infection? How does one place value to the patient on the less toxic and more effective and convenient regimen? What are the profit margins of the company involved? Who should make decisions about costs and choices of patients to receive various treatments? How should we consider cases (unlike that for HCV) for which the benefits are quite modest, such as when a very expensive cancer drug extends life only briefly? One astute observer (and an industry critic of many drug prices) summarized the situation as follows: "great, important problem; wrong example."

The drug development process is long, expensive, and risky (see Figure 1–6 and Table 1–1). Consequently, drugs must be priced to recover the substantial costs of invention and development and to fund the marketing efforts needed to introduce new products to physicians and patients. Depending on the methods of accounting for sales and dispensing, prescription drugs account for 9% to 13% of total U.S. healthcare expenditures (Conti et al., 2021).

Although the increase in prices is significant in certain classes of drugs (e.g., anticancer agents), the total price of prescription drugs is growing at a slower rate than other healthcare costs. Even drastic reductions in drug prices that would severely limit new drug invention would not lower the overall healthcare budget by more than a few percent. Are profit margins excessive among the major pharmaceutical companies? There is no objective answer to this question. Pragmatic answers come from the markets and from company survival statistics. The U.S. free-market system provides greater rewards for particularly risky and important fields of endeavor, and many people argue that the rewards should be greater for those willing to take the risk. The pharmaceutical industry is clearly one of the more risky:

- The costs to bring products to market are enormous.
- The success rate of drug development is low (accounting for much of the cost).
- Accounting for the long development time, effective patent protection for marketing a new drug is only about a decade (see Intellectual Property and Patents).
- Regulation is stringent.
- Product liability is great.
- Competition is fierce.
- With mergers and acquisitions, the number of companies in the pharmaceutical world is shrinking.

Many feel that drug prices should be driven more by their therapeutic impact and their medical need, rather than by simpler free-market considerations; there is movement in this direction. There are many components and points of contention in estimating a drug's value (Schnipper et al., 2015), and, as a consequence, there is no well-accepted approach to answer the question of value.

Who Pays?

The cost of prescription drugs is borne by consumers ("out of pocket"), private insurers, and public insurance programs such as Medicare, Medicaid, and the State Children's Health Insurance Program (SCHIP). Some major retailers and mail-order pharmacies run by private insurers offer consumer incentives for purchase of generic drugs, and these initiatives have helped to contain the portion of household expenses spent on pharmaceuticals; however, more than one-third of total retail drug costs in the U.S. are paid with public funds—tax dollars. Healthcare in the U.S. is more expensive than everywhere else, but it is not, on average, demonstrably better than everywhere else. One way in which the U.S. system falls short is with regard to healthcare access. Although the Patient Protection and Affordable Care Act of 2010 ("Obamacare") has reduced the percentage of Americans without health insurance to a historic low, practical solutions to the challenge of providing healthcare for all who need it must recognize the importance of incentivizing innovation.

Intellectual Property and Patents

Drug invention produces intellectual property eligible for patent protection, protection that is enormously important for innovation. As noted by Abraham Lincoln, the only U.S. president to ever hold a patent (for a device to lift boats over shoals; never commercially produced):

> *Before* [patent laws], *any man might instantly use what another had invented; so that the inventor had no special advantage from his own invention. The patent system changed this; secured to the inventor, for a limited time, the exclusive use of his invention; and thereby added the fuel of interest to the fire of genius, in the discovery and production of new and useful things.* (Lincoln, 1859)

The U.S. patent protection system provides protection for 20 years from the time the patent is filed. During this period, the patent owner of a drug has exclusive rights to market and sell the drug. When the patent expires, equivalent nonproprietary products can come on the market. A generic product must be therapeutically equivalent to the original, contain equal amounts of the same active chemical ingredient, and achieve equal concentrations in blood when administered by the same routes. These generic preparations are sold much more cheaply than the original drug and without the huge development costs borne by the original patent holder. The long time course of drug development, often more than 10 years (see Figure 1–6), reduces the time during which patent protection functions as intended. The Drug Price Competition and Patent Term Restoration Act of 1984 (Public Law 98-417, informally called the Hatch-Waxman Act) permits a patent holder to apply for extension of a patent term to compensate for delays in marketing caused by FDA approval processes; nonetheless, the average new drug brought to market now enjoys only about 10 to 12 years of patent protection. Some argue that patent protection for drugs should be shortened, so that earlier generic competition will lower healthcare costs. The counterargument is that new drugs would have to carry even higher prices to provide adequate compensation to companies during a shorter period of protected time. If that is true, lengthening patent protection would actually permit lower prices. Recall that patent protection is worth little if a superior competitive product is invented and brought to market.

Bayh-Dole Act

The Bayh-Dole Act (35 U.S.C. § 200) of 1980 created strong incentives for federally funded scientists at academic medical centers to approach drug invention with an entrepreneurial spirit. The act transferred intellectual property rights to the researchers and their respective institutions (rather than to the government) to encourage partnerships with industry that would bring new products to market for the public's benefit. While the need to protect intellectual property is generally accepted, this encouragement of public-private research collaborations has given rise to concerns about conflicts of interest by scientists and universities (Kaiser, 2009).

Biosimilars

The path to approval of a chemically synthesized small molecule that is identical to an approved compound whose patent protection has expired is relatively straightforward. The same is not true for large molecules (usually proteins), which are generally derived from a living organism (e.g., eukaryotic cell or bacterial culture). Covalent modification of proteins (e.g., glycosylation) or conformational differences may influence pharmacokinetics, pharmacodynamics, immunogenicity, or other properties, and demonstration of therapeutic equivalence may be a complex process. The Biologics Price Competition and Innovation Act was enacted as part of the Affordable Care Act in 2010. The intent was to implement an abbreviated licensure pathway for certain "similar" biological products. Biosimilarity is defined to mean "that the biological product is highly similar to a reference product notwithstanding minor differences in clinically inactive components" and that "there are no clinically meaningful differences between the biological product and the reference product in terms of the safety, purity, and potency of the product." In general, an application for licensure of a biosimilar must provide satisfactory data from analytical studies, animal studies, and one or more clinical studies. However, the interpretation of this language has involved endless discussion, and hard-and-fast rules seem unlikely.

Drug Promotion

In an ideal world, physicians would learn all they need to know about drugs from the medical literature, and good drugs would sell themselves. Instead, we have print advertising, visits from salespeople directed at physicians, and extensive direct-to-consumer advertising aimed at the public (in print, on the radio, and especially on television). There are roughly 80,000 pharmaceutical sales representatives in the U.S. who target about 10 times that number of physicians. The number of salespeople is down

from about 100,000 in 2010, a decline possibly related to increased attention to conflicts of interest. The amount spent on promotion of drugs approximates or perhaps even exceeds that spent on research and development. Pharmaceutical companies have been especially vulnerable to criticism for some of their marketing practices (Angell, 2015). Promotional materials used by pharmaceutical companies cannot deviate from information contained in the FDA-approved package insert. In addition, there must be an acceptable balance between presentation of therapeutic claims for a product and discussion of unwanted effects. Such requirements notwithstanding, direct-to-consumer advertising of prescription drugs remains controversial and is permitted only in the U.S. and New Zealand. Canada allows a modified form of advertising in which either the product or the indication can be mentioned, but not both. The efficacy of direct televised marketing is measurable (Gray et al., 2020; Sullivan et al., 2021), and physicians frequently succumb, albeit with misgivings, to patients' advertising-driven requests for specific medications.

The counterargument to such marketing is that patients are educated by such marketing efforts and are thereby encouraged to seek medical care, especially for conditions (e.g., depression) that they may have been denying (Avery et al., 2012). A major criticism of drug marketing involves some of the unsavory approaches used to influence physician behavior. Gifts of value (e.g., sports tickets) are now forbidden, but dinners where drug-prescribing information is presented by non–sales representatives are widespread. Large numbers of physicians are paid as "consultants" to make presentations in such settings. The acceptance of any gift, no matter how small, from a drug company by a physician is now forbidden at many academic medical centers and by law in several states. In 2009, the board of directors of the Pharmaceutical Research and Manufacturers of America (PhRMA) adopted an enhanced *Code on Interactions With Healthcare Professionals* that prohibits the distribution of noneducational items, prohibits company sales representatives from providing restaurant meals to healthcare professionals (although exceptions are granted when a third-party speaker makes the presentation), and requires companies to ensure that their representatives are trained about laws and regulations that govern interactions with healthcare professionals.

Concerns About Global Injustice

Drug discovery is expensive (see Table 1–1), and economic realities influence the direction of pharmaceutical research. For example, investor-owned companies generally cannot afford to develop products for rare diseases or for diseases that are common only in economically underdeveloped parts of the world. Funds to invent drugs targeting rare diseases or diseases primarily affecting developing countries (e.g., malaria, schistosomiasis, and other parasitic diseases) often come from taxpayers or wealthy philanthropists.

Because development of new drugs is so expensive, private-sector investment in pharmaceutical innovation has focused on products that will have lucrative markets in wealthy countries such as the U.S., which combines patent protection with a free-market economy. Accordingly, there is concern about the degree to which U.S. and European patent protection laws have restricted access to potentially lifesaving drugs in developing countries. To lower costs, pharmaceutical companies increasingly test their experimental drugs outside the U.S. and the E.U., in developing countries where there is less regulation and easier access to large numbers of patients. According to the U.S. DHHS, there has been a 2000% increase in foreign trials of U.S. drugs over the past 25 years. When these drugs are successful in obtaining marketing approval, consumers in the countries where the trials were conducted often cannot afford them. Some ethicists have argued that this practice violates the justice principle articulated in the Belmont Report (DHHS, 1979, p. 10), which states that "research should not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research." A counterargument is that the conduct of trials in developing nations also frequently brings needed medical attention to underserved populations. This is another controversial issue.

Product Liability

Product liability laws are intended to protect consumers from defective products. Pharmaceutical companies can be sued for faulty design or manufacturing, deceptive promotional practices, violation of regulatory requirements, or failure to warn consumers of known risks. Failure-to-warn claims can be made against drug makers even when the product is approved by the FDA. With greater frequency, courts are finding companies that market prescription drugs directly to consumers responsible when advertisements fail to provide an adequate warning of potential adverse effects. Although injured patients are entitled to pursue legal remedies, the negative effects of product liability lawsuits against pharmaceutical companies may be considerable. First, fear of liability may cause pharmaceutical companies to be overly cautious about testing, thereby delaying access to the drug. Second, the cost of drugs increases for consumers when pharmaceutical companies increase the length and number of trials they perform to identify even the smallest risks and when regulatory agencies increase the number or intensity of regulatory reviews. Third, excessive liability costs create disincentives for development of so-called orphan drugs, pharmaceuticals that benefit a small number of patients. Should pharmaceutical companies be liable for failure to warn when all of the rules were followed, and the product was approved by the FDA but the unwanted effect was not detected because of its rarity or another confounding factor? The only way to find "all" of the unwanted effects that a drug may have is to market it—to conduct a phase IV "clinical trial" or observational study. This basic friction between risk to patients and the financial risk of drug development does not seem likely to be resolved except on a case-by-case basis, in the courts. The U.S. Supreme Court added further fuel to these fiery issues in 2009 in the case *Wyeth v. Levine*. A patient (Levine) suffered gangrene of an arm following inadvertent arterial administration of the antinausea drug *promethazine*, subsequently losing her hand. The healthcare provider had intended to administer the drug by so-called intravenous push. The FDA-approved label for the drug warned against, but did not prohibit, administration by intravenous push. The state court and then the U.S. Supreme Court held both the healthcare provider and the company liable for damages. Specifically, the Vermont court found that Wyeth, the drug's maker, had inadequately labeled the drug. This means that FDA approval of the label does not protect a company from liability or prevent individual states from imposing regulations more stringent than those required by the federal government.

"Me Too" Versus True Innovation: The Pace of New Drug Development

As noted previously, the term *me-too drug* describes a pharmaceutical that is usually structurally similar to a drug already on the market. Other names used are derivative medications, molecular modifications, and follow-up drugs. In some cases, a me-too drug is a different molecule developed deliberately by a competitor company to take market share from the company with existing drugs on the market. When the market for a class of drugs is especially large, several companies can share the market and make a profit. Other me-too drugs result coincidentally from the simultaneous development of products by several companies without knowing which drugs will be approved for sale (Box 1–4). There are

BOX 1–4 ■ A Not-So-New Drug

Some me-too drugs are only slightly altered formulations of a company's own drug, packaged and promoted as if really offering something new. An example is the heartburn medication *esomeprazole*, marketed by the same company that makes *omeprazole*. *Omeprazole* is a mixture of two stereoisomers; *esomeprazole* contains only one of the isomers and is eliminated less rapidly. Development of *esomeprazole* created a new period of market exclusivity, although generic versions of *omeprazole* are marketed, as are branded congeners of *omeprazole/esomeprazole*. Both *omeprazole* and *esomeprazole* are now available over the counter—narrowing the previous price difference.

valid criticisms of me-too drugs. First, an excessive emphasis on profit may stifle true innovation. Second, some me-too drugs are more expensive than the older versions they seek to replace, increasing the costs of healthcare without corresponding benefit to patients. Nevertheless, for some patients, me-too drugs may have better efficacy or fewer side effects or promote compliance with the treatment regimen. For example, the me-too drug that can be taken once a day rather than more frequently is convenient and promotes compliance. Some me-too drugs add great value from a business and medical point of view. For instance, *atorvastatin* was the seventh statin to be introduced to market; it subsequently became the best-selling drug in the world. Critics argue that pharmaceutical companies are not innovative and do not take risks and, further, that medical progress is actually slowed by their excessive concentration on me-too products.

Figure 1–7 summarizes a few of the facts behind this and other arguments. Clearly, only a modest number of new molecular entities (NMEs), about two dozen a year, achieved FDA approval between 1980 and 2016. In recent years (2017 through 2021), the annual number of approved NMEs has averaged 38 (and approval of biologicals has averaged 13 a year). Thus, there is a recent uptick in FDA-approved NMEs and BLAs. However, from 1980 to 2021, the industry's annual investment in research and development grew 45-fold, from $2 billion to $91 billion. This disconnect between research and development investment and new drugs approved occurred at a time when combinatorial chemistry was blooming, the human genome was being sequenced, highly automated techniques of screening were being developed, and new techniques of molecular biology and genetics were offering novel insights into the pathophysiology of human disease. A continued increase in productivity will be needed to sustain today's pharmaceutical companies as they face waves of patent expirations. There are strong arguments that development of much more targeted, individualized drugs, based on a new generation of molecular diagnostic techniques and improved understanding of disease in individual patients, will improve both medical care and the survival of pharmaceutical companies. Many of the advances in genetics and molecular biology are still new, particularly when measured in the time frame required for drug development. Moreover, the techniques of computational chemistry and computerized drug design described earlier in this chapter are still advancing and being integrated into the process. One can hope that modern molecular medicine will sustain the development of more efficacious and more specific pharmacological treatments for an ever-wider spectrum of human diseases.

Chapter 2

Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, Metabolism, and Elimination

Iain L. O. Buxton

The human body restricts access to foreign molecules; therefore, to reach its target within the body and have a therapeutic effect, a drug molecule must cross several restrictive barriers en route to its target site. Following administration, the drug must be absorbed and distributed, usually via vessels of the circulatory and lymphatic systems. In addition to crossing membrane barriers, the drug must survive metabolism (primarily hepatic) and elimination (by the kidney and liver and in the feces). ADME, the absorption, distribution, metabolism, and elimination of drugs, are the processes of *pharmacokinetics* (Figure 2–1). Understanding these processes and their interplay and employing pharmacokinetic principles increase the probability of therapeutic success and reduce the occurrence of adverse drug events and drug-drug interactions.

The absorption, distribution, metabolism, and excretion of a drug involve its passage across numerous cell membranes. Mechanisms by which drugs cross membranes and the physicochemical properties of molecules and membranes that influence this transfer are critical to understanding the disposition of drugs in the human body. The characteristics of a drug that predict its movement and availability at sites of action are its molecular size (i.e., molecular weight) and structural features, degree of ionization, the relative lipid solubility of its ionized and nonionized forms, and its binding to serum and tissue proteins. Although physical barriers to drug movement may be a single layer of cells (e.g., intestinal epithelium) or several layers of cells and associated extracellular protein (e.g., skin), the plasma membrane is the basic barrier.

Passage of Drugs Across Membrane Barriers

The Plasma Membrane Is Selectively Permeable

The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase, with their hydrophilic heads oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves into microdomains (e.g., regions with sphingolipids and cholesterol, forming lipid rafts), endowing the membrane with fluidity, flexibility, functional organization, high electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as structural anchors, receptors, ion channels, or transporters to transduce electrical or chemical signaling pathways and provide selective targets for drug actions. Far from being a sea of lipids with proteins floating randomly about, membranes are ordered and compartmented (Banani et al., 2017; Kitamata et al., 2020) with structural scaffolding elements linking to the cell interior. Membrane proteins may be associated with caveolin and sequestered within caveolae, excluded from caveolae, or organized in signaling domains rich in cholesterol and sphingolipids not containing caveolin or other scaffolding proteins.

Modes of Permeation and Transport

Passive diffusion dominates transmembrane movement of most drugs. However, carrier-mediated mechanisms (*active transport* and *facilitated diffusion*) play important roles (Figure 2–2; Figure 4–4).

Passive Diffusion

In passive transport, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid:water partition coefficient of the drug, and to the membrane surface area exposed to the drug. At steady state, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a nonelectrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which will influence the state of ionization of the molecule disparately on either side of

Abbreviations

ABC: ATP-binding cassette
ACE: angiotensin-converting enzyme
AUC: area under the concentration-time curve of drug absorption and elimination
BBB: blood-brain barrier
***CL*:** clearance
CNS: central nervous system
CNT1: concentrative nucleoside transporter 1
C_p: plasma concentration
CSF: cerebrospinal fluid
C_{ss}: steady-state concentration
CYP: cytochrome P450
***F*:** bioavailability
FDA: Food and Drug Administration
GI: gastrointestinal
h: hours
k: a rate constant
MDR1: multidrug resistance protein
MEC: minimum effective concentration
min: minutes
PLLR: Pregnancy and Lactation Labeling Rule
SLC: solute carrier
T, t: time
$t_{1/2}$: half-life
***V*:** volume of distribution
V_{ss}: volume of distribution at steady state

the membrane and can effectively trap ionized drug on one side of the membrane.

Influence of pH on Ionizable Drugs

Many drugs are weak acids or bases that are present in solution as both the lipid-soluble, diffusible nonionized form and the ionized species that is relatively lipid insoluble and poorly diffusible across a membrane. Common ionizable groups are carboxylic acids and amino groups (primary, secondary, and tertiary; quaternary amines hold a permanent positive charge). The transmembrane distribution of a weak electrolyte is influenced by its pK_a and the pH gradient across the membrane. The pK_a is the pH at which half the drug (weak acid or base electrolyte) is in its ionized form. The ratio of nonionized to ionized drug at any pH may be calculated from the Henderson-Hasselbalch equation:

$$\log \frac{[\text{protonated form}]}{[\text{unprotonated form}]} = pK_a - pH \qquad \text{(Equation 2–1)}$$

Equation 2–1 relates the pH of the medium around the drug and the drug's acid dissociation constant (pK_a) to the ratio of the protonated (HA or BH^+) and unprotonated (A^- or B) forms, where

$$HA \leftrightarrow A^- + H^+, \text{ where } K_a = \frac{[A^-][H^+]}{[HA]}$$

describes the dissociation of an acid, and

$$BH^+ \leftrightarrow B + H^+, \text{ where } K_a = \frac{[B][H^+]}{[BH^+]}$$

describes the dissociation of the protonated form of a base.

At steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side. This phenomenon, known as *ion trapping*, is an important process in drug distribution with potential therapeutic benefit and in management of the poisoned patient (Ornillo and Harbord, 2020). Figure 2–3 illustrates this effect and shows the calculated values for the distribution of a weak acid between the plasma and gastric compartments.

The effects of pH on transmembrane partitioning can be utilized to alter drug excretion. In the kidney tubules, urine pH can vary over a wide range, from 4.5 to 8. As urine pH drops (as $[H^+]$ increases), weak acids (A^-) and weak bases (B) will exist to a greater extent in their protonated forms (HA and BH^+); the reverse is true as pH rises, where A^- and B will be favored. Thus, alkaline urine favors excretion of weak acids; acidic urine favors excretion of weak bases. Elevation of urine pH (by giving sodium bicarbonate) will promote urinary excretion of weak acids such as aspirin (pK_a ~3.5) and urate (pK_a ~5.8). Another useful consequence of a drug being ionized at physiological pH is illustrated by the relative lack of sedative effects of second-generation histamine H_1 antagonists (e.g., *loratadine*): Second-generation antihistamines are ionized molecules (less lipophilic, more hydrophilic) that poorly cross the BBB compared to first-generation agents such as diphenhydramine, which are now used as sleep aids. Also of note, most bacterial urinary tract infections cause the urine to become alkaline, potentially altering therapy (Huang et al., 2020).

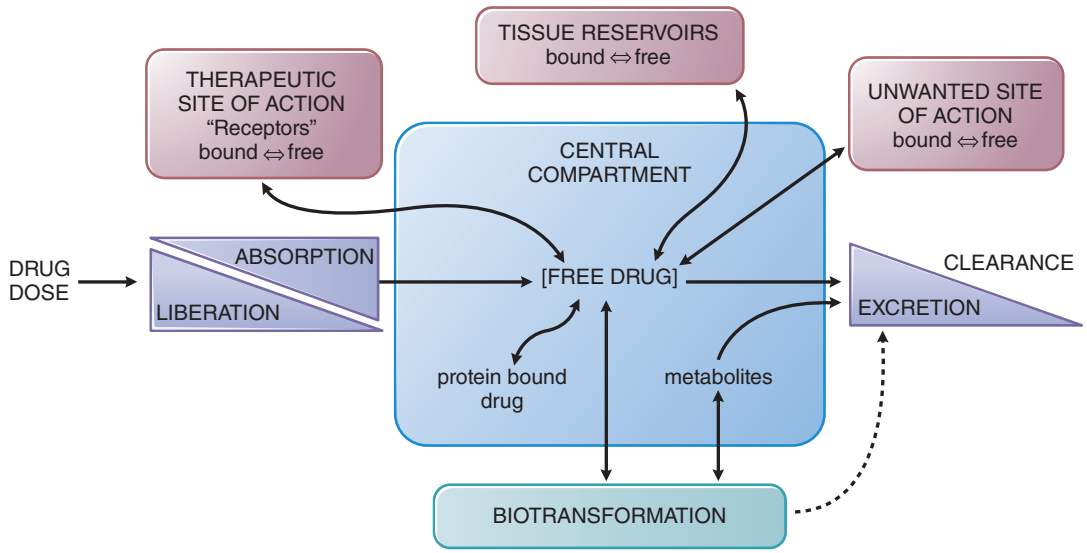

Figure 2–1 *The interrelationship of the absorption, distribution, binding, metabolism, and excretion of a drug and its concentration at its sites of action.* Possible distribution and binding of metabolites in relation to their potential actions at receptors are not depicted.

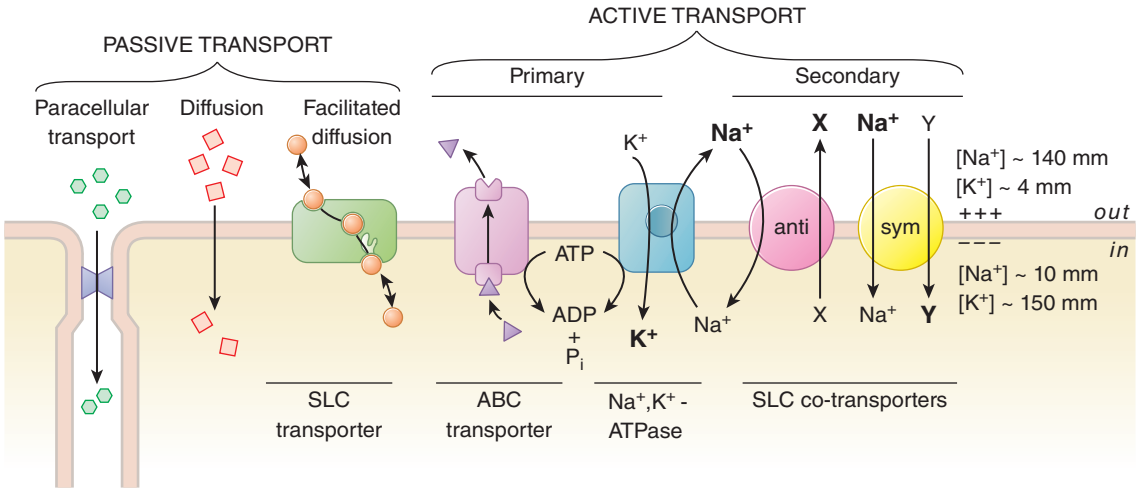

Figure 2–2 *Drugs move across membrane and cellular barriers in a variety of ways.* See details in Figures 4–1 through 4–4.

Carrier-Mediated Membrane Transport

Proteins in the plasma membrane mediate transmembrane movements of many physiological solutes; these proteins also mediate transmembrane movements of drugs and can be targets of drug action. Mediated transport is broadly characterized as *facilitated diffusion* or *active transport* (see Figure 2–2; Figure 4–4). Membrane transporters and their roles in drug response are presented in detail in Chapter 4.

Facilitated Diffusion. *Facilitated diffusion* is a carrier-mediated transport process in which the driving force is simply the electrochemical gradient of the transported solute; thus, these carriers can facilitate solute movement either in or out of cells, depending on the direction of the electrochemical gradient. The carrier protein may be highly selective for a specific conformational structure of an endogenous solute or a drug whose rate of transport by passive diffusion through the membrane would otherwise be quite slow. For instance, the organic cation transporter OCT1 (SLC22A1) facilitates the movement of a physiologic solute, thiamine (Jensen et al., 2020), and drugs, including *metformin*, which is used in treating type 2 diabetes. Chapter 4 describes OCT1 and other members of the human SLC superfamily of transporters.

Active Transport. *Active transport* is characterized by a direct requirement for energy, capacity to move solute against an electrochemical gradient, saturability, selectivity, and competitive inhibition by cotransported compounds. Na^+/K^+-ATPase is an important example of an active transport mechanism, which simultaneously exports three sodium ions in exchange for two potassium ions using ATP as the energy substrate. *Digoxin* is an important Na^+/K^+-ATPase inhibitor used in the treatment of heart failure (see Chapter 29). A group of primary active transporters, the ABC family, hydrolyze ATP to export substrates across membranes. For example, the P-glycoprotein, also called ABCB1 or MDR1, exports bulky neutral or cationic compounds from cells; its physiologic substrates include steroid hormones such as testosterone and progesterone. MDR1 exports many drugs as well, including *digoxin*, and a great variety of other agents (see Table 4–4). P-glycoprotein in the enterocyte limits the absorption of some orally administered drugs by exporting compounds into the lumen of the GI tract subsequent to their absorption (Gessner et al., 2019). ABC transporters perform a similar function in the cells of the BBB, effectively reducing net accumulation of some compounds in the brain (see Chapters 4 and 17). By the same mechanism, P-glycoprotein also can confer resistance to some cancer chemotherapeutic agents (see Chapters 69–73).

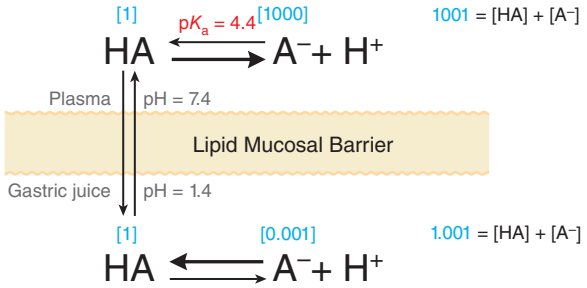

Figure 2–3 *Influence of pH on the distribution of a weak acid (pK_a = 4.4) between plasma and gastric juice separated by a lipid barrier.* **A weak acid dissociates to different extents** in plasma (pH 7.4) and gastric acid (pH 1.4): The higher pH facilitates dissociation; the lower pH reduces dissociation. The uncharged form, HA, equilibrates across the membrane. Blue numbers in brackets show relative equilibrium concentrations of HA and A^-, as calculated from Equation 2–1.

Members of the SLC superfamily can mediate secondary active transport using the electrochemical energy stored in a gradient (usually Na^+) to translocate both biological solutes and drugs across membranes. For instance, the Na^+/Ca^{2+} exchange protein (SLC8 or NCX) uses the energy stored in the Na^+ gradient established by Na^+/K^+-ATPase to export cytosolic Ca^{2+} and maintain it at a low basal level, about 100 nM in most cells. SLC8 is thus an *antiporter*, using the inward flow of Na^+ to drive an outward flow of Ca^{2+}. SLC8 also helps to mediate the positive inotropic effects of digoxin and other cardiac glycosides that inhibit the activity of Na^+/K^+-ATPase and thereby reduce the driving force for the extrusion of Ca^{2+} from the ventricular cardiac myocyte. Other SLC cotransporters are *symporters*, in which the driving force ion and solute move in the same direction. The CNT1 (SLC28A1), driven by the Na^+ gradient, moves pyrimidine nucleosides and the cancer chemotherapeutic agents *gemcitabine* and *cytarabine* into cells. DAT, NET, and SERT, transporters for the neurotransmitters dopamine, norepinephrine, and serotonin, respectively, are secondary active transporters that also rely on the energy stored in the transmembrane Na^+ gradient. These symporters coordinate movement of Na^+ and neurotransmitter in the same direction (into the neuron). DAT, NET, and SERT are also the targets of CNS-active agents used to treat depression and/or anxiety. Members of the SLC superfamily are active in drug transport in the GI tract, liver, and kidney, among other sites, and play a significant role in drug disposition (Liu, 2019).

Paracellular Transport

In the vascular compartment, paracellular passage of solutes and fluid through intercellular gaps is sufficiently large that passive transfer across the endothelium of capillaries and postcapillary venules is generally limited by blood flow. Evidence of this phenomenon can readily be seen in the dependent edema that forms in the ankles of heart failure patients. Capillaries of the CNS and a variety of epithelial tissues have tight junctions that limit paracellular movement of drugs (Spector et al., 2015).

Drug Absorption, Bioavailability, and Routes of Administration

Absorption and Bioavailability

Absorption is the movement of a drug from its site of administration into the central compartment (e.g., bloodstream; see Figure 2–1). For solid dosage forms, absorption first requires dissolution of the tablet or capsule, thus liberating the drug. Except in cases of malabsorption syndromes, the clinician is concerned primarily with bioavailability rather than absorption (Tran et al., 2013).

Bioavailability describes the fractional extent to which an administered dose of drug reaches its site of action or a biological fluid (usually the systemic circulation) from which the drug has access to its site of action. A drug given orally must be absorbed first from the GI tract, but net absorption may be limited by the characteristics of the dosage form, by the drug's physicochemical properties, by metabolic attack in the intestine, and by transport across the intestinal epithelium and into the portal circulation. The absorbed drug then passes through the liver, where metabolism and biliary excretion may occur before the drug enters the systemic circulation. Accordingly, less than all of the administered dose may reach the systemic circulation and be distributed to the drug's sites of action. If the metabolic or excretory capacity of the liver and the intestine for the drug is large, bioavailability will be reduced substantially (*first-pass effect*). This decrease in availability is a function of the anatomical site from which absorption takes place; for instance, intravenous administration generally permits all of a drug to enter the systemic circulation. Other anatomical, physiological, and pathological factors can influence bioavailability (described further in this chapter), and the route of drug administration should be chosen based on an understanding of these conditions. We can define bioavailability F as:

$$F = \frac{\text{Quantity of drug reaching systemic circulation}}{\text{Quantity of drug administered}} \quad \text{(Equation 2–2)}$$

where $0 < F \leq 1$.

Factors modifying bioavailability also apply to prodrugs, in which case availability results from metabolic processes that produce the active form of the drug.

Routes of Administration

Some characteristics of the major administration routes employed for systemic drug effect are compared in Table 2–1.

Oral Administration

Oral ingestion is the most common method of drug administration. It also is the safest, most convenient, and most economical. Its disadvantages include limited absorption of some drugs because of their physical characteristics (e.g., low water solubility or poor membrane permeability), emesis as a result of irritation to the GI mucosa, destruction of some drugs by digestive enzymes or low gastric pH, irregularities in absorption or propulsion in the presence of food or other drugs, and the need for cooperation on the part of the patient. In addition, drugs in the GI tract may be metabolized by the enzymes of the intestinal microbiome, mucosa, or liver before they gain access to the general circulation. The gut microbiome comprises over 1000 species; its alteration may impact disease progression and therapeutic outcomes (see Chapter 6 and Ding et al., 2020).

Absorption from the GI tract is governed by factors such as surface area for absorption; blood flow to the site of absorption; the physical state of the drug (solution, suspension, or solid dosage form); its aqueous solubility; and the drug's concentration at the site of absorption. For drugs given in solid form, the rate of dissolution may limit their absorption. Because most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the nonionized, more lipophilic form. Based on the pH-partition concept (see Figure 2–3), one would predict that drugs that are weak acids would be better absorbed from the stomach (pH 1–2) than from the upper intestine (pH 3–6), and vice versa for weak bases. However, the surface area of the stomach is relatively small, and a mucus layer covers the gastric epithelium. By contrast, the villi of the upper intestine provide an extremely large surface area (~200 m^2). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely nonionized in the stomach.

TABLE 2–1 ■ SOME CHARACTERISTICS OF COMMON ROUTES OF DRUG ADMINISTRATION[a]

ROUTE AND BIOAVAILABILTY (F)	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Intravenous	Absorption circumvented	Valuable for emergency use	Increased risk of adverse effects
$F = 1$ by definition	Potentially immediate effects	Permits titration of dosage	Must inject solutions *slowly* as a rule
	Suitable for large volumes and for irritating substances, or complex mixtures, when diluted	Usually required for high-molecular-weight protein and peptide drugs	Not suitable for oily solutions or poorly soluble substances
Subcutaneous $0.75 < F < 1$	Prompt from aqueous solution	Suitable for some poorly soluble suspensions and for instillation of slow-release implants	Not suitable for large volumes
	Slow and sustained from repository preparations		Possible pain or necrosis from irritating substances
Intramuscular $0.75 < F < 1$	Prompt from aqueous solution	Suitable for moderate volumes, oily vehicles, and some irritating substances	Precluded during anticoagulant therapy
	Slow and sustained from repository preparations	Appropriate for self-administration (e.g., insulin)	May interfere with interpretation of certain diagnostic tests (e.g., creatine kinase)
Oral ingestion $0.05 < F < 1$	Variable, depends on many factors (see text)	Most convenient and economical; usually safer	Requires patient compliance
			Bioavailability potentially erratic and incomplete

[a]See text for more complete discussion and for other routes.

Thus, any factor that accelerates gastric emptying (recumbent position right side) will generally increase the rate of drug absorption, whereas any factor that delays gastric emptying will have the opposite effect. The gastric emptying rate is influenced by numerous factors, including the caloric content of food; volume, osmolality, temperature, and pH of ingested fluid; diurnal and interindividual variation; metabolic state (rest or exercise); and the ambient temperature. Gastric emptying is influenced in women by the effects of estrogen (i.e., compared to men, emptying is slower for premenopausal women and those taking estrogen replacement therapy).

Drugs that are destroyed by gastric secretions and low pH or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. Enteric coatings are useful for drugs that can cause gastric irritation and for presenting a drug such as mesalamine to sites of action in the ileum and colon (see Figure 55–4).

Controlled-Release Preparations. The rate of absorption of a drug administered as a tablet or other solid oral dosage form is partly dependent on its rate of dissolution in GI fluids. This is the basis for *controlled-release, extended-release, sustained-release,* and *prolonged-action* pharmaceutical preparations that are designed to produce slow, uniform absorption of the drug for 8 h or longer. Potential advantages of such preparations are reduction in the frequency of administration compared with conventional dosage forms (often with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and intensity of undesired effects (by dampening of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of troughs in concentration) that often occur after administration of immediate-release dosage forms. Controlled-release dosage forms are most appropriate for drugs with short half-lives ($t_{1/2}$ <4 h) or in select patient groups, such as those receiving antiepileptic or antipsychotic agents (Bera, 2014). Women have also benefited from long-acting hormonal contraception produced by implanted (Friend, 2016) or oral (Conley et al., 2006) controlled-release devices.

Sublingual Administration. Absorption from the oral mucosa has special significance for certain drugs despite the fact that the surface area available is small. Venous drainage from the mouth directly enters the superior vena cava, thus bypassing the portal circulation. As a consequence, a drug held sublingually and absorbed from that site is protected from rapid intestinal and hepatic first-pass metabolism. For example, sublingual nitroglycerin (see Chapter 31) is rapidly effective because it is nonionic, has high lipid solubility, and is not subject to the first-pass effect prior to reaching the heart and regions of the circulatory system where nitroglycerin acts to relieve myocardial ischemia.

Parenteral Injection

Parenteral (i.e., not via the GI tract) injection of drugs has distinct advantages over oral administration. In some instances, parenteral administration is essential for delivery of a drug in its active form, as in the case of monoclonal antibodies and vaccine formulations. Availability is usually more rapid, extensive, and predictable when a drug is given by injection; the effective dose can be delivered more accurately to a precise dose; this route is suitable for the loading dose of medications prior to initiation of oral maintenance dosing (e.g., *digoxin*). In emergency therapy and when a patient is unconscious, uncooperative, or unable to retain anything given by mouth, parenteral therapy may be necessary. Parenteral administration also has disadvantages: Asepsis must be maintained, especially when drugs are given over time (e.g., intravenous or intrathecal administration); pain may accompany the site of injection; and it is sometimes difficult for patients to perform the injections themselves if self-medication is necessary.

The major routes of parenteral administration are intravenous, subcutaneous, and intramuscular. Absorption from subcutaneous and intramuscular sites occurs by simple diffusion along the gradient from drug depot to plasma. The rate is limited by the area of the absorbing capillary membranes and by the solubility of the substance in the interstitial fluid. Relatively large aqueous channels in the endothelial layer account for the indiscriminate diffusion of molecules regardless of their lipid solubility. Larger molecules, such as proteins, slowly gain access to the circulation by way of lymphatic channels. Drugs administered into the systemic circulation by any route, excluding the intra-arterial route, are subject to possible first-pass elimination in the lung prior to distribution to the rest of the body. The lungs also serve as a filter for particulate matter that may be given intravenously and provide a route of elimination for volatile substances.

Intravenous. Factors limiting absorption are circumvented by intravenous injection of drugs in aqueous solution because bioavailability is complete ($F = 1.0$) and distribution is rapid. Also, drug delivery is controlled and achieved with an accuracy and immediacy not possible by any other procedures. Certain irritating solutions can be given only in this manner because the drug, when injected slowly, is greatly diluted by the blood.

There are advantages and disadvantages to intravenous administration. Unfavorable reactions can occur because high concentrations of drug may be attained rapidly in plasma and tissues. There are therapeutic circumstances for which it is advisable to administer a drug by bolus injection (e.g., tissue plasminogen activator) and other circumstances where slower or prolonged administration of drug is advisable (e.g., antibiotics). Intravenous administration of drugs warrants careful determination of dose and close monitoring of the patient's response; once the drug is injected, there is often no retreat. Repeated intravenous injections depend on the ability to maintain a patent vein. Drugs in an oily vehicle, those that precipitate blood constituents or hemolyze erythrocytes, and drug combinations that cause precipitates to form *must not* be given intravenously.

Subcutaneous. Injection into a subcutaneous site can be done only with drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug is generally constant and slow, providing a sustained effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with insulin for injection using particle size, protein complexation, and pH. The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. Absorption of drugs implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (e.g., contraceptives) are administered effectively in this manner.

Intramuscular. Absorption of drugs in aqueous solution after intramuscular injection depends on the rate of blood flow to the injection site and can be relatively rapid. Absorption may be modulated to some extent by local heating, massage, or exercise. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the gluteus maximus. The rate is particularly slower for females after injection into the gluteus maximus, a feature attributed to the different distribution of subcutaneous fat in males and females and because fat is relatively poorly perfused. Slow, constant absorption from the intramuscular site results if the drug is injected in solution in oil or suspended in various other repository (depot) vehicles.

Intra-arterial. Occasionally, a drug is injected directly into an artery to localize its effect in a particular tissue or organ, such as in the treatment of liver tumors and head and neck cancers. Diagnostic agents sometimes are administered by this route (e.g., technetium-labeled human serum albumin). Inadvertent intra-arterial administration can cause serious complications and requires careful management (Ellis et al., 2015).

Intrathecal. The BBB and the blood-CSF barrier often preclude or slow the entrance of drugs into the CNS, reflecting the activity of P-glycoprotein (MDR1) and other transporters to export xenobiotics from the CNS. Therefore, when local and rapid effects of drugs on the meninges or cerebrospinal axis are desired, as in spinal anesthesia, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors or

serious CNS infections also may be treated by direct intraventricular drug administration, increasingly through the use of specialized long-term indwelling reservoir devices (De Andrés et al., 2020). Injections into the CSF and epidural space are covered in chapters on analgesia and local anesthesia (Chapters 24 and 25, respectively).

Pulmonary Absorption

Gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung's surface area is large. In addition, solutions of drugs can be atomized and the fine droplets in air (aerosol) inhaled. Advantages are the almost instantaneous absorption of a drug into the blood, avoidance of hepatic first-pass loss, and in the case of pulmonary disease, local application of the drug at the desired site of action (see Chapters 24 and 44), as in the use of inhaled nitric oxide for pulmonary hypertension in term and near-term infants and adults (see Chapter 35).

Topical Application

Mucous Membranes. Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx, vagina, colon, urethra, and urinary bladder primarily for their local effects. Absorption from these sites is generally excellent and may provide advantages for immunotherapy because vaccination of mucosal surfaces using mucosal vaccines provides the basis for generating protective immunity in both the mucosal and systemic immune compartments due to the presence of antigen-presenting cells in the tissues underlying mucosa such as stratum corneum (Li et al., 2020).

Eye. Topically applied ophthalmic drugs are used primarily for their local effects (see Chapter 69). The use of drug-loaded contact lenses and ocular inserts allows drugs to be better placed where they are needed for direct delivery.

Skin: Transdermal Absorption. Absorption of drugs able to penetrate the intact skin is dependent on the surface area over which they are applied and their lipid solubility (see Chapter 70). Systemic absorption of drugs occurs much more readily through abraded, burned, or denuded skin. Toxic effects result from absorption through the skin of highly lipid-soluble substances (e.g., a lipid-soluble insecticide in an organic solvent). Absorption through the skin can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Hydration of the skin with an occlusive dressing may be used to facilitate absorption. Controlled-release topical patches are increasingly available, with nicotine for tobacco-smoking withdrawal, *scopolamine* for motion sickness, *nitroglycerin* for angina pectoris, testosterone and estrogen for replacement therapy, various estrogens and progestins for birth control, and *fentanyl* for analgesia.

Rectal Administration

Approximately 50% of the drug that is absorbed from the rectum will bypass the liver, thereby reducing hepatic first-pass metabolism. However, rectal absorption can be irregular and incomplete, and certain drugs can cause irritation of the rectal mucosa. In certain clinical situations, rectal administration may be desirable, as in the use of opioids in hospice care.

Novel Methods of Drug Delivery

Drug-eluting stents and other devices such as microneedle drug delivery patches (Waghule et al., 2019) are being used to target drugs locally to maximize efficacy and minimize systemic exposure. Recent advances in drug delivery include the use of biocompatible polymers and nanoparticles for drug delivery (Lee et al., 2018; Santos et al., 2018).

Bioequivalence

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be *bioequivalent* when the rates and extents of bioavailability of the active ingredient in the two products are not significantly different under suitable and identical test conditions. The availability of generic formulations of brand name drugs has increased access and affordability of drugs. Bioequivalence has made it possible for pharmacists to provide these alternatives when not restricted by physician choice. However, courts have not always found generic and brand name drugs to be legally equivalent or permitted the pharmacist to choose generic substitution (Sacks et al., 2021).

Distribution of Drugs

Not All Tissues Are Equal

Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids as functions of the physicochemical properties of the drug, the rate of drug delivery to individual organs and compartments, and the differing capacities of those regions to interact with the drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume affect the rate of delivery and amount of drug distributed into tissues (Table 2–2 and Figure 2–4). Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug; delivery to muscle, most viscera, skin, and fat is slower. This second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass (e.g., muscle) than does the initial phase and generally accounts for most of the extravascular distribution. With exceptions such as the brain, diffusion of drug into the interstitial fluid occurs rapidly because of the highly permeable nature of the capillary endothelium. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue.

Binding to Plasma Proteins

Many drugs circulate in the bloodstream bound to plasma proteins, and therapies based on drug:protein formulations have been advanced (Van de Sande et al., 2020). Albumin is a major carrier for acidic drugs; α_1-acid glycoprotein binds basic drugs. Nonspecific binding to other plasma proteins generally occurs to a much smaller extent. The binding is usually reversible. In addition, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone–binding globulin or the binding of thyroid hormone to thyroxin-binding globulin. Drug-protein binding can also be influenced by foods, beverages, herbal medicines, and dietary supplements (López-Yerena et al., 2020).

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the

TABLE 2–2 ■ DISTRIBUTION OF BLOOD FLOW IN 70-KG MALE AT REST

	KIDNEYS	HEART	LIVER	BRAIN	SKELETAL MUSCLE	FAT	REMAINDER	Σ
Blood flow (mL/min)	1100	250	1500	800	900	250	500	5500
Mass (kg)	0.3	0.3	2.6	1.3	34	10	21.5	70
Flow/mass (mL/min/kg)	3667	833	654	615	26	25	23	
% Cardiac output	20	4.5	31	14.5	16.4	4.5	9.1	100

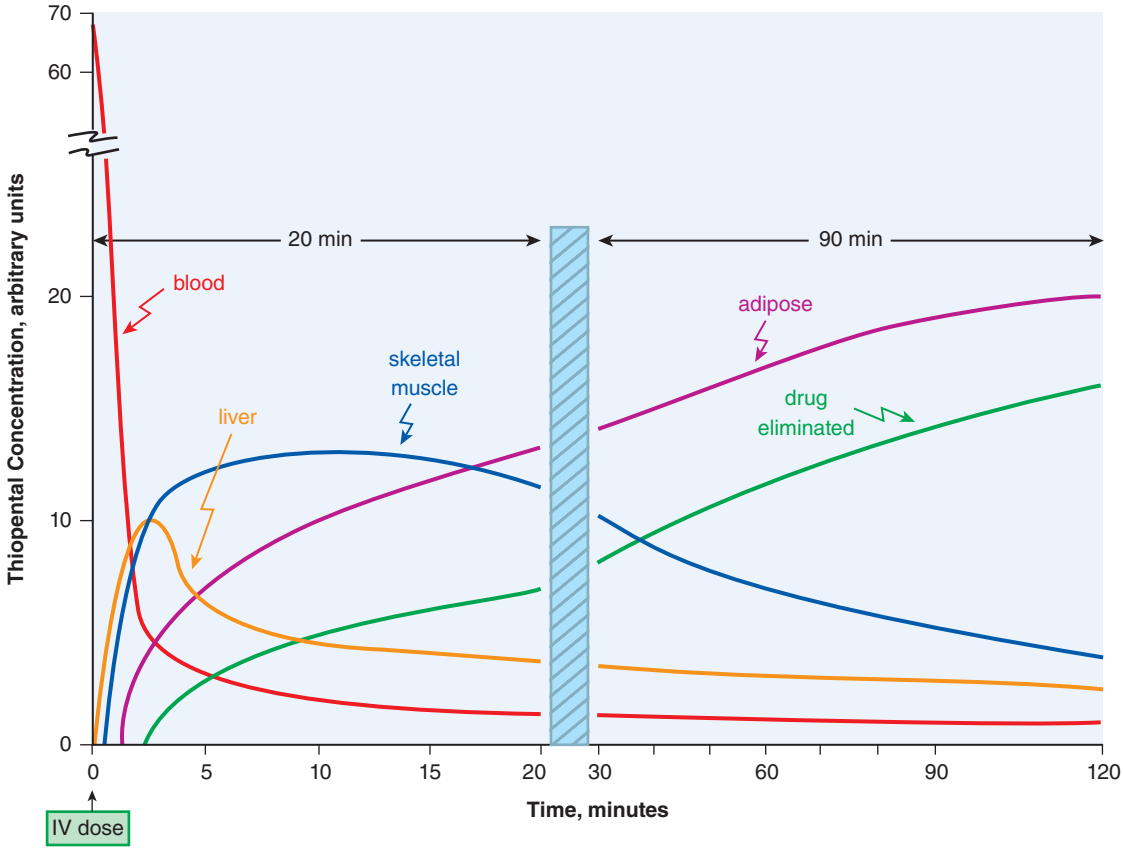

Figure 2–4 *Redistribution.* Curves depict the distribution of the barbiturate anesthetic *thiopental* into different body compartments following a single rapid intravenous dose. Note breaks and changes of scale on both axes. The drug level at *thiopental*'s site of action in the brain closely mirrors the plasma level of the drug. The rate of accumulation in the various body compartments depends on regional blood flow; the extent of accumulation reflects the differing capacities of the compartments and the steady but slow effect of elimination to reduce the amount of drug available. Emergence from the anesthetic influence of this single dose of *thiopental* relies on redistribution, not on metabolism. The drug will partition out of tissue depots as metabolism and elimination take their course. Depletion of compartments will follow the same order as accumulation, as a function of their perfusion.

concentration of available binding sites. For most drugs, the therapeutic range of plasma concentrations is limited; thus, the extent of binding and the unbound fraction are relatively constant. The extent of plasma protein binding also may be affected by disease-related factors (e.g., hypoalbuminemia). Conditions resulting in the acute-phase reaction response (e.g., cancer, arthritis, myocardial infarction, Crohn's disease) lead to elevated levels of α_1-acid glycoprotein and enhanced binding of basic drugs. Changes in protein binding caused by disease states and drug-drug interactions are clinically relevant mainly for a small subset of so-called high-clearance drugs of narrow therapeutic index that are administered intravenously, such as *lidocaine*. When changes in plasma protein binding occur in patients, unbound drug rapidly equilibrates throughout the body, and only a transient significant change in unbound plasma concentration will occur. Only drugs that show an almost-instantaneous relationship between free plasma concentration and effect (e.g., antiarrhythmics) will show a measurable effect. Thus, unbound plasma drug concentrations will exhibit significant changes only when either drug input or clearance of unbound drug occurs as a consequence of metabolism or active transport. A similar situation occurs when a new drug is added that can compete with an existing drug for plasma protein binding sites: Competition for binding sites may cause one drug to transiently elevate the concentration of another that is bound less avidly, but steady-state drug levels will be unchanged unless clearance changes. A more common problem resulting from competition of drugs for plasma protein-binding sites is misinterpretation of measured concentrations of drugs in plasma because most assays do not distinguish free drug from bound drug.

Binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distribution equilibrium is achieved, the concentration of unbound drug in intracellular water is the same as that in plasma except when carrier-mediated active transport is involved. Binding of a drug to plasma protein limits the drug's glomerular filtration and may also limit drug transport and metabolism.

Tissue Binding

Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity (e.g., renal and ototoxicity associated with aminoglycoside antibiotics). The intracellular accumulation of antimicrobial agents has clinical implications, both therapeutic and toxicological (Pea, 2018).

CNS, the BBB, and CSF

The brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells that constitute the BBB are described in detail in Chapter 17, and Chapter 4 describes some aspects of specific transport proteins that move drugs into and out of the CNS. At the choroid plexus, a similar blood-CSF barrier is present, formed by epithelial cells that are joined by tight junctions. The lipid solubility of the nonionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug, the

more likely it is to cross the BBB. In general, the BBB's function is well maintained; however, meningeal and encephalic inflammation increase local permeability.

Bone

The tetracycline antibiotics (and other divalent metal-ion chelating agents) and heavy metals may accumulate in bone by adsorption onto the bone crystal surface and eventual incorporation into the crystal lattice. Bone can become a reservoir for the slow release of toxic agents such as lead or radium; their effects thus can persist long after exposure has ceased. Local destruction of the bone medulla also may result in reduced blood flow and prolongation of the reservoir effect as the toxic agent becomes sealed off from the circulation; this may further enhance the direct local damage to the bone. A vicious cycle results, whereby the greater the exposure to the toxic agent, the slower is its rate of elimination. The adsorption of drug onto the bone crystal surface and incorporation into the crystal lattice have therapeutic advantages for the treatment of osteoporosis as in the use of phosphonates (Black and Rosen, 2016).

Fat as a Reservoir

Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese individuals, the fat content of the body may be as high as 50%, and even in lean individuals, fat constitutes 10% of body weight; hence, fat may serve as a reservoir for lipid-soluble drugs and toxins. Fat is a rather stable reservoir because it has a relatively low blood flow. Fat may also complicate drug treatment by serving as a reservoir for infectious agents such as HIV and by limiting the access of relatively nonlipophilic drugs (Couturier and Lewis, 2018).

Redistribution

Termination of drug effect after withdrawal of a drug usually is by metabolism and excretion, but also may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor in terminating drug effect primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or inhalation. Such is the case of the intravenous anesthetic *thiopental*, a lipid-soluble drug. Because blood flow to the brain is high and *thiopental* readily crosses the BBB, *thiopental* reaches its maximal concentration in brain rapidly after its intravenous injection. Subsequently, the plasma and brain concentrations decrease as *thiopental* redistributes to other tissues, such as muscle and, finally, adipose tissue. This redistribution is the mechanism by which *thiopental* anesthesia is terminated (see Figure 2–4); its actual clearance from the body is rather slow (elimination $t_{1/2}$ after a single dose is 3–8 h). The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, both the onset and the termination of *thiopental* anesthesia are relatively rapid, and both are related directly to the concentration of drug in the brain.

Placental Transfer of Drugs

Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The placenta functions as a selective barrier to protect the fetus against the harmful effects of drugs. Members of the ABC family of transporters limit the entry of drugs and other xenobiotics into the fetal circulation via vectorial efflux from the placenta to the maternal circulation (see Figure 2–2 and Chapter 4). The fetal plasma is slightly more acidic than that of the mother (pH 7.0–7.2 vs. 7.4, respectively), so that ion trapping of basic drugs occurs. The view that the placenta is an absolute barrier to drugs is inaccurate, in part because a number of influx transporters are also present (Tetro et al., 2018). The fetus is, to some extent, exposed to all drugs taken by the mother.

The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus; thus, the need for evidence-based drug use in pregnancy is paramount. Drugs used during pregnancy had been categorized by the FDA in categories A–D and X, progressing from A (no evidence of fetal risk; e.g., folic acid, *levothyroxine*) to D (positive evidence of fetal risk but may be used if absolutely necessary; e.g., *alprazolam*, *losartan*) and to X (risks of use outweigh any benefits; such agents must not be used in pregnancy; e.g., statins, *methotrexate*). In 2015, the FDA established a new labeling system, the Pregnancy and Lactation Labeling Rule (PLLR). The PLLR replaces the letter codes with required labeling on (1) pregnancy, (2) lactation, and (3) issues affecting females and males of reproductive potential, with the intent of permitting better patient-specific counseling and informed decision making for pregnant women seeking medication therapies (Dinatale, 2016; Pernia and Demaagd, 2016). Physicians in the U.S. appear to be adopting the new system only slowly (Namazy et al., 2020).

Metabolism of Drugs

A Few Principles of Metabolism and Elimination

The many therapeutic agents that are lipophilic do not pass readily into the aqueous environment of the urine. The metabolism of drugs and other xenobiotics into more hydrophilic metabolites is essential for their renal elimination from the body, as well as for termination of their biological and pharmacological activity.

From the point of view of pharmacokinetics, the following are the three essential aspects of drug metabolism:

- **First-order kinetics.** For most drugs in their therapeutic concentration ranges, the amount of drug metabolized per unit time is proportional to the plasma concentration of the drug (C_p) and *the fraction of drug removed by metabolism is constant (i.e., first-order kinetics).*
- **Zero-order kinetics.** For some drugs, such as *ethanol* and *phenytoin*, metabolic capacity is saturated at the concentrations usually employed, and drug metabolism becomes *zero order; that is, a constant amount of drug is metabolized per unit time.* Zero-order kinetics can also occur at high (toxic) concentrations as drug-metabolizing capacity becomes saturated.
- **Inducible biotransforming enzymes.** The major drug-metabolizing systems are inducible, broad-spectrum enzymes with some predictable genetic variations. Drugs that are substrates in common for a metabolizing enzyme may interfere with each other's metabolism, or a drug may induce or enhance metabolism of itself or other drugs.

In general, drug-metabolizing reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated. Many of the enzyme systems that transform drugs to inactive metabolites also generate biologically active metabolites of endogenous compounds, as in steroid biosynthesis. The biotransformation of drugs occurs primarily in the liver and involves *phase 1 reactions* (oxidation, reduction, or hydrolytic reactions and the activities of CYP enzymes) and *phase 2 reactions* (conjugations of the phase 1 product with a second molecule generating a polar compound) and subsequent steps that involve transporters that remove conjugates to the extracellular medium from which they are excreted. Other organs with significant drug-metabolizing capacity include the GI tract, kidneys, and lungs. Drug-metabolizing enzymes, especially CYPs, are inducible by some drugs and inhibited by drugs and competing substrates and impacted by disease (Coutant and Hall, 2018). Race, ethnicity, and sex differences play a critical role in drug response due to factors such as body composition as well as expression and activity of drug-metabolizing enzymes (Farkouh et al., 2020). Chapter 5 (Drug Metabolism) covers the basic enzymology of drug metabolism in detail. Chapters 4 (Membrane Transporters and Drug Response), 6 (GI Microbiome and Drug Response), and 7 (Pharmacogenetics) present related aspects of drug metabolism. Understanding metabolism of a given drug and how other drugs may affect that metabolism is crucial to good drug therapy and the future of personalized medicine.

Prodrugs

Prodrugs are pharmacologically inactive compounds that are converted to their active forms by metabolism. Designing prodrugs with the active form as a template can maximize the amount of the active species that reaches its site of action. Inactive prodrugs are converted rapidly to biologically active

metabolites, often by the hydrolysis of an ester or amide linkage. Such is the case with a number of ACE inhibitors employed in the management of high blood pressure. *Enalapril*, for instance, is relatively inactive until converted by esterase activity to the diacid enalaprilat (see Chapter 30).

Pharmacogenetics

For a number of therapeutic areas, clinical pharmacogenetics, the study of the impact of genetic variations or genotypes of individuals on their drug response or drug metabolism, allows for improved treatment of individuals or groups (Ramamoorthy et al., 2015; see Chapter 7).

Excretion of Drugs

Drugs are eliminated from the body either unchanged or as metabolites. Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Thus, lipid-soluble drugs are not readily eliminated until they are metabolized to more polar compounds. The kidney is the most important organ for excreting drugs and their metabolites. Renal excretion of unchanged drug is a major route of elimination for 25% to 30% of drugs administered to humans. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites either excreted in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion from the lung is important mainly for the elimination of anesthetic gases (see Chapter 24).

Excretion of drugs in breast milk is important because the excreted drugs may affect the nursing infant (with lower body mass and poorly developed capacity to metabolize xenobiotics). Currently, there is insufficient information for the clinician to guide breastfeeding mothers in the potential dangers of excretion of medications into breast milk. An estimated 50% to 70% of breastfeeding mothers in the U.S. take some form of medication, and yet as few as 15% of recently approved drugs provide information on breastfeeding (Byrne and Spong, 2019). The most comprehensive information on drugs to which infants may be exposed from breast milk can be found on LactMed®, a database of drugs and other chemicals to which breastfeeding mothers may be exposed; the database is available on the National Library of Medicine Bookshelf. As the FDA's PLLR comes into general use, such information is becoming more widely available as a required part of the drug information on package inserts.

Renal Excretion

Excretion of drugs and metabolites in the urine involves three distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption (Figure 2–5). The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid (see Figures 4–3 and 4–4 and Chapter 29). Indeed, the majority of drugs do not enter the kidney tubule by glomerular filtration but by tubular secretion. Tubular secretion involves carriers that transport basic drugs (e.g., *amiloride*, dopamine, histamine) and carriers for acidic drugs (e.g., *furosemide, penicillin, indomethacin*) (see Figures 4–10 and 4–11). *Penicillin* is rapidly excreted from the body ($t_{1/2}$ = 30 min), largely via tubular secretion, with an injected dose largely eliminated in 2 h. Drug from the tubular lumen may be reabsorbed into the systemic circulation. In the renal tubules, especially on the distal side, the nonionized forms of weak acids and bases undergo net passive reabsorption. The tubular cells are less permeable to the ionized forms of weak electrolytes; thus, passive reabsorption of these substances depends on the pH (see Figure 2–3). When the tubular urine is made more alkaline, weak acids are largely ionized and are excreted more rapidly and to a greater extent; conversely, acidification of the urine will reduce fractional ionization and excretion of weak acids. Effects of changing urine pH are opposite for weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalinization or acidification of the urine.

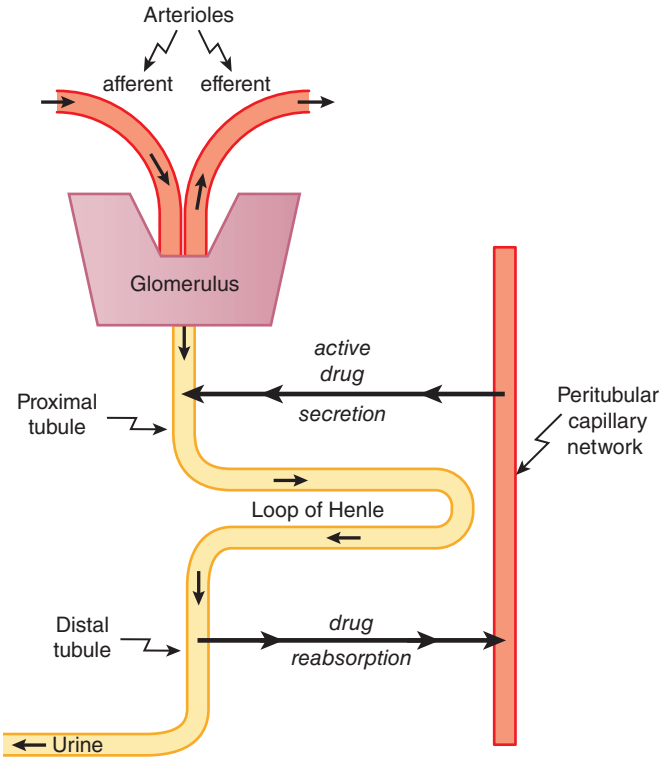

Figure 2–5 *Renal drug handling.* Drugs may be filtered from the blood in the renal glomerulus, secreted into the proximal tubule, reabsorbed from the distal tubular fluid back into the systemic circulation, and collected in the urine. Membrane transporters (OAT, OCT, MDR1, and MRP2, among others) mediate secretion into the proximal tubule (see Figures 4–12 and 4–13 for details). Reabsorption of compounds from the distal tubular fluid (generally acidic) is pH sensitive: Ionizable drugs are subject to ion trapping, and altering urinary pH to favor ionization can enhance excretion of charged species (see Figure 2–2).

The excretion and reabsorption of drugs may sometimes be usefully modified pharmacologically. For instance, co-administration of drugs that compete effectively for tubular secretion of *penicillin* can prolong the therapeutic effect of *penicillin*. *Penicillin* is secreted into the urine by the organic anion transporters OAT1 and OAT3; the acidic drug *probenecid* competes with *penicillin* at OAT1 and OAT3, thereby slowing excretion and prolonging an effective blood level of the antibiotic. *Probenecid* can also affect renal handling of uric acid. Urate is excreted into the urine by the kidney via the interplay of the processes of filtration, secretion, and reabsorption. *Probenecid* also inhibits URAT1, the urate transporter that is located on the apical surface of renal tubular cells and facilitates reabsorption of urate from the urine (Tan et al., 2016). Preventing reabsorption of uric acid (e.g., via administration of *probenecid*) promotes urate excretion, a useful effect in the treatment of hyperuricemia (i.e., gout). These actions of *probenecid* are covered in more detail in the chapters on uricosurics and β-lactam antibiotics (Chapters 42 and 58, respectively).

In older adults, renal function declines gradually at approximately 1% annually. Changes in renal excretion for drugs eliminated primarily by the kidney will be affected, resulting in increased peak drug levels and a longer duration of effect. Thus, elderly patients may require medication adjustments (O'Mahony, 2020); the FDA publishes useful guidance (https://www.fda.gov/drugs/guidance-compliance-regulatory-information/guidances-drugs).

Knowledge of the effects of pregnancy, *per se*, on drug pharmacokinetics is wanting. While enhanced drug elimination has been found in a number of cases, associated alterations in clinical responses and outcomes, or lack thereof, remain largely unknown. In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. The PLLR initiative should bring more information to this area.

Biliary and Fecal Excretion

Transporters present in the canalicular membrane of the hepatocyte (see Figure 4–6) actively secrete drugs and metabolites into bile. Ultimately, drugs and metabolites present in bile are released into the GI tract during the digestive process. Subsequently, the drugs and metabolites can be reabsorbed into the body from the intestine, which, in the case of conjugated metabolites such as glucuronides, may require enzymatic hydrolysis by the intestinal microflora. Such *enterohepatic recycling*, if extensive, may significantly prolong the presence of a drug (or toxin) and its effects within the body prior to elimination by other pathways. To interrupt enterohepatic cycling, substances may be given orally to bind metabolites excreted in the bile (for instance, see bile acid sequestrants and *ezetimibe*, Chapter 37). Biliary excretions and unabsorbed drug are excreted in the feces.

Excretion by Other Routes

Excretion of drugs into sweat, saliva, and tears is quantitatively unimportant. Because milk is more acidic than plasma, basic compounds may be slightly concentrated in this fluid; conversely, the concentration of acidic compounds in the milk is lower than in plasma. Nonelectrolytes (e.g., ethanol and urea) readily enter breast milk and reach the same concentration as in plasma, independent of the pH of the milk (Rowe et al., 2015). Breast milk can also contain heavy metals from environmental exposures. The administration of drugs to breastfeeding women carries the general caution that the suckling infant will be exposed to the medication or its metabolites. Insufficient data hamper a complete understanding of this problem. The PLLR initiative and the use of pharmacokinetic modeling in preclinical drug development in place of conventional animal testing for drug excretion into breast milk will improve needed guidance (Anderson, 2018). Although excretion into hair and skin is quantitatively unimportant, sensitive methods of detection of drugs in these tissues have forensic significance.

Clinical Pharmacokinetics

Clinical pharmacokinetics relate the pharmacological effects of a drug and concentration of the drug in an accessible body compartment (e.g., in blood or plasma) as these change in time. In most cases, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation (see Figure 2–1). The pharmacological effect that results may be the clinical effect desired or an adverse or toxic effect. Clinical pharmacokinetics attempts to provide:

- A quantitative relationship between dose and effect
- A framework within which to interpret measurements of drug concentration in biological fluids and their adjustment through changes in dosing for the benefit of the patient

The importance of pharmacokinetics in patient care is based on the improvement in therapeutic efficacy and the avoidance of unwanted effects that can be attained by application of its principles when dosage regimens are chosen and modified.

The following are the four most important parameters governing drug disposition:

1. *Bioavailability,* the fraction of drug absorbed into the systemic circulation
2. *Volume of distribution,* a measure of the apparent space in the body available to contain the drug based on how much is given versus what is found in the systemic circulation
3. *Clearance,* a measure of the body's efficiency in eliminating drug from the systemic circulation
4. *Elimination* $t_{1/2}$, a measure of the rate of removal of drug from the systemic circulation

Clearance

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain steady-state concentrations of a drug within a *therapeutic window* or range associated with therapeutic efficacy and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration. Thus,

$$\text{Dosing rate} = CL \cdot C_{ss} \qquad \text{(Equation 2–3)}$$

where CL is clearance of drug from the systemic circulation (in units of volume/time), and C_{ss} is the steady-state concentration of drug (in units of mass/volume). When the desired steady-state concentration of drug in plasma or blood is known, the rate of clearance of drug will dictate the rate at which the drug should be administered.

Knowing the clearance of a drug is useful because its value for a particular drug usually is constant over the range of concentrations encountered clinically. This is true because metabolizing enzymes and transporters usually are not saturated; thus, the absolute rate of elimination of the drug is essentially a linear function of its concentration in plasma (first-order kinetics), where a *constant fraction* of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order (the case for *ethanol* and high doses of *phenytoin*), in which case a *constant amount* of drug is eliminated per unit of time.

With first-order kinetics, clearance CL will vary with the concentration of drug (C), often according to Equation 2–4:

$$CL = \frac{V_m}{(K_m + C)} \qquad \text{(Equation 2–4)}$$

where K_m represents the concentration at which half the maximal rate of elimination is reached (in units of mass/volume), and V_m is equal to the maximal rate of elimination (in units of mass/time). Thus, clearance is derived in units of volume cleared of drug/time. This equation is analogous to the Michaelis-Menten equation for enzyme kinetics.

Clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug C in some biological fluid where measurement can be made:

$$CL = \text{Rate of elimination}/C \qquad \text{(Equation 2–5)}$$

Thus, when clearance is constant, the rate of drug elimination is directly proportional to drug concentration. Clearance indicates the volume of biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance per unit of body weight (e.g., mL/min per kg). Clearance can be defined further as blood clearance CL_b, plasma clearance CL_p, or clearance based on the concentration of unbound drug CL_u, depending on the measurement made (C_b, C_p, or C_u). Clearance of drug by several organs is additive. Elimination of drug from the systemic circulation may occur as a result of processes that occur in the kidney, liver, and other organs. Division of the rate of elimination by each organ by a concentration of drug (e.g., plasma concentration) will yield the respective clearance by that organ. Added together, these separate clearances will equal systemic clearance:

$$CL_{renal} + CL_{hepatic} + CL_{other} = CL \qquad \text{(Equation 2–6)}$$

Any significant alteration in renal or hepatic function can result in decreased clearance for those drugs with high renal or hepatic clearance. Systemic clearance may be determined at steady state by using Equation 2–3. For a single dose of a drug with bioavailability of 1 and first-order kinetics of elimination, systemic clearance may be determined from mass balance and the integration of Equation 2–5 over time:

$$CL = \text{Dose}/\text{AUC} \qquad \text{(Equation 2–7)}$$

AUC is the total *area under the curve* that describes the measured concentration of drug in the systemic circulation as a function of time (from zero to infinity), as in Figure 2–10, panel A.

Examples of Clearance

The plasma clearance for the antibiotic *cephalexin* is 4.3 mL/min/kg, with 90% of the drug excreted unchanged in the urine. For a 70-kg man, the clearance from plasma would be 301 mL/min, with renal clearance accounting for 90% of this elimination. In other words, the kidney is able to excrete *cephalexin* at a rate such that the drug is completely removed (cleared) from about 270 mL of plasma every minute (renal clearance = 90% of total clearance). Because clearance usually is assumed to remain constant in a medically stable patient (e.g., no acute decline in kidney function), the rate of elimination of *cephalexin* will depend on the concentration of drug in the plasma (see Equation 2–5).

The β adrenergic receptor antagonist *propranolol* is cleared from the blood at a rate of 16 mL/min/kg (or 1600 mL/min in a 100-kg man), almost exclusively by the liver. Thus, the liver is able to remove the amount of *propranolol* contained in 1600 mL of blood in 1 min, roughly equal to total hepatic blood flow (see Table 2–2). In fact, the plasma clearance of some drugs exceeds the rate of blood flow to this organ. Often, this is so because the drug partitions readily into and out of red blood cells (rbc), and the rate of drug delivered to the eliminating organ is considerably higher than expected from measurement of its concentration in plasma. The relationship between plasma clearance (CL_p) and blood clearance (CL_b; all components of blood) at steady state is given by

$$\frac{CL_p}{CL_b} = \frac{C_b}{C_p} = 1 + H\left[\frac{C_{rbc}}{C_p} - 1\right] \qquad \text{(Equation 2–8)}$$

Clearance from the blood therefore may be estimated by dividing the plasma clearance by the drug's blood-to-plasma concentration ratio, obtained from knowledge of the hematocrit ($H = 0.45$) and concentration ratio of red cells to plasma. In most instances, the blood clearance will be less than liver blood flow (1.5–1.7 L/min) or, if renal excretion is involved, the sum of the blood flows to each eliminating organ. For example, the plasma clearance of the immunomodulator *tacrolimus*, about 2 L/min, is more than twice the hepatic plasma flow rate and even exceeds the organ's blood flow despite the fact that the liver is the predominant site of this drug's extensive metabolism. However, after taking into account the extensive distribution of *tacrolimus* into red cells, its clearance from the blood is only about 63 mL/min, and it is actually a drug with a rather low clearance, not a high-clearance agent as might be expected from the plasma clearance value alone. Clearance from the blood by metabolism can exceed liver blood flow, and this indicates extrahepatic metabolism. In the case of the β_1 receptor antagonist *esmolol*, the blood clearance value (11.9 L/min) is greater than cardiac output (~5.5 L/min) because the drug is metabolized efficiently by esterases present in red blood cells.

A further definition of clearance is useful for understanding the effects of pathological and physiological variables on drug elimination, particularly with respect to an individual organ. The rate of presentation of drug to the organ is the product of blood flow Q and the arterial drug concentration C_A, and the rate of exit of drug from the organ is the product of blood flow and the venous drug concentration C_V. The difference between these rates at steady state is the rate of drug elimination by that organ:

$$\begin{aligned}\text{Rate of elimination} &= Q \cdot C_A - Q \cdot C_V \\ &= Q(C_A - C_V)\end{aligned} \qquad \text{(Equation 2–9)}$$

Dividing Equation 2–8 by the concentration of drug entering the organ of elimination, C_A, yields an expression for clearance of the drug by the organ in question:

$$CL_{organ} = Q\left[\frac{C_A - C_V}{C_A}\right] = Q \times E \qquad \text{(Equation 2–10)}$$

The expression $(C_A - C_V)/C_A$ in Equation 2–10 can be referred to as the extraction ratio E of the drug. While not employed in general medical practice, calculations of a drug's extraction ratio(s) are useful for modeling the effects of disease of a given metabolizing organ on clearance and in the design of ideal therapeutic properties of drugs in development.

Hepatic Clearance (CL_H)

For a drug that is removed efficiently from the blood by hepatic processes (metabolism or excretion of drug into the bile), the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow (800–1500 mL/min). Drugs that are cleared efficiently by the liver (e.g., drugs with systemic clearances >6 mL/min/kg, such as *diltiazem*, *imipramine*, *lidocaine*, *morphine*, and *propranolol*) are restricted in their rate of elimination not by intrahepatic processes, but by the rate at which they can be transported in the blood to the liver.

Pharmacokinetic models indicate that when the capacity of the eliminating organ to metabolize the drug is large in comparison with the rate of presentation of drug to the organ, clearance will approximate the organ's blood flow. By contrast, when the drug-metabolizing capacity is small in comparison with the rate of drug presentation, clearance will be proportional to the unbound fraction of drug in blood (f_{unb}) and the drug's intrinsic clearance (CL_{int}), where intrinsic clearance represents drug binding to components of blood and tissues or the intrinsic capacity of the liver to eliminate a drug in the absence of limitations imposed by blood flow (Guner and Bowen, 2013). Thus, hepatic clearance will be:

$$CL_H = \frac{Q_H(f_{umb})(CL_{int})}{Q_H + (f_{umb})(CL_{int})} \qquad \text{(Equation 2–11)}$$

Renal Clearance

Renal clearance of a drug results in its appearance in the urine. In considering the clearance of a drug from the body by the kidney, glomerular filtration, secretion, reabsorption, and glomerular blood flow must be considered (see Figure 2–5). The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the concentration of unbound drug in plasma (because drug bound to protein is not filtered). The rate of secretion of drug into the tubular fluid is the largest factor determining renal excretion. Secretion will depend on the transporters involved in active secretion as affected by the drug's binding to plasma proteins, the degree of saturation of these transporters, the rate of delivery of the drug to the secretory site, and the presence of drugs that can compete for these transporters. In addition, one must consider processes of drug reabsorption from the tubular fluid back into the bloodstream such as occurs with uric acid. The influences of changes in protein binding, blood flow, and the functional state of nephrons will affect renal clearance.

Aspirin demonstrates the interplay among renal absorption and secretion. *Aspirin* has a bimodal effect on the renal handling of uric acid: High doses of *aspirin* (>3 g/day) are uricosuric (probably by blocking urate reabsorption), while low dosages (1–2 g/day) cause uric acid retention (probably via inhibiting urate secretion). Low-dose *aspirin*, indicated for the prophylaxis of cardiovascular events, can cause changes in renal function and uric acid handling in elderly patients.

Distribution

Volume of Distribution

The volume of distribution V relates the amount of drug in the body to the concentration of drug C in the blood or plasma, depending on the fluid measured. This volume does not necessarily refer to an identifiable physiological volume, but rather to the fluid volume that would be required to contain all of the drug in the body at the same concentration measured in the blood or plasma:

$$\text{Amount of drug in body}/V = C$$

or

$$V = \text{Amount of drug in body}/C \qquad \text{(Equation 2–12)}$$

View V as an imaginary volume because for many drugs V exceeds the known volume of any and all body compartments (Box 2–1). For example, the value of V for the highly lipophilic antimalarial *chloroquine* is

BOX 2–1 ■ *V* Values > Any Physiological Volume?

For many drugs, Equation 2–12 will give *V* values that exceed any physiological volume. For example, if 500 µg of the cardiac glycoside *digoxin* were added into the body of a 70-kg subject, a plasma concentration of about 0.75 ng/mL would be observed. Dividing the amount of drug in the body by the plasma concentration yields a volume of distribution for *digoxin* of about 667 L, or a value about 15 times greater than the total-body volume of a 70-kg man. In fact, *digoxin* distributes preferentially to muscle and adipose tissue and binds to its specific receptors, the Na^+/K^+-ATPase, leaving a very small amount of drug in the plasma to be measured. A drug's volume of distribution therefore can reflect the extent to which it is present in extravascular tissues and not in the plasma. Conversely, a small value for *V* can indicate maintenance of the drug in the bloodstream desirable in the treatment of leukemias. Many newer drug formulations encapsulate one or more drugs in liposomes or engineered nanoparticles to regulate drug distribution (Filipczak et al., 2020). Thus, *V* may vary widely depending on the relative degrees of binding to high-affinity receptor sites, plasma and tissue proteins, the partition coefficient of the drug in fat, accumulation in poorly perfused tissues, and engineered strategies such as encapsulation. The volume of distribution for a given drug can differ according to a patient's age, gender, body composition, and presence of disease. Total-body water of infants younger than 1 year of age, for example, is 75% to 80% of body weight, whereas that of adult males is 60% and that of females is 55%.

approximately 15,000 L, whereas the volume of total-body water is about 42 L in a 70-kg male. The benefit of determining *V* is to understand distribution of drug to the body away from the bloodstream as an indication of its distribution to sites of action.

For drugs that are bound extensively to plasma proteins but are not bound to tissue components, the volume of distribution will approach that of the plasma volume because drug bound to plasma protein is measurable in the assay of most drugs. In contrast, certain drugs have high volumes of distribution even though most of the drug in the circulation is bound to albumin because these drugs are sequestered elsewhere in the body.

The volume of distribution defined in Equation 2–12 considers the body as a single homogeneous compartment. In this one-compartment model, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume *V*. Clearance of drug from this compartment occurs in a first-order fashion, as defined in Equation 2–5; that is, the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment at that time. Figure 2–6A and Equation 2–9 describe the decline of plasma concentration with time for a drug introduced into this central compartment:

$$C = \left[\frac{\text{Dose}}{V}\right][e^{-kt}] \qquad \text{(Equation 2–13)}$$

where *k* is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This rate constant is inversely related to the $t_{1/2}$ of the drug [$kt_{1/2} = \ln 2 = 0.693$]. The idealized one-compartment model does not describe the entire time course of the plasma concentration. Certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 2–6B).

Rates of Distribution

In many cases, groups of tissues with similar perfusion-to-partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial decrease in concentration of intravenously injected drug, as in Figure 2–6B). Essentially, the drug starts in a "central" volume (see Figure 2–1), which consists of plasma and tissue reservoirs that are in rapid equilibrium, then distributes to a "final" volume, at which point concentrations in plasma decrease in a log-linear fashion with a rate constant of *k* (see Figure 2–6B). The multicompartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (the tissue compartment).

If blood flow to certain tissues changes within an individual, rates of drug distribution to these tissues also will change. Changes in blood flow

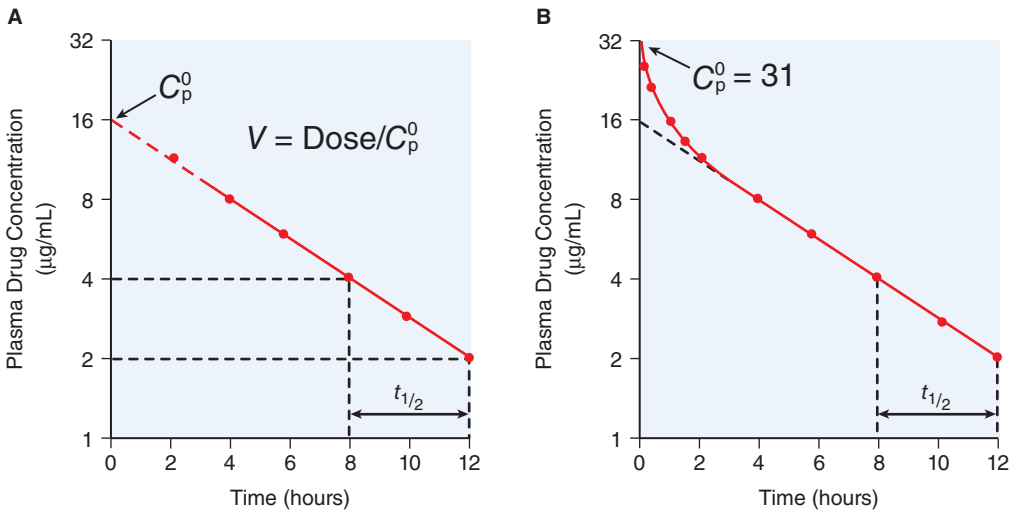

Figure 2–6 *Plasma concentration-time curves following intravenous administration of a drug (500 mg) to a 70-kg patient.* **A.** Drug concentrations are measured in plasma at 2-h intervals following drug administration. The semilogarithmic plot of plasma concentration C_p versus time suggests that the drug is eliminated from a single compartment by a first-order process (see Equation 2–13) with a $t_{1/2}$ of 4 h ($k = 0.693/t_{1/2} = 0.173\ h^{-1}$). The volume of distribution *V* may be determined from the value of C_p obtained by extrapolation to zero-time. Volume of distribution (see Equation 2–12) for the one-compartment model is 31.3 L, or 0.45 L/kg ($V = \text{dose}/C_p^0$). The clearance for this drug is 90 mL/min; for a one-compartment model, $CL = kV$. **B.** Sampling before 2 h indicates that the drug follows multiexponential kinetics. The terminal disposition $t_{1/2}$ is 4 h, clearance is 84 mL/min (see Equation 2–7), and V_{ss} is 26.8 L (see Equation 2–14). The initial or "central" distribution volume for the drug ($V = \text{dose}/C_p^0$) is 16.1 L. The example indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of appropriate dosage.

may cause some tissues that were originally in the "central" volume to equilibrate sufficiently more slowly so they appear only in the "final" volume. This means that central volumes will appear to vary with disease states that cause altered regional blood flow (such as would be seen in cirrhosis of the liver). After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion (e.g., shock) than they would be if perfusion were better. These higher systemic concentrations may in turn cause higher concentrations (and greater effects) in tissues such as brain and heart, whose usually high perfusion has not been reduced. Thus, the effect of a drug at various sites of action can vary depending on perfusion of these sites.

Multicompartment Volumes

In multicompartment kinetics, a volume of distribution term is useful especially when the effect of disease states on pharmacokinetics is to be determined. The volume of distribution at steady-state V_{ss} represents the volume in which a drug would appear to be distributed during steady state if the drug existed throughout that volume at the same concentration as that in the measured fluid (plasma or blood). V_{ss} also may be appreciated as shown in Equation 2–14, where V_C is the volume of distribution of drug in the central compartment and V_T is the volume term for drug in the tissue compartment:

$$V_{ss} = V_C + V_T \qquad \text{(Equation 2–14)}$$

Steady-State Concentration

Equation 2–3 (Dosing rate = $CL \cdot C_{ss}$) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate. At this point, drug elimination (the product of clearance and concentration; Equation 2–5) will equal the rate of drug availability. This concept also extends to regular intermittent dosage (e.g., 250 mg of drug every 8 h). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (Figure 2–7). Equation 2–3 still applies for intermittent dosing, but it now describes the average steady-state drug concentration during an interdose interval. Note the extension of this idea to derive $\bar{C}_{ss}$ during continuous intravenous drug infusion, as explained in the legend to Figure 2–7.

Half-Life

The $t_{1/2}$ is the time it takes for the plasma concentration of drug to be reduced by 50%. For the one-compartment model of Figure 2–6A, $t_{1/2}$ may be determined readily by inspection of the data and used to make decisions about drug dosage. However, as indicated in Figure 2–6B, drug concentrations in plasma often follow a multicomponent pattern of decline.

Half-Life, Volume of Distribution, and Clearance

When using pharmacokinetics to calculate drug dosing in disease, note that $t_{1/2}$ changes as a function of both clearance and volume of distribution:

$$t_{1/2} \cong 0.693 \cdot V_{ss}/CL \qquad \text{(Equation 2–15)}$$

This $t_{1/2}$ reflects the decline of systemic drug concentrations during a dosing interval at steady state as depicted in Figure 2–7.

Terminal Half-Life

With prolonged dosing (or with high drug concentrations), a drug may penetrate beyond the central compartment into "deep" or secondary body compartments that equilibrate only slowly with the plasma. When the infusion or dosing stops, the drug will be initially cleared from plasma as expected. Then the concentration will drop to a point at which net diffusion from the secondary compartments begins, and this slow equilibration will produce a prolongation of the half-life of the drug, referred to as the terminal half-life.

Steady-State $t_{1/2}$ and Terminal $t_{1/2}$ Compared

Examples of drugs with marked differences in terminal $t_{1/2}$ versus steady-state $t_{1/2}$ are *gentamicin* and *indomethacin*. *Gentamicin* has a $t_{1/2}$ of 2 to 3 h following a single administration, but a terminal $t_{1/2}$ of 53 h because drug accumulates in parenchymal cells (where

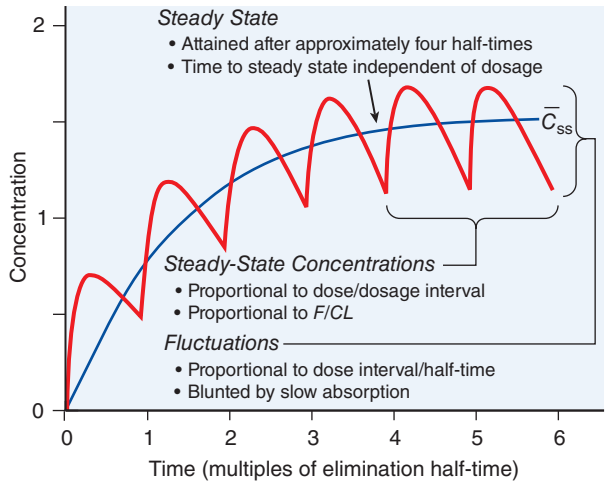

Figure 2–7 *Fundamental pharmacokinetic relationships for repeated administration of drugs.* The red line is the pattern of drug accumulation during repeated administration of a drug at intervals equal to its elimination half-time. With instantaneous absorption, each dose would add 1 concentration unit to C_p at the time of administration, and then half of that would be eliminated prior to administration of the next dose, resulting in the oscillation of C_p between 1 and 2 after four or five elimination half-times. However, this more realistic simulation uses a rate of drug absorption that is not instantaneous but is 10 times as rapid as elimination; drug is eliminated throughout the absorption process, blunting the maximal blood level achieved after each dose. With repeated administration, C_p achieves steady state, oscillating around the blue line at 1.5 units. The blue line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based on the one-compartment model. Average drug concentration at steady state $\bar{C}_{ss}$ is:

$$C_{ss} = \frac{F \cdot \text{dose}}{CL \cdot T} = \frac{F \cdot \text{dosing rate}}{CL}$$

where the dosing rate is the dose per time interval and is dose/T, F is the fractional bioavailability, and CL is clearance. Note that substitution of infusion rate for [$F \cdot$ dose/T] provides the concentration maintained at steady state during continuous intravenous infusion ($F = 1$ with intravenous administration).

this accumulation can result in toxicity). Biliary cycling probably is responsible for the 120-h terminal value for *indomethacin* (compared to the steady-state value of 2.4 h). Intravenous anesthetics provide a good example; many have *context-sensitive* half-times; these agents, with short half-times after single intravenous doses, exhibit longer half-times in proportion to the duration of exposure when used in maintenance anesthesia (see Figure 21–2).

Clearance is the measure of the body's capacity to eliminate a drug. Thus, as clearance decreases, owing to a disease process for example, $t_{1/2}$ will increase as long as the volume of distribution remains unchanged. Alternately, the volume of distribution may change, but CL remains constant or both can change. For example, the $t_{1/2}$ of *diazepam* increases with increasing age; however, this does not reflect a change in clearance, but rather a change in the volume of distribution. Similarly, changes in protein binding of a drug (e.g., hypoalbuminemia) may affect its clearance as well as its volume of distribution, leading to unpredictable changes in $t_{1/2}$ as a function of disease. The $t_{1/2}$ defined in Equation 2–15 provides an approximation of the time required to reach steady state after a dosage regimen is initiated or changed (e.g., four half-lives to reach ~94% of a new steady state).

Extent and Rate of Absorption

Bioavailability

It is important to distinguish between the amount of drug that is administered and the quantity of drug that ultimately reaches the systemic circulation. Dissolution and absorption of drug may be incomplete; some drug may be destroyed prior to entering the systemic circulation,

especially by hepatic first-pass metabolism. The first-pass effect is extensive for many oral medications that enter the portal vein and pass directly to the liver. The fraction of a dose F that is absorbed and escapes first-pass elimination measures the drug's *bioavailability*; thus, $0 < F \leq 1$ (see Equation 2–2).

For some drugs, extensive first-pass metabolism precludes their use as oral agents (e.g., *lidocaine, naloxone*), while other agents, though administered orally, must be given to avoid hepatic metabolism (e.g., *glyceryl trinitrate*) or can be dosed to account for the large first-pass effect (e.g., *propranolol*). For other agents, the extent of absorption may be very low, thereby reducing bioavailability. When drugs are administered by a route that is subject to significant first-pass loss or incomplete absorption, the equations presented previously that contain the terms *dose* or *dosing rate* (see Equations 2–3, 2–7, and 2–13) also must include the bioavailability term F such that the available dose or dosing rate is used (Box 2–2). For example, Equation 2–2 is modified to

$$F \cdot \text{Dosing rate} = CL \cdot C_{ss} \qquad \text{(Equation 2–16)}$$

where the value of F is between 0 and 0.85.

Rate of Absorption

The rate of absorption can be important with a drug given as a single dose, such as a sleep-inducing medication that must act in a reasonable time frame and achieve an effective blood level that is maintained for an appropriate duration. However, with periodic and repeated dosing, the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, provided the drug is stable before it is absorbed; the rate of absorption may, however, still influence drug therapy. If a drug is absorbed rapidly (e.g., a dose given as an intravenous bolus) and has a small "central" volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its "final" (larger) volume (see Figure 2–6B). If the same drug is absorbed more slowly (e.g., by slow infusion), a significant amount of the drug will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release oral preparations are designed to provide a slow and sustained rate of absorption to produce smaller fluctuations in the plasma concentration-time profile during the dosage interval compared with more immediate-release formulations. Because the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

Nonlinear Pharmacokinetics

Nonlinearity in pharmacokinetics (i.e., changes in such parameters as clearance, volume of distribution, and $t_{1/2}$ as a function of dose or concentration of drug) is usually caused by saturation of protein binding, hepatic metabolism, or active renal transport of the drug.

BOX 2–2 ■ Notwithstanding Poor Absorption, Some Agents with Low Bioavailability are Effective Orally

The value of F varies widely for drugs administered by mouth, and successful therapy can still be achieved for some drugs with F values as low as 0.03 (e.g., *etidronate* and *aliskiren*). *Aliskiren* is the first orally applicable direct renin inhibitor approved for treatment of hypertension; its bioavailability is 2.6%. *Etidronate*, a bisphosphonate used to stabilize bone matrix in the treatment of Paget's disease and osteoporosis, has a similarly low bioavailability of 0.03, meaning that only 3% of the drug appears in the bloodstream following oral dosing. In these cases, therapy using oral administration is still useful, although the administered dose of the drug per kilogram is larger than would be given by injection.

Saturable Protein Binding

As the molar concentration of small drug molecules increases, the unbound fraction eventually also must increase (as all binding sites become saturated when drug concentrations in plasma are in the range of tens to hundreds of micrograms per milliliter). For a drug that is metabolized by the liver with a low intrinsic clearance-extraction ratio, saturation of plasma-protein binding will cause both V and CL to increase as drug concentrations increase; $t_{1/2}$ thus may remain constant (see Equation 2–15). For such a drug, C_{ss} will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance-extraction ratios, C_{ss} can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in V will increase the half-time of disappearance by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these two extremes.

Saturable Elimination

In the case of saturable elimination, the Michaelis-Menten equation (see Equation 2–4) usually describes the nonlinearity. All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are at or less than K_m for that process (Box 2–3). When drug concentrations exceed K_m, nonlinear kinetics are observed. Saturable metabolism causes oral first-pass metabolism to be less than expected (higher *fractional bioavailability*),

BOX 2–3 ■ Saturable Metabolism: Phenytoin

The antiseizure medication *phenytoin* is a drug for which metabolism can become saturated by levels of the drug in the therapeutic range. Factors contributing to this are *phenytoin*'s variable half-life and clearance and an effective concentration that varies and can saturate clearance mechanisms, such that the C_{ss} may be saturating clearance mechanisms or be well above or below that value. The $t_{1/2}$ of *phenytoin* is 6 to 24 h. For clearance, K_m (5–10 mg/L) is typically near the lower end of the therapeutic range (10–20 mg/L). For some individuals, especially young children and newborns being treated for emergent seizures, K_m may be as low as 1 mg/L. Consider an extreme case of a 70-kg adult in whom the target concentration (C_{ss}) is 15 mg/L, K_m is 1 mg/L, and the maximal elimination rate, v_m (from Appendix I), is 5.9 mg/kg per day, or 413 mg/day per 70 kg. Substituting into Equation 2–17:

$$15 \text{ mg/L} = (\text{dosing rate})(1 \text{ mg/L})/(413 \text{ mg/day} - \text{dosing rate})$$
$$\text{dosing rate} = 387 \text{ mg/day}$$

In this case, the dosing rate is just below the elimination capacity. If the dosing rate were to vary upward by 10% (to 387 + 38.7 or ~426 mg/day), the dosing rate would exceed the elimination capacity by 13 mg/day and the C_p of *phenytoin* would begin a slow climb to toxic levels due to accumulation. Conversely, if the dosing rate were to vary downward by 10% (to 387 – 38.7 or ~348 mg/day), the C_{ss} achieved would be 5.4 mg/L, a drastic reduction to a level below the therapeutic range.

Consider a more common K_m, 8 mg/L, such that the desired C_{ss} of 15 mg/L is farther from saturating the elimination capacity. In a 70-kg subject (v_m = 413 mg/day), these data require a dosing rate of only 269 mg/day. An increase in this rate by 10% (to 296 mg/day) would not saturate the elimination capacity but would lead to a C_{ss} = 20.2 mg/L. A 10% downward variance in the dosing rate (to 242 mg/day) will produce a C_{ss} = 11.3 mg/L, a much less drastic decrease than above and still in the therapeutic range.

Factoring in all the variables, predicting and controlling dosage so precisely (<10% error) can be difficult. Therefore, for patients in whom the target concentration for *phenytoin* is ≥10 times the K_m, alternating between inefficacious therapy and toxicity is common, careful monitoring is essential, and a pharmacokinetic consult to establish or revise dosing may be appropriate.

Other agents exhibiting saturated metabolism at or near the commonly employed concentrations include *aspirin*, *fluoxetine*, *verapamil*, and *ethanol*.

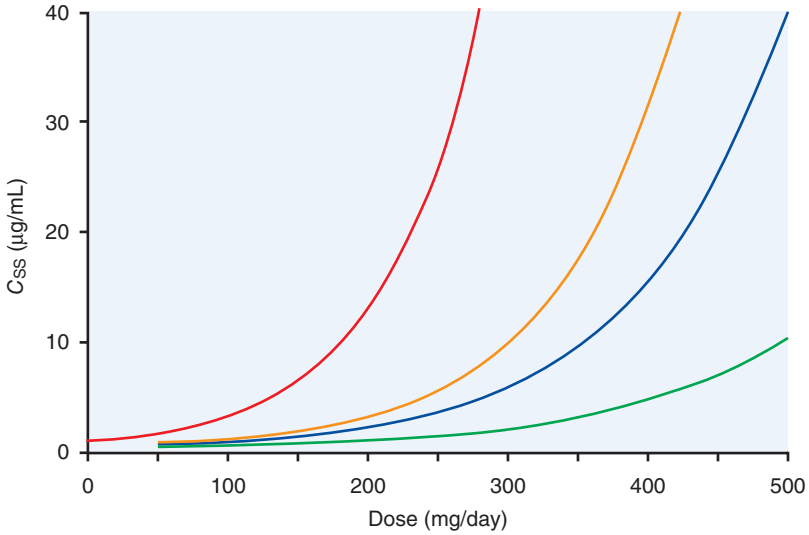

Figure 2–8 *Effect of altered elimination on the steady-state levels of a drug in the central compartment.* Blue line represents the effect of dose on the therapeutic drug level of a drug dosed once daily and eliminated by both hepatic metabolism and renal excretion. The effect of an increase in the rate of elimination, v_m, as might be seen by concurrent administration of drugs that induce metabolism (e.g., *phenytoin*, *rifampin*), is shown in green. The effect of an increase in K_m for elimination, as might be seen with concurrent administration of inhibitors of hepatic CYPs (e.g., *fluconazole*, *fluoxetine*), is shown in orange. The red line depicts the effect of hepatic cirrhosis and/or renal insufficiency, as might be found in an elderly patient. A significantly prolonged $t_{1/2}$ would cause rapid development of toxicity.

resulting in a greater fractional increase in C_{ss} than the corresponding fractional increase in the rate of drug administration; basically, the rate of drug entry into the systemic circulation exceeds the maximum possible rate of drug metabolism, and elimination becomes zero order. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of protein binding will lead to increased *CL* because *CL* increases as drug concentration increases, whereas saturation of metabolism or transport may decrease *CL*.

Figure 2–8 presents hypothetical curves that show the effects of altered metabolism/elimination on plasma drug levels as functions of drug dosage.

Phenytoin offers a good clinical example of how the altered metabolism can alter the clinical outcome of drug therapy. *Phenytoin* is an antiepileptic drug widely used in the treatment of focal epilepsy and status epilepticus and effective in controlling focal seizures with and without tonic-clonic generalization and status epilepticus (see Chapter 20). Ninety percent of the metabolism of *phenytoin* is carried out by CYP2C9. Genetic polymorphisms in CYP2C9 may reduce the metabolism of *phenytoin* by 25% to 50% in patients. The frequency distribution of CYP2C9 polymorphism alleles in patients with epilepsy around the world ranges from 4.5% to 13.6%, being less frequent in African Americans and Asians. *Phenytoin* has a narrow therapeutic range and a nonlinear pharmacokinetic profile. Alterations in *phenytoin* metabolism can have significant clinical implications causing frequent and more serious adverse effects requiring discontinuation of treatment, despite clinical effectiveness. Table 2–3 summarizes some of these alterations, and Box 2–3 uses the example of *phenytoin* to present issues to be considered when a drug's metabolism can be saturated by plasma drug levels within a narrow therapeutic range and monitoring and adjustment of dosage become critical.

C_{ss} can be computed by substituting Equation 2–4 (with $C = C_{ss}$) into Equation 2–3 and solving for the steady-state concentration:

$$C_{ss} = \frac{\text{Dosing rate} \cdot K_m}{v_m - \text{dosing rate}} \qquad \text{(Equation 2–17)}$$

As the dosing rate approaches the maximal elimination rate v_m, the denominator of Equation 2–17 approaches zero, and C_{ss} increases disproportionately. Because saturation of metabolism should have no effect on the volume of distribution, clearance and the relative rate of drug elimination decrease as the concentration increases; therefore, the log C_p time curve is concave-downward until metabolism becomes sufficiently desaturated such that first-order elimination is observed (Figure 2–9).

Thus, during saturation of metabolism, the concept of a constant $t_{1/2}$ is not applicable. Consequently, changing the dosing rate for a drug with nonlinear metabolism is difficult and unpredictable because the resulting steady state is reached more slowly, and importantly, the effect is disproportionate to the alteration in the dosing rate.

Figure 2–9 compares the effects of first-order and zero-order elimination kinetics on important pharmacokinetic parameters.

Design and Optimization of Dosage Regimens

The Therapeutic Window

The intensity of a drug's effect is related to its concentration (usually C_p) above a minimum effective concentration, whereas the duration of the drug's effect reflects the length of time the drug level is above this value (Figure 2–10). These considerations, in general, apply to both desired and

TABLE 2–3 ■ CONDITIONS THAT CHANGE METABOLISM OF PHENYTOIN

CYP2C9	DISEASE OR CONDITION	EXAMPLE
V_{max} is increased	Enzyme induction	Concurrent administration of phenobarbital, rifampicin, or carbamazepine
V_{max} is decreased	Hepatic cirrhosis	Decreased enzyme activity: presence of either of 2 clinically significant CYP2C9 polymorphisms
K_m is increased	Competitive inhibition	Concurrent administration of antidepressants (e.g., fluoxetine), antimicrobials (e.g., chloramphenicol), or others including cimetidine
K_m is decreased	Decreased plasma protein binding	Hypoalbuminemia, competition for binding (e.g., valproic acid or salicylates)

K_m, [drug] at which rate of metabolism = 50% of V*max*; V_{max}, maximal rate of metabolism.

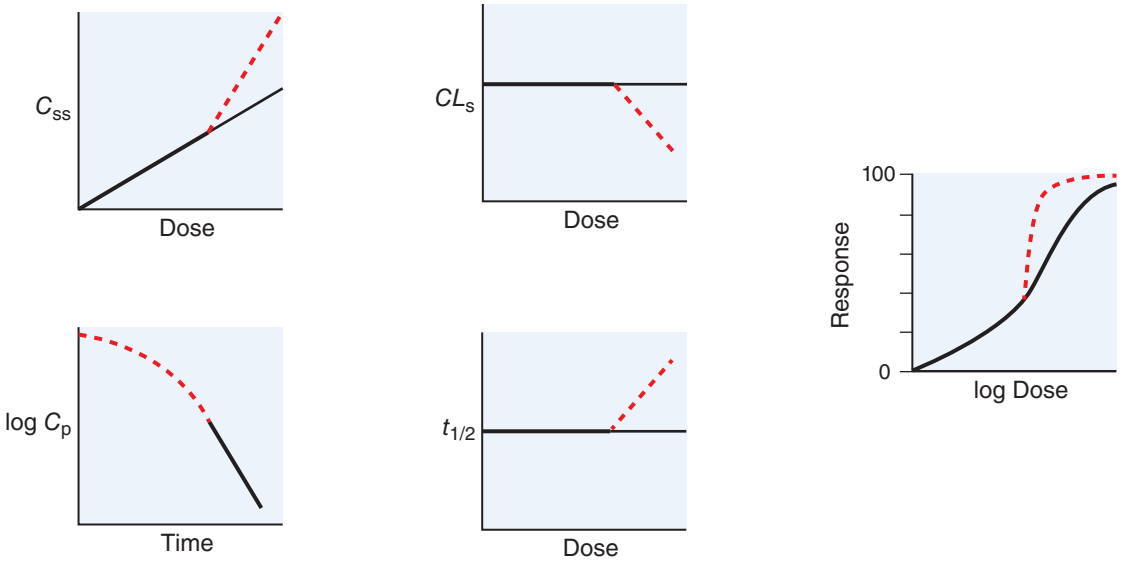

Figure 2–9 *Comparative pharmacokinetic parameters with first-order and zero-order elimination.* Black lines represent the relationships under first-order kinetics of elimination. Dashed red lines indicate the effects of transitioning to a region of saturated elimination (zero-order kinetics).

undesired (adverse) drug effects; as a result, a *therapeutic window* exists that reflects a concentration range that provides efficacy without unacceptable toxicity. Following administration of a single dose, a lag period precedes the onset of the drug effect, after which the magnitude of the effect increases to a maximum and then declines; if a subsequent dose is not administered, the effect eventually disappears as the drug is eliminated. This time course reflects changes in the drug's concentration as determined by the pharmacokinetics of its absorption, distribution, and elimination.

Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. *In general, the lower limit of a drug's therapeutic range is approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no more*

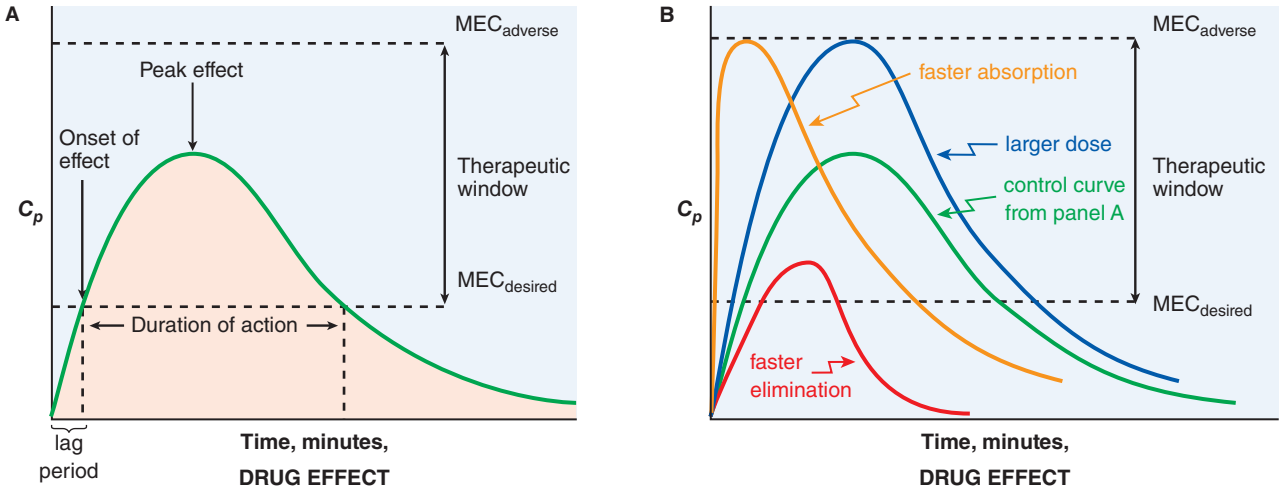

Figure 2–10 **A.** *Temporal characteristics of drug effect and relationship to the therapeutic window (e.g., single dose, oral administration).* A lag period is present before the plasma drug concentration C_p exceeds the minimum effective concentration (MEC) for the desired effect, $MEC_{desired}$. Following onset of the response, the intensity of the effect increases as the drug continues to be absorbed and distributed. This reaches a peak, after which drug elimination results in a decline in C_p and in the effect's intensity. Effect disappears when the drug concentration falls below the $MEC_{desired}$. The duration of a drug's action is determined by the time period over which concentrations exceed the $MEC_{desired}$. An MEC also exists for each adverse response ($MEC_{adverse}$), and if the drug concentration exceeds this, toxicity will result. The therapeutic goal is to obtain and maintain concentrations within the therapeutic window for the desired response with a minimum of toxicity. Drug response *below* the $MEC_{desired}$ will be subtherapeutic; *above* the $MEC_{adverse}$, the probability of toxicity will increase. The AUC (pale red) can be used to calculate the clearance (see Equation 2–7) for first-order elimination. The AUC is also used as a measure of bioavailability (defined as 100% for an intravenously administered drug). Bioavailability is less than 100% for orally administered drugs, due mainly to incomplete absorption and first-pass metabolism and elimination. Changing drug dosage shifts the curve up or down the C_p scale and is used to modulate the drug's effect, as shown in panel B.

B. *Effects of altered absorption, elimination, and dosage and the temporal profile of a single dose administered orally.* The bold green curve is the same as that shown in panel A. Increasing the dose (blue line) decreases the lag period and prolongs the drug's duration of effectiveness but at the risk of increasing the likelihood of adverse effects. Unless the drug is nontoxic (e.g., penicillins), increasing the dose is not a useful strategy for extending the duration of action if the increase puts the drug level near $MEC_{adverse}$. Instead, another dose of drug should be given, timed to maintain concentrations within the therapeutic window (see Figure 2–7). An increased rate of absorption of the dose (orange line) reduces the lag period, leads to a higher maximum C_p at an earlier time, but results in a shorter duration of action (time above $MEC_{desired}$). Increasing the rate of elimination of the dose decreases the maximum C_p and reduces the time of $C_p > MEC_{desired}$.

than 5% to 10% of patients will experience a toxic effect. For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concentrations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., *digoxin*).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose) and can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles presented (e.g., change dosage by no more than 50% and no more often than every three or four half-lives to assure that a new near-steady-state drug concentration has been achieved). Alternatively, some drugs have little dose-related toxicity, and maximum efficacy usually is desired. In such cases, doses well in excess of the average required will ensure efficacy (if this is possible) and prolong drug action. Such a "maximal dose" strategy typically is used for penicillins. For many drugs, therapeutic effects are difficult to measure (or the drug is given for prophylaxis); hence, drug toxicity and lack of efficacy are both potential dangers, especially if the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy.

Thus, the therapeutic goal is to maintain steady-state drug levels within the therapeutic window. When the concentrations associated with this desired range are not known, it is sufficient to understand that efficacy and toxicity depend on concentration and how drug dosage and frequency of administration affect the blood level of the drug. However, for a small number of drugs for which there is a small (2- to 3-fold) difference between concentrations resulting in efficacy and toxicity (e.g., *digoxin, theophylline, lidocaine*, aminoglycosides, *cyclosporine, tacrolimus, sirolimus, warfarin*, and some anticonvulsants), a plasma concentration range associated with effective therapy has been defined. In these cases, a desired (target) steady-state concentration of the drug (usually in plasma) associated with efficacy and minimal toxicity is chosen, and a dosage is computed that is expected to achieve this value. Drug concentrations are subsequently measured, and dosage is adjusted if necessary (described further in the chapter).

Maintenance Dose

In most clinical situations, drugs are administered in a series of repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship is expressed here in terms of the desired target concentration:

$$\text{Dosing rate} = \text{Target } C_p \cdot CL/F \qquad \text{(Equation 2–18)}$$

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated (Box 2–4).

Dosing Interval for Intermittent Dosage

In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug's elimination $t_{1/2}$. If the dosing interval T were chosen to be equal to the $t_{1/2}$, then the total fluctuation would be 2-fold; this is often a tolerable variation. Pharmacodynamic considerations modify this. If a drug is relatively nontoxic such that a concentration many times that necessary for therapy can be tolerated easily, the maximal dose strategy can be used, and the dosing interval can be much longer than the elimination $t_{1/2}$ (for patient convenience). The $t_{1/2}$ of *amoxicillin* is about 2 h, but dosing every 2 h would be impractical. Instead, *amoxicillin* often is given in large doses every 8 or 12 h.

BOX 2–4 ■ Calculating Dosage of Digoxin in Heart Failure

Oral *digoxin* is to be used as a maintenance dose to gradually "digitalize" a 63-year-old, 84-kg patient with congestive heart failure. A steady-state plasma concentration of 0.7 to 0.9 ng/mL is selected as a conservative target based on prior knowledge of the action of the drug in patients with heart failure to maintain levels at or below the 0.5- to 1.0-ng/mL range (Bauman et al., 2006). This patient's creatinine clearance CL_{Cr} is given as 56 mL/min/84 kg; knowing that *digoxin*'s clearance may be estimated by consulting the entry for *digoxin* in Appendix I: $CL = 0.88\ CL_{Cr} + 0.33$ mL/min/kg. Thus,

$$\begin{aligned} CL &= 0.88\ CL_{Cr} + 0.33 \text{ mL/min/kg} \\ &= 0.88 \times 56/84 + 0.33 \text{ mL/min/kg} \\ &= 0.92 \text{ mL/min/kg} \end{aligned}$$

For this 84-kg patient:

$$CL = (84 \text{ kg})(0.92 \text{ mL/min/kg}) = 77 \text{ mL/min} = 4.6 \text{ L/h}$$

Knowing that the oral bioavailability of *digoxin* is 70% ($F = 0.7$) and with a target C_p of 0.75 ng/mL, one can use Equation 2–18 to calculate an appropriate dose rate for this 84-kg patient:

$$\begin{aligned} &\text{Dosing rate} = \text{Target } C_p \cdot CL/F \\ &= [0.75 \text{ ng/mL} \times 77 \text{ mL/min}] \div [0.7] = 82.5 \text{ ng/min} \\ &\text{or } 82.5 \text{ ng/min} \times 60 \text{ min/h} \times 24 \text{ h/day} = 119 \text{ µg/day} \end{aligned}$$

In practice, the dosing rate is rounded to the closest oral dosage size, 0.125 mg/day, which would result in a C_{ss} of 0.79 ng/mL ($0.75 \times 125/119$ or using Equation 2–16). *Digoxin* is a well-characterized example of a drug that is difficult to dose, has a low therapeutic index (~2–3), and has a large coefficient of variation for the clearance equation in patients with heart failure (52%); the effective blood level in one patient may be toxic or ineffective in another. Thus, monitoring the clinical status of patients (new or increased ankle edema, inability to sleep in a recumbent position, decreased exercise tolerance), whether accomplished by home health follow-up or regular visits to the clinician, is essential to avoid untoward results (see Chapter 33).

For some drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration $C_{ss,min}$ may be reasonably determined by:

$$C_{ss,\,min} = \frac{F \cdot \text{dose}/V_{ss}}{1 - e^{-kT}} \cdot e^{-kT} \qquad \text{(Equation 2–19)}$$

where k equals 0.693 divided by the clinically relevant plasma $t_{1/2}$, and T is the dosing interval. The term e^{-kT} is the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval.

For drugs that follow multiexponential kinetics (administered orally), estimation of the maximal steady-state concentration $C_{ss,max}$ involves a set of parameters for distribution and absorption (Box 2–5). If these terms are ignored for multiple oral dosing, one easily may estimate a maximal steady-state concentration by omitting the e^{-kT} term in the numerator of Equation 2–19 (see Equation 2–20 in Box 2–5). Because of the approximation, the predicted maximal concentration from Equation 2–20 will be greater than that actually observed.

Loading Dose

As noted, repeated administration of a drug more frequently than its complete elimination will result in accumulation of the drug to or around a steady-state level (see Figure 2–7). When a constant dosage is given, reaching a steady-state drug level (the desired therapeutic concentration) will take four to five elimination half-times. This period can be too long when treatment demands a more immediate therapeutic response. In such a case, one can employ a *loading dose*, one or a series of doses given

BOX 2–5 ■ Estimating Maximal and Minimal Blood Levels of Digoxin

In the 84-kg patient with congestive heart failure discussed in Box 2–4, an oral maintenance dose of 0.125 mg *digoxin* per 24 h was calculated to achieve an average plasma concentration of 0.79 ng/mL during the dosage interval. *Digoxin* has a narrow therapeutic index, and plasma levels ≤1.0 ng/mL usually are associated with efficacy and minimal toxicity. What are the maximum and minimum plasma concentrations associated with this regimen? This first requires estimation of *digoxin*'s volume of distribution based on pharmacokinetic data (Appendix I).

$$V_{ss} = 3.12\ CL_{Cr} + 3.84\ \text{L} \cdot \text{kg}^{-1}$$
$$= 3.12 \times (56/84) + 3.84\ \text{L} \cdot \text{kg}^{-1}$$
$$= 5.92\ \text{L/kg}$$

or 497 L in this 84-kg patient.

Combining this value with that of *digoxin*'s clearance provides an estimate of *digoxin*'s elimination $t_{1/2}$ in the patient (Equation 2–15).

$$t_{1/2} = 0.693\ V_{ss}/CL$$
$$= \frac{0.693 \times 497\ \text{L}}{4.6\ \text{L/h}} = 75\ \text{h} = 3.1\ \text{days}$$

Accordingly, the fractional rate constant of elimination k is equal to 0.22 day^{-1} (0.693/3.1 days). Maximum and minimum *digoxin* plasma concentrations then may be predicted depending on the dosage interval. With T = 1 day (i.e., 0.125 mg given every day),

$$C_{ss,max} = \frac{F \cdot \text{dose}/V_{ss}}{1 - e^{-kT}}$$
$$= \frac{0.7 \times 0.125\ \text{mg/497 L}}{0.2} \qquad \text{(Equation 2–20)}$$
$$= 0.88\ \text{ng/mL}\ (\sim 0.9\ \text{ng/mL})$$

$$C_{ss,min} = C_{ss,max} \cdot e^{-kt}$$
$$= (0.88\ \text{ng/mL})(0.8) = 0.7\ \text{ng/mL} \qquad \text{(Equation 2–21)}$$

Thus, the plasma concentrations would fluctuate minimally about the steady-state concentration of 0.79 ng/mL, well within the recommended therapeutic range of 0.5 to 1.0 ng/mL.

at the onset of therapy with the aim of achieving the target concentration rapidly. The loading dose is calculated as

$$\text{Loading dose} = \text{Target } C_p \cdot V_{ss}/F \qquad \text{(Equation 2–22)}$$

Consider the case for treatment of arrhythmias with *lidocaine*, for example. The $t_{1/2}$ of *lidocaine* is usually 1 to 2 h. Arrhythmias encountered after myocardial infarction may be life threatening, and one cannot wait four half-lives (4–8 h) to achieve a therapeutic concentration of *lidocaine* by infusion of the drug at the rate required to attain this concentration. Hence, use of a loading dose of *lidocaine* in the coronary care unit is standard.

The use of a loading dose also has significant disadvantages. First, the particularly sensitive individual may be exposed abruptly to a toxic concentration of a drug that may take a long time to decrease (i.e., long $t_{1/2}$). Loading doses tend to be large, and they are often given parenterally and rapidly. This can be particularly dangerous if toxic effects occur because of drug actions at sites in rapid equilibrium with plasma. This occurs because the loading dose calculated on the basis of V_{ss} subsequent to drug distribution is at first constrained within the initial and smaller "central" volume of distribution. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses that are administered over a period of time (Box 2–6). Alternatively, the loading dose should be administered as a continuous intravenous infusion over a period of time using computerized infusion pumps.

BOX 2–6 ■ A Loading Dose of Digoxin

In the 84-kg patient described previously, accumulation of *digoxin* to an effective steady-state level was gradual when a daily maintenance dose of 0.125 mg was administered (for at least 12.4 days, based on $t_{1/2}$ = 3.1 days). A more rapid response could be obtained (if deemed necessary) by using a loading dose strategy and Equation 2–22. Choosing a target C_p of 0.9 ng/mL (the $C_{ss,max}$ calculated in Box 2–5 and below the recommended maximum of 1.0 ng/mL):

$$\text{Loading dose} = 0.9\ \text{ng} \cdot \text{mL}^{-1} \times 497\ \text{L}/0.7 = 639\ \mu\text{g}$$

Using standard dosage sizes, one would use a loading dose of 0.625 mg given in divided doses. To avoid toxicity, this oral loading dose would be given as an initial 0.25-mg dose followed by a 0.25-mg dose 6 to 8 h later, with careful monitoring of the patient, and the final 0.125-mg dose given another 6 to 8 h later. Equivalent loading strategy can be accomplished by administering *digoxin* by intravenous injection.

Therapeutic Drug Monitoring

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of CL/F for the patient being treated, using Equation 2–16 as rearranged:

$$CL/F_{patient} = \text{Dosing rate}/C_{ss}\ \text{(measured)} \qquad \text{(Equation 2–23)}$$

The new estimate of CL/F for an individual patient can be used in Equation 2–18 to adjust the maintenance dose to achieve the desired target concentration (Box 2–7).

Practical details associated with therapeutic drug monitoring should be kept in mind. The first of these relates to the time of sampling for measurement of the drug concentration.

The purpose of sampling during supposed steady state is to modify the estimate of CL/F and thus the choice of dosage. Early postabsorptive concentrations do not reflect clearance. They are determined primarily by the rate of absorption, the "central" (rather than the steady-state) volume of distribution, and the rate of distribution, all of which are pharmaco-kinetic features of virtually no relevance in choosing the long-term maintenance dosage. When the goal of measurement is adjustment of dosage, the sample should be taken just before the next planned dose, when the concentration is at its minimum.

If it is unclear whether efficacious concentrations of drug are being achieved, a sample taken shortly after a dose may be helpful. On the other hand, if a concern is whether low clearance (as in renal failure) may cause accumulation of drug, concentrations measured just before the next dose will reveal such accumulation and are considerably more useful than the maximal concentration.

BOX 2–7 ■ Adjusting the Dose at Steady State

If a drug follows first-order kinetics, the average, minimum, and maximum concentrations at steady state are linearly related to dose and dosing rate (see Equations 2–16, 2–19, and 2–20). Therefore, the ratio between the measured and desired concentrations can be used to adjust the dose, consistent with available dosage sizes:

$$\frac{C_{ss}\ \text{(measured)}}{C_{ss}\ \text{(predicted)}} = \frac{\text{Dose (previous)}}{\text{Dose (new)}} \qquad \text{(Equation 2–24)}$$

Consider the previously described patient given 0.125 mg *digoxin* every 24 h, for example. If the measured minimum (trough) steady-state concentration were found to be 0.35 ng/mL rather than the predicted level of 0.7 ng/mL, an appropriate, practical change in the dosage regimen would be to increase the daily dose by 0.125 mg to 0.25 mg *digoxin* daily.

Determination of both maximal and minimal concentrations is recommended. These two values can offer a more complete picture of the behavior of the drug in a specific patient (particularly if obtained over more than one dosing period) and can better support pharmacokinetic modeling to adjust treatment.

Recall that when constant dosage is given, steady state is reached after four to five elimination half-times. If a sample is obtained too soon after dosage is begun, it will not reflect steady state and clearance accurately. In such cases, the first sample should be taken after two $t_{1/2}$ (75% of expected C_{ss}) assuming that no loading dose has been given. If the concentration already exceeds 90% of the eventual expected mean steady-state concentration, the dosage rate should be halved, another sample obtained in another two (supposed) $t_{1/2}$, and the dosage halved again if this sample exceeds the target. If the first concentration is not too high, the initial rate of dosage is continued. Even if the concentration is lower than expected, it is usually reasonable to await the attainment of steady state after two additional half-lives and then adjust the dose as described in Box 2–7.

Chapter 3

Pharmacodynamics: Molecular Mechanisms of Drug Action

David R. Manning and Donald K. Blumenthal

Pharmacodynamic Concepts

Pharmacodynamics is the study of the biochemical, cellular, and physiological actions of drugs, including the molecular mechanisms by which these actions are achieved. Most drugs are small molecules that interact with macromolecular entities, or *drug targets*, intrinsic to the body or to pathogens. Drug targets include receptors for endocrine and paracrine factors, enzymes, voltage-gated ion channels, membrane transporters, and, for pathogens chiefly, structures relevant to cell viability and replication. As such, targets can be located anywhere on or within a cell, including the cell-surface membrane, cytosol, and nucleus, or entirely in the extracellular compartment. In keeping with the nature of these targets, drugs almost always alter the rate or magnitude of intrinsic cellular or physiological processes rather than create biologically novel phenomena.

Of the new drugs approved by the FDA (U.S. Food and Drug Administration), a growing percentage, averaging approximately 25% over the past 5 years (Figure 1–7), are *therapeutic biological products*. These are defined by the FDA (in the Therapeutic Biologics Applications) as:

- Monoclonal antibodies for *in vivo* use
- Cytokines, growth factors, enzymes, immunomodulators, and thrombolytics
- Proteins intended for therapeutic use that are extracted from animals or microorganisms, including recombinant versions of these products and other nonvaccine therapeutic immunotherapies

A distinction is commonly made between these products, which are often proteins, and the much larger number of small-molecule drugs. Targets in the case of monoclonal antibodies and certain recombinant proteins include inflammatory mediators, immunological checkpoint inhibitors, and cell-surface molecules (Chapters 39, 42, 44, and 72). Genetically modified viruses, for example oncolytic viruses, and microbes, too, are considered biological products and are actively investigated as recombinant vectors for candidate vaccines (Chapter 40).

Another important dimension to pharmacodynamics is gene therapy. Gene therapy uses viruses as vectors to replace defective genes that cause debilitating or lethal diseases, or it can introduce other genes altogether. Recently approved examples of gene therapy include the treatments of a congenital form of retinoblastoma and of spinal muscular atrophy with proteins (RPE65 [retinal epithelium-specific 65-kDa protein] and SMN1 [survival motor neuron 1], respectively) introduced by means of adeno-associated virus (AAV) vectors. The insertion of an anti-CD19 chimeric antigen receptor into T cells for the treatment of B-cell acute lymphoblastic leukemia makes use of a lentiviral vector (Chapter 72). Gene therapy also has the capacity for gene silencing, for example, in the treatment of hereditary transthyretin-mediated amyloidosis with *patisiran* and *inotersen*, two transthyretin-directed short interfering RNAs (siRNAs). Exon skipping represents another facet of gene therapy, as exemplified in the treatment of certain forms of Duchenne muscular dystrophy with the antisense oligonucleotide *eteplirsen*. The CRISPR-Cas9 (clustered regularly interspersed short palindromic repeats/CRISPR-associated protein 9) genome-editing system holds considerable potential in providing highly targeted forms of editing. Drugs can also act by influencing epigenetic regulation. For example, *tazemetostat*, used in the treatment of epithelioid carcinoma, is a recently approved inhibitor of histone methyltransferase EZH2. Clearly, the boundaries among pharmacology, immunology, and genetics overlap.

Quarterly updated eChapters in Section X of the online version of this textbook can provide the reader with reviews of new and noteworthy FDA approvals, including first-in-class drugs and breakthrough therapies (see *AccessMedicine.com or AccessPharmacy.com*; select *Goodman & Gilman*).

Drug Targets

The actions of the vast majority of drugs can be ascribed to their interactions with a relatively small number of protein classes. These classes in humans are receptors for endocrine and paracrine factors; enzymes; voltage-gated ion channels and other ion channels apart from receptors; and membrane transporters (Figure 3–1). Of these, receptors and enzymes are the targets for the majority of drugs in current therapeutic use and are a focus of this chapter. Voltage-gated ion channels are addressed here, as well as in Chapters 16 and 25. Membrane transporters are the subject of Chapter 4.

Abbreviations

AC: adenylyl cyclase
ACE: angiotensin-converting enzyme
ACh: acetylcholine
AKAP: A-kinase anchoring protein
AMPA: α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
AMPK: AMP-activated protein kinase
AngII: angiotensin II
ANP: atrial natriuretic peptide
AP-1: activator protein-1 (transcription factor)
Apaf-1: apoptotic activating protease factor 1
***ATG*:** autophagy gene
AT_1R: angiotensin subtype 1 receptor
BNP: brain natriuretic peptide
CaM: calmodulin
CAR: constitutive androstane receptor
CNP: C-type natriuretic peptide
CYP: cytochrome P450
DAG: diacylglycerol
DHFR: dihydrofolate reductase
EC_{50}: half-maximally effective concentration
ED_{50}: half-maximally effective dose
EGF: epidermal growth factor
eNOS: endothelial NOS (NOS3)
EPAC: exchange protein activated by cyclic AMP
ER: endoplasmic reticulum
FBP: fructose 1,6-bisphosphate
FXR: farnesoid X receptor
GABA: γ-aminobutyric acid
GC: guanylyl cyclase
GEF: guanine nucleotide exchange factor
GnRH: gonadotropin-releasing hormone
GPCR: G protein-coupled receptor
GRK: GPCR kinase
HMG-CoA: hydroxymethylglutaryl–coenzyme A
HRE: hormone response element
5HT: 5-hydroxytryptamine (serotonin)
IFN: interferon
IL: interleukin
iNOS: inducible NOS (NOS2)
IP_3: inositol 1,4,5-trisphosphate
JAK: Janus kinase
JNK: c-Jun N-terminal kinase
K_i: affinity of a competitive antagonist
K_{ir}: inward rectifying K^+ channel
LD_{50}: half-maximal lethal dose
LKB1: liver kinase B1
LXR: liver X receptor
MAPK: mitogen-activated protein kinase
MLCK: myosin light chain kinase
mTOR: mechanistic or mammalian target of rapamycin, a protein kinase
mTORC: mechanistic or mammalian target of rapamycin complex
NAM: negative allosteric modulator
NE: norepinephrine
NF-κB: nuclear factor-κB
NMDA: *N*-methyl-D-aspartate
nNOS: neuronal NOS
NO: nitric oxide
NOS: NO synthase
NPR: natriuretic peptide receptor
NSAID: nonsteroidal anti-inflammatory drug
PAMP: pathogen-associated molecular pattern
PDE: cyclic nucleotide phosphodiesterase
PAM: positive allosteric modulator
PDGF: platelet-derived growth factor
PI3K: phosphatidylinositol 3-kinase
PIP_2: phosphatidylinositol 4,5-bisphosphate
PK: protein kinase, e.g., PKA, PKB (also known as Akt), PKC
PLC: phospholipase C
PPAR: peroxisome proliferator-activated receptor
PTB: phosphotyrosine-binding
PXR: pregnane X receptor
RAR: retinoic acid receptor
RGS: regulator of G protein signaling
RhoGEF: RhoA guanine nucleotide exchange factor
RIP1: receptor interacting protein 1
ROCK: Rho-associated protein kinase
RXR: retinoid X receptor
SERM: selective estrogen receptor modulator
sGC: soluble guanylyl cyclase
SH2: Src homology 2
SMAC: second mitochondria-derived activator of caspase
SMN1: survival motor neuron protein
STAT: signal transducer and activator of transcription
TGF-β: transforming growth factor β
TLR: toll-like receptor
TNF-α: tumor necrosis factor α
TNFR: TNF-α receptor
TOR: target of rapamycin
TRAIL: TNF-related apoptosis-inducing ligand
TRP: transient receptor potential
VEGF: vascular endothelial growth factor
VSMC: vascular smooth muscle cell

More than a few drugs operate through multiple mechanisms, and in this respect the picture regarding their actions continues to evolve. *Amphetamines*, for example, have long been known to be competitive inhibitors of the dopamine transporter but are now recognized to operate additionally through displacement of *dopamine* from vesicular stores and engagement of the trace amine-associated receptor TAAR1 (Chapters 15 and 16). *Metformin* exerts its hypoglycemic actions in large part through the AMP-dependent protein kinase (AMPK) and via inhibition of mitochondrial glycerol phosphate dehydrogenase, but almost certainly through additional mechanisms (Chapter 51). The hypolipidemic actions of *niacin* are achieved through one or more G protein-coupled receptors (GPCRs) at the level of adipocytes, but also through inhibition, in hepatocytes, of diacylglycerol acyltransferase, again among other actions (Chapter 37). The mechanism by which estrogen acts in certain situations extends beyond nuclear receptors to GPCRs at the cell surface (Chapter 48). One should note that the multiple mechanisms by which a drug may act are also quite important elements of unintended adverse drug responses.

The actions of some drugs do not require targets *per se*. *Aluminum* and *magnesium hydroxides* reduce gastric acid chemically, neutralizing H^+ and raising gastric pH. *Methenamine* achieves a formaldehyde-dependent antibacterial action at urinary pH (Chapter 57). *Mannitol* acts osmotically to cause changes in the distribution of water to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema. Chelators are used in situations of acute metal intoxication (Chapters 9 and 76). However, some distinctions of biological targets are a matter of perspective. Bile acid sequestrants lower plasma cholesterol by inhibiting the recycling of bile acids within the

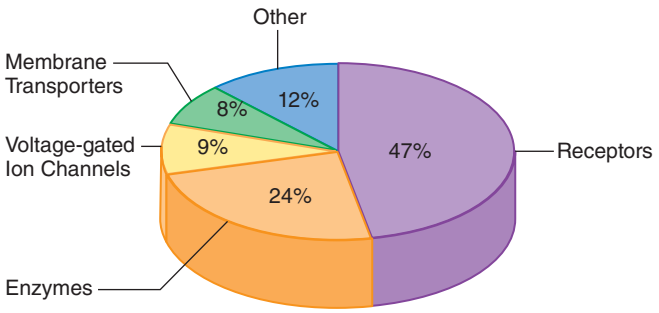

Figure 3–1 *Drug targets in humans.* Depicted are categories of drug targets expressed in humans as a percentage of total number of targets. The principal categories are receptors for endocrine and paracrine factors, enzymes, voltage-gated ion channels (plus a few other ion channels apart from those classified as receptors), and membrane transporters. "Other" includes DNA, RNA, and ribosomes, signaling molecules themselves, enzyme-interacting proteins, and structural proteins. The source for these data is Rask-Andersen et al. (2011), with adjustment according to distinctions in this chapter between ion channels and membrane transporters. The reader may wish to consult as well Imming et al. (2006) and Santos et al. (2017). The figure does not take into account microbial targets. Drugs from the top 100 prescribed in the U.S. for 2018 (source: CliniCalc) for ***receptors*** include: *for GPCRs*, AT_1 receptor antagonists, *albuterol*, *carvedilol*, *tramadol* and other opioids, *tamsulosin* and other α adrenergic receptor antagonists, *atenolol*, *clopidogrel*, *propranolol*, *cyclobenzaprine*, *ranitidine*, *loratadine* and other histamine H_1 receptor blockers, *clonidine* and other α_2 receptor agonists, *buspirone*, *latanoprost*, and *sumatriptan*; for *ligand-gated ion channels*, *alprazolam* and other benzodiazepines and positive $GABA_A$ receptor modulators and *ondansetron*; for *receptor tyrosine kinases*, various forms of *insulin*; for *nuclear hormone receptors*, *levothyroxine*, *fluticasone* and other glucocorticoid agonists, *estradiol* and other estrogen receptor agonists, *norethindrone* and other progesterone receptor agonists, *ergocalciferol*, *spironolactone*, and *fenofibrate*. Those drugs for ***enzymes*** include *lisinopril* and other ACE inhibitors, *atorvastatin* and other HMG-CoA reductase inhibitors, *metformin*, *ibuprofen* and other NSAIDs, *warfarin*, *allopurinol*, *finasteride*, *apixaban*, and *sitagliptin*. Those drugs for ***voltage-gated ion channels*** and other ion channels include *amlodipine*, *gabapentin* and other anticonvulsants that inhibit neuronal voltage-gated calcium channels, *glipizide* and other activators of the ATP-regulated K^+ channel, *lamotrigine* and other anticonvulsants that inhibit voltage-gated sodium channels, and *diltiazem*. Those drugs for ***membrane transporters*** include *omeprazole* and other proton pump inhibitors, *hydrochlorothiazide*, *sertraline* and other monoamine reuptake inhibitors, *digoxin*, and *furosemide*.

lumen of the intestine; bile acids are not "targets" as defined in this chapter, but a key to the mechanism by which bile acid sequestrants work is in fact consequent de-repression of 7α-hydroxylase, which may well be considered a target.

A large number of drugs bind to serum albumin, a protein important to oncotic pressure and the transport of free fatty acids within the bloodstream. The drugs that bind to albumin are generally organic acids. Yet, albumin cannot be considered a drug target in any pharmacodynamic sense, as it does not translate the binding of the drug into a therapeutic action. Nor for the same reason can α_1-acid glycoprotein, a serum protein that binds organic bases, be considered a target. Interactions of drugs with these proteins are more appropriately considered in the context of pharmacokinetics, as the binding impedes the distribution of drugs into tissues (Chapter 2). Likewise, the redistribution of lipophilic drugs such as thiopental into adipose tissue (see Figure 2–4), so important to how the body handles general anesthetics, is the province of pharmacokinetics, since the partitioning of the drug is without a pharmacodynamic effect on a target.

Receptors

Pharmacologists often define a *receptor* as a protein that recognizes a signaling molecule endogenous to the organism, i.e., an endocrine, paracrine, autocrine, or juxtacrine factor (Box 3–1), and that translates that recognition into a meaningful cellular event. Receptors include GPCRs, ligand-gated ion channels, enzyme-linked (i.e., catalytic) receptors, other membrane-associated receptors, and nuclear receptors. Many receptors recognize signals at the cell surface; others, for example the nuclear receptors, recognize those that pass through the cell membrane. The term *ligand* is used for any molecule that binds to a receptor, whether endogenous or not.

Agonism refers to the capacity of a ligand to activate a receptor. If a ligand binds to the same site as the endogenous signaling molecule to achieve activation, it—like the endogenous molecule—is said to be an *orthosteric agonist*. If, instead, the ligand binds to a different site to achieve activation, it is identified as an *allosteric agonist*. Ligands that produce a maximal response for a given population of receptor are *full agonists*, whereas those that produce a response but fall short of producing a maximal response despite fully occupying that population are *partial agonists*. The use of "response" in place of "receptor activation" in defining full and partial agonism here is pragmatic. What constitutes an activated conformation or set of conformations of a receptor is difficult to assess; downstream responses are more easily measured. An important qualification exists in both cases: Any ranking of ligands according to agonism for a given receptor may change depending on the tissue and specific response being measured, i.e., ranking according to agonism, which is later described in terms of *efficacy*, can be a function of context. Context is discussed more fully in the section Biased Agonism.

Antagonism at the receptor level relates to the property of a ligand, almost always an exogenous ligand (i.e., a drug) or toxin, to block the action of an agonist. Numerous *antagonists* are orthosteric and competitive in nature, that is, they bind essentially to the same receptor site as that used by the endogenous agonist and they do so reversibly. A few antagonists bind irreversibly. *Clopidogrel* and *prasugrel*, which inhibit platelet activation as antagonists of the $P2Y_{12}$ subtype of ADP receptor (Chapter 36), are examples of irreversible inhibitors. Many orthosteric antagonists are relatively *neutral* in the sense of having little if any impact *per se* on basal receptor activity, their effect becoming noticeable only in the presence of an agonist. Other antagonists are *inverse agonists*, as discussed below.

Forms of antagonism exist that operate apart from the receptor altogether. *Chemical antagonism* involves neutralization of an agonist through physical complexation. *Adalimumab* and *infliximab*, used in the treatment of several autoimmune disorders (Chapters 39 and 55), bind tightly to tumor necrosis factor α (TNF-α) and antagonize its actions. *Bevacizumab*, used in the treatment of certain cancers and ocular disorders, antagonizes the action of vascular endothelial growth factor (VEGF) by similar complexation (Chapter 72).

BOX 3–1 ■ Types of Intercellular Signaling Molecules

Endocrine factor: A chemical messenger that is released into the circulation to produce effects distant from the point of release. Also referred to as a hormone. Originally, hormones were considered a product of a ductless gland; however, many organs are now considered "endocrine."

Paracrine factor: A chemical messenger that is released from one cell to produce effects on a neighboring cell. Neurotransmitters, cytokines, morphogens, and many growth factors exert paracrine effects.

Autocrine factor: A chemical messenger that exerts actions on the same cell from which it is released. Many endocrine and paracrine factors also play roles in autocrine signaling, exerting negative or positive feedback on their own release, roles that are especially important in neuronal and cytokine signaling.

Juxtacrine factor: A chemical messenger that remains affixed to the cell in which it is produced and exerts actions on a physically juxtaposed cell. The mechanism by which a T cell and an antigen-presenting cell establish an immunological "synapse" is an example of juxtacrine signaling.

Functional antagonism refers to the inhibition of an agonist's action downstream of the receptor. The use of *epinephrine* in countering anaphylaxis represents functional antagonism. Epinephrine increases cyclic AMP levels within bronchiolar smooth muscle cells, which in turn inhibits myosin light chain kinase and thereby diminishes the contractile response engendered by histamine, thromboxane A_2, and other substances released by mast cells (Chapter 43).

Pharmacokinetic antagonism relates to the impediment of the absorption or distribution, or the enhancement of elimination, of a therapeutic drug, as discussed in Chapter 2.

Many receptors exhibit at least a modicum of constitutive activity, that is, activity in the absence of a ligand, which is the product of normal thermodynamic equilibria between active and inactive conformations. *Inverse agonism* refers to the suppression of this activity by ligands, and such ligands are termed *inverse agonists*, acting through stabilization of receptors in an inactive conformation. Depending on the level of constitutive activity and degree of suppression, it can be difficult to distinguish inverse agonists from neutral antagonists. At an orthosteric level, both can be viewed as antagonists of partial or full agonist action.

The actions of full agonists, partial agonists, neutral antagonists, and inverse agonists are easily accommodated by a *two-state model* of receptor activity wherein an equilibrium between inactive and active states for a population of any given receptor is pulled one way or another (or not, in the case of neutral antagonists) by ligands (Figure 3–2). More sophisticated models exist to account for what appears to be a large number of functional states for GPCRs, either intrinsic or dependent on proteins with which the receptors interact (Weiss and Kobilka, 2018).

As implied above for inverse agonists, what defines a ligand as an antagonist at an operational level can sometimes be a matter of semantics. Focusing on orthosteric ligands for the moment, inverse agonists can antagonize the actions of partial and full agonists. A partial agonist will antagonize the actions of a full agonist, or of an inverse agonist for that matter, similarly by occluding the binding site. The duality of agonism and antagonism for partial agonists is therapeutically relevant. *Varenicline*, used in the treatment of nicotine addiction, is a partial agonist at the α4β2 nicotinic receptor; it is posited to at least partly block the actions of nicotine derived from nicotine-containing products but to have sufficient activity as a partial nicotinic agonist to blunt the craving for nicotine (Chapter 13). *Buprenorphine* likely operates by a similar principle in the treatment of opioid abuse and withdrawal (Chapter 23). *Aripiprazole* is a partial agonist used in the treatment of psychosis to inhibit activation of the D_2 receptor by endogenous dopamine but also provides an important, low-level degree of activation (Chapter 19). Certain β_1 receptor–selective antagonists (e.g., *pindolol* and *acebutolol*) are in fact partial agonists whose "intrinsic sympathomimetic activity" may prevent profound bradycardia or negative inotropy (Chapter 14).

Receptor ligands also include allosteric modulators, both positive and negative. These are discussed in the section Allosteric Modulation of Receptor Function.

Enzymes

Enzymes are important targets for drugs for essentially two reasons. First, enzymes have especially varied and selective roles in essential life processes. Second, the mechanisms of catalysis and allosteric regulation are well defined and therefore amenable to pharmacological manipulation. Enzymes that are drug targets are almost always those that are rate-limiting or otherwise necessary in the metabolic process of interest, for example, hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase in the synthesis of cholesterol, which is inhibited by *statins* (Chapter 37); angiotensin-converting enzyme (ACE) in the synthesis of angiotensin II,

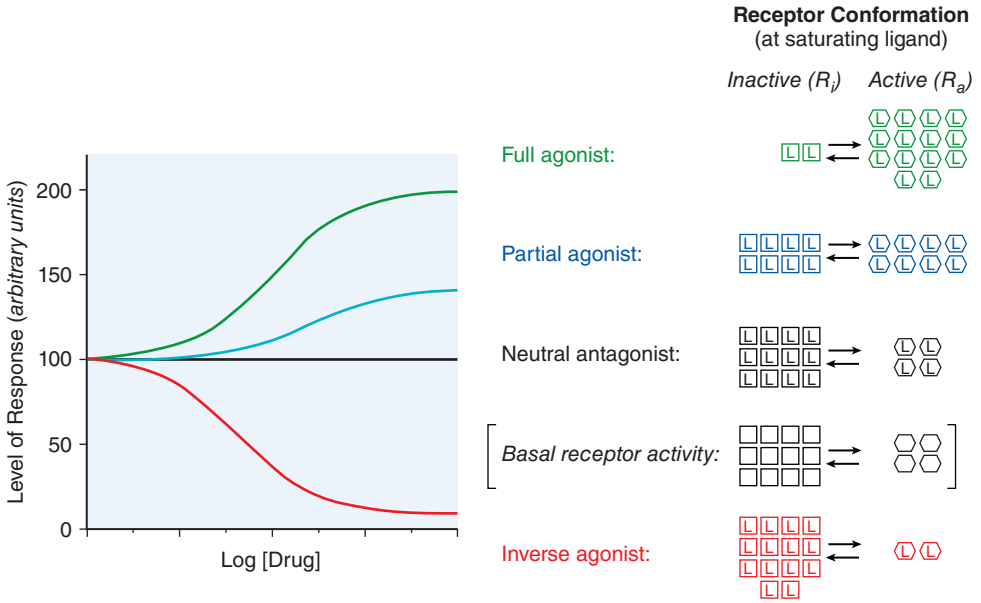

Figure 3–2 *Two-state model of receptor activity.* In this model, receptor *R* can exist in active (R_a, depicted as a hexagon) and inactive (R_i, depicted as a square) conformations in thermodynamic equilibrium. The equilibrium in the absence of drug or endogenous ligands (a "response" set arbitrarily to "100" units in the graph to the left and noted in brackets in the depiction of receptor states to the right) underlies what is commonly referred to as "basal" or "constitutive" activity, terms connoting a certain—usually small—level of active receptor. Drugs binding individual receptor states or both states simultaneously can influence the balance of the two forms of *R* and the net effect of receptor-controlled events. The ordinate of the graph on the left is the response of the receptor produced by R_a, the active receptor conformation (e.g., stimulation of AC by an active β adrenergic receptor conformation). If a drug *L* (*L*, for ligand) binds to R_a with a certain degree of selectivity relative to R_i, it will produce a positive response; the greater the selectivity for R_a, the greater the response. The difference in selectivity differentiates *full* from *partial* agonists; no "full" agonist, however, is likely able to pull the equilibrium entirely to the right. If *L* has an equal affinity for R_i and R_a, it will not perturb the basal equilibrium between them and will therefore have no effect on basal activity; this is the case for a *neutral antagonist*. If the drug selectively binds to R_i, then the net influence and amount of R_a will be diminished. If there is sufficient R_a to produce an observable basal response, and *L* binds selectively to R_i, then that basal response will be inhibited; *L* will then be an *inverse agonist*. In systems in which basal activity is not observable, inverse agonists seem to behave like neutral antagonists, which helps explain that the properties of inverse agonists and the number of such agents previously described as competitive antagonists were only recently appreciated. The panel on the right represents equilibria at saturating concentrations of *L*; whether the ligands bind through induced fit or conformational selection is not depicted.

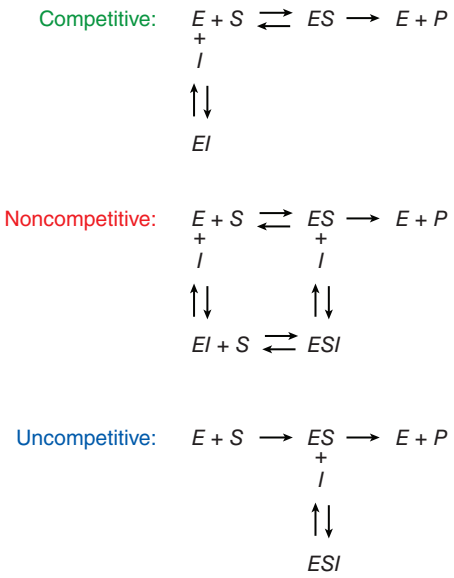

Figure 3–3 *Reversible enzyme inhibition.* The three different forms of reversible inhibition for enzymes are depicted. *E*, enzyme; *S*, substrate; *I*, inhibitor; *P*, product. The reader is directed to an excellent monograph covering enzyme inhibition, both reversible and irreversible, in a pharmacological context by Copeland (2013).

which is inhibited by *ACE inhibitors* (Chapter 30); cyclooxygenase in the synthesis of prostaglandins, which is inhibited by *aspirin* (acetylsalicylate) and other nonsteroidal anti-inflammatory drugs (NSAIDs; Chapter 42); and dihydrofolate reductase in the production of the nucleotide thymidylate, which is inhibited by *methotrexate* (Chapter 70).

Most drugs that utilize enzymes as targets can be divided broadly into *reversible* and *irreversible inhibitors* of the catalytic process. Reversible inhibitors bind to the enzyme in a fashion that can be described reasonably by on- and off-rate constants serving to establish a dynamic chemical equilibrium (Figure 3–3). Most of these inhibitors are *competitive*, wherein the binding of the inhibitor and substrate to the enzyme is mutually exclusive. Others are *noncompetitive* or *uncompetitive*. Noncompetitive inhibition refers to a mechanism in which the inhibitor binds to the enzyme regardless of bound substrate, whereas uncompetitive inhibition is that in which the binding of inhibitor requires the conjoint binding of substrate. In both noncompetitive and uncompetitive inhibition, the enzyme to which substrate and inhibitor are bound is less able to effect catalysis than with substrate alone.

Irreversible enzyme inhibitors form stable covalent linkages with the enzyme, thereby disrupting catalytic activity generally for the enzyme's lifetime. *Aspirin*, which acetylates cyclooxygenases near the catalytic site, is an irreversible inhibitor of arachidonic acid conversion to prostaglandins G_2 and H_2, the first intermediates in the synthesis of a variety of prostanoids (Chapter 41). Irreversible inhibitors also include those that are mechanism-based, commonly referred to as *suicide substrates*. These inhibitors are recognized by the enzyme as a substrate, but during the process of catalysis, generally at the transition state, they are converted to intermediates capable of attacking the enzyme. *Organophosphates*, which irreversibly inhibit acetylcholinesterase through phosphorylation, provide an example of such a mechanism-based irreversible inhibition (Chapter 12). *Omeprazole*, an inhibitor of the gastric H^+/K^+ ATPase, is another example (Chapter 53). *Heparin*, an anticoagulant, potentiates the ability of an endogenous suicide substrate, antithrombin, to irreversibly inhibit thrombin and factor Xa (Chapter 36).

Not all drugs that target enzymes are inhibitors. *Organic nitrates*, for example, activate soluble guanylyl cyclase. In this case, nitric oxide (NO), a product of enzymatic transformation of the organic nitrates, combines with the heme of the enzyme to achieve activation. The subsequent increase in intracellular cyclic GMP is the basis for NO-induced vasodilation (Chapter 31).

Ion Channels

Changes in the flux of ions across the plasma membrane achieved through ion channels are critical regulatory events in both excitable and nonexcitable cells. These changes are superimposed on electrochemical gradients, prominently those underlying cell-surface membrane electrical potential, which are established by ion transporters for Na^+, K^+, Ca^{2+}, and Cl^-. For instance, the Na^+/K^+-ATPase expends cellular ATP to pump Na^+ out of the cell and K^+ into the cell. The electrochemical gradients thus established are used by excitable tissues such as nerve and muscle through ion channels to generate and transmit electrical impulses, by nonexcitable cells to trigger biochemical and secretory events, and by all cells to support a variety of secondary symport and antiport processes (see Figures 2–2 and 4–4).

Humans express about 230 ion channels (Jegla et al., 2009). These are divided into families based principally on the ions they conduct, molecular architecture, and method of gating. They are subdivided according to properties of conduction, including the kinetics of activation and deactivation. Those relevant to pharmacology are primarily voltage-, G protein-, and ligand-gated ion channels. Voltage-gated ion channels are discussed here; G protein- and ligand-gated ion channels are discussed in the section Receptor-Mediated Mechanisms of Drug Action.

Voltage-gated ion channels are sensitive to changes in the electrochemical potential across a membrane, undergoing activation upon membrane depolarization. Any introduction to pharmacodynamics must pay attention to them: They are exceedingly important drug targets; a considerable number of them are downstream of receptors engaged by endocrine and paracrine factors, for example neurotransmitters; and they provide a context for understanding all other types of channels. Moreover, mutations in voltage-gated ion channels can lead to diseases (referred to as *channelopathies*) including various seizure disorders (Chapter 20), other neurological diseases, and cardiac arrhythmias (Chapter 34).

Voltage-Gated Na^+ Channels. Voltage-gated Na^+ channels are responsible for the propagation in nerve and muscle cells of robust action potentials that depolarize the membrane from its resting potential of about –70 mV, depending on the cell, to a potential of +20 mV within a few milliseconds. The activation of these channels that sets into motion the action potential generally occurs in response to a localized depolarization achieved by ligand-gated cation channels in neurons and skeletal muscle and by activated L-type Ca^{2+} channels in the sinoatrial node of the heart; the propagation of the action potential is achieved through sequential activation of, and by, the Na^+ channels themselves.

Voltage-gated Na^+ channels comprise three subunits, a pore-forming α subunit and two regulatory β subunits (Catterall et al., 2020). The α subunit is a single 260-kDa protein containing four domains, each consisting of six membrane-spanning helices (S1–S6), that arrange into a pseudotetrameric shape to form a Na^+ ion-selective pore (Figures 3–4A and 25–2). The β subunits are 36-kDa proteins that span the membrane once. An extracellular loop between S5 and S6 of the α subunit, termed the pore-forming or P loop, dips back into the pore and, combined with residues from the corresponding P loops from the other domains, provides a selectivity filter for the Na^+ ion. Four other helices surrounding the pore (one S4 helix from each of the domains) each contain a set of charged amino acids that form the voltage sensor and cause the pore to open at more positive membrane voltages, those that initiate activation.

The voltage-gated Na^+ channels in neurons that sense pain (*nociception*) are targets for local anesthetics, such as *lidocaine* and *tetracaine*, which block the pore to inhibit depolarization and thus block the transmission relevant to the sensation of pain (see Figure 25–3). They are also targets for certain *antiepileptics* (Chapter 20) and *antiarrhythmics* (Chapter 34). Catterall et al. (2020) provide an extensive discussion of the state-dependent blockade by these drugs (i.e., the dependence of these drugs on resting membrane potential and frequency of the action potential). The channels are also the targets of the naturally occurring marine toxins, including *tetrodotoxin*, *saxitoxin*, and a number of *conotoxins*.

Voltage-Gated Ca^{2+} Channels. Voltage-gated Ca^{2+} channels are architecturally quite similar to Na^+ channels, with a large α subunit (four

domains of six membrane-spanning helices) and auxiliary regulatory subunits (e.g., β and $\alpha_2\delta$ subunits; Figures 3–4C and 16–2) (Catterall et al., 2020). Ca^{2+} channels can be major components of an action potential, as in pacemaker cells of the heart, but are more commonly responsible for translating, via Ca^{2+} influx, action potentials into intracellular responses. There are three general types of Ca^{2+} channels. L-type Ca^{2+} channels are expressed in cardiac, smooth muscle, and skeletal muscle cells and in cells of endocrine tissues, where they are involved in excitation-contraction coupling and secretion. Currents conducted by L-type Ca^{2+} channels may require strong depolarization, and they are long-lasting (hence, "L" as the type identifier). These channels are blocked by *dihydropyridines*, such as *nifedipine*, and by *diltiazem* and *verapamil*, drugs widely used to treat hypertension, angina, and certain cardiac arrhythmias (see Chapters 31, 32, and 34). P/Q-, N-, and R-type Ca^{2+} channels are expressed mostly in neurons and are involved in neurotransmitter release. They also require strong depolarization for activation. The T-type channels are expressed in neurons and in cardiac and smooth muscle cells. The currents generated by ion flux through these channels are activated by weak depolarizations and are transient. These channels facilitate cardiac pacemaker depolarization. They are also found in thalamic neurons, where the current amplifies oscillations in membrane potential, one oscillation being that observed in absence seizure (Chapter 20); *ethosuximide* and *valproate* are antiepileptics used to inhibit the T-type channel. L-type Ca^{2+} channels are subject to modulation via phosphorylation by protein kinase A (PKA), while the P/Q, N-, and R-type channels are more proximately modulated by GPCRs, as discussed later (Receptor-Mediated Mechanisms of Drug Action).

Voltage-Gated K⁺ Channels. Voltage-gated K^+ channels are the most numerous of the voltage-gated ion channel family (Gutmann et al., 2005; Wulff et al., 2009). These channels are tetramers of four similar or identical six-transmembrane $K_V\alpha$ subunits that together form a conductance pore with voltage-sensing capability (Figure 3–4B). There are 40 human $K_V\alpha$ genes that sort into 12 subfamilies. The channels regulate the waveform and pattern of action potentials (Attali et al., 2019). Several antiarrhythmic drugs, for example *amiodarone* and *sotalol*, modulate these channels directly or indirectly and typically together with other voltage-gated ion channels (Chapter 34). A common mechanism by which drugs prolong action potentials in heart and provoke arrhythmias is inhibition of a specific delayed rectifier current generated by hERG, a channel more often referred to as $K_V11.1$ (the product of *KCNH2*; Chapter 34).

Specificity of Drug Responses

The degree to which a drug achieves an intended action relative to other actions is referred to as *specificity* or *selectivity* of action. The affinity of a drug for its molecular target is of obvious importance in this regard, as a high-affinity interaction minimizes the chance of off-target effects at therapeutic concentrations. Specificity depends on other factors as well. One is the extent to which the site at which a drug interacts is unique to that target. The conservation of orthosteric sites among subtypes of muscarinic receptors, for example, makes the pharmacological manipulation of any single subtype difficult (Chapter 11). Moreover, certain seemingly disparate receptors or enzymes have orthosteric binding sites of common ontological origin. This is the case for muscarinic receptors and the H_1-histamine receptor, as manifest in the atropine-like effects of classical antihistamines (Chapter 43). That said, an example of an orthosteric site where there has been some success in achieving relatively high target specificity is the ATP-binding site of protein kinases, for which there are approximately 800 different genes in the human genome, many of which are involved in the pathogenesis of cancer (Chapter 71). *Imatinib* targets the ATP-binding site of the Bcr-Abl protein kinase and is used to treat chronic myeloid leukemia; *imatinib* was the first protein kinase inhibitor targeting a specific protein kinase to be FDA-approved (Cohen et al., 2021).

Specificity of action can also depend on the extent to which the target is distributed among tissues. A target expressed in one or only a few tissues will almost certainly support a higher degree of therapeutic specificity than one expressed throughout the body, as drug-elicited effects in the latter case would occur in tissues likely irrelevant to the pathological event. The manner in which the drug itself distributes among tissues, an important concept in pharmacokinetics, will also have an impact on specificity of action. Peripherally restricted μ-opioid receptor antagonists such as *methylnaltrexone*, unlike *naloxone* or *naltrexone*, have little impact on the (central) analgesic actions of opioids (Chapter 23).

No drug is entirely specific in terms of action. The departure from a high degree of specificity in certain circumstances can be advantageous. The sedation exerted by classical antihistamines, for example, can be a welcome action secondary to the peripheral blockade of histamine in the treatment of pruritis. However, more often, the unintended actions of a drug are a nuisance, or worse if the unintended actions rise to the level of physical or psychological harm (i.e., to the point of becoming adverse drug events).

On occasion, the promiscuity is not that of a drug, but of the target. The $K_V11.1$ (hERG) channel contains a site that can interact with a variety of structurally dissimilar molecules. The prolongation of the QT interval with consequent *torsades de pointes* (a form of ventricular tachycardia) is a serious off-target effect of many drugs. The FDA now requires all new drugs to be tested for their capacity to bind the $K_V11.1$ channel and prolong the QT interval.

Complicating the picture of specificity is the fact that some drugs are administered as racemic mixtures of stereoisomers, each of which can

Figure 3–4 *Voltage-dependent Na⁺, Ca²⁺, and K⁺ channels.* Voltage-dependent channels provide for rapid changes in ion permeability along axons and within dendrites and for excitation-secretion coupling that causes neurotransmitter release from presynaptic sites. **A.** *Structure of Ca^{2+} and Na^+ channels.* The α subunit in both Ca^{2+} and Na^+ channels consists of four sub-subunits or segments (labeled **I** through **IV**), each with six transmembrane (TM) hydrophobic domains (blue cylinders). The hydrophobic regions that connect TM5 and TM6 in each segment associate to form the pore of the channel. Segment 4 in each domain includes the voltage sensor. (Adapted with permission from Catterall W. *Neuron* **2000**, *26*:13–25. © Elsevier). **B.** *Structural diversity of K^+ channels.* Inward rectifier, K_{ir}: The basic subunit of the inwardly rectifying K^+ channel protein K_{ir} has the general configuration of TM5 and TM6 of a segment of the α subunit shown in panel **A**. Four of these subunits assemble to create the pore. Voltage-sensitive K^+ channel, K_V: The α subunits of the voltage-sensitive K^+ channel K_V and the rapidly activating K^+ channel K_A share a hexaspanning structure resembling in overall configuration a single segment of the Na^+ and Ca^{2+} channel structure, with six TM domains. Four of these assemble to form the pore. Regulatory β subunits (cytosolic) can alter K_V channel functions. **C.** *Multisubunit assembly of Ca^{2+} channels.* Ca^{2+} channels variably require several auxiliary small proteins (α_2, β, γ, and δ); α_2 and δ subunits are linked by a disulfide bond. Likewise, regulatory subunits also exist for Na^+ channels. **D**. *Ionic gradients across a mammalian nerve cell membrane.* The kidney is the primary regulator of the extracellular ionic environment. Active transport of cations and the relatively selective permeabilities of ion channels maintain the intracellular milieu. In this figure, the numbers below the various ions are resting state concentrations in mM; the large bold lettering of the elements indicates the location of the higher concentration of the ion; the red and green arrows indicate the direction of the electrical and concentration gradients. In the resting state, Na^+ channels are closed, K^+ channels are open, and the membrane potential approaches the Nernst potential for K^+. The opening of Na^+ channels results in depolarization. In contrast, the K^+ gradient is such that increased permeability to K^+ results in *hyperpolarization*. Changes in the concentration of intracellular Ca^{2+} (entry via Ca^{2+} channels and mobilization of Ca^{2+} sequestered in the cell) affect multiple cellular processes and are critical for the release of neurotransmitters. Cl^- flows through membrane channels, a large fraction of which are gated by GABA or glycine. Activation of neuronal $GABA_A$ receptors generally leads to a net influx of Cl^-, resulting in membrane hyperpolarization and inhibition of depolarization. The equilibrium potential for Cl^- is relatively close to the membrane resting potential, and small changes in cellular Cl^-, the membrane potential, and the activities of Cl^- transporters (e.g., KCC2 and NKCC1) can influence transmembrane Cl^- movements.

exhibit different pharmacodynamic as well as pharmacokinetic properties. The antiarrhythmic drug *sotalol* is a good example. While the *D*- and *L*-enantiomers of *sotalol* are equipotent as K^+ channel blockers, the *L*-enantiomer is a much more potent β adrenergic antagonist. A variety of drugs initially available as racemic mixtures are now available in single-stereoisomeric forms, often underscoring differences in the properties of resolved forms.

The metabolic conversion of a drug to one or more metabolites that retain activity is also a confounding factor in specificity. Active metabolites typically differ from the parent drug in efficacy, but some differ qualitatively as well in their actions. Aside from prodrugs, these are commonly recognized as toxic metabolites and include, for example, normeperidine, a metabolite of *meperidine* likely responsible for CNS excitation (Chapter 23) and *N*-acetyl-*p*-benzoquinone imine, a metabolite of *acetaminophen* responsible for hepatic and renal necrosis (Chapter 5).

Additivity and Synergism: Isobolograms

Drugs with different mechanisms of action are often used in combination to achieve *additive* and *positive synergistic* effects. Such interactions of two agents may permit use of reduced concentrations of each drug, thereby reducing concentration-dependent adverse effects. Positive synergism refers to the *superadditive* effects of drugs used in combination, in which the effect of the two drugs together is larger than the sum of their individual effects. Drugs used in combination can also demonstrate *negative synergism* or *subadditive* effects, where the efficacy of the drug combination is less than would be expected if the effects were additive. Isobolograms, such as that depicted in Figure 3–5, provide a quantitative depiction of positive and negative synergism. The basis for the use of isobolograms has been developed and reviewed by Tallarida (2012) and explained in the legend to Figure 3–5. Using isobolograms to characterize the possible synergistic pharmacodynamic interactions of several different antiseizure drugs in a mouse model is demonstrated by Metcalf et al. (2018).

Attenuation of Drug Responses

Feedback regulation is a defining feature of biological systems. A cell or an organism may perceive the actions of a drug as a perturbation of homeostasis and attempt to counter the actions of that drug in order to restore the *status quo* through molecular and physiological mechanisms. Mechanisms include those accomplished through the sympathetic nervous system and the renin-angiotensin-aldosterone system (Chapters 29 and 32), among many other cellular and system-wide feedback loops. Reflex tachycardia mediated by the sympathetic nervous system is a common response to vasodilators used to lower blood pressure, such as *dihydropyridines*, *hydralazine*, and *organic nitrates*, sometimes requiring administration of a β blocker to blunt the increase in heart rate (Chapters 31–33).

Tachyphylaxis and *fade* are overlapping terms for a decline in response to a drug with repeated application or time, respectively. The two terms generally have a physiological connotation. While no mechanism needs be implied (Neubig et al., 2003), underlying processes include modulation of target expression and function, responses of superimposed tissue homeostatic mechanisms, and, in the limit for therapies directed toward cancer or pathogens, mechanisms of frank resistance. *Desensitization* also refers to attenuation of response, but typically at the level of the drug target itself. Desensitization is often distinguished from *downregulation*, the loss of a target with prolonged exposure to the ligand, although the two can be intimately related mechanistically.

Desensitization and downregulation are particularly well understood for GPCRs. *Homologous desensitization* refers to a relatively rapid decline

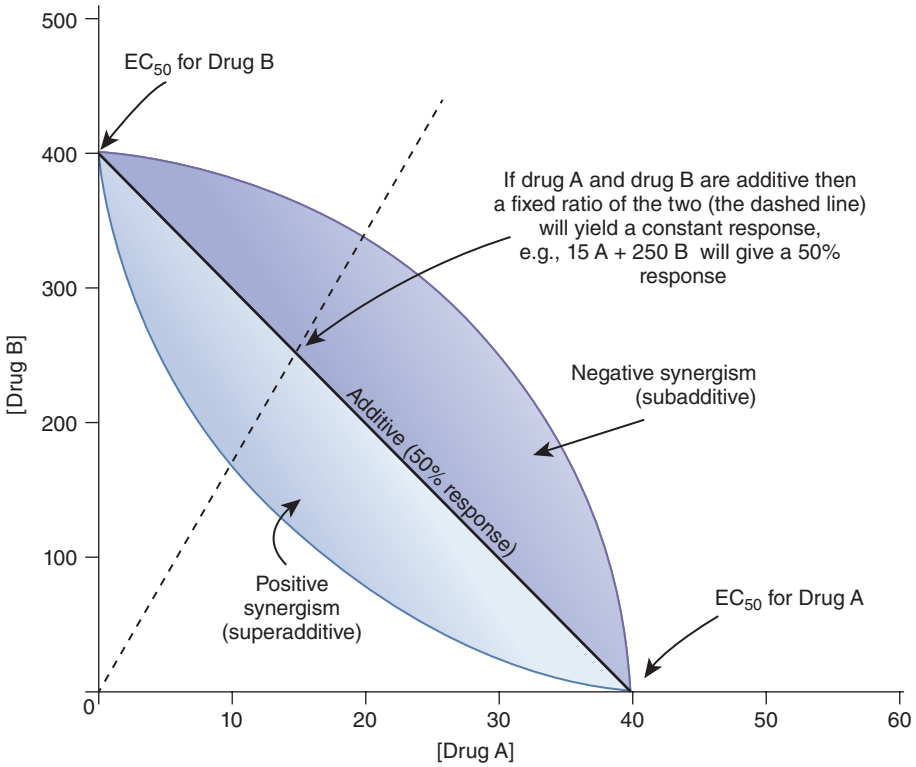

Figure 3–5 *Isobologram showing additivity and synergism of a drug combination.* The isobologram shows the line of additivity for a 50% effect obtained with a combination of two drugs (concentrations of drug A are on the *x* axis, concentrations of drug B are on the *y* axis) that have similar effects but different mechanisms of action. The intercept of the line of additivity (50% effect) with the *x* axis is the EC_{50} for A, while the intercept on the *y* axis is the EC_{50} for B. If the combination of A and B exhibits positive synergism (superadditivity), then the 50% effect with a combination of the two drugs will fall somewhere below the line of additivity, whereas negative synergism (subadditivity) will fall above the line of additivity. Lines of additivity for different percentage effects (e.g., 90% effect) are parallel to the 50% line of additivity. The isobologram can be used to estimate the concentrations of two drugs needed to obtain a given effect when used in combination. For a full explanation of the concept and utility of isoboles, consult Tallarida (2012).

in response of a GPCR to an agonist as a consequence of an interaction between the two. One form of homologous desensitization entails phosphorylation of the GPCRs by G protein-coupled receptor kinases (GRKs) with subsequent engagement of arrestins and internalization of receptors, as discussed in the section GRK- and Arrestin-Mediated Desensitization. Other forms of homologous desensitization exist, including those mediated by protein kinases, with or without arrestins, and involving other forms of internalization. *Heterologous desensitization* refers to a decline in response of a receptor to an agonist as a result of the activation of a different receptor-signaling pathway, typically by a different agonist. Phosphorylation of receptors by PKA and PKC figure prominently in heterologous desensitization, as do other posttranslational modifications, such as ubiquitination and palmitoylation (Patwardhan et al., 2021). Desensitization of GPCRs, while permitting a variable degree of recycling from endosomes, predisposes the receptors to downregulation through lysosomal degradation.

Desensitization and downregulation, while generally perceived to blunt the efficacy of agonists, are in some instances therapeutically valuable. The mechanisms by which selective serotonin reuptake inhibitors (SSRIs) attenuate depression are thought to involve downregulation of autoinhibitory $5HT_{1A}$, $5HT_{1D}$, and $5HT_{7}$ receptors and postsynaptic $5HT_{2A}$ receptors, while other serotonergic receptors remain responsive to the now increased levels of serotonin (Chapter 18). The downregulation of the gonadotropin-releasing hormone (GnRH) receptor by the sustained signaling achieved with GnRH congeners is the basis for the utility of these drugs in the treatment of GnRH-dependent precocious puberty (Chapter 46).

The phenomenon of *supersensitivity* reflects an adaptive process as well, often an adaptation to prolonged suppression of receptor signaling and usually manifested as enhanced receptor expression. It is most noticeable when an inhibitor or antagonist is abruptly withdrawn. Supersensitivity related to the dopaminergic D2 receptor is proposed to account for tolerance to antipsychotics (Chapter 19) and the enhanced β adrenergic responsiveness in physically active patients who, after long-term treatment with a β antagonist, abruptly stop the medication (Chapter 14). Supersensitivity is also easily observed for certain postsynaptic neurotransmitter receptors in instances of chronic denervation.

Attenuation of response to drugs that inhibit enzymes can be related to increases in target expression. The inhibition by *statins* of HMG-CoA reductase is opposed, albeit incompletely, by a substantive elevation in levels of the enzyme through autoregulatory forms of gene transcription and reduced protein degradation.

Attenuation of a drug's response, regardless of its target, can result from *auto*-induced expression of the enzymes responsible for the drug's degradation, a pharmacokinetic phenomenon. The induction of CYP3A4 (cytochrome P450 isoform 3A4) by *carbamazepine* is a classic example: After a single dose, the half-life ($t_{1/2}$) of *carbamazepine* is approximately 36 h; after repeated dosing, the $t_{1/2}$ drops by half.

The term *drug resistance* is used almost solely in relation to antimicrobial and cancer therapy and refers to the capacity of the pathogen or cell to avoid destruction by the drug. The overuse of antimicrobials leads to the selection of drug-resistant strains of microbes, a critical problem in human medicine and in animal husbandry for food production. Common mechanisms of antimicrobial resistance, discussed in detail in Chapter 56, are:

- Reduced entry of the drug into the pathogen or cell
- Enhanced export of the drug out of the pathogen or cell
- Alteration of target proteins
- Development of alternative pathways to circumvent those inhibited by the drug
- Release of enzymes that alter or destroy the drug

In cancer cells, one of several mechanisms of resistance to *methotrexate*, a competitive inhibitor of dihydrofolate reductase (DHFR), is upregulation of the enzyme through gene amplification or altered gene regulation (Chapter 70). Other mechanisms of resistance to *methotrexate* include impaired drug transport into cells due to low expression of the reduced folate carrier, diminished intracellular retention of the drug due to decreased polyglutamylation and/or an increased expression of an efflux transporter, and production of altered forms of DHFR that have a decreased affinity for *methotrexate*.

Pharmacodynamic Drug Interactions

While drugs can be used in combination to achieve an additive or synergistic therapeutic effect, combinations are also used simply to treat multiple concurrent conditions. In either case, *drug interactions* must be considered. The term *interactions*, as generally used, is not related to therapeutic interactions, but rather to interactions of the drugs that have the potential to cause adverse effects. Understanding the basis of such interactions provides the backdrop for preventing them.

Drug interactions are most often framed from a pharmacokinetic perspective in which one drug alters the absorption, distribution, metabolism, or elimination (ADME) of another drug. Pharmacokinetic drug interactions are discussed in Chapter 2. Those of a pharmacodynamic nature are less well categorized. Perhaps the most commonly encountered type of pharmacodynamic drug interaction relates to sedation. A large number of drugs exert sedative actions, and a combination of such drugs, through additive or synergistic forms of sedation, can cause excessive sedation, loss of consciousness, and even death. Another type of pharmacodynamic drug interaction pertains to prolongation of the QTc interval, wherein coadministration of two drugs that both cause prolongation of the interval has a greater chance of causing polymorphic ventricular tachycardia than either agent alone.

Other pharmacodynamic drug interactions are more selective or idiosyncratic in nature. For example, nitrovasodilators produce vasodilation via NO-dependent elevation of cyclic GMP in vascular smooth muscle, while *sildenafil*, *tadalafil*, and *vardenafil* achieve their pharmacological effects in the vasculature from inhibition of phosphodiesterase (PDE) 5 that hydrolyzes cyclic GMP to 5′GMP. Thus, coadministration of an NO donor (e.g., *nitroglycerin*) with a PDE5 inhibitor can cause profound vasodilation and potentially catastrophic hypotension. *Warfarin* has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to numerous important pharmacokinetic and pharmacodynamic drug interactions. Alterations in dietary vitamin K intake may significantly affect the pharmacodynamics of *warfarin* and mandate altered dosing; antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of *warfarin*; and concurrent administration of NSAIDs with *warfarin* increases the risk of gastrointestinal bleeding almost 4-fold compared with *warfarin* alone.

What About Pharmacokinetics and Pharmacodynamics at the Extremes of Age?

Most drugs are evaluated in young and middle-aged adults. Data for children and the elderly are relatively sparse. Yet, pharmacokinetic and pharmacodynamic parameters at the extremes of age can differ radically from those of the prototypic adult, requiring avoidance of certain drugs or substantial alteration in the dose or dosing regimen to safely produce the desired clinical effect. A variety of resources cover neonatal and pediatric pharmacology. With regard to the elderly, the American Geriatrics Society publishes the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults, which is an explicit list of drugs that should be avoided in older adults, drugs that should be avoided or be used at lower doses in older patients with reduced kidney function, and specific drug-disease and drug-drug interactions that are known to be harmful in this population.

Precision Medicine: A Pharmacodynamic Perspective

The intent of precision medicine is to understand an individual's genetic makeup, environment, and lifestyle in order to optimize approaches to the prevention and treatment of disease. From a pharmacodynamic perspective, the key to this pursuit is the identification of *biomarkers* or other surrogates that anticipate a response, whether therapeutic or adverse, to a

given drug. The overwhelming emphasis to date has been on biomarkers at a genetic level, in part due to the relative ease in sequencing DNA. The classification of such biomarkers is the province of *pharmacogenetics* and *pharmacogenomics*, which are discussed in Chapter 7. *Epigenetics*, the study of modifications and changes in chromatin structure superimposed on the DNA sequence, will almost certainly prove as important, especially given its connection to environment and lifestyle.

Examples of genetic biomarkers at this point in time relate primarily to singular changes in DNA structure through somatic mutations and through single-nucleotide or structural polymorphisms. Good examples of biomarkers relating to therapeutic effectiveness are the V600E mutation in Raf-B required for the treatment of melanoma with *vemurafenib*; the overexpression of the HER2/neu receptor required for the treatment of breast cancer with *trastuzumab*; and the Philadelphia chromosome required for the treatment of chronic myelogenous leukemia with *imatinib* (Chapter 71). Landscapes of multiple polymorphisms and mutations, whose functional impact individually are not necessarily known, are proving important as well. For example, a high "mutational load" and tumor-specific neoantigens relating to T-cell recognition are associated with the degree of clinical benefit afforded by CTLA4 (cytotoxic T lymphocyte–associated protein 4) blockade in melanoma (Snyder et al., 2014).

Requirements for genetic testing that relate to minimization of especially harmful adverse effects include those for the human leukocyte antigen allele B*1502 polymorphism prior to administration of *carbamazepine* in patients of Asian ancestry and for glucose-6-phosphate dehydrogenase deficiency prior to administration of *rasburicase* in patients of African or Mediterranean ancestry. Testing for the AA polymorphic variant of the vitamin K epoxide reductase complex-1 (together with polymorphic variants of CYP2C9) can provide guidance in the initial dosing of *warfarin*. Why? Because the optimal dose can vary by greater than 10-fold among patients, with significant consequences for dosing that is too high (bleeding complications) or too low (clot formation).

Pharmacokinetic perspectives relating to precision medicine, and to pharmacogenetics/genomics in general, are provided in Chapter 7. The Pharmacogenomics Knowledge Base (PharmGKB) and FDA/European Medicines Agency drug labels provide guidelines at both pharmacodynamic and pharmacokinetic levels.

Concentration- and Dose-Response Relationships

The terms most often employed to describe the capacity of a drug to achieve an effect are *efficacy* and *potency*. These terms can be approached through evaluating the relationship between the concentration or dose of a drug and the elicited response(s). *Concentration-* or *dose-response curves* are typically modeled, as we do here, for the effects of agonists through receptors, but they are extensible to all targets. The focus of these curves tends to be placed on individuals, as opposed to populations, or on cells, tissues, or experimental samples in such a manner as to minimize variability. Populations are more easily evaluated by means of quantal concentration- or dose-effect curves (see the next section).

The concentration- or dose-response curve as it relates to receptors depicts the observed effect of an agonist as a function of its concentration in the receptor compartment or of the dose administered to an individual. Figure 3–6 shows a concentration-response curve, usually plotted as in Figure 3–6B. The exact placement and shape of the curve will depend on the affinity of the drug for the receptor, the extent to which the population of receptors might be in excess of the number required for a maximal response (*spare receptors*), and cooperative effects. Responses conforming to the depicted relationship share the property of being mathematically continuous, as opposed to quantal, in nature, a difference discussed later.

Some agonists elicit a response at one range of concentrations and suppress the same response at a higher range. The basis for this biphasic relationship, sometimes referred to as *hormesis*, is generally unknown; however, it may be at the root of some adverse drug responses (see Figure 9–2).

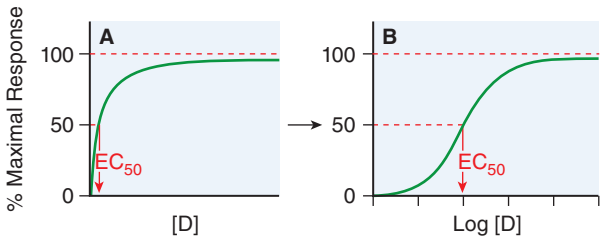

Figure 3–6 *Concentration-response curve.* **A.** *A selected response to an agonist "D" as a function of the agonist's concentration is plotted as a percentage of the maximum response to the agonist.* The concentration of agonist that produces 50% of the maximal response is referred to as EC_{50} (effective concentration, indexed to 50% maximal response). **B.** *The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semi-logarithmically.* The range of concentrations needed to fully depict the dose-response relationship (~3 $\log_{10}$ [10] units) is too wide to be useful in the linear format of Figure 3–6A; thus, most dose-response curves use *log [Drug]* on the *x* axis, as in Figure 3–6B. The sigmoidal shape has three noteworthy features: threshold, slope, and maximal asymptote.

At a molecular level, efficacy relates to the ability of a ligand to bind to the receptor and promote a change in receptor conformation that evokes the measured downstream response. Differences in efficacy among ligands are most easily evaluated at saturating concentrations of the ligands, when the targeted receptors are fully occupied and the maximal response for each ligand is attained. This is depicted in Figure 3–7A, where the asymptotes relating to maximal effects, and hence efficacies, of two drugs differ. Full and partial agonists differ in efficacy; a neutral antagonist, having no effect on receptor conformation, has zero efficacy.

Potency is an expression of the activity of a drug in terms of the concentration or amount required to produce a defined effect (Neubig et al., 2003). The *median effective concentration* (EC_{50}) or dose (ED_{50}) is commonly used. In this case, a drug whose concentration-response curve lies to the left of another, as in Figure 3–7B, is said to be the more potent, regardless of differences in maximal responses. That said, the notion of a "defined effect" in the definition above lends itself to other interpretations of potency, for example, those not based on EC_{50} or ED_{50} but on

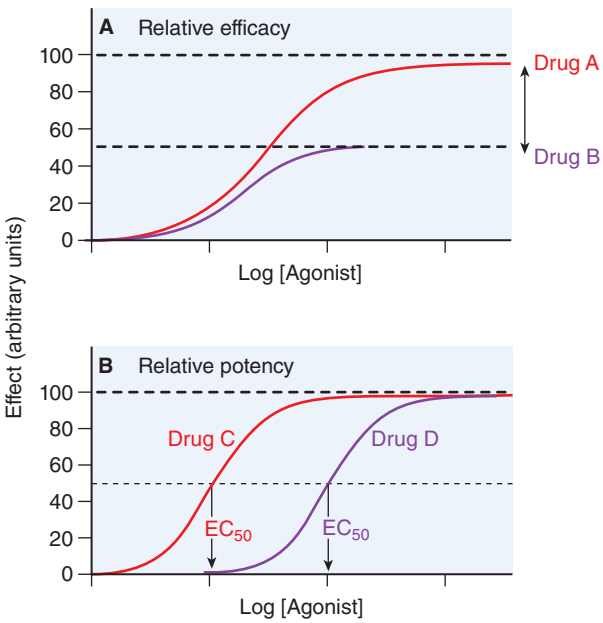

Figure 3–7 *Two ways of quantifying agonism.* **1.** The relative efficacy of two agonists (*Drug A*, ——; *Drug B*, ——) for a given type of receptor in the same cell or tissue is evaluated based on a comparison of responses. The asymptotic response of Drug A is two times that of Drug B; hence, Drug A is twice as efficacious as Drug B. **2.** The EC_{50} of Drug C is one-tenth that of Drug D; hence, Drug C is 10-fold more potent than Drug D.

concentrations or doses required to achieve an absolute or given therapeutic effect. In either case, potency does not refer to the maximum effect attainable.

Differences in efficacies and potencies between two or more drugs operating through a given receptor can change depending on the response measured and the cellular context. Context can refer to the relative proximity of downstream effectors, receptor conformations differentially recognized in different cells, whether receptors are limiting for the measured response, and adaptive responses. Moreover, the translation of efficacy from a molecular to a physiological or clinical level, where the desired therapeutic effect is the most important concern, can be a fraught process. The therapeutic effect is often far downstream of changes in receptor conformation and represents an integration of actions and reactions at the level of cells, tissues, and superimposed homeostatic mechanisms. Furthermore, the variability among humans in terms of response is confounding (see below). Moreover, an antagonist, while having no effect on a receptor in its own right, cannot be said to have no effect *in vivo* if it blocks the actions of an endogenous agonist, which could rightly be considered a measurable, therapeutic response.

Pharmacodynamic Variability: Individual and Population Pharmacodynamics

Individuals vary among themselves in the magnitude of their response to the same concentration of a single drug, and a given individual may not always respond in the same way to the same drug. Factors underlying this variability are poorly understood but are both pharmacokinetic and pharmacodynamic in nature (Figure 3–8). As such, these factors can change in relation to physiological and pathophysiological status, for example, pregnancy, age, and cardiovascular, hepatic, or renal function. Further complicating issues of variability is the fact that molecular targets for drugs are often up- or downregulated by endogenous or exogenous factors, including previous or concurrent drug administration.

Data on the correlation of drug levels with therapeutic response and toxicity for a population must be interpreted within this context of variability. The concentration- and dose-response curves discussed previously, which attempt to minimize variability, will not generally suffice. Potency and efficacy as they relate to a population must instead

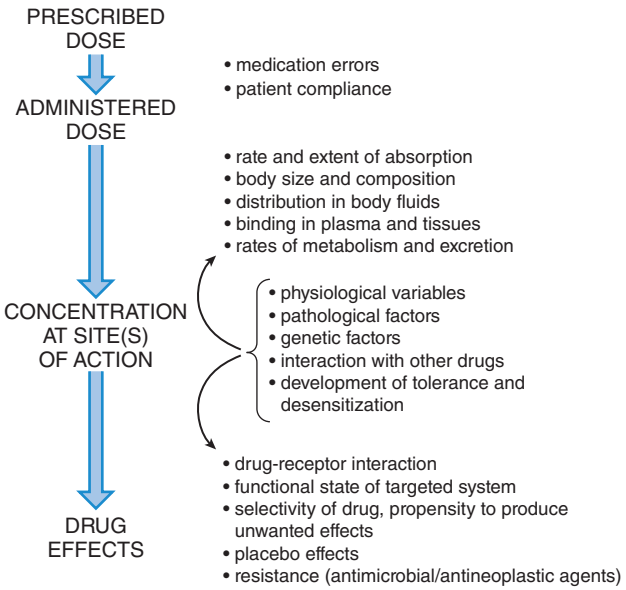

Figure 3–8 *Factors influencing the response to a prescribed drug dose.*

be handled through *quantal* concentration- or dose-effect curves (Figure 3–9). Quantal refers to whether an individual responds, or not, to a given concentration or dose of drug; the concentration of the drug, if used instead of the dose, is usually that in the plasma. In the case of biological events that are themselves quantal (e.g., consciousness, convulsion, or death), the response is simply the occurrence of the event. In the case of endpoints that are mathematically continuous (e.g., blood pressure, level of pain, plasma glucose concentration, P_{CO_2}), a specified increment of change constitutes the quantal response. In either case, the number or percentage of individuals responding in this quantal fashion is plotted as a function of concentration or dose of drug. The concentration or dose required to produce a specified response in 50% of the population is the EC_{50} or ED_{50}.

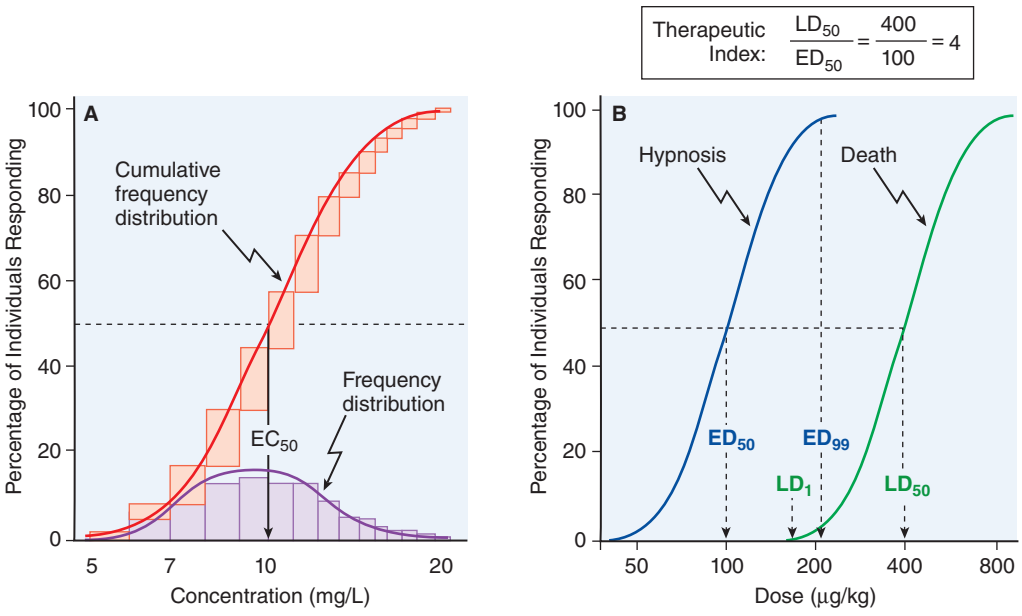

Figure 3–9 *Quantal concentration- and dose-response curves.* **A.** *Frequency distribution and concentration-response curve.* An experiment was performed on 100 subjects, in which the plasma concentration of drug that produced a quantal response, in this case hypnosis, was determined for each individual. The number of subjects responding to each concentration was plotted, giving a log-normal frequency distribution (purple bars). The normal frequency distribution, when summated, yields the cumulative frequency distribution—a sigmoidal curve that is a quantal concentration-response curve (red bars, red line). **B.** *Quantal dose-response curves.* Animals were injected with varying doses of a drug, and the responses were determined and plotted. The therapeutic index, the ratio of the LD_{50} to the ED_{50}, is an indication of how selective a drug is in producing its desired effects relative to its lethality. See text for additional explanation.

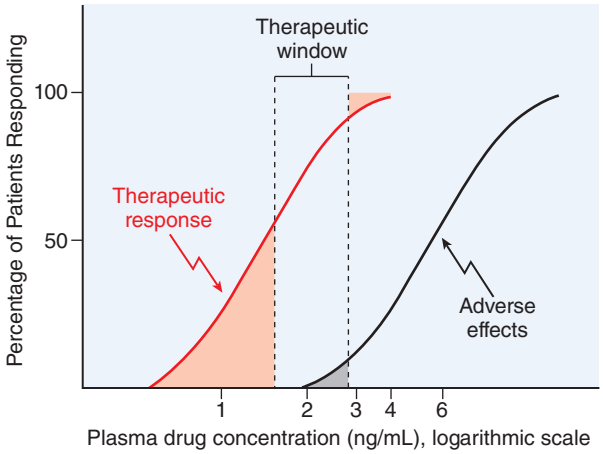

Figure 3–10 *Relation of the therapeutic window of drug concentrations to therapeutic and adverse effects in the population.* The ordinate is linear; the abscissa is logarithmic. This particular therapeutic window represents the difference in drug concentrations eliciting a therapeutic response in 50% of the patients and adverse effects in 10%.

In preclinical studies of drugs, the *median lethal dose* (LD_{50}) is determined in experimental animals (Figure 3–9B). The LD_{50}/ED_{50} ratio in animals is an indication of the *therapeutic index* in humans, a term that reflects how selective the drug is in producing desired versus serious adverse effects. Another term, the *therapeutic window*, is the range of concentrations or doses of drug that provide therapeutic efficacy with minimal toxicity (Figures 2–11 and 3–10). The concentration or dose of a drug required to produce a therapeutic effect in most of the population will usually overlap to some extent with that required to produce toxicity in some of the population. Thus, a therapeutic window defined for a population expresses a range of concentrations or doses for which the likelihood of efficacy is high and the probability of adverse effects is low but does not guarantee efficacy or safety for any single individual. Use of the therapeutic window to optimize the dosage of a drug in a given patient should therefore be complemented by monitoring appropriate clinical and surrogate markers of the drug's effects.

Antimicrobial Pharmacodynamics

In antimicrobial pharmacology, macromolecules that serve metabolic, replicative, and structural needs *distinct from the host* come to the fore as targets. Such targets allow for selective toxicity (microbe as opposed to human host). A good example is the inhibition of folic acid synthesis by a combination of a sulfonamide with *trimethoprim* (Chapter 57). A very large number of microorganisms must synthesize folic acid, while mammalian cells require preformed folic acid from the diet. *Sulfonamides* block the synthesis of dihydropteroic acid, a precursor to dihydrofolic acid, through competitive inhibition of the enzyme dihydropteroate synthase, for which *para*-aminobenzoic acid is the normal substrate. *Trimethoprim* blocks the subsequent conversion of dihydrofolic acid to tetrahydrofolic acid through competitive inhibition of DHFR. While this latter conversion is required in mammalian cells, *trimethoprim* has a several thousand–fold greater affinity for the microbial reductase.

Pharmacologically exploitable differences between microbes and the host are extensive. Among the many additional examples are the production of heme cofactor by plasmodia responsible for malaria, which provides the basis for the therapeutic actions of *artemisinin*, *quinolines*, and *chloroquine* (Chapter 66); electron transport components in certain protozoa and bacteria that have a uniquely negative redox potential, leading to activation of *metronidazole* (Chapters 57 and 67); a glutamate-gated Cl^- channel found only in invertebrates, the target for *avermectins* (Chapter 68); the bacterial cell wall, whose synthesis is the target of *β-lactams*, *glycopeptides*, and *lipopeptides* (Chapter 58); the 30S ribosomal subunit unique to bacteria, the target of *aminoglycosides* and *tetracyclines* (Chapters 59 and 60); the 50S ribosomal subunit also unique to bacteria, the target of *chloramphenicol*, *macrolides*, *lincosamides*, and *oxazolidinones* (Chapter 60); unique topological rearrangements of DNA coiling represented by requirements for DNA gyrase and topoisomerase IV, the targets of *quinolone antibiotics* (Chapter 57); unique composition of surface membranes of protozoa, fungi, and bacteria, whose constituents are the target of *amphotericin B*, *polymyxin*, *daptomycin*, and *isoniazid* (Chapters 59, 61, and 65); viral forms of thymidylate kinase and DNA polymerase, relevant to the actions of *acyclovir* and *ganciclovir* (Chapter 62); and enzymes and structures unique to retroviral replication, targets for inhibitors of fusion, uncoating, reverse transcription, and viral release and maturation (Chapters 62–64).

Receptor-Mediated Mechanisms of Drug Action

The investigation of receptors in terms of their identities and properties has played a pivotal role in the development of pharmacology as a discipline. The majority of drugs used therapeutically, moreover, are directed toward receptors or toward ligands that receptors recognize. Given these facts, and that voltage-gated ion channels, transporters, and enzymes are devoted substantial attention in other chapters of this textbook or elsewhere, the remainder of the chapter will focus primarily on receptors and, specifically, the mechanisms by which receptors mediate drug action.

Quantitative Aspects of Drug Interactions With Receptors

Binding and Fractional Occupancy

The reactions describing the interaction of a drug, or more generally ligand *L*, with a receptor are illustrated in Equation 3–1. The first reaction is the reversible formation of the ligand-receptor complex, *LR*. The second, depending on the nature of the ligand, is conversion of the complex to *LR**, in which the receptor attains a conformation capable of engendering a biological response.

$$L + R \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} LR \underset{k_{-2}}{\overset{k_{+2}}{\rightleftharpoons}} LR^* \qquad \text{(Equation 3–1)}$$

The affinity of the ligand for the receptor, *R*, ignoring for the moment conversion to *LR**, depends on the forward or *association rate constant*, k_{+1}, and the reverse or *dissociation rate constant*, k_{-1}. The concentration of *LR* at any given instant is equal to the rate of its formation, $k_{+1}[L][R]$, minus the rate of its dissociation, $k_{-1}[LR]$. At equilibrium, where $[LR]$ is unchanging:

$$k_{+1}[L][R] = k_{-1}[LR] \qquad \text{(Equation 3–2)}$$

The ratio of the dissociation and association rate constants, k_{-1}/k_{+1}, defines what is referred to as the *equilibrium dissociation constant*, K_D. Thus, with a small amount of rearrangement of terms, and at equilibrium:

$$\frac{[L][R]}{[LR]} = \frac{k_{-1}}{k_{+1}} = K_D \qquad \text{(Equation 3–3)}$$

A numerically low K_D signifies a high affinity of the ligand for receptor, while a high K_D signifies a low affinity. As a practical matter, differences in affinities of similar compounds most often reflect differences in dissociation rate constants. Also of note, the *affinity constant* or *equilibrium association constant*, K_A, is the reciprocal of the equilibrium dissociation constant (i.e., $K_A = 1/K_D$).

Given that the concentration of free receptor is equal to that of total receptor, R_t, minus receptor bound to ligand, and assuming that the concentration of drug is unaffected by receptor binding, Equation 3–3 can be rearranged to describe *fractional occupancy*, or *f*, which is the ratio of $[LR]$ to $[R_t]$, as a function of ligand concentration:

$$\textit{Fractional occupancy} = f = \frac{[LR]}{[R_t]} = \frac{[L]}{K_D + [L]} \qquad \text{(Equation 3–4)}$$

Equation 3–4 describes a hyperbolic relationship (Figure 3–11). Here, K_D is revealed as a "positioning constant"; namely, K_D is the concentration

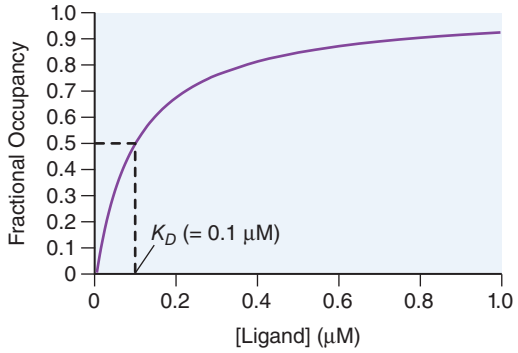

Figure 3–11 *Receptor fractional occupancy.* Portrayed is the binding of a ligand, expressed as fractional occupancy, to a population of homogeneous receptors as a function of ligand concentration. In this example, the equilibrium dissociation constant, K_D, is 0.1 μM. The K_D, defined as the ratio of k_{-1}/k_{+1}, is equal to the concentration of ligand that supports half-maximal occupancy; it can be viewed graphically as a positioning constant. Were the ligand to have a higher affinity (i.e., lower K_D), the curve would be shifted leftward. Were the ligand to have a lower affinity (i.e., higher K_D), the curve would be shifted rightward.

of ligand that yields half-maximal occupancy of the receptor. This follows from setting fractional occupancy in Equation 3–4 to 0.5 (i.e., 50% occupancy).

While the derivation of fractional occupancy is correct for complexation of L with R, and remains appropriate for the behavior of an antagonist, for which no transition to LR^* occurs, the conversion to LR^* in the case of an agonist results in a higher fractional occupancy than would be predicted by K_D alone. This is because more receptor-bound ligand exists than can be accounted for by LR, or said another way, the conversion to LR^* pulls the equilibrium rightward. With GPCRs, the binding of LR^* to a G protein to form the so-called ternary complex further distorts the equilibrium.

If ligand-bound receptors are limiting with regard to the ultimate measured response throughout the entire range of occupancy, then K_D and the concentration of the drug producing a half-maximal effect (EC_{50}) will be nearly equal, the effects of LR^* on binding notwithstanding. Owing to downstream amplification, however, many signaling systems can reach a full biological response with only a fraction of receptors occupied. In this case, the EC_{50} is shifted leftward from K_D; the receptors are said to be in excess, or that *spare receptors* exist.

Quantifying Antagonism

Characteristic patterns of antagonism are associated with certain mechanisms of receptor blockade. One is straightforward *competitive antagonism*, in which a drug with an affinity for a receptor but lacking intrinsic efficacy competes with the agonist for the orthosteric site. The characteristic pattern of such antagonism is a parallel, rightward shift of the agonist concentration- or dose-response curve with no change in maximal response (Figure 3–12A). The magnitude of the rightward shift depends on the concentration of the antagonist and its affinity for the receptor (Schild, 1957). A competitive antagonist at sufficiently high concentrations relative to the agonist can reduce the response to near zero; however, the antagonism remains *surmountable*.

Other mechanisms of receptor blockade are *pseudoirreversible* and *irreversible antagonism*, in which the antagonist once bound to receptor, whether through noncovalent or covalent mechanisms, respectively, dissociates quite slowly or not at all. Both types of antagonists will produce the pattern of antagonism shown in Figure 3–12B. Pseudoirreversible and irreversible forms of antagonism are not surmountable.

The majority of orthosteric receptor antagonists are competitive. One may write mathematical expressions of fractional occupancy of the receptor by an agonist, f, and by the agonist in the presence of a competitive antagonist, f_{+I}.

For the agonist alone, the fractional occupancy is provided by the previously developed Equation 3–4:

$$\textit{Fractional occupancy} = f = \frac{[LR]}{[R_t]} = \frac{[L]}{K_D + [L]}$$

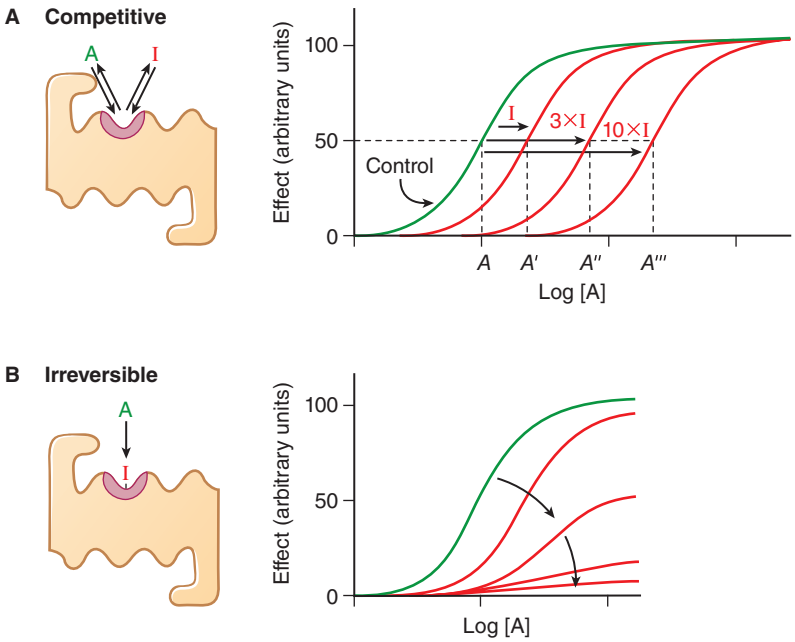

Figure 3–12 *Mechanisms of receptor antagonism.* The effect achieved by an agonist unmodulated by antagonist is depicted in each panel by the green curve. **A.** Competitive antagonism occurs when the agonist **A** and antagonist **I** compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a manner dependent on antagonist concentration such that the EC_{50} for the agonist increases (e.g., L vs. L', L'', and L'''). **B.** Irreversible antagonism occurs when the antagonist forms a covalent bond with the receptor, in this example, at the same site as agonist, causing a progressive depression of the maximal response as the concentration of antagonist increases; the rightward shift in EC_{50} initially would suggest some degree of spare receptors. Irreversible antagonism need not occur at the orthosteric site, and sometimes, the antagonism is in fact pseudoirreversible, in which case, the antagonist does not form a covalent bond but instead dissociates quite slowly.

For the agonist *plus* antagonist, one must first consider two equilibria. The first is the equilibrium already described between the agonist, L, and receptor, R, and summarized here as Equation 3–5.

$$L + R \rightleftharpoons LR;\ K_D = \frac{[L][R]}{[LR]},\ \text{or}\ [LR] = \frac{[L][R]}{K_D} \qquad \text{(Equation 3–5)}$$

The second is the equilibrium between the antagonist, defined as the inhibitor I, and R.

$$I + R \rightleftharpoons IR;\ K_i = \frac{[I][R]}{[IR]},\ \text{or}\ [IR] = \frac{[I][R]}{K_i} \qquad \text{(Equation 3–6)}$$

Fractional occupancy by the agonist L in the presence of I is defined as:

$$f_{+I} = \frac{[LR]}{[LR]+[IR]+[R]} \qquad \text{(Equation 3–7)}$$

The concentration of agonist needed to achieve a designated fractional occupancy in the presence of antagonist, $[L']$, will be greater than the concentration of agonist needed to achieve the same fractional occupancy in the absence of inhibitor, $[L]$. Using Equations 3–5 and 3–6, and applying some algebraic tinkering to the right-hand side of Equation 3–7, the fractional occupancy in the presence of the competitive inhibitor, f_{+I}, can be expressed in terms of L', K_D, K_i, and I:

$$f_{+I} = \frac{[L']}{[L']+K_D\left(1+\frac{[I]}{K_i}\right)} \qquad \text{(Equation 3–8)}$$

Assuming that equal responses result from equal fractional receptor occupancies in both the absence and presence of antagonist, one can set the fractional occupancies equal at experimentally determined agonist concentrations ($[L]$ and $[L']$) that generate equivalent responses, as depicted in Figure 3–12A. Thus,

$$f = f_{+I} \qquad \text{(Equation 3–9)}$$

$$\frac{[L]}{[L]+K_D} = \frac{[L']}{[L']+K_D\left(1+\frac{[I]}{K_i}\right)} \qquad \text{(Equation 3–10)}$$

Simplifying, one obtains

$$\frac{[L']}{[L]} - 1 = \frac{[I]}{K_i} \qquad \text{(Equation 3–11)}$$

where all values are known except K_i. Thus, one can determine the K_i for a reversible, competitive antagonist without knowing the K_D for the agonist and without needing to define the precise relationship between receptor and response.

Allosteric Modulation of Receptor Function

Some drugs interact with receptors through allosteric mechanisms, wherein drug binding at a site distinct from the orthosteric site can alter the receptor's affinity for the orthosteric agonist, the capacity of the orthosteric agonist to induce or stabilize conformational changes equated with activation, or both. These drugs are termed *allosteric modulators*. Some patterns of allosteric modulation are shown in Figure 3–13. *Cinacalcet* is a *positive allosteric modulator* (PAM), enhancing the actions of Ca^{2+} on the calcium-sensing receptor (Chapter 52). Benzodiazepines and barbiturates are also PAMs; they *potentiate* the actions of γ-aminobutyric acid (GABA) on the $GABA_A$ receptor (see Figure 16–11 and Chapter 22). *Maraviroc* is a *negative allosteric modulator* (NAM), blocking the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor and hence fusion and entry of HIV into macrophages and $CD4^+$ T cells (see Figure 64–7). *Ticagrelor* and *cangrelor* are similarly NAMs, blocking the actions of ADP binding to the orthosteric site on platelet $P2Y_{12}$ receptors (Chapter 36). Allosteric modulation is not confined to receptors. Allosteric modulators also act on voltage-gated ion channels, including L-type and T-type Ca^{2+} channels. For example, the dihydropyridine Ca^{2+}

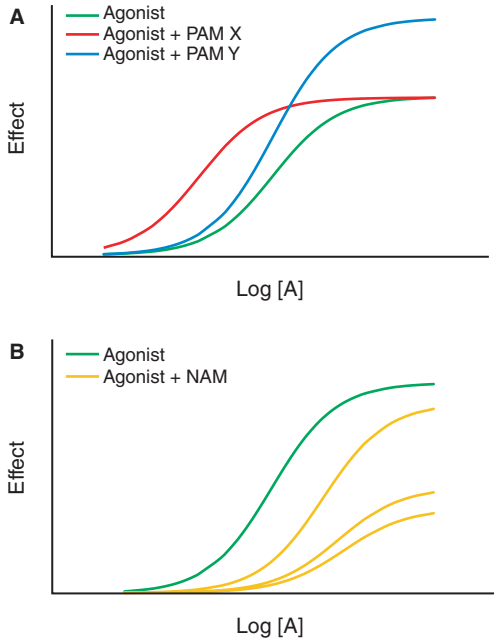

Figure 3–13 *Allosteric modulation.* **A.** Concentration-response curves for an orthosteric agonist in the absence and presence of two positive allosteric modulators (PAMs). For clarity, assume maximal occupancy of the receptor population by the PAMs. PAM X shifts the EC_{50} for the agonist leftward (i.e., increases the potency of the agonist), whereas PAM Y increases the E_{max} for the agonist (i.e., increases efficacy). Note that neither modulator has any effect in the absence of the agonist, which is to say that they are not allosteric agonists. **B.** Concentration-response curves for an orthosteric agonist in the absence and presence of *increasing* concentrations of a negative allosteric modulator (NAM). In this instance, the NAM has a negative impact on both EC_{50} and E_{max}, reducing potency and efficacy.

channel blocker *amlodipine* allosterically modulates binding of *diltiazem* and Ca^{2+} to the pore of the L-type Ca^{2+} channel by causing the channel to mimic the conformation of the inactivation state. Of note, *diltiazem* can both directly block and allosterically modulate Ca^{2+} binding in the channel's pore (Tang et al., 2019).

Despite the small number of allosteric modulators recognized at present, considerable effort is currently devoted to the development of those that distinguish receptor subtypes for which orthosteric sites are highly conserved, as discussed in Chapter 1 (see Protein-Drug Binding: Affinity and Allostery) and in Chapter 11 for muscarinic receptors. Because many positive allosteric modulators have no activity *per se* but rather condition the receptor to activation by the endogenous agonist, they have the advantage of preserving the spatial and temporal pattern of receptor activation when present (Foster and Conn, 2017).

Classes of Receptors Relevant to Drug Actions

Cellular receptors of relevance to therapeutics include GPCRs, ligand-gated ion channels, enzyme-linked (catalytic) receptors, still other cell-surface membrane receptors, and nuclear receptors (Table 3–1).

The activation of receptors by agonists sets into motion a number of proximal subcellular events. One such set of events, achieved primarily by GPCRs through G proteins as transducers, is the generation or mobilization of *second messengers*. Second messengers are small, intracellular, and sometimes interdependent molecules that include the cyclic nucleotides cyclic AMP and cyclic GMP, NO, inositol trisphosphate (IP_3), diacylglycerol (DAG), and Ca^{2+}. Also achieved by GPCRs, and more directly by ligand-activated ion channels, are alterations in membrane permeability to one or more ions, notably Na^+, K^+, Ca^{2+}, and Cl^-. Changes in permeability result in changes in electrical potential across the cell membrane and hence the degree of cell excitability. Other actions are attributable to receptors that have intrinsic enzymic activity,

TABLE 3–1 ■ CELLULAR RECEPTORS OF RELEVANCE TO THERAPEUTICS

CLASSES	SUBCLASSES OR FAMILIES	PHYSIOLOGICAL LIGANDS	TRANSDUCERS, PRINCIPAL EFFECTS, OR IONS
G protein-coupled receptors (GPCRs)[a]	Adhesion Frizzled Glutamate Rhodopsin Secretin	Very large number of endocrine and paracrine factors, but other types of ligands as well	G proteins G_s: Adenylyl cyclases (stimulation) G_i: Adenylyl cyclases (inhibition), delayed rectifier K^+ channel (stimulation), N-type voltage-gated Ca^{2+} channel (inhibition) G_q: Phospholipase C-β (stimulation) $G_{12/13}$: Rho GEFs (stimulation) Arrestins: MAP kinases, nonreceptor tyrosine kinases, transcription factors
Ligand-gated ion channels[b]	Glutaminergic	Glutamate	Na^+ and K^+ principally, but Ca^{2+} as well in certain circumstances
	Nicotinic cholinergic	ACh	Na^+, K^+, Ca^{2+}
	P2X	ATP	Na^+, K^+, Ca^{2+}
	5-HT_3	5-HT_3	Na^+, K^+, Ca^{2+}
	TRP	Many ligands	Na^+, Ca^{2+}, Mg^{2+}
	$GABA_A$	GABA	Cl^-
	Glycine	Glycine	Cl^-
Enzyme-linked (catalytic) receptors	Receptor tyrosine kinases	Insulin, PDGF, EGF, VEGF, growth factors[d]	Proteins containing SH2 and PTB domains
	Receptor serine kinases	TGF-β family	SMADs
	Membrane bound GC	Natriuretic peptides	Cyclic GMP
Other cell-surface membrane receptors	Cytokine receptors	Interleukins and other cytokines, growth hormone, prolactin	JAK/STATs, soluble tyrosine kinases
	Toll-like receptors	PAMPs	TIRAP, TRAM
	TNFα receptors	TNF-α	TRADD, RIP-1, TRAF2
Nuclear receptors[c]	Steroid receptors (subfamily 3)	Corticosteroids, sex hormones	Coactivators
	Nonsteroid receptors (subfamilies 1, 2, 4–6)	Thyroxine, retinoic acid, hydroxycholesterols, bile acids, Vitamin D	Coactivators, corepressors

SMAD, a concatenation of SMA (small worm phenotype in *C. elegans*) and MAD (Mothers Against Decapentaplegic in *Drosophila*); TIRAP, toll-interleukin 1 receptor domain-containing adaptor protein; TRADD, TNF receptor–associated death domain; TRAF2, TNF receptor–associated factor 2; TRAM, TRIF-related adapter molecule, wherein TRIF represents TIR domain-containing adapter-inducing interferon-β and TIR is toll-interleukin 1 receptor.

[a]The GPCR families are listed according to the GRAFS system (Fredriksson et al., 2003), which is based on phylogenetic analyses of the human genome; other systems of classification exist. It is important to note that each family of GPCRs contains a large number of receptors that respond to agonists and communicate with transducers distinct from the family's namesake. See Figure 3–14 and legend.

[b]Glutaminergic receptors comprise the AMPA, kainate, and NMDA receptors. Many permutations of each of these subtypes and of other subclasses of ligand-gated ion channels exist owing to combinatorial diversity in subunit composition. Ion channels that are gated by internal ligands are not listed for the purposes of brevity but are discussed in the text.

[c]Nuclear receptors are generally grouped into six subfamilies. The table groups the subfamilies into two major classes, steroid receptors and nonsteroid receptors, as does the IUPHAR/BPS Guide to Pharmacology, available at: https://www.guidetopharmacology.org/.

[d]The list comprises only a selection from among many different agonists.

for example, receptor tyrosine kinases. Tyrosine phosphorylation promotes the stable interaction of the phosphorylated proteins, including the receptors themselves through autophosphorylation, with proteins containing Src homology 2 (SH2) and phosphotyrosine-binding (PTB) domains; changes in the conformations of the interacting proteins and the process of scaffolding itself propagates the internal signal. Stable interactions with proteins can also be achieved by receptors without intrinsic enzymic activity, through conformational changes alone or abetted by phosphorylation by protein kinases distinct from the receptor. This is the case for cytokine and toll-like receptors in their interaction with adaptor proteins, nuclear receptors with coactivators and corepressors, and GPCRs with arrestins. Still another important setting for receptor activity is transcription. While all of the above phenomena can affect transcription, nuclear hormone receptors interact directly with transcriptional regulatory elements.

One tends to think of an activated receptor as eliciting a singular, linear chain of events. That is true in some instances, but viewing events in the context of multiple and branching pathways is usually more realistic. Many GPCRs interact with two or more G proteins that have distinct downstream actions and with transducers beyond G proteins, such as arrestins. Signals from multiple pathways are frequently integrated within the responsive cell, and there is ample cross talk among multiple signaling pathways. For example, pathways employing cyclic AMP and Ca^{2+} are integrated in most excitable tissues, where levels of cyclic AMP are controlled by GPCRs and those of intracellular Ca^{2+} by ligand- or voltage-gated ion channels or by other GPCRs. In cardiac myocytes, activation of the β_1 receptor–G_s–adenylyl cyclase (AC)–cyclic AMP–PKA pathway enhances cardiac contractility by augmenting Ca^{2+} entry through voltage-gated Ca^{2+} channels and Ca^{2+} mobilization from intracellular stores via the ryanodine receptor; thus, both cyclic AMP and Ca^{2+} are positive contractile signals in cardiac myocytes. By contrast, smooth muscle cells integrate these signals differently: In smooth muscle, Ca^{2+} is a contractile signal, but an elevation of cyclic AMP leads to relaxation via the phosphorylation of proteins that mediate Ca^{2+} signaling, such as myosin light chain kinase (MLCK).

BOX 3–2 ■ Fertile Ground

Research on cell signaling involving GPCRs, G proteins, and cyclic nucleotides has garnered a number of Nobel Prizes in Physiology or Medicine and in Chemistry. Early work in cell signaling involved the regulation of glycogen metabolism, building on the accomplishments of Gerty and Carl Cori, who shared the 1947 Nobel Prize in Physiology or Medicine "for their discovery of the course of the catalytic conversion of glycogen." Earl Sutherland, who discovered cyclic AMP, won the 1972 Nobel Prize in Physiology or Medicine "for his discoveries concerning the mechanisms of the action of hormones." In 1992, Edmond Fischer and Edwin Krebs won "for their discoveries concerning reversible protein phosphorylation as a biological regulatory mechanism." Two years later, Alfred Goodman Gilman and Martin Rodbell won "for their discovery of G-proteins and the role of these proteins in signal transduction in cells." Three pharmacologists, Robert Furchgott, Louis Ignarro, and Ferid Murad, shared the 1998 Nobel Prize in Physiology or Medicine "for their discoveries concerning nitric oxide as a signaling molecule in the cardiovascular system," and in 2000, Arvid Carlsson, Paul Greengard, and Eric Kandel shared the prize "for their discoveries concerning signal transduction in the nervous system." In 2012, Robert Lefkowitz and Brian Kobilka won the Nobel Prize in Chemistry "for studies of G-protein-coupled receptors." Fertile ground indeed.

Transmembrane Signaling via GPCRs and G Proteins

In general terms, agonists at the cell surface interact with GPCRs that couple to G proteins at the inner membrane leaflet, which in turn interact with effectors similarly situated or present within the cytosol. We consider these individual elements of transmembrane signaling below. The study of signaling through GPCRs and G proteins has been recognized at the level of several Nobel Prizes (Box 3–2).

G Protein-Coupled Receptors. GPCRs are a large family of receptors (Figure 3–14) that exhibit a seven-transmembrane α-helical motif. Of the over 800 GPCRs expressed by the human genome, some 130 are current targets for therapeutic drugs, either agonists or antagonists (Sriram and Insel, 2018). The remainder include "orphan" receptors (~130), for which endogenous ligands and functions have yet to be ascribed, sensory receptors (~420), most of which are olfactory but may also have other roles, and receptors not yet targeted. GPCRs are typically, though not always, situated in the cell-surface membrane. They recognize a very large number of endocrine and paracrine factors, as well as visual, olfactory, and gustatory stimuli. GPCRs engage G proteins and/or arrestins as transducers on the cytoplasmic aspect of the membrane. Many cells will contain several dozen different GPCRs and hundreds to thousands of copies each. The variety, accessibility, specificity, distribution, and relevance of GPCRs to disease make them important targets for drugs.

GPCR Subtypes. Quite commonly an endogenous agonist (e.g., an endocrine or paracrine factor) is recognized by two or more GPCRs. These receptors are defined as *receptor subtypes*. Acetylcholine, for example, is recognized by five subtypes of muscarinic (M) receptor, M_1 to M_5; histamine by four subtypes of receptor, H_1 to H_4; 5-hydroxytryptamine (5HT), or serotonin, by at least 10 subtypes; and so on. In fact, the existence of receptor subtypes is more the rule than the exception. Initially identified through binding studies with endogenous and synthetic ligands, the number has climbed through genomic analyses.

Receptor subtypes, while recognizing a given endogenous agonist, can differ among themselves in several important respects. First, subtypes often exhibit differences in affinities for endogenous or synthetic ligands (i.e., subtypes can be distinguished pharmacologically). Second, subtypes may be differentially distributed among cells or tissues, and the distribution of a single subtype may be relatively restricted. Pharmacological targeting of a given subtype can therefore minimize the extent to which generalized adverse effects occur. Subtypes of the β adrenergic receptor are a good example. β_2 Adrenergic receptor agonists such as *terbutaline* are used for bronchodilation in the treatment of asthma in the hope of minimizing cardiac side effects caused by stimulation of the cardiac β_1 adrenergic receptor (see Chapter 14). Conversely, the use of β_1 receptor–selective antagonists in patients being treated for hypertension or angina (see Chapters 14, 31, and 32) minimizes the likelihood of bronchoconstriction.

Receptor subtypes can also differ with respect to the G proteins (or other transducers) with which they interact. For instance, M_1, M_3, and M_5 muscarinic receptors couple to the G protein G_q with consequent increases in intracellular Ca^{2+}; M_2 and M_4 receptors couple to G_i to decrease the activity of AC (thus reducing intracellular cyclic AMP accumulation) and, in a variety of excitable cells, to activate inwardly rectifying K^+ channels and inhibit voltage-gated Ca^{2+} channels.

G Proteins. GPCRs couple to heterotrimeric GTP-binding regulatory proteins, or G proteins. G proteins, upon activation by agonist-occupied GPCRs, activate or inhibit any number of target enzymes and ion channels; G proteins are thus the transducers in the process of *transmembrane signal transduction*. The structure of a G protein conforms to that of an α, β, and γ subunit heterotrimer (Figure 3–15). Based on primary structural similarities among the α subunits (Strathmann and Simon, 1991), G proteins sort into four families (Table 3–2)—the G_s, G_i (sometimes $G_{i/o}$), G_q, and G_{12} (sometimes $G_{12/13}$) families—each with 2 to 10 members that have more or less common activities depending on the differentiated properties of responsive cell types. Virtually every cell in the body contains one or more members of each family. A given GPCR can couple to G proteins of one or two families and, in some instances, more.

With regard to the transduction event, an agonist-activated GPCR promotes exchange of GDP for GTP on the α subunit of the G protein heterotrimer, resulting in dissociation of the α subunit from the βγ heterodimer. The actions of the G protein on a target enzyme or ion channel are achieved through the monomeric α subunit alone, the βγ heterodimer alone, and sometimes both working coordinately. Reversion of the activated G protein to a heterotrimeric configuration occurs upon hydrolysis of GTP by the α subunit and recombination of the subunit with the βγ heterodimer.

Activation of members of the G_s family most often equates with the *activation* of ACs and an increase in cellular cyclic AMP. Activation of members of the G_i family links to the *inhibition* of ACs and to the activation of inwardly rectifying K^+ channels and inhibition of voltage-gated Ca^{2+} channels. *Transducin*, a member of the G_i family, couples to rhodopsin in retinal outer segments and cones and activates a cyclic GMP-selective phosphodiesterase (see Figure 74–9). Activation of members of the G_q family results in the activation of phospholipase C-β and the consequent release of DAG and IP_3. DAG and IP_3 initiate many downstream effects: IP_3 mobilizes Ca^{2+} from intracellular stores, thereby activating myriad Ca^{2+}-dependent events; Ca^{2+} and DAG are essential cofactors in the activation of PKC. The two members of the G_{12} family, G_{12} and G_{13}, activate the monomeric G protein RhoA through RhoA-selective guanine nucleotide exchange factors (GEFs). However, the G proteins of the G_{12} family, and those of every other G protein family, have an array of targets well beyond those highlighted here.

GRK- and Arrestin-Mediated Desensitization. GPCRs are subject to various forms of desensitization following exposure to agonists. One of the best characterized is a homologous desensitization initiated by phosphorylation of the activated receptor by one or more GPCR-specific kinases (GRKs) (Figure 3–16) (DeWire et al., 2007). The phosphorylation occurs at specific serine or threonine residues on the cytosolic aspect of the receptor, often within the C-terminal tail. Specificity for phosphorylation of the activated receptor is keyed to the receptor's conformation and, for some GRKs, recruitment of the GRK to the inner cell surface membrane by heterodimeric βγ subunits released upon activation of G proteins.

The phosphorylation of the receptor results in recruitment of arrestins. Of the several arrestins, β-arrestins-1 and -2 are widely expressed. The recruited arrestin binds conjointly to the phosphorylated C-terminal tail and exposed portions of the transmembrane core of the activated GPCR. This interaction of arrestin with the GPCR disrupts the interaction of the receptor with the G protein, thus terminating G protein signaling.

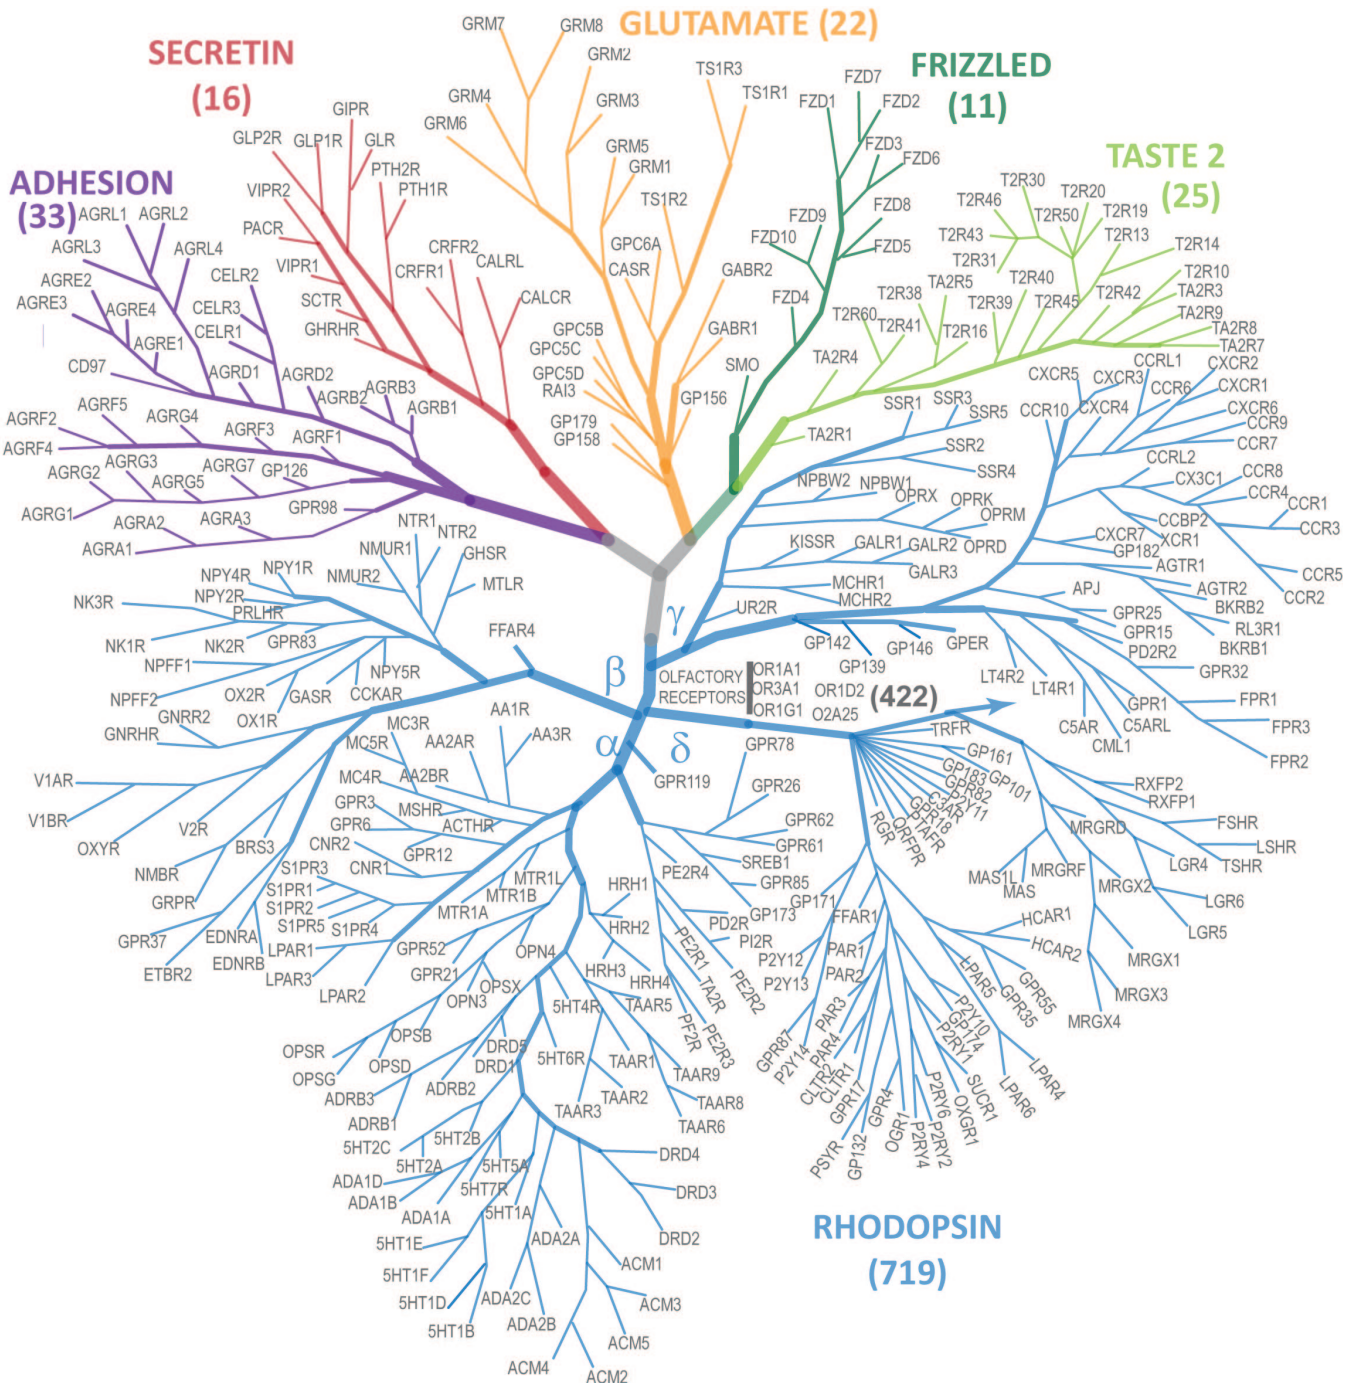

Figure 3–14 *The human GPCR superfamily.* Human GPCRs are targeted by about 30% of marketed drugs. This dendrogram, constructed using sequence similarities within the seven-transmembrane region, identifies GPCRs by their names in the UniProt database. There are over 825 human GPCRs, which can be subdivided into the color-coded groups named by the capitalized words on the outer edge of the dendrogram (number of group members in parentheses). These groups can be further subdivided on the basis of sequence similarity. The large Rhodopsin class is subdivided into four broad groups: α, β, δ, and γ. Olfactory receptors constitute the largest fraction of the Rhodopsin class of GPCRs, with 422 members. Receptors on the dendrogram that readers will frequently encounter include AA2AR, A_{2A} adenosine receptor; ACM3, M_3 muscarinic acetylcholine receptor; ADRB1, β_1 adrenergic receptor; AGTR1, AT_1 angiotensin receptor; CNR1, CB_1 cannabinoid receptor; CXCR4, CXC_4 chemokine receptor; DRD2, D_2 dopamine receptor; EDNRA, ET_A endothelin receptor; FPR1, f-Met-Leu-Phe receptor; GCGR, glucagon receptor; GRM1, $mGluR_1$ metabotropic glutamate receptor; HRH1, H_1 histamine receptor; 5HT2B, the $5HT_{2B}$ serotonin receptor; OPRM, μ opioid receptor; RHO, rhodopsin; SMO, smoothened homolog; S1PR1, S1P1 sphingosine-1-phosphate receptor, also known as EDG_1; TSHR, thyrotropin (TSH) receptor; and VIPR1, V_1 vasoactive intestinal peptide receptor. Details of entries on the dendrogram are available from the GPCR Network (http://gpcr.usc.edu). Additional information on GPCRs is available from the IUPHAR/BPS Guide to Pharmacology (http://www.guidetopharmacology.org). (Reproduced with permission from Angela Walker, Vsevolod Katrich, and Raymond Stevens of the GPCR Network at the University of Southern California, as created in the Stevens lab by Yekaterina Kadyshevskaya.)

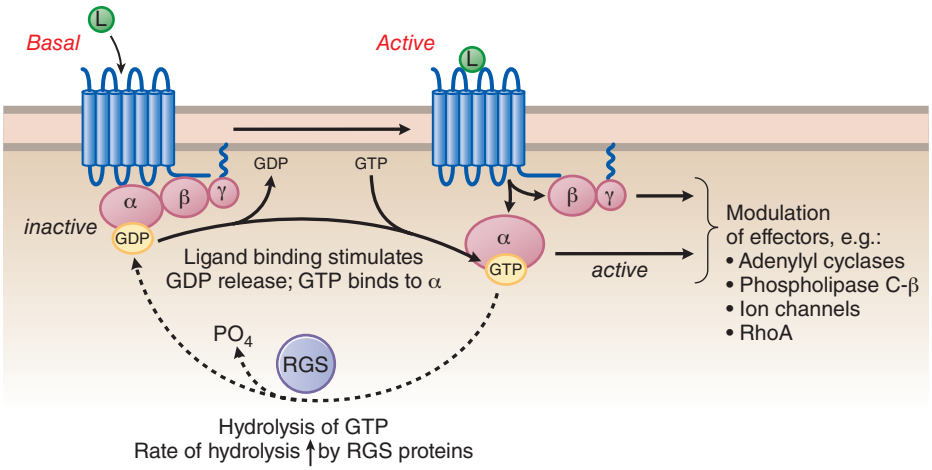

Figure 3–15 *The basic GPCR–G protein–effector pathway.* The GPCR and G protein heterotrimer, absent an activating ligand ("Basal"), are generally thought to form a complex in the cell surface membrane, in which GDP is bound to the Gα subunit. Following the binding of an activating ligand "L" to the receptor, the receptor and G protein α subunit undergo a conformational change leading to exchange of GDP for GTP and dissociation of both the complex and the G protein into monomeric Gα and heterodimeric Gβγ subunits. The activated GTP-bound Gα subunit and the Gβγ dimer bind to and regulate effectors individually or in coordination. The system returns to the basal state upon hydrolysis of the GTP by the α subunit, a reaction that can be markedly enhanced by regulator of G-protein signaling (RGS) proteins. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting them. The physical interaction between the inactive GPCR and G protein has been posited in the ternary complex model but has not been explicitly demonstrated for any but several GPCRs and G proteins. The βγ dimer is tethered to the membrane by a geranylgeranyl modification. Not shown are the lipid modifications for most α subunits, notably palmitoylation and myrisotylation.

The recruited arrestin also links to cytoskeletal elements, promoting internalization of the receptor for recycling to the membrane or lysosomal destruction. Some GPCRs, designated class A receptors, interact only transiently with arrestins (DeWire et al., 2007). Others, designated class B receptors, interact stably. A stable interaction is associated with a decreased rate of recycling to the cell surface.

Arrestins as Transducers. Quite importantly, while arrestins have the ability to displace G proteins from GPCRs, they serve as transducers in their own right (DeWire et al., 2007). The binding of an arrestin to an activated, phosphorylated GPCR induces a change in conformation of the arrestin. The "activated" arrestin can serve as a scaffold, an essential step in the activation of certain mitogen-activated protein kinases (MAPKs). Effectors for arrestins include the MAPKs (ERK1/2, JNK3, and p38), nonreceptor tyrosine kinases such as Src, certain members of the Ras superfamily of GTP-binding proteins (e.g., ARF6 and RhoA), and nuclear factor-κB (NF-κB). Arrestins that are stably bound to class B GPCRs can signal deep within the cytoplasm from endocytotic vesicles. Moreover, arrestins may signal within the nucleus, as both β-arrestin-1 and -2 contain nuclear localization signals.

The activation of G proteins and arrestins is often posited to occur sequentially, with G proteins preceding arrestins. Interactions of G proteins with effectors in this scenario would be constrained to the inner surface of the plasma membrane, and those of arrestins could extend more deeply into the cell, depending on the receptor. Yet, the signaling through G proteins by some GPCRs is sustained, and a variety of biophysical data for G_s-mediated signaling indicate that class B GPCRs, G proteins, and arrestins can exist as megacomplexes that persist at the level of endocytotic vesicles (Cahill et al., 2017; Thomsen et al., 2016). The link of arrestin to the GPCR in such a complex is through the C-terminal tail of the receptor alone, not the transmembrane core. The temporal and spatial import of GPCR signal transduction within subcellular compartments will almost certainly prove significant.

TABLE 3–2 ■ FAMILIES OF HETEROTRIMERIC G PROTEINS

FAMILY	A SUBUNITS
G_s	α_s (short and long forms) α_{olf}
G_i (or $G_{i/o}$)	α_{i1}, α_{i2}, α_{i3} α_{oA}, α_{oB} α_{t1}, α_{t2} α_g α_z
G_q	α_q α_{11}, α_{14}, α_{15}, α_{16}
G_{12} (or $G_{12/13}$)	α_{12}, α_{13}

G proteins that serve as transducers for GPCRs are αβγ heterotrimers. Many subtypes of α, β, and γ subunits exist; however, a G protein is typically defined by its α subunit. The G protein containing the α_{i1} subunit, for example, is G_{i1}. Based on primary structural homology among α subunits, G proteins sort into four families.

Biased Agonism. The two-state model of receptor activity is a convenient and useful simplification, but GPCRs can exist in a variety of active conformations, some of which may have the capacity to communicate differentially with downstream elements of transduction. *Biased agonism* refers to the property of an agonist to stabilize one conformation relative to another of a receptor and thus to set into motion a qualitatively distinct set of cellular events. The concept of biased agonism emerged first in the differential activation of G proteins, for example, G_i versus G_q and G_i versus G_{12}, depending on the agonist. Subsequently, differences between G protein and arrestin signaling were recognized (Smith et al., 2018), where certain agonists were found to stabilize conformations that signal through G proteins predominantly, while others stabilize conformations that signal through arrestins instead (Figure 3–17).

Carvedilol, for example, has long been classified as a β adrenergic receptor antagonist. However, in addition to antagonizing β receptor activation of G_s, the carvedilol-receptor complex also engages arrestin (Wisler et al., 2007). Thus, from the viewpoint of arrestin signaling, carvedilol is an agonist. Can the two pathways be manipulated separately? Can therapeutic and adverse effects be distinguished according to the pathway engaged? Drug discovery efforts are seeking to answer these questions, synthesizing putative *biased agonists*, especially targeting the GPCRs for *opioids* (Chapter 23), *dopamine* (Chapter 15), and *angiotensin* (Chapter 30).

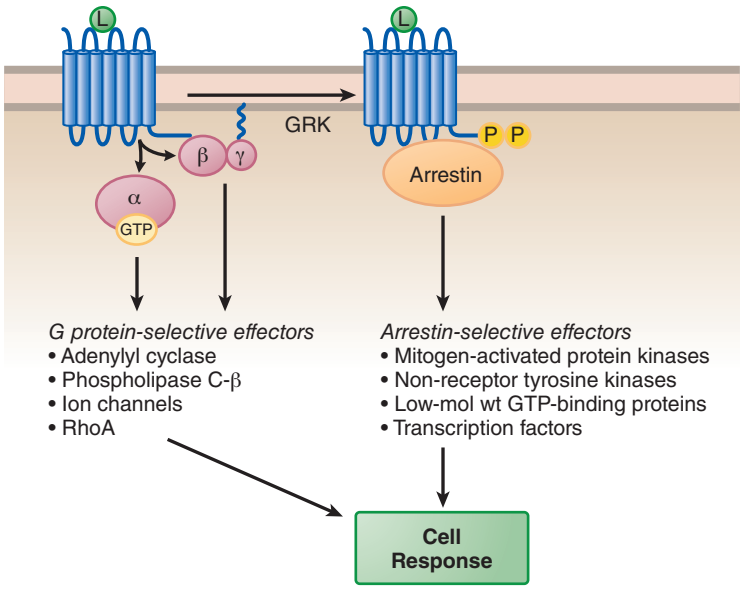

Figure 3–16 *Dual actions of arrestin.* Arrestins were initially characterized in the context of receptor desensitization related to G protein signaling. The recruitment of an arrestin requires phosphorylation of the GPCR by a GRK. The recruitment, and specifically the binding of arrestin to the GPCR "core," sterically hinders subsequent G protein activation. The recruitment also effects a change in the conformation of arrestin that is equated with an adaptor functionality and/or frank activation of signaling intermediates and thus downstream signaling in its own right. At an overt level, the signaling achieved by activation of G proteins at the outset integrates with the signaling achieved by arrestin subsequently. The temporal and subcellular (e.g., endosomal) aspects of signaling are not shown in this figure but are discussed in the text. Adapted from Lefkowitz and Shenoy (2005).

Consider the analgesic actions of opioids. One hypothesis being tested is that the analgesic actions of opioids through the μ opioid receptor are exerted through G proteins and that signaling via β-arrestin-2 mediates many of the adverse responses to opiates (e.g., respiratory depression, tolerance, dependence). A study of opiate action in β-arrestin-2 gene knockout [*βarr2(–/–)*] animals reported potentiation of morphine analgesia and reduction of side effects (Raehal et al., 2005). Development of the recently approved *oliceridine*, designed as a biased μ receptor agonist, is based on this premise (Markham, 2020). Some initial findings were promising, but subsequent data on several putatively biased agonists have not supported such a clean separation of antinociceptive and adverse effects (Gillis et al., 2020a) and have challenged the proposition that *oliceridine* provides increased separation of desired and adverse effects (see Chapter 23). In addition, other explanations of apparent bias (e.g., low intrinsic agonism and differential signal amplification in the G protein and arrestin pathways) have been offered and refuted (Azevedo Neto et al., 2020; Gillis et al., 2020b; Stahl and Bohn, 2021). Stay tuned. Biased agonists could offer advantages for a higher level of specificity in drug-induced signaling through GPCRs.

A distinction must be made between biased agonism, or *ligand bias*, as discussed here and *receptor bias* and *system bias* (Smith et al., 2018). Receptor bias is the predisposition of a receptor toward signaling through one G protein or another or through a G protein versus arrestin. Certain receptors signal through arrestin alone, and others can be made (through mutation) to signal only through G proteins. System bias is the difference among cells in expression of transducers, effectors, and downstream proteins, brought into sharp focus for systems in which the expression of a G protein relative to arrestin differs substantially. As always, but especially with the emergence of bias as a concept, it is important to remember that efficacy depends on the context in which it is evaluated.

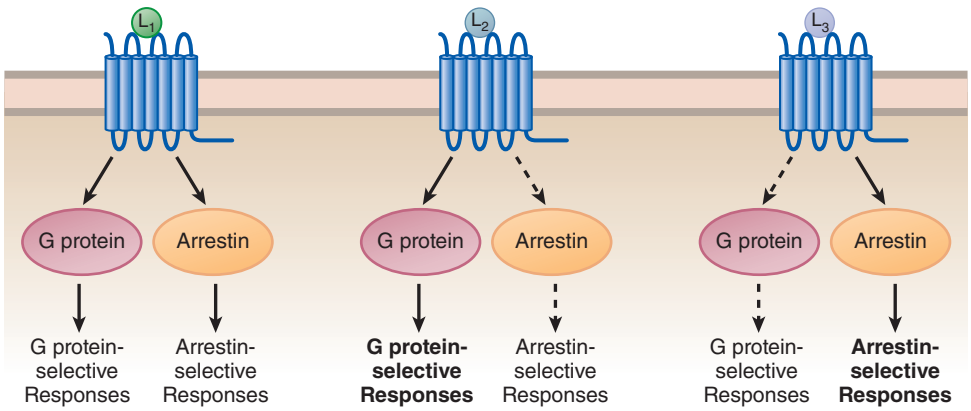

Figure 3–17 *Biased agonism.* One form of biased agonism is that relating to differential engagement of G proteins and arrestins. A single GPCR can assume any number of conformations (not expressly depicted) that are differentially stabilized by activating ligands. One or more of these conformations can translate into the engagement of both G protein and arrestin (*left*), the G protein selectively (*middle*), or arrestin selectively (*right*). In this sense, the ligand *biases*, or predisposes, the GPCR toward a particular screen of signaling. See the text for other forms of bias.

Proximal Forms of Signaling by GPCRs Through G Proteins. The second messengers regulated by GPCRs through G proteins include cyclic nucleotides, DAG, IP_3, and (through IP_3) Ca^{2+}. Also engaged as important forms of signaling are G protein-gated ion channels and the monomeric G protein RhoA.

Cyclic AMP. Cyclic AMP is synthesized by the enzyme AC, for which nine membrane-bound isoforms and one soluble isoform exist in mammals (Dessauer et al., 2017; Hanoune and Defer, 2001). All membrane-bound isoforms are activated by the α subunit of G_s. Inhibition of the activated enzyme by G_i is usually attributed to release of the βγ heterodimer and consequent sequestration of α_s; however, the heterodimer and α_i can have direct and idiosyncratic actions, depending on the isozyme of AC (Taussig et al., 1994). Cyclic AMP generated by ACs has two major targets in most cells: the cyclic AMP-dependent protein kinase (PKA) and the cyclic AMP-regulated GEFs termed EPACs (exchange proteins activated by cyclic AMP) (Cheng et al., 2008; Roscioni et al., 2008). The transcription factor CREB (cyclic AMP response element–binding protein) is activated via PKA phosphorylation and provides a link of cellular cyclic AMP transients to transcriptional regulation (Mayr and Montminy, 2001; Sands and Palmer, 2008). In cells with specialized functions, cyclic AMP can have additional targets, such as the cyclic nucleotide-gated (CNG) ion channels and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels (Wahl-Schott and Biel, 2009) and cyclic nucleotide-regulated PDEs. For an overview of cyclic nucleotide action and a historical perspective, see Beavo and Brunton (2002). A discussion of cyclic GMP is presented later (Guanylyl Cyclases).

PKA. The PKA holoenzyme consists of two catalytic (C) subunits reversibly bound to an inhibitory regulatory (R) subunit dimer to form a heterotetrameric complex (R_2C_2). In response to an increase in cellular cyclic AMP, four cyclic AMP molecules bind to the R_2C_2 complex, two to each R subunit, causing a conformational change in the R subunits that removes the inhibitory domain from the C subunit catalytic domain, resulting in their activation. The active C subunits phosphorylate serine and threonine residues on specific protein substrates. There are multiple isoforms of PKA; molecular cloning has revealed α and β isoforms of both the regulatory subunits (RI and RII), as well as three C subunit isoforms, Cα, Cβ, and Cγ. The R subunits exhibit different subcellular localization and binding affinities for cyclic AMP, giving rise to PKA holoenzymes with different thresholds for activation (Taylor et al., 2008). PKA function and specificity are also modulated by subcellular localization mediated by A-kinase anchoring proteins (AKAPs). Indeed, compartmentation of cyclic AMP signaling components (including components described below as well as GPCRs, ACs, phosphodiesterases, and protein phosphatases) within multiprotein nanometer scale *signalosomes* is now recognized as being essential for normal cell responses to cyclic AMP (Brunton et al., 1981; reviewed by Zaccolo et al., 2020).

EPAC. EPAC, also known as cyclic AMP-GEF, is a novel cyclic AMP–dependent signaling protein (Schmidt et al., 2013). EPAC serves as a cyclic AMP–regulated GEF for the family of small Ras GTPases (especially the Rap small GTPases), catalyzing the exchange of GTP for GDP, thereby activating the small GTPase. The two isoforms of EPAC, EPAC1 and EPAC2, differ in their architecture and tissue expression. Both EPAC isoforms are multidomain proteins that contain a regulatory cyclic AMP–binding domain, a catalytic domain, and domains that determine their intracellular localization. Compared to EPAC2, EPAC1 contains an additional N-terminal low-affinity cyclic AMP–binding domain. The expressions of EPAC1 and EPAC2 are differentially regulated during development and in a variety of disease states. EPAC2 can promote incretin-stimulated insulin secretion from pancreatic β cells through activation of Rap1 (see Figure 51–3). *Sulfonylureas*, oral drugs used to treat type 2 diabetes mellitus, may act in part by activating EPAC2 in β cells and increasing insulin release.

PDEs. Cyclic nucleotide phosphodiesterases (PDEs) hydrolyze the cyclic 3′,5′-phosphodiester bond in cyclic AMP and cyclic GMP, thereby terminating action of the cyclic nucleotide. The PDEs comprise a superfamily with more than 50 different proteins (Conti and Beavo, 2007). The substrate specificities of the different PDEs include those specific for cyclic AMP hydrolysis and for cyclic GMP hydrolysis and some that hydrolyze both cyclic nucleotides. The activities of PDEs are regulated via gene transcription as well as by cyclic nucleotides, Ca^{2+}-calmodulin, and interactions with other signaling proteins such as arrestins and protein kinases. Some PDEs are localized to specific signaling complexes via AKAPs and other scaffolding proteins. PDEs (mainly PDE3 isoforms) are drug targets for treatment of diseases such as asthma (Chapter 44), a variety of cardiovascular diseases (Chapters 31–33), and atopic dermatitis (Chapter 75), among others. PDE5 inhibitors (e.g., *sildenafil*) are used in treating chronic obstructive pulmonary disease (see Figures 44–4 and 44–5) and erectile dysfunction (see Figure 49–6).

DAG/IP_3/Ca^{2+}. The activation of GPCRs that are coupled to G_q (and occasionally to G_i) results in recruitment of an isoform of phospholipase C (PLC), PLCβ-2, to the plasma membrane. Activated PLC hydrolyzes a minor membrane phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP_2), to generate two intracellular signals, DAG and IP_3. DAG directly activates some members of the PKC family. IP_3 diffuses to the endoplasmic reticulum (ER), where it activates the IP_3 receptor in the ER membrane, causing release of stored Ca^{2+}. This raises Ca^{2+} levels in the cytoplasm manyfold within seconds and activates Ca^{2+}-dependent enzymes such as some of the PKCs and Ca^{2+}/calmodulin-sensitive enzymes such as PDE1 and a family of Ca^{2+}/calmodulin-sensitive PKs (e.g., phosphorylase kinase, MLCK, and CaM [calmodulin] kinases II and IV) (Hudmon and Schulman, 2002). The second messenger functions of Ca^{2+} cannot be understated. Ca^{2+} is integral to the regulation of diverse metabolic processes, secretion, contraction, gene expression, and electrical activity across the membrane.

G Protein-Gated Ion Channels. Of the several types of ion channels regulated directly by G proteins, the inwardly rectifying K^+ (K_{ir}) channels have risen to prominence. The subset of K_{ir} channels activated through GPCRs are homo- and heterotetrameric complexes of two-transmembrane helical subunits from the $K_{ir}3$ subfamily (Hibino et al., 2010) (Figure 3B). These subunits are expressed to varying extents in neurons, atrial myocytes, and endocrine cells, among other cells. The channels are activated by the βγ heterodimer released from G_i, perhaps through βγ-enhanced PIP_2 binding. The selectivity for G_i as opposed to other G proteins that likewise contain βγ is probably related to preformed complexes between the channels and the G_i heterotrimer.

K_{ir} channels help stabilize the resting potential of the cell-surface membrane. Because the resting membrane potential is generally positive to the K^+ equilibrium potential, the activated channel conducts net outward current and thereby hyperpolarizes the membrane, making cells less responsive to depolarizing stimuli. In neurons, the $K_{ir}3$ subunit–containing channels can be activated by acetylcholine, adenosine, dopamine, cannabinoids, GABA (through the $GABA_B$ receptor), serotonin, somatostatin, and opioids. Considerable attention has been devoted to the postsynaptic inhibition achieved by opioids through G protein-regulated K_{ir} channels in both central and peripheral neurons as a basis for the analgesic actions of these compounds. G protein-regulated K_{ir} channel signaling is associated with behavioral responses of various drugs of abuse, psychostimulants, and ethanol (Luján et al., 2014).

The decrease in heart rate by acetylcholine via the M_2 muscarinic cholinergic receptor is achieved in part through $K_{ir}3$ subunit–containing channels as well. These channels are an important component of the heart's response to parasympathetic tone. The $K_{ir}3$ subunit–containing channels in heart respond also to adenosine through adenosine A_1 receptors; adenosine is used therapeutically to rapidly halt supraventicular tachyarrhythmias (Chapter 34).

Members of the G_i family also regulate voltage-gated Ca^{2+} channels. The channels best studied in this context are those formed from Ca_V2 subunits, that is, the P/Q-, N-, and R-type channels, in contrast to L- and T-type channels (Proft and Weiss, 2015). The regulation is again achieved by the βγ heterodimer, which *inhibits* channel activity. The Ca_V2 subunit–containing neuronal channels are located presynaptically, and their

inhibition is manifest as an inhibition of neurotransmitter release. Opioids, for instance, not only repress neuronal activation through activation of inwardly rectifying K^+ channels but inhibit the release of neurotransmitters through inhibition of voltage-gated Ca^{2+} channels at the presynaptic terminal. Virtually all endogenous agonists and drugs operating through $G_{i/o}$-linked GPCRs within the CNS can achieve these molecular actions, with the precise neurological impact depending on the type and location of the neuron.

RhoA Activation. The activation of members of the $G_{12/13}$ family invariably links to the activation of RhoA, an important member of the Ras superfamily of low-molecular-weight (~21 kDa) monomeric G proteins. RhoA controls phenomena related to cell shape, migration, and contraction, accomplished largely through the Rho-associated protein kinase (ROCK). RhoA action through ROCK and other protein kinases also regulates the expression of numerous genes (Yu and Brown, 2015). The importance of RhoA to events of pharmacological interest is illustrated in the actions of angiotensin II (Ang II) on vascular smooth muscle cells in relation to hypertension, as discussed in Physiological Systems Must Integrate Multiple Signals. The activation of RhoA, together with events engaged by G_q and arrestin, is also implicated in the growth and proliferation of cardiomyocytes and vascular smooth muscle cells and in abnormalities that are associated with the progression of heart failure (Balakumar and Jagadeesh, 2014; Chapters 30 and 33). The activation of RhoA by thrombin is the basis for the shape change and activation of platelets in hemostasis. Inhibitors of ROCK are of interest in the treatment of pulmonary hypertension (Chapter 35), pathologies involving bronchoconstriction (Chapter 44), erectile dysfunction (Chapter 49), and elevated ocular pressure in patients with open-angle glaucoma or ocular hypertension (Chapter 74). *Netarsudil*, FDA approved for the treatment of these ocular disorders, is a first-in-kind inhibitor of ROCK for therapeutic use.

The $G_{12/13}$ family activates Rho via the interaction of the α subunit of G_{12} or G_{13} with one of several RhoA guanine nucleotide exchange factors (RhoGEFs), each containing a regulator of G protein signaling (RGS) domain. GEFs facilitate the exchange of GDP for GTP and, hence, activation of low-molecular-weight G proteins such as RhoA; RGS domains interact with activated heterotrimeric G protein α subunits to hasten GTP hydrolysis yet are often contained within proteins that have downstream signaling functionalities (Ross and Wilkie, 2000). In certain cells, the activation of RhoA can be achieved by G_i and G_q, also through RGS-containing RhoGEFs.

Ligand-Gated Ion Channels

Channels Gated by Excitatory and Inhibitory Neurotransmitters.

The principal ligand-gated ion channels in the nervous system are those activated by *excitatory* or *inhibitory neurotransmitters*. Those activated by excitatory neurotransmitters conduct Na^+ and K^+ nonspecifically, and sometimes Ca^{2+}, and include the cholinergic nicotinic receptors, glutaminergic receptors (AMPA [α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid], kainate, and NMDA [*N*-methyl-D-aspartate] subtypes), and certain purinergic and serotonergic receptors. Channels activated by inhibitory neurotransmitters conduct Cl^- and are the $GABA_A$ and glycine receptors. Activation of channels by excitatory and inhibitory neurotransmitters is responsible for the majority of events relevant to synaptic transmission by neurons both in the CNS and in the periphery. These ligand-gated ion channels are pentamers of distinct subunits, each a large protein with four transmembrane spans (Figure 3–18).

The nicotinic acetylcholine (ACh) receptor is an instructive example of an excitatory ligand-gated ion channel. Isoforms of this channel are expressed in the CNS, in autonomic ganglia, and at the neuromuscular junction. The channel is a pentamer that, in neurons, consists of two to five α subunits (drawn from among the α_2–α_{10} subtypes) and up to three β subunits (drawn from among the β_2–β_4 subtypes) and, at the neuromuscular junction, consists of two α_1, one β_1, one δ, and one γ (embryo) or one ε (adult) subunit. Each subunit of the receptor contains a large, extracellular N-terminal domain, four membrane-spanning helices (one of which helps to line the pore in the assembled complex), and an internal loop between helices 3 and 4 that forms the intracellular domain of the channel (see Figure 3–18). ACh binds at interfaces involving the α subunits (e.g., at α/α or α/β interfaces). The different compositions of the subunits account for the ability of competitive antagonists such as *rocuronium* to inhibit the receptor in the neuromuscular junction without effect on the ganglionic or CNS receptor. This property is exploited to provide muscle relaxation during surgery with minimal autonomic side effects (Chapter 13). The pore opening in the channel measures about 3 nm, whereas the diameter of a Na^+, K^+, or Ca^{2+} ion is only 0.3 nm or less, and for this reason, the channel does not possess the exquisite ion selectivity found in most voltage-activated channels. The passage of Na^+, K^+, and Ca^{2+} ions has the net effect of depolarization.

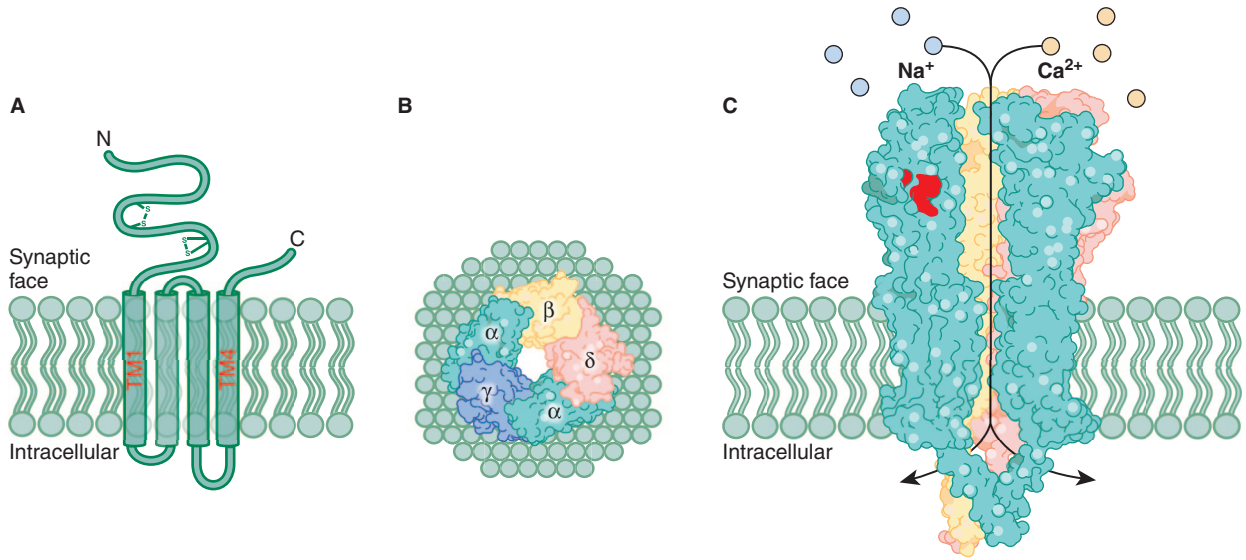

Figure 3–18 *Structure of the nicotinic acetylcholine receptor.* **A.** A schematic representation of a nicotinic ACh receptor subunit, one of the five that constitute the receptor pentamer. It depicts the four-transmembrane helical motif with the extracellular N- and C-terminal domains. **B.** The nicotinic receptor structure viewed from the perspective of the neuromuscular junction. Conductance is achieved through the central axis pore, defined by the pseudosymmetric arrangement of receptor subunits. **C.** Longitudinal view of the same receptor as recently determined by electron microscopy, with the γ subunit removed; the depolarizing ions alone (Na^+ and Ca^{2+}) are shown. See Chapter 3 for further details.

The pentameric $GABA_A$ receptor containing α, β, and γ subunits conducts Cl^- when activated by GABA. With an equilibrium potential for Cl^- around –65 mV, the activation of the receptor does not generally cause membrane hyperpolarization but does impede generation and propagation of action potentials. The $GABA_A$ receptor is a target for *benzodiazepines* and *barbiturates*, among many other drugs. The multiplicity of isoforms of each of the constituent subunits of these pentameric ion channels accounts for the distinct pharmacology of these receptors.

Channels Gated by Intracellular Ligands. There is a category of ion channels activated by *intracellular* ligands: the IP_3-sensitive Ca^{2+} channel responsible for release of Ca^{2+} from the ER; cyclic nucleotide-gated ion channels responsible for nonselective cation conductance; and the sulfonylurea "receptor" (SUR1) that associates with the $K_{ir}6.2$ channel to regulate the ATP-gated K^+ current in pancreatic β cells. This latter channel, or K_{ATP} channel, is the target of oral hypoglycemic drugs such as *sulfonylureas* and *meglitinides* that stimulate insulin release from pancreatic β cells and are used to treat type 2 diabetes (see Chapter 51).

Transient Receptor Potential Channels. Transient receptor potential (TRP) cation channels are involved in a variety of sensory processes, including nociception, heat and cold sensation, mechanosensation, and perception of chemicals such as capsaicin and menthol. The superfamily consists of 28 channels in six families (Moran, 2018). Most TRP channels are homotetramers, with each monomer consisting of six transmembrane helices (S1–S6) with a pore-forming loop between S5 and S6 and large intracellular regions at the intracellular amino and carboxyl termini. TRP channels are relatively nonselective with regard to the conductance of cations, generally conducting Na^+ and Ca^{2+} and sometimes Mg^{2+}. Two scientists who have done seminal work on TRP channels, David Julius and Ardem Patapoutian, shared the 2021 Nobel Prize in Physiology/Medicine "for their discoveries of receptors for temperature and touch" (Latorre and Diaz-Franulic, 2021).

Pharmacological agents are under development to treat heritable diseases associated with TRP channel mutations and to treat pain, itching, and skin and respiratory disorders (Bamps et al., 2021). Formulations of *capsaicin*, an agonist for the TRPV1 receptor, are available for certain forms of pain relief, including that associated with postherpetic neuralgia.

Enzyme-Linked (Catalytic) Receptors

Receptor Tyrosine Kinases. The receptor tyrosine kinases include receptors for hormones such as insulin; growth factors such epidermal growth factor (EGF), platelet-derived growth factor (PDGF), nerve growth factor (NGF), fibroblast growth factor (FGF), and VEGF; and ephrins. With the exception of the insulin receptor, consisting of α and β polypeptide chains (see Chapter 51), these receptors are single polypeptide chains. Each has a large, cysteine-rich extracellular domain, a short transmembrane segment, and an intracellular region containing one or two protein tyrosine kinase domains. Activation of growth factor receptors generally supports cell survival, cell proliferation, and differentiation. Activation of the ephrin receptors supports neuronal angiogenesis, axonal migration, and guidance.

Ligand binding induces dimerization of the receptor and cross-phosphorylation of tyrosine residues within the now proximal intracellular regions, notably in the kinase domains themselves to enhance activity but also in stretches beyond these domains. Phosphotyrosine residues constitute docking sites on the receptor for proteins containing SH2 and PTB domains. Over 100 such proteins, namely enzymes and adaptors, are encoded in the human genome.

Recruited enzymes are often phosphorylated and activated in turn. These include PLCγ, the activity of which raises intracellular levels of Ca^{2+} and activates PKC, and the α and β isoforms of phosphatidylinositol 3-kinase (PI3K). PI3K binds directly to the phosphorylated receptor by means of SH2 domains or indirectly via insulin receptor substrate-1 (IRS-1), is activated, and increases the level of phosphatidylinositol 3,4,5-trisphosphate (PIP_3) with consequent activation of PKB (also known as Akt). PI3K can also be activated directly by the monomeric GTP-binding protein Ras. PKB can regulate mTOR (mechanistic/mammalian target of rapamycin), which is upstream of various signaling pathways (Figure 3–19A, also see Autophagy below) and the *Bad* protein that is important in apoptosis (Figure 3–25; also see section on Apoptosis below).

Adaptors are proteins without enzymic activity that serve accessory functions, often those of placing potentially interacting proteins in close proximity to each other. Grb2, for example, is an adaptor prebound to Sos, a GEF that can activate Ras (Figure 3–19B). Activation of Ras leads in turn to activation of a protein kinase cascade termed the Ras-MAPK pathway. Activation of the MAPK pathway is one of the major routes used by growth factor receptors to signal to the nucleus and stimulate cell growth. Oncogenic mutations that result in constitutively activated growth factor receptors and Ras can also activate the MAPK pathway and drive tumor proliferation. Anticancer agents that target the MAPK pathway and the protein tyrosine kinase activity of oncogenic growth factors are now important agents in treating several forms of cancer (see Chapter 69 and 71).

Receptor Serine-Threonine Kinases. The transforming growth factor β (TGF-β) family of ligands, which include different forms of TGF-β and bone morphogenic proteins (BMPs), activate receptors that are analogous to receptor tyrosine kinases but have a serine-threonine kinase functionality. The ligands bind and stabilize a heteromeric complex of two type I and two type II cell-surface receptors. Humans express seven type I and five type II receptors, which are engaged differentially by TGF-β family members (Derynck and Budi, 2019). Ligand-induced changes in conformation and/or proximity allow the type II receptors to phosphorylate the type I receptors at serine and threonine residues and activate downstream signaling via SMADs (Figure 3–20). Drugs that inhibit TGF-β ligand signaling are under development and are of particular interest in the therapy of cancer and fibrosis.

Guanylyl Cyclases. The synthesis of intracellular cyclic GMP in cells is achieved either through ligand-activated cell-surface receptors with intrinsic guanylyl cyclase (GC) activity or through soluble GC (sGC) (Figure 3–21). The cell-surface receptors are those for natriuretic peptides; sGC is responsive to NO. The downstream effects of cyclic GMP are carried out by multiple isoforms of PKG, cyclic GMP–gated ion channels, and cyclic GMP–modulated PDEs that degrade cyclic AMP.

Transmembrane Receptors With Intrinsic GC Activity. Natriuretic peptides are small peptide ligands released from cells in cardiac tissues, the vascular system, and certain other tissues. The peptides are: (1) atrial natriuretic peptide (ANP), released from atrial storage granules following expansion of intravascular volume or stimulation with pressor hormones; (2) brain natriuretic peptide (BNP), synthesized and released in large amounts from ventricular tissue in response to volume overload; and (3) C-type natriuretic peptide (CNP), synthesized in the brain, endothelial cells, and chondrocytes and released in response to growth factors and sheer stress on vascular endothelial cells (Potter et al., 2009). The major physiological effects of these hormones are to decrease blood pressure (ANP, BNP), to reduce cardiac hypertrophy and fibrosis (BNP), and to stimulate long-bone growth (CNP). The receptors for the natriuretic peptides are natriuretic peptide receptor (NPR)-A, which responds to ANP and BNP, and NPR-B, which responds to CNP. NPR-C is thought to function as a clearance receptor, removing excess natriuretic peptide from the circulation. Chapter 29 has an extensive discussion of the effects of the natriuretic peptides and of the pathways involved. *Nesiritide*, a synthetic BNP agonist, and *sacubitril*, an inhibitor of an enzyme (neprilysin) that degrades ANP and BNP, are used in the treatment of heart failure.

sGC, a Cytosolic Receptor/Enzyme That Responds to a Membrane-Permeable Paracrine Factor, NO. NO is produced locally in cells by *nitric oxide synthase* (NOS). There are three forms of NOS: neuronal NOS (nNOS or NOS1), endothelial NOS (eNOS or NOS3), and inducible NOS (iNOS or NOS2). All three forms are widely expressed but are especially important in the cardiovascular system, where they are found in myocytes, vascular smooth muscle cells, endothelial cells, hematopoietic cells, and platelets. Elevated cell Ca^{2+}, acting via CaM, markedly activates nNOS and eNOS; the inducible form (iNOS) is less sensitive to Ca^{2+}, but its synthesis can be induced many fold by inflammatory stimuli such as endotoxin, TNF-α, interleukin (IL)-1β, and interferon (IFN) γ.

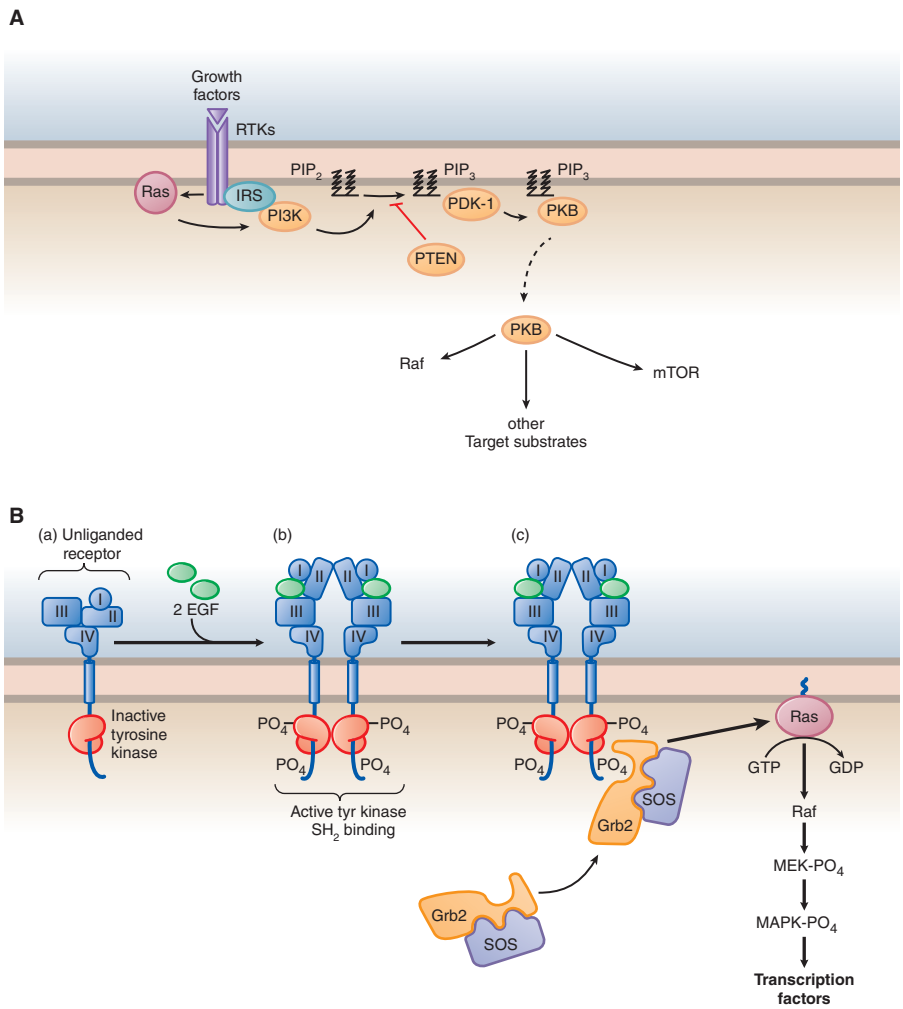

Figure 3–19 *Two events downstream of receptor tyrosine kinases.* **A.** *Activation of the mTOR pathway.* Signaling via this pathway promotes growth, proliferation, and survival of cells via a complex web of signaling pathways (see Guri and Hall, 2016). mTOR signaling is emerging as a major consideration in immunosuppression and cancer pharmacotherapy, and inhibitors of mTOR signaling are sometimes included as adjunct therapy. **B.** *Activation of the EGF receptor.* The extracellular structure of the unliganded receptor (a) contains four domains (I–IV), which rearrange significantly on binding two EGF molecules. In (b), the conformational changes lead to activation of the cytoplasmic tyrosine kinase domains and tyrosine phosphorylation of intracellular regions to form SH2-binding sites. (c) The adaptor molecule Grb2 bound to Sos via two so-called SH3 domains binds to the phosphorylated tyrosine residues and activates the Ras-MAPK cascade. Ras is attached to the inner surface of the plasma membrane normally by a farnesyl moiety. Translocation of Sos to the inner surface of the membrane occurs by the binding of Grb2 to an activated receptor through an SH2 domain. The translocation places Sos in proximity to the membrane-bound Ras and thus supports activation of Ras.

NOS produces NO by catalyzing the oxidation of the guanido nitrogen of L-arginine, producing L-citrulline and NO. NO activates sGC, which is an αβ heterodimer that contains a protoporphyrin-IX heme domain. NO binds to the heme domain at low nanomolar concentrations and produces a 200- to 400-fold increase in the V_{max} of the enzyme, leading to an elevation of cellular cyclic GMP (Murad, 2006).

In vascular smooth muscle, activation of PKG leads to vasodilation by inhibiting IP_3-mediated Ca^{2+} release from intracellular stores; phosphorylating voltage-gated Ca^{2+} channels to inhibit Ca^{2+} influx; phosphorylating phospholamban, a modulator of the sarcoplasmic Ca^{2+} pump, leading to a more rapid reuptake of Ca^{2+} into intracellular stores; phosphorylating and opening the Ca^{2+}-activated K^+ channel, leading to hyperpolarization of the cell membrane, which closes L-type Ca^{2+} channels and reduces the flux of Ca^{2+} into the cell; phosphorylating and thereby inhibiting myosin light chain kinase; and phosphorylating and thereby activating myosin light chain phosphatase.

Drugs that activate sGC are the organic nitrates (*nitroglycerin*, *isosorbide dinitrate*, and *isosorbide-5-monitrate*), which produce NO, and inhaled NO gas, all of which are used in the treatment of stable angina (Chapter 31). NO is also used as a tocolytic agent (Chapter 48) and in the treatment of term and near-term neonates with persistent pulmonary hypertension and acute hypoxemic respiratory failure (Chapter 35). The recently approved drugs *riociguat* and *vericiguat* are used as well in the treatment of pulmonary hypertension (Chapter 35); *riociguat* sensitizes sGC to endogenous NO and also stimulates the enzyme directly.

The counterpart to activation of sGC is the inhibition of cyclic GMP–selective PDE (i.e., PDE5). The inhibition is accomplished by the drugs *sildenafil*, *vardenafil*, *tadalafil*, and *avanafil*. PDE5 inhibitors are used in the treatment of erectile dysfunction (Chapter 49) and pulmonary hypertension (Chapter 35).

Other Cell-Surface Membrane Receptors

JAK-STAT Receptor Pathway. Cytokines (interleukins, interferons, erythropoietin, and colony-stimulating factors) and certain hormones (e.g., growth hormone and prolactin) signal to transcriptional elements via *signal transducers and activators of transcription*, or STATs. Most of the receptors, although not all, are multi-subunit complexes consisting of separate ligand-binding and signal-transducing subunits. The receptors have no intrinsic enzymatic activity; rather, each is associated with a distinct intracellular tyrosine kinase termed a *Janus kinase*, or JAK (Figure 3–22A). Receptor dimerization or oligomerization induced by a

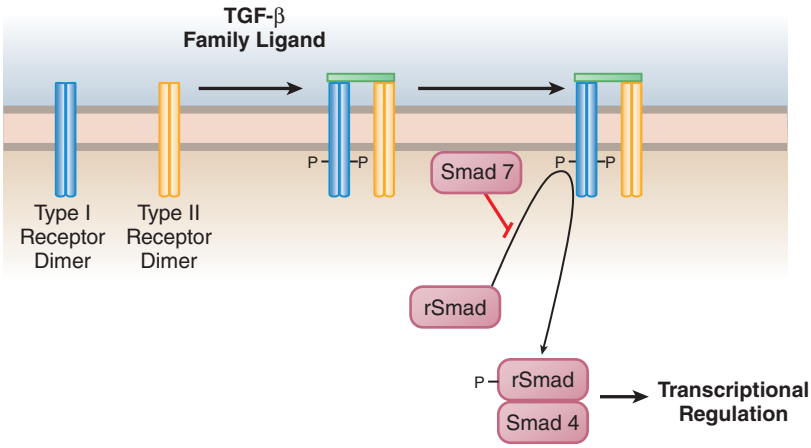

Figure 3–20 *Signaling through type I and type II heteromeric receptors by TGF-ß family members.* TGF-β ligands stabilize a heteromeric receptor structure consisting of two type I and two type II receptors. The type II receptors then catalyze phosphorylation of the type I receptors on serine residues, permitting them to interact with and phosphorylate, again on serine residues, any number of "receptor-activated" Smads (rSmads). Phosphorylated rSmads bind Smad4, an effector Smad, to subsequently translocate to the nucleus where they regulate transcriptional events. Smad7 (and Smad6) are inhibitory Smads. Variations and dynamics of type I and type II receptor association, posttranslational modifications relevant to their stability, non-Smad signaling through these receptors, and the use by TGF-β–like ligands of alternate receptors are reviewed by Derynck and Budi (2019).

ligand brings at least two JAKs into close proximity, resulting in their transphosphorylation and the phosphorylation of the cytoplasmic tails of the receptors. STATs are recruited to the receptors via their SH2 domains and phosphorylated in turn by the JAKs. Phosphorylated STATs translocate as dimers to the nucleus to directly regulate transcription. The entire pathway is termed the JAK-STAT pathway. There are four JAKs and seven STATs in mammals that, depending on the cell type and signal, combine differentially to regulate gene transcription.

A variety of cytokines employing JAK-STAT pathways are used clinically, including *aldesleukin* (a recombinant IL-2) in metastatic renal cell cancer and metastatic melanoma (Chapter 72), *pegylated IFN-α* in viral hepatitis (Chapter 63), *sargramostim* (a recombinant granulocyte-macrophage colony-stimulating factor) to stimulate myelopoiesis, *oprelvekin* (a recombinant IL-11) to stimulate megakaryocyte maturation, and recombinant forms of *erythropoietin* to stimulate red blood cell production (Chapter 45). Receptor antagonists include *dupilumab* (IL-4

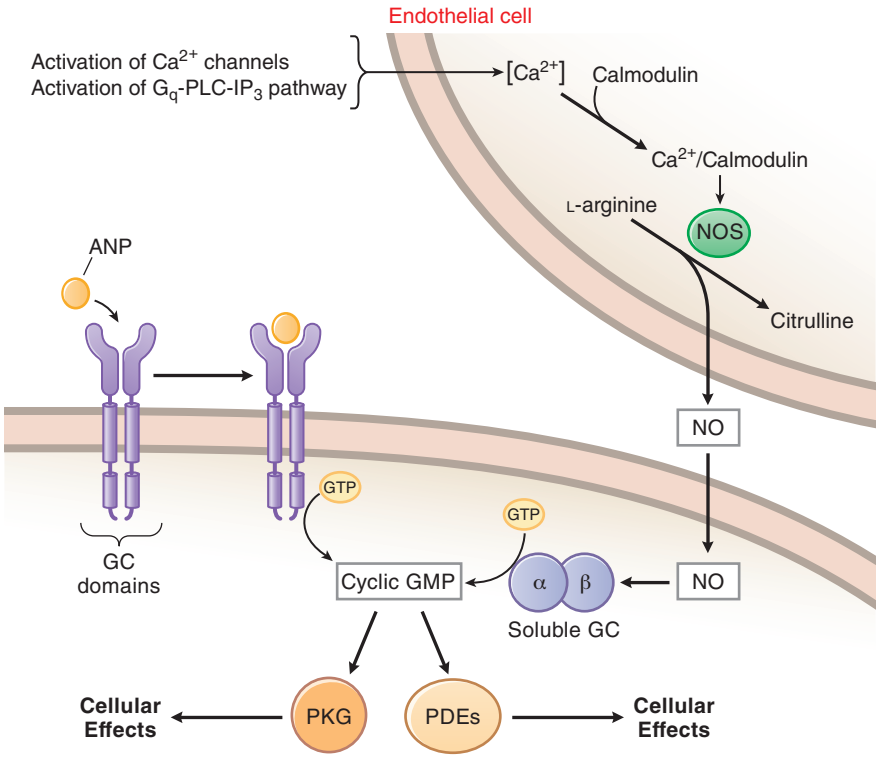

Figure 3–21 *Cyclic GMP signaling pathways.* Formation of cyclic GMP is regulated by cell-surface receptors with intrinsic GC activity and by soluble forms of GC. The cell-surface receptors respond to natriuretic peptides such as ANP with an increase in cyclic GMP. sGC responds to NO generated from L-arginine by NOS. Cellular effects of cyclic GMP are carried out by PKG and cyclic GMP–regulated PDEs. In this diagram, NO is produced by a Ca^{2+}/calmodulin–dependent NOS in an adjacent endothelial cell. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

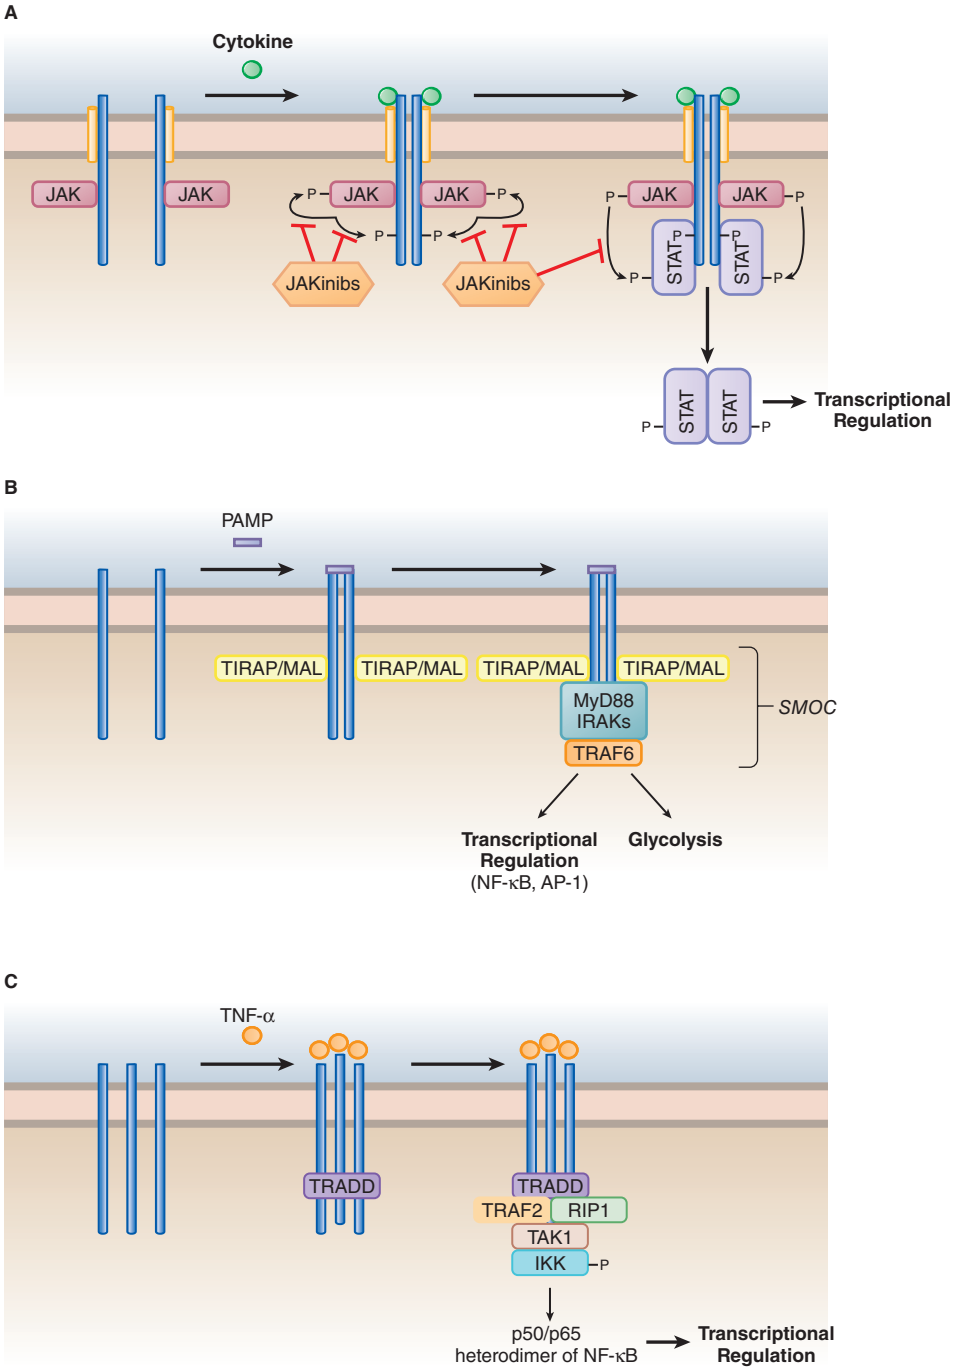

Figure 3–22 *Signaling by several other cell-surface membrane receptors.* **A.** *Cytokine signaling through JAK/STAT.* Cytokine-induced dimerization of cytokine receptors (highly schematized) results in cross-phosphorylation and activation of associated JAKs. These tyrosine kinases in turn phosphorylate the receptor, leading to recruitment of STATs via their SH2 domains and phosphorylation of them as well. The phosphorylation promotes STAT dimerization. The phosphorylated, dimerized STATs translocate to the nucleus to act directly as transcription factors. Orally effective JAK inhibitors, JAKinibs, are now available as immunomodulators (see text). **B.** *Signaling by toll-like receptors.* PAMP-induced dimerization of a TLR, here at the cell-surface membrane, attracts TIRAP/MAL to the dimerized cytosolic TIR domains of the receptor. TIRAP/MAL engages multiple copies of MyD88 (myeloid differentiation protein 88) and the serine kinases of the IRAK (interleukin-1 receptor–associated kinase) family, which recruit the E3 ubiquitin lyase TNF receptor–associated factor (TRAF) 6. TRAF6 sets into motion events resulting in activation of NF-κB and AP-1 and glycolysis, among other events depending on the cell. SMOC refers to the aggregate of these proteins as the supramolecular organizing center. Other SMOCs exist depending on the identity and subcellular location of the TLR. **C.** *Signaling by TNF-α through TNFR1.* The signaling shown is that relevant to activation of NF-κB; other activities exist. The signaling begins with the formation of TNFR1 homotrimers stabilized by TNF-α (here, the soluble form). Activated TNFR1 recruits the TNFR type 1 death-associated protein (TRADD), which in turn recruits the receptor interacting protein-1 (RIP1) kinase and TRAF2. RIP1 and TRAF2 achieve activation of NF-κB by promoting phosphorylation via TGF-β–activated kinase-1 (TAK1), causing ubiquitin-dependent degradation of the inhibitor of NF-κB, IKK (IκB kinase), allowing the p50/p65 heterodimer to translocate to the nucleus and activate the transcription of inflammatory genes. Activated TNFR2 (not shown) recruits TRAF2 directly, among other proteins. TRAF2 also results in activation of the kinase JNK, relevant to the activation of the transcription factors c-Jun, AP-1, and ATF-2. Signaling by TNF-α through the two receptors is reviewed by Wajant and Siegmund (2019).

receptor) for atopic dermatitis, *ustekinumab* (IL-12 and IL-13 receptors) for plaque psoriasis and psoriatic arthritis (Chapter 75), and *pegvisomant* (pegylated recombinant growth hormone receptor) in the treatment of growth hormone excess (Chapter 46). A number of inhibitors of JAKs, referred to as *JAKinibs*, inhibit ATP binding to the JAK catalytic domain and are employed as immunomodulators (Chapter 39), especially in the treatment of ulcerative colitis (Chapter 55), psoriasis (Chapter 75), and myelofibrosis, polycythemia vera, and graft-versus-host disease (Chapter 71).

Toll-Like Receptors. Signaling related to the innate immune system is carried out in part by a family of 10 single membrane-spanning *toll-like receptors* (TLRs). These receptors are highly expressed in macrophages, monocytes, dendritic cells, and natural killer cells (Chapter 38). TLRs contain a large extracellular ligand-binding domain and a cytoplasmic region devoid of intrinsic enzymatic activity but containing a "TIR" domain that mediates protein/protein interactions.

Ligands for TLRs represent conserved microbial products often referred to as *pathogen-associated molecular patterns* (PAMPs), which include lipopolysaccharide, bacterial lipoproteins, single- and double-stranded RNA, unmethylated CpG-containing single-stranded DNA, and bacterial ribosomal DNA. TLRs that detect nucleic acids are expressed in endosomes; the others are present at the cell surface. Activation of TLRs produces an inflammatory response to the pathogens consisting principally of the production of inflammatory cytokines via enhanced gene transcription and a variety of cell-specific changes.

The first step in the activation of TLRs by ligands is dimerization of the receptors as either homo- or heterodimers (Figure 3–22B). The dimerization recruits adaptor proteins that, in turn, instigate assembly of a supramolecular organizing center. Scaffolded proteins include protein kinases relevant to the activation of the transcription factors NF-κB, activator protein-1 (AP-1), and IRF-3, and of glycolysis (Fitzgerald and Kagan, 2020).

Agonists for TLRs, especially for TLR3, TLR7, TLR8, and TLR9, have generated interest as immunomodifiers in cancer chemotherapy, as adjuvants in vaccines utilizing specific tumor agonists, and, tentatively, as viral prophylaxis (Vanpouille-Box et al., 2019). *Imiquimod* is a TLR7 agonist approved for the treatment of actinic keratosis, superficial basal cell carcinoma, and genital and anal warts. Recombinant herpes zoster virus and hepatitis B virus vaccines are formulated with TLR4 and TLR9 agonists, respectively. Antagonists for the TLRs are being investigated for the treatment of autoimmune diseases.

TNF-α Receptors. There are two primary TNF-α receptors (TNFRs), TNFR1 and TNFR2, both single-spanning membrane proteins. TNFR1 is the more widely expressed and is responsible for TNF-induced apoptosis (see Apoptosis below); however, signaling is more relevant to the production of inflammatory cytokines, principally through activation of the transcription factor NF-κB. Figure 3–22C summarizes signaling through TNFR1 to NF-κB. Humanized monoclonal antibodies to TNF-α itself, such as *infliximab* and *adalimumab*, are important in the treatment of rheumatoid arthritis and Crohn's disease.

Nuclear Hormone Receptors

Nuclear hormone receptors in humans constitute a superfamily of 48 receptors that respond to ligands capable of traversing the cell-surface membrane. The *steroid receptors* (family 3; Table 3–3) are a subset that comprise those for androgens, estrogens, glucocorticoids, mineralocorticoids, and progesterone. Other subsets, in which receptors show the capacity to form heterodimers with retinoid X receptors (RXRs) (families 1 and 2), are receptors for lipid metabolites, xenobiotics, vitamin D, and thyroid hormones. Included in these families are the receptors that mediate induction of drug-metabolizing enzymes such as CYP3A4 (see Figure 5–13). Receptors from yet other subsets serve uncertain functions, some apparently in a ligand-independent manner (Evans and Mangelsdorf, 2014). Isoforms of virtually all the receptors are generated by means of alternate transcriptional or translational start sites and differential RNA splicing.

Nuclear hormone receptors consist of five or six domains, denoted A through F, based on regions of conserved sequence and function (Figure 3–23A). The N-terminal A/B domain contains a *transcriptional activation region* (AF-1). This region is poorly conserved among receptors and is often portrayed to be autonomous. However, it can be controlled by ligands, depending on the receptor, and is a target for posttranslational modification. Domain C is the *DNA-binding domain*. This domain is highly conserved among receptors apart from elements that contribute to *hormone response element* (HRE) specificity (see below). Domain D is the hinge region between the DNA-binding domain, and domain E, the *ligand-binding domain*, has many functions. Beyond presenting a binding site for the ligand, domain E plays a role in receptor dimerization and provides surfaces for the binding of coactivators and corepressors. It also contains a ligand-dependent transcriptional activation region (AF-2). Domain F, if present, can serve as a site for posttranslational modification.

Steroid receptors exist as monomers in the absence of agonist. The monomers exist in the cytosol, complexed with chaperone proteins, although some may exist as well in the nucleus (Chapters 48 and 50). Upon binding agonist, the receptors form homodimers, with those in the cytosol translocating to the nucleus. The activated homodimers bind HREs, which are in this instance two inverted six-nucleotide repeats separated by three nucleotides and are specific for the identity of the homodimer. Activated homodimers associate at the same time with *coactivators*, a diverse group of proteins responsible for chromatin remodeling and posttranslational modifications of the general transcriptional machinery, in order to facilitate transcription. Mechanisms of action may exist beyond the genomic level for several of the steroid receptors. In the case of the estrogen receptor, a small fraction of the receptor associates with the plasma membrane and, together with a GPCR (GPER/GPR30), may mediate the relatively rapid actions of estrogen.

Receptors that can bind RXR exist in the nucleus as homo- or heterodimers (with RXR) regardless of agonist. Those that can function either as homodimers or as heterodimers with RXR include the RXRs themselves, thyroid receptors, vitamin D receptors, and retinoic acid receptors (RARs). Those that require heterodimerization with RXR are peroxisome proliferator-activated receptors (PPARs), liver X receptor (LXR), farnesoid X receptor (FXR), pregnane X receptor (PXR), and constitutive androstane receptor (CAR). The dimeric receptors bind two six-nucleotide "half-sites" in tandem, the sequence and spacing depending on the dimer. Some of the receptors in the absence of agonist exist in association with corepressors to keep the DNA tightly packed and otherwise inhibit transcription (Figure 3–23B). Agonists for the heterodimers promote exchange of bound corepressors for coactivators. Some RXR heterodimers are *permissive*, that is, they can be activated by ligands for either RXR or the partner nuclear receptor; others are *nonpermissive*, being activated only by the ligand for the partner nuclear receptor (Evans and Mangelsdorf, 2014).

An agonist-bound nuclear hormone receptor often activates a large number of genes to carry out a program of cellular differentiation or metabolic regulation. The activity of a receptor in a given cell depends not only on the ligand but also on the ratio of coactivators and corepressors recruited to the complex. *Selective estrogen receptor modulators* (SERMs) such as *tamoxifen* and *raloxifene* (Chapter 48) are thought to recruit either coactivators or corepressors depending on the cell.

The means by which agonists for nuclear receptors, particularly those for glucocorticoids, exert anti-inflammatory actions involves considerable complexity beyond the traditional gene activation paradigm (Hardy et al., 2020). Featuring prominently are mechanisms of *transrepression* that undercut the actions of NF-κB and AP-1. Transrepression can include competition between dimeric nuclear receptors and NF-κB and AP-1 for coactivators, enhanced expression of proteins by the dimeric receptors that interfere with the activation of such transcription factors, and binding of the dimeric receptors to *negative response elements* (i.e., inhibiting in some fashion gene expression directly).

TABLE 3–3 ■ NUCLEAR HORMONE RECEPTORS[a]

FAMILY[b]	RECEPTORS	PHYSIOLOGICAL LIGANDS	EXAMPLES OF THERAPEUTIC AGENTS[c]
1A	Thyroid hormone receptors: THR-α and THR-β	Thyroxine (T_4) and thyroid hormone	Levothyroxine, liothyronine
1B	Retinoic acid receptors: RAR_α, RAR_β, and RAR_γ	Vitamin A–derived tretinoin and alitretinoin	Tretinoin, tazarotene, adapalene ($RAR_{\beta,\gamma}$), alitretinoin, etretinate, acitretin
1C	Peroxisome proliferator-activated receptors: $PPAR_\alpha$, $PPAR_{\beta/\delta}$, and $PPAR_\gamma$	Leukotriene B ($PPAR_\alpha$), 15-Deoxy-$\Delta^{12,14}$-PGJ_2 ($PPAR_\gamma$), many fatty acids and eicosanoids, among others	Fibrates ($PPAR_\alpha$), thiazolidinediones ($PPAR_\gamma$)
1H	Liver X receptor-like receptors: liver X receptor (LXR) and farnesoid X receptor (FXR)	Hydroxycholesterols (LXR), bile acids (FXR)	Obeticholic acid (FXR)
1I	Vitamin D receptors (VDR), pregnane X receptor (PXR), and constitutive androstane receptor (CAR)	Vitamin D (VDR), 17β-estradiol (PXR), and a wide range of exogenous compounds (PXR and CAR)	Calcitriol (VDR), calcipotriene (VDR) Note: PXR and CAR are activated by a wide variety of drugs in the context of inducing CYPs, phase 2 enzymes, and drug transporters.
2B	Retinoid X receptors: RXR_α, RXR_β, and RXR_γ	Vitamin A–derived alitretinoin	Bexarotene, alitretinoin
3A	Estrogen receptors: ER_α and ER_β	Estriol (ERα), estrone (ERα)	Estrogens; selective estrogen receptor modulators (SERMs) tamoxifen, raloxifene, and toremifene
3C	3-Ketosteroid receptors: androgen receptor (AR), glucocorticoid receptor (GR), mineralocorticoid receptor (MR), and progesterone receptor (PR)	Dihydrotestosterone and testosterone (AR), cortisol and corticosterone (GR), aldosterone (MR), progesterone (PR)	Testosterone esters (AR), and the antagonists flutamide, bicalutamide, nilutamide, and enzalutamide (AR); hydrocortisone, prednisone, and dexamethasone (GR); the antagonists spironolactone and eplerenone (MR); progesterone, progesterone esters, and 19-nor steroids (PR)

[a]Listed are receptors known to be activated by physiological ligands, with the exception of CAR, which is included by virtue of its importance (together with that of PXR) to the handling of xenobiotics.
[b]The nomenclature regarding families and physiological ligands is taken from Alexander et al., 2019.
[c]Listed are examples of agents whose therapeutic actions are mediated by one or more members of the noted family, unless otherwise specified. If specific for a specific member of the family, this is noted parenthetically.

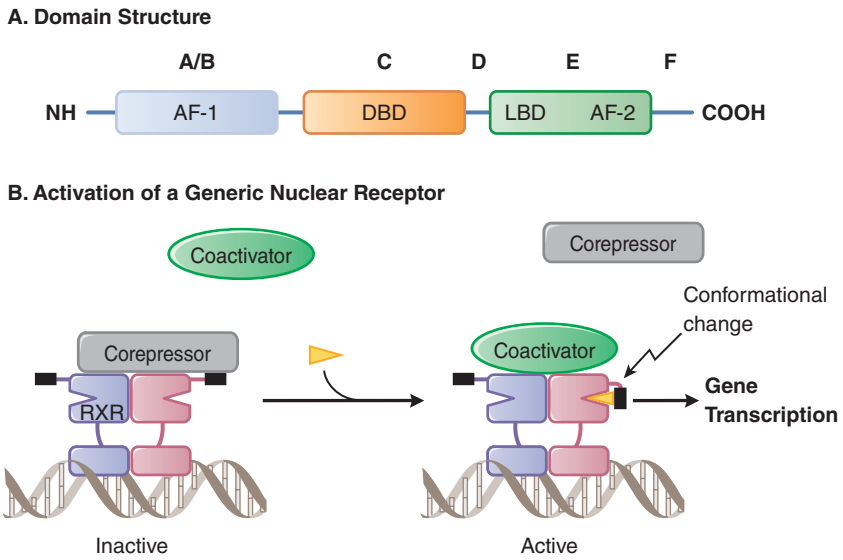

Figure 3–23 *Structure and activation of a nuclear hormone receptor.* **A.** The domain structure of a nuclear hormone receptor (after Moore et al., 2006). The functions of domains A through F are described in the text. **B.** A generic nuclear hormone receptor is shown as a dimer with an RXR. When an agonist (yellow triangle) and coactivator bind, a conformational change occurs in helix 12 (black bar), and gene transcription is stimulated.

Diseases Resulting From Receptor and Pathway Dysfunction

Alteration in receptors and their downstream signaling pathways can be the cause of disease. The loss of a receptor in a highly specialized signaling system may cause a phenotypic disorder (e.g., deficiency of the androgen receptor and testicular feminization syndrome; see Chapter 49). Deficiencies in widely employed signaling pathways have broad effects, as are seen in myasthenia gravis (due to autoimmune disruption of nicotinic cholinergic receptor function; Chapter 13) and in some forms of insulin-resistant diabetes mellitus (as a result of autoimmune depletion of insulin-producing cells and interference with insulin receptor function; Chapter 51). Mutations in GPCRs cause a variety of monogenic diseases (Schöneberg and Liebscher, 2021). The same is true for mutations in TRP channels (Moran, 2018). Many forms of cancer are now known to arise from mutations that result in constitutive activity of growth factor receptors and downstream signaling enzymes in the Ras-MAPK pathway, or loss of tumor suppressors and other proteins that regulate cell proliferation (see Chapter 72).

Common polymorphisms in receptors and proteins downstream of the receptor can also lead to variability in therapeutic responses in patient populations from different geographic and ethnic origins (Johnson, 2019).

Intrinsic Pathways Regulated by Nutrients, Energy, and Cell Damage

In addition to cell-extrinsic regulation of cell growth mediated by growth factors and cytokines, cell-intrinsic pathways that arose during the early evolution of eukaryotes regulate cell growth and survival by sensing the availability of nutrients and cellular energy status. These ancient nutrient-sensing pathways consist of the *AMP-activated protein kinase* (AMPK) pathway and the *target of rapamycin* (TOR) pathway, which work in opposition to control cell growth and the process of *autophagy* (González et al., 2020). Autophagy is an intracellular degradation pathway that is important for cell survival during conditions of stress or cell damage. Programmed cell death (*apoptosis*) is also dually regulated by extrinsic factors, including TNF-α, Fas ligand, and TNF-related apoptosis-inducing ligand (TRAIL), and by intrinsic pathways that sense cell damage. Organ development and renewal require a balance between cell population growth and survival versus cell death and removal, and both autophagy and apoptosis play important roles in normal tissue and cell function. However, aberrant autophagy or apoptosis pathways play roles in many disease processes, and pharmacological perturbation of these pathways may be important therapeutically in such diseases, including neurodegenerative diseases, and drug- and radiation-resistant cancers.

AMPK and TOR Pathways

AMPK is a serine/threonine protein kinase that occurs as a heterotrimeric complex consisting of a catalytic α subunit and regulatory β and γ subunits. Canonical activation of AMPK occurs in the cytoplasm and is triggered by energy stress (cellular increases in AMP:ATP or ADP:ATP ratios) mediated by binding of AMP or ADP to allosteric sites on the AMPK γ-subunit (Figure 3–24). AMP/ADP binding to these sites is antagonized by ATP. Canonical activation of AMPK also requires phosphorylation by LKB1 (liver kinase B1) on Thr172 in the activation loop of the kinase domain of AMPK.

Noncanonical AMPK activation results from glucose deprivation, release of Ca^{2+} from the ER, or increased Ca^{2+} in the nucleus. The activation of AMPK in response to glucose starvation (the *lysosomal pathway*) occurs independently of changes in adenine nucleotide ratios and is mediated by aldolase, the glycolytic enzyme that binds fructose 1,6-bisphosphate (FBP) and converts it to triose phosphates. Glucose starvation leads to FBP depletion, which alters aldolase's interactions with the v-ATPase complex on the surface of the lysosome, promoting interactions of LKB1 with the lysosome that lead to phosphorylation and activation of lysosome-associated AMPK. Noncanonical Ca^{2+} activation of AMPK in the cytoplasm and nucleus is mediated by CaMKK2 (Ca^{2+}/calmodulin-dependent kinase kinase-2) in response to IP_3-dependent release of Ca^{2+} from the ER (cytoplasmic activation) or increases in nuclear Ca^{2+} caused by DNA damage (activation in the nucleus).

Activated AMPK phosphorylates more than 60 downstream targets that activate catabolic pathways and inactivate anabolic (biosynthetic) pathways, with acute overall effects of increasing ATP synthesis, reducing ATP consumption, and inhibiting cell growth (González et al., 2020). An important target for AMPK is the *mechanistic or mammalian target of rapamycin complex 1* (mTORC1), which is inactivated by AMPK phosphorylation.

TOR is a serine/threonine protein kinase that was first identified in yeast mutants that were resistant to the growth-inhibiting effects of *rapamycin*. Rapamycin (*sirolimus*) and its several structurally and mechanistically related compounds (*everolimus, temsirolimus*) are described in more detail in Chapter 39. In humans, there are two structurally and functionally different forms of mTOR, mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2); only mTORC1 is inhibited by rapamycin. mTORC1 is regulated intrinsically by amino acids that cause translocation of mTORC1 from the cytosol to lysosomes and extrinsically by growth factors that activate the small G protein RHEB (Ras homolog enriched in brain) on the surface of lysosomes. Figure 3–24 summarizes some of the details of the regulation of mTORC1 and AMPK and the anabolic and catabolic processes of the cell.

Autophagy

Autophagy is a highly conserved, tightly regulated, multistep catabolic pathway in which cellular contents (including aggregation-prone proteins, organelles such as mitochondria and peroxisomes, and infectious agents) are sequestered within double-membrane vesicles known as *autophagosomes* and then delivered to lysosomes, where fusion occurs and autophagosome contents are degraded by lysosomal proteases (Bento et al., 2016). The functions of autophagy are to remove cell contents that are damaged and to provide cells with substrates for energy and biosynthesis under conditions of stress and starvation. Autophagy plays an important protective role in a number of diseases, including neurodegenerative diseases (e.g., Alzheimer's, Parkinson's, and Huntington's diseases) caused by aggregation-prone proteins and certain infectious diseases (*Salmonella typhi* and *Mycobacterium tuberculosis*). Autophagy-related genes may also play a role in tumor suppression, and decreased autophagic capacity is correlated with poor prognosis in brain tumors. However, in breast, ovarian, and prostate cancers, autophagy can function as a tumor promoter and may enhance the survival of metastatic cells at sites where nutrients are limited.

Autophagy is directly controlled by autophagy-related genes (known as *ATG*s, AuTophaGy genes). More than 30 *ATG*s have been identified in eukaryotes, and the ATG proteins function at various steps in autophagy, including induction of cargo packaging, vesicle formation, vesicle fusion with lysosomes, and degradation of vesicular contents. Autophagy is primarily regulated at the cellular level by stress-mediated and growth factor signaling pathways that integrate signaling output via mTORC1 and AMPK as described above (see Figure 3–24). Activated mTORC1 inhibits autophagy; AMPK can promote autophagy.

Apoptosis

Apoptosis is a highly regulated program of biochemical reactions that leads to cell rounding, shrinkage of the cytoplasm, condensation of the nucleus and its contents, and changes in the cell membrane that eventually lead to presentation of phosphatidylserine on the outer surface of the cell. Phosphatidylserine is recognized as a sign of apoptosis by macrophages, which engulf and phagocytize the dying cell. During this process, the membrane of the apoptotic cell remains intact, and the cell does not release its cytoplasm or nuclear material. Thus, unlike necrotic cell death, the apoptotic process does not initiate an inflammatory response. Alterations in apoptotic pathways are implicated in cancer, neurodegenerative diseases, and autoimmune diseases. Thus, maintaining or restoring normal apoptotic

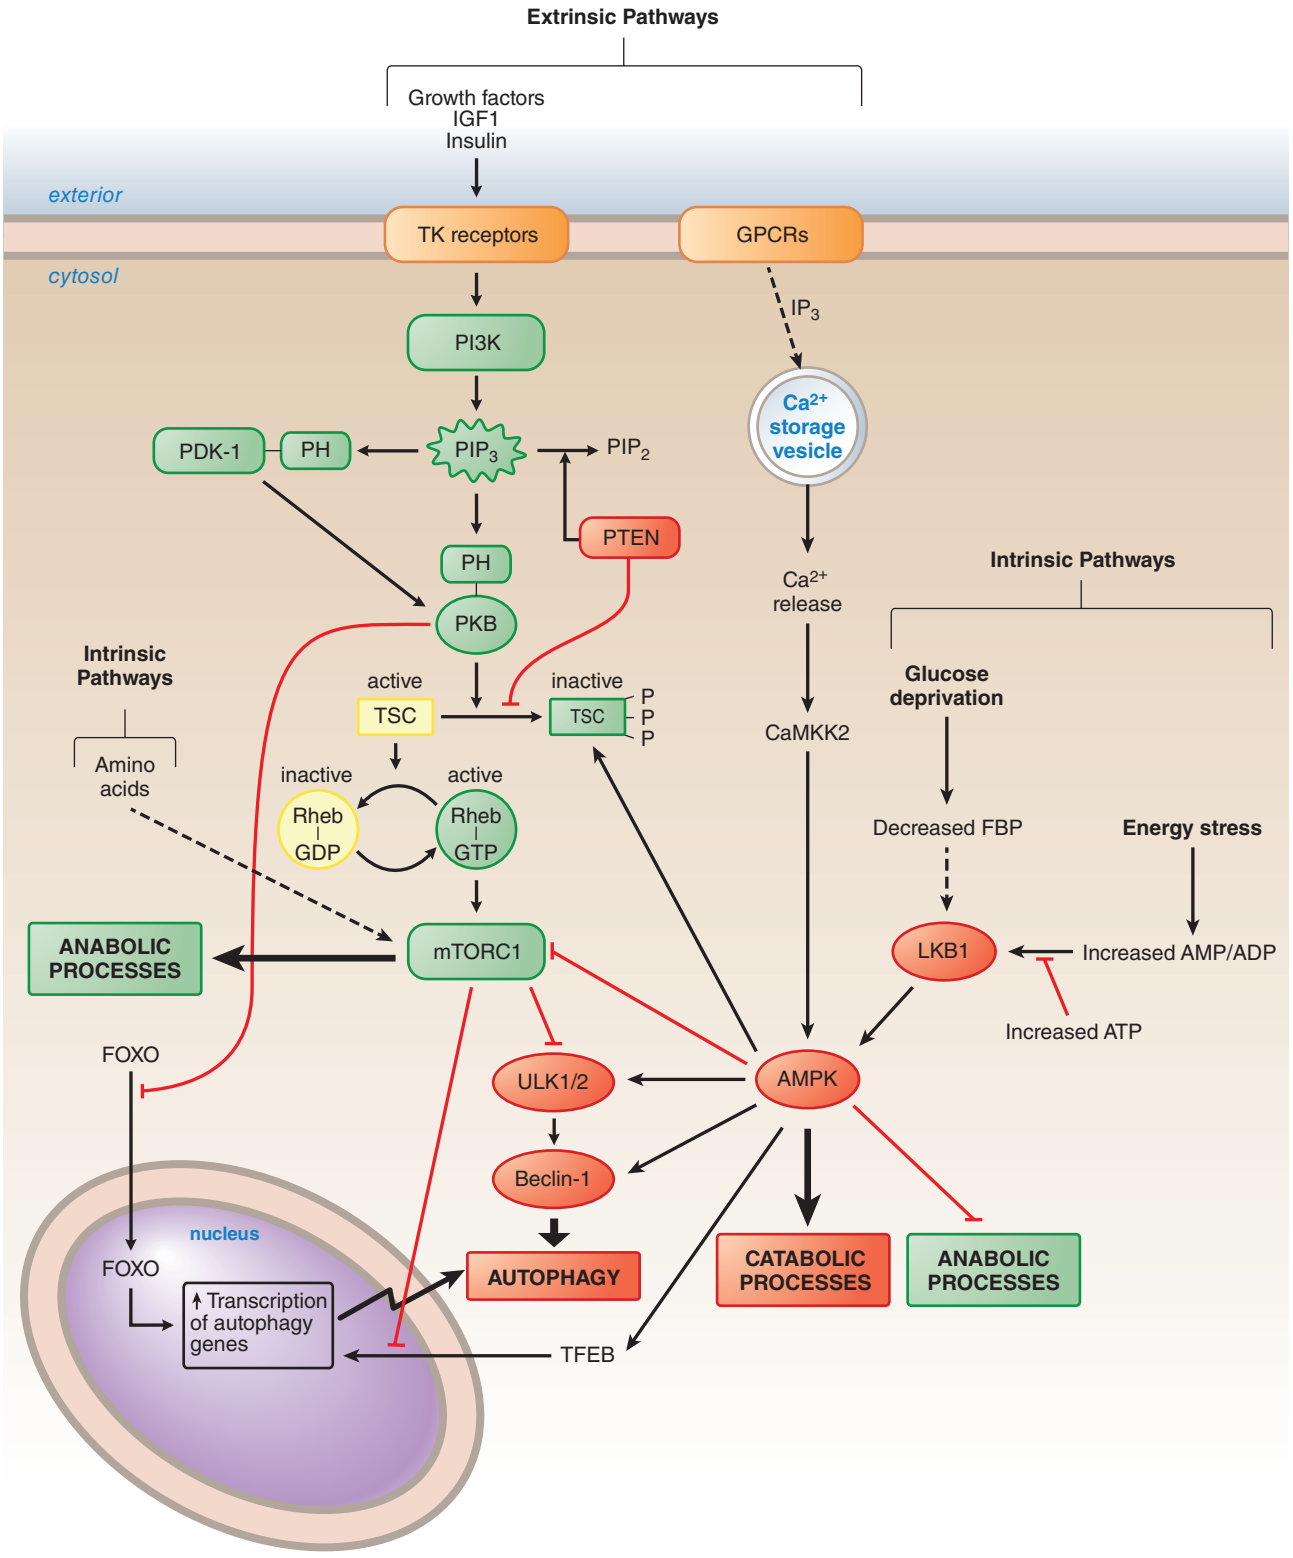

Figure 3–24 *Pathways regulating cell proliferation, cell survival, and autophagy.* The primary regulators of cell proliferation and growth (*anabolic processes*) and opposing cell survival (*catabolic processes*) and autophagy are growth factor signaling (*extrinsic pathways*) and *intrinsic pathways* regulated by amino acids, glucose, and cellular stress. Growth factor signaling pathways that lead to activation of mTORC1 (green boxes) promote anabolic processes and inhibit autophagy (red boxes), whereas cellular stress caused by nutrient starvation enhance catabolic processes and autophagy through activation of AMPK (red boxes). These pathways interact not only with one another but also with other pathways including apoptosis pathways, as described in the text. See Figure 39–2 for the effect of mTOR inhibitors as immunosuppressants. Mammalian FOXOs (FOXO 1, 3, 4, and 6) are a subclass of Forkhead transcription factors that function mainly as transcriptional activators, with effects on myriad cell functions including apoptosis and drug resistance; insulin and growth factor signaling can inhibit FOXO activity. Additional signaling pathways not depicted here regulate transcription factor EB (TFEB).

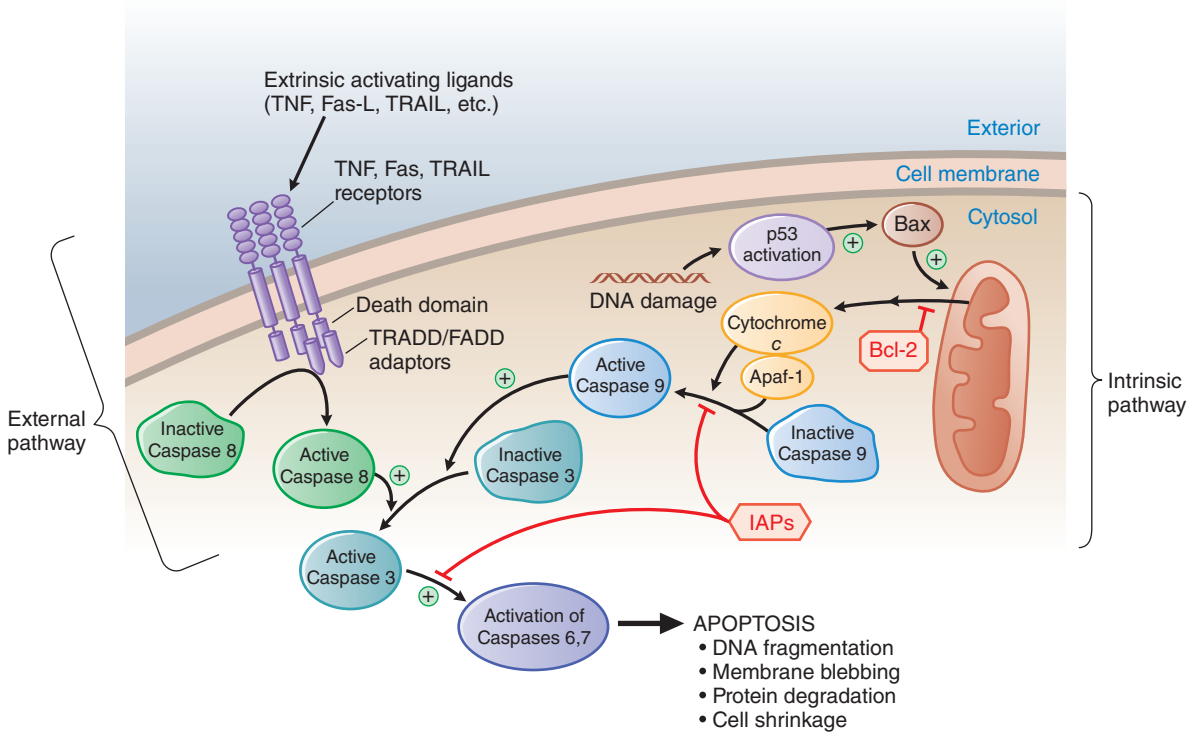

Figure 3–25 *Two pathways leading to apoptosis.* Apoptosis can be initiated by external ligands such as TNF, Fas ligand, or TRAIL, binding to specific transmembrane receptors (left half of figure: the *external pathway*). Activation leads to trimerization of the receptor, and binding of adaptor molecules such as TRADD, to the intracellular death domain. The adaptors recruit caspase 8 and activate it, leading to cleavage and activation of the effector caspase, caspase 3, which activates the caspase pathway leading to apoptosis. Apoptosis can also be initiated by an *intrinsic pathway* regulated by Bcl-2 family members such as Bax and Bcl-2. Bax is activated by DNA damage or malformed proteins via p53 (right half of figure). Activation of this pathway leads to release of cytochrome *c* from the mitochondria and formation of a complex with Apaf-1 and caspase 9. Caspase 9 is activated in the complex and initiates apoptosis through activation of caspase 3. Either the external or the intrinsic pathway can overwhelm the inhibitors of apoptosis proteins (IAPs), which otherwise keep apoptosis in check.

pathways is the goal of major drug development efforts to treat diseases that involve dysregulated apoptotic pathways. Resistance to many cancer chemotherapies is associated with reduced function of apoptotic pathways.

Two major signaling pathways induce apoptosis. Apoptosis can be initiated by external signals that have features in common with those used by ligands such as TNF-α or by an internal pathway activated by DNA damage, improperly folded proteins, or withdrawal of cell survival factors (Figure 3–25). The apoptotic program is carried out by a large family of cysteine proteases termed *caspases*. The caspases are highly specific cytoplasmic proteases that are inactive in normal cells but become activated by apoptotic signals.

The external or extrinsic apoptosis signaling pathway, also known as the death receptor pathway, can be activated by ligands such as TNF, Fas ligand, or TRAIL. The receptors for TNF (TNF receptor), Fas ligand (Fas or Apo-1), and TRAIL (TRAIL receptor) are transmembrane receptors with no enzymatic activity, similar to the organization of the TNF receptor described previously. On binding TNF, Fas ligand, or TRAIL, the cognizant receptors form a homotrimer, undergo a conformational change, and recruit adaptor proteins to the receptor's death domain. The adaptor proteins then recruit RIP1 (receptor-interacting protein 1) and caspase 8 to form a complex that results in the activation of caspase 8. Activation of caspase 8 leads to the activation of caspase 3, which initiates the apoptotic program. The final steps of apoptosis are carried out by caspases 6 and 7, leading to degradation of enzymes, structural proteins, and DNA fragmentation characteristic of cell death (see Figure 3–25).

The internal apoptosis pathway can be activated by signals such as DNA damage, leading to increased transcription of the *p53* gene, and involves damage to the mitochondria by proapoptotic members of the Bcl-2 family of proteins. This family includes proapoptotic members such as Bax, Bak, and Bad, which induce damage at the mitochondrial membrane. There are also antiapoptotic Bcl-2 members, such as Bcl-2, Bcl-X, and Bcl-W, which serve to inhibit mitochondrial damage and are negative regulators of the system. When DNA damage occurs, p53 transcription is activated and the cell is held at a cell cycle checkpoint until the damage is repaired. If the damage cannot be repaired, apoptosis is initiated through the proapoptotic Bcl-2 members, such as Bax. Bax is activated, translocates to mitochondria, overcomes the antiapoptotic proteins, and induces the release of cytochrome *c* and a protein termed SMAC (second mitochondria-derived activator of caspase). SMAC binds to and inactivates the inhibitor of apoptosis proteins (IAPs) that normally prevent caspase activation. Cytochrome *c* combines in the cytosol with another protein, Apaf-1 (apoptotic activating protease factor 1), and with caspase 9. This complex leads to activation of caspase 9 and ultimately to the activation of caspase 3. Once activated, caspase 3 activates the same downstream pathways as the external pathway described previously, leading to the cleavage of proteins, cytoskeletal elements, and DNA repair proteins, with subsequent DNA condensation and membrane blebbing that eventually lead to cell death and engulfment by macrophages.

Physiological Systems Must Integrate Multiple Signals

Consider the vascular wall of an arteriole (Figure 3–26). Several types of cells interact at this site, including vascular smooth muscle cells (VSMCs), endothelial cells, platelets, and postganglionic sympathetic neurons. The contractility of VSMCs in the arteriole is the focal point for local and systemic forms of regulation related to vascular resistance. Local regulation by substances such as adenosine, CO_2, and lactic acid can decrease VSMC contractility and hence promote local blood flow. Systemic regulation of blood pressure homeostasis occurs via endocrine, paracrine, and neuronal signaling.

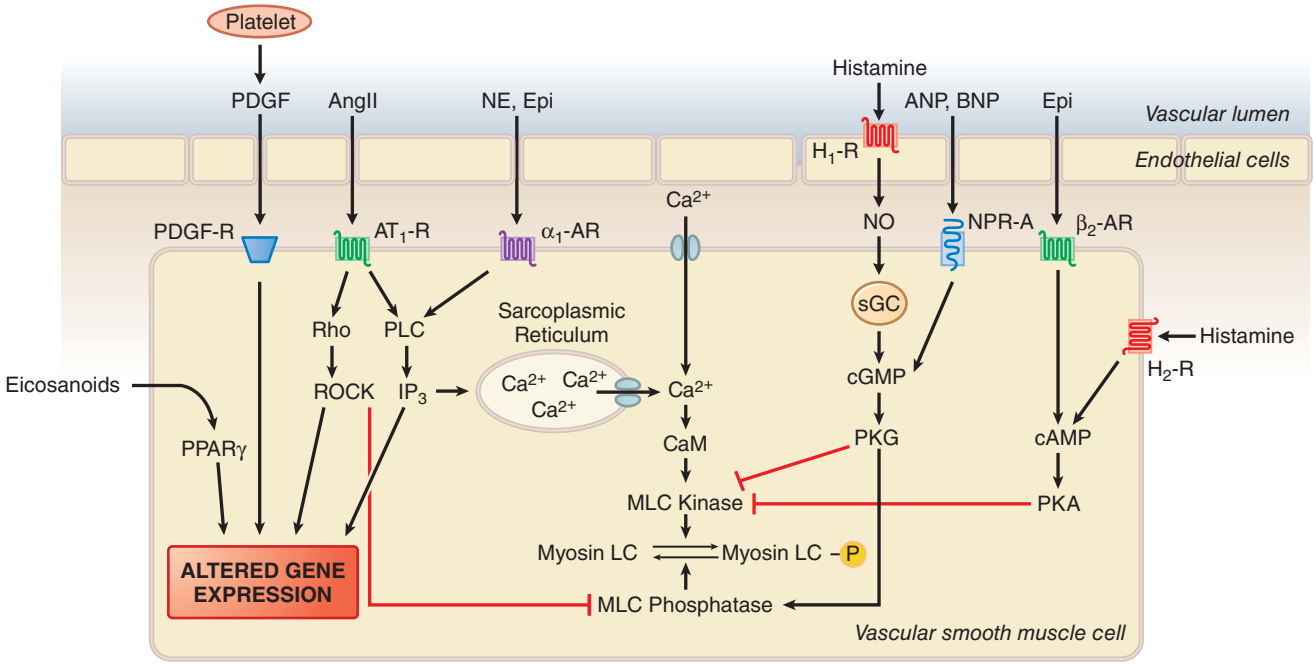

Figure 3–26 *Interaction of multiple signaling systems regulating VSMCs.* It is essential to know that the contractile activity of VSMCs is based on the degree to which myosin, and specifically the light chain of myosin (MLC), is phosphorylated. It is myosin with a phosphorylated light chain that is able to interact with actin filaments to generate force. Note that the degree of phosphorylation is a balance between MLC kinase, which phosphorylates the MLC, and MLC phosphatase, which dephosphorylates MLC. Depicted is a composite VSMC; the relaxation in response to epinephrine is best fit to VSMCs in the skeletal muscle vasculature. See text for a detailed explanation of signaling.

Activation of the sympathetic nervous system regulates VSMC tone in part through release of norepinephrine (NE) from postganglionic sympathetic neurons. NE binds α_1 adrenergic receptors on VSMCs, which activates the G_q-PLC-IP_3-Ca^{2+} pathway. Ca^{2+} binds and activates CaM, which in turn activates MLCK. MLCK phosphorylates light chains of myosin, leading to an increase in VSMC contractile activity. Epinephrine released from the adrenal medulla activates the same pathway in the vasculature of most tissues; however, for the vasculature of skeletal muscle, epinephrine binds β_2 adrenergic receptors and thus engages the G_s-AC-cyclic AMP pathway, as does histamine via the H_2 receptor. The increase in cyclic AMP inhibits MLCK through PKA-mediated phosphorylation and therefore causes a *decrease* in VSMC contraction. The differential engagement of α_1 versus β_2 adrenergic receptors by epinephrine is the basis for the shunt of blood flow from viscera and skin to skeletal muscle in the fight-or-flight response.

Activation of the renin-angiotensin-aldosterone system, which occurs in response to a drop in blood pressure and/or loss in fluid volume, produces angiotensin II (AngII). AngII binding to the AT_1 receptor in VSMCs mobilizes stored Ca^{2+} via the G_q-PLC-IP_3-Ca^{2+} pathway and therefore increases VSMC contractility in part through the same means as NE. But AngII-activated AT_1 receptor also engages $G_{12/13}$ and as a consequence activates the RhoA monomeric G protein. RhoA activates ROCK, which phosphorylates and inhibits myosin light chain phosphatase. The increase in phosphorylated myosin light chain, and hence contractile activity, is thus the product of two pathways. As noted, the activation of RhoA through $G_{12/13}$ and events engaged by G_q and arrestin are also implicated in the growth and proliferation of vascular smooth muscle cells.

The contraction of VSMCs is opposed by mediators that promote relaxation, including NO, atrial natriuretic peptides, and, in the skeletal muscle vasculature, epinephrine. NO is formed in endothelial cells by eNOS when the G_q-PLC-IP_3-Ca^{2+} pathway is activated, for example by histamine via H_1 histaminergic receptors, and by iNOS when that isoform is induced (e.g., by proinflammatory cytokines). The NO formed in the endothelium diffuses into VSMCs and activates sGC, which catalyzes the formation of cyclic GMP and leads to activation of PKG and phosphorylation of both MLC kinase and myosin light chain phosphatase to inhibit and stimulate, respectively, their activities and to promote relaxation. PKG also inhibits IP_3-mediated Ca^{2+} release from intracellular stores and activates a K^+ channel to inhibit, through hyperpolarization, the activity of the L-type Ca^{2+} channel, thereby reducing Ca^{2+} influx (not shown). Intracellular concentrations of cyclic GMP are also increased by activation of transmembrane natriuretic peptide receptors by ANP and BNP, which are released from cardiac atrial cells and cardiomyocytes, respectively, in response to volume overload.

As a consequence of the variety of pathways that affect arteriolar tone, a patient with hypertension may be treated with one or several drugs that alter signaling through these pathways. Drugs commonly used to treat hypertension include β_1 adrenergic receptor antagonists to reduce secretion of renin, the first step in AngII synthesis; a direct inhibitor of renin (*aliskiren*); ACE inhibitors (e.g., *enalapril*) to reduce conversion of AngI to AngII; angiotensin subtype 1 receptor (AT_1R) blockers (e.g., *losartan*) to block AngII binding to AT_1Rs on VSMCs; α_1 adrenergic blockers to block NE binding to VSMCs; *sodium nitroprusside* to increase quantities of NO produced; and Ca^{2+} channel blockers (e.g., *nifedipine*) to block Ca^{2+} entry into VSMCs. β_1 Adrenergic receptor antagonists would also block the baroreceptor reflex-mediated increase in heart rate and blood pressure that would otherwise attempt to counter the drop in blood pressure induced by the therapy. ACE inhibitors also inhibit the degradation of a vasodilating peptide bradykinin (see Chapter 43). Thus, the choices and mechanisms are complex, and the appropriate therapy in a given patient depends on many considerations, including the diagnosed causes of hypertension in the patient, possible side effects of the drug, efficacy in a given patient, and cost.

Signaling Pathways and Drug Action

Throughout this text, cellular signaling pathways figure prominently in explaining the actions of therapeutic agents. Not all pathways have been mentioned or fully explored in this chapter. To aid readers in finding more information on signaling and important sites of action, Table 3–4 lists relevant figures that appear *in other chapters*.

TABLE 3–4 ■ SUMMARY: IMPORTANT SITES OF DRUG ACTION

RECEPTOR/PATHWAY	FIGURE TITLE	FIGURE NUMBER
Drug transport proteins	Major mechanisms by which transporters mediate adverse drug responses	**Figure 4–3**
CYPs, drug metabolism	Location of CYPs in the cell	**Figure 5–2**
Nuclear receptors	Induction of drug metabolism by nuclear receptor–mediated signal transduction	**Figure 5–14**
GI Microbiome	Pathway of an orally administered drug	**Figure 6–1**
CYP variant	Effects of Splice Variant in CYP3A5 on PK	**Figure 7–3**
General neurotransmission	Steps involved in excitatory and inhibitory neurotransmission	**Figure 10–3**
Exocytosis	Molecular basis of exocytosis: docking and fusion of synaptic vesicles with neuronal membranes	**Figure 10–4**
Cholinergic neurotransmission	A typical cholinergic neuroeffector junction	**Figure 10–6**
Adrenergic neurotransmission	A typical adrenergic neuroeffector junction	**Figure 10–8**
AChE and its inhibition	Steps involved in the hydrolysis of ACh by AChE and in the inhibition and reactivation of the enzyme	**Figure 12–2**
Transmission at the NMJ	A pharmacologist's view of the motor end plate	**Figure 13–4**
α and β effects/CV system	Comparative effects of intravenous infusion of NE, EPI, and INE.	**Figure 14–2**
β Blockers and vasodilation	Mechanisms underlying actions of vasodilating β blockers in blood vessels	**Figure 14–4**
Serotonergic neurotransmission	A serotonergic synapse	**Figure 15–4**
Dopaminergic neurotransmission	A dopaminergic synapse	**Figure 15–9**
Voltage-sensitive cation channels	Voltage-sensitive Na^+, Ca^{2+}, and K^+ channels	**Figure 16–2**
Neurotransmission	Transmitter release, action, and inactivation	**Figure 16–4**
Ligand-gated ion channels	Pentameric ligand-gated ion channels	**Figure 16–6**
NMDA receptor	Pharmacologic binding sites on the NMDA receptor	**Figure 16–9**
$GABA_A$ receptor	Pharmacologic binding sites on the $GABA_A$ receptor	**Figure 16–11**
Histamine signaling	Signal transduction pathways for histamine receptors	**Figure 16–12**
Actions of antidepressants	Sites of action of antidepressants at noradrenergic and serotonergic nerve terminals	**Figure 18–1**
Ketamine action	Proposed mechanisms for the antidepressant effects of ketamine.	**Figure 18–2**
Na^+ channel	Antiseizure drug–enhanced Na^+ channel inactivation	**Figure 20–2**
$GABA_A$ receptor/channel	Some antiseizure drugs enhance GABA synaptic transmission	**Figure 20–3**
T-type Ca^{2+} channel	Antiseizure drug–induced reduction of current through T-type Ca^{2+} channels	**Figure 20–4**
Opioid signaling	Simplified scheme of opioid receptor signaling	**Figure 23–2**
Cation signaling	Structure and function of voltage-gated Na^+ channels	**Figure 25–2**
Local anesthetic action on Na^+ channels	A structural view of the interaction of a local anesthetic with a voltage-gated Na^+ channel	**Figure 25–3**
Cannabinoids	Cannabinoid synthesis and signaling	**Figures 26–2, 26–3, 26–4**
Diuretics	Sites and mechanisms of action of diuretics	**Figure 29–5**
Aldosterone signaling	Diuretic mechanism of aldosterone antagonists	**Figure 29–6**
ANP signaling	Inter medullary collecting duct Na^+ transport and its regulation	**Figure 29–7**
V_1 receptor signaling	Mechanism of V_1 receptor-effector coupling	**Figure 29–11**
V_2 receptor signaling	Mechanism of V_2 receptor-effector coupling	**Figure 29–12**
Signals regulating renin release	Mechanisms by which the macula densa regulates renin release	**Figure 30–3**
Renin-Angiotensin System	Schematic diagram of opposing arms in the RAS	**Figure 30–4**
Signals regulating blood pressure	Principles of blood pressure regulation and its modification by drugs	**Figure 32–3**
E-C coupling	Cardiac excitation-contraction coupling and positive inotropic drugs	**Figure 33–6**
NO/cGMP signaling in PAH	Stimulators of NO/cGMP signaling	**Figure 35–3**
cAMP signaling in PAH	Membrane receptor agonists that increase cAMP	**Figure 35–4**
PLC signaling in PAH	Membrane receptor antagonists that inhibit activation of phospholipase C	**Figure 35–5**

TABLE 3–4 ■ SUMMARY: IMPORTANT SITES OF DRUG ACTION (*CONTINUED*)

RECEPTOR/PATHWAY	FIGURE TITLE	FIGURE NUMBER
Endothelium–smooth muscle signaling	Interactions between endothelium and vascular smooth muscle in PAH	**Figure 35–7**
Aggregatory signaling	Platelet adhesion and aggregation	**Figure 36–1**
Coagulatory signaling	Major reactions of blood coagulation	**Figure 36–2**
Fibrinolytic signaling	Fibrinolysis	**Figure 36–3**
Blood clotting and its prevention	Sites of action of antiplatelet drugs	**Figure 36–7**
LDLR and endocytosis	Regulation of LDL-receptor life cycle	**Figure 37–5**
T cell activation	T cell activation: costimulation and coinhibitory checkpoints	**Figure 38–3**
T cell receptor (TCR) ligands	TCR signaling and its modulation by co-receptors and antibodies	**Figure 38–4**
Leukocyte inflammatory response	The leukocyte inflammatory response	**Figure 38–6**
T cell signaling	T cell activation and sites of action of immunosuppressive agents	**Figure 39–2**
Sphingosine-1-phosphate signaling	S1P formation and action at $S1P_1R$; fingolimod and its active metabolite.	**Figure 39–3**
Prostanoid receptors	Prostanoid receptors and their primary signaling pathways	**Figure 41–1**
Eicosanoid signaling	Human Eicosanoid Receptors	**Table 41–4**
Probenecid action; urate transport	A pharmacologist's view of renal urate transport and its inhibition by drugs.	**Figure 42–2**
Inflammatory signaling; asthma	Mechanism of anti-inflammatory action of corticosteroids in asthma	**Figure 44–7**
Growth hormone receptor (GHR)	Mechanisms of GH and PRL action and of GHR antagonism	**Figure 46–5**
Oxytocin receptor signaling	Sites of action of oxytocin and tocolytic drugs in the uterine myometrium	**Figure 46–8**
Estrogen receptor signaling	Molecular mechanism of action of nuclear ER	**Figure 48–4**
Soluble guanylyl cyclase and PDE5	Mechanism of action of PDE5 inhibitors in the corpus cavernosum	**Figure 49–6**
Glucocorticoid receptor (GR)	Mechanisms of transcriptional regulation by GR.	**Figure 50–8**
Insulin secretion	Regulation of insulin secretion from a pancreatic β cell	**Figure 51–3**
Insulin receptor	Pathways of insulin signaling	**Figure 51–4**
FGF receptor	FGF23-FGFR-Klotho complex	**Figure 52–4**
H_2 and gastrin receptors; gastric secretion	Pharmacologist's view of gastric secretion and its regulation: the basis for therapy of acid-peptic disorders	**Figure 53–1**
EP_2 and EP_4 receptors; GI ion transporters; cAMP, cGMP	Mechanism of action of drugs that alter intestinal epithelial secretion and absorption	**Figure 54–4**
Emetic signaling	Pharmacologist's view of emetic stimuli	**Figure 54–6**
EGF receptor	Targeting the EGFR in cancer	**Figure 71–1**
Growth factor receptors	Cancer cell signaling pathway and drug targets	**Figure 71–2**
B cell kinases	Inhibitors of signaling in B cells	**Figure 71–4**
mTOR, AMPK, growth factor signaling	Caveat mTOR: effect of rapamycin on growth factor signaling	**Figure 71–5**
Hypoxia-inducible genes.	Oxygen-sensing and hypoxia-inducible genes targeted	**Figure 71–6**
Apoptotic signaling	BH3 mimetics enhance apoptosis	**Figure 71–10**
IgG1 structure	IgG1 elements relevant for their use in cancer treatment.	**Figure 72–1**
EGF receptor	Antibody targeting and domains of EGFR (HER1).	**Figure 72–2**
T cell/APC signaling	Targeting of immune checkpoints	**Figure 72–3**
IL-2 receptor	A pharmacologist's view of IL-2 receptors, signaling pathways, and inhibitors	**Figure 72–4**
CAR T cells	Chimeric antigen receptor (CAR) T-cell activation by a target antigen on cancer cells.	**Figure 72–6**
Rhodopsin	Pharmacologist's view of photoreceptor signaling	**Figure 74–9**

Chapter 4

Membrane Transporters and Drug Response

Kathleen M. Giacomini and Yuichi Sugiyama

Membrane transport proteins are present in all organisms. These proteins control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, drugs, and other xenobiotics (Figure 4–1). Consistent with their critical roles in cellular homeostasis, about 2000 genes in the human genome, or ~7% of the total number of genes, code for transporters or transporter-related proteins. The functions of membrane transporters may be facilitated (equilibrative, not requiring energy) or active (requiring energy). In considering the transport of drugs, pharmacologists generally focus on transporters from two major superfamilies, ABC and SLC transporters (Nigam, 2015).

Most ABC (ATP binding cassette) proteins are primary active transporters, which rely on ATP hydrolysis to actively pump substrates across membranes. Among the best-recognized transporters in the ABC superfamily are Pgp (encoded by *ABCB1*, also termed *MDR1*) and CFTR (encoded by *ABCC7*).

The SLC (solute carrier) superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters. Sixty-five SLC families with about 460 transporters have been identified in the human genome (Pizzagalli et al., 2021). Many SLC transporters serve as drug targets or in drug absorption and disposition. Widely recognized SLC transporters include SERT and DAT, both targets for antidepressant medications.

Membrane Transporters in Therapeutic Drug Responses

Pharmacokinetics

Transporters important in pharmacokinetics generally are located in intestinal, renal, and hepatic epithelia, where they function in the selective absorption and elimination of endogenous substances and xenobiotics, including drugs. Transporters work in concert with drug-metabolizing enzymes to eliminate drugs and their metabolites (Figure 4–2). In addition, transporters in various cell types mediate tissue-specific drug distribution (drug targeting). Conversely, transporters also may serve as protective barriers to particular organs and cell types. For example, Pgp in the BBB protects the CNS from a variety of structurally diverse drugs through its efflux mechanisms.

Pharmacodynamics: Transporters as Drug Targets

Membrane transporters are the targets of many clinically used drugs. SERT (*SLC6A4*) is a target for a major class of antidepressant drugs, the SSRIs. Other neurotransmitter reuptake transporters serve as drug targets for the tricyclic antidepressants, various amphetamines (including

Abbreviations

ABC: ATP binding cassette
ABCC: ATP binding cassette family C
ACE: angiotensin-converting enzyme
AUC: area under the concentration-time curve
BBB: blood-brain barrier
BCRP: breast cancer resistance protein
BSEP: bile salt export pump
CAR: constitutive androstane receptor
CFTR: cystic fibrosis transmembrane regulator
$CL_{int,all}$: overall hepatic intrinsic clearance
CL_{met}: metabolic clearance
CPT-11: irinotecan hydrochloride
Cryo-EM: cryo-electron microscopy
CSF: cerebrospinal fluid
DA: dopamine
DAT: dopamine transporter
FDA: U.S. Food and Drug Administration
FXR: farnesoid X receptor
GABA: γ-aminobutyric acid
GAT: GABA reuptake transporter
GI: gastrointestinal
GLUT: glucose transporter
GSH, GSSG: reduced and oxidized glutathione
HCV: hepatitis C virus
HIV: human immunodeficiency virus
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
HNF4α: hepatic nuclear factor 4 alpha
5HT: serotonin
α-KG: α-ketoglutarate
LAT: large amino acid transporter
LeuT: leucine transporter
MAO: monoamine oxidase
MATE1: multidrug and toxin extrusion protein 1
MDMA: 3,4-methylenedioxymethamphetamine
MFS: major facilitator superfamily
MRP: multidrug resistance protein
NBDs: nucleotide-binding domains
NE: norepinephrine
NET: NE transporter
NME: new molecular entity
NTCP: Na^+-taurocholate cotransporting polypeptide
OAT1: organic anion transporter 1
OCT1: organic cation transporter 1
OCTN: novel organic cation transporter
OSTα/β: organic solute transporter α/β heterodimer
PAH: *p*-aminohippurate
PBPK: physiologically based pharmacokinetic
PGE_2: prostaglandin E_2
Pgp: P-glycoprotein
PPARα: peroxisome proliferator-activated receptor α
PXR: pregnane X receptor
RAR: retinoic acid receptor
RFC: reduced folate carrier
RXR: retinoid X receptor
SERT: serotonin transporter
SHP1: Src homology region 2 domain-containing phosphatase-1
SLC: solute carrier
SNP: single-nucleotide polymorphism
SSRI: selective serotonin reuptake inhibitor
SXR: steroid X receptor
TMD: transmembrane domain
URAT1: uric acid transporter 1
XOI: xanthine oxidase inhibitor

amphetamine-like drugs used in the treatment of attention-deficit disorder in children), and anticonvulsants.

These transporters also may be involved in the pathogenesis of neuropsychiatric disorders, including Alzheimer's and Parkinson's diseases. An inhibitor of the vesicular monoamine transporter VMAT2 (SLC18A2), *tetrabenazine*, is approved for the symptomatic treatment of Huntington's disease; the antichorea effect of *tetrabenazine* likely relates to its capacity to deplete stores of biogenic amines by inhibiting their uptake into storage vesicles by VMAT2. Transporters that are nonneuronal also may be potential drug targets (e.g., cholesterol transporters in cardiovascular disease, nucleoside transporters in cancers, glucose transporters in metabolic syndromes, and Na^+-Cl^- cotransporters in the SLC12 family in hypertension).

Recently, first-in-class drugs that inhibit Na^+-glucose transporters in the SLC5 family (SGLT1 and SGLT2) have been FDA-approved for the treatment of type 2 diabetes. These drugs, the gliflozins, which include *canagliflozin, dapagliflozin*, and *empagliflozin*, reduce renal reabsorption of glucose, thereby facilitating glucose elimination in the kidney. All three are prescribed as second-line therapy for treatment of inadequately controlled diabetes. *Dapagliflozin* has proven useful in treating declines in kidney function in patients with chronic kidney disease, irrespective of the presence or absence of diabetes (Heerspink et al., 2020). *Dapagliflozin* is also being used in treating heart failure with reduced ejection fraction (see Chapter 33).

In addition, renal transporters for uric acid such as URAT1 (SLC22A12) (Nakata et al., 2020) and GLUT9 (SLC2A9) are being targeted by drugs in clinical trials for the treatment of gout when used with an XOI. These drugs are uricosurics and act by selectively inhibiting uric acid reabsorption in the kidney.

Mutations in the transmembrane gated anion (chloride) channel CFTR (cystic fibrosis transmembrane conduction regulator or ABCC7) reduce function of that protein and cause thickened secretions in the lung and other tissues. Drugs directed toward CFTR can modulate and enhance CFTR function in patients with cystic fibrosis. A first-in-class drug, *ivacaftor*, is used for the treatment of patients who harbor the coding mutation CFTR-p.G551D. *Ivacaftor*, termed a *potentiator*, increases the probability that the mutant chloride channel, CFTR-p.G551D, remains in the open state. Other agents, termed *correctors* (e.g., *tezacaftor, elexacaftor*), enhance trafficking and insertion of mutant CFTR proteins into the plasma membrane. Combinations of potentiators and correctors of CFTR mutants are now in use for cystic fibrosis patients who are homozygous or heterozygous for the common deletion mutation, CFTR-p.F508del (Gramegna et al., 2020).

Drug Resistance

Membrane transporters play critical roles in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. *Decreased uptake of drugs*, such as folate antagonists, nucleoside analogues, and platinum complexes, is mediated by reduced expression of influx transporters required for these drugs to access the tumor. *Enhanced efflux of hydrophobic drugs* is one mechanism of antitumor resistance in cellular assays of resistance. The overexpression of MRP4 is associated with resistance to antiviral nucleoside analogues (Aceti et al., 2015). Pgp (MDR1, ABCB1) and BCRP (ABCG2) can be overexpressed in tumor cells after exposure to cytotoxic anticancer agents and are implicated in resistance to these agents, exporting anticancer drugs, reducing their intracellular concentration, and rendering cells resistant to the drugs' cytotoxic effects. Modulation of MDR1 expression and activity to regulate drug resistance could be a useful adjunct in pharmacotherapy (Seelig, 2020).

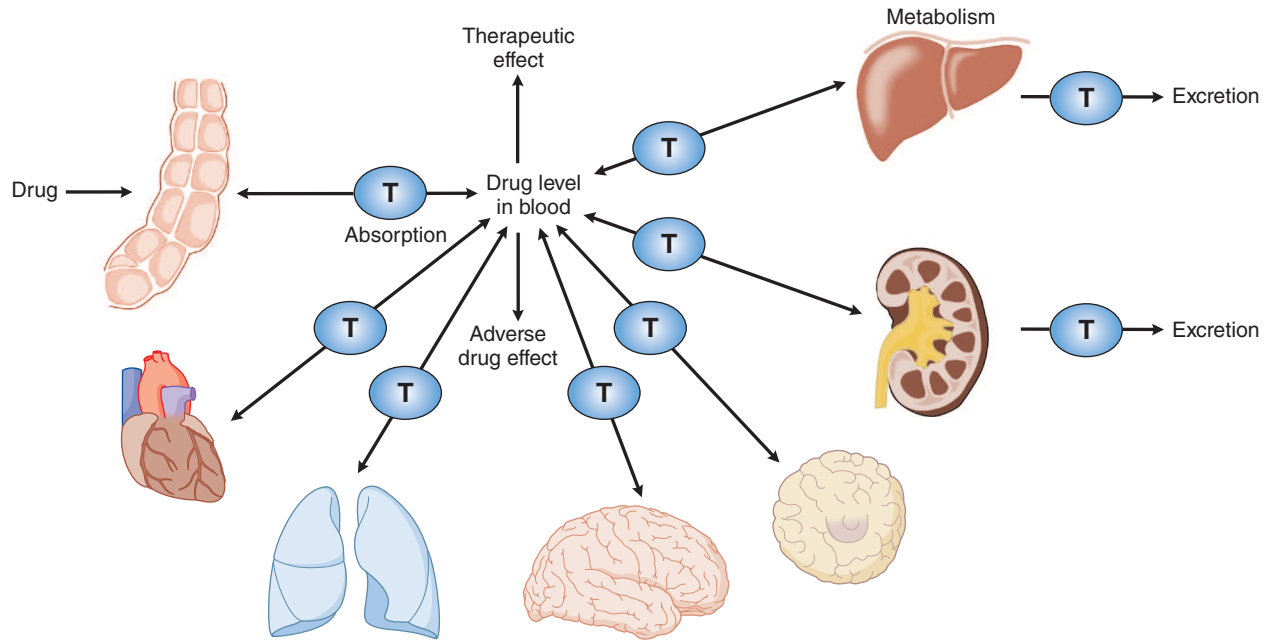

Figure 4–1 *Membrane transporters in pharmacokinetic pathways.* Membrane transporters (T) play roles in pharmacokinetic pathways (drug absorption, distribution, metabolism, and excretion), thereby setting systemic drug levels. Drug levels often drive therapeutic and adverse drug effects.

Membrane Transporters and Adverse Drug Responses

As controllers of import and export, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play crucial roles in the cellular activities and toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories (Figure 4–3):

- Decreased uptake or excretion at clearance organs
- Increased uptake or decreased efflux at target organs
- Altered transport of endogenous compounds at target organs

Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the systemic circulation, thereby affecting exposure, and hence toxicity, in all organs (Figure 4–3, top panel). For example, after oral administration of an HMG-CoA reductase inhibitor (e.g., *pravastatin*), the efficient first-pass hepatic uptake of the drug by the SLC OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses, such as skeletal muscle myopathy.

Transporters expressed in tissues that may be targets for drug toxicity (e.g., brain) or in barriers to such tissues (e.g., the BBB) can tightly control local drug concentrations and thus control the exposure of these tissues to the drug (Figure 4–3, middle panel). For example, endothelial cells in the BBB are linked by tight junctions, and some efflux transporters are expressed on the blood-facing (luminal) side, thereby restricting the penetration of compounds into the brain. The interactions of *loperamide* and *quinidine* are good examples of transporter-controlled drug exposure at this site. *Loperamide* is a peripheral opioid used in the treatment of diarrhea and is a substrate of Pgp, which prevents accumulation of

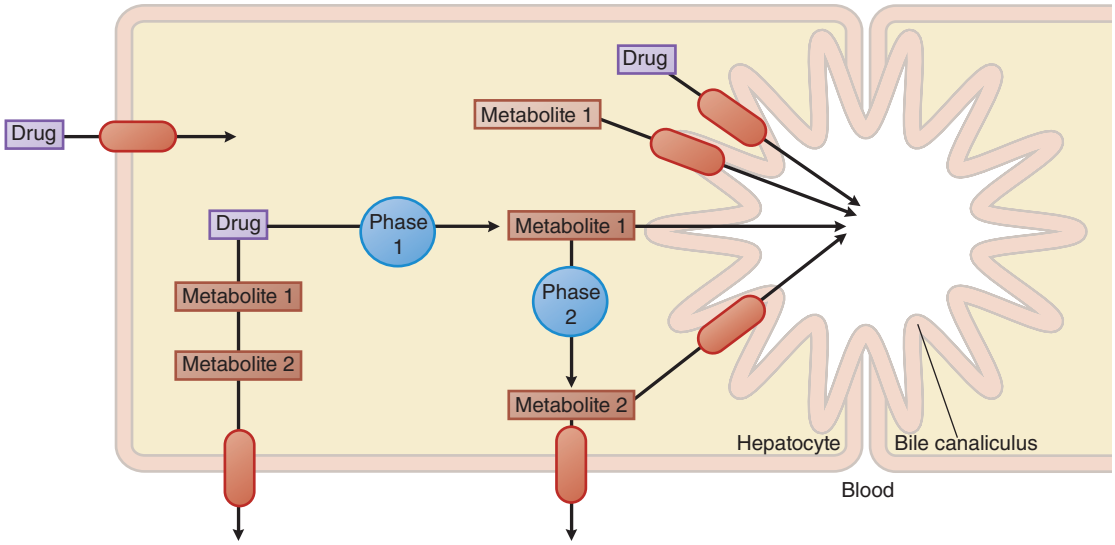

Figure 4–2 *Hepatic drug transporters.* Membrane transporters (red ovals with arrows) work in concert with phase 1 and phase 2 drug-metabolizing enzymes in he hep ıto vte to mediate the up ak and effl x of drugs and their ı ıetabolites.

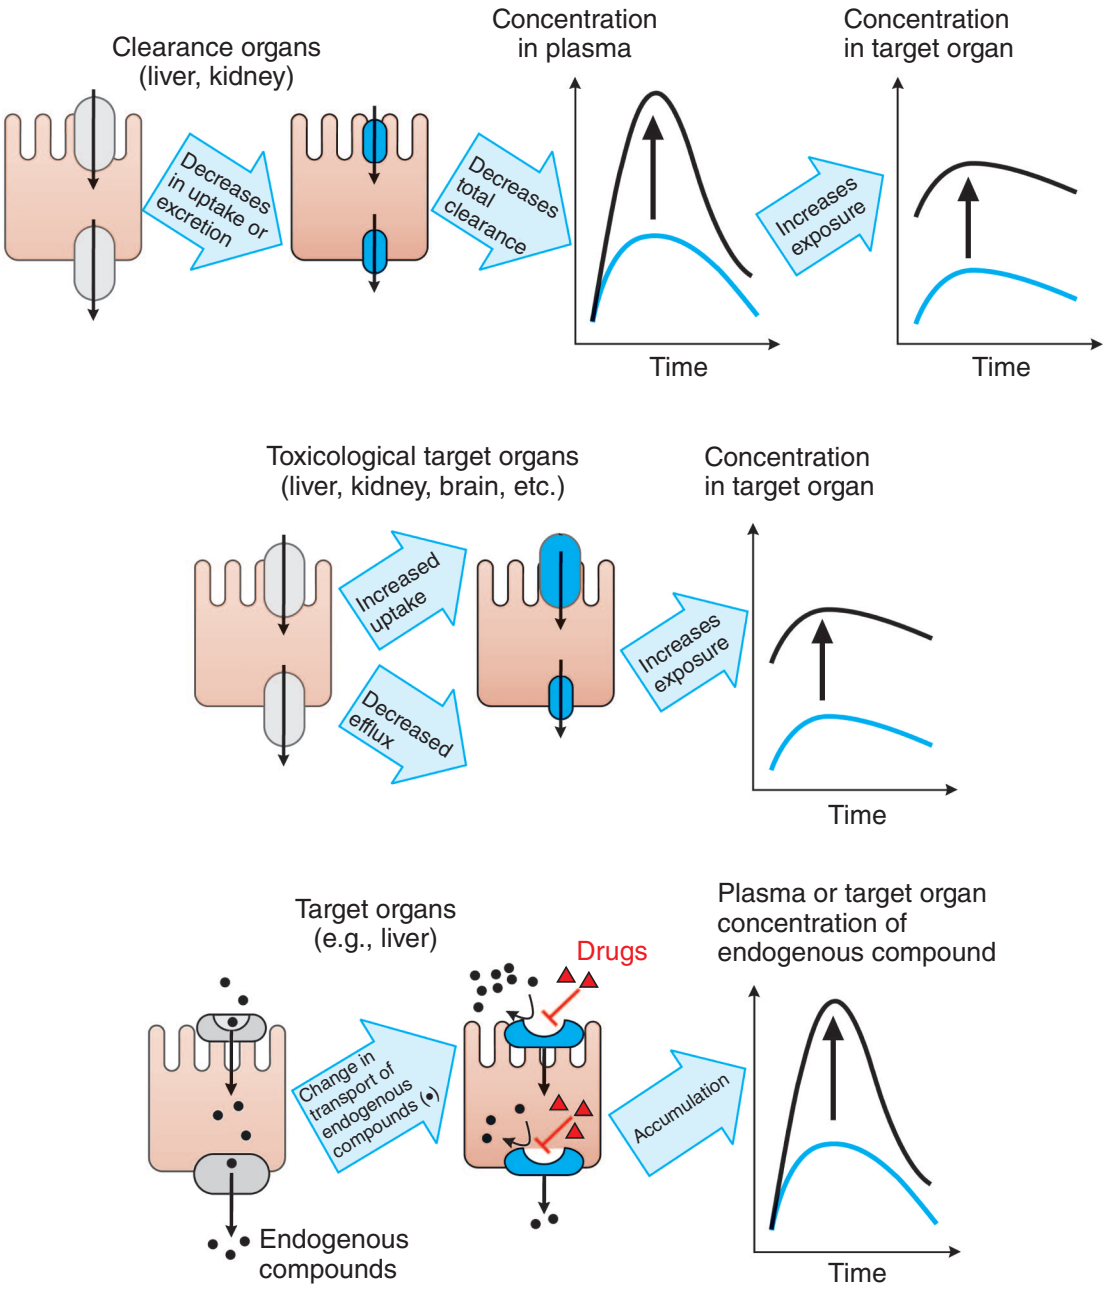

Figure 4–3 *Major mechanisms by which transporters mediate adverse drug responses.* Three cases are given. The left panel of each case provides a representation of the mechanism; the right panel shows the resulting effect on drug levels. (*Top panel*) Increase in the plasma concentrations of drug due to a decrease in the uptake or secretion in clearance organs (e.g., liver and kidney). (*Middle panel*) Increase in the concentration of drug in toxicological target organs due to enhanced uptake or reduced efflux. (*Bottom panel*) Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-inhibited efflux of the endogenous compound.

loperamide in the CNS. Inhibition of Pgp-mediated efflux in the BBB would cause an increase in the concentration of *loperamide* in the CNS and potentiate adverse effects. Indeed, coadministration of *loperamide* and the potent Pgp inhibitor *quinidine* results in significant respiratory depression, an adverse response to *loperamide*. Pgp is also expressed in the intestine, where inhibition of Pgp will reduce intestinal efflux of *loperamide*, increase its systemic concentrations, and contribute to increased concentrations in the CNS.

Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters. For example, biguanides (e.g., *metformin*), used for the treatment of type 2 diabetes mellitus, can produce lactic acidosis, a lethal side effect. Biguanides are substrates of OCT1 (SLC22A1), which is highly expressed in the liver; of OCT2 (SLC22A2), expressed in the kidney; and of OCT3 (SLC22A3) in adipocytes and skeletal muscle. In experimental animals lacking OCT1, hepatic uptake of biguanides and development of lactic acidosis are greatly reduced. These results indicate that OCT1-mediated hepatic uptake of biguanides and uptake into tissues such as kidney and skeletal muscle mediated by other OCTs play an important role in facilitating tissue concentrations of biguanides and thus the development of lactic acidosis (Wang et al., 2003), which may result from biguanide-induced impairment of mitochondrial function and consequent increased glycolytic flux (Dykens et al., 2008). Biguanides are exported by the MATE1 transporter, and inhibition of this efflux by a variety of drugs, including tyrosine kinase inhibitors, enhances biguanide toxicity (DeCorter et al., 2012).

OAT1 (SLC22A1), OCT1, and OCT2 provide other examples of transporter-related toxicity. OAT1 is expressed mainly in the kidney and is responsible for the renal tubular secretion of anionic compounds. Substrates of OAT1, such as *cephaloridine* (a β-lactam antibiotic) and *adefovir* and *cidofovir* (antiviral drugs), reportedly cause nephrotoxicity. Exogenous expression of OCT1 and OCT2 enhances the sensitivities of tumor cells to the cytotoxic effect of *oxaliplatin* for OCT1 and *cisplatin* and *oxaliplatin* for OCT2 (Zhang et al., 2006a). Renal toxicity of *cisplatin* is modulated by OCT2 present on the basolateral membrane of the proximal tubule as well as by transporters in the SLC47 family, MATE1 (SLC47A1) and MATE2 (SLC47A2), on the apical membrane (Harrach and Ciarimboli, 2015).

Drugs may modulate transporters for endogenous ligands and thereby exert adverse effects (Figure 4–3, bottom panel). For example, bile acids are taken up mainly by NTCP and excreted into the bile by BSEP (*ABCB11*). Bilirubin is taken up by OATP1B1 and conjugated with glucuronic acid; bilirubin glucuronide is excreted into the bile by MRP2 (*ABCC2*) and transported into the blood by MRP3. Bilirubin glucuronide in the blood undergoes reuptake into the liver by OATP1B1. Inhibition of these transporters by drugs may cause cholestasis or hyperbilirubinemia.

In addition to the simple mechanism of controlling plasma and tissue concentrations of xenobiotics, transporters may act through more complicated mechanisms to mediate adverse drug reactions. For example, Pgp is involved in the extrusion of inflammatory cytokines from T cells and dendritic cells. Notably, Pgp knockout mice may spontaneously develop inflammation associated hepatocellular carcinoma (Seelig, 2020). Pgp modulators may thus dysregulate immune responses.

Uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics, thereby influencing the systemic or site-specific toxicity of drugs.

Basic Mechanisms of Membrane Transport

Transporters Versus Channels

Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds. Recent technological advances in X-ray crystallography and cryo-electron microscopy have resulted in a plethora of new ion channel structures leading to enhanced understanding of the mechanisms underlying their function (Thompson and Baenziger, 2020). In general, ion channels follow two archetypal classes: voltage-gated channels and ligand-gated channels. In both models, the channel forms a gated pore that controls the passage of ions as they move through the pore and across a membrane (Isacoff et al., 2013). The gate may be controlled by voltage or by ligand binding, leading to two primary states, open and closed, that are stochastic phenomena. Only in the open state do such channels act as pores that allow the selected ions to flow down their electrochemical gradients. After opening, channels stop conducting ions as a function of time by either returning to the closed state or by inactivating. As noted, drugs termed *potentiators* (e.g., *ivacaftor*) may increase the probability that a channel is in the open state. By contrast, a *transporter* forms an intermediate complex with the substrate (solute), and a subsequent conformational change in the transporter induces translocation of the substrate to the other side of the membrane. As a consequence, the kinetics of solute movement differ between transporters and channels. Typical turnover rate constants of channels are 10^6 to 10^8 sec^{-1}; those of transporters are, at most, 10^1 to 10^3 sec^{-1}. Because a particular transporter forms intermediate complexes with specific compounds (referred to as *substrates*), transporter-mediated membrane transport is characterized by saturability and inhibition by substrate analogues, as described in the section Kinetics of Transport.

The basic mechanisms involved in solute transport across biological membranes include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. Figure 4–4 depicts these mechanisms.

Passive Diffusion

Simple diffusion of a solute across the plasma membrane consists of three processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Passive diffusion of any solute (including drugs) occurs down an electrochemical potential gradient of the solute.

Facilitated Diffusion

Diffusion of ions and organic compounds across the plasma membrane may be facilitated by a membrane transporter. Facilitated diffusion is a form of transporter-mediated membrane transport that does not require

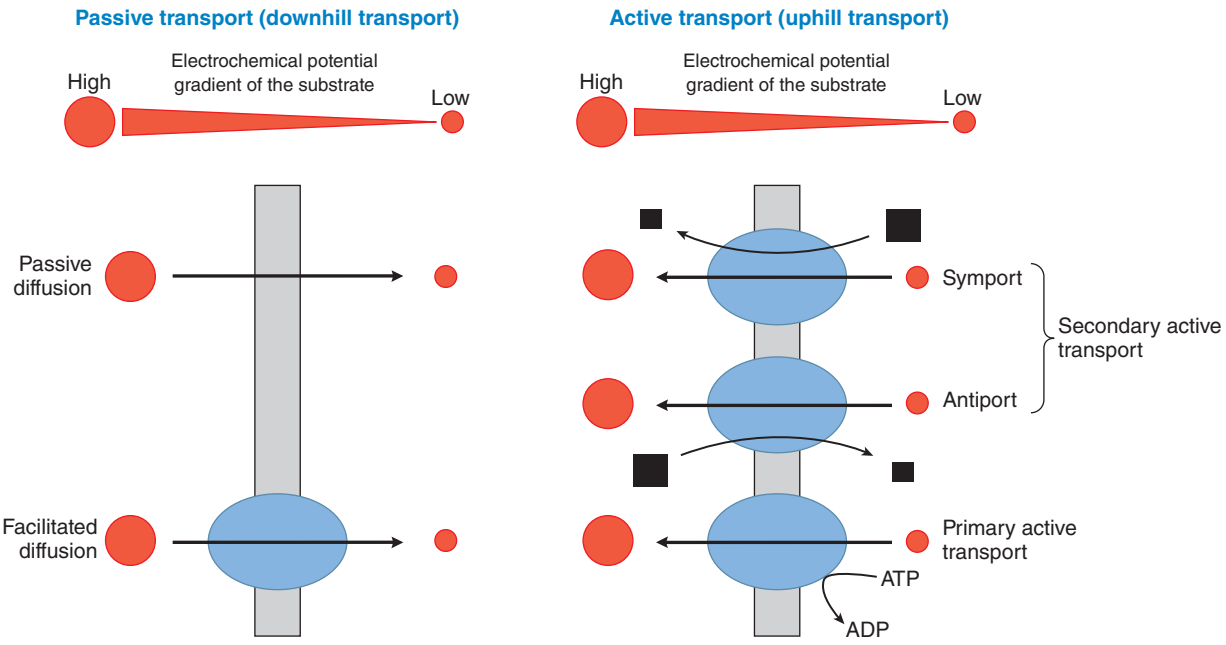

Figure 4–4 *Classification of membrane transport mechanisms.* Red circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Blue ovals depict transport proteins.

energy input. Just as in passive diffusion, the transport of ionized and nonionized compounds across the plasma membrane occurs down their electrochemical potential gradients. Therefore, steady state will be achieved when the electrochemical potentials of a compound on both sides of the membrane become equal.

Active Transport

Active transport is the form of membrane transport that requires the input of energy. It is the transport of solutes against their electrochemical gradients, leading to the concentration of solutes on one side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary active transport in which ATP hydrolysis is coupled directly to solute transport, and secondary active transport, in which transport uses the energy in an existing electrochemical gradient established by an ATP-using process to move a solute uphill against its electrochemical gradient. Secondary active transport is further subdivided into symport and antiport. Symport describes movement of driving ion and transported solute in the same direction. Antiport occurs when the driving ion and the transported solute move in opposite directions, as when the sodium/calcium exchanger (SLC8A1) transports $3Na^+$ *into* and $1Ca^{2+}$ *out of* a cardiac ventricular myocyte (see Figure 4–4).

Primary Active Transport

Membrane transport that directly couples with ATP hydrolysis is called *primary active transport*. ABC transporters are examples of primary active transporters. In mammalian cells, ABC transporters mediate the unidirectional efflux of solutes across biological membranes. Another example of primary active transport that establishes the inward Na^+ gradient and outward K^+ gradient across the plasma membrane, found in all mammalian cells, is the Na^+,K^+-ATPase.

Secondary Active Transport

In secondary active transport, the transport across a biological membrane of a solute, S_1, against its concentration gradient is energetically driven by the transport of another solute, S_2, in accordance with its electrochemical gradient. Depending on the transport direction of the solute, secondary active transporters are classified as either symporters or antiporters. For example, using the inwardly directed Na^+ concentration gradient across the plasma membrane that the Na^+,K^+-ATPase maintains, the inward movement of 3 Na^+ can drive the outward movement of 1 Ca^{++} via the Na^+/Ca^{++} exchanger, NCX. This is an example of *antiport*, or exchange transport, in which the transporter moves S_2 and S_1 in opposite directions. *Symporters*, also termed *cotransporters*, transport S_2 and S_1 in the same direction, as for glucose transport into the body from the lumen of the small intestine by the Na^+-glucose transporter SGLT1 (see Figure 4–4).

Kinetics of Transport

The flux of a substrate (rate of transport) across a biological membrane via a transporter-mediated process is characterized by saturability. The relationship between the flux v and substrate concentration S in a transporter-mediated process is given by the Michaelis-Menten equation:

$$v = \frac{V_{max} S}{K_m + S} \qquad \text{(Equation 4–1)}$$

where V_{max} is the maximum transport rate and is proportional to the density of transporters on the plasma membrane, and K_m is the Michaelis constant, which represents the substrate concentration at which the flux is half the V_{max} value. K_m is an approximation of the dissociation constant of the substrate from the intermediate complex. The K_m and V_{max} values can be determined by examining the flux at different substrate concentrations. Rearranging Equation 4–1 gives

$$v/S = -v/K_m + V_{max}/K_m \qquad \text{(Equation 4–2)}$$

Plotting v/S versus v provides a convenient graphical method for determining the V_{max} and K_m values, the Eadie-Hofstee plot (Figure 4–5): The slope is $-1/K_m$ and the x intercept is V_{max}

Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. The manner of inhibition can be categorized as one of three types: *competitive*, *noncompetitive*, and *uncompetitive*. Competitive inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent K_m value in the presence of inhibitor. The flux of a substrate in the presence of a competitive inhibitor is

$$\text{Competitive inhibition} \quad v = \frac{V_{max} \cdot S}{K_m \cdot \left(1 + \frac{I}{K_i}\right) + S} \qquad \text{(Equation 4–3)}$$

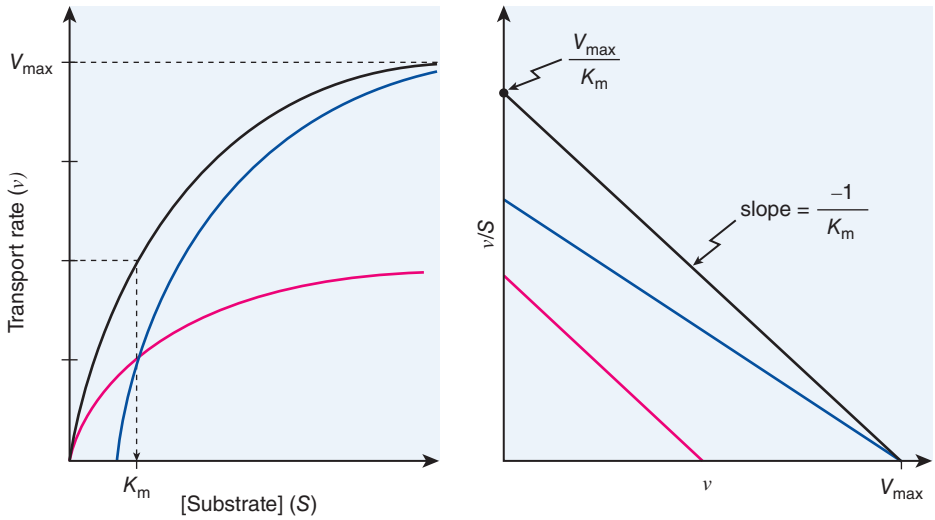

Figure 4–5 *Eadie-Hofstee plot of transport data.* The black lines show the hyperbolic concentration-dependence curve (v vs. S, left panel) and the Eadie-Hofstee transformation of the transport data (v/S vs. v, right panel) for a simple transport system. The blue lines depict transport in the presence of a competitive inhibitor (surmountable inhibition; achieves same V_{max}). The red lines depict the system in the presence of a noncompetitive inhibitor that effectively reduces the number of transporting sites but leaves the K_m of the functional sites unchanged. Involvement of multiple transporters with different K_m values gives an Eadie-Hofstee plot that is curved and can be resolved into multiple components. Algebraically, the Eadie-Hofstee plot of kinetic data is equivalent to the Scatchard plot of equilibrium binding data (see Chapter 3).

where I is the concentration of inhibitor, and K_i is the inhibition constant. Noncompetitive inhibition assumes that the inhibitor has an allosteric effect on the transporter, does not inhibit the formation of an intermediate complex of substrate and transporter, but does inhibit the subsequent translocation process.

$$\text{Noncompetitive inhibition} \quad v = \frac{V_{max} \cdot S}{\left(1 + \frac{I}{K_i}\right)\left(K_m + S\right)} \qquad \text{(Equation 4–4)}$$

Uncompetitive inhibition assumes that inhibitors can form a complex only with an intermediate complex of the substrate and transporter and inhibit subsequent translocation.

$$\text{Uncompetitive inhibition} \quad v = \frac{V_{max} \cdot S}{K_m + S\left(1 + \frac{I}{K_i}\right)} \qquad \text{(Equation 4–5)}$$

Transporter Structure and Mechanism

Predictions of secondary structure of membrane transport proteins based on hydropathy analysis indicate that membrane transporters in the SLC and ABC superfamilies are multimembrane-spanning proteins. Emerging crystal structures are adding to our ideas of the mechanisms of transport via these proteins.

ABC Transporters

The ABC superfamily includes 49 genes, each containing one or two conserved ABC regions. The core catalytic ABC regions of these proteins bind and hydrolyze ATP, using the energy for uphill transport of their substrates across the membrane. Most ABC transporters in eukaryotes move compounds from the cytoplasm to the cell exterior or into an intracellular compartment (endoplasmic reticulum, mitochondria, peroxisomes). ABC transporters also are found in prokaryotes, where they are involved predominantly in the import of essential compounds that cannot be obtained by passive diffusion (sugars, vitamins, metals, etc.).

Recent studies using cryo-electron microscopy (cryo-EM) have led to an enhanced understanding of the structure and function of ABC transporters. In general, ABC transporters are organized symmetrically with two major components, a nucleotide-binding domain (NBD) and a transmembrane domain (TMD), each associated with a function (Lusvarghi et al., 2020). The NBDs on the cytoplasmic side are considered the motor domains of ABC transporters and contain conserved motifs (e.g., Walker-A motif, ABC signature motif) that participate in binding and hydrolysis of ATP. Crystal structures of all four full ABC transporters show two NBDs, which are in contact with each other, and a conserved fold. The mechanism shared by these ABC transporters appears to involve binding of ATP to the NBDs, which subsequently triggers an outward-facing conformation of the transporters. Dissociation of the hydrolysis products of ATP appears to result in an inward-facing conformation. The TMDs are involved in substrate recognition and translocation. TMDs from Pgp are formed from a single peptide chain, whereas TMDs from BCRP are formed from a homodimer. A floppase model for Pgp-mediated efflux was proposed in 1992 and subsequently validated (Seelig, 2020). In brief, amphiphilic molecules constitute the substrates of Pgp; an amphiphilic substrate partitions from the aqueous intracellular environment to the adjacent lipid bilayer, where it binds to the transporter; with the hydrolysis of ATP, the transporter-substrate complex changes conformation and the substrate is released into the outer region of the bilayer; the substrate then partitions into the aqueous extracellular compartment. Presumably, one ATP molecule is hydrolyzed for every drug molecule transported. On dissociation of the hydrolysis products, the transporter returns to the inward-facing conformation, permitting the binding of ATP and substrate to repeat the cycle (Figure 4–6). Although some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function.

SLC Transporters

The SLC superfamily of transporters comprises a structurally diverse group that includes channels, facilitators, and secondary active transporters (Hediger et al., 2013). Although structurally diverse, most SLC transporters share certain structural characteristics. For example, all have TMDs, with most having between 7 and 12 TMDs (Garibsingh and Schlessinger, 2019; Pizzagalli et al., 2021). Crystal structures reveal that the TMDs have a pseudosymmetry and that SLC protein folds fall into

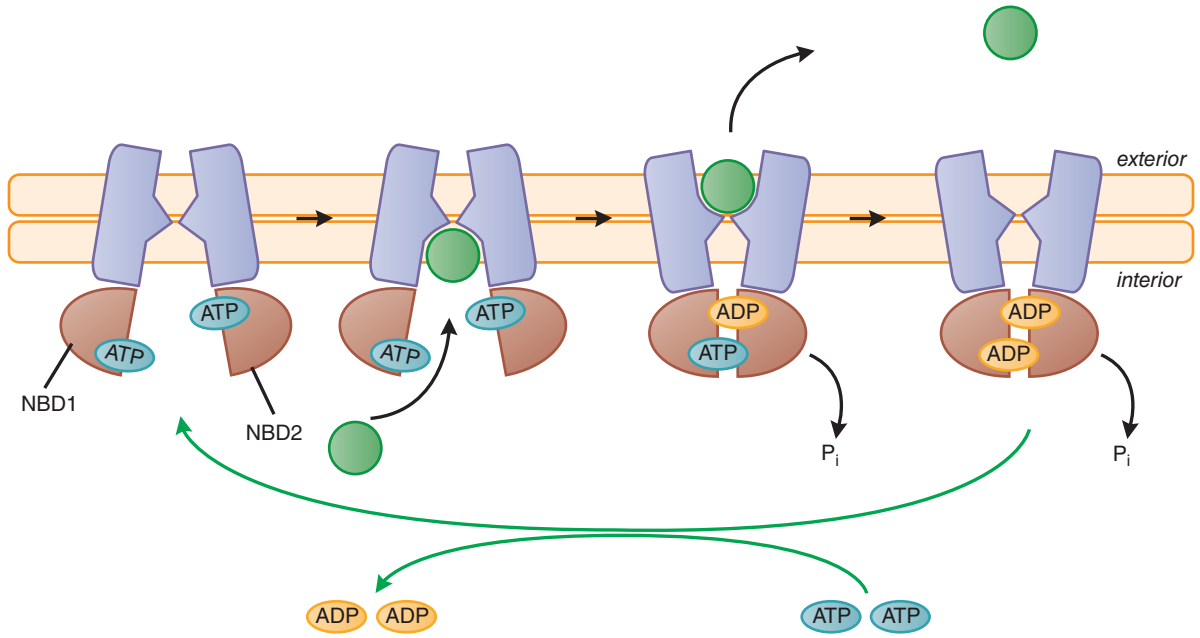

Figure 4–6 *Model of ABC transporter function.* The transporter accepts a solute molecule at the cytoplasmic membrane surface when its nucleotide NBDs are fully charged with ATP. Sequential hydrolysis of the ATP molecules produces steric change and leads to the translocation and release of the solute at the exterior membrane surface. Exchange of ADP for ATP on both NBDs completes the cycle and restores the system for readiness to transport another solute molecule.

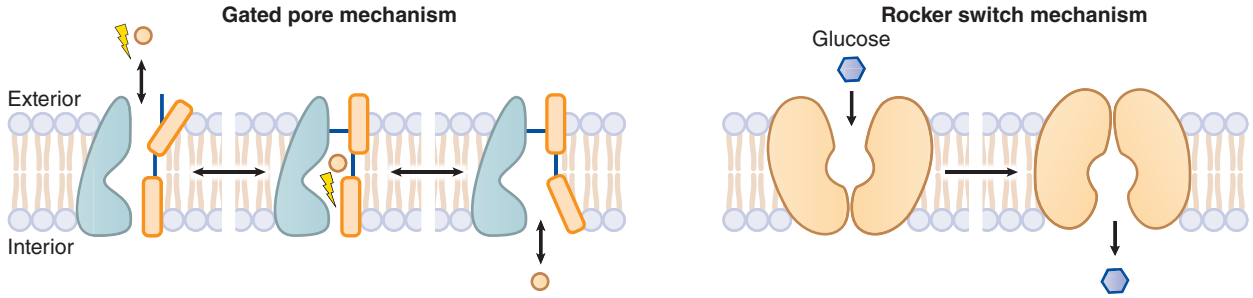

Figure 4–7 *Two alternating access models of membrane transport.* The gated pore represents a model that includes two domains, a stationary domain and a mobile domain that undergoes a hinge-like rearrangement to release the substrate to the intracellular side. The substrate is shown as a sphere and the lightning bolt represents an energizer such as sodium. This model is applicable to some sodium-dependent SLC transporters. The rocker switch represents the model by which major facilitator superfamily (MFS) proteins, such as Lac Y, work. This example models a facilitated glucose transporter, GLUT2.

two major groups, MFS and LeuT. Several members of the SLC2 family, glucose transporters (GLUTs), have been crystallized and have the MFS fold. Common drug transporters in the SLC22 family also have the MFS fold, which basically implies that they have two pseudo-repeats of six TMDs. The two pseudo-repeats serve in a rocker switch mechanism, alternating the substrate binding site to the intracellular or extracellular surface of the plasma membrane (Figure 4–7). Once a substrate binds to an accessible site (e.g., on the extracellular side) the TMDs shift, exposing the binding site to the other surface and releasing the substrate. The transport cycle is as follows: the substrate accesses the substrate binding site on one side of the membrane; substrate binding induces structural changes in the carrier protein, reorienting the opening of the binding site to the opposite side. The substrate dissociates from the transport site, allowing another substrate to be bound and transported in the opposite direction. Such a mechanism requires binding of different substrates (the "outbound" and "inbound" substrates) to be mutually exclusive; that is, there is a single reorienting binding site. Another common fold is the LeuT fold, which forms a rocker bundle or a gated pore (Garibsingh and Schlessinger, 2019; Pizzagalli et al., 2021). Transporters in the SLC5 and SLC6 families have the LeuT fold, which works in a slightly different way than the rocker switch. In brief, there are two pseudo-repeats of five TMDs, and only one arm is responsible for the alternating access of the binding site to the intracellular or extracellular surfaces of the plasma membrane. The other arm is stationary (Figure 4–7). SLC substrates include ionic and nonionic species and a variety of xenobiotics and drugs.

Vectorial Transport

Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called *vectorial transport* (Figure 4–8). Vectorial transport is important for the absorption of nutrients and bile acids in the intestine and in the intestinal absorption of drugs (from lumen to blood). Vectorial transport also plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen. In addition, efflux of drugs from the brain via brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport. The ABC transporters mediate only unidirectional efflux, whereas SLC transporters mediate either drug uptake or drug efflux. For lipophilic compounds that have sufficient membrane permeability, ABC transporters alone are able to achieve vectorial transport without the help of influx transporters. For relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. A typical configuration involves a primary or secondary active transporter at one membrane and a passive transporter at the other. In this way, common substrates of coordinated transporters are transferred efficiently across the epithelial barrier.

In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into the hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such

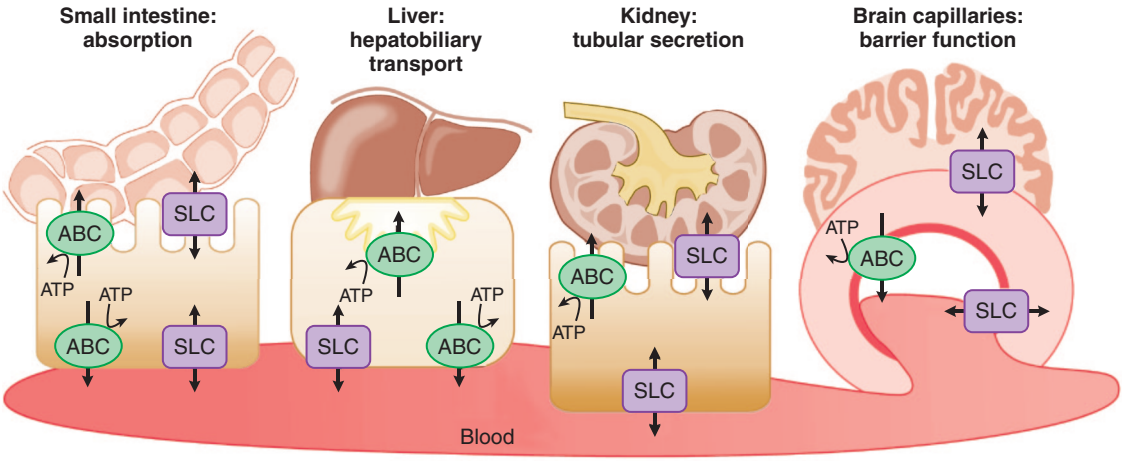

Figure 4–8 *Transepithelial and transendothelial flux.* Transepithelial or transendothelial flux of drugs requires distinct transporters at the two surfaces of the epithelial or endothelial barrier. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney, liver (elimination), and brain capillary endothelial cells that compose the BBB.

compounds into the bile. Multiple combinations of uptake (OATP1B1, OATP1B3, OATP2B1) and efflux transporters (MDR1, MRP2, and BCRP) are involved in the efficient transcellular transport of a wide variety of compounds in the liver by using a system called "doubly transfected cells"; these cells express both uptake and efflux transporters on each side. In many cases, overlapping substrate specificities between the uptake transporters (OATP family) and efflux transporters (MRP family) make the vectorial transport of organic anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (see Figure 4–8).

Transporter expression in various tissues can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or downregulation of transporter mRNAs. Type II nuclear receptors, which form heterodimers with the 9-*cis*-retinoic acid receptor (RXR), can regulate transcription of genes for drug-metabolizing enzymes and transporters (see Table 5–4, Figures 3–23, 5–13 and 5–14; see also Urquhart et al., 2007). Such receptors include PXR (NR1I2), CAR (NR1I3), FXR (NR1H4), PPARα, and RAR. Except for CAR, these are ligand-activated nuclear receptors that, as heterodimers with RXR, bind specific elements in the enhancer regions of target genes. CAR has constitutive transcriptional activity that is antagonized by inverse agonists, such as androstenol and androstanol, and induced by barbiturates. PXR, also referred to as SXR in humans, is activated by synthetic and endogenous steroids, bile acids, and drugs such as *clotrimazole, phenobarbital, rifampicin, sulfinpyrazone, ritonavir, carbamazepine, phenytoin, sulfadimidine, paclitaxel*, and *hyperforin* (a constituent of St. John's wort) (Guo and Zhou, 2015). The potency of activators of PXR varies among species, such that rodents are not necessarily a model for effects in humans. There is an overlap of substrates between CYP3A4 and Pgp, and PXR mediates coinduction of CYP3A4 and Pgp, supporting their synergy in efficient detoxification. Recent studies in human hepatocytes treated with an activator of PXR suggested that the expression levels of enzymes in the CYP family are much more highly increased than the levels of transporters in the SLC or ABC families (Smith et al., 2014). Table 4–1 summarizes the effects of drug activation of type II nuclear receptors on expression of transporters in the liver (Amacher, 2016).

DNA methylation is one mechanism underlying the epigenetic control of gene expression. Reportedly, the tissue-selective expression of transporters is achieved by DNA methylation (silencing in the transporter-negative tissues) as well as by transactivation in the transporter-positive tissues. Transporters subjected to epigenetic control in the liver and kidney include OATP1B1, OATP1B3, OCT2, OAT1, and OAT3. Other transporters that have been shown to be subject to epigenetic regulation in a variety of cell lines include MDR1 and BCRP in the ABC superfamily and OCT1, OCT3, and OCTN2 in the SLC22 family (Hirota et al., 2017).

Transporter Superfamilies in the Human Genome

The SLC Superfamily

The SLC superfamily includes 65 families and represents about 458 genes in the human genome, the products of which are membrane-spanning proteins, some of which are associated with genetic diseases (Table 4–2)

TABLE 4–1 ■ REGULATION OF TRANSPORTER EXPRESSION BY NUCLEAR RECEPTORS IN HUMANS

TRANSPORTER	TRANSCRIPTION FACTOR	LIGAND	EFFECT
MDR1 (P-gp)	PXR	Rifampin	↑ Transcription activity
			↑ Expression in duodenum
			↓ Oral bioavailability of digoxin
			↓ AUC of talinolol
			↑ Expression in primary hepatocyte
		St John's wort	↑ Expression in duodenum
			↓ Oral bioavailability of digoxin
	CAR	Phenobarbital	↓ Expression in primary hepatocyte
MRP2	PXR	Rifampin	↑ Expression in duodenum
		Rifampin/hyperforin	↑ Expression in primary hepatocyte
	FXR	GW4064/chenodeoxycholate	↑ Expression in HepG2-FXR
	CAR	Phenobarbital	↑ Expression in hepatocyte
BCRP	PXR CAR	Rifampin Phenobarbital	↑ Expression in primary hepatocyte
MRP3	PXR	Rifampin	↑ Expression in hepatocyte
OATP1B1	SHP1	Cholic acid	Indirect effect on HNF1α expression
	PXR	Rifampin	↑ Expression in hepatocyte
	FXR	Chenodeoxycholate	↑ Expression in hepatocyte
OATP1B3	FXR	Chenodeoxycholate	↑ Expression in hepatoma cells
	PXR	Rifampin	↓ Expression in hepatocyte
OCT1	PXR	Rifampin	↓ Expression in hepatocyte
	HNF4α	Berberine	↑ Expression in hepatocyte
BSEP	FXR	Chenodeoxycholate	↑ Transcription activity
OSTα/β	FXR	Chenodeoxycholate/GW4064	↑ Transcription activity
		Chenodeoxycholate	↑ Expression in ileal biopsies

CAR, constitutive androstane receptor; FXR, farnesoid X receptor; HNF α, hepatocyte nuclear factor α; PXR, pregnane X receptor; SHP, small heterodimer partner.

TABLE 4–2 ■ THE HUMAN SOLUTE CARRIER SUPERFAMILY

GENE	FAMILY	SELECTED DRUG SUBSTRATES	EXAMPLES OF LINKED HUMAN DISEASES
SLC1	Low-K_m glu/neutral aa T		Dicarboxylic aminoaciduria
SLC2	Facilitative GLUT		Fanconi-Bickel syndrome
SLC3	Heavy subunits, heteromeric aa Ts	Melphalan	Classic cystinuria type I
SLC4	Bicarbonate T		Distal renal tubule acidosis
SLC5	Na^+ glucose co-T	Dapagliflozin	Glucose-galactose malabsorption
SLC6	Na^+/Cl^--dependent neurotransmitter T	Paroxetine, fluoxetine	Cerebral creatine deficiency syndrome
SLC7	Cationic aa T	Melphalan	Lysinuric protein intolerance
SLC8	Na^+/Ca^{2+} Exch	Di-CH_3-arg	
SLC9	Na^+/H^+ Exch	Thiazide diuretics	Hypophosphatemic nephrolithiasis
SLC10	Na^+ bile salt co-T	Benzothiazepines (diltiazem)	Primary bile acid malabsorption
SLC11	H^+-coupled metal ion T		Hereditary hemochromatosis
SLC12	Electroneutral cation–Cl^- co-T		Gitelman syndrome
SLC13	Na^+–SO_4^-/COO^- co-T	SO_4^-/cys conjugates	
SLC14	Urea T		Kidd antigen blood group
SLC15	H^+–oligopeptide co-T	Valacyclovir	
SLC16	Monocarboxylate T	Salicylate, T_3/T_4, atorvastatin	Familial hyperinsulinemic hypoglycemia 7
SLC17	Vesicular glu T		Sialic acid storage disease
SLC18	Vesicular amine T	Reserpine	Myasthenic syndromes
SLC19	Folate/thiamine T	Methotrexate	Thiamine-responsive megaloblastic anemia
SLC20	Type III Na^+–PO_4^- co-T		
SLC21 (SLCO)	Organic anion T	Pravastatin	Rotor syndrome, hyperbilirubinemia
SLC22	Organic ion T	Pravastatin, metformin	Primary systemic carnitine deficiency
SLC23	Na^+-dependent ascorbate T	Vitamin C	
SLC24	$Na^+/(Ca^{2+}$-$K^+)$ Exch		Congenital stationary night blindness type 1D
SLC25	Mitochondrial carrier		Familial hypertrophic cardiomyopathy
SLC26	Multifunctional anion Exch	Salicylate, ciprofloxacin	Multiple epiphyseal dysplasia 4
SLC27	Fatty acid T		Ichthyosis prematurity syndrome
SLC28	Na^+-coupled nucleoside T	Gemcitabine, cladribine	
SLC29	Facilitative nucleoside T	Dipyridamole, gemcitabine	
SLC30	Zn efflux		Hypermanganesemia with dystonia
SLC31	Cu T	Cisplatin	
SLC32	Vesicular inhibitory aa T	Vigabatrin	
SLC33	Acetyl-CoA T		Congenital cataracts
SLC34	Type II Na^+-PO_4^-/ co-T		Hypercalciuric rickets
SLC35	Nucleoside-sugar T		Leukocyte adhesion deficiency II
SLC36	H^+-coupled aa T	D-Serine, cycloserine	Iminoglycinuria
SLC37	Sugar-phosphate/PO_4^- Exch		Glycogen storage disease
SLC38	Na^+-coupled neutral aa T		
SLC39	Metal ion T		Acrodermatitis enteropathica
SLC40	Basolateral Fe T		Hemochromatosis type IV
SLC41	MgtE-like Mg^{2+} T		
SLC42	Rh ammonium T		Rh-null regulator type disease
SLC43	Na^+-independent L-like aa T	Riboflavin	Oculocutaneous albinism type 4
SLC44	Choline-like transporter family		Neurodegeneration, childhood-onset, with ataxia, optic atrophy and cognitive decline, CONATOC

SLC65	NPC-type cholesterol transporters		

aa, amino acid; Exch, exchanger; T, transporter; T_3/T_4, thyroid hormone.

(Pizzagalli et al., 2021). Myriad substrates, including inorganic and organic ions, interact with SLC transporters. There are highly selective transporters that interact with structurally similar molecules, such as transporters in the SLC6 family that interact with specific monoamines, including dopamine (DAT, SLC6A2) and norepinephrine (NET, SLC6A3). On the other hand, there are transporters that accept a broad range of chemically diverse substrates, such as organic ion transporters in the SLC22 family. Unlike ABC transporters that rely on ATP hydrolysis to actively translocate their substrates, SLC transporters are mostly facilitative transporters, although some are secondary active transporters (see Figure 4–4). Knowledge of the SLC superfamily continues to grow; 13 new SLC families representing 63 genes have been identified since the prior edition of this text.

The physiologic roles of SLC transporters are important and diverse. For example, transporters in the SLC1, SLC3, SLC6, SLC7, SLC25, and SLC36 families, which are expressed in the intestine and kidney, among other organs, transport an array of amino acids critical in protein synthesis and energy homeostasis. Glucose and other sugars interact with transporters in the SLC2, SLC5, and SLC50 families for absorption, elimination, and cellular distribution. Proteins in the SLC11, SLC30, SLC39, and SLC40 families transport zinc, iron, and other metals. Members of the SLC19, SLC46, and SLC52 families transport water-soluble vitamins. Transporters in the SLC6 family move neurotransmitters across the plasma membrane; SLC18 family members transport neurotransmitters into storage vesicles.

Pharmacologically, SLC transporters have been characterized for their role in drug absorption, elimination, and tissue distribution and importantly as mediators of drug-drug interactions. Notably, transporters in the solute carrier organic anion family, SLCO, interact with diverse substrates, including statins and antidiabetic drugs. Transporters in the SLC22 family interact with anionic and cationic drugs, including many antibiotics and antiviral agents, to mediate active renal secretion. SLC transporters are increasingly being targeted for treatment of human disease. Over 100 SLC transporters are associated with monogenic disorders and therefore may be usefully targeted in the treatment of rare diseases (Lin et al., 2015). Several monogenic disorders associated with mutations in SLC transporters are detected in newborn screening programs, including carnitine transporter deficiency, an autosomal recessive disorder caused by mutations in SLC22A5 (OCTN2). Many SNPs in SLC transporters have reached a genome-wide level of significance in association studies of human disease. Notably, polymorphisms in *SLC30A8* are associated with type 1 diabetes mellitus, and polymorphisms in *SLC22A4* and *SLC22A5* are associated with inflammatory bowel disease.

An estimated 30% of SLC transporters in the human genome remain orphans, that is, they or their direct species orthologs have no known substrates. Recent efforts in transporter biology are aimed at discovering substrates for these transporters, and several such studies have been successful: SLC22A24 has been found to transport conjugates of steroids and to play a role in steroid homeostasis; SLC22A15 is a zwitterion transporter that transports endogenous and xenobiotic zwitterions such as ergothioneine and *gabapentin* (Yee et al., 2019, 2020).

The ABC Superfamily

The seven subfamilies of human ABC transporters are essential for many cellular processes, and mutations in at least 13 of the genes for ABC transporters cause or contribute to human genetic disorders (Table 4–3) (Arana

TABLE 4–3 THE HUMAN ATP BINDING CASSETTE (ABC) SUPERFAMILY

GENE	FAMILY	NUMBER OF MEMBERS	EXAMPLES OF LINKED HUMAN DISEASES
ABCA	ABC A	12	Tangier disease (defect in cholesterol transport; ABCA1), Stargardt syndrome (defect in retinal metabolism; ABCA4)
ABCB	ABC B	11	Bare lymphocyte syndrome type 1 (defect in antigen presenting; ABCB3 and ABCB4), progressive familial intrahepatic cholestasis type 3 (defect in biliary lipid secretion; MDR3/ABCB4), X-linked sideroblastic anemia with ataxia (a possible defect in iron homeostasis in mitochondria; ABCB7), progressive familial intrahepatic cholestasis type 2 (defect in biliary bile acid excretion; BSEP/*ABCB11*)
ABCC	ABC C	13	Dubin-Johnson syndrome (defect in biliary bilirubin glucuronide excretion; MRP2/*ABCC2*), pseudoxanthoma (unknown mechanism; *ABCC6*), cystic fibrosis (defect in Cl^- channel regulation; *ABCC7*), persistent hyperinsulinemic hypoglycemia of infancy (defect in inwardly rectifying K^+ conductance regulation in pancreatic B cells; SUR1/*ABCC8*)
ABCD	ABC D	4	Adrenoleukodystrophy (a possible defect in peroxisomal transport or catabolism of very-long-chain fatty acids; ABCD1)
ABCE	ABC E	1	
ABCF	ABC F	3	
ABCG	ABC G	5	Sitosterolemia (defect in biliary and intestinal excretion of plant sterols; ABCG5 and ABCG8)

and Altenberg, 2019). In addition to conferring multidrug resistance, an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/*ABCB1*, MRP2/*ABCC2*, and BCRP/*ABCG2* are involved in overall drug disposition.

Tissue Distribution of Drug-Related ABC Transporters

Table 4–4 summarizes the distribution of human drug-related ABC transporters in tissues involved in the absorption, elimination, or distribution of drugs, along with information about typical substrates. MDR1 (*ABCB1*), MRP2 (*ABCC2*), and BCRP (*ABCG2*) are all expressed in the apical side of the intestinal epithelia, where they serve to pump out xenobiotics, including many orally administered drugs. MRP3 (*ABCC3*) is expressed in the basal side of the epithelial cells.

Key to the vectorial excretion of drugs into urine or bile, ABC transporters are expressed in the polarized tissues of kidney and liver: MDR1, MRP2, BCRP, and MRP4 (*ABCC4*) on the brush border membrane of renal epithelia; MDR1, MRP2, and BCRP on the bile canalicular membrane of hepatocytes; and MRP3 and MRP4 on the sinusoidal membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side (luminal) of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood-CSF barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood-testis barrier (MRP1 on the basolateral membrane of mouse Sertoli cells and MDR1 in several types of human testicular cells), and the blood-placenta barrier (MDR1, MRP2, and BCRP on the luminal maternal side and MRP1 on the antiluminal fetal side of placental trophoblasts). BCRP is expressed on the apical membrane of mammary gland epithelium and is highly induced during lactation.

MRP/ABCC Family

The substrates of transporters in the MRP/ABCC family are mostly organic anions (see Table 4–4). Both MRP1 and MRP2 accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and nonconjugated organic anions of an amphipathic nature (at least one negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as vinca alkaloids and anthracyclines, possibly by means of a cotransport or symport mechanism with GSH. MRP3 also has a substrate specificity that is similar to that of MRP2 but with a lower transport affinity for glutathione conjugates compared with MRP1 and MRP2. MRP3 is expressed on the sinusoidal side of hepatocytes and is induced under cholestatic conditions. MRP3 functions to return toxic bile salts and bilirubin glucuronides into the blood circulation. MRP4 accepts negatively charged molecules, including cytotoxic compounds (e.g., *6-mercaptopurine* and *methotrexate*), cyclic nucleotides, antiviral drugs (e.g., *adefovir* and *tenofovir*), diuretics (e.g., *furosemide* and *trichlormethiazide*), and cephalosporins (e.g., *ceftizoxime* and *cefazolin*). Glutathione enables MRP4 to accept taurocholate and leukotriene B_4. MRP5 has a narrower substrate specificity and accepts nucleotide analogue and clinically important anti-HIV drugs. No substrates have been identified that explain the mechanism of the MRP6-associated disease pseudoxanthoma.

BCRP/ABCG2

BCRP accepts both neutral and negatively charged molecules, including cytotoxic compounds (e.g., *topotecan, flavopiridol*, and *methotrexate*); sulfated conjugates of therapeutic drugs and hormones (e.g., estrogen sulfate); antibiotics (e.g., *nitrofurantoin* and fluoroquinolones); statins (e.g., *pitavastatin* and *rosuvastatin*); and toxic compounds found in normal food (phytoestrogens, 2-amino-1-methyl-6-phenylimidazo[4,5-*b*] pyridine, and pheophorbide A, a chlorophyll catabolite). In addition, genetic variants in the transporter have been implicated in hyperuricemia and gout and in the disposition of uric acid and the XOIs *allopurinol* and *oxypurinol*.

Physiological Roles of ABC Transporters

The physiological significance of the ABC transporters has been amply illustrated by studies involving knockout animals or patients with genetic defects in these transporters. Many ABC transporters serve in xenobiotic disposition. For instance, mice deficient in MDR1 function are viable and fertile and do not display obvious phenotypic abnormalities other than hypersensitivity to the toxicity of drugs. There are equally remarkable data for MRP1, MRP4, BCRP, and BSEP. The lesson is this: complete absence of these drug-related ABC transporters is not lethal and can remain unrecognized in the absence of exogenous perturbations due to food, drugs, or toxins. However, inhibition of physiologically important ABC transporters (especially those related directly to the genetic diseases described in Table 4–3) by drugs should be avoided to reduce the incidence of drug-induced side effects.

ABC Transporters in Drug Absorption and Elimination

With respect to clinical medicine, MDR1, also known as Pgp, is the most renowned ABC transporter yet identified. The systemic exposure to

TABLE 4–4 ■ ABC TRANSPORTERS INVOLVED IN DRUG ABSORPTION, DISTRIBUTION, AND EXCRETION PROCESSES

NAME Tissue Distribution[a]	SUBSTRATES
MDR1 (ABCB1) Liver, kidney, intestine, BBB, BTB, BPB	**Characteristics:** Bulky neutral or cationic compounds (many xenobiotics)—etoposide, doxorubicin, vincristine; diltiazem, verapamil; indinavir, ritonavir; erythromycin, ketoconazole; testosterone, progesterone; cyclosporine, tacrolimus; digoxin, quinidine, fexofenadine, loperamide
MRP1 (ABCC1) Ubiquitous	**Characteristics:** Negatively charged amphiphiles—vincristine (with GSH), methotrexate; GSH conjugate of LTC_4, ethacrynic acid; glucuronide of estradiol, bilirubin; estrone-3-sulfate; saquinavir; grepafloxacin; folate, GSH, GSSG
MRP2 (ABCC2) Liver, kidney, intestine, BPB	**Characteristics:** Negatively charged amphiphiles—methotrexate, vincristine; GSH conjugates of LTC_4, ethacrynic acid; glucuronides of estradiol, bilirubin; taurolithocholate sulfate; statins, AngII receptor antagonists, temocaprilat; indinavir, ritonavir; GSH, GSSG
MRP3 (ABCC3) Liver, kidney, intestine	**Characteristics:** Negatively charged amphiphiles—etoposide, methotrexate; GSH conjugates of LTC_4, PGJ_2; glucuronides of estradiol, etoposide, morphine, acetaminophen, hymecromone, harmol; sulfate conjugates of bile salts; glycocholate, taurocholate; folate, leucovorin
MRP4 (ABCC4) Ubiquitous, including BBB and BCSFB	**Characteristics:** Nucleotide analogues, 6-mercaptopurine, methotrexate; estradiol glucuronide; dehydroepiandrosterone sulfate; cyclic AMP/GMP; furosemide, trichlormethiazide; adefovir, tenofovir; cefazolin, ceftizoxime; folate, leucovorin, taurocholate (with GSH)
MRP5 (ABCC5) Ubiquitous	**Characteristics:** Nucleotide analogues 6-mercaptopurine; cyclic AMP/GMP; adefovir
MRP6 (ABCC6) Liver, kidney	**Characteristics:** Doxorubicin,[b] etoposide,[b] GSH conjugate of LTC_4; BQ-123 (cyclic penta peptide antagonist at the ETA endothelin receptor)
BCRP(MXR) (ABCG2) Liver, intestine, BBB	**Characteristics:** Neutral and anionic compounds—methotrexate, mitoxantrone, camptothecins, SN-38, topotecan, imatinib; glucuronides of 4-methylumbelliferone, estradiol; sulfate conjugates of dehydroepiandrosterone, estrone; nitrofurantoin, fluoroquinolones; pitavastatin, rosuvastatin; cholesterol, estradiol, dantrolene, prazosin, sulfasalazine, uric acid, allopurinol, oxypurinol
MDR3 (ABCB4) Liver	**Characteristics:** Phospholipids
BSEP (ABCB11) Liver	**Characteristics:** Bile salts
ABCG5, ABCG8 Liver, intestine	**Characteristics:** Plant sterols

BBB, blood-brain barrier; BCSFB, blood-cerebrospinal fluid barrier; BPB, blood-placenta barrier; BTB, blood-testis barrier; LTC, leukotriene C; PGJ, prostaglandin J.
[a]Tissue distribution refers to tissues that play a role in drug absorption, distribution, and elimination.
[b]Substrates and cytotoxic drugs with increased resistance (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drugs). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5, and ABCG8 are not directly involved in drug disposition, their inhibition will lead to unfavorable side effects.

orally administered *digoxin* is decreased by coadministration of *rifampin* (an MDR1 inducer) and is negatively correlated with the MDR1 protein expression in the human intestine. MDR1 is also expressed on the brush border membrane of renal epithelia, and its function can be monitored using *digoxin* (>70% excreted in the urine). MDR1 inhibitors (e.g., *quinidine, verapamil, valspodar, spironolactone, clarithromycin*, and *ritonavir*) all markedly reduce renal excretion of *digoxin*. Drugs with narrow therapeutic windows (e.g., *digoxin, cyclosporine, tacrolimus*) should be used with great care if MDR1-based drug-drug interactions are likely.

In the intestine, MRP3 can mediate intestinal absorption in conjunction with uptake transporters. MRP3 mediates sinusoidal efflux in the liver, decreasing the efficacy of the biliary excretion from the blood and excretion of intracellularly formed metabolites, particularly glucuronide conjugates. Thus, dysfunction of MRP3 results in shortening of the elimination $t_{1/2}$. MRP4 substrates also can be transported by OAT1 and OAT3 on the basolateral membrane of the epithelial cells in the kidney. The rate-limiting process in renal tubular secretion is likely the uptake process at the basolateral surface. Dysfunction of MRP4 enhances the renal concentration but has limited effect on the blood concentration.

Intestinal BCRP also plays a critical role in drug absorption and is the target for several clinically important drug-drug interactions. Consider the case of coadministration of *rosuvastatin* and *cyclosporin*. *Rosuvastatin* is a substrate for both BCRP and OATP1B1, both of which *cyclosporin* inhibits. Inhibition of BCRP by *cyclosporin* reduces efflux and enhances absorption of *rosuvastatin* from the GI tract, where the BCRP is abundantly expressed on the apical membrane of intestinal epithelia. Inhibition of OATP1B1 by *cyclosporin* reduces tissue uptake of *rosuvastatin*. The overall result is an increase in systemic plasma levels of *rosuvastatin*, which may result in increased susceptibility to statin-induced myopathy. Efficacy will depend upon the net effect on hepatic levels of *rosuvastatin*, driven by both the higher portal vein levels (from BCRP inhibition) and the lower hepatic uptake via OATP1B1 inhibition.

Transporters Involved in Pharmacokinetics

Drug transporters play a prominent role in pharmacokinetics (see Figure 4–1 and Table 4–4). Transporters in the liver and kidney have important roles in removal of drugs from the blood and hence in metabolism and excretion.

Hepatic Transporters

Hepatic uptake of organic anions (e.g., drugs, leukotrienes, and bilirubin), cations, and bile salts is mediated by SLC-type transporters in the basolateral (sinusoidal) membrane of hepatocytes: OATPs (SLCO)/OAT2 (SLC22A7) OCTs (SLC22), and NTCP (SLC10A1), respectively.

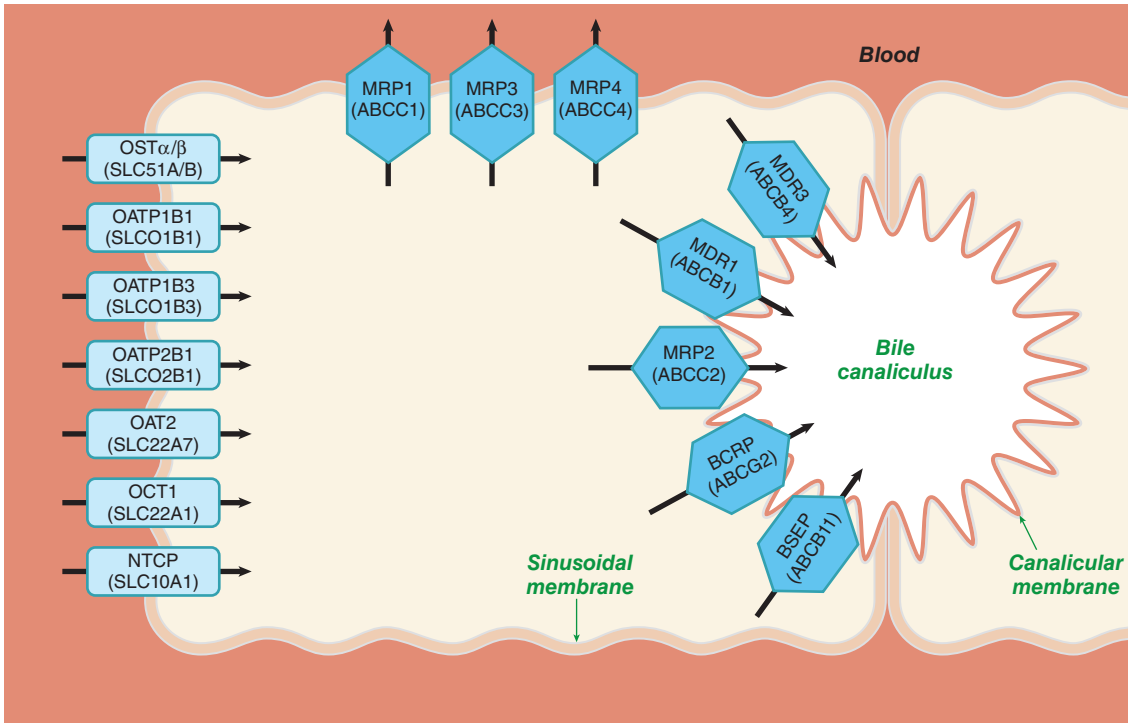

Figure 4–9 *Transporters in the hepatocyte that function in the uptake and efflux of drugs across the sinusoidal membrane and efflux of drugs into the bile across the canalicular membrane.* Arrows show the primary direction of transport. See text for details of the transporters pictured.

These transporters mediate uptake by either facilitated or secondary active mechanisms.

ABC transporters such as MRP2, MDR1, BCRP, BSEP, and MDR3 in the bile canalicular membrane of hepatocytes mediate the efflux (excretion) of drugs and their metabolites, bile salts, and phospholipids against a steep concentration gradient from liver to bile. This primary active transport is driven by ATP hydrolysis.

Vectorial transport of drugs from the circulating blood to the bile using an uptake transporter (OATP family) and an efflux transporter (MRP2, BCRP, MDR1) is important for determining drug exposure in the circulating blood and liver. Moreover, there are many other uptake and efflux transporters in the liver (Figure 4–9).

The following examples illustrate the importance of vectorial transport in determining drug exposure in the circulating blood and liver and the role of transporters in drug-drug interactions.

HMG-CoA Reductase Inhibitors

Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (see Chapter 37). Most of the statins in their acid form are substrates of hepatic uptake transporters and undergo enterohepatic recirculation (see Figure 4–9). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 act cooperatively to produce *bisubstrate vectorial transcellular transport*. The efficient first-pass hepatic uptake of these statins by OATP1B1 helps concentrate them in the liver where they produce their pharmacological effects, thus minimizing their systemic levels and adverse effects in muscle. Genetic polymorphisms of OATP1B1 also affect the function of this transporter (Meyer zu Schwabedissen et al., 2015).

Anti–Hepatitis C Virus Drugs

Drug therapy of hepatitis C virus (HCV) has made great strides through the discovery of direct-acting antiviral agents. Sustained virological response, an indicator of therapeutic effect, exceeds 90%, and it is now possible to cure hepatitis C infections (Hong et al., 2020). Several HCV NS3/4A protease inhibitors such as *simeprevir, glecaprevir*, and *grazoprevir* display nonlinear pharmacokinetics at therapeutic doses, at least partly due to the saturation of OATP1B-mediated hepatic uptake (Hong et al., 2020; Snoeys et al., 2016). The saturation of other components such as the ABC transporters and CYP enzymes may also contribute to the nonlinear pharmacokinetics. For these HCV drugs, their systemic exposure increases markedly when coadministered with a single dose of *rifampicin* or *cyclosporin A*, which suggests the occurrence of OATP1B-mediated drug-drug interactions (Hong et al., 2020; Snoeys et al., 2016). The likelihood of drug-drug interactions with HCV drugs is greater with NS3/4A protease inhibitors than NS5A inhibitors and NS5B polymerase inhibitors (Hong et al., 2020). The majority of clinically relevant drug-drug interactions are predictable, based on the known pharmacokinetic properties of transporters and enzymes. NS5A inhibitors and NS5B polymerase inhibitors are not substrates of OATP1B but are known to cause drug-drug interactions by inhibiting OATP1B (Hong et al., 2020).

Gemfibrozil, Pemafibrate

Gemfibrozil is a PPARα activator that is used to lower cholesterol levels (see Chapter 37). The drug can enhance toxicity (myopathy) to several statins at a therapeutic dose of 600 mg (bid) by a mechanism that involves a transporter (OATP1B) and a drug-metabolizing enzyme (CYP2C8). *Gemfibrozil* is metabolized to gemfibrozil 1-O-β-glucuronide. The parent compound and its glucuronide inhibit the uptake of the active acid forms of statins into hepatocytes by OATP1B1, and the glucuronide is also a potent mechanism based inhibitor of CYP2C8, an enzyme that metabolizes the statin such as cerivastatin. The net result is that coadministration of a statin and *gemfibrozil* causes an increase in the plasma concentrations of the statin and a concomitant increase in toxicity.

Fortunately, not all fibrates cause toxicity by these mechanisms. *Pemafibrate* also belongs to the class of fibrates (selective PPARα modulator) and displays efficacy and safety profiles superior to other conventional fibrates due to its high selectivity for PPARα. Like *gemfibrozil*, *pemafibrate* is a substrate for OATP1B and CYP enzymes. However, *pemafibrate* is effective at much lower blood levels than *gemfibrozil*, and a therapeutic dose is 0.1 mg; thus, *pemafibrate* does not increase tissue exposure to statins (typical OATP1B substrates). On the other hand, the blood exposure of *pemafibrate* is increased more than 10-fold by a single dose of *rifampicin* and *cyclosporin A*, suggesting the occurrence of drug-drug interactions via inhibition of hepatic OATP1Bs (Park et al., 2021).

Irinotecan

CPT-11 is a potent anticancer drug, but late-onset GI toxicities, such as severe diarrhea, make this a difficult agent to use safely. After intravenous administration of CPT-11, a carboxylesterase converts the drug to SN-38, an active metabolite. SN-38 is subsequently taken up by OATP1B followed by conjugation with glucuronic acid in the liver. SN-38 and SN-38 glucuronide are then excreted into the bile by MRP2, entering the GI tract and causing adverse effects (Toshimoto et al., 2017). The inhibition of MRP2-mediated biliary excretion of SN-38 and its glucuronide by coadministration of probenecid reduces the drug-induced diarrhea in experimental systems and may prove useful in humans (Horikawa et al., 2002). For additional details, see Figures 5–6, 5–8, and 5–9.

Bosentan

Bosentan is an endothelin antagonist used to treat pulmonary arterial hypertension. It is taken up in the liver by OATP1B1 and OATP1B3 and subsequently metabolized by CYP2C9 and CYP3A4. Transporter-mediated hepatic uptake can be a determinant of elimination of bosentan, and inhibition of its hepatic uptake by *cyclosporine* and *rifampicin* can affect its pharmacokinetics. Saturation of OATP1B-mediated hepatic uptake accounts for the nonlinear pharmacokinetics of *bosentan* following therapeutic doses (Sato et al., 2018).

Temocapril and Other ACE Inhibitors

Temocapril is an ACE inhibitor (see Chapter 30). Its active metabolite, temocaprilat, is excreted both in the bile and in the urine by the liver and kidney, respectively, whereas other ACE inhibitors are excreted mainly by the kidney. A special feature of *temocapril* among ACE inhibitors is that the plasma concentration of temocaprilat remains relatively unchanged even in patients with renal failure. However, the plasma AUC of *enalaprilat* and other ACE inhibitors is markedly increased in patients with renal disorders. Temocaprilat is a bisubstrate of the OATP family and MRP2, whereas other ACE inhibitors are not good substrates of MRP2 (although they are taken up into the liver by the OATP family). Taking these findings into consideration, the affinity for MRP2 may dominate in determining the biliary excretion of any series of ACE inhibitors. Drugs that are excreted into both the bile and urine to the same degree thus are expected to exhibit minimum interindividual differences in their pharmacokinetics.

Angiotensin II Receptor Antagonists

Angiotensin II receptor antagonists are used for the treatment of hypertension, acting on AT_1 receptors expressed in vascular smooth muscle, proximal tubule, adrenal medullary cells, and elsewhere. For most of these drugs, hepatic uptake and biliary excretion are important factors for their pharmacokinetics and pharmacological effects. *Telmisartan* is taken up into human hepatocytes in a saturable manner, predominantly via OATP1B3 (Ishiguro et al., 2006). On the other hand, both OATPs 1B1 and 1B3 are responsible for the hepatic uptake of *valsartan* and *olmesartan*, although the relative contributions of these transporters are unclear. Studies using doubly transfected cells with hepatic uptake transporters and biliary excretion transporters have clarified that MRP2 plays the most important role in the biliary excretion of *valsartan* and *olmesartan*.

Repaglinide, Nateglinide, and Glibenclamide

Repaglinide is a meglitinide analogue antidiabetic drug. Although it is eliminated almost completely by the metabolism mediated by CYPs 2C8 and 3A4, transporter-mediated hepatic uptake is one of the determinants of its elimination rate. In subjects with the OATP1B1 (*SLCO1B1*) 521CC genotype, a significant change in the pharmacokinetics of *repaglinide* was observed (Niemi et al., 2005). Genetic polymorphism in *SLCO1B1* 521T>C results in altered pharmacokinetics of *nateglinide* and *glibenclamide*, suggesting OATP1B1 is a determinant of their elimination, although they are subsequently metabolized by CYPs 2C9, 3A4, and others (Zhang et al., 2006b).

Renal Transporters

Organic Cation Transport

Structurally diverse organic cations are secreted in the proximal tubule. Many secreted organic cations are endogenous compounds (e.g., choline, *N*-methylnicotinamide, and DA), and renal secretion helps to eliminate excess concentrations of these substances. Another function of organic cation secretion is ridding the body of xenobiotics, including many positively charged drugs and their metabolites (e.g., *cimetidine, ranitidine, metformin, varenicline*, and *trospium*) and toxins from the environment (e.g., nicotine and paraquat). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights less than 400 Da; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 4–10 involving the transporters described next.

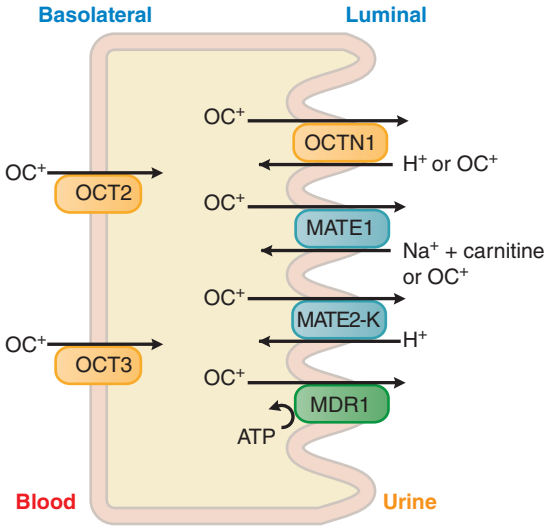

Figure 4–10 *Organic cation secretory transporters in the proximal tubule.* OC^+, organic cation. See text for details of the transporters pictured.

For the transepithelial flux of a compound (e.g., secretion), the compound must traverse two membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Organic cations appear to cross the basolateral membrane in the human proximal tubule by two distinct transporters in the SLC family 22 (SCL22): OCT2 (*SLC22A2*) and OCT3 (*SLC22A3*). Organic cations are transported across this membrane down an electrochemical gradient.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs through an electroneutral proton–organic cation exchange, which is mediated by transporters in the SLC47 family, which comprises members of the MATE family. Transporters in the MATE family, assigned to the apical membrane of the proximal tubule, appear to play a key role in moving hydrophilic organic cations from tubule cell to lumen. In addition, OCTNs, located on the apical membrane, appear to contribute to organic cation flux across the proximal tubule. In humans, these include *OCTN1* (SLC22A4) and *OCTN2* (SLC22A5). These bifunctional transporters are involved not only in organic cation secretion but also in carnitine reabsorption. In the reuptake mode, the transporters function as Na^+ cotransporters, relying on the inwardly driven Na^+ gradient created by Na^+/K^+-ATPase to move carnitine from tubular lumen to cell. In the secretory mode, the transporters appear to function as proton–organic cation exchangers. That is, protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen. The inwardly directed proton gradient (tubular lumen → cytosol) is maintained by transporters in the SLC9 family, which are Na^+/K^+ exchangers (NHEs, antiporters). Of the two steps involved in secretory transport, transport across the luminal membrane appears to be rate limiting.

***OCT2* (SLC22A2).** Human, mouse, and rat orthologs of OCT2 are expressed in abundance in human kidney and to some extent in neuronal tissue, such as choroid plexus. In the kidney, OCT2 is localized in the proximal and distal tubules and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. OCT2-mediated transport of model organic cations MPP^+ (1-methyl-4-phenylpyridinium)

and TEA (tetraethylammonium) is electrogenic, and both OCT2 and OCT1 can support organic cation–organic cation exchange. OCT2 generally accepts a wide array of monovalent organic cations with molecular weights below 400 Da. OCT2 is also present in neuronal tissues; however, monoamine neurotransmitters have low affinities for OCT2.

***OCT3* (SLC22A3).** The OCT3 gene is located in tandem with genes for OCT1 and OCT2 on chromosome 6. Tissue distribution studies suggest that human OCT3 is expressed in liver, kidney, intestine, placenta, skeletal muscle, and adipose tissue, although in the kidney it appears to be expressed in considerably less abundance than OCT2, and in the liver it is less abundant than OCT1. Like OCT1 and OCT2, OCT3 appears to support electrogenic potential-sensitive organic cation transport. OCT3 plays a role in both the renal elimination and the intestinal absorption of metformin.

***OCTN1* (SLC22A4).** OCTN1 seems to operate as an organic cation–proton exchanger. OCTN1-mediated influx of model organic cations is enhanced at alkaline pH, whereas efflux is increased by an inwardly directed proton gradient. OCTN1 contains a nucleotide-binding sequence motif, and transport of its substrates appears to be stimulated by cellular ATP. OCTN1 also can function as an organic cation–organic cation exchanger. OCTN1 functions as a bidirectional pH- and ATP-dependent transporter at the apical membrane in renal tubular epithelial cells and appears to be important in renal transport of *gabapentin*.

***OCTN2* (SLC22A5).** OCTN2 is a bifunctional transporter; it functions as both a Na^+-dependent carnitine transporter and a Na^+-independent OCT. OCTN2 transport of organic cations is sensitive to pH, suggesting that OCTN2 may function as an organic cation exchanger. The transport of L-carnitine by OCTN2 is a Na^+-dependent electrogenic process. Mutations in OCTN2 can result in insufficient renal reabsorption of carnitine and appear to be the cause of primary systemic carnitine deficiency (Tamai, 2013).

***MATE1 and MATE2-K* (SLC47A1, SLC47A2).** Multidrug and toxin extrusion family members MATE1 and MATE2-K interact with structurally diverse hydrophilic organic cations, including the antidiabetic drug *metformin*, the H_2 antagonist *cimetidine*, and the anticancer drug *topotecan*. In addition to cationic compounds, the transporters recognize some anions, including the antiviral agents *acyclovir* and *ganciclovir*. The zwitterions *cephalexin* and *cephradine* are specific substrates of MATE1. The herbicide paraquat, a bis-quaternary ammonium compound that is nephrotoxic in humans, is a high-affinity substrate of MATE1. Both MATE1 and MATE2-K have been localized to the apical membrane of the proximal tubule. MATE1, but not MATE2-K, is also expressed on the canalicular membrane of the hepatocyte. These transporters appear to be the long-searched-for organic cation–proton antiporters on the apical membrane of the proximal tubule; that is, an oppositely directed proton gradient can drive the movement of organic cations via MATE1 or MATE2-K. The antibiotics *levofloxacin* and *ciprofloxacin*, though potent inhibitors, are not translocated by either MATE1 or MATE2-K.

Polymorphisms of OCTs and MATEs. OCT1 exhibits the greatest number of amino acid polymorphisms, followed by OCT2 and then OCT3. Recent studies suggest that genetic variants of OCT1 and OCT2 are associated with alterations in the renal elimination and response to the antidiabetic drug metformin. MATEs have fewer amino acid polymorphisms; however, recent studies suggested that noncoding region variants of SLC47A1 and SLC47A2 are associated with variation in response to *metformin*.

Organic Anion Transport

As with organic cation transport, a primary function of organic anion secretion appears to be the removal of xenobiotics from the body. The candidate substrates are structurally diverse and include many weakly acidic drugs (e.g., *pravastatin, captopril*, PAH, and penicillins) and toxins (e.g., ochratoxin). OATs not only move both hydrophobic and hydrophilic anions but also may interact with cations and neutral compounds.

Figure 4–11 shows a current model for the transepithelial flux of organic anions in the proximal tubule. Two primary transporters on the basolateral membrane mediate the flux of organic anions from interstitial fluid to tubule cell: OAT1 (*SLC22A6*) and OAT3 (*SLC22A8*). Energetically, hydrophilic organic anions are transported across the basolateral membrane against an electrochemical gradient, exchanging with intracellular α-ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α-ketoglutarate is maintained at least in part by a basolateral Na^+-dicarboxylate transporter (NaDC3), using the Na^+ gradient established by Na^+,K^+-ATPase. Transport of low-molecular-weight organic anions by the cloned transporters OAT1 and OAT3 can be driven by α-ketoglutarate; coupled transport of α-ketoglutarate and low-molecular-weight organic anions (e.g., PAH) occurs in isolated basolateral membrane vesicles. The molecular pharmacology and molecular biology of OATs have been reviewed (Srimaroeng et al., 2008).

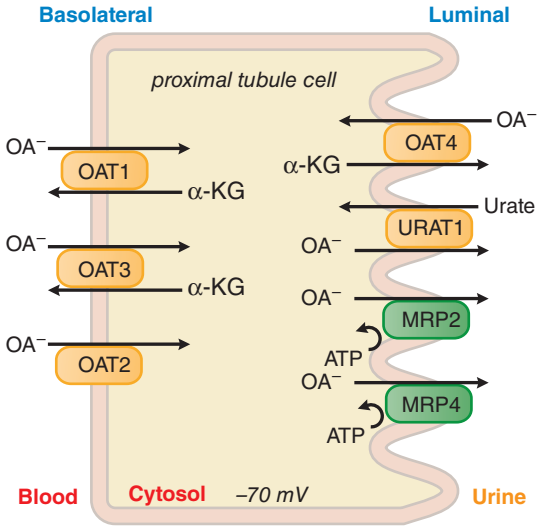

Figure 4–11 *Organic anion (OA) secretory transporters in the proximal tubule.* Two primary transporters on the basolateral membrane mediate the flux of OAs from interstitial fluid to tubule cell: OAT1 (*SLC22A6*) and OAT3 (*SLC22A8*). Hydrophilic OAs are transported across the basolateral membrane against an electrochemical gradient in exchange with intracellular α-ketoglutarate (α-KG), which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α-KG is maintained at least in part by a basolateral Na^+-dicarboxylate uptake transporter (NaDC3). The Na^+ gradient that drives NaDC3 is maintained by Na^+,K^+-ATPase.

The mechanism responsible for the apical membrane transport of organic anions from tubule cell cytosol to tubular lumen remains controversial. OAT4 may serve as the luminal membrane transporter for organic anions, but the movement of substrates via this transporter can be driven by exchange with an α-ketoglutarate, suggesting that OAT4 may function in the reabsorptive, rather than secretory, flux of organic anions. NaPT1, originally cloned as a phosphate transporter, can support the low-affinity transport of hydrophilic organic anions such as PAH. MRP2 and MRP4, multidrug resistance transporters in the ABCC family, can interact with some organic anions and may actively pump them from tubule cell cytosol to tubular lumen.

***OAT1* (SLC22A6).** Mammalian isoforms of OAT1 are expressed primarily in the kidney, with some expression in brain and skeletal muscle. Immunohistochemical studies suggest that OAT1 is expressed on the basolateral membrane of the proximal tubule in humans, with highest expression in the middle segment, S2 (see Figure 25–1). Based on quantitative polymerase chain reaction, OAT1 is expressed at a third of the level of OAT3. OAT1 exhibits saturable transport of organic anions such as PAH. This transport is transstimulated by other organic anions, including α-ketoglutarate. Thus, the inside negative-potential difference drives the efflux of the dicarboxylate α-ketoglutarate, which in turn supports the influx of monocarboxylates such as PAH. Sex steroids regulate expression of OAT1 in the kidney. OAT1 generally transports low-molecular-weight

organic anions, either endogenous (e.g., PGE_2 and urate) or exogenous (ingested drugs and toxins). Some neutral compounds are also transported by OAT1 at a lower affinity (e.g., *cimetidine*).

***OAT2* (SLC22A7).** OAT2 is present in both kidney and liver; renal OAT2 is localized to the basolateral membrane of the proximal tubule. OAT2 functions as a transporter for nucleotides, particularly guanine nucleotides such as cyclic GMP, for which it is a bidirectional facilitative transporter (Cropp et al., 2008). Cellular studies indicate that OAT2 functions in both the influx and the efflux of guanine nucleotides. OAT2 transports organic anions such as PAH and *methotrexate* with low affinity, PGE_2 with high affinity, and some neutral compounds but with lower affinity (e.g., *cimetidine*).

***OAT3* (SLC22A8).** Human OAT3 is confined to the basolateral membrane of the proximal tubule. This protein consists of two variants, one of which transports a wide variety of organic anions, including PAH, estrone sulfate, and many drugs (e.g., *pravastatin, cimetidine, 6-mercaptopurine*, and *methotrexate*) (Srimaroeng et al., 2008). The longer variant does not support transport. The specificities of OAT3 and OAT1 overlap, although kinetic parameters differ: Estrone sulfate is transported by both but by OAT3 with a much higher affinity; OAT1 transports the H_2 receptor antagonist *cimetidine* with high affinity.

***OAT4* (SLC22A11).** Human OAT4 is expressed in placenta and kidney (on the luminal membrane of the proximal tubule). Organic anion transport by OAT4 can be stimulated by transgradients of α-ketoglutarate, suggesting that OAT4 may be involved in the reabsorption of organic anions from tubular lumen into cell (see Figure 4–11). The specificity of OAT4 includes the model compounds estrone sulfate and PAH, as well as *zidovudine, tetracycline,* and *methotrexate*. Collectively, emerging studies suggest that OAT4 may be involved not in secretory flux of organic anions but in reabsorption instead.

Other Anion Transporters. URAT1 (*SLC22A12*) is a kidney-specific transporter confined to the apical membrane of the proximal tubule. URAT1 is primarily responsible for urate reabsorption, mediating electroneutral urate transport that can be transstimulated by Cl^- gradients. NPT1, Na^+-dependent phosphate transport protein 1 (SLC17A1), is expressed on the luminal membrane of the proximal tubule as well as in the brain. NPT1 transports PAH, *probenecid*, and *penicillin G*. It appears to be involved in organic anion efflux from tubule cell to lumen and interacts with uric acid. Figure 42–2 depicts renal urate transport.

MRP2 (*ABCC2*) is considered to be the primary transporter involved in efflux of many drug conjugates (e.g., GSH conjugates) across the canalicular membrane of the hepatocyte. MRP2 is also found on the apical membrane of the proximal tubule, where it is thought to play a role in the efflux of organic anions into the tubular lumen. In general, MRP2 transports larger, bulkier compounds than do most of the OATs in the SLC22 family. MRP4 (*ABCC4*), localized on the apical membrane of the proximal tubule, transports a wide array of conjugated anions, including glucuronides and GSH conjugates. MRP4 appears to interact with *methotrexate*, cyclic nucleotide analogues, and antiviral nucleoside analogues. BCRP (ABCG2) is localized to the apical membrane of the proximal tubule and duodenum and is involved in uric acid secretion and secretion of the XOIs *allopurinol* and *oxypurinol*.

Polymorphisms in OAT1 and OAT3 have been identified in ethnic human subpopulations (see https://www.pharmgkb.org). Notably, polymorphisms in ABCG2 have been associated with reduced response to *allopurinol* and *oxypurinol*.

Transporters and Pharmacodynamics: Drug Action in the Brain

Biogenic amine neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by fusion of the vesicles with the plasma membrane, and then taken back into the presynaptic neurons or postsynaptic cells (see Chapters 10 and 16). Plasma membrane transporters involved in the neuronal reuptake of the neurotransmitters and the regulation of their levels in the synaptic cleft belong to two major superfamilies, SLC1 and SLC6. Transporters in both families play roles in reuptake of GABA, glutamate, and the monoamine neurotransmitters NE, 5HT, and DA. These transporters may serve as pharmacologic targets for neuropsychiatric drugs. SLC6 family members localized in the brain and involved in the reuptake of neurotransmitters into presynaptic neurons include NET (*SLC6A2*), DAT (*SLC6A3*), SERT (*SLC6A4*), and several GATs (GAT1, GAT2, and GAT3). Each of these transporters appears to have 12 transmembrane (TM) regions and a large extracellular loop with glycosylation sites between TM3 and TM4.

SLC6 family members are secondary active transporters, depending on the Na^+ gradient to transport their substrates into cells. Cl^- is also required, although to a variable extent depending on the family member. Through their reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and dwell times of neurotransmitters in the synaptic cleft. The extent of transmitter uptake also influences subsequent vesicular storage of transmitters, which occurs via transporters in the SLC17 (vesicular glutamate) and SLC18 (vesicular monoamine) families. Many of the transporters in the SLC6, SLC17, and SLC18 families are present in other tissues (e.g., intestine, kidney, and platelets) and may serve other roles. Further, the transporters can function in the reverse direction; that is, the transporters can export neurotransmitters in a Na^{2+}-independent fashion.

GABA Uptake: GAT1 (*SLC6A1*), GAT3 (*SLC6A11*), GAT2 (*SLC6A13*), and BGT1 (*SLC6A12*)

GAT1 is the most important GABA transporter in the brain, expressed in GABAergic neurons and found largely on presynaptic neurons. GAT1 is abundant in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord, retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and within the CNS in the choroid plexus and meninges. Physiologically, GAT1 appears to be responsible for regulating the interaction of GABA at receptors. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining the homeostasis of GABA in the CSF. GAT1 is the target of the antiepileptic drug *tiagabine* (a nipecotic acid derivative), which presumably acts to prolong the dwell time of GABA in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. A fourth GAT, BGT1, occurs in extrasynaptic regions of the hippocampus and cortex (Madsen et al., 2011).

Catecholamine Uptake: NET (*SLC6A2*)

NET is found in central and peripheral nervous tissues as well as in adrenal chromaffin tissue. NET colocalizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. NET provides reuptake of NE (and DA) into neurons, thereby limiting the synaptic dwell time of NE and terminating its actions, salvaging NE for subsequent repackaging. NET serves as a drug target for the antidepressant *desipramine*, other tricyclic antidepressants, and cocaine. NET is also a target for serotonin-norepinephrine reuptake inhibitor antidepressants (e.g., *duloxetine* and *venlafaxine*), which also target SERT (*SLC6A4*). Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to changes in posture, has been associated with a mutation in NET.

Dopamine Uptake: DAT (*SLC6A3*)

DAT is located primarily in the brain in dopaminergic neurons. The primary function of DAT is the reuptake of DA, terminating its actions. Although present on presynaptic neurons at the neurosynaptic junction, DAT is also present in abundance along the neurons, away from the synaptic cleft. Physiologically, DAT is involved in functions attributed to the dopaminergic system, including mood, behavior, reward, and cognition. Drugs that interact with DAT include cocaine and its analogues, amphetamines, and the neurotoxin MPTP (methylphenyltetrahydropyridine).

Serotonin Uptake: SERT (*SLC6A4*)

SERT is responsible for the reuptake and clearance of 5HT in the brain. Like the other SLC6A family members, SERT transports its substrates in a Na^+-dependent fashion and is dependent on Cl^- and possibly on the countertransport of K^+. Substrates of SERT include 5HT, various tryptamine derivatives, and neurotoxins such as MDMA (ecstasy) and *fenfluramine*. SERT is the specific target of the SSRI antidepressants (e.g., *fluoxetine* and *paroxetine*) and one of several targets of tricyclic antidepressants (e.g., *amitriptyline*). Genetic variants of SERT have been associated with an array of behavioral and neurological disorders. The precise mechanism by which reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects behavior, including depression, is not known.

Transporters and Pharmacodynamics: Antidiabetic Drug Action

Glucose requires transporters to cross plasma membranes. The homoeostatic mechanisms for glucose are controlled primarily by glucose transporters in the SLC2 (facilitated GLUT transporter family) and SLC5 (sodium glucose co-transporter family) families. Within the SLC family, SLC5A1, commonly known as SGLT1, is expressed in the intestine, where it mediates glucose absorption, and in the kidney, where it participates in reabsorption. SGLT2 (SLC5A2) is primarily expressed in the renal proximal tubule, where it plays an almost exclusive role in glucose reabsorption. In fact, patients with genetic mutations in SLC5A2 have profound glucosuria, whereas those with mutations in SLC5A1 have only mild glucosuria. These observations spurred the development of SGLT2 inhibitors, the gliflozins, in the treatment of type 2 diabetes. Through targeting of SGLT2, the gliflozins inhibit glucose reabsorption in the kidney, leading to reduced systemic blood levels of glucose in patients with type 2 diabetes. This inhibition effect is particularly beneficial in patients with type 2 diabetes, in whom SGLT2 expression in the kidney and reabsorption of filtered glucose are increased. Though the mechanisms are not completely understood, the inhibition of glucose reabsorption and, consequently, renal glucose metabolism appears to contribute to the ancillary benefits of gliflozins on diabetic nephropathy. SGLT2 inhibitors are also finding utility in the treatment of heart failure with reduced ejection fraction (see Chapter 33).

The Blood-Brain Barrier: A Pharmacological View

The CNS is well protected from circulating neurotransmitters, well supplied with necessary nutrients and ions, and able to exclude many toxins, bacteria, and xenobiotics. This careful set of conditions is achieved by a barrier called the BBB, the blood-brain barrier. Chapter 17 describes the BBB in considerable detail. From the viewpoint of membrane transport, a short introduction to the BBB follows below.

The BBB results from the specialized properties of the microvasculature of the CNS, which consists of endothelial cells that limit permeability and various neural and immune cells (Profaci et al., 2020). Functionally, the BBB is partly physical, partly a consequence of selective permeability (export of undesirable molecules and import of necessary molecules), and partly a consequence of the enzymatic destruction of certain permeants by enzymes in the barrier. There are some neurosensory and neurosecretory regions of the brain that lack the barrier: posterior pituitary, median eminence, area postrema, subfornical organ, subcommissural organ, and laminar terminalis.

The *physical part* of the BBB derives from the distinctive structure of the capillary endothelium in the brain and choroid plexus. Unlike the endothelial cells of peripheral microvasculature that have gaps between them that permit flow of water and small molecules to the interstitial space, endothelial cells in the BBB have tight junctions that limit paracellular flow and generally have very low rates of vesicular transport (transcytosis) compared to peripheral endothelium. Moreover, the luminal surface of CNS endothelium is covered by a glycocalyx, which is denser than the glycocalyx of peripheral microvasculature. This glycocalyx prevents large molecules from interacting with the endothelial cell itself. Further, the abluminal surface is wrapped by a basement membrane, pericytes, and the pseudopodial processes of astroglia. Lipophilic molecules and gases such as O_2 and CO_2 can readily diffuse across these layers from blood to brain. Hydrophilic molecules (nutrients, ions, charged molecules, many drugs) cannot cross these multiple membrane barriers by diffusion at sufficient rates.

Thus, the system relies on *selective permeability*. For instance, certain transporters in the two major superfamilies, ABC and SLC, are enriched in the endothelial cells of the BBB (Profaci et al., 2020). ABC transporters that are expressed in abundance on the luminal membrane include ABCB1 (MDR1) and ABCG2 (BCRP). These transporters (see Table 4–4) are involved in the efflux of numerous small molecules and endogenous molecules such as steroids, extruding their substrates across the luminal membrane of the brain capillary endothelial cells into the blood, thereby limiting penetration into the brain. Many transporters in the SLC superfamily are involved in nutrient flux, ensuring that the brain receives nutrients such as glucose (SLC2A1/GLUT1), amino acids (SLC7A1 and SLC7A5/LAT1), and folic acid (SLC19A1, RFC). Metabolic salvage products also cross the BBB by transporters in the SLC16 family (SLC16A1 and SLC16A2). Members of the SLC22 family including both organic anion transporters (SLC22A6 [OAT1] and SLC22A8 [OAT3]) and organic cation transporters (SLC22A1 [OCT1] and SLC22A3 [OCT3]) are expressed in the endothelial cells. There are receptor-mediated transport systems for ferritin and insulin, and there is a low level of transcytosis (caveolin-dependent vesicle trafficking). Thus, the selective permeability of the BBB, conferred through its complement of transporters, allows necessary physiological compounds to enter the brain while limiting the entry of various xenobiotics including many drugs.

There is a *metabolic barrier* for some compounds. For instance, circulating catecholamines are inactivated by MAO in the endothelial cells and endothelial MAO, and dopa decarboxylase (aromatic amino acid decarboxylase; see Chapter 10) metabolizes L-dopa to 3,4-dihydroxyphenylacetate (hence the necessity of including a dopa decarboxylase inhibitor when giving L-dopa to treat Parkinson's disease). The metabolic barrier enzyme γ-glutamyl transpeptidase cleaves LTC_4, the leukotriene mediator produced by the 5-lipoxygenase pathway (see Chapter 41), and other glutathione adducts.

What about drug molecules? Once they reach the systemic circulation, delivery to the general region of the brain is not a problem: The brain receives about 15% of cardiac output (see Table 2–2). What about crossing the BBB? Small drugs can diffuse across the BBB as a function of their lipid solubility (oil/water partition coefficient). Thus, anesthetics such as nitrous oxide and *thiopental* move readily across the BBB. Some drugs may resemble substrates that are transported into the brain (e.g., amino acids, nucleosides) and thereby gain entry. LAT1 (SLC7A5) is involved in the influx of several drugs, such as L-dopa and *gabapentin*, across the BBB. OAT1 and OAT3, which generally play a role in the efflux of drugs from the CSF, mediate the uptake of organic compounds such as β-lactam antibiotics, statins, and H_2 receptor antagonists. Charged and large drugs, on the other hand, generally do not penetrate so easily into the brain. The transport proteins, especially MDR1, BCRP, and MRP4, actively extrude many drugs; clearly, recognition by these transporters is a major disadvantage for a drug used to treat CNS disease. Further, there is ongoing research suggesting that MDR1 and BCRP expression levels in the BBB may be modulated in neurological diseases, which may represent an important pathological mechanism for certain neurodegenerative diseases.

There are methods of permeation under development, which largely consist of emerging developments in nanotechnology: nanoparticles and liposomes containing drugs, drugs adducted to ferritin, and development of drug forms with suitable lipophilicity. Basic biomedical research is advancing our understanding of the role of nuclear receptors in the regulation of drug transporters and enzymes in the BBB and of the development of the BBB and the interaction of its cellular and subcellular

components to maintain barrier function (Profaci et al., 2020). Kim and Bynoe (2016) reported that activation of the adenosine A_{2A} receptor in an *in vitro* human brain endothelial barrier model reversibly decreased expression of Pgp (MDR1), suggesting that adenosine A_{2A} receptor agonists may be useful in modulating permeability of the BBB. Such studies and techniques may provide progress in putting the control of BBB permeability into the hands of physicians. Chapter 17 reviews developing strategies for providing regulated drug entry into the CNS.

The Extended Clearance Concept and Physiologically Based Pharmacokinetic (PBPK) Modeling

Based on the "extended clearance concept," hepatic clearance consists of some intrinsic processes, such as hepatic uptake PS_1, backflux from hepatocytes to blood PS_2, hepatic metabolism CL_{met}, and biliary sequestration PS_3 (Figure 4–12) (Shitara et al., 2006, 2013).

The overall hepatic intrinsic clearance $CL_{int,all}$ is expressed as

$$CL_{int,all} = PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3} \qquad \text{(Equation 4–6)}$$

If the sum of the intrinsic clearance of metabolism and biliary sequestration is much larger than the backflux clearance [$PS_2 << (CL_{met} + PS_3)$], $CL_{int,all}$ approximates PS_1, and uptake is a rate-determining process of the overall hepatic intrinsic clearance. In general, many transporter substrates are efficiently excreted into bile or extensively metabolized rather than fluxed back into blood, so their uptake clearances often determine their overall intrinsic hepatic clearance. Assuming that an orally administered drug is completely absorbed from the small intestine and predominantly cleared by the liver, its blood AUC based on the "well-stirred model" can be described as

$$AUC_{blood} = \frac{Dose}{f_B \cdot CL_{int,all}} = \frac{Dose}{f_B \cdot PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3}} \qquad \text{(Equation 4–7)}$$

where f_B represents the unbound fraction in blood.

The AUC_{liver} is described as (Shitara et al., 2013)

$$\begin{aligned} AUC_{liver} &= \frac{PS_1}{PS_2 + CL_{met} + PS_3} \cdot AUC_{blood} \\ &= \frac{PS_1}{PS_2 + CL_{met} + PS_3} \cdot \frac{Dose}{f_B \cdot PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3}} \qquad \text{(Equation 4–8)} \\ &= \frac{Dose}{f_B \cdot (CL_{met} + PS_3)} \end{aligned}$$

Equations 4–6 through 4–8 suggest that if the uptake clearance PS_1 is decreased, AUC_{blood} is increased in inverse proportion to PS_1, while AUC_{liver} is not affected. On the other hand, if drug uptake is a rate-determining process of the overall hepatic intrinsic clearance, the decrease in the function of metabolism or biliary sequestration causes the increase in AUC_{liver}, but not AUC_{blood}. Therefore, if the molecular targets of pharmacological effect and adverse effect induced by drugs are located inside and outside hepatocytes, respectively, as in the case of statins, decrease in the hepatic uptake clearance of drugs caused by drug-drug interaction or genetic polymorphism of transporters affects mainly adverse effect and not so much pharmacological effect.

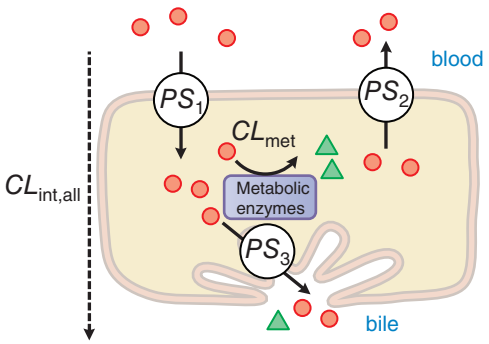

Figure 4–12 *Extended clearance concept: hepatic uptake, backflux into blood, metabolism, and efflux into bile.* The red circles represent parent drugs; the green triangles represent drug metabolites.

To simulate the impact of variations in the transporter activities on the systemic and liver exposure of a statin, which is eliminated mainly via OATP1B1 and MRP2, a PBPK model has been used (Jamei et al., 2014; Watanabe et al., 2009).

In a PBPK model, compartments representing actual tissues are connected by blood flow to predict the time course of drug disposition in the body. A PBPK model allows deep insight into the factors governing the systemic exposure and tissue distribution of drugs and simulates the impact of variations in physiological or drug-dependent parameters on drug disposition. Sensitivity analyses based on the PBPK model indicate that the variation in OATP1B1 activities will have a minimal impact on the therapeutic efficacy but a large impact on the side effect (myopathy) of *pravastatin*; the opposite will be true for variations in MRP2/BCRP activities: a large impact on efficacy, a small impact on the side effect (Watanabe et al., 2009) (Figure 4–13). Such characteristics have been demonstrated for some statins (e.g., *simvastatin* and *rosuvastatin*): Pharmacogenomic variation of OATP1B1 activity is associated with the risk of adverse reactions, whereas variation of biliary excretion and intestinal absorption mechanisms results in variation in therapeutic response (Chasman et al., 2012; SEARCH Collaborative Group, 2008).

Genetic Variation in Membrane Transporters: Implications for Clinical Drug Response

There are inherited defects in SLC transporters (see Table 4–2) and ABC transporters (see Table 4–3) that lead to disease. However, more common genetic polymorphisms in membrane transporters play roles in drug response and are yielding new insights into pharmacogenetics and pharmacology (see Chapter 7).

Clinical studies reveal that polymorphisms in three transporters, *ABCG2* (BCRP), *SLCO1B1* (OATP1B1), and *SLC22A1* (OCT1), contribute to interindividual variation in the response to many drugs and should be considered in drug development (Yee et al., 2018). For example, a common missense polymorphism (rs2231142), p.Gln141Lys in BCRP, is associated with increased response to *rosuvastatin*. BCRP provides for intestinal efflux of *rosuvastatin*. The p.Gln141Lys polymorphism results in reduced function of BCRP and hence reduced intestinal efflux of *rosuvastatin* and a concomitant increase in the bioavailability of the drug. The BCRP polymorphism has also been associated with poor response to *allopurinol* in several genome-wide association studies, albeit the mechanisms for the association are unclear. A common missense polymorphism (rs4149056) in OATP1B1, p.Val174Ala, is associated with elevated blood levels of statins and the resultant muscle toxicities of statins (see Chapter 37) and with interindividual variation in the pharmacokinetics of *methotrexate* and *ticagrelor* (Yee et al., 2018). Myriad studies indicate that multiple missense genetic variants in transporters in the SLC22A family are associated with interindividual variation in clearance and response to various drugs. For example, there are significant associations between SLC22A1 missense variants (reduced function variants) and systemic levels of the antidiabetic drug *metformin*, the antimigraine drug *sumatriptan*, the opiate analgesic *morphine*, and the antinausea drug ondansetron (Yee et al., 2018). Transporters in addition to OATP1B1, ABCG2, and OCT1 harbor polymorphisms that have been associated with *interindividual* variation in drug response (Rungtivasuwan et al., 2015). For example, the altered disposition of *tenofovir*, an antiviral agent, has been associated with polymorphisms in both ABCC2 (MRP2) and ABCC4 (MRP4).

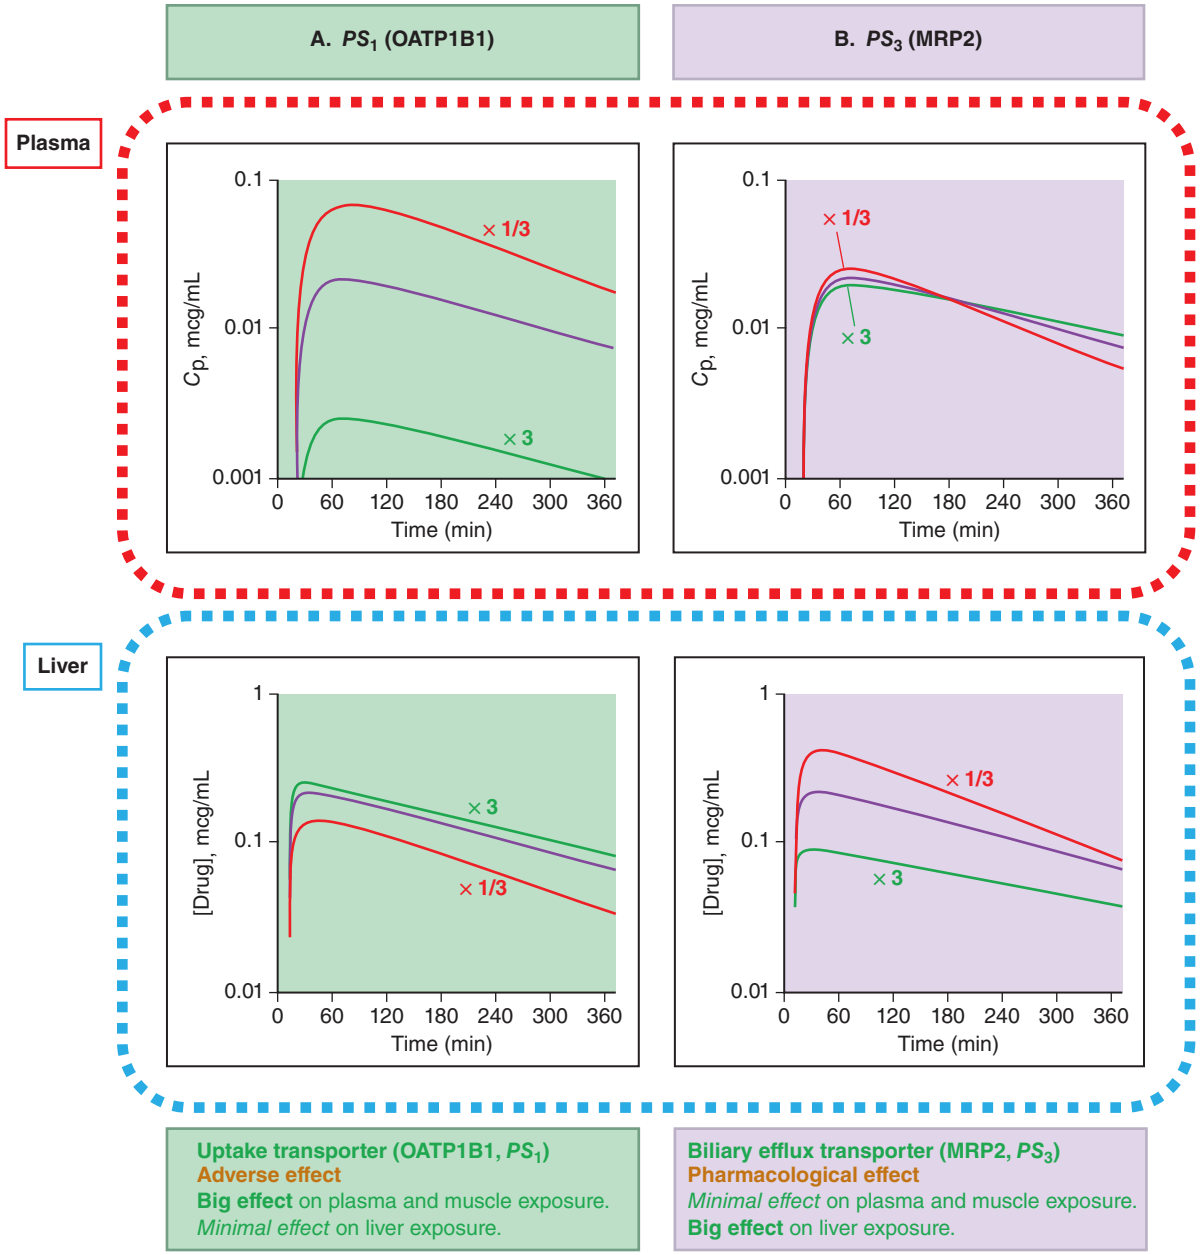

Figure 4–13 *Sensitivity analysis of the effect of functional changes of hepatic uptake clearance PS_1 (A) and biliary excretion clearance PS_3 (B) on the plasma and liver concentrations of pravastatin (Watanabe et al., 2009).* These sensitivity analyses were made based on the PBPK model, which connected five sequential liver compartments by blood flow so that this model can be used for drugs exhibiting transporter-mediated high clearance. Plasma and liver concentrations after oral administration (40 mg) were simulated with varying hepatic transport activities over a 1/3- to 3-fold range of the initial values.

Transporters in Regulatory Sciences

Because of their importance in drug disposition and action, transporters are major determinants of variation in therapeutic and adverse drug reactions. As a result, transporters may mediate drug-drug interactions that result in drug safety issues. A notable example is the interaction between *gemfibrozil* and *cerivastatin*. Gemfibrozil glucuronide formed in hepatocytes reduces the hepatic uptake and metabolism of *cerivastatin*; the result is a high C_p for *cerivastatin*. Elevated statin levels result in statin-induced myopathies, including rhabdomyolysis, a life-threatening adverse effect. This interaction resulted in the removal of *cerivastatin* from the market because of deaths due to rhabdomyolysis. The U.S. FDA has issued a clinical pharmacology guidance on performing drug-drug interaction studies during clinical drug development (FDA, 2020). The guidance presents information on how to use *in vitro* data for transporter studies to make decisions about whether to conduct a clinical drug-drug interaction study. For example, if a new molecular entity (NME) inhibits the *in vitro* transport of a canonical substrate of OCT2 and MATE1 at clinically relevant (unbound) concentrations, the guidance recommends that the sponsor consider performing a clinical drug-drug interaction study to determine whether the NME inhibits the renal clearance of an OCT2 and MATE1 substrate (e.g., metformin) *in vivo* (Nishiyama et al., 2019). On the other hand, if the NME neither inhibits OCT2 nor MATE1 mediated transport in *in vitro* assays at therapeutic concentrations, the guidance does not recommend a clinical study. Although only a handful of transporters (OATP1B1, OATP1B3, Pgp, BCRP, OCT2, MATE1, OAT1, and OAT3) are included in the FDA guidance, an increasing number of studies are being performed to identify and characterize transporters that mediate clinical drug-drug interactions.

Various endogenous biomarkers have been identified as *in vivo* probes for a number of hepatic and renal drug transporters. Available clinical data indicate the utility of endogenous biomarkers in phase I trials in facilitating subject phenotyping and drug-drug interaction

TABLE 4–5 ■ ENDOGENOUS BIOMARKERS TO ASSESS THE DRUG-DRUG INTERACTION RISK

TARGET TRANSPORTER	COMPOUND	FORMATION	PK PARAMETER
OATP1B1/OATP1B3	CP-I/III	Byproduct of heme biosynthesis	C_{max} or AUC
	GCDCA-S, GCDCA-G, CDCA-24G	Bile acid metabolites	C_{max} or AUC
	HDA and TDA	Fatty acid metabolites	C_{max} or AUC

assessment (Table 4–5) (Chu et al., 2018; Rodrigues et al., 2018). The use of such endogenous biomarkers offers benefits in downstream planning of clinical studies. The two most commonly used endogenous biomarkers are coproporphyrin-I for OATP1B-mediated hepatic uptake and *N*-methylnicotinamide for the renal uptake and excretion transporters (OCT2/MATEs) (Chu et al., 2018; Rodrigues et al., 2018). A useful PBPK model (Yoshikado et al., 2018) and a population pharmacokinetic model (Barnett et al., 2018) for the OATP1B biomarker (coproporphyrin-I) have been proposed. The models support the translation of the effect of a new chemical entity on changes in plasma coproporphyrin-I level to that on clinically used drugs (e.g., statins). Thus, the modeling can complement existing OATP1B-mediated drug-drug interaction risk assessment approaches based on regulatory agency guidelines.

Chapter 5

Drug Metabolism

Frank J. Gonzalez and Michael Coughtrie

Coping With Xenobiotics

Humans come into contact with thousands of foreign chemicals or xenobiotics (substances foreign to the body) through diet and exposure to environmental contaminants. Fortunately, humans have developed a means to rapidly eliminate xenobiotics so that they do not accumulate in the tissues and cause harm. Plants are a common source of dietary xenobiotics, providing many structurally diverse chemicals, some of which are associated with pigment production and others that are toxins (called *phytoalexins*) that protect plants against predators. Poisonous mushrooms are a common example: They have many toxins that are lethal to mammals, including amanitin, gyromitrin, orellanine, muscarine, ibotenic acid, muscimol, psilocybin, and coprine. Animals must be able to metabolize and eliminate such chemicals to consume vegetation. While humans can now choose their dietary sources, a typical animal does not have this luxury and as a result is subject to its environment and the vegetation that exists in that environment. Thus, the ability to metabolize unusual chemicals in plants and other food sources is critical for adaptation to a changing environment and ultimately the survival of animals.

Enzymes that metabolize xenobiotics have historically been called drug-metabolizing enzymes by pharmacologists; however, these enzymes are involved in the metabolism of many foreign chemicals to which humans are exposed and are more appropriately called *xenobiotic-metabolizing enzymes*. Myriad diverse enzymes have evolved in animals to metabolize foreign chemicals. Dietary differences amongst species during the course of evolution could account for the marked species variation in the complexity of the xenobiotic-metabolizing enzymes. Additional diversity within these enzyme systems has also derived from the necessity to "detoxify" a host of endogenous chemicals that would otherwise prove harmful to the organism, such as bilirubin, steroid hormones, and catecholamines. Many of these endogenous compounds are detoxified by the same or closely related xenobiotic-metabolizing enzymes.

Drugs are xenobiotics, and the capacity to metabolize and clear drugs involves the same enzymatic pathways and transport systems that are used for normal metabolism of dietary constituents. Indeed, many drugs are derived from chemicals found in plants, some of which have been used in traditional medicines for thousands of years. Of the prescription drugs in use today for cancer treatment, some are also derived from plants (see Chapters 69 and 73); investigating folkloric claims led to the discovery of many drugs. The capacity to metabolize xenobiotics, although largely beneficial, has made development of drugs more time consuming and costly due in part to:

- Species differences in expression of enzymes that metabolize drugs and thereby limit the utility of animal models to predict drug effects in humans
- Interindividual variations in the capacity of humans to metabolize drugs
- Drug-drug interactions involving xenobiotic-metabolizing enzymes
- Metabolic activation of chemicals to toxic and carcinogenic derivatives

Today, most xenobiotics to which humans are exposed come from sources that include environmental pollution, food additives, cosmetic products, agrochemicals, processed foods, and drugs.

In general, most xenobiotics are hydrophobic chemicals; in the absence of metabolism, these would not be efficiently eliminated and thus would accumulate in the body, potentially resulting in toxicity. With few exceptions, all xenobiotics are subjected to one or multiple enzymatic pathways that constitute *phase 1 oxidation* and *phase 2 conjugation*. As a general paradigm, metabolism serves to convert these hydrophobic chemicals into more hydrophilic derivatives that can easily be eliminated from the body through the urine or the bile.

To enter cells and reach their sites of action, drugs generally must possess physical properties that allow them to move down a concentration gradient and across cell membranes. Many drugs are hydrophobic, a property that allows entry via diffusion across lipid bilayers into the systemic circulation and then into cells. With some compounds, transporters on the plasma membrane facilitate entry (see Chapter 4). Hydrophobic drugs are difficult to eliminate because, in the absence of metabolism, they accumulate in fat and cellular phospholipid bilayers. The xenobiotic-metabolizing enzymes convert drugs and other xenobiotics into derivatives that are more hydrophilic and thus easily eliminated via excretion into the aqueous compartments of the tissues and ultimately into the urine. High-molecular-weight drugs are preferentially eliminated via the bile into the intestine and feces.

Abbreviations

ADR: adverse drug reaction
AHR: aryl hydrocarbon receptor
AUC: area under the plasma concentration–time curve
CAR: constitutive androstane receptor
CYP: cytochrome P450
EH: epoxide hydrolase
ER: endoplasmic reticulum
FMO: flavin-containing monooxygenase
GI: gastrointestinal
GSH and GSSG: reduced and oxidized glutathione
GST: glutathione-*S*-transferase
HGPRT: hypoxanthine guanine phosphoribosyl transferase
HIF: hypoxia-inducible factor
HIV: human immunodeficiency virus
INH: isonicotinic acid hydrazide (isoniazid)
MAPK: mitogen-activated protein kinase
mEH: microsomal epoxide hydrolase
6-MP: 6-mercaptopurine
MT: methyltransferase
NADPH: nicotinamide adenine dinucleotide phosphate
NAPQI: *N*-acetyl-*p*-benzoquinone imine
NAT: *N*-acetyltransferase
PAPS: 3′-phosphoadenosine-5′-phosphosulfate
PPAR: peroxisome proliferator–activated receptor
PXR: pregnane X receptor
SULT: sulfotransferase
TPMT: thiopurine methyltransferase
UDP-GA: uridine diphosphate–glucuronic acid
UGT: uridine diphosphate–glucuronosyltransferase

Metabolism of a drug can begin even before a drug is absorbed: Gut bacteria represent the first metabolic interface between orally administered drugs and the body (see Chapter 6). The microbiome of the gastrointestinal (GI) tract can metabolize xenobiotics; interindividual differences in composition of the gut flora could influence drug action and contribute to differences in drug response. Indeed, diurnal oscillations in GI bacteria and their metabolic capacity, superposed on host clock gene oscillations, appear to affect drug disposition and effect (Fitzgerald et al., 2015).

The process of drug metabolism that leads to elimination also plays a major role in diminishing the biological activity of a drug. For example, *(S)-phenytoin*, an anticonvulsant used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by the phase 1 CYPs followed by phase 2 UGTs (uridine diphosphate–glucuronosyltransferases) produces a metabolite that is highly water soluble and readily eliminated from the body (Figure 5–1). Metabolism also terminates the biological activity of *(S)-phenytoin*. Because conjugates are generally hydrophilic, elimination via the bile or urine is dependent on the actions of many efflux transporters to facilitate transmembrane passage (see Chapter 4).

While xenobiotic-metabolizing enzymes facilitate the elimination of chemicals from the body, paradoxically these same enzymes can also convert certain chemicals to highly reactive, toxic, and carcinogenic metabolites. This occurs when an unstable intermediate is formed that has reactivity toward other compounds in the cell. Chemicals that can be converted by xenobiotic metabolism to cancer-causing derivatives are called carcinogens. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes can produce electrophilic metabolites that react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. This can cause cell death and organ toxicity. Most drugs and other xenobiotics that cause hepatotoxicity damage mitochondria, leading to hepatocyte death. Reaction of these electrophiles with DNA can

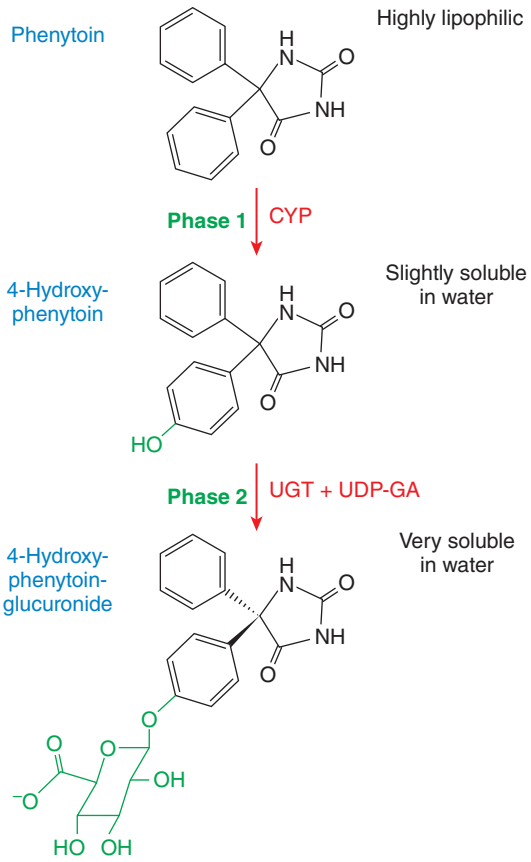

Figure 5–1 *Metabolism of phenytoin.* In phase 1, CYP facilitates 4-hydroxylation of *phenytoin* to yield HPPH. In phase 2, the hydroxy group serves as a substrate for UGT, which conjugates a molecule of glucuronic acid using UDP-GA as a cofactor. Together, phase 1 and phase 2 reactions convert a very hydrophobic molecule to a larger hydrophilic derivative that is eliminated via the bile. HPPH, 5-(-4-hydroxyphenyl)-5-phenylhydantoin.

sometimes result in cancer through the mutation of oncogenes or tumor suppressor genes. It is generally believed that most human cancers are due to exposure to chemical carcinogens.

This potential for carcinogenic activity makes testing the safety of drug candidates vitally important. Testing for cancer-causing potential is particularly critical for drugs that will be used for the treatment of chronic diseases. Because each species has evolved a unique combination of xenobiotic-metabolizing enzymes, nonprimate models (mostly rodents) cannot be solely used for testing the safety of new drug candidates targeted for human diseases. Nevertheless, testing in rodent models (e.g., mice and rats) can usually identify potential carcinogens. Fortunately, there are no instances of drugs that test negative in rodents but cause cancer in humans, albeit some chemicals that cause cancer in rodents are not associated with human cancer. Many cytotoxic drugs used to treat cancer also have the potential to cause cancer; this risk is minimized by their acute, rather than chronic, use in cancer therapy.

The Phases of Drug Metabolism

Xenobiotic-metabolizing enzymes have historically been categorized as

- *phase 1 reactions*, which include oxidation, reduction, and hydrolytic reactions; or
- *phase 2 reactions*, in which enzymes catalyze conjugation of the substrate (the phase 1 product) with a second molecule.

The *phase 1 enzymes* lead to the introduction of functional groups, such as –OH, –COOH, –SH, –O–, or NH_2 (Table 5–1). The addition of functional groups does little to increase the water solubility of the drug

TABLE 5–1 ■ XENOBIOTIC-METABOLIZING ENZYMES

ENZYMES	REACTIONS
Phase 1 enzymes (CYPs, FMOs, EHs)	
Cytochrome P450s (P450 or CYP)	C and O oxidation, dealkylation, others
Flavin-containing monooxygenases (FMOs)	N, S, and P oxidation
Epoxide hydrolases (EHs)	Hydrolysis of epoxides
Phase 2 "transferases"	
Sulfotransferases (SULT)	Addition of sulfate
UDP-glucuronosyltransferases (UGTs)	Addition of glucuronic acid
Glutathione-*S*-transferases (GSTs)	Addition of glutathione
N-Acetyltransferases (NATs)	Addition of acetyl group
Methyltransferases (MTs)	Addition of methyl group
Other enzymes	
Alcohol dehydrogenases	Reduction of alcohols
Aldehyde dehydrogenases	Reduction of aldehydes
NADPH-quinone oxidoreductase (NQO)	Reduction of quinones

mEH and sEH, microsomal and soluble epoxide hydrolase, respectively; NADPH, reduced nicotinamide adenine dinucleotide phosphate; UDP, uridine diphosphate.

but can dramatically alter the biological properties of the drug. Reactions carried out by phase 1 enzymes usually lead to the inactivation of a drug. However, in certain instances, metabolism, usually the hydrolysis of an ester or amide linkage, results in bioactivation of a drug. Inactive drugs that undergo metabolism to become active drugs are called prodrugs (Rautio et al., 2018). Prodrugs can be activated by gut bacterial enzymes, enzymes in blood, or intracellular enzymes such as cytochromes P450 (CYPs), flavin-containing monooxygenases (FMOs), and hydrolytic enzymes. Examples of prodrugs bioactivated by CYPs are the antitumor drug *cyclophosphamide*, which is bioactivated to a cell-killing electrophilic derivative (see Chapter 70), and the anti-thrombotic agent *clopidogrel*, which is activated to 2-oxo-clopidogrel and further metabolized to an irreversible inhibitor of platelet ADP $P2Y_{12}$ receptors. Through conjugation reactions, *phase 2 enzymes* produce metabolites with improved water solubility, a property that facilitates drug elimination from the tissue, normally via efflux transporters described in Chapter 4. Thus, in general, phase 1 reactions result in biological inactivation of a drug, and phase 2 reactions facilitate the drug elimination and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation.

Superfamilies of evolutionarily related enzymes and receptors are common in the mammalian genome. Superfamilies are designated based on similar structure and function. Within the superfamilies are more closely related subfamilies of genes that are usually co-localized on a chromosome. The enzyme systems responsible for drug metabolism are good examples. The phase 1 oxidation reactions are carried out by CYPs, FMOs, and epoxide hydrolases (EHs). The CYPs and FMOs are composed of superfamilies and subfamilies encoded by multiple genes. The phase 2 enzymes include several superfamilies of conjugating enzymes. Among the more important are the glutathione-*S*-transferase (GSTs), UGTs, sulfotransferases (SULTs), *N*-acetyltransferases (NATs), and methyltransferases (MTs) (Table 5–1).

The conjugation reactions of the phase 2 enzymes usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, or sulfur atoms that serve as acceptor sites for a hydrophilic moiety, such as glutathione, glucuronic acid, sulfate, or an acetyl group, that can be covalently conjugated to an acceptor site on the substrate. The metabolism of phenytoin (Figure 5–1) illustrates the two-phase metabolic sequence. The oxidation by phase 1 enzymes either adds or exposes a functional group, permitting the products of phase 1 metabolism to serve as substrates for the phase 2 conjugating or synthetic enzymes. In the case of UGTs, glucuronic acid is delivered to the functional group, forming a glucuronide metabolite that is more water soluble and is targeted for excretion in the urine or bile. When the substrate is a drug, these reactions usually convert the original drug to a form that is not able to bind to its target receptor, thus attenuating the biological response to the drug.

Sites of Drug Metabolism

Xenobiotic-metabolizing enzymes are found in most tissues in the body, with the highest levels located in the GI tract (liver, small and large intestines). The small intestine plays a crucial role in drug metabolism. Orally administered drugs are first exposed to the GI flora, which can metabolize some drugs (see Chapter 6). During absorption, drugs are exposed to xenobiotic-metabolizing enzymes in the epithelial cells of the GI tract; this is the initial site of drug metabolism. Once absorbed, drugs enter the portal circulation and reach the liver, where they may be extensively metabolized (the "first-pass effect") before entering the general circulation. The liver is the major "metabolic clearinghouse" for both endogenous chemicals (e.g., cholesterol, steroid hormones, fatty acids, and proteins) and xenobiotics. Subsequent passes through the liver result in more metabolism of the parent drug until the agent is eliminated. Drugs that are poorly metabolized remain in the body for longer periods of time, and their pharmacokinetic profiles show much longer elimination half-lives than drugs that are rapidly metabolized.

During drug development, desirable compounds are those that have a favorable pharmacokinetic profile and are eliminated over the course of 24 h after administration. This allows the use of daily single dosing. If a compound with a favorable efficacy cannot be modified to improve its pharmacokinetic profile, twice-a-day or even three-times-a-day dosing needs to be used. Other organs that contain significant xenobiotic-metabolizing enzymes include tissues of the nasal mucosa and lung, which play important roles in the metabolism of drugs that are administered through aerosol sprays. These tissues are also the first line of contact with hazardous substances that are airborne.

Within the cell, xenobiotic-metabolizing enzymes are found in the intracellular membranes and in the cytosol. The phase 1 CYPs, FMOs, and EHs and some phase 2 conjugating enzymes, notably the UGTs, are all located in the endoplasmic reticulum (ER) of the cell (Figure 5–2). The ER consists of phospholipid bilayers organized as tubes and sheets throughout the cytoplasm. This network, which is very extensive in liver hepatocytes where most xenobiotic metabolism occurs, has an inner lumen that is physically distinct from the rest of the cytosolic components of the cell and has connections to the plasma membrane and nuclear envelope. This membrane localization is ideally suited for the metabolic function of these enzymes: Hydrophobic molecules enter the cell and become embedded in the lipid bilayer, where they come into direct contact with the phase 1 enzymes. Once subjected to oxidation, drugs can be directly conjugated by the UGTs (in the lumen of the endoplasmic reticulum) or by the cytosolic transferases, such as GSTs and SULTs. The UGT co-substrate UDP-GA (uridine diphosphate–glucuronic acid) must be transported in the lumen of the ER, from which the glucuronide conjugates must be exported. After metabolism in the liver, metabolites are transported across the plasma membrane into the bloodstream and eliminated via the kidney or transported into the bile via the bile canaliculus, from which they are deposited in the gut and eliminated in the feces (as shown for the topoisomerase inhibitor SN-38 in Figure 5–9). Whether a compound is targeted to the kidneys or to the bile depends in part on its molecular weight, with high-molecular-weight compounds preferentially eliminated through the bile, and also on the substrate specificities of the membrane transporters involved.

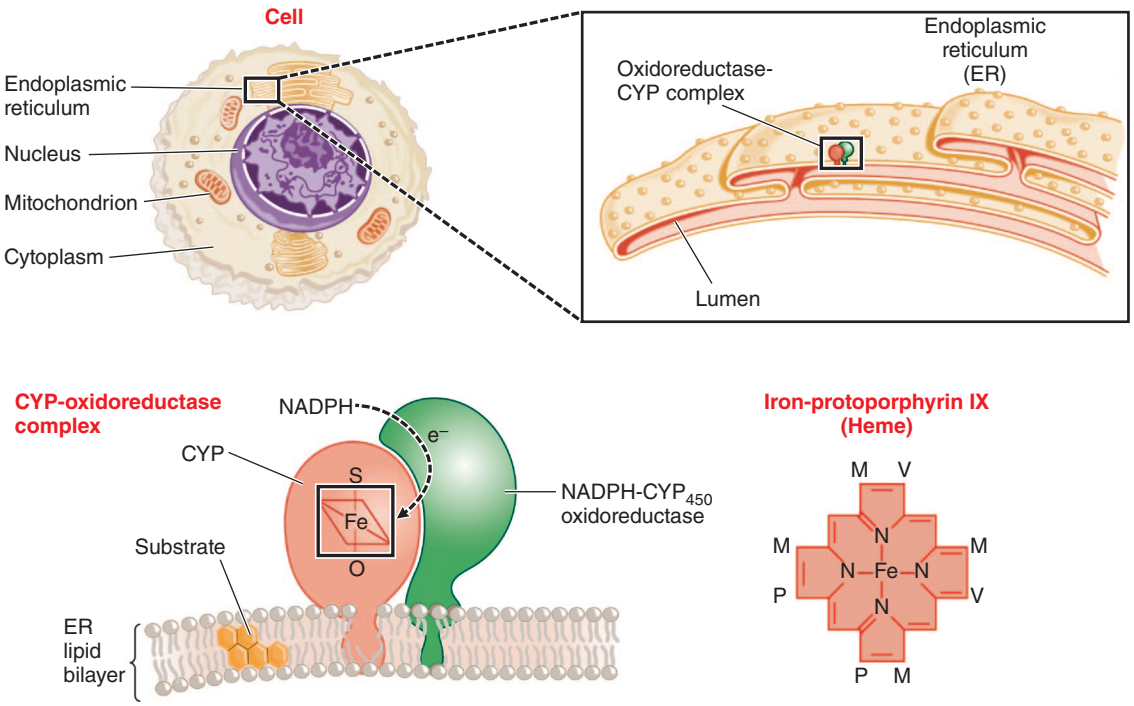

Figure 5–2 *Location of CYPs in the cell.* Increasingly microscopic levels of detail are shown, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the ER. Most of the enzyme is located on the cytosolic surface of the ER. A second enzyme, NADPH-CYP oxidoreductase, transfers electrons to the CYP where it can, in the presence of O_2, oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O_2. Substituents on the porphyrin ring are methyl (M), propionyl (P), and vinyl (V) groups.

Phase 1 Reactions

CYPs: The Cytochrome P450 Superfamily

The CYPs are a superfamily of enzymes, each of which contains a molecule of heme bound noncovalently to the polypeptide chain (Figure 5–2). Many enzymes that use O_2 as a substrate for their reactions contain heme, and heme is the oxygen-binding moiety in hemoglobin. Heme contains one atom of iron in a hydrocarbon cage that functions to bind O_2 in the active site of the CYP as part of the catalytic cycle of these enzymes. CYPs use O_2, plus H^+ derived from the cofactor-reduced NADPH, to carry out the oxidation of substrates. The H^+ is supplied through the enzyme NADPH-CYP oxidoreductase. Metabolism of a substrate by a CYP consumes one molecule of O_2 and produces an oxidized substrate and a molecule of H_2O as a by-product. However, for most CYPs, depending on the nature of the substrate, the reaction is "uncoupled," consuming more O_2 than substrate metabolized and producing what is called activated oxygen or O_2^-. The O_2^- is usually converted to water by the enzyme superoxide dismutase. However, when elevated by excess oxidation and metabolism of certain substrates, O_2^-, also called a reactive oxygen species (ROS), can cause oxidative stress that is detrimental to cellular physiology and is associated with diseases such as hepatic cirrhosis.

Substrate Specificity and Promiscuity Among CYPs

Among the diverse reactions carried out by mammalian CYPs are *N*-dealkylation, *O*-dealkylation, aromatic hydroxylation, *N*-oxidation, *S*-oxidation, deamination, and dehalogenation (Table 5–2). Fifty-seven individual CYPs have been identified in humans. Metabolism of dietary and xenobiotic chemicals is not the only role that CYPs play. Other members of the CYP family are involved in the synthesis of endogenous compounds such as steroids, fatty acid signaling molecules (e.g., epoxyeicosatrienoic acids; see Figure 5–5), and bile acids.

The CYPs that catalyze steroid and bile acid synthesis have specific substrate preferences. For example, the CYP that produces estrogen from testosterone, CYP19 or aromatase, can metabolize only testosterone or androstenedione and does not metabolize xenobiotics. Specific inhibitors for aromatase, such as *anastrozole*, are used in the treatment of estrogen-dependent tumors (see Chapters 48 and 73).

The synthesis of bile acids from cholesterol occurs in the liver, where, subsequent to CYP-catalyzed oxidation, the bile acids are conjugated with amino acids and transported through the bile duct and gallbladder into the small intestine. Bile acids are emulsifiers that facilitate the elimination of high-molecular-weight conjugated drugs from the liver and serve to enhance the absorption of fatty acids and vitamins from the diet. More than 90% of bile acids are reabsorbed by the gut and transported back to hepatocytes in a tightly regulated process of enterohepatic transport (Gonzalez, 2012). Similar to the steroid biosynthetic CYPs, CYPs involved in bile acid production have strict substrate requirements and do not participate in xenobiotic or drug metabolism.

In contrast to CYPs that carry out highly specific reactions, the xenobiotic-metabolizing CYPs are promiscuous in their capacity to bind and metabolize multiple substrates (Table 5–2). As a group, the CYPs that carry out xenobiotic metabolism have the capacity to metabolize a large number of structurally diverse chemicals. This is due to the multiplicity of CYPs and their isoforms and to the capacity of a single CYP to metabolize many structurally diverse chemicals. A single compound may also be metabolized, albeit at different rates, by different CYPs. In addition, CYPs can metabolize a single compound at different positions on the molecule, and two CYPs can carry out the metabolism of a single compound at distinct oxidation sites.

This promiscuity of CYPs is due to large and fluid substrate-binding sites in CYPs, a feature that sacrifices enzymatic turnover rates for broad specificity: CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs generally have half-lives on the order of 3 to 30 h, while endogenous compounds have half-lives on the order of seconds or minutes when exogenously administered (e.g., catecholamines and glucose). Even though CYPs have slow catalytic rates, their activities are sufficient to metabolize drugs that are administered at high concentrations.

TABLE 5–2 ■ MAJOR REACTIONS INVOLVED IN DRUG METABOLISM

	REACTION	EXAMPLES
I. Oxidative reactions		
N-Dealkylation		Imipramine, diazepam, codeine, erythromycin, morphine, tamoxifen, theophylline, caffeine
O-Dealkylation		Codeine, indomethacin, dextromethorphan
Aliphatic hydroxylation		Tolbutamide, ibuprofen, phenobarbital, meprobamate, cyclosporine, midazolam
Aromatic hydroxylation		Phenytoin, phenobarbital, propanolol, ethinyl estradiol, amphetamine, warfarin
N-Oxidation		Chlorpheniramine, dapsone, meperidine
S-Oxidation		Cimetidine, chlorpromazine, thioridazine omeprazole
Deamination		Diazepam, amphetamine
II. Hydrolysis reactions		
		Carbamazepine (see Figure 5-4)
		Procaine, aspirin, clofibrate, meperidine, enalapril, cocaine
		Lidocaine, procainamide, indomethacin
III. Conjugation reactions		
Glucuronidation		Acetaminophen, morphine, oxazepam, lorazepam
Sulfation		Acetaminophen, steroids, methyldopa
Acetylation		Sulfonamides, isoniazid, dapsone, clonazepam
Methylation*		L-dopa, methyldopa, mercaptopurine, captopril
Glutathionylation		Adriamycin, fosfomycin, busulfan

PAPS, 3′-phosphoadenosine-5′-phosphosulfate; PAP, 3′-phosphoadenosine-5′-phosphate; AdoMet, S-adenosylmethionine; AdoHomCys, S-adenosylhomocysteine.
*also on S- or N-

The metabolism of a particular drug can often be ascribed to the activity of a single CYP. However, when two coadministered drugs are both metabolized by a single CYP, they compete for binding to the enzyme's active site. This can result in the inhibition of metabolism of one or both of the drugs, leading to elevated plasma drug levels. If there is a narrow therapeutic index for the drugs, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of adverse drug reactions (ADRs). Prescription drug labeling provides warnings about drug interactions, including identity of the CYPs most prominently involved in the metabolism of a particular drug. Preclinical studies must take into consideration any drug on the market that might be coadministered with the drug under development. For example, treatment of syndrome X (metabolic syndrome) would involve statins and antidiabetic drugs. If these drugs are metabolized by the same CYP, drug interactions could be predicted and adverse responses avoided by suitable drug choices or dosage adjustments.

The Naming of CYPs

The CYPs, responsible for metabolizing the vast majority of therapeutic drugs, are the most actively studied of the xenobiotic-metabolizing enzymes. CYPs are complex and diverse in their regulation and catalytic activities. Genome sequencing has revealed the existence of 102 putatively functional CYP genes and 88 pseudogenes in the mouse and 57 putatively functional genes and 58 pseudogenes in humans. These genes are grouped, based on amino acid sequence similarity, into a superfamily comprising families and subfamilies with increasing sequence similarity. CYPs are named with the root CYP followed by a number designating the family, a letter denoting the subfamily, and another number designating the CYP form. Thus, CYP3A4 is family 3, subfamily A, and gene number 4.

A Small Number of CYPs Metabolize the Majority of Drugs

A limited number of CYPs from familes 1, 2, and 3 account for a preponderance of xenobiotc metabolism in humans. Twelve CYPs - CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5) - are mentioned repeatedly in discussions of drug metabolism in this book. Moreover, because a single CYP can metabolize a large number of structurally diverse compounds, these enzymes can collectively metabolize not just pharmaceuticals but also scores of chemicals found in the diet and the environment. The liver contains the greatest abundance of xenobiotic-metabolizing CYPs, thus ensuring efficient first-pass metabolism of drugs. CYPs are also expressed throughout the GI tract and in lower amounts in lung, kidney, and even in the CNS.

The expression of the CYPs can differ markedly as a result of dietary and environmental exposure to inducers or through interindividual heritable differences in CYP structure that can affect overall drug metabolism and clearance. The most active CYPs involved in drug metabolism are those in the CYP2C, CYP2D, and CYP3A subfamilies. CYP3A4, the most abundantly expressed in liver, is involved in the metabolism of over 50% of clinically used drugs (Figure 5–3A). The CYP1A, CYP1B, CYP2A, CYP2B, and CYP2E subfamilies are not significantly involved in the metabolism of most therapeutic drugs, but they can catalyze the metabolic activation of protoxins and procarcinogens found in the diet and environment to their reactive metabolites that can cause toxicity and cancer.

CYP Polymorphism

There are large differences in levels of expression of each CYP between individuals as assessed by both clinical pharmacologic studies and analysis of expression in human liver samples. This large interindividual variability in CYP expression is due to the presence of genetic polymorphisms and differences in gene regulation (see discussion that follows). Several human CYP genes exhibit polymorphisms, including *CYP2A6*, *CYP2C9*, *CYP2C19*, and *CYP2D6*. Polymorphisms in CYPs are significant contributors to interindividual differences in drug metabolism, and marked ethnic differences exist in the extent of the genetic polymorphisms. For instance, up to 10% and 25% of Caucasians and Asians lack expression of CYP2D6 and CYP2C19, respectively. The CYP2D6 polymorphism has led to the withdrawal of several clinically used drugs (e.g., *debrisoquine*

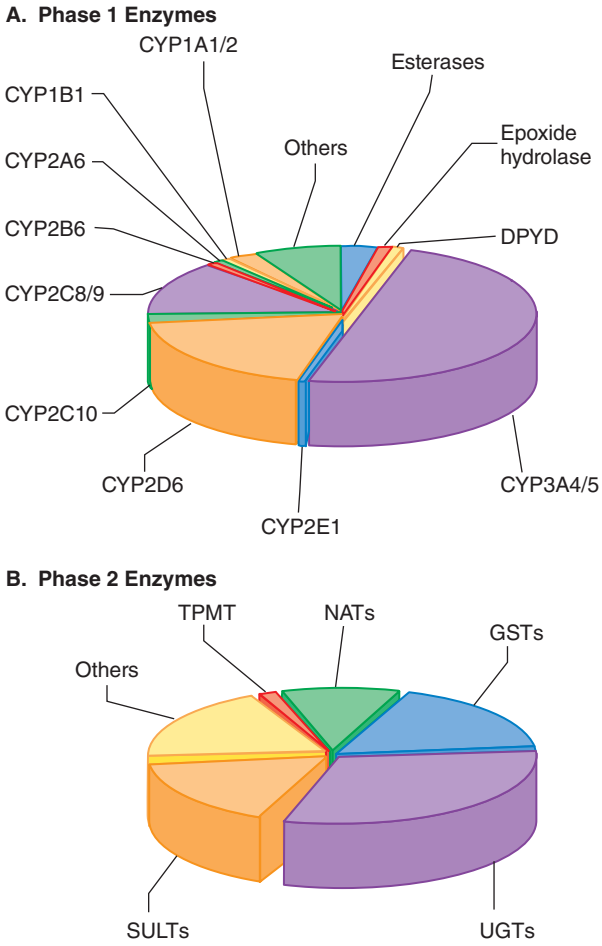

Figure 5–3 *The fraction of clinically used drugs metabolized by the major phase 1 and phase 2 enzymes.* The relative size of each pie section represents the estimated percentage of drugs metabolized by the major phase 1 (**A**) and phase 2 (**B**) enzymes, based on studies in the literature. In some cases, more than a single enzyme is responsible for metabolism of a single drug.

and *perhexiline*) and more cautious use of other drugs that are known CYP2D6 substrates (e.g., *encainide* and *flecainide* [antiarrhythmics], *desipramine* and *nortriptyline* [antidepressants], and *codeine*). In the case of codeine, individuals who lack CYP2D6 activity experience lower or no analgesic effects due to lack of codeine *O*-demethylation to morphine.

Allelic variants have been found in the *CYP1B1* and *CYP3A4* genes, but they are present at low frequencies in humans and appear not to have a major role in interindividual levels of expression of these enzymes. However, homozygous mutations in the *CYP1B1* gene, although rare, are associated with primary congenital glaucoma.

Drug-Drug Interactions

Differences in the rate of metabolism of a drug can be due to drug interactions. Most commonly, this occurs when two drugs (e.g., a statin and a macrolide antibiotic or antifungal agent) are coadministered and subjected to metabolism by the same enzyme. Because most of these drug-drug interactions are due to CYPs, it is important to determine the identity of the CYP that metabolizes a particular drug and to avoid coadministration of drugs that are metabolized by the same enzyme. The common antifungal agent *ketoconazole* is metabolized by CYP3A4 and other CYPs, and coadministration of ketoconazole with the anti-HIV (human immunodeficiency virus) protease inhibitors that are also CYP3A4 substrates reduces the clearance of the protease inhibitors and increases their plasma concentrations and the risks of toxicity. If a drug has a narrow therapeutic index, that is, a narrow range between the concentration required for therapeutic efficacy and the lowest concentration that causes toxicity, then consequential drug interactions are more likely.

If a drug has a narrow therapeutic index and coadministration with other drugs sharing the CYP cannot be avoided, then medicinal chemists may try to modify the drug to eliminate the CYP oxidation site while retaining the drug's efficacy (receptor binding affinity).

Some drugs are CYP inducers that not only can increase their own rates of metabolism but also can induce metabolism of other coadministered drugs (see the following discussion and Figure 5–12). Steroid hormones and herbal products such as St. John's wort (*Hypericum perforatum*) can increase hepatic levels of CYP3A4, thereby increasing the metabolism of many orally administered drugs. Drug metabolism can also be influenced by diet. CYP inhibitors and inducers are sometimes found in foods and can influence the toxicity and efficacy of a drug through induction or inhibition of CYPs. For most drugs, information found on the package insert lists the CYP that carries out its metabolism and the potential for drug interactions. Components found in grapefruit juice (e.g., naringin, furanocoumarins) are potent inhibitors of CYP3A4, and thus some drug inserts recommend not taking medication with grapefruit juice because it could increase the bioavailability of a drug.

Terfenadine, a once-popular antihistamine, was removed from the market because its metabolism was inhibited by CYP3A4 substrates such as *erythromycin* and grapefruit juice. *Terfenadine* is actually a prodrug that requires oxidation by CYP3A4 to its active metabolite, and at high doses, the parent compound caused arrhythmias. Elevated plasma levels of the parent drug resulting from CYP3A4 inhibition caused potentially fatal ventricular tachycardia in some individuals, an adverse response that led to the withdrawal of *terfenadine* from the market. The CYP3A4 metabolite of *terfenadine*, *fexofenadine*, which is not cardiotoxic, was developed as a replacement for *terfenadine*.

Flavin-Containing Monooxygenases

The FMOs are another superfamily of phase 1 enzymes involved in drug metabolism. Similar to CYPs, the FMOs are expressed at high levels in the liver and are bound to the ER, a site that favors interaction with and metabolism of hydrophobic drug substrates. There are six families of FMOs, with FMO3 the most abundant in liver. FMO3 is able to metabolize nicotine, as well as H_2 receptor antagonists (*cimetidine* and *ranitidine*), antipsychotics (*clozapine*), and antiemetics (*itopride*). Trimethylamine *N*-oxide (TMAO) occurs in high concentrations, up to 15% by weight, in marine animals, where it acts as an osmotic regulator. In humans, FMO3 normally metabolizes TMAO to TMA (trimethylamine), but a rare genetic deficiency of FMO3 causes the fish-odor syndrome, in which unmetabolized TMAO accumulates in the body and causes a socially offensive fish odor. This can be controlled by limiting dietary intake of foods containing TMAO.

FMOs are considered minor contributors to drug metabolism, and they almost always produce benign nonelectrophilic metabolites. In addition, FMOs are not readily inhibited and are not induced by any of the *xenobiotic receptors* (see discussion that follows); thus, in contrast to CYPs, FMOs would not be expected to be involved in drug-drug interactions. In fact, this has been demonstrated by comparing the pathways of metabolism of two drugs used in the control of gastric motility: *itopride* and *cisapride*. *Itopride* is metabolized by FMO3; *cisapride* is metabolized by CYP3A4. As predicted, *itopride* is less likely to be involved in drug-drug interactions than is *cisapride*. CYP3A4 participates in drug-drug interactions through both induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs. It is possible that FMOs may be important in the development of new drugs. A candidate drug could be designed by introducing a site for oxidation by FMOs with the knowledge that selected metabolism and pharmacokinetic properties could be accurately predicted for efficient drug-based biological efficacy.

Hydrolytic Enzymes

Epoxide Hydrolases

Two forms of epoxide hydrolase (EH) carry out hydrolysis of epoxides, most of which are produced by CYPs. Soluble epoxide hydrolase (sEH)

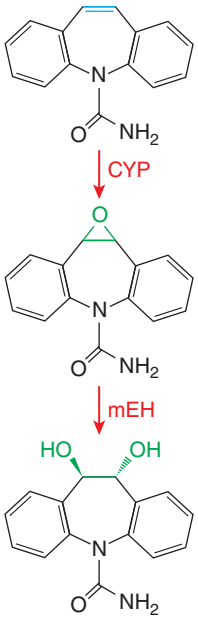

Figure 5–4 *Metabolism of carbamazepine by CYP and mEH.* *Carbamazepine* is oxidized to the pharmacologically active metabolite carbamazepine-10,11-epoxide by CYP. The epoxide is converted to a trans-dihydrodiol by mEH. This metabolite is biologically inactive and can be conjugated by phase 2 enzymes.

is expressed in the cytosol; mEH (microsomal epoxide hydrolase) is localized to the membrane of the ER. Epoxides are highly reactive electrophiles produced by CYPs that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Thus, EHs participate in the deactivation of potentially toxic metabolites.

There are a few examples of the influence of mEH on drug metabolism. The antiepileptic drug *carbamazepine* is a prodrug that is converted to its pharmacologically active derivative carbamazepine-10,11-epoxide, by CYP3A4. This metabolite is efficiently hydrolyzed to a dihydrodiol by mEH, resulting in inactivation of the drug (Figure 5–4). Inhibition of mEH can cause an elevation in plasma concentrations of the active metabolite and consequent side effects. The tranquilizer *valnoctamide* and anticonvulsant *valproate* inhibit mEH, resulting in clinically significant drug interactions with *carbamazepine*. This has led to efforts to develop new antiepileptic drugs, such as *gabapentin* and *levetiracetam*, that are metabolized by CYPs and not by EHs.

In general, the sEH complements the mEH in terms of substrate selectivity, with mEH degrading epoxides on cyclic systems and sEH having a high V_m and low K_m for fatty acid epoxides. Fatty acid epoxides are chemical mediators in the CYP branch of the arachidonic acid cascade. Simplistically, they can be thought of as balancing the generally proinflammatory and hypertensive prostaglandins, thromboxanes, and leukotrienes. The epoxides of arachidonic acid and docosahexaenoic acid reduce inflammation, hypertension, and pain but are normally degraded quickly by sEH to vicinal diols that are generally less biologically active (Figure 5–5). Thus, by inhibiting sEH, one can obtain dramatic biological effects. Recent work has focused on pain, where sEH inhibitors reduce both inflammatory and neuropathic pain and synergize with nonsteroidal anti-inflammatory drugs (Kodani and Hammock, 2015). In experimental systems, epoxides of dietary omega-3 and omega-6 fatty acids have anti-inflammatory properties, moderating inflammation and autophagy in insulin-sensitive tissues, effects that inhibitors of sEH promote (Lopez-Vicario et al., 2015).

Carboxylesterases

The carboxylesterases comprise a superfamily of enzymes that catalyze the hydrolysis of ester- and amide-containing chemicals. These enzymes are found in both the ER and the cytosol of many cell types and are involved in detoxification or metabolic activation of various drugs, environmental toxicants, and carcinogens. Carboxylesterases also catalyze

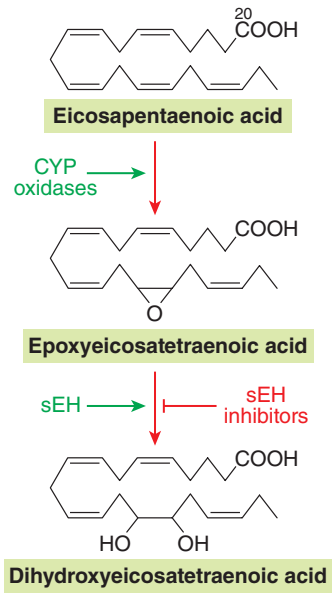

Figure 5–5 *Production and metabolism of an omega-3 fatty acid epoxide.* Fatty acid epoxides, such as the epoxide of the omega-3 fatty acid shown here, have a variety of anti-inflammatory and antinociceptive properties in test systems but are usually evanescent, metabolized to biologically less-active dihydroxy forms by sEH. Inhibition of sEH may promote the salutary effects of these epoxides.

the activation of prodrugs to their respective free acids. For example, the prodrug and cancer chemotherapeutic agent *irinotecan* is a camptothecin analogue that is bioactivated by intracellular carboxylesterases to the potent topoisomerase inhibitor SN-38 (Figure 5–6). Similar to FMOs, carboxylesterases are not involved in significant drug interactions.

Phase 2 Reactions: Conjugating Enzymes

There are a large number of phase 2 conjugating enzymes, all of which are considered to be synthetic in nature because they result in the formation of metabolites with increased molecular mass. Phase 2 reactions also normally terminate the biological activity of the drug, although there are exceptions. For *morphine* and *minoxidil,* glucuronide and sulfate conjugates, respectively, are more pharmacologically active than the parent. The relative contributions of different phase 2 reactions to drug metabolism are shown in Figure 5–3B.

Two of the phase 2 reactions, glucuronidation and sulfation, result in the formation of metabolites with significantly increased water-to-lipid partition coefficients. Sulfation and glucuronidation generally terminate the biological activity of drugs, and the minor change in overall charge increases the aqueous solubility of the metabolite. The enhanced hydrophilicity facilitates metabolite transport into the aqueous compartments of the cell and the body. Characteristic of the phase 2 reactions is the dependency of the catalytic reactions on cofactors (or, more correctly, cosubstrate): UDP-GA for UGT and 3′-phosphoadenosine-5′-phosphosulfate (PAPS) for SULTs, which react with available functional groups on the substrates. The reactive functional groups are often generated by the phase 1 CYPs, although there are many drugs (e.g., *acetaminophen*) for which glucuronidation and sulfation occur directly without prior oxidative metabolism. All of the phase 2 reactions are carried out in the cytosol of the cell, with the exception of glucuronidation, which is localized to the luminal side of the endoplasmic reticulum.

The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs. Thus, if a drug is targeted for phase 1 oxidation through the CYPs, followed by a phase 2 conjugation reaction, usually the rate of elimination will depend on the initial (phase 1) oxidation reaction. Because the rate of conjugation is faster and the process leads to an increase in hydrophilicity of the drug, phase 2 reactions are generally considered to ensure efficient elimination and detoxification of most drugs.

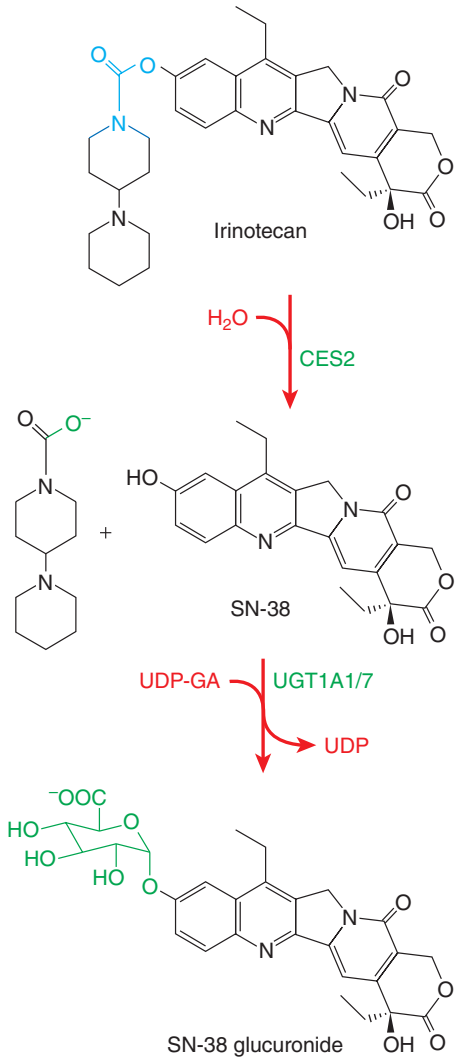

Figure 5–6 *Metabolism of irinotecan (CPT-11).* The prodrug CPT-11 is initially metabolized by a serum carboxylesterase 2 (CES2) to the topoisomerase inhibitor SN-38, which is the active camptothecin analogue that slows tumor growth. SN-38 is then subject to glucuronidation, which results in loss of biological activity and facilitates elimination of SN-38 in the bile.

Glucuronidation

Among the more important of the phase 2 reactions in drug metabolism are those carried out by uridine diphosphate–glucuronosyltransferases (UGTs) (Figure 5–3B). These enzymes catalyze the transfer of glucuronic acid from the cofactor UDP-GA to a substrate to form β-d-glucopyranosiduronic acids (glucuronides), metabolites that are sensitive to cleavage by β-glucuronidase. Glucuronides can be formed at alcoholic and phenolic hydroxyl groups; carboxyl, sulfuryl, and carbonyl moieties; and primary, secondary, and tertiary amine sites on molecules. UGT substrates include hundreds of chemically unique pharmaceuticals; dietary substances; environmental agents; humoral agents such as circulating hormones (androgens, estrogens, mineralocorticoids, glucocorticoids, thyroxine); bile acids; retinoids; and bilirubin, the end product of heme catabolism.

Examples of glucuronidation reactions are shown in Table 5–2 and Figures 5–1 and 5–6. The structural diversity of the drugs and other xenobiotics that are processed through glucuronidation ensures that many clinically efficacious therapeutic agents will be excreted as glucuronides.

The UGTs are expressed in a highly coordinated, tissue-specific, and often inducible fashion, with the highest concentration found in the GI

tract and liver. Per tissue weight, there are a greater number and higher concentration of the UGTs in the small intestine than in liver, so efficient first-pass metabolism plays a role in predicting bioavailability of many orally administered medications. Formation of glucuronides and their increased polarity can result in their passage into the circulation, from which they are excreted into the urine. Alternatively, as xenobiotics enter the liver and are absorbed into hepatocytes, glucuronide formation provides substrates for active transport into the bile canaliculi and ultimate excretion with components of the bile (see, for example, Figure 5–9). Many of the glucuronides that are excreted into the bile eventually become substrates for soluble microbial β-glucuronidase in the large intestine, resulting in the formation of free glucuronic acid and the initial substrate. The colon actively absorbs water and a variety of other compounds (see Figure 54–3); depending on its solubility, the glucuronide or the original substrate may be reabsorbed via passive diffusion or by apical transporters in the small intestine and colon to reenter systemic circulation. This process of *enterohepatic recirculation* is responsible for reuptake of bile acids and can extend the half-life of a xenobiotic that is conjugated in the liver because the compound's ultimate excretion is delayed (see Figure 5–8).

There are 19 human genes that encode the UGT proteins. Nine are encoded by the *UGT1A* locus on chromosome 2q37 (1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, and 1A10), while 10 genes are encoded by the *UGT2* family of genes on chromosome 4q13.2 (2A1, 2A2, 2A3, 2B2, 2B4, 2B7, 2B10, 2B11, 2B15, and 2B17). Of these proteins, the major UGTs involved in drug metabolism are UGT1A1, 1A3, 1A4, 1A6, 1A9, and 2B7 (for a list of common UGT drug substrates, see Rowland et al., 2013). Although both families of proteins are associated with metabolism of drugs and xenobiotics, the UGT2 family of proteins appears to have greater specificity for the glucuronidation of endogenous substances.

The *UGT1* locus on chromosome 2 (Figure 5–7) spans nearly 200 kb, with over 150 kb of a tandem array of cassette exonic regions that encode approximately 280 amino acids of the amino terminal portion of the UGT1A proteins. Four exons are located at the 3′ end of the locus; these encode the carboxyl 245 amino acids that combine with one of the consecutively numbered arrays of first exons to form the individual *UGT1A* gene products. Because exons 2 to 5 encode the same sequence for each UGT1A protein, the variability in substrate specificity for each of the UGT1A proteins results from the significant divergence in sequence encoded by the exon 1 regions. Reduced UGT activity resulting from allelic mutations in exons 2 to 5 affect all of the UGT1A proteins, whereas inactivating mutations in the exon 1 region lead to reduced glucuronidation by only the affected UGT1A protein. Over 100 allelic variants targeting the divergent exon 1 regions have been identified, many of which result in lowered UGT activity.

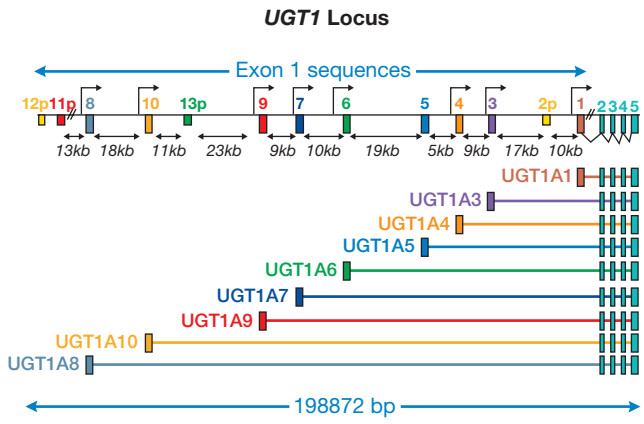

Figure 5–7 *Organization of the UGT1A locus.* Transcription of the *UGT1A* genes commences with the activation of PolII, which is controlled through tissue-specific events. Conserved exons 2 to 5 are spliced to each respective exon 1 sequence, resulting in the production of unique *UGT1A* sequences. The *UGT1A* locus encodes nine functional proteins.

From a clinical perspective, the expression of UGT1A1 assumes an important role in drug metabolism because the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step in ensuring efficient bilirubin clearance, and this rate can be affected by both genetic variation and competing substrates (drugs). Deficiency in CYP1A1 activity and bilirubin clearance results in Gilbert's syndrome, usually an autosomal recessive disorder, but sometime autosomal dominant, depending on the type of mutation (Strassburg, 2008). Bilirubin is the breakdown product of heme, 80% of which originates from circulating hemoglobin and 20% from other heme-containing proteins, such as the CYPs. Bilirubin is hydrophobic, associates with serum albumin, and must be metabolized further by glucuronidation to ensure its elimination. The failure to efficiently metabolize bilirubin by glucuronidation leads to elevated serum levels and a clinical symptom called hyperbilirubinemia or jaundice. Delayed expression of the *UGT1A1* gene in newborns is the primary reason for neonatal hyperbilirubinemia.

There are more than 40 genetic lesions in the *UGT1A1* gene that can lead to inheritable unconjugated hyperbilirubinemia. Crigler-Najjar syndrome type 1 (CN-1) is diagnosed as a complete lack of bilirubin glucuronidation and results from inactivating mutations in exon 1 or in the common exons of the *UGT1A1* gene. CN-2 is differentiated by the detection of low amounts of bilirubin glucuronides in duodenal secretions and is linked to promoter mutations or reading frame mutations in the *UGT1A1* gene that lead to greatly reduced glucuronide formation. The danger associated with CN-1 and CN-2 is the accumulation of toxic levels of unconjugated bilirubin, which can lead to CNS toxicity. Children diagnosed with CN-1 require immediate and extensive blue light therapy to break down circulating bilirubin; these patients eventually require liver transplantation. Agents that induce *UGT1A1* gene expression, such as phenobarbital, can improve the glucuronidation and elimination of bilirubin in patients with CN-2. The *UGT1A1* gene is the only gene associated with xenobiotic metabolism that is essential for life because there is an absolute requirement for the daily elimination of serum bilirubin. Allelic variants associated with other xenobiotic-metabolizing genes (phase 1 and phase 2) can enhance disease and toxicity associated with drug use but show few or no phenotypic effects.

Gilbert syndrome is a generally benign condition that is present in 8% to 23% of the population, based on ethnic diversity. It is diagnosed clinically by circulating bilirubin levels that are 100% to 300% higher than normal. There is increasing epidemiological evidence to suggest that Gilbert syndrome may be protective against cardiovascular disease, potentially as a result of the antioxidant properties of bilirubin. The most common genetic polymorphism associated with Gilbert syndrome is a mutation in the *UGT1A1* gene promoter, identified as the *UGT1A1*28* allele, that leads to an $A(TA)_7TAA$ promoter sequence that differs from the more common $A(TA)_6TAA$ sequence. The elevated total serum bilirubin levels are associated with significantly reduced expression levels of hepatic UGT1A1.

Subjects diagnosed with Gilbert syndrome may be predisposed to ADRs (Table 5–3) resulting from a reduced capacity to metabolize drugs by UGT1A1. If a drug undergoes selective metabolism by UGT1A1, competition for drug metabolism with bilirubin glucuronidation will exist, resulting in pronounced hyperbilirubinemia as well as reduced clearance of the metabolized drug. *Tranilast* [*N*-(3′4′-demethoxycinnamoyl)-anthranilic acid] is an investigational drug used for the prevention of restenosis in patients who have undergone transluminal coronary revascularization (intracoronary stents). *Tranilast* therapy in patients with Gilbert syndrome can lead to hyperbilirubinemia, as well as potential hepatic complications resulting from elevated levels of *tranilast*.

Gilbert syndrome also alters patient responses to *irinotecan*. *Irinotecan*, a prodrug used in chemotherapy of solid tumors (see Chapter 70) is metabolized to its active form, SN-38, by tissue carboxylesterases (Figure 5–6). SN-38, a potent topoisomerase inhibitor, is inactivated by UGT1A1 and excreted in the bile (Figures 5–8 and 5–9). Once in the lumen of the intestine, the SN-38 glucuronide undergoes cleavage by bacterial β-glucuronidase and reenters the circulation through intestinal absorption. Elevated levels of SN-38 in the blood lead to hematological toxicities

TABLE 5–3 ■ DRUG TOXICITY AND GILBERT SYNDROME

PROBLEM	FEATURE
Gilbert syndrome	UGT1A1*28 (main variant in Caucasians)
Established toxicity reactions	Irinotecan, atazanavir
UGT1A1 substrates (potential risk?)	Gemfibrozil,[a] ezetimibe
	Simvastatin, atorvastatin, cerivastatin[a]
	Ethinylestradiol, buprenorphine, fulvestrant
	Ibuprofen, ketoprofen

[a]A severe drug reaction owing to the inhibition of glucuronidation (UGT1A1) and CYP2C8 and CYP2C9 when both drugs were combined led to the withdrawal of cerivastatin.

characterized by leukopenia and neutropenia, as well as damage to the intestinal epithelial cells, resulting in acute and life-threatening ileocolitis. Patients with Gilbert syndrome who are receiving *irinotecan* therapy are predisposed to the hematological and GI toxicities resulting from elevated serum levels of SN-38, the net result of insufficient UGT1A activity and the consequent accumulation of a toxic drug in the GI epithelium.

While most of the drugs that are metabolized by UGT1A1 compete for glucuronidation with bilirubin, patients with Gilbert syndrome who are HIV positive and on protease inhibitor therapy with *atazanavir* develop hyperbilirubinemia because *atazanavir* inhibits UGT1A1 function even though *atazanavir* is not a substrate for glucuronidation. Severe hyperbilirubinemia can develop in patients with Gilbert syndrome who contain enzyme-inactivating mutations in the *UGT1A3* and *UGT1A7* genes. Clearly, drug-induced side effects attributed to the inhibition of the UGT enzymes can be a significant concern and can be complicated in the presence of gene-inactivating mutations.

Sulfation

The sulfotransferases (SULTs), located in the cytosol, conjugate sulfate derived from PAPS to hydroxyl and, less frequently, amine groups of aromatic and aliphatic compounds. Like all of the xenobiotic-metabolizing enzymes, the SULTs metabolize a wide variety of endogenous and exogenous substrates. In humans, 13 SULT isoforms have been identified; based on sequence comparisons, they are classified into four families: the SULT1 family (SULT1A1, 1A2, 1A3/4, 1B1, 1C2, 1C3, 1C4, 1E1); the SULT2 family (SULT2A1, SULT2B1a, SULT2B1b); and the SULT4 (4A1) and SULT6 (6A1) families. There are major interspecies differences in the expressed complement of SULTs, which makes extrapolation of data on xenobiotic sulfation in animals to humans particularly unreliable.

SULTs play an important role in normal human homeostasis. For example, SULT2B1b is a predominant form expressed in skin, carrying out the catalysis of cholesterol. Cholesterol sulfate is an essential metabolite in regulating keratinocyte differentiation and skin development. SULT2A1 is highly expressed in the fetal adrenal gland, where it produces the large quantities of dehydroepiandrosterone sulfate that are required for placental estrogen biosynthesis during the second half of pregnancy. SULTs 1A3 and 1A4 (identical proteins produced from different genes) are highly selective for catecholamines, while estrogens (17β-estradiol in particular) are sulfated by SULT1E1. In humans, significant fractions of circulating catecholamines, estrogens, iodothyronines, and dehydroepiandrosterone (DHEA) exist in the sulfated form.

Some human SULTs display unique substrate specificities, whereas others are promiscuous. Members of the SULT1 family are the major isoforms involved in xenobiotic metabolism, with SULT1A1 quantitatively and qualitatively the most important in the liver (Riches et al., 2009).

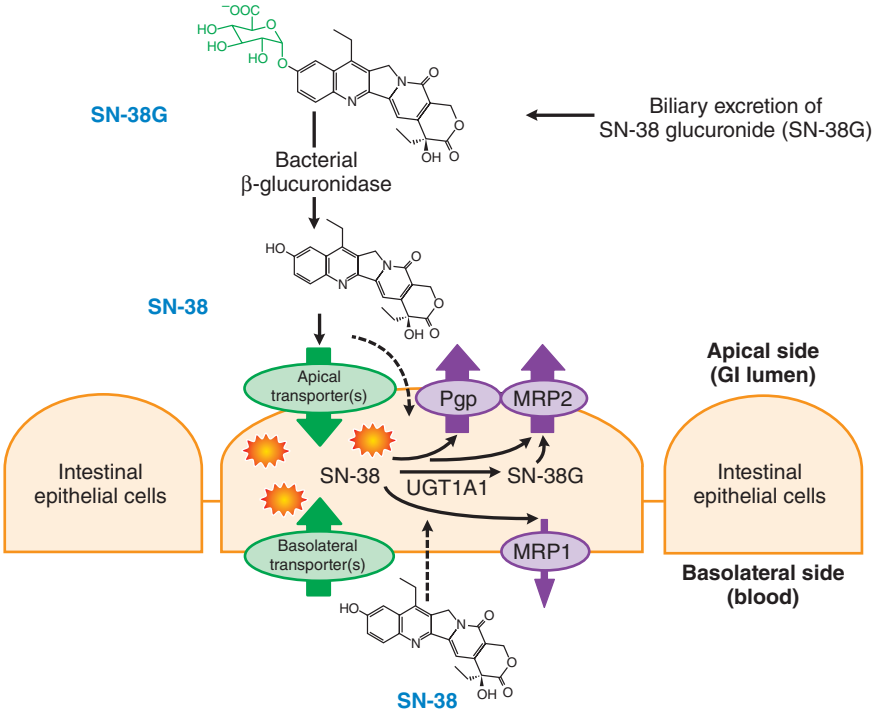

Figure 5–8 *Routes of SN-38 transport and exposure to intestinal epithelial cells.* SN-38 is transported into the bile following glucuronidation by liver UGT1A1 and extrahepatic UGT1A7. Following cleavage of luminal SN-38 glucuronide (SN-38G) by bacterial β-glucuronidase, reabsorption into epithelial cells can occur by passive diffusion (indicated by the dashed arrows entering the cell) as well as by apical transporters. Movement into epithelial cells may also occur from the blood by basolateral transporters. Intestinal SN-38 can be transported into the lumen by P-glycoprotein (Pgp) and multidrug resistance protein 2 (MRP2) and into the blood via multidrug resistance protein (MRP1). Excessive accumulation of the SN-38 in intestinal epithelial cells, resulting from reduced glucuronidation, can lead to cellular damage and toxicity. (Modified and reproduced with permission from Tukey RH et al. Pharmacogenomics of human UDP-glucuronosyltransferases and irinotecan toxicity. *Mol Pharmacol*, **2002**, *62*:446–450. SULT1A1 displays extensive diversity in its capacity to catalyze the sulfation of a broad variety of structurally heterogeneous xenobiotics with high affinity. Enzymes in the SULT1 family are recognized as phenol SULTs; they catalyze the sulfation of phenolic molecules such as *acetaminophen*, *minoxidil*, and *17α-ethinyl estradiol*. SULT1B1 is similar to SULT1A1 in its wide range of substrates, although it is much more abundant in the intestine than the liver. Three SULT1C enzymes exist in humans, but little is known of their substrate specificity. In rodents, SULT1C enzymes are capable of sulfating the hepatic carcinogen *N*-OH-2-acetylaminofluorene and are responsible for the bioactivation of this and related carcinogens. Their role in this pathway in humans is not clear. SULT1C enzymes are expressed abundantly in human fetal tissues; however, abundance declines significantly in adults. SULT1E catalyzes the sulfation of endogenous and exogenous steroids and is localized in liver and in hormone-responsive tissues such as the testis, breast, adrenal gland, and placenta. In the upper GI tract, SULT1A3/4 and SULT1B1 are particularly abundant, whereas SULT1A3/4 is absent from the adult liver.

The conjugation of drugs and xenobiotics is considered primarily a detoxification step, ensuring that the metabolites enter the aqueous compartments of the body and are targeted for elimination. However, drug metabolism through sulfation often leads to the generation of chemically reactive metabolites, wherein the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Most examples of the generation by sulfation of a carcinogenic or toxic response in animal or mutagenicity assays have been documented with chemicals derived from the environment or from heterocyclic arylamine food mutagens generated from well-cooked or burnt meat. Thus, it is important to understand whether genetic linkages can be made by associating known human SULT polymorphisms to cancers that are believed to originate from environmental sources. Because SULT1A1 is the most abundant SULT form in human tissues and displays broad substrate specificity, the polymorphic profiles associated with this gene and their associations with various human cancers are of considerable interest.

Copy number polymorphisms within the *SULT1A1*, *SULT1A3*, and *SULT1A4* genes have been identified, which may help explain much of the interindividual variation in the expression and activity of these enzymes. Knowledge of the structure, activities, regulation, and polymorphisms of the *SULT* superfamily will aid in understanding the linkages between sulfation and cancer susceptibility, reproduction, and development. Structural data, the results of kinetic studies, and molecular dynamics simulations are beginning to provide a picture of the mechanisms by which the SULTs express their unique patterns of substrate specificity (Tibbs et al., 2015).

Glutathione Conjugation

The glutathione-*S*-transferases (GSTs) catalyze the transfer of glutathione to reactive electrophiles, a function that serves to protect cellular macromolecules from interacting with electrophiles that contain electrophilic heteroatoms (–O, –N, and –S) and in turn protects the cellular environment from damage (Vaish et al., 2020). The cosubstrate in the reaction is glutathione, a tripeptide consisting of γ-glutamic acid, cysteine, and glycine (Figure 5–10). Glutathione exists in the cell in oxidized (GSSG) and reduced (GSH) forms, and the GSH:GSSG ratio is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state that has been linked to a number of human health issues.

In the formation of glutathione conjugates, the GST reaction generates a thioether linkage with a drug or xenobiotic to the cysteine moiety of the tripeptide. Characteristically, all GST substrates contain an electrophilic atom and are hydrophobic by nature; they will associate with cellular proteins. Because the concentration of glutathione in cells is usually high, typically 7 μmol/g of liver or in the 10 mM range, many drugs and xenobiotics can react nonenzymatically with glutathione. However, the GSTs occupy up to 10% of the total hepatocellular protein concentration,

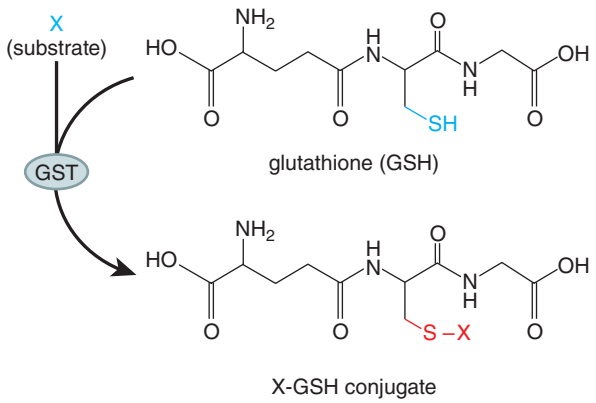

Figure 5–10 *Glutathione is a cosubstrate in the conjugation of a xenobiotic (X) by GST.*

a property that ensures efficient conjugation of glutathione to reactive electrophiles. The high concentration of GSTs also provides the cells with a sink of cytosolic protein, a property that facilitates noncovalent and sometimes covalent interactions with compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs, once identified as *ligandin*, binds steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

There are in excess of 20 human GSTs, divided into two subfamilies: the *cytosolic* and the *microsomal* forms. The major differences in function between the microsomal and cytosolic GSTs reside in the selection of substrates for conjugation: the cytosolic forms have more importance in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs are important in the endogenous metabolism of leukotrienes and prostaglandins. The cytosolic GSTs comprise seven classes termed alpha (GSTA1 and 2), mu (GSTM1 through 5), omega (GSTO1), pi (GSTP1), sigma (GSTS1), theta (GSTT1 and GSTT2), and zeta (GSTZ1). Those in the alpha and mu classes can form heterodimers, allowing for a large number of active transferases to form. The cytosolic forms of GST catalyze conjugation, reduction, and isomerization reactions.

The high concentration of GSH in the cell, as well as the overabundance of GSTs, means that few reactive molecules escape detoxification. Despite the appearance of overcapacity of enzyme and reducing equivalents, there is always concern that some reactive intermediates will escape detoxification and, by nature of their electrophilicity, will bind to cellular components and cause havoc. The potential for such an occurrence is heightened if GSH is depleted or if a specific form of GST is polymorphic and dysfunctional. While it is difficult to deplete cellular GSH levels, therapeutic agents that require large doses to be clinically efficacious have the greatest potential to lower cellular GSH levels.

Acetaminophen, normally metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1 and CYP3A4, which generate the toxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI), which, following normal dosing, is readily neutralized through conjugation with GSH. However, an overdose of *acetaminophen* can deplete cellular GSH levels and thereby increase the potential for NAPQI to interact with other cellular components, resulting in toxicity and cell death. *Acetaminophen* toxicity, with its increased levels of NAPQI and potential hepatic necrosis, may be treated in a time- and drug concentration–dependent manner by administration of *N*-acetylcysteine, which replenishes the depleted GSH, permitting detoxification of the excess NAPQI before it can cause more cellular damage (see Figure 9–4).

All of the GSTs are polymorphic. The mu *(GSTM1*0)* and theta (*GSTT1*0)* genotypes express a null phenotype; thus, individuals who are polymorphic at these loci are predisposed to toxicities by agents that are selective substrates for these GSTs. For example, the mutant *GSTM1*0* allele is observed in 50% of the Caucasian population and links genetically to human malignancies of the lung, colon, and bladder. Null activity in the *GSTT1* gene associates with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient clearance of the drugs via GSH conjugation. Expression of the null genotype can be as high as 60% in Chinese and Korean populations. Thus, GST polymorphisms may influence efficacies and severity of adverse side effects of drugs.

While the GSTs play an important role in cellular detoxification, their activities in cancerous tissues have been linked to the development of drug resistance toward chemotherapeutic agents that are both substrates and nonsubstrates for the GSTs. Many anticancer drugs are effective because they initiate cell death or apoptosis, which is linked to the activation of mitogen-activated protein kinases (MAPKs) such as JNK and p38. Overexpression of GSTs is associated with resistance to apoptosis and the inhibition of MAPK activity. In a variety of tumors, GSTs are overexpressed, leading to a reduction in MAPK activity and reduced efficacy of chemotherapy. Taking advantage of the relatively high levels of GST in tumor cells, inhibition of GST activity has been exploited as a therapeutic strategy to modulate drug resistance by sensitizing tumors to anticancer drugs. TLK199, a glutathione analogue, is a prodrug that plasma esterases

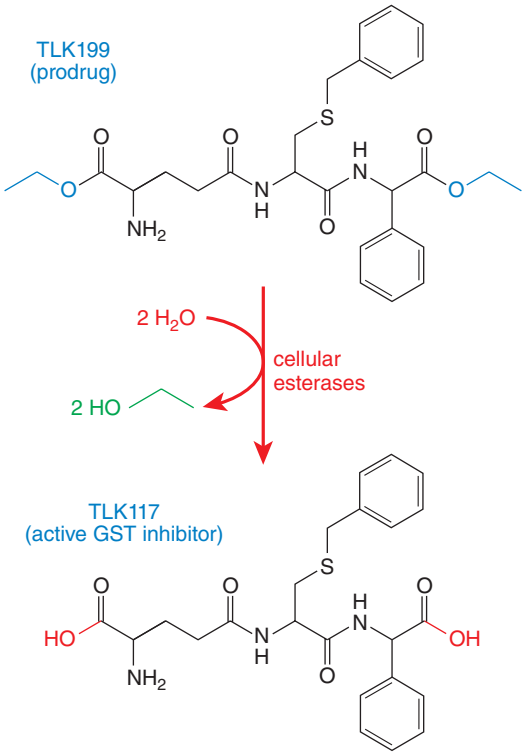

Figure 5–11 *Activation of TLK199 to TLK117, a GST inhibitor.*

convert to a GST inhibitor, TLK117, which potentiates the toxicity of different anticancer agents (Figure 5–11).

Alternatively, the elevated GST activity in cancer cells has been the basis for the development of prodrugs that can be activated by the GSTs to form electrophilic intermediates. For example, TLK286 is a substrate for GST that undergoes a β-elimination reaction, forming a glutathione conjugate and a nitrogen mustard (Figure 5–12) that is capable of alkylating cellular nucleophiles, resulting in cell killing and antitumor activity (Townsend and Tew, 2003).

N-Acetylation

The cytosolic NATs are responsible for the metabolism of drugs and environmental agents that contain an aromatic amine or hydrazine group (Mitchell, 2020). Addition of the acetyl group from the cofactor acetylcoenzyme A often leads to a metabolite that is *less* water soluble because the potential ionizable amine is neutralized by the covalent addition of the acetyl group. NATs are among the most polymorphic of all the human xenobiotic drug-metabolizing enzymes.

The characterization of an acetylator phenotype in humans was one of the first hereditary traits identified and was responsible for the development of the field of pharmacogenetics (see Chapter 7). Following the discovery that *isoniazid* (isonicotinic acid hydrazide, INH) could be used to treat tuberculosis, a significant proportion of the patients (5%–15%) experienced toxicities that ranged from numbness and tingling in their fingers to CNS damage. After finding that INH is metabolized by acetylation and excreted in the urine, researchers noted that individuals who experienced the toxic effects of the drug excreted the largest amount of unchanged drug and the least amount of acetylated INH. Pharmacogenetic studies led to the classification of "rapid" and "slow" acetylators, with the slow phenotype predisposed to toxicity (see Figure 65–4). The NAT alleles for slow and fast acetylators were characterized, revealing genetic changes that correspond to the slow acetylator phenotype.

There are two functional NAT genes in humans, *NAT1* and *NAT2*. Over 25 allelic variants of *NAT1* and *NAT2* have been characterized. In individuals in whom acetylation of drugs is compromised, homozygous genotypes for at least two variant alleles are required to predispose a patient to slower drug metabolism. Polymorphism in the *NAT2* gene

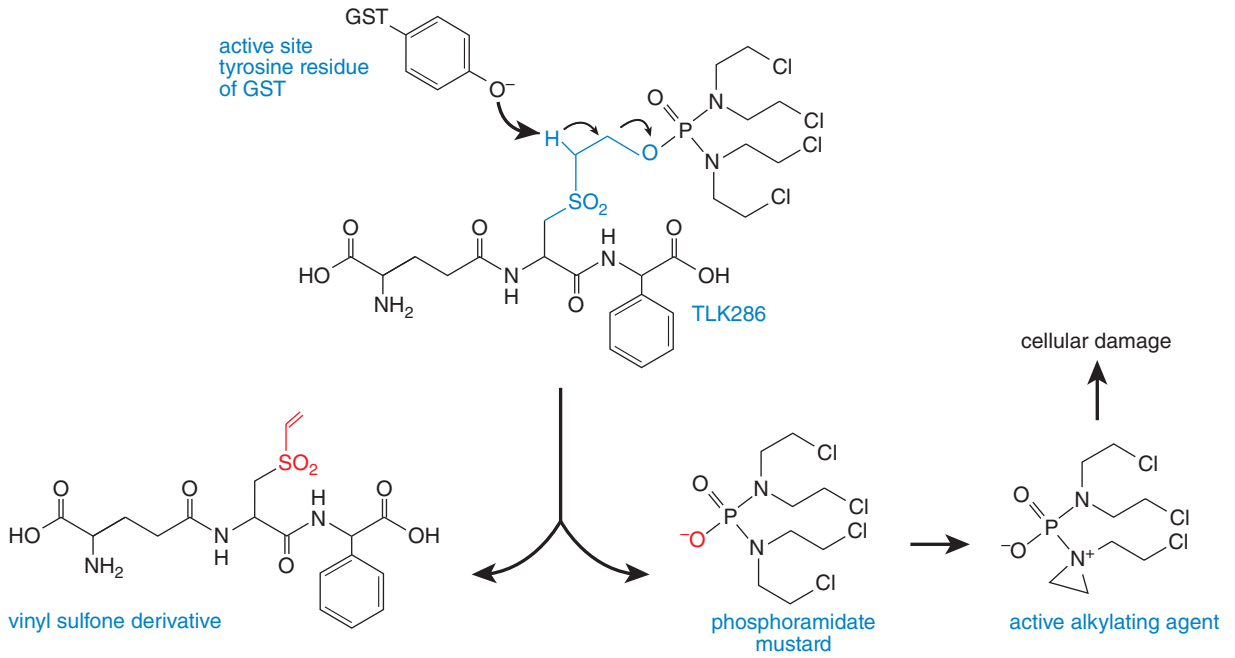

Figure 5–12 *Generation of the reactive alkylating agent following the conjugation of glutathione to TLK286.* GST interacts with the prodrug and GSH analogue TLK286 via a tyrosine in the active site of GST. The GSH portion is shown in blue. The interaction promotes β-elimination and cleavage of the prodrug to a vinyl sulfone and an active alkylating fragment.

and its association with the slow acetylation of INH were one of the first completely characterized genotypes shown to affect drug metabolism, thereby linking pharmacogenetic phenotype to a genetic polymorphism. Although nearly as many mutations have been identified in the *NAT1* gene as the *NAT2* gene, the frequency of the slow acetylation patterns is attributed mostly to the polymorphism in the *NAT2* gene.

Some common drug substrates of NAT and their known toxicities are listed in Table 5–4 (see Meisel, 2002, for details). The therapeutic relevance of NAT polymorphisms is in avoiding drug-induced toxicities. The adverse drug response in a slow acetylator resembles a drug overdose; thus, reducing the dose or increasing the dosing interval is recommended. Aromatic amine or hydrazine groups exist in many classes of clinically used drugs, and if a drug is known to be subjected to metabolism through acetylation, determining an individual's phenotype can be important in maximizing a positive therapeutic outcome. For example, *hydralazine*, a once-popular orally active antihypertensive (vasodilator) drug, is metabolized by NAT2. The administration of therapeutic doses of *hydralazine* to a slow acetylator can result in extreme hypotension and tachycardia.

Several known targets for acetylation, such as the sulfonamides, have been implicated in idiosyncratic hypersensitivity reactions; in such instances, an appreciation of a patient's acetylation phenotype is particularly important. Sulfonamides are transformed into hydroxylamines that interact with cellular proteins, generating haptens that can elicit autoimmune responses, to which slow acetylators are predisposed.

Tissue-specific expression patterns of NAT1 and NAT2 have a significant impact on the fate of drug metabolism and the potential for

TABLE 5–4 ■ THERAPEUTIC USES AND ADVERSE EFFECTS OF COMMON *N*-ACETYLTRANSFERASE SUBSTRATES

NAT SUBSTRATE	THERAPEUTIC USES	ADVERSE EFFECTS
Acebutolol	Adrenal cortex carcinoma, breast cancer	Drowsiness, weakness, insomnia
Aminoglutethimide	β Blockade, arrhythmias, hypertension	Clumsiness, nausea, dizziness, agranulocytosis
Aminosalicylic acid	Ulcerative colitis	Allergic fever, itching, leukopenia
Amrinone	Positive inotrope in heart failure	Thrombocytopenia, arrhythmias
Benzocaine	Local anesthesia	Dermatitis, itching, rash, methemoglobinemia
Caffeine	Neonatal respiratory distress syndrome	Dizziness, insomnia, tachycardia
Clonazepam	Seizures, anxiety	Drowsiness, ataxia, dizziness, slurred speech
Dapsone	Leprosy, dermatitis	Hemolysis, methemoglobinemia, nausea, dermatitis
Hydralazine	Hypertension (acts via vasodilation)	Hypotension, sympathetic baroreceptor reflex effects
Isoniazid	Tuberculosis	Peripheral neuritis, hepatotoxicity
Nitrazepam	Insomnia	Dizziness, somnolence
Phenelzine	Depression (acts via MAO inhibition)	Dizziness, CNS excitation, insomnia, orthostatic hypotension, hepatotoxicity
Procainamide	Ventricular tachyarrhythmia	Hypotension, bradycardia, lupus erythematosus
Sulfonamides	As bacteriostatic agents	Hypersensitivity, acute hemolytic anemia, reversible bone marrow suppression (with AIDS or myelosuppressive chemotherapy)

eliciting a toxic episode. NAT1 is ubiquitously expressed among most human tissues, whereas NAT2 is found predominantly in liver and the GI tract. Characteristic of both NAT1 and NAT2 is the capacity to form *N*-hydroxy–acetylated metabolites from bicyclic aromatic hydrocarbons, a reaction that leads to the nonenzymatic release of acetyl groups and the generation of highly reactive nitrenium ions. Thus, *N*-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct *N*-acetylation of bicyclic aromatic amines is stable and leads to detoxification. Individuals who are NAT2 fast acetylators are able to efficiently metabolize and detoxify bicyclic aromatic amines through liver-dependent acetylation. However, slow acetylators (NAT2 deficient) accumulate bicyclic aromatic amines that become substrates for CYP-dependent *N*-oxidation. These N-OH metabolites are eliminated in the urine. In tissues such as bladder epithelium, NAT1 is highly expressed and can efficiently catalyze the *N*-hydroxy acetylation of bicyclic aromatic amines, a process that leads to deacetylation and the formation of the mutagenic nitrenium ion, especially in NAT2-deficient subjects. Epidemiological studies have shown that slow acetylators are predisposed to bladder cancer if exposed environmentally to bicyclic aromatic amines.

Methylation

In humans, drugs and xenobiotics can undergo *O*-, *N*-, and *S*-methylation catalyzed by methyltransferases. Humans express two COMTs, three *N*-methyl transferases, a phenol-*O*-methyltransferase (POMT), a thiopurine methyltransferase (TPMT), and a thiol methyltransferase (TMT). All of the MTs exist as monomers and use SAM (*S*-adenosylmethionine, AdoMet) as the methyl donor. With the exception of a signature sequence that is conserved among the MTs, there is limited similarity among these enzymes, indicating that each MT has evolved to display a unique catalytic function. Although the common theme among the MTs is the generation of a methylated product, substrate specificity is high and distinguishes the individual enzymes.

Among the *N*-methyl transferases, nicotinamide *N*-methyltransferase (NNMT) methylates serotonin and tryptophan as well as pyridine-containing compounds such as nicotinamide and nicotine. Phenylethanolamine *N*-methyltransferase (PNMT) is responsible for methylation of the neurotransmitter norepinephrine to form epinephrine; histamine *N*-methyltransferase (HNMT) metabolizes drugs containing an imidazole ring. Catechol-*O*-methyltransferase (COMT), which exists as two isoforms generated by alternate exon usage, methylates neurotransmitters containing a catechol moiety, such as dopamine and norepinephrine, and drugs such as *methyldopa* and *ecstasy* (3,4-methylenedioxymethamphetamine, MDMA).

From a clinical perspective, the most important MT may be TPMT, which catalyzes the *S*-methylation of aromatic and heterocyclic sulfhydryl compounds, including the thiopurine drugs *azathioprine (AZA)*, *6-mercaptopurine (6-MP)*, and *thioguanine*. AZA and 6-MP are used for the management of inflammatory bowel disease (see Chapter 55), as well as autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. *Thioguanine* is used in the treatment of acute myeloid leukemia, and 6-MP is used worldwide for the treatment of childhood acute lymphoblastic leukemia (see Chapter 70). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking the drug (see metabolic scheme in Figure 55–5). When given orally at clinically established doses, 6-MP serves as a prodrug that is metabolized by hypoxanthine guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides (6-TGNs), which become incorporated into DNA and RNA, resulting in arrest of DNA replication and cytotoxicity.

Toxic side effects arise when a lack of 6-MP methylation by TPMT causes a buildup of 6-MP and the consequent generation of toxic levels of 6-TGNs. The identification of the inactive TPMT alleles and the development of a genotyping test to identify homozygous carriers of the defective allele permit identification of individuals who may be predisposed to the toxic side effects of 6-MP therapy. Simple adjustments in the dosage regimen are a lifesaving intervention for patients with TPMT deficiencies.

Role of Xenobiotic Metabolism in Safe and Effective Use of Drugs

Any xenobiotics entering the body must be eliminated through metabolism and excretion via the urine or bile/feces. Mechanisms of metabolism and excretion prevent foreign compounds from accumulating in the body and possibly causing toxicity. In the case of drugs, metabolism normally results in inactivation of their therapeutic effectiveness and facilitates their elimination. The rate and extent of metabolism can determine the efficacy and toxicity of a drug by controlling its biological half-life. Among the most serious considerations in the clinical use of drugs are ADRs. If a drug is metabolized too quickly, it rapidly loses its therapeutic efficacy. This can occur if specific enzymes involved in metabolism are overly active or are induced by dietary or environmental factors. If a drug is metabolized too slowly, the drug can accumulate in the bloodstream; as a consequence, the plasma clearance of the drug is decreased, the area under the plasma concentration–time curve (AUC; see Figure 2–9) is elevated, and exposure to the drug may exceed clinically appropriate levels. An increase in AUC often results when specific xenobiotic-metabolizing enzymes are inhibited. Such an event may occur when an individual is taking a combination of therapeutic agents and two or more of the agents target a specific enzyme involved in drug metabolism; similarly, a drug and a dietary product may interact. For example, the consumption of grapefruit juice can inhibit intestinal CYP3A4, blocking the metabolism of numerous drugs. Among the components of grapefruit juice that inhibit CYP3A4 are *naringin* and *furanocoumarins*. The inhibition of specific CYPs in the gut by dietary consumption of grapefruit juice alters the oral bioavailability of many classes of drugs, including certain antihypertensives, immunosuppressants, antidepressants, antihistamines, and the statins, among others.

While environmental factors can alter the steady-state levels of specific enzymes or inhibit their catalytic potential, these phenotypic changes in drug metabolism are also observed clinically in groups of individuals who are genetically predisposed to ADRs because of pharmacogenetic differences in the expression of xenobiotic-metabolizing enzymes (see Chapter 7). Most of the xenobiotic-metabolizing enzymes display polymorphic differences in their expression, resulting from heritable changes in the structure of the genes. For example, hyperbilirubinemia can result from a reduction in the ability to glucuronidate circulating bilirubin due to a lowered expression of the *UGT1A1* gene (Gilbert syndrome). Drugs that are subject to glucuronidation by UGT1A1, such as the topoisomerase inhibitor SN-38 (Figures 5–6, 5–8, and 5–9), will display an increased AUC in individuals with Gilbert syndrome because such patients cannot detoxify these drugs. Most cancer chemotherapeutic agents have a narrow therapeutic index; thus, increases in the circulating levels of the active form, due to a deficiency in drug clearance, can result in significant toxicities.

Nearly every class of therapeutic agent has been reported to initiate an ADR. In the United States, ADRs annually cost an estimated at $100 billion and cause over 100,000 deaths. An estimated 56% of drugs associated with ADRs are substrates for xenobiotic-metabolizing enzymes. Because many of the CYPs and UGTs are subject to induction as well as inhibition by drugs, dietary factors, and other environmental agents, these enzymes play an important role in most ADRs. Thus, prior to filing a New Drug Application (NDA), a new drug's route of metabolism must be known. It is now routine practice in the pharmaceutical industry to establish which enzymes are involved in metabolism of a drug candidate and to identify the metabolites and determine their potential toxicity. In consideration of the major role of CYPs in the generation of ADRs, there is likely to be a move to avoid the major oxidative routes of metabolism when developing new small-molecule drugs.

Induction of Drug Metabolism

Xenobiotics can influence drug metabolism by activating transcription and inducing the expression of genes encoding drug-metabolizing enzymes. Thus, a foreign compound may induce its own metabolism, as may certain drugs. One potential consequence of this is a decrease in

TABLE 5–5 ■ NUCLEAR RECEPTORS THAT INDUCE DRUG METABOLISM

RECEPTOR	LIGANDS
Aryl hydrocarbon receptor (AHR)	Omeprazole
Constitutive androstane receptor (CAR)	Phenobarbital
Pregnane X receptor (PXR)	Rifampin
Farnesoid X receptor (FXR)	Bile acids
Vitamin D receptor (VDR)	Vitamin D
Peroxisome proliferator–activated receptor (PPARs)	Fibrates
Retinoic acid receptor (RAR)	All-*trans*-retinoic acid
Retinoid X receptor (RXR)	9-*cis*-Retinoic acid

plasma drug concentration over the course of treatment, resulting in loss of efficacy as the autoinduced metabolism of the drug exceeds the rate at which new drug enters the body. A list of ligands and the receptors through which they induce drug metabolism is shown in Table 5–5. A particular receptor, when activated by a ligand, can induce the transcription of a series of target genes. Among these target genes are certain CYPs and drug transporters; induction of CYPs and transport proteins could lead to drug interactions. Figure 5–13 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism.

The Aryl Hydrocarbon Receptor

The aryl hydrocarbon receptor (AHR) is a member of a superfamily of transcription factors with diverse roles in mammals, such as serving a regulatory role in the development of the mammalian CNS and modulating the response to chemical and oxidative stress. This superfamily of transcription factors includes Per (Period) and Sim (Simpleminded), two transcription factors involved in development of the CNS, and hypoxia-inducible factor 1α (HIF1α), HIF2α, and their dimerization partner HIF1β. Under hypoxic conditions, a cytosolic HIFα subunit translocates to the nucleus and forms a dimer with HIF1β; the dimer binds to the hypoxia response element to activate gene transcription.

The AHR induces expression of genes encoding CYP1A1, CYP1A2, and CYP1B1, which are able to metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Thus, induction of these CYPs by a drug could potentially result in an increase in the toxicity and carcinogenicity of procarcinogens. For example, *omeprazole*, a proton pump inhibitor used to treat gastric and duodenal ulcers (see Chapter 53), is a ligand for the AHR and can induce CYP1A1 and CYP1A2, with the possible consequences of toxin/carcinogen activation as well as drug-drug interactions in patients receiving agents that are substrates for either of these CYPs.

Type 2 Nuclear Receptors

Another important induction mechanism is due to type 2 nuclear receptors that are in the same superfamily as the steroid hormone receptors. Many of these receptors, identified on the basis of their structural similarity to steroid hormone receptors, were originally termed *orphan receptors* because no endogenous ligands were known to interact with them. We now know that some of these receptors are activated by xenobiotics, including drugs. The type 2 nuclear receptors of most importance to drug metabolism and drug therapy include the pregnane X receptor (PXR), the constitutive androstane receptor (CAR), and peroxisome proliferator–activated receptors (PPARs).

PXR, discovered because it is activated by the synthetic steroid pregnenolone-16α-carbonitrile, is also activated by a number of other drugs, including antibiotics (*rifampicin* and *troleandomycin*), Ca^{2+} channel blockers (*nifedipine*), statins (*mevastatin*), antidiabetic drugs (*troglitazone*), HIV protease inhibitors (*ritonavir*), and anticancer drugs (*paclitaxel*) (Nicolussi et al., 2020).

Hepatotoxicity during antiretroviral therapy provides a good example of the role of CYP regulation in drug toxicity. Patients treated with the antibiotic *rifampicin* (for tuberculosis) or *efavirenz* (for HIV), followed by *ritonavir*-containing cocktails for HIV, develop liver toxicity with high frequency. The mechanism of toxicity appears to involve PXR activation

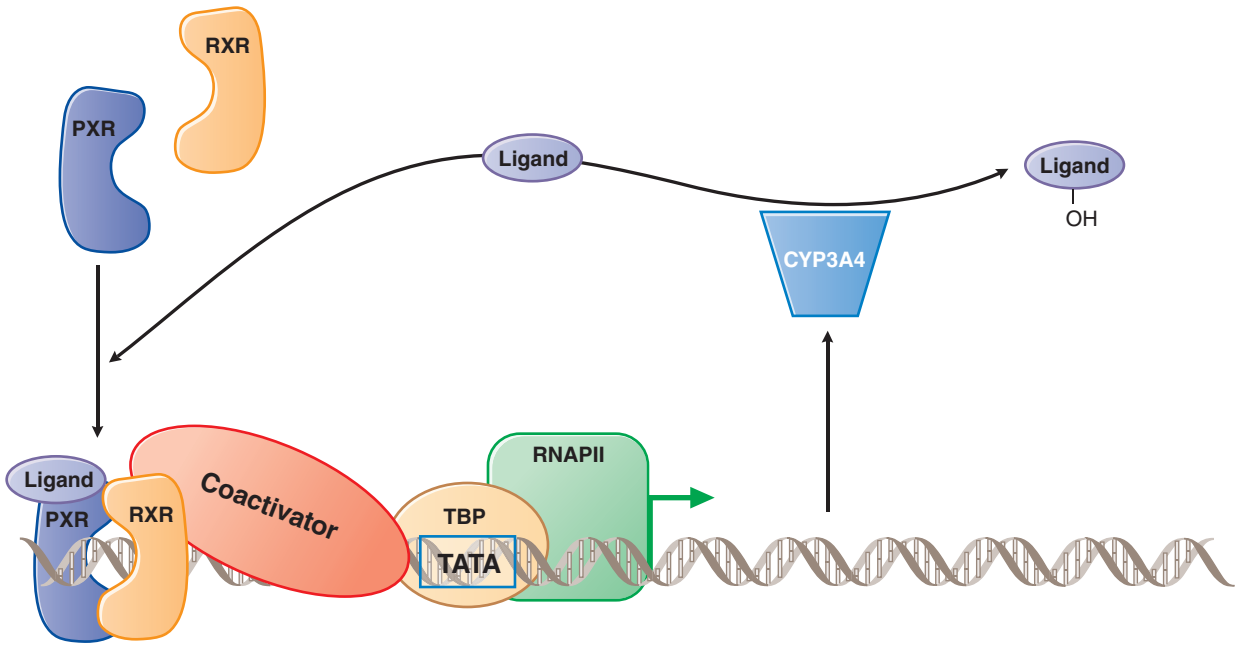

Figure 5–13 *Induction of drug metabolism by nuclear receptor–mediated signal transduction.* When a drug such as *atorvastatin* (Ligand) enters the cell, it can bind to a nuclear receptor such as the PXR. The PXR then forms a complex with the RXR (retinoid X receptor), binds to DNA upstream of target genes, recruits coactivator (which binds to the TATA box–binding protein, TBP), and activates transcription. Among PXR target genes is *CYP3A4,* which can metabolize *atorvastatin* nd dec rea e its cellular concent ati n. Thus, torvastatin induces i s own metabolism. *Atorvastatin* ur dergoes both ortho- and parahydroxylation.

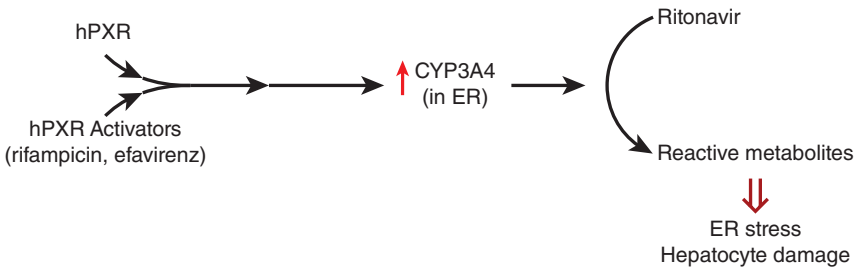

Figure 5–14 *Potentiation of ritonavir hepatotoxicity by activators of hPXR.* *Ritonavir*, a potent inhibitor and substrate of CYP3A4, is used in HIV-AIDS therapy as a pharmacokinetic enhancer of HIV protease inhibitors that are also substrates of CYP3A4 (see Table 64–4). *Ritonavir* is metabolized to reactive metabolites that can damage hepatic cells, and the hepatotoxicity of *ritonavir* is markedly increased in patients treated with *rifampicin* (for tuberculosis) or *efavirenz* (a nonnucleoside reverse transcriptase inhibitor used to treat HIV). The drug-induced potentiation of *ritonavir* toxicity may be explained by the activation of hepatic hPXR by either *rifampicin* or *efavirenz* that leads to induction of high levels of CYP3A4, which catalyzes increased production of toxic reactive metabolites of *ritonavir* that stress the ER and cause hepatocyte damage (Shehu et al., 2019). AIDS, acquired immunodeficiency syndrome; hPXR, human pregnane X receptor.

(Figure 5–14): Metabolism of *ritonavir* by CYP3A4 produces reactive metabolites that cause stress to the ER and cellular toxicity; *rifampicin* and *efavirenz* activate PXR and induce high levels of CYP3A4; metabolism of *ritonavir* by CYP3A4 is thereby increased, resulting in elevated levels of hepatotoxic metabolites (Shehu et al., 2019). This drug interaction could be decreased by developing strategies to decrease PXR activation, lower CYP3A4 metabolism, or mitigate downstream pathways to improve the safe use of *ritonavir* in the clinic.

Hyperforin, a component of St. John's wort, an over-the-counter herbal remedy used for depression, also activates PXR. This activation is thought to be the basis for the increase in failure of oral contraceptives in individuals taking St. John's wort: Activated PXR is an inducer of CYP3A4, which can metabolize steroids found in oral contraceptives and thereby lower the concentration of steroids below the range of effective contraception. PXR also induces the expression of genes encoding certain drug transporters and phase 2 enzymes, including SULTs and UGTs. Thus, PXR can facilitate the metabolism and elimination of numerous xenobiotics, sometimes with notable consequences.

The nuclear receptor CAR was discovered based on its ability to activate genes in the absence of ligand. Steroids such as *androstanol*, the antifungal agent *clotrimazole*, and the antiemetic *meclizine* are inverse agonists that inhibit gene activation by CAR; the steroid 5-β-pregnane-3,20-dione (and probably other endogenous compounds) and the pesticide 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding several CYPs (2B6, 2C9, and 3A4); various phase 2 enzymes (including GSTs, UGTs, and SULTs); and drug and endobiotic transporters. CYP3A4 is induced by both PXR and CAR; thus, its level is highly influenced by a number of drugs and other xenobiotics. In addition to inducing the degradation of drugs, CAR and PXR appear to function in the control of multiple aspects of hepatic physiology, including bilirubin degradation, energy metabolism, and cell proliferation (Cai et al., 2021).

Clearly, PXR and CAR can be activated or inhibited by a great variety of ligands. As with the xenobiotic-metabolizing enzymes, species differences also exist in the ligand specificities of these receptors. For example, low clinically relevant concentrations of *rifampicin* activate human PXR, while only very high concentrations of the drug activate mouse or rat PXR; pregnenolone-16α-carbonitrile preferentially activates the mouse and rat PXR but not human PXR. Paradoxically, *meclizine* activates mouse CAR but inhibits gene induction by human CAR. These findings further underscore that rodent model systems do not always reflect the response of humans to drugs.

The PPAR family is composed of three members: α, β/δ, and γ. PPARα is the target for the fibrate class of hyperlipidemic drugs, including the widely prescribed *gemfibrozil* and *fenofibrate*. Activation of PPARα results in induction of target genes encoding fatty acid–metabolizing enzymes, resulting in lowering of serum triglycerides. In addition, activation of PPARα induces CYP4 enzymes that carry out the oxidation of fatty acids and drugs with fatty acid–containing side chains, such as *leukotriene* and arachidonate analogues. PPARγ is the target for the thiazolidinedione class of anti–type 2 diabetic drugs, including *rosiglitazone* and *pioglitazone*. PPARγ and PPARβ/δ do not induce enzymes involved in xenobiotic metabolism.

The UGT genes, in particular *UGT1A1*, are targets for AHR, PXR, CAR, PPARα, and NRF2 (nuclear factor 2–erythroid-derived 2-like factor, a major transcriptional regulator of cytoprotective genes induced by an antioxidant response). Because the UGTs are abundant in the GI tract and liver, regulation of the UGTs by drug-induced activation of these nuclear receptors would be expected to play a role concerning the pharmacokinetic parameters of many orally administered therapeutic agents.

Role of Drug Metabolism in Drug Development

There are two key elements associated with successful drug development: *efficacy* and *safety*. Both depend on drug metabolism. It is necessary to determine which enzymes metabolize a new drug candidate to predict whether the compound may cause drug-drug interactions or be susceptible to marked interindividual variation in metabolism due to genetic polymorphisms.

For determination of metabolism, the compound under development that shows efficacy in preclinical models is subjected to analysis by human hepatocytes, human liver, or liver extracts that contain all the drug-metabolizing enzymes. Such studies can predict how humans will metabolize a particular drug and, to a limited extent, predict the rate of metabolism. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions. Prior to entering clinical trials, the structure of a drug candidate can be modified to change the sites on the molecule that are metabolized, particularly by CYPs, in order to mitigate potential rapid degradation and toxicities.

Interactions become a problem when multiple drugs are simultaneously administered, for example, in elderly patients, who on a daily basis may take prescribed anti-inflammatory drugs, cholesterol-lowering drugs, blood pressure medications, a gastric acid suppressant, an anticoagulant, and a number of over-the-counter medications. An ideal drug candidate would be metabolized by several CYPs so that variability in expression levels of one CYP or drug-drug interactions would not significantly affect its metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters to predict the metabolic fate of a drug. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based systems or cell lines expressing nuclear receptors are used to determine whether a particular drug candidate is a ligand or activator of PXR, CAR, or PPARα. For example, a drug that activates PXR may result in rapid clearance of other drugs that are CYP3A4 substrates, thus decreasing their bioavailability and efficacy.

Computer-based computational (*in silico*) prediction of drug metabolism is a prospect for the near future. The structures of several CYPs have been determined, including those of CYPs 2A6, 2C9, and 3A4. These structures may be used to predict metabolism of a drug candidate by fitting the compound to the enzyme's active site and determining oxidation potentials of sites on the molecule. However, the structures, determined by X-ray analysis of crystals of enzyme-substrate complexes, are static, whereas enzymes are flexible; this vital distinction may be limiting. The large size of the CYP active sites, which permits them to metabolize many different compounds, also renders them difficult to model. The potential for modeling ligand or activator interactions with nuclear receptors also exists with limitations similar to those discussed for the CYPs.

Determining the potential of a drug candidate to produce acute toxicity in preclinical studies is vital and routine in drug development. This is typically done by administering escalating doses of the drug candidate to rodents, usually above the predicted human therapeutic dose. For drug candidates proposed for chronic use in humans, such as for lowering serum triglycerides and cholesterol or for treatment of type 2 diabetes, long-term carcinogenicity studies are carried out in rodent models. Signs of toxicity are monitored and organ damage assessed by postmortem pathologies. This process is not high throughput and can be a bottleneck in development of lead compounds.

A new technology of high-throughput screening for biomarkers of toxicity is being adopted for drug development using *metabolomics* (Jacob et al., 2019). Metabolomics is the systematic identification and quantification of all metabolites in a given organism or biological sample. Analytical platforms such as ^{1}H nuclear magnetic resonance and liquid chromatography or gas chromatography coupled to mass spectrometry, in conjunction with chemometric and multivariate data analysis, allow the simultaneous determination and comparison of thousands of chemicals in biological fluids such as serum and urine, as well as the chemical constituents of cells and tissues. This technology can screen for drug toxicity in whole-animal systems during preclinical drug development and can obviate the need for time-consuming and expensive necropsies and pathologies on thousands of animals.

Using metabolomics, animals, treated and not treated with a drug candidate, can be analyzed for the presence of one or more metabolites in urine that correlate with drug efficacy or toxicity. Urine metabolites that are fingerprints for liver, kidney, and CNS toxicity have been identified using known chemical toxicants. Metabolic fingerprints of specific compounds that are elevated in urine can be used to determine whether a particular drug causes toxicity and can also be employed in early clinical trials to monitor for potential toxicities. Metabolomics can be used to find biomarkers for drug efficacy and toxicity that can be of value in clinical trials to identify responders and nonresponders. Drug metabolism can be studied in whole-animal model systems and in humans to determine the metabolites of a drug or indicate the presence of a polymorphism in drug metabolism that might signal an adverse clinical outcome. Finally, biomarkers developed from experimental metabolomics could eventually be developed for routine monitoring for signs of toxicity in patients receiving pharmacotherapy.

Animal Models for Preclinical Drug Development

By use of the *in silico*, *in vitro*, and cell culture tools described above, drug companies can determine the human CYPs and other enzymes that carry out metabolism of a drug candidate, thereby facilitating prediction of drug interactions that might occur in the clinic. These techniques can also establish whether a compound has the potential to be metabolically activated to a cytotoxic or carcinogenic derivative. A more accurate assessment on how a drug will behave in humans can be obtained with small animal models that have the advantage of a higher throughput analysis of many derivatives of a potential drug. However, mouse and rat CYPs markedly differ from CYPs found in humans. To this end, humanized mice that express human CYPs and the receptors that regulate CYPs, such as PXR as described above, have been developed (Gonzalez et al., 2015). UGTs that exhibit species differences have also been humanized (Fujiwara et al., 2018). In most cases, the endogenous mouse genes have been replaced by the corresponding human genes. Since drug transporters, FMOs, EHs, and phase 2 enzymes do not display large species differences in regulation and catalytic activities, the CYP-PXR humanized mice can be widely employed to estimate drug stability and bioavailability prior to launching phase I clinical trials. These humanized mice can also be used for long-term toxicity and carcinogenicity studies. Another model that has been developed is the human liver replacement strategy in which human liver is used to replace mouse liver (Naratomi et al., 2019). However, this model requires immunocompromised mice and has the issue that each human liver used to replace the mouse liver may express different levels of individual CYPs due to the genetic (polymorphisms) and dietary (inducers in food from the donor) factors.

Chapter 6

The Gastrointestinal Microbiome and Drug Response

Shirley M. Tsunoda, Pieter C. Dorrestein, and Rob Knight

The Human Microbiome

What Is It?

The microbiome is the genetic repertoire of the ecosystem of microbes (bacteria, viruses including phages, and sometimes archaea, fungi, and microbial eukaryotes) that coexist at a given site within each human. The human microbiota consists of the collection of microbes that exist in a specific area within the body, such as the oral cavity, esophagus, skin, gut, vagina, and other sites. The composition, regulation, and dynamics of the microbiomes and microbiota inhabiting these body areas are individualized and compartmentalized. The organisms in the oral cavity and gut are more diverse than those in other body sites (Costello et al., 2009; Human Microbiome Project Consortium, 2012). Establishment of the microbiome begins at delivery, with the infant inheriting microbes from the mother and the environment. The mode of delivery affects the infants' microbial colonization, with babies born via cesarean section dominated by epidermal bacterial species with predisposition to asthma and allergies later in life (Bager et al., 2008; Dominguez-Bello et al., 2010). After the child is weaned, the microbiome is established with an individual signature that persists long term (Faith et al., 2013), possibly throughout life (Maynard et al., 2012). Genes from the microbiome far outnumber human genes, with estimates of over 200 million microbial genes compared to 20,000 human germline genes (Qin et al., 2010). Microbial cells (mainly gut bacteria), on the other hand, are in approximately 1:1 ratio with human cells (Sender et al., 2016). Although an individual's microbiome appears to be generally stable over that individual's lifetime, numerous environmental factors can alter the microbial composition, including geographic location, diet, lifestyle, and xenobiotics (Human Microbiome Project Consortium, 2012; Kaplan et al., 2019; Kurilshikov et al., 2021). Other influences include circadian rhythms, age, and season of the year.

More than 90% of the gut microbiota are members of two bacterial phyla, *Bacteroidetes* and *Firmicutes* (Turnbaugh et al., 2007). Previously, it was thought that human gut microbiomes could be categorized into discrete "enterotypes" with enrichment of *Bacteroides*, *Prevotella*, or *Ruminococcus* forming the basis for three different enterotypes. However, it is now thought that the variability of the gut microbiome across the human population likely forms a continuum as opposed to discrete groups (Jeffery et al., 2012). The person-to-person variability in the gut microbiome is expansive, with individual microbiomes differing by greater than 90% (Parfrey and Knight, 2012).

Disease and the Microbiome

Although the mechanisms await definition, the gut microbiome is implicated in numerous poor health outcomes and diseases including autoimmune conditions, autism, cardiovascular diseases, cancer, and liver diseases such as nonalcoholic fatty liver disease (Gilbert et al., 2016). The National Cancer Institute estimates that 16% of all cancers in the U.S. are demonstrably due to components of the microbiome (e.g., *Helicobacter pylori*, human papillomavirus, hepatitis C). Not yet counted among the causes of that 16% are colibactin-producing *Escherichia coli*, which can cleave human DNA (Li et al., 2019) and also induce colorectal cancer. One challenge for the future will be to determine whether functional changes in the gut microbiome can serve as biomarkers or targets for therapeutic intervention or whether the microbiome itself can serve as therapeutic intervention in disease states.

Drugs and the Microbiome

The gut microbiome is a prominent contributor to variation in drug response. Gut bacteria directly metabolize xenobiotics, indirectly affect drug metabolism by influencing the activities of phase I and phase II enzymes and intestinal drug transporters, play a role in enterohepatic recycling of drugs, and are involved in pharmacodynamic responses to drugs (Lam et al., 2019; Tsunoda et al., 2021). In today's era of precision medicine, understanding how and to what extent the gut microbiome interacts with drugs and their actions will be key to individualizing therapy. With its distribution throughout the gastrointestinal (GI) tract, the gut microbiome interfaces with many of the chemicals encountered in daily life, including endogenous ligands, environmental sources, food, inhaled substances, and exogenous chemicals such as drugs. There is a bidirectional nature to this interaction between drugs and the microbiota. Drugs alter the microbiome; one needs only to consider the example of antibiotics that disrupt the quantity and variety of gut microbes.

Abbreviations

5-ASA: 5-aminosalicylic acid
cgr: cardiac glycoside reductases
CYP: cytochrome P450
FMT: fecal microbiota transplantation
FXR: farnesoid X receptor
GI: gastrointestinal
ICI: immune checkpoint inhibitor
LPS: lipopolysaccharide
OAT: organic anion transporter
OATP: organic anion-transporting polypeptide
PD-1: programmed cell death protein 1
Pgp: P-glycoprotein
PPI: proton pump inhibitor
PXR: pregnane X receptor
UGT: uridine diphosphate glucuronosyltransferase

However, many nonantibiotic compounds can impact gut microbiota, with 240 drugs showing inhibition of at least one bacterial strain *in vitro* (Maier et al., 2018); such a result may have implications for antibiotic resistance from drugs traditionally characterized as nonantibiotic agents. Conversely, it is known that the microbiome can directly modify drugs. Gastroenterologists depend on the actions of gut microbiota when administering the prodrug *sulfasalazine* to treat inflammatory bowel disease. Gut bacteria reduce the azo bond of *sulfasalazine*, releasing the metabolite sulfapyridine and the active drug 5-aminosalicylate (*mesalamine*) (see Figure 55–3). Recent animal and human studies show evidence for indirect metabolism by gut microbes via modification of the machinery of host drug metabolism (Selwyn et al., 2016; Toda et al., 2009b). Gut microbes also play a role in the gut-liver cross talk that affects enterohepatic recycling of drugs (see later section on enterohepatic recycling).

Therapeutic Interventions Using the Microbiome

Once we have a deeper understanding of what constitutes a "healthy" microbiome, how the microbes regulate and coordinate function, and factors that influence the variability within and between individuals, we will be better poised to rationally design therapeutic interventions to manipulate the microbiome for health. One such intervention, fecal microbiota transplantation (FMT), is already being used in the clinical setting to treat *Clostridioides difficile* (formerly, *Clostridium difficile*) colitis and involves a dramatic reshaping of the microbiome from an unhealthy state to a state resembling the healthy donor (Weingarden et al., 2015). Other prebiotics, probiotics, postbiotics, and living microbes are being studied for a variety of indications such as inflammatory bowel disease, autism (Kang et al., 2017), and phenylketonuria. New guidelines for studying and approving clinical use of these "living microbes" will need to be created and agreed upon by the scientific and clinical community.

Techniques for Studying the Microbiome

The ability to study the microbiome has improved greatly in the last few decades due to the advancement of technologies to interrogate and characterize microbes. One technological advancement that has been instrumental is the ability to sequence and inventory the microbiome. Early in the microbiome field, the focus was on taking inventories using 16S rRNA, allowing genus information. With lowered cost and improved throughput of sequencing, it is now becoming routine to get species information using metagenomic sequencing. The 16S rRNA gene is shared by all bacteria and archaea and has regions that can be used as primer sites for polymerase chain reaction. Microbes can be identified at the family, genus, and sometimes near-species level. The most notable technology to revolutionize the field is the higher-level resolution and functional-based DNA assay, shotgun metagenomics (Figure 6–1), which is rapidly becoming the standard method of studying the microbiome. Shotgun metagenomics relies on extracting total DNA from a sample, breaking it into small fragments, sequencing those fragments, and interpreting the fragments or "assembled" longer sequences in terms of the taxa represented (sometimes to the level of species or strain) and the gene functions contained in the assembly. Thus, in addition to higher taxonomic resolution, shotgun metagenomics helps describe and identify microbial genes and pathways. For expression-level information, metatranscriptomics, metaproteomics, and metabolomics provide information at the levels of RNA, protein, and metabolite, information that can be utilized in tandem with DNA-based assays. The availability of gnotobiotic mouse models (i.e., mice without a microbiome) has enabled more mechanistic studies to be performed such as introducing single microbial species or groups of microbes and testing their influences on various parameters of disease and pharmacotherapy, studies that provide greater information about causality.

Pharmacomicrobiomics

An orally administered drug encounters many obstacles *en route* to the systemic circulation. There are physicochemical barriers within the stomach and small intestine that can alter absorption, metabolizing enzymes such as intestinal and hepatic CYPs (cytochromes P450), and membrane

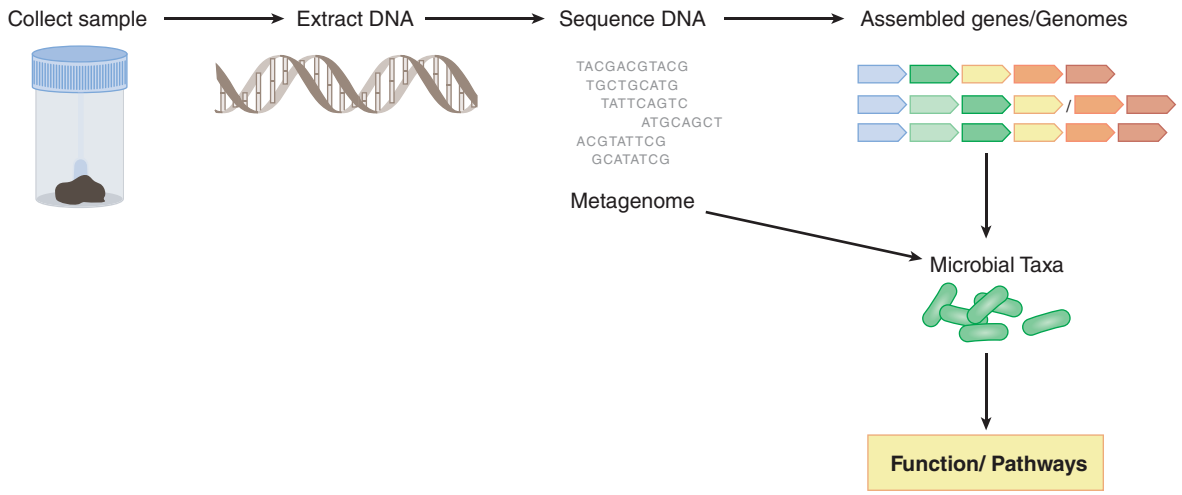

Figure 6–1 *Shotgun metagenomics.*

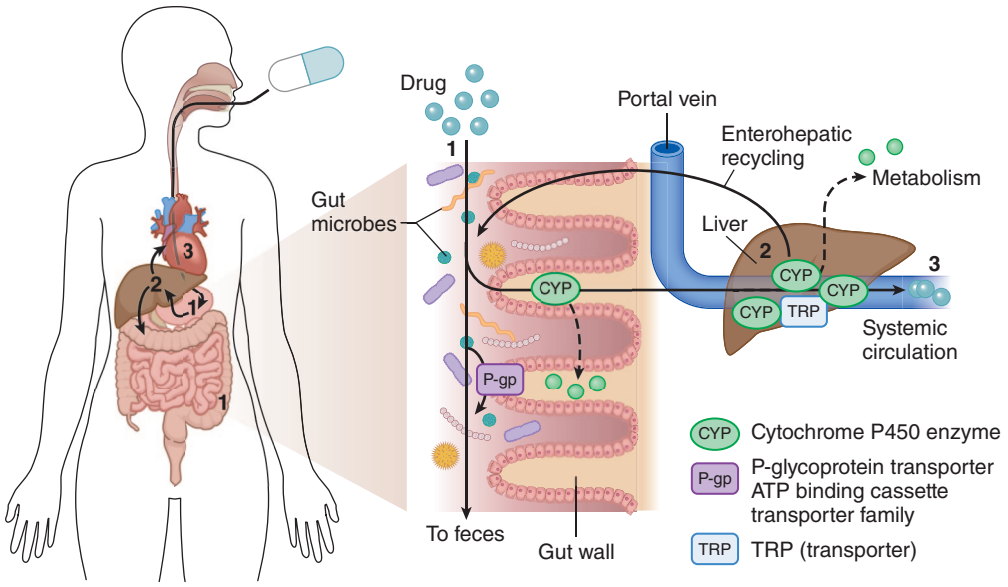

Figure 6–2 *Pathway of an orally administered drug.* When a drug is administered orally (1), it encounters gut microbes, CYPs, and transporters such as P-glycoprotein in the small and large intestine. Some drug will be lost in the feces in these processes. Drug that remains unmetabolized in the small intestine is absorbed and then travels through the portal vein to the liver where it encounters more transporters and CYPs, whereby more drug may be lost to metabolism (2). The amount of drug that enters the systemic circulation is often a fraction of what was originally ingested (3). Many absorbed drugs are subsequently metabolized in the liver and excreted into the GI tract via the bile as polar conjugates with UDP-glucuronic acid, glutathione, or sulfate and are not sufficiently lipophilic to be reabsorbed. The intestinal microbiome plays a role in deconjugation, hydrolyzing glucuronides and sulfates and rendering them more lipophilic; the more lipophilic moieties are reabsorbed and reenter the portal circulation, as though they had been administered orally, and begin the cycle again. Thus, enterohepatic cycling can prolong the elimination half-life of a xenobiotic.

transporters such as the intestinal multidrug-efflux transporter Pgp (P-glycoprotein; MDR1, ABCB1) that interact with drugs but can also be inhibited by competing solute such as other drugs and can be induced by drugs. The picture can get complex, especially when we realize that gut bacteria can modify drugs directly and also indirectly by modifying host metabolic processes (Figure 6–2). Such interactions are not confined to orally administered agents. Parenterally administered drugs and their metabolites may reach the intestine through biliary secretion and thus also interact with the gut microbiota.

The myriad processes acting on a drug—acidic environment of the stomach, metabolism in the gut and liver before distribution throughout the body, membrane barriers and selective permeabilities, extrusion from intestinal cells into the lumen of the GI tract, and effects of the microbiome that may alter a drug's solubility or chemical identity and efficacy as a drug—affect the fraction of an orally administered drug that actually enters the systemic circulation. This fraction (total drug administered/total drug actually entering the systemic circulation) is called the bioavailability of the drug, or F, a fraction that varies between 0 and 1, $0 < F < 1$ (see Chapter 2).

CYPs and drug-efflux transporters are key drivers of bioavailability. The variability in bioavailability within and between individuals is a major cause of therapeutic failure and toxicity. CYP enzymes metabolize 70% to 80% of all marketed drugs (see Figure 5–3). CYP3A is responsible for over 50% of CYP-mediated drug metabolism. In the intestine, CYP3A enzymes metabolize substrates prior to their entering the portal circulation, and Pgp pumps drugs out of the intestine, thus limiting bioavailability. Hepatic CYP3A can further metabolize substrates. Considering the extended time that orally administered drugs spend in the small and large intestines where the bulk of the gut microbiome resides, it is important to understand the impact of the gut microbiota on drug efficacy and toxicity.

The new field that studies interactions of the microbiome with xenobiotics is called pharmacomicrobiomics. Among the complexities of studying the contributions of the microbiome to drug effect and toxicity are an individual's disease state and genetic, environmental, and lifestyle characteristics. Interindividual variability in response to drug therapy is a major cause for therapeutic inefficacy and toxicity with resulting hospitalizations and morbidity/mortality. Much progress has been made in determining genetic variability in drug-metabolizing enzymes, drug transporters, and drug target genes, resulting in clinically actionable guidelines for select drugs (Relling and Klein, 2011). Gut microbes may impact drugs by influencing pharmacokinetics and pharmacodynamics. Bacteria may metabolize drugs before absorption, after absorption through the intestinal epithelia, and after biliary excretion from the liver, which may alter or lead to reabsorption of the drug through enterohepatic recycling. The gut microbiome may impact the activity of transporters (Walsh et al., 2020) and drug-metabolizing enzymes that affect a drug's pharmacokinetics. The microbiome can also bioaccumulate drugs, actually storing them without altering them (Klünemann et al., 2021), thereby reducing the drugs' bioavailability in the GI tract. Data are emerging on the gut microbiome's effect on pharmacodynamics and the complex intersection with the gut-brain axis as well as the gut–immune system axis. It will be important to incorporate the contribution of the gut microbiome to drug efficacy and toxicity along with other factors such as genetics, age, sex, circadian rhythms, inflammation, disease, and coadministered drugs.

Direct Drug Metabolism by Gut Microbes

Bacterial metabolism consists of distinct types of reactions that differ in significant ways from human host metabolism. Bacterial metabolism of drugs often results in increased hydrophobicity of the compounds, enhancing their lipid solubility and potentially increasing their toxicity, whereas host metabolism generally produces more hydrophilic compounds, decreasing their toxicity and facilitating excretion. Modifications performed by bacteria include reduction, hydrolysis, hydroxylation, dealkylation, and demethylation, among others. Bacteria also can add or remove functional groups through hydrolysis and deconjugation (Sousa et al., 2008) (Table 6–1). Reduction and hydrolysis appear to predominate because these two reactions reflect the energetic demands of the largely anaerobic gut microbes. Reduction reactions facilitate anaerobic respiration by providing a wider range of electron acceptors available, while

TABLE 6–1 ■ REPRESENTATIVE METABOLISM OF DRUGS MEDIATED BY THE MICROBIOME

MODIFICATION	TYPE	EXAMPLE DRUGS	INDICATION	MICROBES	EFFECT ON ACTIVITY
Reduction	Azoreduction	Sulfasalazine	Anti-inflammatory	Many; e.g., *Bacteroides fragilis, Streptococcus faecium, Streptococcus faecalis*	Activates
	Nitroreduction	Chloramphenicol	Antibiotic	*Escherichia coli, Haemophilus influenzae, Neisseria meningitides, Bacteroides fragilis*	Deactivates
	Reduction	Digoxin	Cardiovascular	*Eggerthella lenta*	Deactivates
	Reduction	Fluorouracil–once attached to ribose	Antineoplastic		Deactivates
	Sulfoxide reduction	Omeprazole	Gastric acid–related disorders	*Bacillus megaterium*	Deactivates
Acylation	Proprionylation	Tobramycin	Antibiotic	Cutured cystic fibrosis communities	Unknown
	Acetylation	Aminoglycosides (e.g., kanamycin A)	Antibiotic	*Mycobacterium tuberculosis*	Deactivates
	Hydroxylation	Simvastatin	Antihypolipidemic	Cultured gut community	Deactivates
Hydrolysis	Ester hydrolysis	Lovastatin	Antihypolipidemic		Activates
	Deglucuronidation	Irinotecan (SN-38-G)	Antineoplastic	*E. coli, Lactobacillus rhamnosus, Ruminococcus gnavus, Faecalibacterium prausnitzii*	Activates
	Desulfation	Sodium picosulfate	Laxative	*Eubacterium rectale*	Deactivates
	Dephosphorylation	5-Fluorouracil	Antineoplastic	Gut community	Activates
	Amide hydrolysis	Methotrexate	Antimetabolite	Firmicutes association	Activates
	Deacetylation	Diltiazem	Antihypertensive	*Bacteroides thetaiotaomicron*	Reduced activity
Demethylation	Demethylation	Altretamine	Antineoplastic	Pooled fecal microbial culture	Activates
Decarboxylation	Decarboxylation	Levodopa	Parkinson's disease	Cultured gut community	Deactivates

Tabulated data drawn from: Wilson and Nicholson, 2017; Guthrie et al., 2019; Letertre et al., 2020; Onuora, 2021; Aura et al., 2011; Swanson, 2015; Pellock and Redinbo, 2017; Biernat et al., 2019; Tsodikov et al., 2014; Jarmusch et al., 2020; Jang et al., 2017; Guo et al., 2020; Zimmermann et al., 2019; Clarke et al., 2019; Guthrie and Kelly, 2019; Koppel et al., 2017; Sun et al., 2019.

hydrolysis provides substrates for microbial growth. These bacterial metabolic modifications complement those performed by the host's CYPs that include *N*- and *S*-oxidation, *N*- and *O*-dealkylation, aromatic hydroxylation, deamination, and dehalogenation (Zanger and Schwab, 2013).

Although direct biotransformation of drugs by bacteria has been known for over a century, only recently have we appreciated its widespread nature, reflecting advances in tools to identify and characterize these bacterial transformations. Gut microbiota can directly metabolize drugs into active, inactive, or toxic metabolites. Microbial azoreductases are ubiquitous across several bacterial phyla found in the gut microbiome. The therapeutic effects of several prodrugs are activated by the reduction of the azo bond following oral administration. For example, the ulcerative colitis drug *sulfasalazine* is activated by gut microbial azoreductases to cleave into sulfapyridine and 5-aminosalicylic acid (5-ASA). 5-ASA is the active drug that inhibits inflammation within the colon of ulcerative colitis patients. 5-ASA can be inactivated by bacterial arylamine *N*-acetyltransferases. The activity of these enzymes can vary over a 10-fold range (Deloménie et al., 2001), leading to significant interindividual variability in the metabolism and possibly the efficacy of *sulfasalazine* among patients.

Unlike human drug biotransformation, for which phase I and II drug-metabolizing enzymes are well characterized, a comprehensive knowledge base of drug-metabolizing bacteria is lacking. The field is progressing, however. Using a combination of *in vitro* drug incubations and untargeted metabolomics, 76 gut bacterial species were shown to metabolize 176 nonantibiotic drugs spanning a diverse set of clinical indications (Zimmermann et al., 2019). Some patterns of direct bacterial drug metabolism have emerged. Bacterial isolates share phylum-specific metabolic activities and predictably metabolize drugs with specific functional groups. For example, drugs metabolized by *Bacteroidetes* contain ester or amide groups that can be hydrolyzed. Drugs with lactones, nitro, azo, and urea groups are more susceptible to microbial metabolism. In addition, results suggest that identification to the species level is insufficient to explain bacterial metabolism and that identification of gene markers directly associated with microbial enzymatic drug metabolism may be necessary (Zimmermann et al., 2019).

To date, there are few examples of direct gut microbiota drug metabolism that are clinically significant enough to change drug efficacy or toxicity, but a few drugs with narrow ranges demonstrate the issue nicely. The cardiac glycoside *digoxin*, which is used clinically for atrial fibrillation and heart failure, is a good example. Signs of *digoxin* toxicity can occur at around twice the level required for effective treatment. Staying within this narrow therapeutic window requires therapeutic drug monitoring and careful titration of dosage. In approximately 10% of patients, high levels of an inactive metabolite, dihydrodigoxin, are produced that

lead to a significant decrease in the systemic concentration of the active drug. The gut microbe *Eggerthella lenta* is responsible for the reduction of *digoxin*'s α,β-unsaturated lactone ring, leading to the formation of dihydrodigoxin. More precisely, only a specific strain of *E. lenta* (DMS2243) that induces the expression of a two-gene operon, cardiac glycoside reductases (cgr) 1 and 2, reduces the lactone ring of *digoxin* (Haiser et al., 2013). Interestingly, a diet high in arginine inhibits cgr, thus mitigating the bacterial reduction (Haiser et al., 2013). This demonstrates the highly specific nature of interindividual variability that can influence the therapeutic efficacy of *digoxin*. *Tacrolimus*, an immunosuppressive with a narrow therapeutic range, also exhibits variability of efficacy that is linked to a member of the microbiota, *Faecalibacterium prausnitzii*. Kidney transplant patients who required higher doses of *tacrolimus* had gut microbiomes enriched in *F. prausnitzii*, a nonmotile gram-positive bacterium (Lee et al., 2015). Further investigation showed that incubation of *tacrolimus* with *F. prausnitzii* produces a keto-reduction product of *tacrolimus* that was not found when incubated in hepatic microsomes, suggesting a direct and unique biotransformation of *tacrolimus* by gut microbes (Guo et al., 2019).

Indirect Drug Metabolism by Gut Microbes

In addition to direct enzymatic transformation by gut microbes, intestinal bacteria can also indirectly affect drug biotransformation by regulating host drug-metabolizing genes. Animal studies have demonstrated that gene expression, protein levels, and activity of drug-metabolizing enzymes are altered. For instance, gene expression for Cyp3a (the mouse ortholog to human *CYP3A*) is markedly downregulated in both intestine and liver of germ-free mice (Toda et al., 2009b) compared to wild-type controls. This was correlated with decreased nuclear binding of the pregnane X receptor (PXR), a transcriptional upregulator of Cyp3a in the liver (Björkholm et al., 2009). Conventionalization of the germ-free mice restored Cyp3a to near normal levels (Selwyn et al., 2016). Treatment of conventional mice with the quinolone antibiotic *ciprofloxacin* reduced hepatic Cyp3a expression and decreased metabolism of the Cyp3a substrate *triazolam*; *ciprofloxacin* caused no changes to Cyp3a activity in germ-free mice (Toda et al., 2009a). These data suggest that microbes or microbial products may bind to nuclear factors such as PXR to downregulate the expression of drug-metabolizing enzymes such as CYP3A.

Other phase I and phase II enzymes and transporters are altered by gut microbes in animals. Germ-free mice had higher intestinal mRNA expression of the phase I enzymes alcohol dehydrogenase and aldehyde dehydrogenase, the phase II enzyme UDP-glucuronosyltransferase 1a1 (Ugt1a1), two bile acid transporters (Fu et al., 2017), and the hepatic Mdr1b, the mouse ortholog to human *MDR*, the gene encoding Pgp (Walsh et al., 2020). By contrast, germ-free mice had decreased hepatic expression of organic anion transporter (OAT) protein Oatp1a1 (the ortholog to human OATP1A1), the breast cancer resistance protein Bcrp1 (ortholog to human BCRP), and the organic cation transporter Oct1 (ortholog to human OCT1) (Kuno et al., 2016). Human studies with respective protein levels and activities of these enzymes and transporters will be important to determine the clinical relevance of these results.

The available human data are limited but are consistent with the data from studies with animals. A study in healthy volunteers showed decreases in the activity of CYPs 1A2, 2C19, and 3A4 after a 7-day course of the cephalosporin *cefprozil* (Jarmusch et al., 2020); the substrates used were caffeine for CYP1A2, *omeprazole* for CYP2C19, and *midazolam* for CYP3A4 (Table 6–2). Analysis of the microbial community showed decreased alpha diversity (a measure of the variance of organisms within a given sample) and a correlation between loss of alpha diversity and increased drug and metabolite formation for all three probe substrates (Jarmusch et al., 2020). Altering the microbiome with antibiotic therapy modestly decreased enzyme activity, suggesting that a healthy and diverse microbiome may be necessary for optimal functioning of drug-metabolizing enzymes. Future investigations into the mechanism of this effect as well as those of other antibiotics may provide additional clinically actionable information.

The analgesic *acetaminophen* provides an example of gut microbes altering host phase II hepatic metabolism (see Table 6–2). *Acetaminophen* undergoes glucuronidation, and bacterial glucuronidases can deconjugate the glucuronide metabolite, allowing for reabsorption of the parent *acetaminophen* or further metabolism to sulfate and/or glucuronide conjugates. With antibiotic treatment, there is a decrease in the sulfate conjugate of *acetaminophen* (Malfatti et al., 2020). In addition, gut bacteria produce a metabolite of aromatic amino acid metabolism, p-cresol, that competes with *acetaminophen* for binding to the sulfotransferase (SULT1A1). Individuals who produce high levels of p-cresol have lower capacity to sulfonate *acetaminophen* (Clayton et al., 2009). Therefore, antibiotic therapy and high levels of the bacterially derived metabolite p-cresol could predispose individuals to the hepatotoxic effects of *acetaminophen*.

Enterohepatic Recycling

Enterohepatic recycling occurs when xenobiotics or endogenous substances are absorbed through enterocytes, processed by hepatocytes, and then secreted into the bile where they are then reabsorbed by intestinal cells (see Figure 6–1). Enterohepatic recycling can often be accompanied by hepatic conjugation and intestinal deconjugation. This process can occur continuously and results in a prolonged mean residence time for the substrate. Many drugs and endogenous substances are modified by phase II enzymes such as uridine diphosphate glucuronosyltransferases (UGTs), which add a glucuronic acid moiety to make a more water-soluble metabolite that is more easily excreted into urine or bile. In the intestine, the metabolites can encounter bacterial enzymes such as β-glucuronidase, β-glucosidase, demethylase, desulfase, and other enzymes with phase II reversing activity that cleave off the small molecules such as glucuronide, making the parent compound available again for reabsorption.

β-Glucuronidases are among the most studied gut-derived microbial enzymes. In addition to cleaving glucuronide moieties from drugs, they also breakdown complex carbohydrates, thereby providing a source of carbon for bacterial growth (Dabek et al., 2008). Members of multiple bacterial phyla can catalyze the hydrolysis of glycosidic bonds, including *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, and *Proteobacteria* (Pellock and Redinbo, 2017), highlighting the widespread phylogenetic distribution of this process. Notably, β-glucuronidases from opportunistic (as opposed to commensal) bacteria may play the larger role in xenobiotic-induced toxicity (Dashnyam et al., 2018). One clinically important example of the role of β-glucuronidases occurs with *irinotecan*, a chemotherapy agent used in the treatment of colorectal cancer. Severe diarrhea is a dose-limiting adverse effect that occurs in approximately 50% of patients. *Irinotecan* is a prodrug that is metabolized to the active compound SN-38, which is then glucuronidated in the liver by UGT1A1. Subsequently, the inactive SN-38 glucuronide is secreted into the bile and reabsorbed by intestinal cells via enterohepatic recycling. SN-38 glucuronide is then subjected to gut bacterial β-glucuronidases that remove the glucuronide, producing active SN-38. High intestinal levels of SN-38 are responsible for the diarrhea (see Figures 5–8 and 5–9). Inhibitors of β-glucuronidases such as *ciprofloxacin* may exert a protective effect from the diarrhea (Kodawara et al., 2016; Wallace et al., 2010). Other medications metabolized by β-glucuronidases include *morphine*, *estrogen*, *ibuprofen*, and *midazolam*. The activity of β-glucuronidases may vary with sex, age, and bacterial species (Elmassry et al., 2021); that variation may have consequences on drug bioavailability.

Bile acids, produced in the liver, mediate significant cross talk between the intestine and liver. Bile acids, modified by bacteria in the gut, are important signaling molecules that regulate host metabolism. Microbes can modify host-derived bile acids (Gentry EC et al., 2021; Foley et al., 2019). Microbes from several genera including *Lactobacillus*, *Clostridium*, and *Bifidobacterium* populate the upper intestine, where they deconjugate taurine and glycine conjugates via the action of dedicated hydrolases. Other microbe-catalyzed modifications of bile acids include de-hydroxylation (e.g., converting cholic acid to deoxycholic acid) and epimerization and

TABLE 6–2 ■ INDIRECT DRUG METABOLISM BY MICROBES AND THEIR EFFECT ON PHARMACOKINETIC (PK) PARAMETERS

INDIRECT METABOLISM						
DRUG	**ANIMAL/ HUMAN**	***IN VIVO/IN VITRO***	**EFFECT ON PK (INTACT GUT MICROBIOME)**	**ENZYME**	**DIVERSITY**	**COMMENTS**
Acetaminophen (Malfatti et al., 2020)	Animal	*In vivo*	↑ AUC and C_{max}	SULT1A1	NA	P-cresol competes with acetaminophen binding to SULT1A1 → prevents host from detoxifying acetaminophen
Caffeine (Jarmusch et al., 2020)	Human	*In vivo*	↓ CL	CYP1A2	↓ α ↑ β	↓ CYP activity when treated with cefprozil
Metformin (Wu et al., 2017)	Animal	*In vivo*	↓ C_{max} and ↑ half-life	Oct1	NA	PK changes likely due to ↓ Oct1 expression in the liver → altered hepatic uptake of metformin *in vivo*
Midazolam (Jarmusch et al., 2020; Togao et al., 2020)	Animal Human	*In vitro* *In vivo*	↓ C_{max}, AUC, half-life ↓ CL	Cyp3a; Ugt	NA ↓ α ↑ β	Low levels of Cyp3a activity in GF mice ↓ drug metabolism *in vivo* ↓ CYP activity when treated with cefprozil
Omeprazole (Jarmusch et al., 2020)	Human	*In vivo*	↓ AUC metabolite ratio	CYP2C19	↓ α ↑ β	↓ CYP activity when treated with cefprozil
Progestogens (Coombes et al., 2020)	Human	*In vivo*	MPA had longest half-life	CYP450	NA	Hydroxylation of progestins are likely CYP mediated
Triazolam (Toda et al., 2009a, 2009b)	Animal	*In vivo*	↑ metabolite to parent drug ratio in SPF vs. GF mice	Cyp3a Cyp3a11 Cyp3a25	NA	↑ hepatic Cyp activity in SPF mice (*Bacteroides* and *Escherichia coli*) Ciprofloxacin administration to SPF mice → significant ↓ mRNA expression of hepatic Cyp3a11

AUC, area under the curve; CL, clearance; GF, germ-free; MPA, medroxyprogesterone; NA, not applicable; SPF, specific pathogen free.

oxidation of alcohols. In 2020, it was discovered that microbiota also have the ability to deconjugate with different amino acids, vastly expanding the diversity of bile acids made by microbes (Gentry et al., 2021; Guzior and Quinn, 2021).

Bile acids achieve their signaling properties by binding to nuclear receptors such as the farnesoid X receptor (FXR), and TGR5, a G protein-coupled receptor activated by bile acids (Pols et al., 2011). Binding of bile acids to FXR modulates CYP3A (Gnerre et al., 2004) and transporter activity (Ananthanarayanan et al., 2001). Other microbial products such as the secondary bile acid lithocholic acid, lipopolysaccharides (LPS) produced from gram-negative bacteria, and indole-3-propionic acid can activate PXR (Staudinger et al., 2001). This is a plausible mechanism by which bacterially derived bile acids could regulate host drug metabolism.

Pharmacodynamics

The role of the microbiome in modifying pharmacodynamics—what the drug does to the body—is emerging. Two examples of drugs used in cancer are highlighted here: immune checkpoint inhibitors (ICIs) and a panel of cytotoxic agents.

Immune checkpoint inhibitors are used for a variety of solid and hematological malignancies. They induce an immune response by suppressing pathways targeting cytotoxic T-lymphocyte–associated antigen (CTLA-4) and the programmed cell death protein 1 (PD-1) involved in negative regulation of the immune system (see Figure 39–5 and Chapter 72). The responses to ICIs are often variable and not durable. Gut microbiome composition is associated with ICI efficacy. An abundance of *Faecalibacterium* was observed in melanoma patients who responded to ICI therapy and had significantly longer progression-free survival. Conversely, patients with higher relative abundance of *Bacteroidales* had a shorter progression-free survival. In fact, the strongest microbial predictors of response to ICI therapy were alpha diversity and an abundance of *Faecalibacterium* and *Bacteroidales* (Gopalakrishnan et al., 2018). Loss of microbial diversity from antibiotic exposure has been shown to decrease survival in cancer patients on ICI therapy (Derosa et al., 2018; Routy et al., 2018). Animal and human studies suggest that a gut microbiome with high diversity and an abundance of *Faecalibacterium* plays a role in enhancing the antitumor immune responses mediated by antigen presentation and effector T cells.

Chemotherapy resistance is a major challenge in oncology that often leads to therapeutic inefficacy and significant mortality (see Chapter 71). The gut microbiome may play a role in limiting the efficacy of some chemotherapy agents. A specific gut microbe, *Fusobacterium nucleatum*, is associated with shorter survival in colorectal cancer patients (Mima et al., 2016) and is increased in patients with postchemotherapy recurrence compared to patients without recurrence. *F. nucleatum* targets innate immune signaling and specific microRNAs to activate the autophagy pathway and control chemoresistance of *5-fluorouracil*, *capecitabine*, and *oxaliplatin*, drugs commonly used in colorectal cancer (Yu et al., 2017). In addition, *Gammaproteobacteria* can metabolize the chemotherapeutic agent *gemcitabine* to its inactive form, 2′,2′-difluorodeoxyuridine. In a colon cancer mouse model, intratumor *Gammaproteobacteria* induced

gemcitabine resistance. Resistance was ameliorated by the antibiotic *ciprofloxacin* (Geller et al., 2017). The potential for modifying specific gut bacteria or communities of gut bacteria to enhance drug efficacy or minimize drug toxicity is a compelling goal.

Drug Effects on the Microbiome

Antibiotics have varying but profound effects on the gut microbiome. The effects of antibiotics at birth and early infanthood may have permanent consequences on the developing microbiome (Nobel et al., 2015). In addition, emerging evidence suggests that antibiotics interfere with the microbiome and the immune system resulting in immunological disorders (Mårild et al., 2013). Not surprisingly, antibiotic use is associated with a lower abundance of susceptible GI microbes; in one recent *in vitro* high-throughput drug screen, 78% of 156 antibacterials tested had activity against at least one gut microbial species. Interestingly, sulfonamides, aminoglycosides, and antimycobacterial agents had no activity against gut commensals (Maier et al., 2018). A notable consequence of antibiotic use on the gut microbial community is the increased risk for *C. difficile* infection, a bacterial infection of the colon that causes significant morbidity and mortality. *C. difficile* infections are difficult to treat, with up to 65% of patients relapsing. Although the risk of *C. difficile* infection varies with the particular antibiotic, the metabolic effects of antibiotics on the gut microbiome may depend more on the concentration of antibiotics in the gut. For example, in mice, high concentrations of antibiotics reduce or eliminate most products of microbial metabolism such as short-chain fatty acids and secondary bile acids, whereas precursors such as oligosaccharides, sugar alcohols, and primary bile acids accumulate (Jump et al., 2014; Zhao et al., 2013).

There are also many non-antibiotic pharmaceuticals that influence the gut microbiota. Proton pump inhibitors (PPIs) and *metformin* are good examples. In a large *in vitro* study, PPIs were one of four drug classes (PPIs, *metformin*, laxatives, and antibiotics) associated with the largest impact on gut microbial taxa, with a total of 40 altered taxa. The impact of PPIs on gut microbes may be mediated by the changes in GI pH and also by direct inhibition of certain commensal gut bacteria such as *Dorea* and *Ruminococcus* species (Maier et al., 2018). Microbiome functional changes associated with PPIs include an increase in fatty acid and lipid biosynthesis, fermentation, nicotinamide adenine dinucleotide metabolism, and biosynthesis of L-arginine. These functional changes are likely explained by changes to taxa. For example, *Streptococcus mutans* is enriched in PPI users, and this taxa is associated with biosynthesis of L-arginine (Vich Vila et al., 2020). PPIs are also associated with *C. difficile* infection. Long-term PPI use may decrease bacterial diversity (Seto et al., 2014) and may increase Enterococcaceae and Streptococcaceae taxa (Freedberg et al., 2015), which have been associated with antibiotic exposure and increased risk for *C. difficile* infection. Additionally, PPIs induce hypochlorhydria, which permits increased gastric and fecal populations of *Streptococcus,* leading to an increased risk for *C. difficile* infection.

Metformin is often used to treat type 2 diabetes. In metagenomic studies of gut flora and alterations associated with type 2 diabetes, data were conflicting. Further investigation showed that the results were confounded by the effect of *metformin* on the gut microbiome. *Metformin* significantly altered the relative abundance of 86 bacterial strains and 48 microbial pathways (Forslund et al., 2015; Wu et al., 2017). This was associated with changes in the metabolic potential of the microbiome, including increases in butanoate production, quinone biosynthesis, degradation of sugar derivatives, and polymyxin resistance pathways. Analysis of metagenomic pathways and gene families showed that *E. coli* was the major contributor to these functional changes associated with *metformin* (Vich Vila et al., 2020).

The therapeutic effects of *metformin* on glucose metabolism may be mediated by microbes. *Metformin* can alter the composition and function of the gut microbiota in concert with its effects on blood glucose and hemoglobin A_{1c}. *Metformin* treatment promoted changes in the abundance of *Escherichia* and *Intestinibacter* and increased LPS biosynthesis and short-chain fatty acid metabolism (Wu et al., 2017), two factors that may play a role in glucose homeostasis. When these *metformin*-treated microbiota were transferred to germ-free mice, glucose tolerance was improved and hemoglobin A_{1c} was reduced (Wu et al., 2017). Thus, the gut microbiota may play a role in *metformin*'s therapeutic effects in type 2 diabetes.

Diet and the Microbiome

Food has a strong effect on the microbiome, but the microbiome also has a strong effect on the health outcomes of diet (Rowland et al., 2018). Microbiota use food to biosynthesize and supply many of our key vitamins, essential amino acids, and essential lipids and to help digest diet-derived molecules such as complex carbohydrates, polyphenols, and proteins to allow uptake of the metabolized molecules as nutrients. Because diet can be changed, microbiome-mediated therapy is a viable strategy to develop interventions to change the microbiome and affect health outcomes. When fruits and vegetables are consumed, the microbiome has a higher diversity, whereas consumption of a meat-based diet leads to decreased diversity, thus resulting in large changes in metabolism. There are studies that have mechanistically revealed the importance of diet and the microbiome in relation to health outcomes. For example, in mice, *Clostridium orbiscindens* metabolizes flavonoids, a class of molecules found in fruits and vegetables, to make desaminotyrosine via hydrolysis from the desaminotyrosine-conjugated flavonoids. Desaminotyrosine, in turn, protects the host from *Haemophilus influenzae* by boosting the immune system through type I interferon signaling (Steed et al., 2017). Another example is the production of trimethylamine oxide in the liver from ammonia. Trimethylamine oxide is damaging to the cardiovascular and renal systems, leading to increased risk of stroke, myocardial infarction, and other cardiovascular diseases. Its production is mediated by the microbiome via release of ammonia from foods rich in choline and choline-containing lipids such as eggs, fish, and meat.

The interconnections of nutrition, diet, and the microbiome are significant to our understanding of health and disease and are a key component of the 2020–2030 strategic plan for the National Institutes of Health as part of their nutritional health initiative (National Institutes of Health, 2020). Dietary influence of microbiota or microbiota-mediated digestion of food has been linked to growth stunting in infants, metabolic disease, neurological decline, and cardiovascular and renal problems, among others. For example, the PREDICT (Personalised Responses to Dietary Composition Trial) study found that *Prevotella copri* and *Blastocystis* species largely associated with a healthy and plant-based diet improved cardiometabolic blood markers (postprandial glycemic, lipemic, and inflammatory indices) (Asnicar et al., 2021). Similarly, a Mediterranean diet resulted in a decreased cardiovascular risk and also a lowered abundance of *P. copri*, an organism that is also protectively associated with rheumatoid arthritis inflammation pathology (Wang et al., 2021). Indeed, diet can significantly reduce or even eliminate rheumatoid arthritis through alteration of the microbiome. A ketogenic diet, however, leads to a decrease of *Bifidobacterium* due to the production of ketone bodies that are inhibitory to *Bifidobacterium*. Because *Bifidobacterium* species are proinflammatory via stimulating T_H17 cells, inflammation was also decreased. Thus, diet-mediated microbiome alterations might usefully be explored as a strategy to control chronic inflammatory diseases such as Crohn's disease, ulcerative colitis, and other T_H17 cell–mediated skin and lung disorders. Consequently, diet interventions targeting the microbiome as a therapeutic strategy to improve health are a viable option. As the National Institutes of Health nutritional health initiative advances evidence-based rules of diet, nutrition, microbiome, and health connections, diet as a therapeutic strategy will become more commonplace and clinically routine.

Future of Drugs and the Microbiome

Fecal Transplants

In livestock, transfaunation, the practice of transferring rumen microorganisms from a healthy donor to a sick recipient, usually provided orally, has been performed for well over a century, with documented examples

going back to the 1700s. Transfaunation has been successfully used to treat horses, cattle, goats, and many other animals with indigestion, diarrhea, and drop in milk production, among other conditions. The related process in humans is the fecal transplant. The first documented human fecal transplant was delivered via enema in 1958 to treat fulminant pseudomembranous colitis (antibiotic-induced syndrome), now known to be a result of *C. difficile* infection. Despite the success of these fecal transplants, there was not a wide adoption of the practice. Only in 2013 was a randomized clinical trial performed on patients for whom antibiotic therapy for *C. difficile* had failed. The trial was halted when the 90% cure rate among the fecal transplant recipients with *C. difficile* infections made it unethical to withhold treatment from the control group. Fecal transplant, sometimes referred to as bacteriotherapy, is still controversial but has become more widely used as an option for treatment of *C. difficile* infections. Fecal transplant therapy is not approved by the FDA (U.S. Food and Drug Administration); rather, the current guidance by the FDA on fecal transplant is "enforcement discretion under limited conditions." These conditions are as follows: "1) the licensed health care provider treating the patient obtains adequate consent from the patient or his or her legally authorized representative for the use of FMT products. The consent should include, at a minimum, a statement that the use of FMT products to treat *C. difficile* is investigational and a discussion of its reasonably foreseeable risks; 2) the FMT product is not obtained from a stool bank; and 3) the stool donor and stool are qualified by screening and testing performed under the direction of the licensed health care provider for the purpose of providing the FMT product for treatment of the patient" (FDA, 2020).

The microbiome has now been connected not only to intestinal infections but also immunological disorders and the brain-gut-microbiome axis. Currently, FMT is being used or evaluated to treat myriad diseases including Crohn's disease, ulcerative colitis, irritable bowel syndrome, obesity, steatohepatitis, autism, some neurological disorders (Vendrik et al., 2020), establishment of normal flora for infants delivered via cesarean section (Korpela et al., 2020), pediatric cytomegalovirus disease, and as anti-PD-1 co-therapy for cancers.

Because there is no standardized, controlled process to prepare fecal transplants, a fecal transplant cannot be guaranteed to be safe and is not without risk and side effects. For this reason, the FDA has released warnings about the possible transmission of parasites; bacterial pathogens; viruses, including HIV (human immunodeficiency virus) and SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2); and other infectious diseases. One death has been reported after a fecal transplant. Side effects observed with successful FMT include constipation, diarrhea, cramping, bloating, and changes in stool consistency. Sometimes, anecdotally, the recipient also takes on metabolic characteristics associated with the donor, such as gain or loss of weight due to changes in the microbiome metabolic capacity. For example, the transfer of intestinal microbiota from lean donors increases insulin sensitivity (Bibbò et al., 2020). Other characteristics such as obesity, dietary preferences, and energy consumption have been observed to be transferred, albeit documented infrequently. The long-term effects of a fecal transplant are unknown.

Defined Microbial Communities

Fecal transplant relies on donors, and since donor microbiomes differ, fecal transplants vary considerably in efficacy. For this reason, controlled and defined consortium of microbes and single-strain microbiota, including probiotics or (bacterio)phage therapy, are being explored (Weiman, 2018). Currently, no single defined microbial community is FDA approved for therapy; however, clinical trials with defined communities are ongoing and include *C. difficile* treatments (phase III) and treatment of ulcerative colitis (phase IIb).

Probiotics

The use of single microbial treatments has a long history and is a $6 billion industry in the U.S. alone. An early and important probiotic is *E. coli* Nissle 1917, discovered in World War I from a corporal that, unlike his fellow soldiers, did not get sick with *Shigella* (Sonnenborn, 2016). *E. coli* Nissle was also found to be beneficial against *Salmonella* and other GI infections. It is now manufactured under Good Manufacturing Practice conditions and licensed in Germany as an active pharmaceutical ingredient. Another example is *Bacillus subtilis*, isolated from camel dung, that treated dysentery in World War II (Ayalah, 2010). Capsules of *B. subtilis* were commonly used for human consumption worldwide until the 1960s, when single antibiotics became favored. Elsewhere (e.g., in Germany, France, and Israel), *B. subtilis* is still a commercial product for human (and animal) consumption under a doctor's supervision (Casula and Cutting, 2002). In the U.S., *B. subtilis* has become widely used in agriculture to prevent crop infections and as an active ingredient of fertilizers due to its crop growth-promoting properties. Other probiotics such as *Lactobacillus*, *Bifidobacterium*, and *Saccharomyces* are taking its place, especially in treatments of GI disorders and infections. Single microbial treatments have remained on the periphery of therapeutic options due to the limited evidence of their efficacy. Due to the increasing appreciation of health-related roles the microbiota may play, both the Food and Agriculture Organization/World Health Organization and the American Gastroenterological Association have provided clinical practice guidelines for the evaluation of probiotics for treating GI disorders and for general probiotic use (Brüssow, 2019; Su et al., 2020). Currently, numerous clinical trials are evaluating single microbial species as treatments for diseases associated with the intestine (e.g., *C. difficile*, autism), oral cavity (e.g., reduction in *S. mutans*) (Twetman and Stecksén-Blicks, 2008), and skin (e.g., atopic dermatitis) (Hsiao et al ., 2013; Sharon et al., 2019).

Designer Microbiota

One emerging interest of the scientific community is the use of genetically engineered microbial strains or synthetic ecosystems (Ainsworth, 2020). These designer microbiota can be engineered to deliver specific therapeutics, to make up for deficiencies, or to focus in specific areas. One example is in phenylketonuria, in which the patient cannot produce functional phenylalanine hydroxylase or has a deficiency in the cofactor tetrahydrobiopterin that converts the amino acid phenylalanine to tyrosine, resulting in the accumulation of phenylalanine. Excess phenylalanine leads to neurological defects (autism-like behavior, motor deficiencies, seizures) or even death. The treatment is a diet low in phenylalanine. Both *E. coli* and *Lactococcus lactis*, two common microbiota, have been engineered to contain phenylalanine hydroxylase and were shown to significantly reduce phenylalanine levels. This is an encouraging example where engineered strains may, one day, serve as probiotics to overcome errors in metabolism.

Phage Therapy

The viriome (including both host-associated viruses and phages that attack bacteria) comprises an often-overlooked part of the microbiome. Viruses that infect bacteria and archaea are known as bacteriophages or phages. Phages infect and kill selected hosts and are a key component of our innate immune system (Barr et al., 2013; Carroll-Portillo and Lin, 2019), protecting mucus-covered epithelial layers from microbial invasion. The ability of phages to kill bacterial pathogens and provide protection against infection is the main driver behind the development of phage therapy. Phage therapy is being evaluated in clinical trials as a strategy to treat drug-resistant urinary tract infections due to pathogenic *E. coli*, *Klebsiella pneumoniae*, *Burkholderia cenocepacia*, *Pseudomonas aeruginosa*, *Staphylococcus aureus,* and other multidrug-resistant pathogens, and also to treat inflammatory bowel disease, lung infections, chronic wounds, osteomyelitis, mastoiditis, prosthetic joint infections, and other chronic diseases. The field got a boost from the widely publicized example of phage therapy used to treat a professor who was comatose after becoming infected with a multidrug-resistant form of *Acinetobacter baumannii* after vacationing in Egypt. The patient's wife, an infectious disease epidemiologist, and a team of physicians and researchers located candidate phages active against *A. baumannii*. With emergency approval from the FDA, a phage cocktail was administered intravenously and the professor ultimately recovered, apparently the first person in the U.S. to be cured from a multidrug-resistant

BOX 6–1 ■ Phage Therapy Is Not a New Idea

Twort (1915) and d'Hérelle (1917) discovered phages and their capacity to kill bacteria during World War I. These researchers had observed that some bacterial cultures from patients with dysentery lysed and then cleared, and addition of a bacterium-free supernatant from a clear culture promoted clearing in infected cultures. There were reports of such "blooms" of very tiny microbes shortly before soldiers recovered from *Shigella* infection, with the microbes apparently killing the *Shigella.* d'Hérelle presented his observations to the Academy of Sciences in Paris, describing "an invisible microbe, an antagonist of the dysentery bacillus," which he termed a *bacteriophage,* a "bacteria eater." These and other observations stimulated considerable interest. In the period between World War I and World War II, d'Hérelle and others developed several therapies using phages, and phage therapies for bacterial infections became commercially available in Europe and the U.S. Meanwhile, basic scientists debated the nature of the bacteriophage: an "ultramicrobe" (virus) or an "autocatalytic bacterial enzyme." In the U.S.S.R., Russian scientists developed strategies for harvesting phages for therapeutic purposes up to World War II. From the 1940s onward, phages became the focus of much basic research as work on molecular genetics and the basis of heredity progressed, exemplified by the work of Lwoff and Delbrück. In the West, interest in phage therapy waned with Fleming's discovery of *penicillin*, its isolation and purification by Chain and Florey, and its mass production by the U.S. and Britain during the war. There was a proliferation of antibiotics during the postwar and Cold War periods. East of the Iron Curtain, however, interest in phages and their therapeutic potential persisted and flourished, especially in the Georgian capital of Tbilisi, at the bacteriophage institute now known as the Eliava Institute, named after its founder, George Eliava, a protégé of d'Hérelle. This history, especially work in the U.S.S.R., is well summarized by Myelnikov (2018).

In Western medicine, there is a burgeoning rediscovery of bacteriophages as antimicrobial therapies. At the same time, new techniques for customizing genomes have become available that can help to direct the vigorous reciprocal interplay between the defense mechanisms of bacteria (e.g., restriction-modification, CRISPR-Cas9 [clustered regularly interspaced short palindromic repeats–CRISPR-associated endonuclease 9; a gene editing tool]) and the counterdefense mechanisms of bacteriophages (covalent genome modification) (Liu et al., 2020). As a result, biotech companies have begun phase I/II clinical trials on multiphage cocktails to treat the most common multidrug-resistant pathogens. Chapter 59 presents some aspects of the current use of phages as antimicrobials.

infection by phage therapy (Tara Rava Zolnikov, 2019). At least 16 other patients have been successfully treated in a similar phage therapy to treat *A. baumannii* infections and at least 39 other people have been treated for nine other multidrug-resistant microbes using different phages. The FDA has also provided emergency clearance to treat COVID-19 (coronavirus disease 2019) patients coinfected with multidrug-resistant *A. baumannii*. For more on phages and phage therapy, see the section on bacteriophages in Chapter 59 and also Figure 59–4.

Chapter 7

Pharmacogenetics and Pharmacogenomics

Dan M. Roden and Sara L. Van Driest

Patients vary in their responses to drug therapy. Some patients derive striking and sustained benefits from drug administration, others may display no benefit, and still others display mild, severe, or even fatal adverse drug reactions (ADRs). Common sources of such variability include noncompliance, medication errors, clinical factors, drug interactions (see Chapter 4 and Appendices I and II), and genetic factors. Pharmacogenetics is the study of the genetic basis for variation in drug response and often implies large effects of a small number of DNA variants. Pharmacogenomics, on the other hand, studies larger numbers of variants, in an individual or across a population, to explain the genetic influences on drug response. Discovering which variants or combinations of variants have functional consequences for drug effects, validating those discoveries, and ultimately applying them to patient care and to drug discovery are the tasks of modern pharmacogenetics and pharmacogenomics.

Importance of Pharmacogenetics to Variability in Drug Response

An individual's response to a drug depends on the complex interplay of drug factors (e.g., dose, route, formulation), environmental factors (e.g., diet, infections, other drugs, exercise level, exposure to toxins), clinical factors (e.g., age, indication for drug, organ function), and genetic factors. Key genes known to be involved in driving variable drug actions, called *pharmacogenes*, may influence drug response via variable drug concentrations (*pharmacokinetics*) or variable drug effects (*pharmacodynamics*). Pharmacogenes include those encoding drug-metabolizing enzymes, drug transport molecules, drug targets, and a host of other genes that modulate the molecular context within which drugs act, notably genes dysregulated in the disease for which the drug is administered. In some situations, variation in non-germline genomes (e.g., in cancer cells or in infectious agents) can be critical determinants of drug response.

Many well-established pharmacogenes encode drug-metabolizing enzymes. Drug metabolism is highly heritable, as assessed using drug exposures in monozygotic versus fraternal twins, drug exposures in cell lines from related subjects, and analysis of very large data sets using technologies such as genome-wide genotyping, discussed further in this chapter. Some drug metabolism traits behave in a conventional "monogenic" fashion, with clearly definable (and separable) groups of drug response phenotypes: poor metabolizers who inherit two alleles with no function, intermediate metabolizers who have one functional allele and one nonfunctional allele (heterozygotes), and normal metabolizers who have two functional alleles. The study of these traits has helped define key genetic variants that contribute to the individual variability in responses described in this chapter. However, drug responses predicted by a small number of large effect size variants in a single gene are the exception. For most drug responses, understanding the influence of genetic variability will require a truly pharmacogenomic approach. A major challenge to the field is to accrue large numbers of subjects with well-characterized drug responses to enable discovery, and subsequent replication and validation, of multigene effects and of interactions of genomic predictors with environmental factors. The important variants within pharmacogenes often differ across different populations; this chapter includes several examples of the potential influence of ancestry on drug response. Thus, an additional major challenge to the field is to accrue data from diverse populations to ensure generalizability of findings to populations worldwide.

A Brief History of Pharmacogenetic Discovery

In the early 20th century, Garrod (Box 7–1) proposed that specific enzyme defects could not only cause "inborn errors of metabolism" such as alkaptonuria but also could account for variability in drug responses (Roden et al., 2019). Interestingly, however, the first examples of genetically determined variable drug responses were not based on variable drug metabolism but were pharmacodynamic. The widespread use of antimalarials in the Pacific theater during World War II led to the recognition that certain individuals, predominantly African-Americans, were susceptible to hemolysis due to glucose-6-phosphate dehydrogenase (G6PD) deficiency. Subsequent studies identified malignant hyperthermia following anesthetic exposure as a second genetically determined pharmacodynamic trait. Not long thereafter, Garrod's hypothesis was confirmed when the first examples of genetically determined variable drug responses due to pharmacokinetic variability were described: prolonged paralysis after *succinylcholine* resulting from

Abbreviations

ACE: angiotensin-converting enzyme
ADR: adverse drug reaction
CNV: copy number variant
EGFR: epidermal growth factor receptor
EHR: electronic health record
FH: familial hypercholesterolemia
G6PD: glucose-6-phosphate dehydrogenase
GWAS: genome-wide association studies
HER2: human epidermal growth factor receptor 2
HLA: human leukocyte antigen
iPSC: induced pluripotent stem cell
LDL: low-density lipoprotein
MHC: major histocompatibility complex
NAT: *N*-acetyl transferase
RCT: randomized clinical trial
SNV: single-nucleotide variant
TYMS: thymidylate synthase

pseudocholinesterase deficiency and isoniazid hepatotoxicity due to a deficiency of *N*-acetyl transferase (NAT).

In the 1970s, using analysis of plasma drug concentrations, two groups identified striking variability in response to *debrisoquine* (an antihypertensive) and sparteine (an antiarrhythmic) with side effects attributable to defective drug metabolism and consequent accumulation of high (toxic) drug concentrations. Subsequent work established that the same enzymatic defect—decreased CYP2D6 enzyme function—was responsible in both cases. Decades of research then established the role of variable CYP2D6-mediated metabolism in response to dozens of other drugs, identified specific common genetic variants determining variable metabolism, linked unusually high drug concentrations due to pharmacogenetic defects for myriad drug-metabolizing enzymes such as TPMT, UGT1A1, CYP2C19, and others (see Tables 7–2 and 7–3), and defined the role of pharmacogenetic traits in mediating responses to prodrugs such as *codeine* or *clopidogrel* due to variable metabolic bioactivation. As described below, the application of methods in contemporary genome science, such as genome-wide association and sequencing, is helping to expand our understanding of the genetic basis of variable drug responses.

Foundations of Pharmacogenetics and Pharmacogenomics

Types of Genetic Variation That Alter Drug Response

Genetic variations can be categorized by many characteristics, including frequency in a population, number of base pairs involved, location in the encoded gene, and the effect on the encoded protein. Pharmacogenetic variants include variants in each of these categories. In some cases, important pharmacogene variants are unusually common compared to disease genes in which sequence variations with large potential adverse effects are rare. The high population frequency is thought to reflect the lack of selection pressure. Since pharmacogenetic traits are often imperceptible until drug is administered, the frequencies of variant alleles in pharmacogenes are not reduced in populations over time. Important variants in pharmacogenes can be so rare as to be documented only in a single individual or so common that it is difficult to define which allele is the "wild type." The frequency of specific alleles is often highly variable across populations. For example, most individuals of European descent have no CYP3A5 enzymatic activity (two *no function* alleles), whereas in many populations of African descent, most individuals have one or two alleles expressing functional CYP3A5 protein. The mechanism underlying loss of function in this case is described below.

Pharmacogenetic variants also span the spectrum with respect to size. Single base pairs to large stretches of DNA (including entire genes or chromosomes) can be altered by insertions, deletions, inversions, and duplications of DNA. The smallest genetic variants are substitutions of a single base pair of DNA, called *single-nucleotide variants* (SNVs). Large deletions or duplications are called *copy number variants* (CNVs). For example, the amount of functional CYP2D6 enzyme in an individual depends on the interplay of over 100 possible SNVs, many insertion/deletions, and CNVs deleting or duplicating the entire gene.

BOX 7–1 ■ Origins of Pharmacogenetics

As an assistant physician at the Hospital for Sick Children in London, Archibald Edward Garrod (1857–1936) pursued his interest in metabolism, heredity, and disease. Through diligent collection of family histories and urine samples of affected patients, Garrod identified the pattern of inheritance of alkaptonuria, his paper becoming the first published account of an autosomal recessive disease (Garrod, 1902). Continuing this line of thinking with studies of albinism and cystinuria, he developed the concept of "inborn [genetically transmitted] errors of metabolism" (Garrod, 1909). His work showed the relationship among biochemistry, genetics, and medical practice; Garrod described alkaptonuria as follows: "the splitting of the benzene ring of homogentisic acid in normal metabolism is the work of a special enzyme [and] . . . in congenital alcaptonuria this enzyme is wanting" (Garrod, 1923). In *The Inborn Factors in Disease* (Garrod, 1931), Garrod proposed that inborn errors of metabolism are "extreme examples of variations of chemical behaviour which are probably everywhere present in minor degrees" and put forward the concept of "chemical individuality," postulating that the aberrant metabolism of exogenous substances could account for unusual reactions to food or drugs, a foundational principle of pharmacogenetics and precision medicine.

After World War II, genetically determined drug responses began to be well characterized. In North America, the field was advanced by two German expatriates, Arno Motulsky (1923–2018) and Werner Kalow (1917–2008). Motulsky, generally considered the father of pharmacogenetics, established the Division of Medical Genetics within the Department of Medicine at the University of Washington and defined the field of pharmacogenetics (Motulsky, 1957). He had broad interests, studying the genetics of G6PD deficiencies, blood groups, and sundry protein polymorphisms. With one trainee, Joseph Goldstein, Motulsky studied familial hyperlipidemia, suggesting that familial hypercholesterolemia was a monogenic disorder. Thirteen years later, Goldstein and Michael Brown won a Nobel prize "for their discoveries concerning the regulation of cholesterol metabolism" (Motulsky, 1986).

Joining the Department of Pharmacology at the University of Toronto in 1951, Werner Kalow studied the metabolism of *succinylcholine* and inherited differences in serum cholinesterase activity. He concluded that the observed differences in cholinesterase activity resulted from different affinities for the substrate, implying different enzyme structures and hence different amino acid sequences. His analysis of multiple families confirmed high, intermediate, and low enzyme activities with a Mendelian pattern of inheritance. Based on these and other studies, Kalow proposed that individual differences in metabolic function due to genetic variation could lead to unique outcomes following drug therapy (Kalow, 1961). Kalow, himself, homozygous for low CYP2D6 activity, described his career as "the rich life of a poor metabolizer" (Grant and Tyndale, 2008).

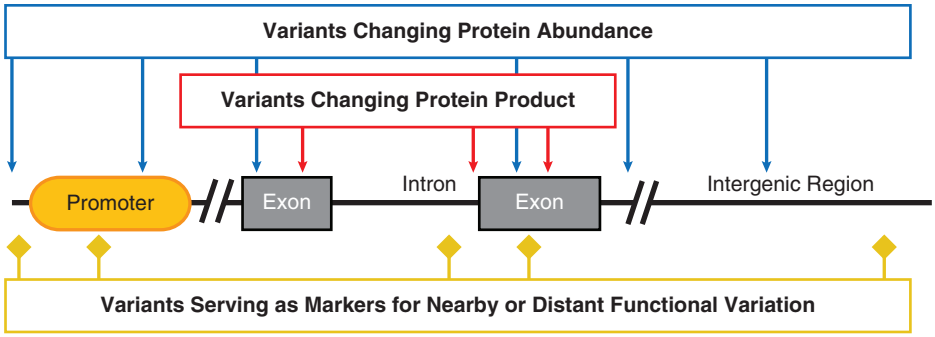

Figure 7–1 *Many types of genetic variants can lead to drug response outcomes.* A simplified gene, including a promotor sequence (orange oval), exons (gray boxes), and introns (black line between exons), is shown. The DNA between genes is referred to as intergenic. Variants that change protein abundance, indicated by blue arrows, can be found throughout all these regions. Variants that change the protein sequence, indicated by red arrows, are generally found in or near exons. Variants that serve as markers for other functional variations in linkage disequilibrium (which may affect protein abundance or product and may be nearby or distant) can be found throughout all of these regions. These variants are indicated in yellow diamonds.

Regardless of size, some variants in pharmacogenes alter the sequence of the encoded protein, for example, by substituting one amino acid for another, deleting or adding an amino acid, changing the start or stop codon, or introducing a frameshift affecting the remainder of the transcribed protein. Variants within or outside the coding sequence can also affect protein abundance (Figure 7–1). The number of TA repeats in the *UGT1A1* promoter affects the level of expression of this important glucuronosyltransferase in liver; the most common allele has six repeats, and the seven-repeat variant (*UGT1A1*28*) decreases *UGT1A1* expression. The frequency of the *UGT1A1*28* allele is up to 30%, with up to 10% of subjects (depending on ancestry) being homozygous. Decreased *UGT1A1* transcription can modulate drug actions and also accounts for a common form of mild hyperbilirubinemia (Gilbert's syndrome; see Table 5–3 and Figure 5–7).

Many pharmacogenetic variants can be identified through association studies, including genome-wide association studies (GWAS; see below). These association studies, unless coupled with functional characterization, do not prove the causal link between the genetic variant(s) and the pharmacogenetic trait. Genetic variants are often not inherited in isolation, but as a constellation of variants frequently found together (termed *linkage disequilibrium*). An association study may identify a variant in linkage disequilibrium with a functional variant, rather than the functional variant itself. These patterns of linkage disequilibrium are population specific. As a result, a variant associated with a particular drug outcome by GWAS in one population may not replicate in another population. This highlights the importance of functional studies and population-specific replication of pharmacogenetic associations.

Pharmacogenomic Terminology Used to Describe Effects of Genetic Variation

A *haplotype*—a series of alleles found at a linked locus on a chromosome—specifies the DNA sequence variation in a gene or a gene region. A haplotype represents the constellation of variants that occur together. For any gene, individuals will have two haplotypes, one maternal and one paternal in origin. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally important. In others, however, a single variant may be functionally important regardless of other linked variants within the haplotype(s). Selected common *CYP2C19* variants and haplotypes are illustrated in Figure 7–2.

For many important pharmacogenes (but not all), a shorthand nomenclature for haplotypes has been adopted. This "star allele" nomenclature allows communication of the entire haplotype by stating the gene name followed by an asterisk and the specific haplotype designation. By convention, **1* designates a functional allele; for example, *CYP3A5*1* and *CYP2C19*1* encode functional enzymes. In *CYP3A5,* a common noncoding intronic variant creates an alternative splice site, resulting in a transcript with an early stop codon (Figure 7–3). This allele, designated as *CYP3A5*3* generates a *nonfunctional* protein and is the predominant allele in European ancestry individuals, whereas *CYP3A5*1* is the predominant allele in African ancestry individuals (Figure 7–4). Star allele designations often include information about several variants across an allele, as seen in the example of *CYP2C19* in Figure 7–2. Web-based resources such as PharmGKB and PharmVar (Table 7–1) provide information on specific star alleles.

Standard nomenclature has also been developed for specifying drug metabolism enzyme function. The terms poor, intermediate, normal, rapid, and ultrarapid metabolizer are used to describe individuals who, based on the combination of maternal and paternal alleles present in their genome, have no enzyme activity (poor metabolizer) to greatly increased enzyme activity (ultrarapid metabolizer).

Scenarios for Clinically Important Pharmacogenetic Interactions

Given the complexity and redundancy of most pharmacokinetic and pharmacodynamic pathways, variations in a single pharmacogene will often have a small effect. There are specific scenarios that lead to large effects of variation in a single pharmacogene. Recognition of these scenarios led to the fundamental early discoveries in pharmacogenetics discussed above and form the basis for most of the pharmacogenetic predictors clinically implemented at this time.

Scenarios leading to clinically important pharmacogenetic interactions include:

- Drugs for which a key step in their metabolism or transport depends on single enzymes or transporters with functional variability (*pharmacokinetic alterations*), such as *debrisoquine*, *sparteine*, *codeine*, and other drugs metabolized by CYP2D6.
- Drugs interacting with proteins with functional variability, either as the intended drug target or as an off-target effect (*pharmacodynamic alterations of the receptor/target*), such as some aminoglycosides, β blockers, and antiarrhythmic drugs.
- Drugs with differential effect depending on the broad biologic milieu (*pharmacodynamic alterations beyond the receptor/target*), such as antimalarial drugs and *rasburicase*, where G6PD deficiency predicts ADRs.

Some drug responses are associated with more than one gene and may be described as multigenic traits. This section summarizes important examples of well-established pharmacokinetic, pharmacodynamic, and multigenic traits, but cannot be all inclusive. Web-based resources such as PharmGKB (see Table 7–1) provide information on specific genes, variants, drugs, and diseases.

Pharmacokinetic Alterations

Variations in genes that encode drug-metabolizing enzymes and transporters affect drug concentrations and are therefore major determinants of drug response (at the end of the chapter, see Table 7–3 for additional

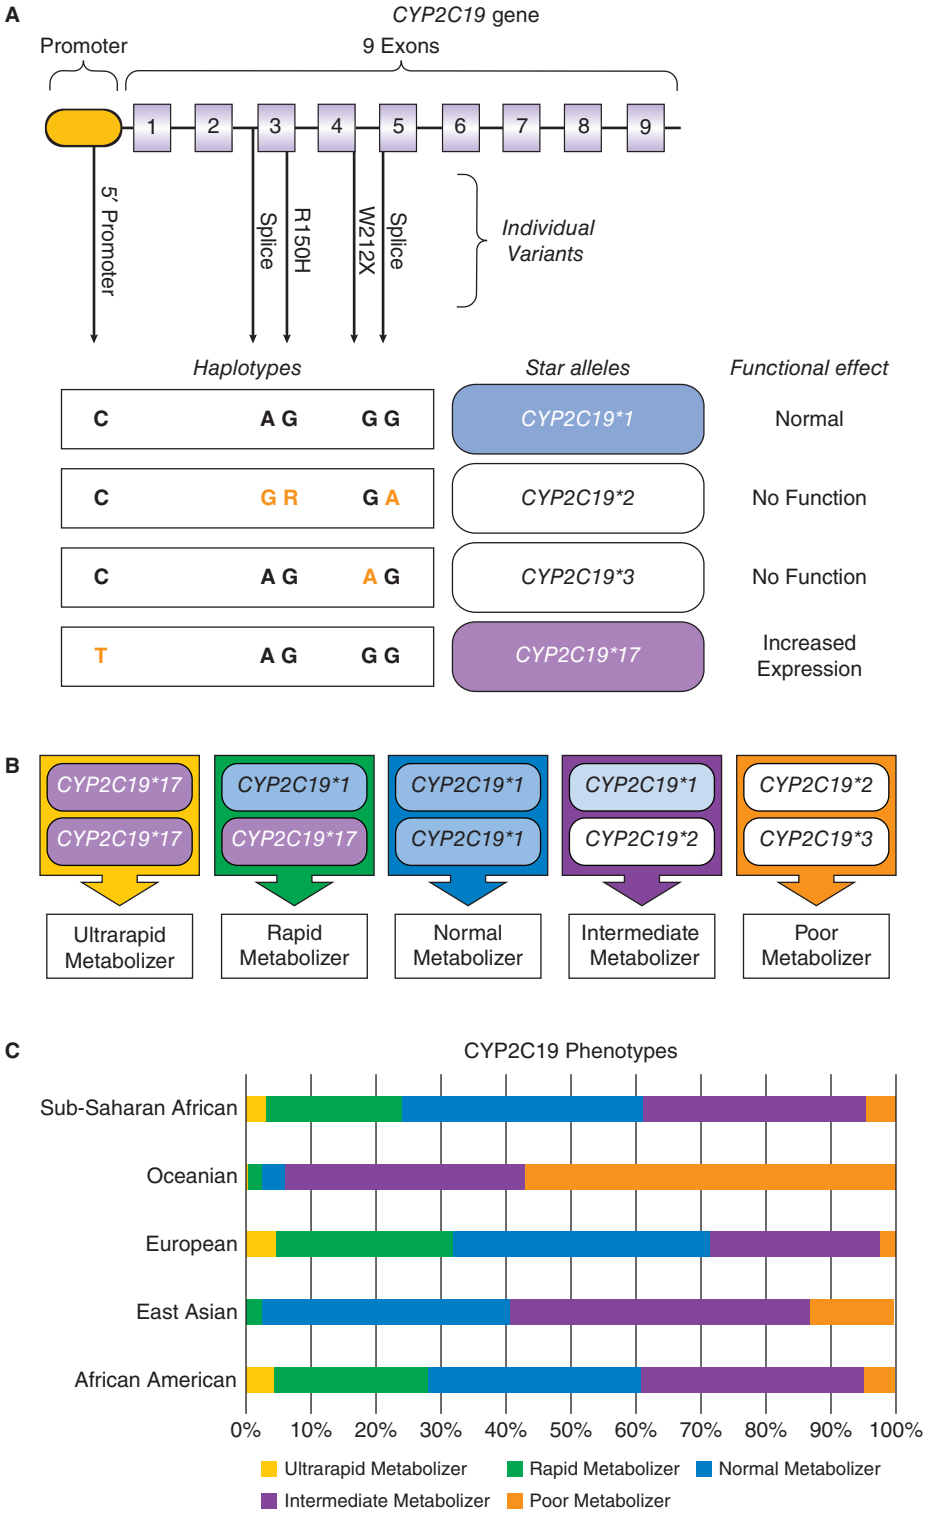

Figure 7–2 *Common CYP2C19 variants, haplotypes, star alleles, functional effects, and metabolizer status.* The gene encoding CYP2C19 has nine exons, shown in gray boxes in panel **A**. Common variants are found in the 5′ promoter, the introns, and the exons. The patterns of individual variants define haplotypes, which in turn are designated using specific star alleles. *CYP2C19*1* has normal enzyme function, **2* and **3* have no enzyme function, and **17* has increased function (due to a promoter variant that increases expression of the enzyme). Note that there are many additional known variants and star alleles in *CYP2C19* than those depicted in the figure. Each individual inherits two *CYP2C19* alleles (one maternal and one paternal), as shown in panel **B**. The combination of alleles determines the total amount of CYP2C19 enzyme functional activity or metabolizer status. The distribution of CYP2C19 metabolizer status varies by ancestral population, as shown in panel **C**. In Oceanian populations, poor metabolizers are very common, whereas this phenotype is uncommon among those of European ancestry.

examples of genetic polymorphisms influencing drug response). A particularly high-risk situation is a drug with a narrow therapeutic margin where a step in the metabolic pathway is dependent on a single enzyme. Loss of enzyme function will lead to increases in exposure to the parent drug and any metabolites upstream in the metabolic pathway. There will also be lower concentrations of metabolites downstream of the critical enzyme. Variants that increase enzymatic function have the opposite effect, leading to low concentrations of parent compound and upstream

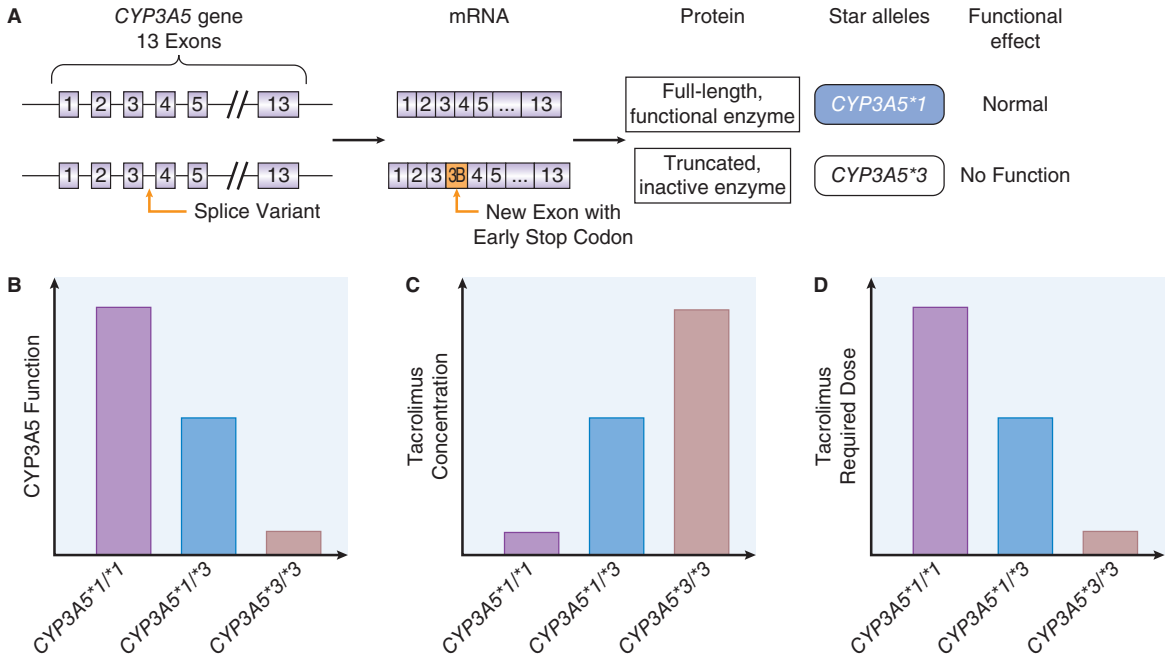

Figure 7–3 *A splice variant in the CYP3A5 gene affects protein function, drug concentrations, and required dose to achieve therapeutic levels.* Panel **A** depicts the *CYP3A5* gene. A common variant in the intron between exons 3 and 4 creates an alternate splice site. Transcription of this allele leads to an mRNA with a new, early stop codon. Translation of the mRNA results in truncated, inactive enzyme. This variant is referred to as the *CYP3A5*3* allele. Individuals with two alleles coding for functional CYP3A5 enzyme (e.g., **1/*1*) have the highest CYP3A5 function, whereas those with two alleles coding for enzyme with no function (e.g., **3/*3*) have the least CYP3A5 function (**B**). *Tacrolimus*, a calcineurin inhibitor/immunosuppressant (see Chapter 39), is a CYP3A5 substrate; thus, when administered the same dose of drug, those with the *CYP3A5*1/*1* genotype will have lower plasma concentrations than those with **1/*3* or **3/*3* genotypes (**C**). To achieve a therapeutic plasma drug concentration, those with the *CYP3A5*1/*1* genotype require higher doses than those with **1/*3* or **3/*3* genotypes (**D**).

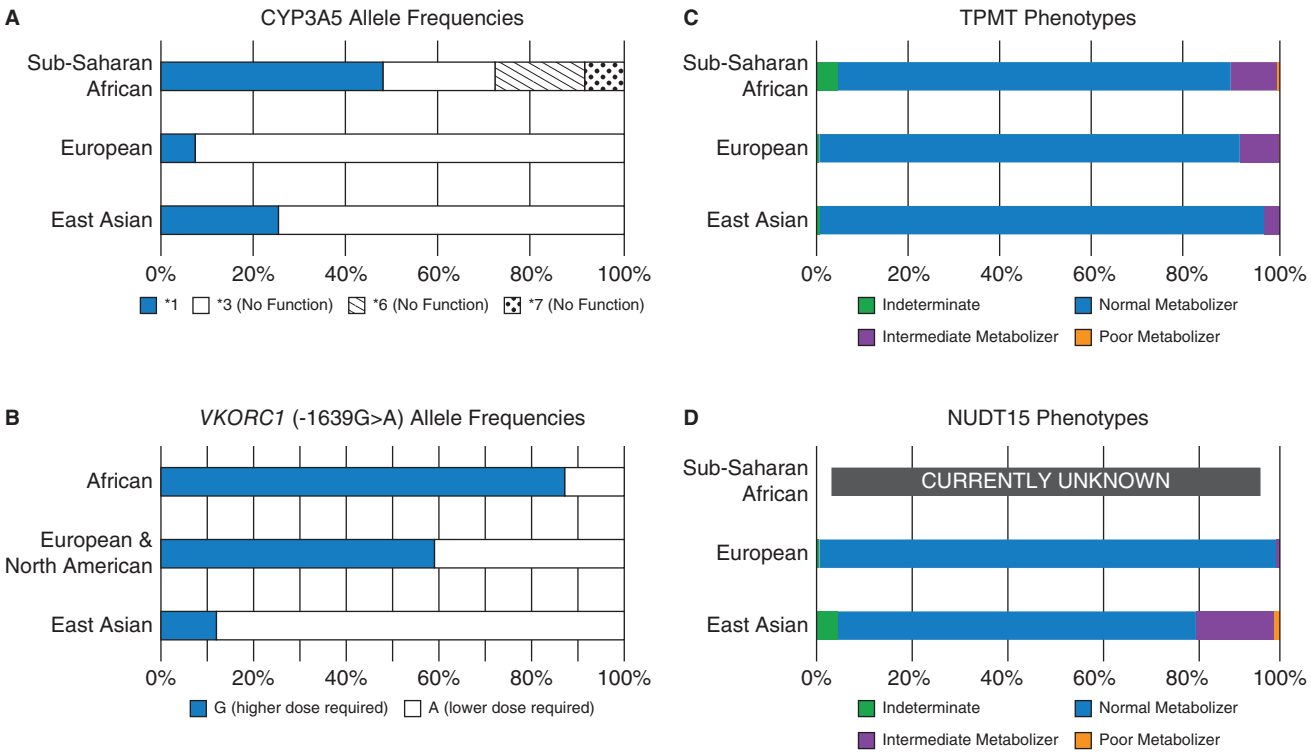

Figure 7–4 *The frequencies of pharmacogenetic variants and metabolizer phenotypes vary across populations.* Panels **A** and **B** depict the allele frequencies for common variants in *CYP3A5* and *VKORC1*, respectively. Of note, the most common *CYP3A5* allele in populations of European ancestry is the no function **3* allele (see Figure 7–3). In contrast, in many African ancestry populations, the functional **1* allele is the most common. In addition, there are variants observed in African ancestry populations that are very rare in other populations (e.g., **6* and **7*). A promoter variant that determines hepatic *VKORC1* expression varies widely by ancestry (**B**). Panels **C** and **D** show the phenotypes resulting from variation in the *TPMT* and *NUDT15* genes, respectively. Poor metabolizer status for either gene can increase risk of toxicity from thiopurine drugs. Of note, TPMT poor metabolizers are rare in East Asian populations, but this same population has a higher frequency of NUDT15 poor and intermediate metabolizers. The frequency of *NUDT15* variants in those of African ancestry has not been well characterized, highlighting the need to include diverse worldwide populations in research efforts.

TABLE 7–2 ■ EXAMPLES OF SELECTED WELL-ESTABLISHED, CLINICALLY ACTIONABLE PHARMACOGENES

GENE	DRUG(S)	RESPONSES AFFECTED
Drug metabolism and transport		
CYP2B6	Efavirenz	Plasma levels, risk for toxicity
CYP2C19	Amitriptyline, citalopram, clopidogrel, escitalopram, lansoprazole, omeprazole, pantoprazole, voriconazole	Drug efficacy
CYP2C9	Celecoxib, flurbiprofen, fosphenytoin, ibuprofen, lornoxicam, meloxicam, phenytoin, piroxicam, siponimod, tenoxicam, warfarin	Drug efficacy, toxicity, or required dose
CYP2D6	Amitriptyline, atomoxetine, codeine, nortriptyline, ondansetron, paroxetine, pitolisant, tamoxifen, tramadol, tropisetron	Drug efficacy, toxicity, or required dose
CYP3A5	Tacrolimus	Required dose
CYP4F2	Warfarin	Required dose
DPYD	Capecitabine, fluorouracil	Toxicity
NUDT15 and *TPMT*	Azathioprine, mercaptopurine, thioguanine	Toxicity and efficacy, risk of second cancers
SLC01B1	Simvastatin	Plasma levels, risk for toxicity (myopathy)
Targets and receptors		
CFTR	Ivacaftor	Efficacy
VKORC1	Warfarin	Anticoagulant effect, bleeding risk
Modifiers		
CACNA1S and *RYR1*	Desflurane, enflurane, halothane, isoflurane, methoxyflurane, sevoflurane, succinylcholine	Risk for toxicity (malignant hyperthermia)
G6PD	Rasburicase, tafenoquine	Risk for toxicity (hemolytic anemia, methemoglobinemia)
HLA-A	Carbamazepine	Risk for toxicity (hypersensitivity reactions)
HLA-B	Abacavir, allopurinol, carbamazepine, fosphenytoin, oxcarbazepine, phenytoin	Risk for toxicity (hypersensitivity reactions)
IFNL3 and *IFNL4*	Peginterferon alfa-2a, peginterferon alfa-2b	Efficacy
UGT1A1	Atazanavir, irinotecan	Risk for toxicity (hyperbilirubinemia)

metabolites and higher concentrations downstream. When the active compound is the parent drug or a metabolite formed upstream of the defect, low enzyme function leads to higher risk for toxicity or ADRs, mimicking an overdose. Increased enzyme function leads to loss of efficacy, as the exposure to active drug is decreased (Roden and Stein, 2009).

The immunosuppressive drug *tacrolimus*, which is metabolized by the CYP3A5 enzyme, provides an example. This drug is known to have a narrow therapeutic index, leading to clinical therapeutic drug monitoring. Individuals with one or two functional copies of *CYP3A5* require higher doses of *tacrolimus* to achieve therapeutic levels of drug (see Figure 7–3) (Birdwell et al., 2015). Because *CYP3A5*1* alleles are more common in individuals of African ancestry and relatively rare in those of European ancestry, it has been suggested that increased rates of transplant rejection in those of African descent may reflect decreased plasma concentrations (Birdwell et al., 2012). Similarly, several proton pump inhibitors, including *omeprazole* and *lansoprazole*, are inactivated by CYP2C19. Thus, CYP2C19 poor metabolizers have higher exposure to active parent drug, a greater pharmacodynamic effect (higher gastric pH), and a higher probability of ulcer cure than CYP2C19 rapid or ultrarapid metabolizers (Furuta et al., 1998; Lima et al., 2021).

A variation on this theme comes from drugs that require bioactivation to achieve pharmacological effect. When that bioactivation is achieved through the action of a single enzyme, variants that decrease enzymatic function can lead to inefficacy, and variants that increase enzymatic function can lead to ADRs (Roden and Stein, 2009). *Clopidogrel*, bioactivated by CYP2C19, is an example (see Table 7–2). CYP2C19 poor metabolizers display decreased antiplatelet effects and increased stent thrombosis during *clopidogrel* treatment (Claassens et al., 2019; Mega et al., 2010; Pereira et al., 2020; Shuldiner et al., 2009). CYP2C19 intermediate metabolizers (~20% of European ancestry populations and >45% of East Asian ancestry populations) receiving *clopidogrel* may achieve adequate antiplatelet effects by increasing the dose. Poor metabolizers (2%–3% of European ancestry populations and >10% of East Asian ancestry populations) should be treated with an alternate antiplatelet drug, because even large dose increases do not lead to drug effect. *Codeine* (a prodrug bioactivated to *morphine* by CYP2D6) provides another example. In CYP2D6 poor metabolizers, analgesia is absent. Perhaps more important, excess *morphine* is generated by CYP2D6 ultrarapid metabolizers, and overdose symptoms, including respiratory depression and death, have been reported (Crews et al., 2021).

Pharmacodynamic Alterations of the Receptor/Target

Genetic alterations leading to changes in the target protein for a drug can lead to variability in drug response. In some cases, drugs are specifically designed to target proteins affected by these changes (see Cancer as a Special Case); in these cases, genetic testing is used to determine the gene sequence and select the appropriate drug. In other instances, variations in the target (whether that is the intended target or a potential off-target interaction) can lead to differences in drug efficacy and toxicity. An example is provided by the aminoglycoside antibiotic drugs and variation in the mitochondrial *MT-RNR1* gene. Aminoglycosides act by binding to the A-site of the 16S rRNA of the 30S ribosomal subunit and altering its conformation, thereby disrupting bacterial protein synthesis (see Chapter 59). Hearing loss is a known dose-related toxicity of aminoglycosides, likely due to off-target binding of drug to human mitochondrial ribosomes in the inner ear, where drug concentrations are high. However, some individuals experience partial or profound aminoglycoside-induced hearing loss after a single dose of drug and with "nontoxic" serum levels. Pharmacogenetic studies have revealed associations of variants in the *MT-RNR1* gene to ototoxicity. These variants are thought to alter the structure of human mitochondrial rRNA, making it more closely resemble bacterial rRNA and increasing affinity for aminoglycosides (Barbarino et al., 2016).

Other examples of drug target variants affecting drug response are presented in Table 7–2. In addition, serotonin receptor polymorphisms have been implicated as predictors of responsiveness to antidepressants and of the overall risk of depression. β Adrenergic receptor polymorphisms have been linked to asthma response, changes in renal function following ACE (angiotensin-converting enzyme) inhibitors, sinus heart rate following β blockers, and the incidence of atrial fibrillation during β blocker therapy. The degree of lowering of LDL (low-density lipoprotein) cholesterol by statins has been linked to polymorphisms in HMG-CoA reductase, the statin target (see Chapter 37). Ion channel polymorphisms have been linked by both candidate gene and exome sequencing approaches to a risk of cardiac arrhythmias in the presence and absence of drug triggers (Kaab et al., 2012; Weeke et al., 2014).

Pharmacodynamic Alterations Beyond the Receptor/Target

There are genetic variants that influence drug outcomes without affecting pharmacokinetics or the pharmacodynamics of the drug's interaction with its target. Instead, these variants alter the outcome of drug exposure through changes in the biologic milieu. One example is seen with G6PD and *rasburicase*, a recombinant enzyme used to prevent and treat hyperuricemia by increasing the breakdown of uric acid to allantoin and hydrogen peroxide (see Chapter 42). As described above, individuals with G6PD deficiency are more susceptible to ADRs to antimalarial drugs. Individuals with G6PD deficiency are unable to handle the increased oxidative stress from the hydrogen peroxide formation and are susceptible to drug-induced lysis of red blood cells (hemolytic anemia) if treated with *rasburicase* (Relling et al., 2014). Further, oxidation of the iron in hemoglobin leads to the formation of methemoglobin, which cannot carry oxygen or carbon dioxide. Methemoglobinemia can lead to arrhythmias, seizures, and death. Although G6PD is not involved in the metabolism of *rasburicase* and is not the target of *rasburicase* action, *G6PD* genotype is highly predictive of ADRs with antimalarials and *rasburicase*. Thus, *rasburicase* is contraindicated in individuals with G6PD deficiency.

Multigenic Pharmacogenomic Traits

Many drug responses have genetically mediated influences on both pharmacokinetics and pharmacodynamics. *Warfarin* is one example (Figure 7–5). The more active *S*-enantiomer of *warfarin* is metabolized by CYP2C9. CYP2C9 poor and intermediate metabolizers require lower steady-state *warfarin* dosages and are at increased risk of bleeding (Aithal et al., 1999; Kawai et al., 2014) (see also Table 36–2). *Warfarin* exerts its anticoagulant effect by interfering with the synthesis of vitamin K–dependent clotting factors, and the target molecule with which *warfarin* interacts to exert this effect is encoded by *VKORC1*, an enzyme in the vitamin K cycle (see Figures 7–5 and 36–6). There are variants that alter the encoded VKORC1 protein and that lead to partial or complete *warfarin* resistance; interestingly, these variants are rare in

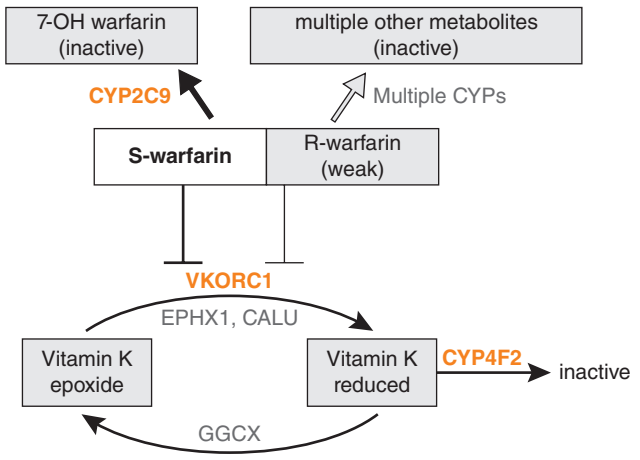

Figure 7–5 *Simplified pharmacokinetic and pharmacodynamic pathways for warfarin, with important pharmacogenes highlighted.* *Warfarin* is primarily metabolized by CYP2C9 to inactive metabolites and exerts its anticoagulant effect partly via inhibition of VKORC1, an enzyme necessary for reduction of inactive to active vitamin K. Reduced vitamin K is metabolized by CYP4F2. Common polymorphisms in all three genes, *CYP2C9*, *VKORC1*, and *CYP4F2*, affect *warfarin* pharmacokinetics and pharmacodynamics.

many populations, but relatively common (5% allele frequency) in Ashkenazi patients and may account for high dosage requirements in carrier subjects. On the other hand, there are promoter variants that lead to low levels of expression of VKORC1; individuals with these variants require lower steady-state *warfarin* doses. These variants are more common in those of Asian ancestry than in European or African ancestry populations (see Figure 7–4). Vitamin K is removed from the vitamin K cycle by the metabolism of reduced vitamin K to hydroxyvitamin K_1, a process that is catalyzed by CYP4F2, and variation in the *CYP4F2* gene has been shown to influence *warfarin* response (Caldwell et al., 2008). Together, inherited variation in *CYP2C9, VKORC1,* and *CYP4F2* accounts for more than 50% of the variability in *warfarin* doses needed to achieve the desired coagulation level (Johnson et al., 2017).

Another example of a drug with multiple genes influencing response is the antiepileptic drug *phenytoin* (and its prodrug *fosphenytoin*). *Phenytoin* is metabolized by CYP2C9; CYP2C9 poor metabolizers are at increased risk for toxicity compared to normal metabolizers due to higher plasma concentrations (see Box 2–3). *Phenytoin* ADRs include Stevens-Johnson syndrome and toxic epidermal necrolysis, which can be life threatening. Risk for these severe ADRs appears to be especially high in patients who carry variants in *CYP2C9* as well as specific human leukocyte antigen B (*HLA-B*) alleles, including *HLA-B*15:02* (see discussion of immunopharmacogenomics below). Thus, knowledge of the genotypes for both *CYP2C9* and *HLA-B* pharmacogenes for an individual can assist in predicting response to *phenytoin* (Karnes et al., 2021).

Cancer as a Special Case

As with many other drugs, variants in the germline (inherited) genome can affect anticancer drug effects. In addition, variants in the tumor (somatic) genome have emerged as a critical determinant of anticancer drug effects.

An example of a germline effect is genetic variation reducing UGT1A1 activity (e.g., in Gilbert's syndrome), which is associated with higher levels of the active metabolite SN-38 of the cancer chemotherapeutic agent *irinotecan* (see Chapter 70), and this increased concentration has been associated with an increased risk of serious toxicities (see Figures 5–6, 5–8, and 5–9). Similarly, for thiopurine drugs, variants in the *TPMT* and *NUDT15* genes alter concentrations of active metabolites and influence risk of bone marrow toxicity (Relling et al., 2013).

Tumor sequencing to identify somatic variants is becoming standard of care for choosing among anticancer drugs in certain settings (see Chapters 69–73). For example, patients with lung cancer with activating mutations in the gene encoding the epidermal growth factor receptor (*EGFR*), display increased responses to the EGFR inhibitor *gefitinib* (Maemondo et al., 2010). Thus, patients with the activating mutation have, in treatment terms, a distinct pharmacogenetic category of lung cancer. Further, EGFR inhibitors are not indicated in patients with tumors that do not carry these EGFR mutations. The human epidermal growth factor receptor 2 (HER2) antibody *trastuzumab* can produce cardiomyopathy in exposed patients. Patients with breast cancer whose tumors express the HER2 antigen may benefit from *trastuzumab*, whereas those whose tumors do not express HER2 do not benefit but are nevertheless susceptible to cardiomyopathy. Similarly, only patients with melanoma whose tumors express the mutant BRAF V600E respond to *vemurafenib*, an inhibitor of BRAF (V600E) kinase; interestingly, *vemurafenib* may also be effective in other tumors (e.g., thyroid cancer, hairy cell leukemia) that express BRAF V600E. Some genetic alterations affect both tumor and host: the presence of two instead of three copies of a thymidylate synthase (*TYMS*) enhancer repeat polymorphism not only increases the risk of host toxicity but also increases the chance of tumor susceptibility to TYMS inhibitors, and the level of TYMS expression in multiple tumor types has been associated with outcome (Johnston et al., 1994; Marsh, 2005).

Immunopharmacogenomics as a Special Case

There are several drugs where toxicity has been associated with HLA alleles. *HLA-B* is one of three genes that comprise the human major histocompatibility complex (MHC) class I cluster. *HLA-A, HLA-B,* and *HLA-C* genes encode a cell surface protein that enables the immune system to distinguish self-proteins from foreign proteins. The HLA genes, and specifically *HLA-B*, are among the most polymorphic genes in the entire genome, and a specific nomenclature system has been developed for them. HLA nomenclature is posted on the IMGT/HLA database, available online (Robinson et al., 2015) (see Table 7–1). As described above, toxicity of *phenytoin* has been linked to a specific allele of the *HLA-B* locus, designated as *HLA-B*15:02*.

The frequencies of specific HLA alleles differ across populations, similar to many pharmacogenetic variants. The *phenytoin* risk allele *HLA-B*15:02* is most prevalent in East Asian and Central/South Asian populations. In some of these populations, up to 20% of individuals carry the risk allele. In contrast, this allele is absent or very rare in populations of European and sub-Saharan African descent. Depending on the population, other *HLA* alleles have been reported to increase risk for ADRs, including the related *HLA-B*15:21, HLA-B*15:11,* and *HLA-B*15:08* alleles in other Asian populations, and the more distinct *HLA-B*56:02* allele in Aboriginal Australian populations (Somogyi et al., 2019). The ability to confidently rule out risk for a *phenytoin* ADR based on HLA testing depends on testing the correct complement of *HLA* alleles for the target population. Incomplete knowledge will lead to false reassurance from a pharmacogenomic test result. Other drugs with ADR risk associated to *HLA* genes include *allopurinol* and *HLA-B*58:01*, *abacavir* and *HLA-B*57:01*, *oxcarbazepine* and *HLA-B*15:02*, and *carbamazepine* and *HLA-B*15:02* (in East Asian individuals) and *HLA-A*31:01* (in European ancestry individuals). The mechanism of action for these HLA-associated ADRs has been proposed to include noncovalent binding of the drug or a metabolite to immune receptors such as HLA or the T-cell receptor; however, the details of the ensuing immunologic response have not been characterized.

Methods for Pharmacogenomic Discovery

Associating Genetic Variation with Variable Drug Actions

Initial studies with pseudocholinesterase deficiency or the poor metabolizer trait used biochemical methods to establish that individuals with aberrant drug responses displayed anomalous *in vitro* behaviors. Thus, for example, a biochemical assay was used to establish the lack of succinylcholine esterase activity in patients with pseudocholinesterase deficiency. In the case of G6PD, it was found that antimalarials increase red blood cell fragility, probably by reducing the levels of the antioxidant glutathione in individuals with G6PD deficiency, leading to profound hemolytic anemia. Drug level assays were used to identify poor metabolizers because of unusually high drug concentrations; further studies, often using liver microsomes, were used to identify common substrates and inhibitors for specific metabolic pathways such as CYP2D6 or CYP2C19. As mentioned above, these methods were then applied to relatives of affected patients or in twin studies to establish that the traits were in fact familial and thus likely genetic.

It was only with the cloning of individual genes in the 1980s and subsequently the cloning of whole genomes that the field could move to identifying specific variants underlying increasingly well-recognized pharmacogenetic traits. Initial studies demonstrated that surprisingly common genetic variants identified in poor metabolizer patients, or liver preparations, did in fact reduce or eliminate enzymatic activity and, thus, were definitively linked to the poor metabolizer trait. Other methods to strengthen the association between a genetic variant and a variable drug response are discussed below. Further studies identified variants responsible for rapid metabolizer phenotypes, including specific missense alleles that increase enzymatic function, CNVs resulting in multiple copies of functional enzyme (e.g., *CYP2D6* duplication, described above), and promotor variants leading to increased expression.

Candidate Gene Versus Agnostic Approaches

In many domains of genome science, associations between logically chosen variants in candidate genes and variable human traits have not been

replicated (Ioannidis et al., 2001) and thus the candidate gene approach has fallen into disfavor. Key pharmacogenetic variants constitute an exception to this general rule. This likely reflects the idea that candidate pharmacogenes were initially identified using clear understanding of the mechanisms of action and disposition pathways of drugs found to exert strikingly variable effects in patients, often through highly variable drug concentrations. This biologic understanding then naturally led to the identification of variation in genes such as *CYP2D6* and pseudocholinesterase as key candidate modulators of variable drug actions; such variants can have relatively large effects, and these associations have been repeatedly replicated.

While the traditional starting point for identifying pharmacogenes has been an understanding of the mechanisms underlying variability in drug action, the agnostic approach of GWAS has also been applied to identify pharmacogenes that mediate important drug responses, notably those underlying ADRs (Motsinger-Reif et al., 2013). Unlike GWAS for common diseases, these studies may generate clear signals at genome-wide significance even with small numbers of subjects. One example is the development of Stevens-Johnson syndrome during treatment with the anticonvulsant *carbamazepine*. Previous studies had implicated the *HLA-B*15:02* as a risk allele in subjects of Asian origin. A GWAS in 65 subjects of European ancestry with Stevens-Johnson syndrome–related ADRs and 3987 controls found an association with *HLA-A*31:01* (McCormack et al., 2011). Studies of dozens of immune-function-related genes assayed with an "immunochip" and a subsequent GWAS have not only validated *TPMT* variants as mediators of thiopurine-related bone marrow suppression (previously identified using candidate gene approaches) but have also identified variants in *NUDT15* (Yang et al., 2014; Yang et al., 2015). This is especially important in subjects of Asian ancestry in whom thiopurine-related toxicity is more common than in other ancestries but *TPMT* variants are less common (see Figure 7–4). Similarly, a GWAS in a small number ($n = 85$) of subjects with *simvastatin*-related myotoxicity and 90 controls identified a strong association with a nonsynonymous variant in *SLCO1B1* (Link et al., 2008), which encodes a transporter (OATP1B1) important for modulating intracellular drug concentrations, although the exact mechanism underlying the toxicity remains undefined. GWAS has validated other associations previously established by candidate gene approaches; examples include *CYP2C19*2* and failure of *clopidogrel* to inhibit platelet function (Shuldiner et al., 2009) and *CYP2C9*, *VKORC1*, and *CYP4F2* variants and variability in changes in *warfarin* maintenance dose (Cooper et al., 2008; Takeuchi et al., 2009).

These GWAS have been enabled by the collection of large numbers of patients exposed to the drugs of interest and phenotyped in some fashion for drug response. These collections can be developed during the course of clinical trials, as in the case of *simvastatin-SLCO1B1*; collected in healthcare systems (*HLA-carbamazepine*); or extracted from very large cohorts developed for epidemiologic study or derived from electronic health records (EHRs). These resources are also enabling GWAS of drug response phenotypes known to be variable but where the candidate gene approach has not yielded large effect size variants. Examples include renal dysfunction during *vancomycin* administration (Van Driest et al., 2015), *heparin*-induced thrombocytopenia (Karnes et al., 2015), ACE inhibitor–related cough (Mosley et al., 2016), and anthracycline-related heart failure (Wells et al., 2017).

Methods to Strengthen the Associations Between Genetic Variation and Variable Drug Actions

With increasing application of exome or whole-genome sequencing in populations, millions of DNA variants are being identified, and methods to establish their function are evolving. *In silico* methods to predict the effects of amino acid substitutions on protein function have been developed using sequence comparisons across species, assuming that mutations of highly conserved residues are more likely to alter protein function. Integrating increasingly well-developed structural models will complement and extend these approaches. Further, while single experimental approaches can suggest a relationship between variable drug responses and a variant in a specific locus or gene, the use of multiple complementary approaches provides the strongest evidence supporting such relationships.

In some cases, the effect of candidate pharmacogenetic variants can be approached in well-defined *in vitro* systems. The activity of nonsynonymous coding region variants in drug-metabolizing or drug transport molecules can be studied using heterologous expression and compared to that of wild type. These approaches can be extended to study the effect of variants on drug interactions with target molecules such as G protein-coupled receptors or ion channels, and in these cases, the assays are tailored to the specific pharmacology of the drug target.

Different approaches must be developed to establish the effect of candidate variants that do not disrupt pharmacogene coding sequence. Liver microsomes expressing wild-type or variant promoter sequences have been used to establish the extent to which promoter variants drive variability in expression of key pharmacogenes, as was done for *VKORC1* (Rieder et al., 2005). A synonymous coding region variant in the drug transport molecule P-glycoprotein encoded by *ABCB1* is associated with variable drug concentrations of substrates such as *digoxin*; *in vitro* studies suggested that the variant results in altered folding of the nascent protein and its insertion into the cell membrane (Kimchi-Sarfaty et al., 2007). It is now possible to generate very large numbers of variants across genes of interest and to use novel high-throughput approaches to simultaneously assess effects on functional properties such as enzymatic activity or cell surface expression in the case of targets such as ion channels (Esposito et al., 2019; Matreyek et al., 2018; Starita et al., 2017).

The effect of drug administration to genotyped humans can be used to define the consequences of variation in candidate pharmacogenes using outcomes such as drug concentrations or effects. The same approach can be used in genetically modified mice or other model systems. An emerging complementary approach is to generate induced pluripotent stem cells (iPSCs) from humans with specific genetic variants of interest; these can then be matured into specific cell types of interest (e.g., hepatocytes, cardiomyocytes) to study the effects of candidate variants. The ability to easily and reliably edit DNA in iPSCs allows the study of specific variants even if human carriers are not available and to control for the genetic background, providing evidence for functional consequence.

Very large DNA biobanks that also capture drug response phenotypes are another emerging tool. These biobanks often capture target phenotypes, including drug response, using EHRs and may complement EHR-based interrogation with direct patient-provided information (Allen et al., 2014; Denny et al., 2019; Roden et al., 2008). Such biobanks have been used to validate and extend (e.g., to other ancestries) known high effect size associations such as *clopidogrel-CYP2C19* and *warfarin-CYP2C19/VKORC1/CYP4F2* (Delaney et al., 2012; Ramirez et al., 2012) and to enable GWAS, as described above.

Cell-based transcriptomics and proteomics have also been used to study modulators of drug response. For example, studying the transcriptomic consequences of exposure to *simvastatin* in cell lines identified six potential modulators of *simvastatin* effect; variants in one of these genes, glycine amidinotransferase, were associated with *simvastatin* myotoxicity in a clinical trial (Mangravite et al., 2013). Large repositories of cell-specific transcriptional profiles (e.g., the GTEx project, see Table 7–1) will enable further studies in this area.

Polygenic Approaches

The traditional view of pharmacogenetics has focused on common variants in one or occasionally a few genes that mediate substantial variability in drug action (e.g., thiopurines, *warfarin*). However, this approach does not capture variability in drug response that arises because of the effects of many small effect size variants across multiple genes, such as those captured by GWAS. GWAS for common disease has enabled the development of polygenic risk scores that may identify individuals at substantially increased disease risk over a lifetime, even in the absence of individual high effect size variants (Khera et al., 2018). A number of studies have now used this approach to analyze polygenic drug responses.

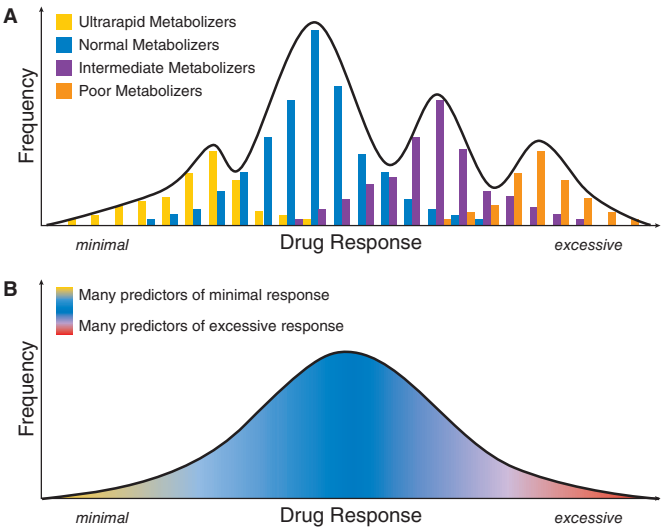

Figure 7–6 *Monogenic and polygenic effects of pharmacogene variation on drug response.* Panel **A** depicts the drug responses that may be observed across a population when the response is predominantly influenced by one or very few genes. Discrete groups may be evident in the population (e.g., representing ultrarapid to poor metabolizers). In contrast, Panel **B** depicts observed drug responses for a drug influenced by many genes. A normal distribution with no clear subgroups is observed, as individuals are on a spectrum from one extreme (many predictors of minimal response) to another (many predictors of excessive response).

Using idealized data, Figure 7–6 depicts the effects of pharmacogene variation on drug response when the variation involves a small number versus a large number of genes.

A polygenic risk score for baseline QTc interval, created by 62 individual variants derived from a large GWAS, predicted both QTc interval prolongation during drug exposure and the risk for the associated arrhythmia torsades de pointes (Strauss et al., 2017). Similarly, polygenic risk scores for coronary artery disease identified patients most likely to derive benefit from newer LDL cholesterol–lowering drugs (Damask et al., 2020; Marston et al., 2020), possibly reflecting the fact that individuals with a higher genetic risk for disease are more likely to respond than those with a high burden of conventional risk factor such as diabetes, hypertension, or smoking. This result may be useful in selecting patients most likely to benefit from newer drugs that are much more expensive than statins. One recent study reported that the extent of variation explained by small and medium effect size variants derived from GWAS accounted for 38% to 98% of variability for 11 drug response phenotypes (Muhammad et al., 2020).

Genomics as a Pathway to Identify New Drug Targets

The identification of genetic pathways in normal physiology and in disease can provide important clues to new drug targets. Indeed, studies from the drug development community suggest that when the actions of a candidate drug are supported by human genetics studies, that drug is three times more likely to be marketed compared to drug candidates for which such evidence is absent (Nelson et al., 2015).

Seminal studies by Brown and Goldstein of patients with the rare disease familial hypercholesterolemia (FH) identified a defect in the regulation of HMG-CoA reductase, the key rate-limiting enzyme in LDL cholesterol biosynthesis (Schekman, 2013). The statins, which inhibit that enzyme, are now among the most effective and widely used medications in cardiovascular therapy (see Chapter 37). PCSK9 contributes to the degradation of LDL receptors, which are responsible for removing LDL cholesterol from the circulation; rare gain-of-function variants in *PCSK9* thereby increase LDL cholesterol and cause FH. Conversely, work in the Dallas Heart Study and in the Atherosclerosis Risk in Communities epidemiologic study showed that relatively common nonsense (i.e., loss-of-function) variants in *PCSK9* in African American subjects associated with lower LDL cholesterol values decreased risk for coronary artery disease (Cohen et al., 2006). This result, in turn, identified PCSK9 as a potential drug target for high LDL in all ancestries, again highlighting the importance of ancestral diversity to enable genomic discovery. In 2015, two antibodies that target PCSK9, *alirocumab* and *evolocumab*, were approved by the U.S. Food and Drug Administration for clinical use in FH and other lipid disorders. These PCSK9 inhibitors prevent degradation of LDL receptors and enhance their recycling to the hepatocyte membrane, thereby facilitating removal of LDL cholesterol and lowering blood LDL cholesterol levels (see Figure 37–5).

In a similar fashion, new drug targets have been identified by work showing that loss-of-function variants reduce risk for common diseases; examples are *APOC3*, where variants lower triglycerides and reduce the risk of coronary artery disease (Stitziel et al., 2014); *SLC30A8*, where variants reduce risk for type 2 diabetes (Flannick et al., 2014); and *HSD17B13*, where variants reduce risk of chronic liver disease (Abul-Husn et al., 2018). Patients homozygous for *SCN9A* loss-of-function variants are pain insensitive (Cox et al., 2006); inhibitors of SCN9A might be useful analgesics.

Hundreds of mutations in the chloride transporter encoded by *CFTR* cause cystic fibrosis, but through diverse mechanisms. *Ivacaftor* partially corrects abnormal gating of certain rare variants of *CFTR* (G551D and others), while *lumacaftor* improves cell surface expression of the most common variant, ΔF508. *Ivacaftor* (Whiting et al., 2014) and the *ivacaftor/lumacaftor* combination (Wainwright et al., 2015) improve symptoms and outcomes in patients with cystic fibrosis. These agents, and other combinations with similar mechanisms of action, have now been approved for genotype-guided use.

One interesting approach using DNA biobanks described above is to turn the GWAS paradigm "on its head" and to ask with what human phenotype a particular genetic variant associates. This "phenome-wide association study" (PheWAS) approach can be used to replicate a GWAS result or to identify entirely new associations (Denny et al., 2016). New associations with variants in genes known to encode drug targets have then been used to suggest new indications for existing drugs ("repurposing") (Diogo et al., 2018; Pulley et al., 2017; Rastegar-Mojarad et al., 2015) and to predict adverse effects of available or new drugs (Jerome et al., 2018).

Genetic variant information is the key driver for the prescribing of newer, targeted anticancer therapies, as described above. GWAS data have also been proposed as a route to identify a target population in whom a new therapy may be especially effective. One example may be the high-density lipoprotein–elevating drug *dalcetrapib*. A large phase III trial showed no difference in clinically important endpoints between treatment and placebo groups, but a subsequent GWAS identified a variant in *ADCY9* (adenylyl cyclase type 9) as a predictor of efficacy (Tardif et al., 2015). Follow-up *in vitro* and mouse studies (Rautureau et al., 2018) supported this suggestion, and a large trial randomizing only subjects with the genotype predicting a favorable drug effect has been mounted.

Pharmacogenetics in Clinical Practice

The increasing understanding of genetic contributors to variable drug actions raises questions of how these data might be used by healthcare providers to choose among drugs, doses, and dosing regimens. One approach is point-of-care testing, in which genotyping is ordered at the time of drug prescription; platforms that reliably deliver relevant genotypes rapidly (often in less than an hour) now make such approaches feasible. However, one difficulty with this approach is that each drug requires a separate assay. An alternate approach envisions genotyping at multiple loci relevant for responses to large numbers of drugs, embedding this information in each patient's EHR, and using clinical decision support to advise on drug selection and dosing when a relevant drug is prescribed to a patient with a variant genotype. This approach is being tested in a number of "early adopter" sites (Rasmussen-Torvik et al., 2014; Van Driest et al., 2014).

TABLE 7–3 ■ ADDITIONAL GENETIC VARIANTS INFLUENCING DRUG RESPONSE

GENE PRODUCT (*GENE*)	DRUGS	EXAMPLES OF RESPONSES AFFECTED
Drug Metabolism and Transport		
CYP2C9 (*CYP2C9*)	Tolbutamide, warfarin*, phenytoin*, nonsteroidal anti-inflammatory drugs*	Anticoagulant effect of warfarin; exposure-related toxicity to phenytoin
CYP2C19 (*CYP2C19*)	Mephenytoin, omeprazole*, voriconazole*, hexobarbital, mephobarbital, proguanil, phenytoin*, clopidogrel*, citalopram*	Peptic ulcer response to omeprazole; cardiovascular events after clopidogrel
CYP2D6 (*CYP2D6*)	β-Blockers*, antidepressants*, anti-psychotics*, codeine*, debrisoquine, atomoxetine*, dextromethorphan*, encainide, flecainide, fluoxetine, guanoxan, *N*-propylajmaline, perhexiline, phenacetin, phenformin, propafenone*, sparteine, tamoxifen*	β-Blocker effect, tardive dyskinesia from antipsychotics, narcotic side effects, codeine efficacy and toxicity, imipramine dose requirement, breast cancer recurrence after tamoxifen
CYP3A4/3A5/3A7 (*CYP3A5/3A5/3A7*)	Macrolides, cyclosporine, tacrolimus, Ca^{2+} channel blockers, midazolam, terfenadine, lidocaine, dapsone, quinidine, triazolam, etoposide, teniposide, lovastatin, alfentanil, tamoxifen, steroids	Efficacy of immunosuppressive effects of tacrolimus
CYP2B6 (*CYP2B6*)	Methadone, cyclophosphamide	Arrhythmia during methadone, ovarian failure during cyclophosphamide
CYP2A6 (*CYP2A6*)	Nicotine	Smoking addiction risk
Dihydropyrimidine dehydrogenase (*DPYD*)	Fluorouracil*, capecitabine*	5-Fluorouracil toxicity; capecitabine toxicity
N-acetyltransferase (*NAT2*)	Isoniazid, hydralazine, sulfonamides, amonafide, procainamide, dapsone, caffeine	Hypersensitivity to sulfonamides, amonafide toxicity, hydralazine- and procainamide-induced lupus, isoniazid neurotoxicity
Glutathione transferases (*GSTM1, GSTT1, GSTP1*)	Several anticancer agents	↓response in breast cancer, ↑toxicity and worse response in acute myelogenous leukemia
Thiopurine methyltransferase (*TPMT*)	Mercaptopurine*, thioguanine*, azathioprine*	Thiopurine toxicity and efficacy, risk of second cancers
UDP-glucuronosyl-transferase (*UGT1A1*)	Irinotecan*, atazanavir	Irinotecan toxicity, hyperbilirubinemia during atazanavir
P-glycoprotein (*ABCB1*)	Natural product anticancer drugs, HIV protease inhibitors, digoxin	↓ CD4 response in HIV-infected patients, ↓ digoxin concentration, drug resistance in epilepsy
UGT2B7 (*UGT2B7*)	Morphine	Morphine plasma levels
Organic anion transporter (*SLCO1B1*)	Statins*, methotrexate, ACE inhibitors	Statin plasma levels, myopathy; methotrexate plasma levels, mucositis
COMT (*COMT*)	Levodopa	Enhanced drug effect
Organic cation transporter (*SLC22A1, OCT1*)	Metformin	Pharmacologic effect and pharmacokinetics
Organic cation transporter (*SLC22A2, OCT2*)	Metformin	Renal clearance
Novel organic cation transporter (*SLC22A4, OCTN1*)	Gabapentin	Renal clearance
Drug Targets		
Thymidylate synthase (*TYMS*)	5-Fluorouracil	Colorectal cancer response
Chemokine receptor 5 (*CCR5*)	Antiretrovirals, interferon	Antiviral response
β_2 Adrenergic receptor (*ADBR2*)	β_2 Antagonists (e.g., albuterol, terbutaline)	Bronchodilation, susceptibility to agonist-induced desensitization, cardiovascular effects (e.g., increased heart rate, cardiac index, peripheral vasodilation)
β_1 Adrenergic receptor (*ADBR1*)	β_1 Antagonists	Blood pressure and heart rate after β_1 antagonists
5-Lipoxygenase (*ALOX5*)	Leukotriene receptor antagonists	Asthma response

(*Continued*)

TABLE 7–3 ■ ADDITIONAL GENETIC VARIANTS INFLUENCING DRUG RESPONSE (*CONTINUED*)

GENE PRODUCT (*GENE*)	DRUGS	EXAMPLES OF RESPONSES AFFECTED
Dopamine receptors D_2, D_3, D_4 (*DRD2, DRD3, DRD4*)	Antipsychotics (e.g., haloperidol, clozapine, thioridazine, nemonapride)	Antipsychotic response (D_2, D_3, D_4), antipsychotic-induced tardive dyskinesia (D_3) and acute akathisia (D_3), hyperprolactinemia in females (D_2)
Estrogen receptor α (*ESR1*)	Estrogen hormone replacement therapy	High-density lipoprotein cholesterol
Serotonin transporter 1 (*SLC6A4, 5-HTT*)	Antidepressants (e.g., clomipramine, fluoxetine, paroxetine, fluvoxamine)	Clozapine effects, 5HT neurotransmission, antidepressant response
Serotonin receptor (*HTR2A, 5-HT$_{2A}$*)	Antipsychotics	Clozapine antipsychotic response, tardive dyskinesia, paroxetine antidepression response, drug discrimination
HMG-CoA reductase (*HMGCR*)	Statins	Reduction in serum cholesterol
Vitamin K oxidoreductase (*VKORC1*)	Warfarin*	Anticoagulant effect, bleeding risk
Corticotropin releasing hormone receptor (*CRHR1*)	Corticosteroids	Response to corticosteroids in asthma
Ryanodine receptor (RYR1)	General anesthetics*	Malignant hyperthermia
Modifiers		
Apolipoprotein E (*APOE*)	Statins (e.g., simvastatin)	Lipid-lowering
Human leukocyte antigen (*HLA-A, HLA-B*)	Abacavir*, carbamazepine*, phenytoin*, allopurinol*	Hypersensitivity reactions
G6PD deficiency (*G6PD*)	Rasburicase*, dapsone*	Methemoglobinemia, hemolytic anemia
Cholesteryl ester transfer protein (*CETP*)	Statins	Slowing atherosclerosis progression
Cardiac ion channels (*KCNH2, KCNQ1, KCNE1, KCNE2*)	QT prolonging antiarrhythmics (e.g. sotalol, dofetilide, quinidine), many other drugs (e.g. erythromycin, methadone, thioridazine, haloperidol, pentamidine)	Drug-induced polymorphic ventricular tachycardia (*torsades de pointes*), increased QT interval
Coagulation factor V (*F5*)	Oral contraceptives	Venous thrombosis
Voltage-gated K^+ channel interacting protein 4 (*KCNIP4*)	ACE inhibitors	Cough

*Drug-gene pair included on U.S. Food and Drug Administration Table of Pharmacogenomic Biomarkers in Drug Labeling, available at *https://www.fda.gov/drugs/science-and-research-drugs/table-pharmacogenomic-biomarkers-drug-labeling*; accessed 29 May 2022.

There are several barriers that must be addressed if either approach is to become widely adopted. *First*, the evidence linking a variant to a variable drug response must be solid, the variable outcome must be clinically important, and some form of genetically guided advice should be provided (e.g., choose another drug, choose another dose). Drug-gene pairs such as *clopidogrel-CYP2C19* or *warfarin-CYP2C19/VKORC1/CYP4F2* may fall into this category; the Clinical Pharmacogenomics Implementation Consortium provides guidelines on such advice by genotype across multiple drugs (Table 7–1) (Relling et al., 2020). *Second,* the strength of the evidence supporting a genotype-specific prescribing strategy varies. The strongest level of evidence comes from randomized clinical trials (RCTs), in which a clinically important, genotype-guided treatment strategy is compared to a standard of care. Using this approach, genotyping for *HLA-B*57:01* has been shown to eliminate the risk for severe skin reactions (e.g., Stevens-Johnson syndrome) during treatment with the antiretroviral agent *abacavir* (Mallal et al., 2008). RCTs comparing *clopidogrel* to other antiplatelet agents have shown fewer bleeding events and no increase in stent thrombosis (the ADR associated with failure of *clopidogrel* bioactivation) with a genotype-guided approach (Claassens et al., 2019; Pereira et al., 2020). A number of trials have studied the utility of genotyping for *CYP2C9* and *VKORC1* variants during *warfarin* therapy. When the main outcome metric has been duration of drug exposure in therapeutic range during the first 30 to 90 days of therapy, the results have been inconsistent, with none showing a huge effect (Kimmel et al., 2013; Pirmohamed et al., 2013). These studies have few bleeding events, and an RCT that focused on bleeding as a primary endpoint did show a significant benefit of a genotyping approach to therapy (Gage et al., 2017). EHR-based case-control studies looking at *warfarin*-related bleeding have implicated variants in *CYP2C9* or *CYP4F2* as risk alleles (Kawai et al., 2014; Roth et al., 2014). Nonrandomized study designs are weaker than RCTs, but performing RCTs to target small subsets of patients carrying uncommon variants may not be feasible. There is debate about the level of evidence required for clinical implementation of pharmacogenetics, since adjustments to drug choice and dosing are routinely pursued by clinicians for other factors, without supporting evidence from RCTs (e.g., drug choice based on ADR risk and dose reduction for renal impairment).

An 8100-patient European RCT (van der Wouden et al., 2017) is comparing usual therapy for 43 target drugs to therapy guided using a multiplexed assay that interrogates variants in 13 key pharmacogenes. The study has randomized hospital systems in seven countries using a crossover design (18 months using standard therapy; 18 months genotype-guided). The results should be available in 2022.

Chapter 8

Postmarketing Drug Safety

C. Michael Stein and Wayne A. Ray

Introduction

Initiatives to improve the safety of drugs after they are marketed arose from the recognition that rare potentially serious adverse drugs reactions (ADRs) are usually identified only after a drug is in clinical use. One has only to recall the example of phocomelia in newborns from exposure to *thalidomide*, a drug not approved for use in the U.S. at the time but used widely elsewhere from 1957 to 1961 to treat morning sickness in pregnant women and that caused congenital malformations in over 10,000 children (Vargesson, 2015). As a result of this tragedy and other ADRs, many countries have developed postmarketing surveillance systems to identify ADRs and to determine their prevalence and impact.

Approaches to drug safety have evolved in response to increased recognition of three important principles. First, the safety and efficacy of a drug are not fixed at the time of its approval but must be reassessed over its life cycle. Second, drug safety after marketing is affected not only by rare ADRs but also (and perhaps more importantly) by increased risk of common events not recognized initially as ADRs (e.g., myocardial infarction with *rofecoxib*). Third, strategies that mitigate risk effectively can allow drugs with serious adverse effects to remain on the market (e.g., use of *thalidomide* for multiple myeloma).

Counterfeit, substandard, and adulterated drugs; incorrect or unsafe clinical use; overdose; and accidental exposure to drugs also impact drug safety (Figure 8–1). This chapter focuses on efforts to improve drug safety by identifying and managing risks associated with the drug and its appropriate use in clinical practice after it is marketed, and on subsequent reevaluation of the drug's risk-benefit ratio. Many countries implement variations of the approaches we describe; for simplicity, we describe the U.S. system.

History of Postmarketing Drug Safety

Landmark Laws That Improved Drug Safety

Three landmark laws in the U.S. have been enacted in response to public health disasters. These laws focused on improving evidence of preclinical safety, clinical efficacy, and postmarketing safety, respectively.

1. The Food, Drug, and Cosmetic Act of 1938 was passed in response to the death of more than 100 patients who received a preparation of *sulfanilamide* elixir with diethylene glycol as a solvent (Paine, 2017). The legislation required that manufacturers test new drugs for toxicity before marketing to prove their safety.
2. The Kefauver-Harris amendment to the Food, Drug, and Cosmetic Act of 1962 was a response to the aforementioned *thalidomide* disaster. The U.S. avoided that disaster because a reviewer for the U.S. Food and Drug Administration (FDA), Francis Kelsey, did not allow the approval of *thalidomide* due to concerns about insufficient safety data and risk of peripheral neuropathy (Ross and Kesselheim, 2015). The legislation required proof of drug efficacy in well-controlled clinical studies prior to marketing and report of serious side effects (Greene and Podolsky, 2012; Ross and Kesselheim, 2015).
3. The FDA Amendments Act of 2007 was developed after a reexamination of postmarketing drug safety resulted in an Institute of Medicine (IOM) report (IOM, 2007) in response to the withdrawal of *rofecoxib* from the market for increased risk of myocardial infarction and stroke after millions of people had been exposed and potentially tens of thousands suffered serious adverse events (Topol, 2004). The legislation instructed the FDA to build a population-based surveillance system; allowed authorities to require changes to the label, postapproval studies, and risk evaluation and mitigation strategies (REMS); and mandated that the parties responsible for clinical trials post information about the trials and their results in a public database (Avorn et al., 2018).

Why We Need Postmarketing Drug Safety Information

Premarketing Clinical Trials Do Not Adequately Define the Safety of a Drug

Premarketing clinical trials are essential to determine if the benefits of a medication outweigh its immediate risks, but the idea that a drug is safe because it has passed the threshold required for marketing fails to recognize the limitations of premarketing trials.

Abbreviations

ADR: adverse drug reaction
CI: confidence interval
DSC: drug safety communication
FAERS: FDA Adverse Event Reporting System
HR: hazard ratio
HRT: hormone replacement therapy
ICSR: individual case safety report
IOM: Institute of Medicine
RCT: randomized controlled trial
REMS: risk evaluation and mitigation strategy

Premarketing Trials Are Small

The total number of patients exposed to a new drug in the clinical trials that lead to approval is often in the hundreds or low thousands. In the 253 pivotal clinical trials for 109 new drugs and biologics approved between 2015 and 2017, the median number of patients studied was 467 (interquartile range, 209–722) (Zhang et al., 2020). For several medications withdrawn from the market, the contrast between the small number of patients studied in premarketing trials and the large number exposed prior to withdrawal is striking (Table 8–1) (Friedman et al., 1999).

The small number of patients studied in most premarketing clinical trials makes it impossible to detect uncommon side effects and accurately define the prevalence of common ones (Table 8–2). For example, the antidepressant *nefazodone* causes liver damage at the rate of one case of death or transplant per 250,000 to 300,000 patient-years, an event that could not be captured reliably even in a large clinical trial. Also, with small premarketing studies, there is little chance of identifying subgroups of patients more likely to suffer particular adverse effects. For example, the increased risk of angioedema after treatment with an angiotensin-converting enzyme (ACE) inhibitor in patients of African ancestry was recognized only long after the drugs were marketed (Brown et al., 1996).

Genetic variation is an important risk factor for adverse drug responses (ADRs); in small clinical trials, there will be few patients with uncommon, but important, genetic variants. For example, approximately 0.3% of people of European ancestry are homozygous for genetic variants in *TPMT*, the gene that encodes the enzyme thiopurine methyltransferase that metabolizes thiopurine drugs such as *azathioprine* and *6-mercaptopurine*. These people are at risk of life-threatening myelosuppression if they receive thiopurines (Osanlou et al., 2018). The genetic mechanisms underlying an ADR may be unknown during premarketing drug trials (e.g., *abacavir* hypersensitivity in patients carrying HLA-B*5701), and there may be a delay in recognizing the clinical importance of patient genetics. Consider the interaction of CYP2D6 with *codeine*: CYP2D6 metabolizes *codeine* to *morphine*, the active analgesic. *CYP2D6* polymorphisms give rise to a range of activities, from absent or very slow to ultrarapid metabolization. As a result, children who are ultrarapid metabolizers of *codeine* are at risk of respiratory depression, a symptom of opiate excess, whereas very slow metabolizers may be undertreated for pain (see Chapters 7 and 23).

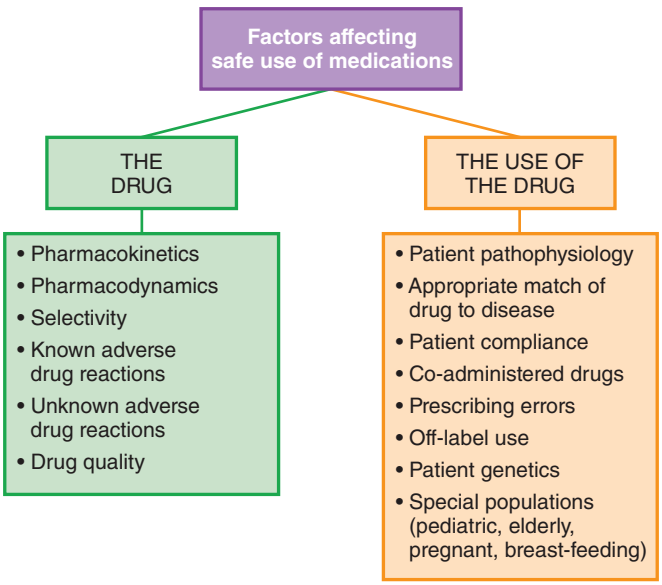

Figure 8–1 *Postmarketing drug safety is affected by many factors intrinsic to the drug itself and the way it is used.*

TABLE 8–1 ■ FIVE ILLUSTRATIVE DRUG WITHDRAWALS

These examples illustrate that drugs may be approved based on studies in a small number of patients in clinical trials yet be later withdrawn when postmarketing surveillance of a much larger patient cohort reveals safety issues.

DRUG	NUMBER OF PATIENTS EXPOSED TO THE DRUG IN PREMARKETING STUDIES	NUMBER OF PATIENTS EXPOSED POSTMARKETING BEFORE THE DRUG WAS WITHDRAWN
Terfenadine	5000	7,500,000
Fenfluramine	340	6,900,000
Dexfenfluramine	1200	2,300,000
Mibefradil	3400	600,000
Bromfenac	2400	2,500,000

Source: Adapted from Friedman MA, et al. The safety of newly approved medicines: do recent market removals mean there is a problem? *JAMA*. **1999**, *281*:1728–1734.

Premarketing Trials Are Short

Although some drugs are used by patients for years, even for life, premarketing clinical trials are relatively short. The median duration of pivotal clinical trials for drugs and biologics approved between 2015 and 2017 in the U.S. was 24.0 weeks (interquartile range, 12.0–37.6 weeks); only 46.2% of drugs were supported by one or more clinical trials of at least 6 months in duration (Zhang et al., 2020). Serious adverse effects may only manifest after long-term use of a drug or after a long latent period and thus would not emerge in premarketing studies. For example,

TABLE 8–2 ■ EXAMPLES OF THE INCREASES IN RELATIVE RISK THAT ARE DETECTABLE FOR OUTCOMES OF VARYING FREQUENCY IN CLINICAL TRIALS OF DIFFERENT SIZE COMPARING A DRUG TO A CONTROL

EVENT PROPORTION (RISK) IN CONTROLS	SAMPLE SIZE (BOTH ARMS)		
	2000 PATIENTS	4000 PATIENTS	8000 PATIENTS
	DETECTABLE RELATIVE RISK		
5 per 100	1.73	1.50	1.34
1 per 100	3.04	2.31	1.86
5 per 1000	4.32	3.05	2.31
1 per 1000	13.13	7.77	4.95

Calculations assume a trial in which the follow-up for both the control and treatment arms is fixed (e.g., 30 days or 1 year) and the outcome is binary. They assume 90% power, a two-sided type 1 error of 0.05, a 1:1 ratio between patients receiving control and study drug, and a null hypothesis that the true relative risk is 1.0. Relative risk is the ratio of risk in the treatment group to that in the control group; a relative risk of 1.50 indicates a 50% increase in risk.

bisphosphonates—used to prevent and treat osteoporosis, often a lifelong condition—have infrequent side effects such as avascular necrosis of the jaw and atypical femoral shaft fractures that typically occur after long-term therapy. Moreover, because premarketing studies are short, the relationship between duration of therapy and long-term efficacy is poorly defined. Thus, despite lack of rigorous studies, current practice for treating osteoporosis has evolved to recommending bisphosphonate drug holidays for some patients with the aim of decreasing the risk of long-term side effects while maintaining protection against fractures (Camacho et al., 2020).

Premarketing Trials Study Select Populations

The primary goal of premarketing clinical trials is to demonstrate efficacy and safety (i.e., acceptable benefit vs. risk). The most efficient approach is to study a homogeneous population selected to maximize the efficacy signal and minimize the risk of adverse events. Thus, many premarketing studies exclude or have small numbers of children, pregnant women, patients older than 75 years of age, subjects with comorbidities such as impaired renal function, and patients at high risk of adverse events or drug-drug interactions. Consequently, new information about such patient groups frequently only emerges after marketing. For example, even for statins, one of the most intensively studied and heavily prescribed classes of drugs, the cardiovascular benefits of treating elderly patients (Gencer et al., 2020) and the increased risk of diabetes (Swerdlow et al., 2015) were shown only recently.

As a result of the premarketing approval process, a drug that has been studied in a few hundred or thousand carefully selected people can be prescribed rapidly to millions of people that include patient populations and indications not studied in premarketing trials. For example, the high dose of *rofecoxib* (50 mg/day) that subsequently was found to confer a 5-fold increased risk of myocardial infarctions (Curfman et al., 2005) was approved only for the treatment of acute pain for a maximum of 5 days but was prescribed widely off-label to patients with chronic pain for long periods of time (Griffin et al., 2004), substantially increasing their risk of adverse cardiovascular effects.

Premarketing Trials Often Use Surrogate Endpoints

The goal of treatment with a drug is to improve direct measures of patient health such as survival, prevention of disease, symptoms, or function. To reduce trial size or shorten its duration, premarketing studies often use surrogate endpoints—biomarkers or other measures thought to mediate or be predictors of the ultimate clinical endpoint (Fleming and DeMets, 1996). Examples of surrogate endpoints include blood pressure, lipid levels, hemoglobin A_{1c}, and CD4 counts. Some surrogate endpoints such as HIV viral load (plasma HIV ribonucleic acid [RNA] levels) are excellent predictors of clinical outcomes and response to drug therapy; however, others have been misleading. For example, ventricular premature depolarizations are a risk factor for mortality after myocardial infarction; the antiarrhythmic drugs *flecainide* and *encainide* reduced ventricular premature depolarizations (the surrogate endpoint); thus, these two agents were widely used to prevent death after myocardial infarction until the CAST clinical trial showed they increased rather than decreased mortality in this setting (Echt et al., 1991).

Surrogate endpoints are frequently used for drug approval, particularly for drugs evaluated through one of the special expedited programs of the FDA (Priority Review, Accelerated Approval, Fast Track, Breakthrough Therapy) designed for drugs that address unmet medical needs for serious or life-threatening conditions. An analysis of 253 pivotal U.S. premarketing trials supporting new drugs and biologics approved from 2015 to 2017 found that, overall, 59% used surrogate endpoints. The rate was 67% in 128 trials for drugs that used any expedited regulatory approval program and 51% in 125 trials for drugs that did not use such programs (Zhang et al., 2020). Thus, when a drug is marketed, its effect on the endpoints of major interest may not be known.

Experience with medications for diabetes illustrates the pitfalls inherent in surrogate endpoints. Although the effect of an antidiabetic drug on blood glucose or the hemoglobin A_{1c} fraction is important, a major goal of treatment is to prevent the complications of diabetes. However, the assumption that a drug's hypoglycemic effect predicts its clinical outcomes has been shown to be flawed. The thiazolidinedione antidiabetic medication *rosiglitazone* was approved in 1999 based on short-term trials of glycemic control; however, in 2007, a meta-analysis of randomized controlled trials found an increased risk of myocardial infarctions due to *rosiglitazone* (Psaty and Furberg, 2007). The ensuing controversy led the FDA to recommend that trials for new antidiabetic drugs should be large enough to exclude an increase in cardiovascular risk of 30% or larger. In order not to delay drug introduction, the guidelines indicated that a two-stage approach was permissible, with premarketing trials powered to exclude an increase of 80% or greater (Chong et al., 2020) and subsequent postmarketing trials powered to exclude an increase of 30% or greater. The mandate resulted in large postmarketing cardiovascular outcomes studies that identified a reduction in cardiovascular risk for the newer sodium-glucose cotransporter-2 inhibitor (SGLT2i) and glucagon-like peptide-1 receptor agonist (GLP-1 RA) antidiabetic drugs.

More recently, the FDA has proposed a new approach for approval of antidiabetic drugs to replace the previously required postmarketing studies to establish cardiovascular safety. Rather than postmarketing studies of cardiovascular drug safety, large premarketing studies will be required that ensure adequate exposure (both the number of patients and the duration of exposure) to the new drug and include patients with common diabetes comorbidities such as cardiovascular disease and impaired renal function (Chong et al., 2020). Table 8–2 illustrates examples of risk for any ADR that such an approach could exclude in large clinical trials of *different* sizes. It is striking that even for a relatively common ADR (e.g., occurring at a rate of 1 event per 100 controls) a study of 8000 patients (4000 each receiving new and control drug) would be unable to exclude an increase in relative risk smaller than 1.86 (i.e., an 86% increase in relative risk) with 90% confidence.

Premarketing Trials Seldom Use Active Comparators

The basis of the FDA requirement for premarketing trials is the language of the 1962 Kefauver-Harris amendments requiring "adequate and well-controlled investigations" to demonstrate efficacy. This requirement has been interpreted to permit placebo-controlled studies because trials that compare a new agent to the best available therapy generally require substantially greater sample size. Consequently, premarketing studies frequently compare a new drug to a placebo; only 29% of pivotal U.S. premarketing studies from 2015 to 2017 used an active comparator (Zhang et al., 2020). As a result, when a drug is marketed, prescribers and patients may not know how the efficacy and safety of the new drug compare to that for drugs already on the market.

New Serious Adverse Drug Effects Are Commonly Discovered After a Drug Is Marketed

As newly approved medications are administered to large numbers of patients over prolonged periods of time, adverse effects are frequently identified by postmarketing surveillance. Between 2001 and 2010, the FDA approved 222 novel drugs and biologics; there were 123 postmarketing safety events (3 withdrawals from the market, 61 boxed warnings, and 59 safety communications) affecting 71 of the new therapies (Downing et al., 2017). Safety-related changes to the drug label are even more common, affecting 70% of drugs after marketing: For 278 new molecular entities approved between 2002 and 2014, there were 703 label changes addressing 2505 safety issues (Pinnow et al., 2018). Label updates occurred throughout the follow-up period of up to 13.2 years and included the addition of 51 (2%) and 842 (33.6%) safety issues to the "boxed warnings" and "warnings and precautions" sections of the label, respectively.

A Life Cycle Approach to Drug Safety

Historically, a drug was often considered "safe" because it had been approved for marketing until events occurred that showed it was "unsafe." However, experience shows that it is dangerous to consider a drug safe

because it has passed the safety threshold required for marketing. Given the many limitations of premarketing trials, a critical experiment takes place after the drug is marketed. We increasingly recognize that information about safety and efficacy evolves over the life cycle of the drug as new knowledge emerges, a central theme that guides modern approaches to drug safety. These approaches include organized systems for reporting and monitoring cases of potential adverse events, controlled postmarketing studies, and vigorous regulatory efforts to assure that new safety information is reflected in clinical practice (Avorn et al., 2018; IOM, 2007).

Approaches to Postmarketing Surveillance

Case Reports and Spontaneous Adverse Event Reporting Systems

Reports of suspected cases of adverse drug effects, including those from spontaneous adverse event reporting systems, can quickly identify potential drug safety problems when drugs are administered to large populations. Such reporting systems are the foundation of postmarketing drug safety surveillance and have rapidly identified many prominent serious ADRs. For example, case reports identified the teratogenicity of *thalidomide* (Avorn, 2011) and the cardiac valvular abnormalities related to *fenfluramine-phentermine* (Connolly et al., 1997). To improve detection of ADRs beyond case reports published in the medical literature, many countries have developed adverse event reporting systems that collect and interpret spontaneous reports of adverse events, such as the FDA Adverse Event Reporting System (FAERS) in the U.S.

The FAERS database is large (Table 8–3), currently receives more than 2 million reports a year, and is accessible to the public (FDA, 2021). Healthcare providers and consumers can report adverse events to the FDA voluntarily through the MedWatch system; reporting these is mandatory for drug manufacturers. The FDA monitors reports in FAERS, issues a quarterly report of new safety information and potential signals of serious risk, and undertakes additional studies if warranted.

Limitations of Spontaneous Reporting Systems

Calculation of the frequency of a particular adverse reaction requires accurate knowledge of the numerator (occurrences of the adverse response) and the denominator (patients exposed to the drug). Neither of these numbers is easy to obtain accurately. The circumstances surrounding the adverse reaction—including severity, duration and dose of the suspect drug, concomitant medications, comorbidities, and patients at greatest risk—may be critical to evaluate causality. Thus, the limitations of spontaneous reporting systems are numerous.

Small Fraction of Cases Reported. Spontaneous reporting systems cannot define how often a particular adverse event occurs with a particular drug (the numerator) because there is substantial underreporting and reporting patterns can change unpredictably over the life cycle of a drug. An analysis across 12 countries found a median underreporting rate of 94% (Hazell and Shakir, 2006). Furthermore, factors such as media coverage, litigation, and how long a drug has been on the market influence reporting. Thus, comparisons of the relative frequency of adverse event reports for a new drug to those of an established drug usually will be misleading (Hazell and Shakir, 2006).

Denominator Is Unknown. Databases of spontaneous adverse event reports contain no information about the total number of patients who received a drug (the denominator). The potential number of patients exposed is often inferred from information about drug sales, but this may not reflect actual use accurately (Hazell and Shakir, 2006), and information about use in pertinent subpopulations or clinical settings is not available.

The Information in Case Reports Often Is Incomplete. Spontaneous reports are frequently missing critical information. The quality of individual case safety reports (ICSRs) in FAERS for the outcome of death, the most serious adverse event, illustrates the problem (Table 8–4). Approximately a quarter of these ICSRs recorded only the outcome of death and no other adverse events; these reports lacked important information more often than those that included additional adverse events (Marwitz et al., 2020). However, both sets of ICSRs were suboptimal; reports with death as the only adverse event and those that included additional adverse events frequently lacked information such as cause of death, past medical history, concomitant medications, and when the drug was started.

It Is Difficult to Detect a Small-to-Moderate Increased Risk for a Common Event. Because of these limitations, true event rates can almost never be calculated from spontaneous reporting systems. If such a rate is estimated, it cannot be compared to that in other medications for the same indication nor can it be adjusted for critical patient comorbidity. Consequently, spontaneous adverse event reporting systems are unable to detect small-to-moderate increases in events that are not rare; this requires properly controlled studies. For example, cardiovascular events are not unexpected in elderly patients, particularly those with diabetes or hypertension, and thus are unlikely to trigger an adverse event report. However, because many more people have myocardial infarction than liver failure, a drug that causes what may appear to be a small increase in a common event (e.g., a relative risk of 1.2 for myocardial infarction) will have a far greater effect on public health than one that causes a rare but eye-catching event such as liver failure.

Finding True Signals Is Challenging. One common use of adverse event reporting systems is to screen for potential adverse events that

TABLE 8–3 ■ NUMBER AND TYPE OF INDIVIDUAL SAFETY CASE REPORTS IN THE FDA ADVERSE EVENT REPORTING SYSTEM FROM 1968 TO MARCH 31, 2022

REPORT	NUMBER OF REPORTS
Total reports	24,251,919
Reports with serious adverse events[a]	13,552,221
Reports with death as outcome	2,290,629

[a]Serious adverse events do not include deaths.
Data are as of June 30, 2021, and adapted from the FDA Adverse Event Reporting public dashboard. https://fis.fda.gov/sense/app/95239e26-e0be-42d9-a960-9a5f7f1c25ee/sheet/7a47a261-d58b-4203-a8aa-6d3021737452/state/analysis, accessed May 23, 2022.

TABLE 8–4 ■ INFORMATION PRESENT IN REPORTS WITH DEATH AS THE OUTCOME IN THE FDA ADVERSE EVENT REPORTING SYSTEM

REPORT INCLUDES	REPORTS WITH DEATH AS ONLY ADVERSE EVENT (N = 994)	REPORTS WITH DEATH AND OTHER ADVERSE EVENTS (N = 998)
Age	76%	84%
Sex	85%	91%
Concomitant medications	10%	41%
Cause of death	7%	72%
Past medical history	54%	74%
Causality assessment	29%	64%
All of criteria on the three lines above	2%	40%

Data are from a stratified random sample of 2000 individual case safety reports in the FDA Adverse Event Reporting System through December 31, 2017, with death reported as the outcome.
Source: Data are extracted from Marwitz K, et al. An evaluation of postmarketing reports with an outcome of death in the US FDA adverse event reporting system. *Drug Safety,* **2020**, *43*:457–465.

warrant further evaluation (signals). The large number of reports and the limitations of their data make it difficult to identify signals. Quantitative signal detection methods have evolved that do not require information about the true volume of drug use (the denominator) but rely only on the spontaneous adverse event database. These approaches often use disproportionality methods that contrast the observed number of particular adverse events reported for a particular drug with the number expected based on information in the entire database (Hazell and Shakir, 2006). However, their accuracy relies on several assumptions that are difficult to verify.

Appropriate Use of Case Reports. Although one does not need to be certain of causality to publish a case report or file an adverse event report, confidence about a causal relationship between a drug and an adverse event is essential for guiding decisions that affect public safety. Thus, signals from spontaneous reporting systems nearly always require additional evaluation. Case reports are most valuable for inferring a causal relationship between a drug and an adverse event when the event is otherwise rare, has few other risk factors, has a close temporal relation with exposure (e.g., anaphylaxis, Stevens-Johnson syndrome), and the drug confers a large excess risk (e.g., rhabdomyolysis with *cerivastatin*; Table 8–5) (Staffa et al., 2002). When these conditions can be met, no other technique can identify adverse drug effects as quickly or inexpensively.

Controlled Studies

Controlled studies can assess signals that arise from case reports and identify new potential drug safety problems. The studies can be observational pharmacoepidemiologic studies, including those from the FDA Sentinel Initiative, or postmarketing clinical trials.

Observational Pharmacoepidemiologic Studies

Pharmacoepidemiologic studies of the relationship between a drug and a potential adverse event frequently use routinely collected clinical or insurance data (real-world data) such as that from large health maintenance organizations and the Medicare and Medicaid programs. The data include records of drug exposures and other medical care encounters that can define both potential outcomes and patient comorbidity. Although much less cumbersome than clinical trials, these epidemiologic studies involve considerable time and expense and may take years to complete. They require identifying one or more suitable databases, obtaining data access (including requisite permissions and payments), cleaning the data, extracting the relevant information, checking data quality, and performing analyses.

The Sentinel System

To facilitate more timely observational studies, the FDA started the Sentinel Initiative. The Sentinel System has evolved into a partnership between the FDA and more than 30 organizations that include academic sites and managed care organizations with access to curated electronic health information on over a 100 million people (Dal Pan, 2019). Participating sites can perform analyses on their own data behind their own firewall and return the results for central analysis, although, when necessary, patient-level analytic data sets can be returned to the Sentinel Operations Center (Adimadhyam et al., 2020). All sites use a Sentinel Common Data Model and have access to a suite of reusable analytical tools that can be used or modified for particular studies (Adimadhyam et al., 2020; Dal Pan, 2019). These include propensity score matching, a statistical technique to reduce confounding in nonrandomized studies by matching individuals in different cohorts for a large number of covariates. Because sites maintain control of their own data, there are fewer concerns about loss of patient privacy or use of the data for commercial advantage; however, a disadvantage of this model is heterogeneity amongst participating sites in data quality and completeness.

The Sentinel System has provided information about drug utilization and has been employed to assess drug safety signals observed in FAERS (*olmesartan*/sprue-like enteropathy, rotavirus vaccine/intussusception, various vaccine combinations/febrile seizures) and has provided information that has obviated the need for expensive postmarketing clinical trials (Adimadhyam et al., 2020; Dal Pan, 2019). As Sentinel has grown in resources and complexity, plans have become more ambitious; in addition to signal assessment and refinement, Sentinel aims to include signal detection, use of artificial intelligence, and expansion of the system to incorporate large-scale pragmatic trials that use real-world data (the FDA-Catalyst program).

Real-World Data: Strengths and Weaknesses

Pharmacoepidemiologic studies, including those supported by the Sentinel System, address many of the limitations of clinical trials. Clinical trials are expensive, complex, may take years to complete, and lack generalizability, thereby precluding study of uncommon side effects, effects of long-term therapy, or many high-risk populations. In contrast, real-world data studies can include a long-term follow-up of large and diverse populations that represent the usual clinical practice population and are more timely and less expensive to conduct.

Two major weakness of real-world data studies are the quality of the data available and their observational nature. Real-world data generally originate from insurance or electronic health records, systems that were not designed for research and thus have limitations in accuracy, completeness, and availability. The accuracy of billing codes varies temporally, across geographic locations, and in different healthcare systems. The accuracy and completeness of the medication information can also vary, and identifying medications for patients who are hospitalized or who change insurers or healthcare systems presents problems. Databases that primarily link billing codes to medications (e.g., Medicare and Medicaid) often lack important clinical information such as weight, smoking history, and laboratory results. On the other hand, electronic health records have clinical details, but these may be incomplete or inaccessible because patients receive treatment from multiple providers and because much of the useful information resides in the text describing the medical encounter rather than in a structured database.

Even if the study data are of very high quality, a fundamental limitation of nonrandomized studies is confounding by unmeasured differences amongst the groups being compared. For example, millions of women in the U.S. received hormone replacement therapy (HRT) because large observational studies had consistently demonstrated a striking protective effect for cardiovascular disease. To the surprise of many, the large

TABLE 8–5 ■ COMPARATIVE RATES OF FATAL RHABDOMYOLYSIS PER MILLION PRESCRIPTIONS IN THE FDA ADVERSE EVENT REPORTING SYSTEM FOR VARIOUS STATINS

VARIABLE	LOVASTATIN	PRAVASTATIN	SIMVASTATIN	FLUVASTATIN	ATORVASTATIN	CERIVASTATIN
Year approved	1987	1991	1991	1993	1996	1997
Fatal cases of rhabdomyolysis	19	3	14	0	6	31
Number of prescriptions dispensed since marketing	99,197,000	81,364,000	116,145,000	37,392,000	140,360,000	9,815,000
Rate per million prescriptions	0.19	0.04	0.12	0	0.04	3.16

Cases were reported to the FDA before June 26, 2001; prescription data were from the National Prescription Audit Plus.
Source: Adapted from Staffa JA, et al. Cerivastatin and reports of fatal rhabdomyolysis. *N Engl J Med*, **2002**, *346*:539–540.

Woman's Health Initiative randomized controlled trial (RCT) demonstrated that there was a possible increase in the risk of cardiovascular disease (Manson et al., 2003) and a 24% increased risk of breast cancer (Chlebowski et al., 2003) in the HRT arm. One of the primary explanations of this discrepancy was that the women who sought HRT, who were the group exposed to HRT in observational studies, were healthier in ways that were very difficult to measure and that this unmeasured factor, rather than exposure to HRT, explained the spurious cardiovascular protective effect reported in observational studies. This and other sobering examples of observational studies that reached incorrect conclusions have led to increasing caution in the interpretation of their findings (Collins et al., 2020).

Despite these limitations, real-world data can often provide critical drug safety information that would be difficult or impossible to obtain in a clinical trial. An example is the identification of the increased risk of type 2 diabetes for children and young adults taking antipsychotics (Bobo et al., 2013). Antipsychotics, particularly the second-generation drugs, have metabolic effects, such as weight gain, increased glucose levels, and insulin resistance, that are considered precursors to diabetes. Epidemiologic studies of adults confirmed an increased risk of type 2 diabetes in antipsychotic users. The frequent use of antipsychotics in children and young adults raised the concern that the risk of type 2 diabetes was increased in this vulnerable population. Addressing this question in a clinical trial would be expensive, logistically difficult, and ethically questionable. A large observational study that compared new users of antipsychotics with matched users of alternative psychiatric medications reported a 3-fold increased risk of newly diagnosed type 2 diabetes (Figure 8–2).

Postmarketing Clinical Trials

Clinical trials performed after a drug is marketed can provide important drug safety information. The motivation for such trials is often a requirement by the FDA to resolve a potential safety signal or a desire by the manufacturer to obtain a new indication. Postmarketing trials can assess suspected safety problems and potentially identify unexpected adverse effects. For example, after the withdrawal of several antiobesity drugs from the market because of adverse cardiovascular effects (e.g., *dexfenfluramine*, *sibutramine*), the FDA required postmarketing cardiovascular trials for new drugs approved for obesity. Lorcaserin, approved for the treatment of obesity in 2012, was withdrawn from the market in 2020 when an FDA analysis of the postmarketing cardiovascular trial data showed an increased risk of cancer (but not cardiovascular disease) (Sharretts et al., 2020).

Postmarketing studies performed specifically to confirm or refute a drug safety signal can raise difficult ethical questions. If two treatments available on the market are equally effective for an illness but one may have increased risk of a serious adverse effect, a person entering an RCT of the two drugs has the expectation of increased risk and no personal benefit. Under what circumstances is that ethical? Uncertainty regarding comparative safety is not necessarily the same as true clinical equipoise. Indeed, few people would agree to be randomly assigned to a two-drug comparison when one of the drugs appears to have a downside, possibly a fatal adverse effect, and no expectation of added benefit.

The ethical problems inherent in randomized safety studies were a major concern for the postmarketing trial that the FDA required to define the cardiovascular safety of *rosiglitazone*. The trial, which compared the safety of *rosiglitazone* to that of *pioglitazone* (with no negative cardiovascular signal), came under ethical scrutiny and subsequent review by an IOM committee (Mello et al., 2012). Among other recommendations, the IOM review emphasized that in these circumstances there should be a transparent and complete evaluation of all existing premarketing studies; that a clinical trial should be mandated only if an observational study could not possibly provide the necessary information; that there must be a necessity to answer a critically important public health question; and that there were heightened obligations to ensure that participants understood the risks posed by study enrollment.

The ethical difficulties of randomizing patients to evaluate a well-established safety signal argue for performing comparative efficacy studies as early as possible in the drug life cycle (Ray and Stein, 2006). As information, even if imperfect, begins to accumulate regarding the relative merits of clinical alternatives, it will become increasingly difficult to perform randomized comparisons.

Postmarketing Actions to Improve Drug Safety

Identification of new adverse events or suboptimal drug use will not by itself improve drug safety. Translating expanded knowledge into clinical practice requires active steps to inform, educate, and change behavior. Just as detecting adverse drug events reliably is difficult, so too is improving drug safety by changing the behavior of patients and prescribers. There

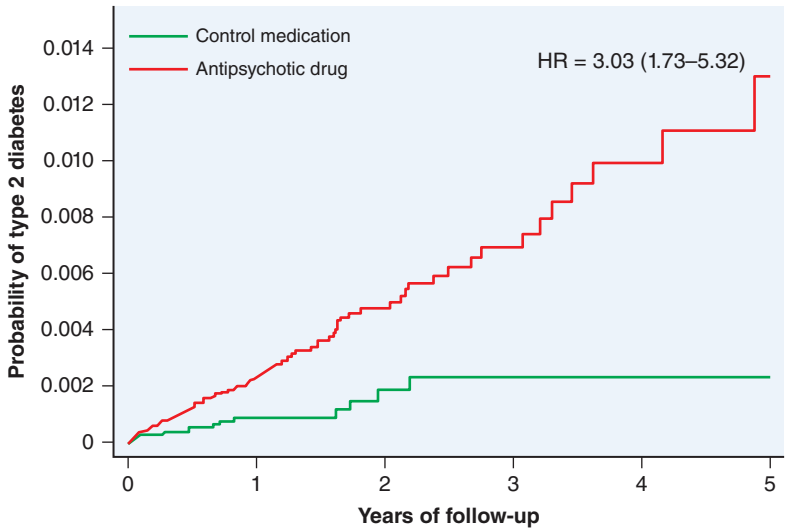

Figure 8–2 *Estimated probability of new-onset type 2 diabetes in Tennessee Medicaid enrollees.* Enrollees were between 6 and 24 years of age and began either an antipsychotic or control medication between January 1, 1996, and December 31, 2007. The study groups were matched according to 112 covariates that are potentially associated with either antipsychotic use or diabetes. The adjusted hazard ratio (HR [95% confidence interval]) estimates the relative risk of new-onset diabetes in the antipsychotic group.

are three common regulatory approaches to change behavior: (1) communication; (2) REMS; and (3) withdrawal of a drug from the market.

Communication With Prescribers and Patients

Tools for Communication

Regulatory authorities use multiple methods to communicate safety concerns, tailoring the message according to the strength of the evidence and the seriousness of the outcome. The earliest communications originate from the regular review of adverse event reports in FAERS or other case reports. Quarterly, the FDA posts information about possible safety problems on the FAERS website (FDA, 2021). These postings, although not necessarily reflecting causality, are an early alert to prescribers and the public about a potential safety issue.

Further communications ensue once the FDA determines there is a credible safety problem. One common measure is to change the drug label or even to add a boxed warning (commonly known as a "black-box warning") that draws attention to serious or potentially fatal adverse events. However, label changes *per se* may have limited efficacy (Smalley et al., 2000).

Another important tool for alerting patients and prescribers to medication risks is the drug safety communication (DSC). DSCs are posted on the FDA website, and the information is also disseminated through emails, podcasts, press releases, social media, and medical societies and associations. If a drug is contaminated or poses an immediate danger, the FDA uses other tools such as Public Health Alerts (Kesselheim et al., 2019).

How Effective Is Communication?

Communications about risk compete with a barrage of other information directed at prescribers. It is difficult to isolate the effect of the communication *per se* on patient and prescriber behavior because many other simultaneously changing factors also influence prescribing. The available evidence suggests that regulatory communications are often ineffective, but the response is so heterogeneous and unpredictable that it is impossible to generalize about communication efficacy (Dusetzina et al., 2012; Rosenberg et al., 2020). A literature review suggests several conclusions: (1) recommendations for increased monitoring (e.g., laboratory tests) have not led to large, sustained changes; (2) warnings are more likely to affect prescribing for new patients than for those already on the drug; (3) warnings are most effective when they are specific and repeated and when alternative drugs are available; and (4) warnings can have unintended consequences (Dusetzina et al., 2012).

A potentially serious unintended consequence of safety warnings is changes in drug prescribing in population groups other than those targeted. For example, warnings to avoid certain antidepressants in children (increased risk of suicide) and atypical antipsychotics in patients with dementia (increased risk of death) resulted in decreased prescribing of these drugs to other patients, with unknown clinical consequences (Dusetzina et al., 2012).

Risk Evaluation and Mitigation Strategies

The FDA can mandate specific actions both pre- and postmarketing to manage medication-associated risks. The REMS for a specific drug can require one or more of several components, including medication guides for patients, patient package inserts, patient enrollment in a registry, evidence that the patient is following guidelines for safe use, laboratory testing, communications to healthcare providers, education and training for providers, and certification of providers and pharmacies. For example, most of these requirements are present in the REMS in place for *isotretinoin* to prevent fetal exposure. Currently, 60 drugs have REMS requirements, and although the program is based on sound reasoning there is limited evaluation of its effectiveness (Boudes, 2017).

Withdrawal of a Drug From the Market

If other strategies do not appropriately manage drug risk, the FDA can require withdrawal of an approved drug from the market. This difficult decision must balance the magnitude of the drug risks, the potential to mitigate them effectively, the benefits of the medication, and the availability of alternative therapies (Sharretts et al., 2020).

Withdrawal of a medication from the market is a drastic action, often resulting from failure to identify a major drug risk earlier in the life cycle. The discovery of adverse effects that lead to withdrawal can have profound effects on future preclinical and premarketing studies. For example, prolongation of the QT interval and torsades de pointes led to the withdrawal of several drugs (*terfenadine*, *astemizole*, *grepafloxacin*, *cisapride*, and others; see Garnett, 2017). As a consequence, the FDA increased requirements to evaluate the propensity of any new drug to prolong the QT interval. Similarly, the withdrawal of antiobesity drugs that caused cardiac valve abnormalities (*fenfluramine, dexfenfluramine*) or increased the risk of myocardial infarction and stroke (*sibutramine*) led to stricter cardiovascular requirements for new antiobesity drugs.

Challenges and Future Approaches

Pharmacovigilance efforts in all countries face similar challenges; harmonization and cooperation will be important as the science evolves. Several areas will be important drivers of future improvements in drug safety.

Better Access to Data

The ability of individual researchers to readily access the data required to perform observational pharmacoepidemiologic studies remains limited. Access to resources, such as Medicare data, is expensive, and the approval process is onerous. The Sentinel System has expanded the ability of the FDA to perform large observational studies rapidly. These resources are available to other investigators but only through collaborations with individual Sentinel sites or through the Sentinel Operations Center (Adimadhyam et al., 2020). A large comprehensive data set for pharmacoepidemiologic research based on a model such as UK Biobank, which provides easy and cheap access to data and also protects individual privacy, would be a major advance. Although commercial insurance-based databases are beginning to provide some of this capability, publicly based systems that are validated and include key linkages to vital records and electronic health record data will be needed.

New Approaches to Detecting and Refining Signals

The millions of adverse event reports every year and information about drug prescriptions linked to clinical outcomes for millions of patients provide great opportunities but also new challenges for improving drug safety. The application of artificial intelligence and natural language processing to this information holds great promise (Lavertu et al., 2021); however, it is important to remember that algorithms and humans both confront the same fundamental challenge: the limitations of observational data. The idea of large simple postmarketing efficacy and safety trials with remote enrollment and outcomes determined through vital records or electronic health records is attractive, but there are many challenges that will limit the types of questions that can be addressed.

Pragmatic studies are best suited to relatively safe interventions that do not require complex consent procedures or close monitoring of patients or have endpoints that require detailed clinical evaluation. The most practical design is open label with little control over exposure to the intervention and co-therapies (i.e., usual clinical care). These trial design features can affect the trial's robustness. The disadvantages of open-label trial designs are well recognized; poor adherence to an intervention or lack of control of confounding co-therapies can make the results difficult to interpret. The ADAPTABLE pragmatic trial, which compared the efficacy of aspirin 81 mg versus 325 mg for the prevention of atherosclerotic heart disease, illustrates some of the challenges. In the ADAPTABLE study, many patients did not continue to take the dose to which they were randomized; 41.6% of patients randomized to the 325-mg dose of aspirin switched to the 81-mg dose. This dose switching may have affected

the results. The intent-to-treat analysis showed no significant difference between the two doses for the primary composite endpoint of death and hospitalization for myocardial infarction or stroke (hazard ratio [HR], 1.02; 95% confidence interval [CI], 0.91–1.14). However, in a sensitivity analysis performed using the aspirin dose the patient was actually taking, the primary endpoint occurred more frequently with the 81-mg dose (HR, 1.25; 95% CI, 1.10–1.43) (Schuyler Jones et al., 2021), leaving open the possibility that poor adherence may have obscured a beneficial effect of the higher dose.

Incorporating Pharmacogenetics Into Risk Detection and Management

The FDA label for approximately 300 drugs already contains pharmacogenetic information, including some boxed warnings. Genetic information in the label often relates to increased risk of an adverse event (e.g., *abacavir* hypersensitivity/*HLA-B*5701*) or altered drug metabolism affecting drug response (e.g., *warfarin*/*CYP2C9*, *clopidogrel*/*CYP2C19*) (see Chapter 7). Defining the clinical significance of pharmacogenetic effects and deciding how they should be incorporated into communications and actions to improve drug safety will become increasingly important, particularly since it will not be possible to perform an RCT for each potential effect.

Genetic information can also be useful to predict the efficacy and adverse effects likely to be associated with a drug when naturally occurring human genetic variation reproduces the effect of a drug. A Mendelian randomization analysis, which classifies the population according to the genetic variation rather than drug exposure, is free of bias related to the multiple factors that influence medication choice, given that genetic makeup is fixed at conception (Denny et al., 2018). For example, variation in the 3-hydroxy-3-methylglutaryl-CoA reductase gene (*HMGCR*) mimics the effects of statin therapy in that some people have lower genetically determined enzyme activity and therefore lower low-density lipoprotein cholesterol levels. Thus, "randomization" at conception to different levels of HMGCR activity occurs because of natural variability in genetic makeup; by studying the consequences of genetically predicted different levels of HMGCR activity in a population, we can learn about possible effects of a drug that alters this enzyme. Indeed, Mendelian randomization analyses predicted an increased risk of diabetes with statin therapy—something that took decades of clinical use to discover (Swerdlow et al., 2015).

Chapter 9

Principles of Clinical Toxicology

Amberly R. Johnson and Kaitlyn M. Brown

Introduction

Toxicology is the study of the adverse effects of substances on living organisms. Any substance is considered a *poison* when exposure results in a damaging physiological effect (toxic effect). Among the agents that can produce toxic effects are pharmaceuticals, illicit drugs, plants and botanicals, and myriad chemicals and pollutants. Chapter 76 focuses on *environmental toxicology*. This chapter focuses on *clinical toxicology*, the discipline of toxicology that studies undesired effects of pharmaceutical therapies in humans and the effects and treatment of poisoning.

Toxicological testing is performed in preclinical studies to assess for the toxicity of a substance in animals and in in vitro models (see Chapters 1 and 76). Additional studies, including carcinogenicity, teratogenicity, and effects on fertility, are performed concurrently with the first stages of a clinical trial. More adverse effects may be discovered in postmarketing surveillance as more doses are administered and more patients are exposed to the drug (see Chapter 9).

Dose-Response

Conventional Dose-Response Curves

Dose-response relationships are *graded in an individual* and *quantal in the population* (see Figures 3–7 and 3–9). In a graded dose-response, the magnitude of an individual's response usually increases as the dose of the drug is increased. In a quantal dose relationship, the percentage of the population that responds increases as the dose of the drug increases, but the response is only judged to be either present or absent in a given individual. This quantal dose-response phenomenon is used to determine the LD_{50} (median lethal dose) of drugs, as defined in Figure 9–1A.

Both a quantal dose-response curve for LD_{50} and a quantal dose-response curve for ED_{50} (median effective dose), the concentration of drug at which 50% of the population will have the desired therapeutic response, can be determined for the same agent (Figure 9–1B). These two curves can be used to generate a therapeutic index (TI) in animal models, which quantifies the relative safety of a drug (Equation 9–1). The median toxic dose (TD_{50}) is the concentration of drug at which 50% of the population will have a toxic effect and is used instead of LD_{50} when calculating a TI in humans.

$$\textbf{In animal toxicity studies: TI} = LD_{50}/ED_{50} \qquad \text{(Equation 9–1A)}$$

$$\textbf{In human toxicity studies: TI} = TD_{50}/ED_{50} \qquad \text{(Equation 9–1B)}$$

For agents in current therapeutic use, values of TI vary widely, from 1 to 2 to more than 100. Drugs with low TIs (e.g., the cardiac glycoside *digoxin* and cancer chemotherapeutic agents) must be administered with caution and therapeutic drug monitoring. Drugs with very high TIs (e.g., *penicillin*) are considered safe in the absence of a known allergic response in a given patient. Note that the use of median doses fails to consider the slopes of the dose-response curves, and there may be considerable overlap between doses in the upper end of the therapeutic curve and the lower end of the lethal or toxic curve (see Figure 9–1). As an alternative, the ED_{99} for the therapeutic effect can be compared to the LD_1 in animals (TD_1 in humans), to yield a *margin of safety*.

$$\textbf{Margin of safety} = \frac{LD_1}{ED_{99}} \qquad \text{(Equation 9–2)}$$

Nonmonotonic Dose-Response Curves

Not all dose-response curves follow a typical sigmoidal shape. Consider three examples. *U-shaped dose-response curves* can be observed for endocrine disrupters and hormones and for essential metals and vitamins. (Figure 9–2A) (Vandenberg et al., 2012). Deficient or low doses produce adverse effects. As dose increases, homeostasis is achieved and there are no adverse effects. When dose surpasses the amount required to maintain homeostasis, toxicity can occur. Thus, there are adverse effects at concentrations both below and above the levels that support homeostasis.

A *"hockey stick" dose-response* (Figure 9–2B) is characterized by a region of no response at low doses, followed by an adverse response as the toxicant exceeds endogenous protective mechanisms. Some toxicants, like

Abbreviations

CYP: cytochrome P450
ED_{50}: median effective dose
GI: gastrointestinal
***hERG*:** human ether-a-go-go gene
Ig: immunoglobulin, as in IgE, IgG, IgM
LD_{50}: median lethal dose
MDAC: multiple-dose activated charcoal
NAPQI: *N*-acetyl-*p*-benzoquinonimine
NSAID: nonsteroidal anti-inflammatory drug
PCC: poison control center
PDE5: phosphodiesterase type 5
Pgp: P-glycoprotein (MDR1, ABCB1)
SNRI: serotonin-norepinephrine reuptake inhibitor
TD_{50}: median toxic dose
TI: therapeutic index
WBI: whole-bowel irrigation

formaldehyde, are also metabolic by-products for which cells have detoxifying mechanisms. Formaldehyde is detoxified through metabolism by alcohol dehydrogenase. Very low doses of exogenous formaldehyde do not overwhelm endogenous alcohol dehydrogenase, and toxic effects are not observed. Adverse responses to formaldehyde are observed when exogenous formaldehyde saturates alcohol dehydrogenase (ADH5, GSNOR; Pontel et al., 2015).

An *inverted U-shaped dose-response curve* (Figure 9–2C) can be observed when receptor downregulation/desensitization occurs following exposure to a ligand or when an additional and distinct negative effect occurs at a concentration beyond that which produces the primary positive effect. For example, cannabidiol at maximal doses can produce anxiolytic effects. However, at submaximal or supramaximal doses, cannabidiol does not produce an anxiolytic effect (Zuardi et al., 2017). High levels of the hormone estrogen can achieve maximal effects; supramaximal levels produce lower effects, possible as a result of receptor downregulation. A number of endocrine-disrupting chemicals appear to have inverted U-shaped or multiphasic dose-response curves. Such curves are common in complex systems where ligands elicit multiple responses. These phenomena indicate the necessity of performimg extensive dose-response and time-course studies when evaluating the effects of potential toxicants.

Toxicokinetics and Alterations in ADME

Exposure to supratherapeutic quantities of a pharmaceutical may lead to alterations in the expected ADME. The pharmacokinetics of a drug under circumstances that produce toxicity are referred to as *toxicokinetics*. Data on toxicokinetics are generally limited to case reports and observational studies. Table 9–1 lists examples of common alterations to ADME in drug overdose.

Drug Absorption in Drug Overdose

In clinical toxicology, the time to peak drug concentration is critical to determining observation periods for asymptomatic patients. Table 9–2 lists prominent factors that may influence drug absorption in instances of overdose.

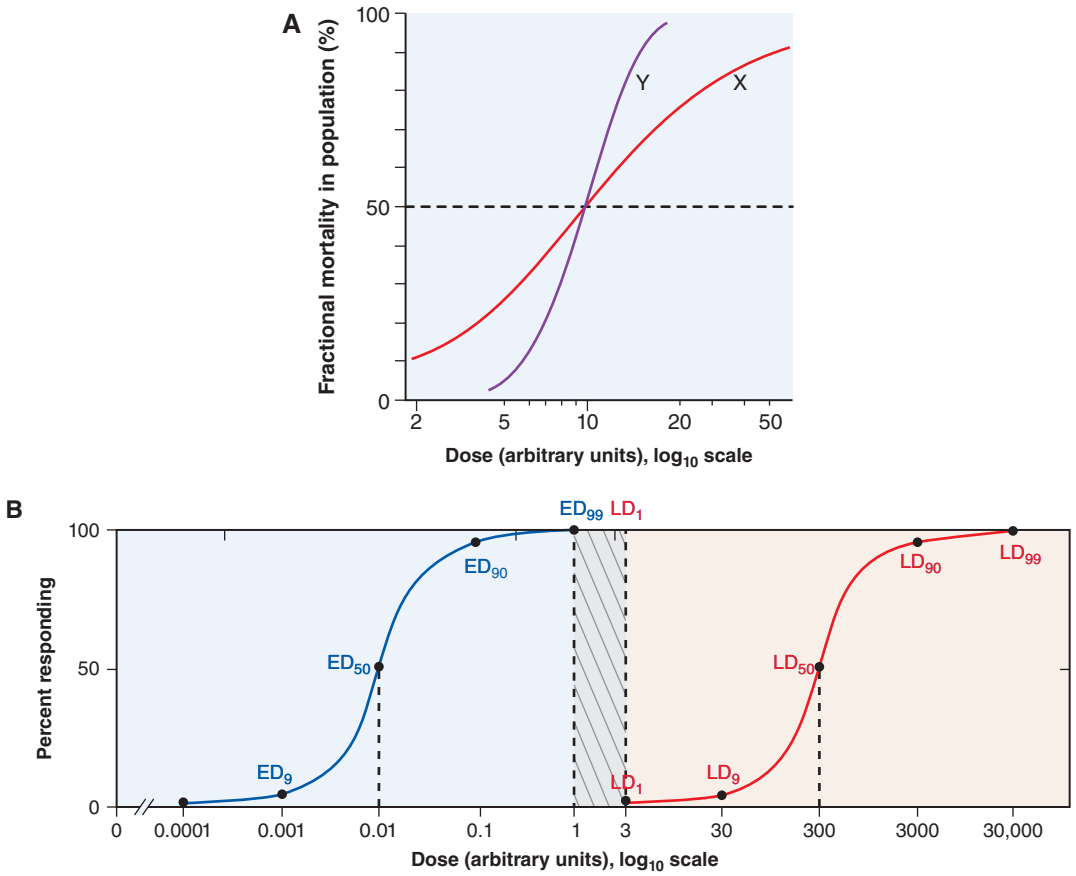

Figure 9–1 *Dose-response relationships.* **A.** The midpoint of the curve represents the LD_{50}, or the dose of drug that is lethal in 50% of the population. The LD_{50} of a compound is determined experimentally, usually by administration of the drug to mice or rats (orally or intraperitoneally). The LD_{50} values for both compounds are the same (~10 mg/kg); however, the slopes of the dose-response curves are quite different. Thus, at a dose equal to one-half the LD_{50} (5 mg/kg), fewer than 5% of the animals exposed to compound Y would die, but about 25% of the animals given compound X would die. **B.** Depiction of the effective dose (ED) and lethal dose (LD). The crosshatched area between the ED_{99} (1 mg/kg) and the LD_1 (3 mg/kg) gives an estimate of the margin of safety.

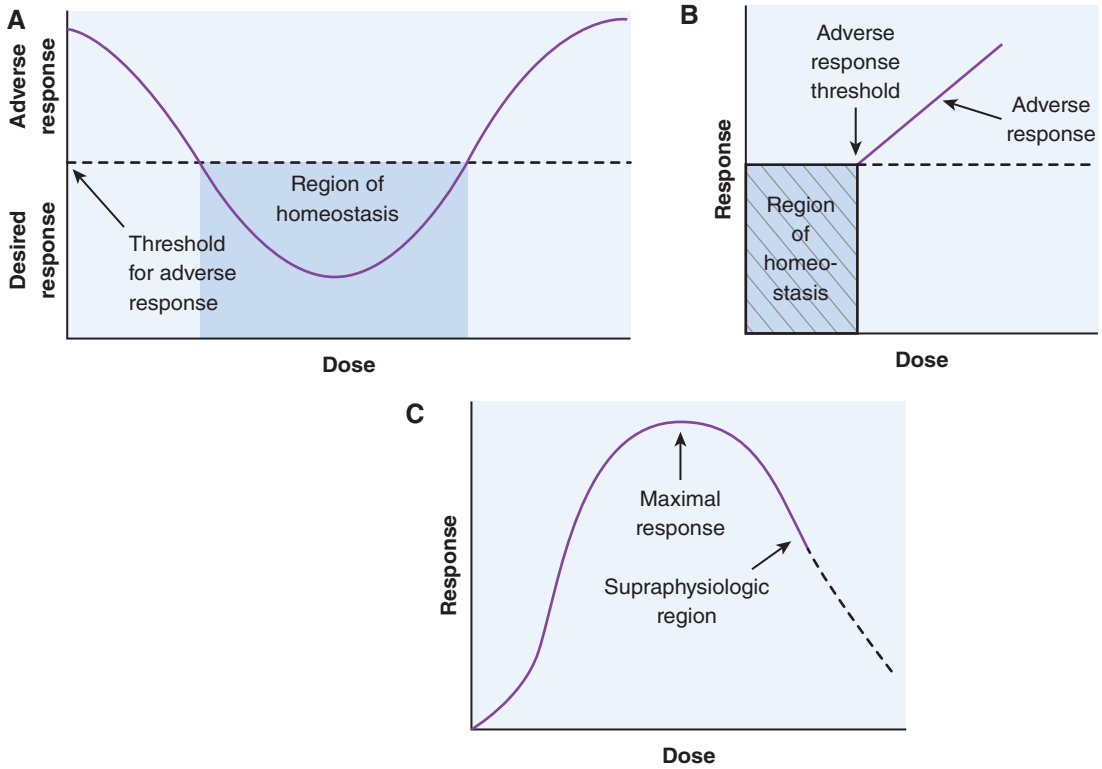

Figure 9–2 *Nonmonotonic dose-response relationships.* **A.** U-shaped dose-response curve such as may be observed for some hormones and endocrine disrupters and for essential metals. **B.** Hockey stick–shaped dose-response curve for toxicants that are removed by a saturable process such that adverse effects occur when toxin removal is saturated and becomes zero-order. **C.** Inverted U-shaped dose-response curve for ligands that downregulate their receptors or have multiple effects, both positive and negative.

Unusual Kinetics of Absorption

Drugs with modified-release forms (i.e., sustained release, controlled release, or extended release) will influence the time to the drug's peak concentration and result in delayed symptoms.

Delayed gastric emptying is typically associated with drugs that have a direct pharmacological effect on smooth muscles of the gastrointestinal (GI) tract. Two classes of medications that have this effect are opioid analgesics and anticholinergics. One prospective study demonstrated significant delays in gastric emptying half-time following ingestion of tricyclic antidepressants, opioid-acetaminophen combinations, *acetaminophen*, and *carbamazepine* as measured by gastric scintigraphy.

In addition to the role that pharmacological activity may play in delayed absorption, one must consider the quantity of tablets or capsules ingested (Adams et al., 2004). Bactrian pharmacokinetics (double-hump) have been described in several cases following *acetaminophen* overdose (Figure 9–3) (Hendrickson et al., 2010). This phenomenon results in two distinct peak serum concentrations separated by 12 to 42 h. The mechanism for this pattern of absorption is unknown, but it occurs following exposures to large quantities of *acetaminophen* alone (30–100 g) and in combination with drugs that slow gastric emptying, suggesting that either factor can influence the pattern of absorption. Thus, the time course of drug absorption in overdose is not always straightforward; knowing the possible pattern of drug absorption is an important aspect in the time course of managing drug overdose.

Enterohepatic Cycling

Enterohepatic recirculation occurs when drugs undergo conjugation in the liver, excretion in the bile, and reabsorption in the small intestine. Many drugs are excreted into the GI tract as polar conjugates with UDP-glucuronic acid, glutathione, or sulfate and are not sufficiently

TABLE 9–1 ■ EXAMPLES OF COMMON ALTERATIONS TO ADME IN DRUG OVERDOSE

Acetaminophen	↑ **Metabolism** through CYP2E1 and subsequent buildup of hepatotoxic metabolite
Aspirin	Delayed and erratic **absorption**; ↑ **distribution** to CNS
Buprenorphine	Prolonged symptoms due to long **half-life**
Bupropion	Delayed **absorption** (modified-release preparations); active **metabolites**
Calcium channel blockers	Delayed **absorption** (modified-release preparations); active **metabolites**
Illicit drugs in rubber or plastic packages (body packers/body stuffers)	Delayed and erratic **absorption**
Insulin	Delayed and prolonged **absorption** due to subcutaneous depot
Monoamine oxidase inhibitors	Delayed time to enzyme inhibition/**metabolism**
Sulfonylureas	Delayed hypoglycemia, mechanism **unclear**
Valproic acid (VPA)	Delayed **absorption** (enteric coating); saturated **protein binding** ↑ free VPA

TABLE 9–2 ■ FACTORS THAT INFLUENCE DRUG ABSORPTION

Modified-release preparations
Delayed/prolonged gastric emptying
Pylorospasm
Enterohepatic recirculation
Pharmacobezoar

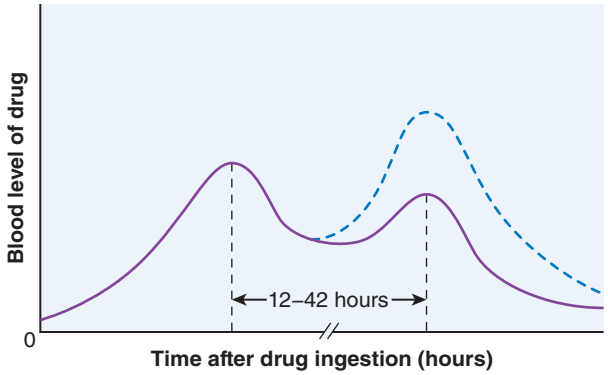

Figure 9–3 *Bactrian "double-hump" kinetics.* Bactrian kinetics are seen in some cases of drug overdose, such as those involving *acetaminophen*. Following an excessive dose of *acetaminophen* (30–100 g), the time course of drug level in the blood may show two peaks. The second peak concentration of *acetaminophen* may occur 12 to 42 h after the first peak and may be less than or greater than (blue dashed line) that of the first peak concentration. See text for details.

lipophilic to be reabsorbed. The intestinal microbiome plays a role in deconjugation, hydrolyzing glucuronides and sulfates, and rendering them more lipophilic and thus more likely to be absorbed across the GI epithelium (see Chapter 6). The more lipophilic moieties reenter the portal circulation, as they would following oral administration, and begin the cycle again. The events of this recirculation require participation of hepatic CYPs (cytochromes P450) and UGTs (see Chapter 5) as well as an assortment of membrane transporters (e.g., members of the SLC and ABC superfamilies; see Figures 4–2, 4–8, and 4–9). Enterohepatic cycling can cause secondary peaks in the C_p-time profile of a drug. Repetitive cycling ultimately prolongs the elimination half-life of the cycled xenobiotic (Ibarra et al., 2021). In the instance of drug overdose or poisoning, it can be useful to interrupt this recycling and promote excretion. Introduction of a suitable nonabsorbable binding agent like activated charcoal, can interrupt the recycling by sequestering the molecule for excretion in the feces. This is the basis for using bile acid sequestrants (e.g., *cholestyramine*; see Chapter 37) to reduce bile acid reabsorption and decrease hepatic cholesterol content and polythiol resins in treating dimethylmercury poisoning, for instance.

In addition to the many drugs that are conjugated for excretion, a number of biological molecules in addition to bile salts are subject to enterohepatic recirculation, including thyroxine and steroid hormones. Bilirubin, excreted in bile as a glucuronide, is hydrolyzed by colonic bacteria to urobilinogen, a portion of which is reabsorbed.

Miscellaneous Contributors to Altered Drug Absorption

Pharmacobezoars form when pharmaceutical preparations conglomerate into a mass in the GI tract. These conglomerates alter absorption by causing gastric obstruction, reducing the effective surface area for absorption, or prolonging drug absorption (Simpson, 2011). The incidence of pharmacobezoar formation is rare in drug overdose.

Pylorospasm results in closure of the pylorus and prevents passage of gastric contents to the small intestine. Drugs that induce pylorospasm can theoretically delay their own GI absorption. Salicylates are commonly cited as a drug class that induces pylorospasm, an effect that may contribute to the erratic absorption of salicylates (Harris, 1973).

Drug Distribution in Drug Overdose

Protein binding affects the toxicity of an agent. In overdose, the toxicity of highly protein bound drugs may be enhanced as the fraction of unbound drug is increased due to saturation of protein binding sites. Additionally, alterations in physiological pH can reduce protein binding. For example, tricyclic antidepressants become less protein bound when plasma pH become more acidic, resulting in more pronounced drug toxicity (Levitt et al., 1986).

Drugs with larger volumes of distribution are associated with more extensive distribution to and sequestration in tissues and often cannot be as easily removed through hemodialysis as drugs with smaller volumes of distribution.

Drug Metabolism and Elimination in Drug Overdose

Elimination via Metabolic Processes May Change From First Order to Zero Order as the Dose Increases

Drug elimination is dependent upon biotransformation and excretion. In the context of drug overdose, saturation of the enzymatic processes of biotransformation can greatly impact drug elimination. Ethanol is a familiar example of saturated metabolism. With the ingestion of miniscule amounts, ethanol metabolism would be first order, that is, a fixed fraction metabolized per unit of time. However, as used socially, ethanol readily achieves blood levels that saturate hepatic alcohol dehydrogenase activity as the supply of the cofactor NAD^+ becomes inadequate due to the limiting rate at which the cofactor NAD^+ can be regenerated from NADH (Alexandrovich et al., 2017). Thus, in practice, ethanol metabolism is zero order, that is, a fixed amount per unit time (~10 g/h in a typical adult); addition of more ethanol to the system increases the blood level and the deleterious effects of ethanol but does not result in a greater rate of metabolic elimination (see Chapter 27).

The antiepileptic medication *phenytoin* is a good clinical example of the potential for toxicity as blood levels rise and enzymatic biotransformation becomes saturated. *Phenytoin* is metabolized predominantly by two polymorphic CYPs, 2C9 and 2C19. At therapeutic doses, *phenytoin* elimination is largely first order with an elimination half-life between 6 and 24 h, averaging about 20 h. However, at supratherapeutic concentrations, CYPs 2C9 and 2C19 become saturated and *phenytoin* elimination becomes zero order (Chua et al., 2000), and the elimination half-life can increase to 103 h (Brandolese et al., 2001) (see Chapter 20).

Shunting From Saturated Metabolic Pathways to Alternative Pathways May Produce Toxic Metabolites

Acetaminophen overdose exemplifies the toxic consequences of saturated metabolic pathways. Under normal conditions, *acetaminophen* largely undergoes conjugation to nontoxic metabolites. A small portion of *acetaminophen* undergoes metabolism through CYP2E1 to the toxic metabolite NAPQI (*N*-acetyl-*p*-benzoquinonimine), but glutathione stores are sufficient to support detoxification of the NAPQI produced by therapeutic doses of *acetaminophen*. Following *acetaminophen* overdose, however, conjugation becomes saturated, resulting in increased metabolism through CYP2E1. Glutathione stores become depleted and insufficient to detoxify the NAPQI produced. NAPQI accumulates and is ultimately responsible for the hepatotoxic effects associated with *acetaminophen* overdose (Figure 9–4).

Drug Metabolites Can Be More Potent and Toxic Species

Drugs with active metabolites can be toxic via the metabolite. For instance, *tramadol* is a serotonin-norepinephrine reuptake inhibitor (SNRI) that binds to SERT (neuronal serotonin transporter) and NET (neuronal norepinephrine transporter) and is also a weak μ-opioid agonist that is used as an analgesic. The active metabolite of *tramadol*, *O*-desmethyl-tramadol (M1), results from the action of CYP2D6 and is a more potent μ-opioid receptor agonist by a factor of approximately 300 (Grond et al., 2004) but lacks activity as an SNRI. Thus, metabolism changes the activity profile of the parent compound. CYP2D6 is highly polymorphic; thus, CYP2D6 activity in the human population runs the gamut from ultra-rapid metabolizers to poor metabolizers. Consequently, production of M1 varies as well, and more rapid metabolizers may have increased exposure to the adverse reactions of the μ-opioid agonist metabolite (Gong et al., 2014). In other cases, the toxic metabolites of a parent drug may simply have longer half-lives, thereby adversely influencing toxicity.

Drug Elimination by Membrane Transporters

Drug transporters play roles in both the absorption and elimination of xenobiotics. The interplay of substrates and inhibitors at transport proteins can give rise to drug-drug interactions that increase the AUC (integrated area under the time-C_p curve) and $C_{p_{max}}$ of drugs into the toxic range by decreasing elimination or decrease the AUC and $C_{p_{max}}$ below

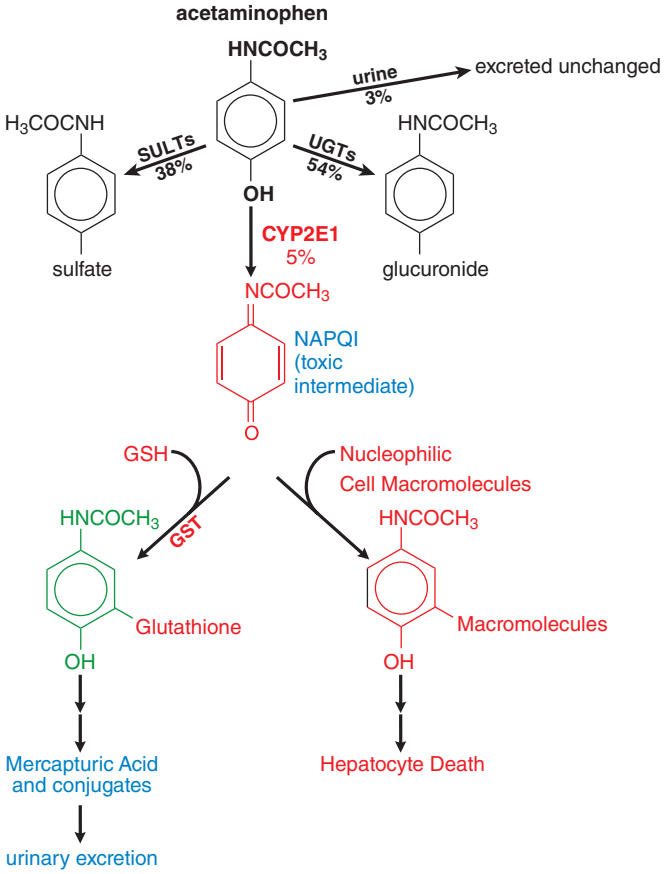

Figure 9–4 *Pathways of acetaminophen metabolism and toxicity in hepatocytes.* With normal dosing (1–3 g/day), *acetaminophen* is metabolized largely by sulfation and glucuronidation; small amounts are excreted unchanged in the urine or oxidized to a reactive and toxic metabolite, *N*-acetyl-*p*-benzoquinonimine (NAPQI); NAPQI is detoxified via conversion to a glutathione (GSH) adduct that is ultimately excreted in the urine. At a dose of 4 g/day, the sulfation pathway becomes saturated, shunting more *acetaminophen* through glucuronidation and oxidation. As the daily dose further increases (>4 g), the glucuronidation pathway also becomes saturated, and higher fractions of the drug get excreted unchanged and oxidized. This increased production of NAPQI depletes cellular GSH; the excess NAPQI interacts with nucleophilic cellular molecules, leading to hepatocyte death. Agents that act to shunt more *acetaminophen* through the oxidative pathway, such as inducers of CYP2E1 activity (e.g., *isoniazid*), will enhance NAPQI formation, GSH depletion, and hepatocyte damage and death. For further details, see Mazaleuskaya et al. (2015). GSTs, glutathione-*S*-transferases; SULTs, sulfotransferases; URTs, uridine diphosphate-glucuronosyltransferases.

an effective level by reducing GI absorption. See Table 9–3 for examples of drugs that are substrates or inhibitors of several common transporters and that can give rise to such effects. Appendix II gives a more quantified presentation of such interactions, as does Chapter 4.

Types of Drug Toxicity

Side effects of drugs are undesirable effects from the therapeutic use but often do not require discontinuation of treatment. Other undesirable effects are characterized as *toxic effects*. Toxic effects may be described as either adverse drug effects or drug toxicity. These terms are often used interchangeably; however, adverse effects occur with normal therapeutic use, whereas drug toxicity occurs as a result of supratherapeutic drug concentrations (unintentional or intentional).

Types of drug toxicity can be classified mechanistically as on-target, off-target, biologic activation, hypersensitivity, and idiosyncratic (Guengerich, 2011; Liebler et al., 2005).

On-Target

On-target toxicity is a result of the interaction of a drug and its primary pharmacologic target (i.e., receptor). On-target toxicity is typically dose dependent. At therapeutic doses, barbiturates bind to $GABA_A$ receptors and prolong the opening of the $GABA_A$-mediated Cl^- channels (the primary inhibitory channels in the central nervous system [CNS]). The desired therapeutic effects are anxiolysis and sedation. At supratherapeutic doses of barbiturates, increased agonism at the $GABA_A$ receptors causes greater Cl^- influx and inhibition of neurotransmission in responding neurons, leading to somnolence, coma, and death.

On-target toxicity is not always specific to the target tissue of the drug administered. At therapeutic doses, *nifedipine*, a dihydropyridine calcium channel blocker, is selective for the L-type calcium channels in peripheral vascular smooth muscle, reducing contraction of these muscles and thereby reducing peripheral vascular resistance and blood pressure. At supratherapeutic doses, however, *nifedipine* blocks the L-type calcium channels in both its target tissue (peripheral vasculature) and the myocardium, resulting in potentially life-threatening hypotension.

Off-Target

Off-target toxicity results from the interaction of a drug with targets other than its intended pharmacological targets. Off-target toxicity is discovered in preclinical testing, the early stages of clinical trials, and in postmarketing surveillance. *Terfenadine* is a good example. *Terfenadine* is a prodrug that is metabolized by CYP3A4 to the active form, *fexofenadine*, a selective H_1 antagonist. In 1997, terfenadine was removed from the U.S. market due to reports of life-threatening dysrhythmias with its use. At therapeutic doses, the primary pharmacological target of *terfenadine* is the H_1 receptor via the metabolite, fexofenadine. At supratherapeutic doses or in the presence of inhibitors of CYP3A4, the toxicity of the parent drug becomes apparent: blockade of K^+ channels (K_v11.1; the channel's α subunit is encoded by *hERG* [human ether-a-go-go gene]) in the myocardium, leading to QTc prolongation and the development of torsades de pointes (DuBuske, 1999). While toxic effects are discovered in clinical trials, postmarketing surveillance involving much larger numbers of patients and administered doses finds the rarer adverse effects. A number of the drug withdrawals in the U.S. from 1969 to mid-2003 were in response to off-target effects and drug-drug interactions (Wysowski and Swartz, 2005).

Biological Activation

A drug can be biologically activated to a toxic metabolite that is capable of causing organ or tissue-specific toxicity. The metabolism of *acetaminophen* to NAPQI is an example of biological activation. NAPQI interacts with nucleophilic cellular macromolecules in the liver leading to cell death (see Figure 9–4). Most genotoxic carcinogens, including many cancer chemotherapeutic agents, are compounds that have been biologically activated to intermediates that directly damage DNA (see Chapters 6, 7, and 71).

Hypersensitivity Reactions

A hypersensitivity reaction, or *allergy,* is mediated by the immune system and results from previous sensitization to a particular chemical or to one that is structurally similar. (See Chapter 38 for a discussion of the immunological basis of hypersensitivity reactions.) Hypersensitivity reactions are divided into four general categories based on the mechanism of immunological involvement.

Type I: Anaphylactic Reactions

Anaphylaxis is mediated by immunoglobulin (Ig) E antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils. If the Fab portion of the IgE antibody then binds an antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the GI tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed *immediate hypersensitivity reactions*.

Many chemical compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization (McNeil, 2021a). Responses of this sort are most likely to occur following intravenous injection of certain categories

TABLE 9–3 ■ SELECTED SUBSTRATES AND INHIBITORS OF TRANSPORTERS

TRANSPORTER	SUBSTRATE		INHIBITOR	
Pgp	Dabigatran Digoxin Fexofenadine Loperamide		Amiodarone Carvedilol Clarithromycin Itraconazole	Propafenone Quinidine Verapamil
OAT1B1 and OAT1B3	Atorvastatin Danoprevir[a] Docetaxel Fexofenadine Glyburide Nateglinide	Paclitaxel Pitavastatin Pravastatin Repaglinide Rosuvastatin Simvastatin	Atazanavir, ritonavir Clarithromycin Cyclosporine Erythromycin Gemfibrozil	Lopinavir, ritonavir Rifampin Simeprevir[a]
OAT1 and OAT3	Adefovir Cefaclor Ceftizoxime[a] Famotidine Furosemide	Ganciclovir Methotrexate Oseltamivir Penicillin G	P-aminohippuric acid Probenecid Teriflunomide

Source: Data from Hachad et al., 2010.

of substances, particularly organic bases. Such secretagogues appear to elicit histamine release by interacting directly with MRGPRX2, a mast cell–specific G protein-coupled receptor, independently of the IgE pathway. The phenomenon is one of clinical concern and may account for unexpected anaphylactoid reactions and adverse drug responses (McNeil, 2021b).

Type II: Cytolytic Reactions

Type II allergies are mediated by both IgG and IgM antibodies and usually are attributed to their capacity to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include *penicillin*-induced hemolytic anemia, *quinidine*-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. This type of reaction usually subsides within several months after removal of the offending agent.

Type III: Arthus Reactions

Type III allergic reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen-antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called *serum sickness* occurs. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. Several drugs, including commonly used antibiotics, can induce serum sickness–like reactions. These reactions usually last 6 to 12 days and then subside after the offending agent is eliminated.

Type IV: Delayed Hypersensitivity Reactions

These reactions are mediated by sensitized T lymphocytes and macrophages. When sensitized cells come in contact with an antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity reaction is allergic contact dermatitis caused by poison ivy.

Idiosyncratic Reactions

An *idiosyncratic reaction* is an abnormal drug reaction to a drug that is unique to an individual. These reactions are rare and often hard to identify in preclinical studies. Idiosyncratic reactions are the least well-understood type of toxicity but generally involve an immunotoxicological reaction in a patient with a pharmacogenetic predisposition. Severe cutaneous adverse reactions, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, and drug-induced liver injury from drugs other than *acetaminophen* are the most commonly reported idiosyncratic reactions (Usui et al., 2017).

Drug-Drug Interactions

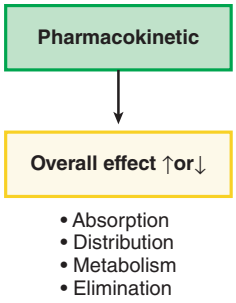
Managing a disease state or multiple disease states may require the use of more than one medication. Some patients may also elect to take additional over-the-counter medications such as vitamins, herbal supplements, and nutraceuticals. The use of multiple medications simultaneously can lead to drug-drug interactions. Two common mechanisms of drug-drug interactions include interactions of pharmacokinetics and interactions of pharmacodynamics. Drug-drug interactions can result in failure of pharmaceutical therapy or unintended toxic effects at therapeutic doses. Figure 9–5 summarizes the mechanisms and types of drug interactions.

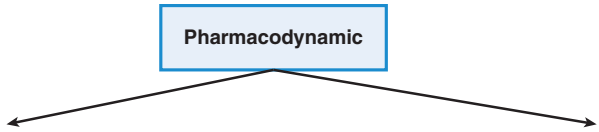
Pharmacokinetic Interactions

Pharmacokinetic drug-drug interactions occur when components of ADME of one chemical are altered by another and result in increased or decreased drug effects.

Absorption. Interactions of absorption occur when the presence of one drug changes the absorption of another drug, generally from the intestinal lumen. These changes may occur due to an alteration of GI pH or adsorption. *Ranitidine*, an H_2 receptor antagonist, raises GI pH and may increase the absorption of basic drugs such as *triazolam* (O'Connor-Semmes et al., 2001). Conversely, coadministration of *levothyroxine* and calcium-containing antacids results in decreased absorption of *levothyroxine* due to adsorption of *levothyroxine* to calcium (Zamfirescu et al., 2011).

Involvement of Transporters. Interactions at transporters can alter drug absorption, distribution, and elimination. Common transporters implicated in clinically relevant drug interactions include P-glycoprotein (Pgp), OATs (organic anion transporters), and BCRP (breast cancer resistance protein) (Torino et al., 2019). Inhibition of intestinal Pgp, an efflux transporter, results in increased absorption and bioavailability. One study of healthy volunteers demonstrated an increase of 91% in the peak concentration and an increase of 71% in the AUC of *dabigatran* (Pgp substrate) when coadministered with *verapamil* (Pgp inhibitor). Table 9–3 lists common substrates, inhibitors, and inducers of transporters recommended by the U.S. Food and Drug Administration (FDA) for use in clinical drug-drug interaction studies. Box 9–1 illustrates how inhibition of transporters on multiple tissues can influence drug toxicity. Chapter 4 presents details of some drug-drug interactions mediated by





↑Overall effect	
Additive	Combined effect of two drugs equals the sum of the effect of each agent given alone
Synergistic	Combined effect exceeds the sum of the effect of each drug given
Potentiation	Accentuation of the effect of one drug due to the presence of another drug that alone has no effect

Antagonism – ↓Overall effect	
Physiological	Two xenobiotics produce opposite effects on the same physiological function
Chemical	Reaction between two chemicals neutralizes their effects
Receptor	Blockade of the effect of one drug by another drug that competes at a common binding site or acts at an allosteric site

Figure 9–5 *Mechanisms and classification of drug interactions.* Drugs can interact by a single mechanism or multiple mechanisms.

transport proteins; Figure 4–3 summarizes the major mechanisms by which transporters mediate adverse responses. Appendix II is a compendium of prominent drug-drug interactions, a number of which derive from interactions at membrane transporters.

Interactions at Protein Binding Sites. Many drugs, such as *aspirin*, barbiturates, *phenytoin*, sulfonamides, *valproic acid*, and *warfarin*, are highly protein bound in the plasma. Coadministration of such drugs can result in competition for binding sites and displacement of one drug by another, altering, for a time, the free concentrations of the drugs. Drugs that are highly bound to plasma proteins may have enhanced toxicity in overdose if protein binding sites become saturated, in physiological states that lead to hypoalbuminemia, or when drugs bound to plasma proteins are replaced on plasma proteins by other drugs (Guthrie et al., 1995).

Interactions via Drug Metabolism. One drug can frequently influence the metabolism of one or several other drugs, especially when hepatic CYPs are involved (see Chapter 5). *Acetaminophen* has complicated interactions with ethanol. During an overdose, normal metabolic pathways become saturated and a larger portion of *acetaminophen* is metabolized through CYP2E1 to the resultant toxic metabolite NAPQI (see Figure 9–4). Ethanol is both a substrate and potent inducer of CYP2E1. Acute coingestion of ethanol may be protective against *acetaminophen*-induced hepatotoxicity as ethanol is preferentially metabolized by CYP2E1 compared to *acetaminophen* (Waring et al., 2008). However, chronic ingestion of alcohol may increase hepatotoxicity due to induction of CYP2E1 and depletion of glutathione (Thummel et al., 2000; Zhao et al., 2002).

Interactions Affecting Elimination. In using *lithium* to treat mania, bipolar disorder, and treatment-resistant depression, maintenance of a therapeutic blood level of Li^+ (0.5–1.0 mEq/L) is crucial (see Chapter 19).

BOX 9–1 ■ Loperamide, Pgp, and Drug-Drug Interactions

Loperamide is a μ-opioid receptor agonist that acts on the myenteric plexus to reduce smooth muscle tone and motility in the GI tract, thereby acting as an antidiarrheal. Efflux via Pgp reduces the intestinal absorption of *loperamide* and excludes it from the CNS. Thus, *loperamide* is considered a safe antidiarrheal. However, when taken in combination with a Pgp inhibitor or substrate, *loperamide*'s bioavailability is increased and the drug can penetrate the blood-brain barrier (Kim et al., 2014; see Chapter 17 for details of the functions of the blood-brain barrier). Clinically, this drug interaction manifests with symptoms of central opioid agonism. There are reports of patients coadministering Pgp inhibitors with high doses of *loperamide* to prevent symptoms associated with opioid withdrawal (Daniulaityte et al., 2013). This drug interaction has resulted in life-threatening cardiovascular toxicity (Eggleston et al., 2016).

Lithium clearance is dependent on renal excretion. Common drug classes implicated in reducing renal clearance of *lithium* include angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), thiazides, and loop diuretics. For example, NSAIDs inhibit prostaglandin synthesis, leading to decreased renal blood flow and clearance. In prospective studies, the mean decrease in *lithium* clearance was 12% to 66% in participants taking *ibuprofen* 400 mg four times daily (Finley, 2016); a 66% drop in clearance would likely cause an increase in C_p beyond the therapeutic range, possibly resulting in toxicity.

Pharmacodynamic Interactions

Pharmacodynamic drug-drug interactions occur due to activity at the same receptor or via physiological effect. Such drug interactions that produce an increase in effect are classified as *agonistic*, which is further differentiated as *additive*, *synergistic*, or *potentiating*. Drug interactions that produce a decrease in effect are classified as *antagonistic*, which can be further described by *physiological*, *chemical*, or *receptor* antagonism. Terms to describe pharmacodynamic interactions in research are not standardized, which leads to variation in their use (Roell et al., 2017). Classifications are often determined in preclinical studies in which the magnitudes of pharmacodynamic drug-drug interactions are not clearly described.

Additive pharmacodynamic interactions are desirable in some instances, such as in treating hypertension with combinations of drugs that block β_1 receptors, inhibit effects of angiotensin, and promote diuresis. On the other hand, some drug combinations produce functionally adverse pharmacodynamic interactions. For example, nitrate vasodilators produce vasodilation via nitric oxide–dependent elevation of cGMP in vascular smooth muscle. *Sildenafil*, *tadalafil*, and *vardenafil*, used for erectile dysfunction, inhibit phosphodiesterase type 5 (PDE5) that hydrolyzes cGMP to 5′GMP in the vasculature. Thus, coadministration of a nitric oxide donor (e.g., *nitroglycerin*) with a PDE5 inhibitor can cause potentially catastrophic vasodilation and severe hypotension.

Descriptive Toxicity Testing in Preclinical Studies

Two main principles or assumptions underlie all descriptive toxicity tests performed in animals.

First, those effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals.

Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal

dose-response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (e.g., cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups instead. The validity of the necessary extrapolation is clearly a crucial question. These issues are considered in Chapters 1 and 8.

Epidemiology of Poisoning

Multiple data sources are needed to understand the scope of pharmaceutical poisoning. Death certificate and hospital discharge data are two common sources of data on drug poisoning but tend to be biased toward more severe overdoses that result in hospitalization or death. Fifty-five regional poison control centers (PCCs) in the U.S. serve as a repository for overdose data. Reporting to PCCs is voluntary and is biased toward less severe poisoning. Nevertheless, PCCs record more than two million human cases annually (Gummin et al., 2020).

Demographics of Poisoning

The 2019 National Poison Data System Annual Report describes a rate of poison exposures reported to PCCs as 643/100,000 population (Gummin et al., 2020). Children account for the majority of exposures reported to PCCs, with the highest rates of exposure in children less than 6 years of age. Adults experience the highest exposure rates between the ages of 20 and 39 years. There are also common poisoning scenarios (Table 9–4). Unintentional exposures predominate in children due to the exploratory nature of development. Intentional exposures, including self-poisoning, have been increasing in adolescents in recent years (Froberg et al., 2019). Adult exposures are mostly due to intentional exposures or adverse reactions. Table 9–5 displays the most common substances involved in human exposure by age group.

Unintentional and intentional drug poisoning were the leading causes of injury-related death in the U.S. in 2019 (70,630, 28.7%), occurring at a rate of 21.6 per 100,000 population in 2019 (Hedegaard et al., 2020). The U.S. opioid epidemic has substantially contributed to the number of drug-related deaths, with opioids being involved in the majority of overdose deaths in 2019 (49,860, 70.6%). Only 0.12% of cases reported to PCCs resulted in a fatality in 2019. The most common substances associated with fatalities reported to PCCs are listed in Table 9–6.

Prevention of Poisoning

Prevention of Poisoning in the Home

Poisoning exposures occur in a number of scenarios and most often in the home. Primary prevention and secondary prevention strategies play a role in reducing the number of poisoning exposures and their associated harm (Table 9–7). The incidence of poisoning in children has dramatically decreased over the past four decades, largely due to improved safety packaging of drugs and household chemicals and increased public awareness of potential poisons.

TABLE 9–4 ■ POTENTIAL SCENARIOS FOR THE OCCURRENCE OF POISONING

UNINTENTIONAL	INTENTIONAL
Exploratory exposure by young children	Self-harm
Environmental exposure	Recreational abuse
Occupational exposure	Misuse
Therapeutic errors	Harm to another
Iatrogenic errors	

TABLE 9–5 ■ SUBSTANCES MOST FREQUENTLY INVOLVED IN HUMAN POISONING EXPOSURES

PEDIATRIC ≤5 YEARS	ADULT ≥20 YEARS
Cosmetics/personal care products	Analgesics
Household cleaning substances	Sedative/hypnotics/antipsychotics
Analgesics	Antidepressants
Foreign bodies/toys/ miscellaneous	Cardiovascular drugs
Dietary supplements/herbals/ homeopathic	Household cleaning substances
Antihistamines	Alcohols
Topical preparations	Anticonvulsants
Vitamins	Antihistamines
Pesticides	Pesticides
Plants	Hormones and hormone antagonists

TABLE 9–6 ■ SUBSTANCES ASSOCIATED WITH THE GREATEST NUMBER OF HUMAN FATALITIES REPORTED TO POISON CONTROL CENTERS IN THE U.S.

Sedatives/hypnotics/ antipsychotics	Ca^{2+} channel blockers
Opioids (illicit and pharmaceutical)	β Adrenergic antagonists
Alcohols	Antidepressants
Stimulants and street drugs	Hypoglycemic agents
Acetaminophen (alone and in combinations)	Sedating antihistamines

Source: Data from Gummin et al., 2020.

TABLE 9–7 ■ POISON PREVENTION GOALS AND STRATEGIES

Primary prevention goal	*Reduce occurrence of poisoning exposures*
Primary prevention examples	Change product formulation • Removing ethanol from mouthwash Decrease amount of poison in a consumer product • Limiting number of pills in a single bottle of baby aspirin Reduce manufacture/sale of poisons • Withdrawal of medications like phenformin from U.S. pharmaceutical market Prevent access to poison • Using child-resistant packaging • Keeping poisons up and out of reach or in locked cabinets
Secondary prevention goal	*Reduce the effect of a poisoning exposure*
Secondary prevention examples	Increase awareness of poison control services • Promoting 24-h poison helpline number 1-800-222-1222

Reduction of Medication Errors

Over the past decade, considerable attention has been given to the reduction of medication errors and adverse drug events. A medication error is "any preventable event that may cause or lead to inappropriate medication use or patient harm while medication is in control of the healthcare professional, patient, or consumer" (Billstein-Leber et al., 2018). Medication errors are estimated to be 50 to 100 times more common than adverse drug events (Bates et al., 1995). In clinical practice, reducing medication errors involves careful evaluation of the systems involved in prescribing, transcribing, dispensing, administering, and monitoring. Good medication use processes focus on a system-based approach and involve adequate training of those involved and the use of mandatory and redundant checkpoints. Several practical strategies can help to reduce medication errors within healthcare settings (Table 9–8). These issues, especially issues of postmarketing surveillance, are covered extensively in Chapter 8.

TABLE 9–8 ■ BEST PRACTICE RECOMMENDATIONS TO REDUCE MEDICATION ERRORS IN THE MEDICATION MANAGEMENT SYSTEM[a]

STEPS	RECOMMENDATIONS
Planning	• Develop system for reporting and reviewing errors • Form a multidisciplinary medication safety team
Selection and procurement	• Limit the number of medications on formulary • Use of standard concentrations
Storage	• Use of barcode scanning • Designate separate areas for each dosage form • Segregate high-alert medications and look-alike, sound-alike (LASA) medications • Rotate stock to prevent expiration of medication • Store certain medications within the pharmacy ONLY (e.g., concentrated electrolyte solutions, concentrated oral opioid solutions, U-500 insulin) • Use automated dispensing cabinets (ADC) on nursing units
Patient admission	• Medication reconciliation
Ordering	• Avoid unapproved abbreviations • Limit as-needed orders • Avoid range of frequency orders • Specify dosage strengths • Use drug's generic name • Pediatric doses in both units/weight and total dose • Use a leading zero before decimal; no trailing zeros • Maximize computerized prescriber order entry (CPOE) • Maximize use of standard order sets
Transcribing	• Minimize error-prone abbreviations • Use a leading zero before a decimal • Check the medication administration record document against active orders • Implement a second check system
Reviewing	• Prospective review of medication orders by a pharmacist prior to preparation and dispensing
Preparing	• Prepare medications under proper conditions • Independent double check of prepared medications by a pharmacist • Use unit-of-use packaging and ready-to-administer packaging • Use oral syringes for oral preparations only
Dispensing	• Nonemergency medications reviewed by a pharmacist prior to dispensing
Administration	• Use barcode-assisted medication administration (BCMA) • Standardize concentrations of IV medications • Perform independent double checks of high-alert medications
Monitoring	• Develop guidelines for standard times to obtain laboratory values • Train staff to identify and report adverse reactions • Build monitoring parameters into order sets
Patient discharge	• Medication reconciliation • Patient education and counseling
Evaluation	• Root cause analysis • Medication-use evaluation • Quality improvement • Event detection

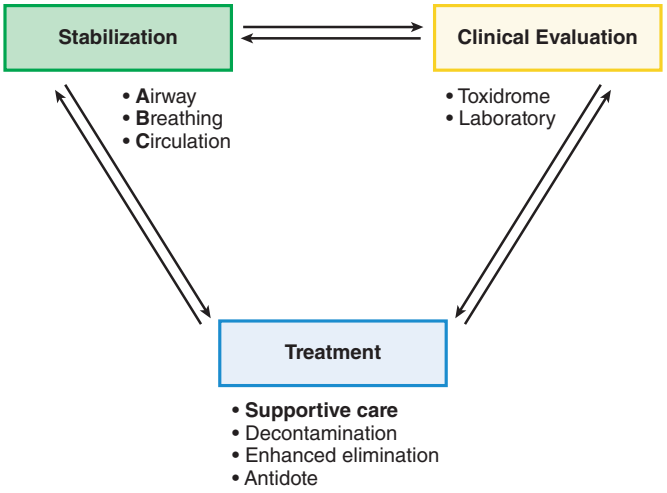

Figure 9–6 *Managing the poisoned patient.* Clinical management of the poisoned patient involves simultaneous stabilization, clinical evaluation, and treatment.

Clinical Management of Poisoned Patients

While most cases reported to U.S. PCCs are managed at home, a significant portion of patients will require medical management in a healthcare facility. Clinically managing a poisoned patient presents a number of challenges. Regional PCCs are available 24/7 to provide expert consultation on poisoned patients and can be contacted within the U.S. by calling the national Poison Help hotline: 1-800-222-1222.

Figure 9–6 illustrates a stepwise approach to managing poisoned patients in an emergency department setting.

Clinical Stabilization and Evaluation

ABCs

The utmost priority in managing a poisoned patient is ensuring their vital physiological functions are maintained. Box 9–2 outlines the "ABC" mnemonic of emergency care as it applies to the management of a poisoned patient. In severely poisoned patients, endotracheal intubation, mechanical ventilation, and pharmacological or extracorporeal circulatory support may be required to support vital physiological functions.

Toxidromes

Groups of physical signs and symptoms associated with specific poisoning syndromes are known as *toxidromes* (Table 9–9) (Erickson et al., 2007). Often, physical symptoms and signs may be the only clues to a poisoning diagnosis. Diagnosis of a specific toxidrome can help guide specific therapeutic options. It is important to recognize that patients may not demonstrate the entire constellation of symptoms in a toxidrome. Further complicating diagnosis, patients with multiple substance exposure can have features of multiple toxidromes.

Toxicology Labs

Most hospital laboratories can quickly test for common substances in serum or urine using qualitative or quantitative assays. Serum toxicology lab tests are commonly ordered for *acetaminophen* and *aspirin* due to their wide availability, quick turnaround times, and utility in guiding treatment. Many other drugs can be detected using serum testing, but results may not be available until after the patient is discharged since testing is often conducted by regional or national laboratories. Urine toxicology screens use immunoassays designed to rapidly detect common drugs of abuse, such as amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, and opiates. Urine toxicology screens are ubiquitous in hospitals and have turnaround times of about 1 h. However, the results may offer little clinical utility for management and must be cautiously interpreted in the context of the patient. Immunoassay positive cross-reactivity (i.e., false positives) and long drug detection windows may misrepresent the patient's acute toxicity. Further laboratory analysis should be tailored to the individual poisoning circumstance. For instance, an electrocardiogram is useful for detecting QRS interval widening (Na^+ channel blockade) and QTc prolongation (K^+ channel blockade) associated with specific medication classes (Table 9–10).

BOX 9–2 ■ ABC Mnemonic for Emergency Care of the Poisoned Patient

Airway	Maintain patency
Breathing	Maintain adequate oxygenation and ventilation
Circulation	Maintain perfusion of vital organs

Treatment

Throughout the process of stabilization and clinical evaluation, treatment options are simultaneously being considered. Supportive therapies are particularly important in managing a poisoned patient, especially if the causative substance(s) is not known. Common examples of supportive therapies include intravenous fluids to restore volume and maintain blood pressure, antiemetics for vomiting, and benzodiazepines for agitation or seizures. More specific therapies may be considered based on the suspected exposure; these options include decontamination, enhanced elimination, and antidotal therapies.

Decontamination of the Poisoned Patient

Poisoning exposures occur by a variety of routes (Table 9–11). Decontamination efforts are used to prevent or reduce the ongoing absorption of a poison into the body. For dermal and ocular exposures, eyes and skin should be washed copiously. Patients with inhalational exposures should be moved to fresh air. Neutralization of an acidic or basic substance is not a recommended form of decontamination.

The most common therapies for GI decontamination after an ingestion are activated charcoal and whole-bowel irrigation (WBI). *Other GI decontamination techniques like gastric emptying* and *catharsis are rarely recommended in current clinical practice* (Benson, 2013; Höjer, 2013). Minimal indications for considering GI decontamination include the following:

- The poison must be potentially dangerous.
- The poison must still be unabsorbed in the stomach or intestine.
- The procedure must be able to be performed safely and with proper technique.

Activated Charcoal

Charcoal is created through controlled pyrolysis of organic matter and is *activated* through steam or chemical treatment, which increases its internal pore structure and adsorptive surface capacity. Carbon moieties on the surface of activated charcoal are capable of adsorbing poisons via hydrogen bonding and van der Waals forces, thereby decreasing the overall absorption of the poison into the body. As a rough estimate, 10 g of activated charcoal is expected to adsorb about 1 g of the drug/poison. The recommended dose is typically 0.5 to 2 g/kg of body weight, up to a maximum tolerated dose of about 75 to 100 g. Alcohols, corrosives, hydrocarbons, and ionic salts (e.g., iron and *lithium*) are poorly adsorbed by charcoal. The most common complications of activated charcoal therapy are nausea, vomiting, and constipation. Deaths secondary to pulmonary aspiration of activated charcoal have occurred (American Academy of Clinical Toxicology, 2008). Activated charcoal is contraindicated in patients at risk of aspiration without an unprotected airway; in patients with a suspected GI perforation; and in patients who may be candidates for endoscopy. The use of activated charcoal in the treatment of poisoning has declined over the last 20 years to 1.59% of cases in 2019 (Gummin et al., 2020).

TABLE 9–9 ■ COMMON TOXIDROMES

TOXIDROME	EXAMPLES	MENTAL STATUS	HR	BP	RR	T	PUPIL SIZE	BOWEL SOUNDS	DIAPHORESIS	OTHER
Sympathomimetic	Cocaine Amphetamine	Agitation	↑	↑	↑	↑	↑	↑	↑	Tremor, seizures
Anticholinergic	Diphenhydramine Atropine	Delirium	↑	↑	±	↑	↑	↓	↓	Flushing, urinary retention, dry mucus membranes
Cholinergic	Organophosphates	Somnolence	±	±	±	nc	↓	↑	↑	DUMBBELLSS,[a] fasciculations
Opioid	Heroin Oxycodone	Somnolence	↓	↓	↓	↓	↓	↓	nc	
Sedative-hypnotic	Benzodiazepines Barbiturates	Somnolence	↓	↓	↓	↓	±	↓	nc	Ataxia, hyporeflexia
Serotonin toxicity	Sertraline Citalopram	Normal or agitation	↑	↑	↑	↑	↑	↑		Clonus, hyperreflexia, tremor, seizures
Sympatholytics	Clonidine	Somnolence	↓	↓	↓	↓	↓	↓	↓	

BP, blood pressure; HR, heart rate; RR, respiratory rate; T, temperature; ±, variable; nc; no change.
[a]DUMBBELLSS: mnemonic for muscarinic effects of diarrhea, urination, miosis, bronchorrhea, bradycardia, emesis, lacrimation, lethargy, salivation, sweating.

TABLE 9–10 ■ DIFFERENTIAL POISONING DIAGNOSIS: DRUGS COMMONLY ASSOCIATED WITH ELECTROCARDIOGRAM CHANGES (PARTIAL LISTING)[a]

BRADYCARDIA/ HEART BLOCK	QRS INTERVAL PROLONGATION	QTc INTERVAL PROLONGATION
Cholinergic agents	Antiarrhythmics (class 1)	Antiarrhythmics (class 1a, 1c, III)
Physostigmine	Bupropion	Atypical antipsychotics (ziprasidone, quetiapine)
Neostigmine	Chloroquine/ hydroxychloroquine	Fluoroquinolones
Organophosphates, carbamates	Cocaine	Loperamide
Sympatholytic agents	Diphenhydramine	Macrolides
β Receptor antagonists	Lamotrigine	Methadone
Clonidine	Propoxyphene[b]	Ondansetron
Opioids	Propranolol	Phenothiazines
Other	Tricyclic antidepressants	SNRIs (venlafaxine, desvenlafaxine)
Digoxin		SSRIs (citalopram, escitalopram)
Ca^{2+} channel blockers		Tricyclic antidepressants
Lithium		Typical antipsychotics (haloperidol, droperidol)

SSRI, selective serotonin reuptake inhibitor.
[a]This is not an exhaustive list. For more information, see Bruccoleri et al. (2016) and CredibleMeds®.
[b]Discontinued in the U.S.

Whole-Bowel Irrigation

Whole-bowel irrigation involves the enteral administration of large amounts of a high-molecular-weight, iso-osmotic polyethylene glycol electrolyte solution with the goal of passing poison by the rectum before it can be absorbed. Table 9–12 lists type of ingestions that may benefit from WBI.

Polyethylene glycol electrolyte solution is typically administered at a rate of 1500 to 2000 mL/h in adults until the rectal effluent is clear and no more drug is being passed. To achieve these high administration rates, a nasogastric tube may be used. Administration of WBI can be complicated by patients experiencing nausea and vomiting or by patients at risk for pulmonary aspiration. Contraindications to WBI include bowel perforation or obstruction, ileus, uncontrollable vomiting, unprotected compromised airway, and GI hemorrhage.

Gastric Emptying

Gastric emptying techniques include gastric lavage (commonly referred to as "stomach pumping") and administration of syrup of ipecac. Gastric emptying reduces drug absorption only by about one-third under optimal conditions (Tenenbein et al., 1987). *Based on the review of existing evidence, the American Academy of Pediatrics no longer recommends syrup of ipecac as part of its childhood injury prevention program, and the American Academy of Clinical Toxicology recommends avoiding its use in the poisoned patient* (American Academy of Pediatrics, 2003; Höjer, 2013). Due to their lack of benefit in published studies and limited availability, both gastric lavage and ipecac are rarely

TABLE 9–11 ■ ROUTES OF EXPOSURE

Bite/sting	Inhalation/nasal	Parenteral
Dermal	Ocular	Rectal
Ingestion*	Otic	Vaginal

*most common

TABLE 9–12 ■ TYPES OF INGESTIONS THAT MAY BENEFIT FROM WBI

Packets of illicit drugs ("body packers")
Iron
Patch pharmaceuticals
Sustained-release pharmaceutical formulations

used in current clinical practice and should only be considered with the consultation of a clinical or medical toxicologist.

Gastric Lavage. The procedure for gastric lavage involves passing an orogastric tube into the stomach with the patient in the left lateral decubitus position with head lower than feet. After withdrawing stomach contents, 10 to 15 mL/kg (up to 250 mL) of saline lavage fluid is administered and withdrawn. This process continues until the lavage fluid returns clear. Additionally, large pills may not pass through the orogastric tube. Complications of the procedure include mechanical trauma to the stomach or esophagus, pulmonary aspiration of stomach contents, and vagus nerve stimulation.

Syrup of Ipecac. Syrup of ipecac contains the alkaloids cephaeline and emetine. Both act as emetics due to their local irritant effect on the GI tract and their central effect on the chemoreceptor trigger zone in the area postrema of the medulla. Ipecac is no longer manufactured in the U.S., and its use is not recommended. As a result, ipecac was administered in only 0.003% of all human poisonings in the U.S. in 2019 (Gummin et al., 2020).

Cathartics

The two most common categories of simple cathartics are the Mg^{2+} salts, such as magnesium citrate and magnesium sulfate, and the nondigestible carbohydrates, such as sorbitol. Sorbitol is found in some activated charcoal preparations. However, the use of simple cathartics alone has been abandoned as a GI decontamination strategy.

Enhancing the Elimination of Poisons

Other therapeutic options for poisoned patients involve enhancing elimination of toxins.

Manipulating Urinary pH

Drugs subject to renal clearance are excreted into the urine by glomerular filtration and active tubular secretion; nonionized compounds may be reabsorbed far more rapidly than ionized polar molecules (see Figure 2–3). Weakly acidic drugs are susceptible to "ion trapping" in the urine. If a weakly acidic xenobiotic depends on renal excretion for the majority of its elimination, alkalizing the urine will increase ionization of the compound and thereby increase its rate of elimination. Urinary alkalinization enhances the elimination of *phenobarbital*, *chlorpropamide*, and *salicylates*. However, the American Academy of Clinical Toxicologists recommends urine alkalinization as a first-line treatment only for moderately severe salicylate poisoning that does not meet the criteria for hemodialysis (Proudfoot et al., 2004).

To achieve alkalinization of the urine, 100 to 150 mEq of sodium bicarbonate in 1 L of 5% dextrose in water (D5W) is infused intravenously and titrated to a serum pH of 7.45 to 7.55. Acidification of the urine is not recommended for basic drugs since the risks of acidification outweigh the benefits.

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal (MDAC) can increase the elimination of absorbed drug by two mechanisms: Charcoal may interrupt enterohepatic circulation of hepatically metabolized drug excreted in the bile, and charcoal may create a diffusion gradient across the GI mucosa and promote movement of drug from the bloodstream onto the charcoal in the intestinal lumen. There is not one standardized dosing regimen, but an example of a reasonable dosage regimen for an adult is 50 g of activated charcoal every 4 h. Table 9–13 lists drugs that may demonstrate an enhanced elimination half-life following MDAC administration.

TABLE 9–13 ■ DRUGS WITH ENHANCED ELIMINATION FOLLOWING MDAC THERAPY

Carbamazepine	Quinine
Dapsone	Salicylate
Digoxin	Theophylline
Phenobarbital	

Sources: American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists, 2004.

Extracorporeal Drug Removal

The ideal drug amenable to removal by hemodialysis has a low molecular weight, a low volume of distribution, high solubility in water, and minimal protein binding. Hemodialysis is often reserved for patients with a life-threatening toxicity that does not respond to maximal supportive care measures. Other patients may necessitate hemodialysis due to impaired elimination, electrolyte abnormalities, or acid-base disturbances. Common poisonings for which hemodialysis is used include *carbamazepine*, *ethylene glycol*, *lithium*, *metformin*, *methanol*, *salicylate*, and *valproate*.

Antidotal Therapies

Antidotes are a diverse class of medications that prevent morbidity and mortality in poisoned patients when administered appropriately. There are a number of unique mechanisms by which antidotes exert their therapeutic action. Common classes of antidotes are described below.

Chemical Antidotes

Chemical antidotes bind to toxins, forming biologically inactive complexes that are subsequently excreted. Antidotes including *digoxin immune Fab* and the antivenom *Crotalidae* polyvalent immune Fab use antigen-binding fragments (Fab) to bind to the target toxin. Metal chelators, like *deferoxamine*, function similarly in that they bind to metals to form stable complexes that are biologically inactive and excreted (see Chapter 76). *Sugammadex* is a modified cyclodextrin that, administered intravenously, binds several aminosteroid muscle relaxants (e.g., *rocuronium*) that are sometimes used in surgical anesthesia, thereby permitting rapid recovery of skeletal muscle tone after surgery.

Pharmacological Antidotes

Pharmacological antidotes work by antagonizing the effect of the toxin at the receptor it innervates. *Naloxone* is a competitive antagonist at μ-opioid receptors and rapidly reverses the effects of opioid toxicity when administered.

Physiological (Functional) Antidotes

A physiological antidote may use a different cellular mechanism to overcome the effects of a poison, as in the use of glucagon to circumvent a blocked β adrenergic receptor and increase cellular cyclic AMP in the setting of an overdose of a β adrenergic antagonist. Antivenoms and chelating agents bind and directly inactivate poisons. The biotransformation of a drug can also be altered by an antidote; for example, *fomepizole* will inhibit alcohol dehydrogenase and stop the formation of toxic acid metabolites from ethylene glycol and methanol. Many drugs used in the supportive care of a poisoned patient (e.g., anticonvulsants, vasoconstricting agents) may be considered nonspecific functional antidotes.

Dispositional Antidotes

Dispositional antidotes can prevent the formation of toxic metabolites by antagonizing toxic metabolic pathways. *Fomepizole* competitively inhibits alcohol dehydrogenase to prevent the metabolism of methanol and ethylene glycol to their respective toxic metabolites. Other antidotes support endogenous detoxifying metabolic pathways. In *valproic acid* overdose, carnitine depletion shunts valproate metabolism to ω-oxidation, producing metabolites that disrupt the urea cycle and cause hepatotoxicity. Administering L-carnitine restores hepatic carnitine to support nontoxic β-oxidation.

Table 9–14 provides a list of commonly recommended antidotes (Dart et al., 2018).

Resources for Information on Drug Toxicity and Poisoning

Additional information on poisoning from drugs and chemicals can be found in many dedicated books of toxicology (Klaassen, 2019; Nelson et al., 2019; Olson et al., 2018; Shannon et al., 2007). Popular drug information databases have toxicology-specific monographs including POISINDEX® (Micromedex, Inc., Denver, CO) and Lexi-Tox™ (Lexicomp online, Lexi-Tox online, Hudson, OH: UpToDate, Inc.). The National Library of Medicine offers information on toxicology through PubChem (https://pubchem.ncbi.nlm.nih.gov/). The Consumer Product Information

TABLE 9–14 ■ ANTIDOTAL THERAPIES AND POISONING INDICATION(S)

ANTIDOTE	POISONING INDICATION(S)
N-Acetylcysteine	Acetaminophen
Atropine sulfate	Pesticide (carbamate and organophosphate types)
Antivenin, *Latrodectus mactans*	Black widow spider envenomation
Antivenin, *Micrurus fulvius*	North American coral snake envenomation
Antivenom, *Centruroides* (scorpion) immune $F(ab')_2$	*Centruroides* scorpion envenomation
Antivenom, *Crotalidae* [Polyvalent immune fab and immune $F(ab')_2$]	North American rattlesnake envenomation
Calcium	Ca^{2+} channel blockers; fluoride
Calcium disodium EDTA	Chronic lead poisoning
Cyproheptadine	Serotonin
Dantrolene	Anesthetic-induced malignant hyperthermia
Deferoxamine	Iron overload (acute and chronic)
Digoxin immune Fab	Cardiac glycosides
Dimercaprol (BAL)	Lead, mercury, arsenic
Fomepizole	Ethylene glycol, methanol
Flumazenil	Benzodiazepines
Glucagon hydrochloride	β Blockers and calcium channel blockers
Glucarpidase	Methotrexate
Hydroxocobalamin	Cyanide
Idarucizumab	Dabigatran
Leucovorin	Methotrexate
L-Carnitine	Valproic acid (off-label use)
Lipid emulsion	Local anesthetics
Methylene blue	Methemoglobinemia
Naloxone	Opioids
Octreotide	Sulfonylurea-induced hypoglycemia
Physostigmine	Anticholinergic delirium
Pralidoxime (2-PAM)	Organophosphate pesticides
Protamine	Heparin
Prothrombin complex concentrate *(3- or 4-factor, or activated)*	Vitamin K antagonist
Prussian blue	Thallium (^{201}Ti); cesium (^{137}Cs)
Pyridoxine	Hydrazine; isoniazid
Sodium bicarbonate	Salicylate; tricyclic antidepressants
Succimer (DMSA)	Lead (on label); mercury and arsenic (off label)
Vitamin K_1 (phytonadione)	Vitamin K antagonist (warfarin, coumarin, etc.)

Database stores information for the health effects of consumer products. (whatsinproducts.com). The Center for Disease Control and Prevention's Agency for Toxic Substances and Disease Registry hosts information on environmental toxins (https://www.atsdr.cdc.gov/). The Extracorporeal Treatments in Poisoning Workgroup publishes evidence-based recommendations for various substances (https://www.extrip-workgroup.org/recommendations). Regional poison control centers are available for poison information 24/7 in the U.S. by calling the Poison Help hotline: 1-800-222-1222.

Chapter 10

Neurotransmission: The Autonomic and Somatic Motor Nervous Systems

Rebecca Petre Sullivan, Steven R. Houser, and Walter J. Koch

Anatomy and General Functions

The autonomic nervous system, also called the *visceral, vegetative,* or *involuntary nervous system,* is distributed widely throughout the body and regulates autonomic functions that occur without conscious control. In the periphery, it consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues. This system enables the body to constantly monitor, analyze, and anticipate needs, and control the response to the organ systems, in order to maintain homeostasis.

Differences Between Autonomic and Somatic Nerves

- The *efferent nerves* of the autonomic nervous system supply all innervated structures of the body except skeletal muscles, which are served by *somatic nerves*.
- The most distal synaptic junctions in the autonomic reflex arc occur in *ganglia* that are entirely *outside the cerebrospinal axis*. Somatic nerves contain no peripheral *ganglia*, and the synapses are located entirely *within the cerebrospinal axis*.
- Many autonomic nerves form extensive peripheral plexuses; such networks are absent from the somatic system.
- Postganglionic autonomic nerves generally are *nonmyelinated*; motor nerves to skeletal muscles are *myelinated*.
- When the spinal efferent nerves are interrupted, smooth muscles and glands generally retain some level of spontaneous activity, whereas the *denervated* skeletal muscles are paralyzed.

Sensory Information: Afferent Fibers and Reflex Arcs

Afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the CNS.

Visceral Afferent Fibers. Information on the status of the visceral organs is transmitted to the CNS through two main sensory systems: the *cranial nerve (parasympathetic) visceral sensory system* and the *spinal (sympathetic) visceral afferent system.* The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information, whereas the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin.

Cranial visceral sensory information enters the CNS by four cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X) nerves. These four cranial nerves transmit visceral sensory information from the internal face and head (V); tongue (taste, VII); hard palate and upper part of the oropharynx (IX); and carotid body, lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs (X), with the exception of the pelvic viscera. The pelvic viscera are innervated by nerves from the second through fourth sacral spinal segments. The visceral afferents from these four cranial nerves terminate topographically in the solitary tract nucleus (STN).

Sensory afferents from visceral organs also enter the CNS from the spinal nerves. Those concerned with muscle chemosensation may arise at all spinal levels, whereas sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. Pelvic sensory afferents from spinal segments S2–S4 enter at that level and are important for the regulation of sacral parasympathetic outflow. In general, visceral afferents that enter the spinal nerves convey information concerned with temperature as well as nociceptive visceral inputs related to mechanical, chemical, and thermal stimulation. The primary pathways taken by ascending spinal visceral afferents are complex. An important feature of the ascending pathways is that they provide collaterals that converge with the cranial visceral sensory pathway at virtually every level (Saper, 2002).

The neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and calcitonin gene-related peptide (CGRP), present in afferent sensory fibers, dorsal root ganglia, and the dorsal horn of the spinal cord, likely communicate nociceptive stimuli from the periphery to the spinal cord and higher structures. Somatostatin (SST), vasoactive intestinal polypeptide (VIP), and cholecystokinin also occur in sensory neurons (Hökfelt et al., 2000). ATP appears to be a neurotransmitter in certain sensory neurons (e.g., the urinary bladder). Enkephalins, present in interneurons in the dorsal spinal cord (within the *substantia gelatinosa*), have antinociceptive effects both pre- and postsynaptically to inhibit the release of substance P and diminish the activity of cells that project from the spinal cord to higher centers in the CNS. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord. These transmitters and their signaling pathways are reviewed in Chapter 16.

Central Autonomic Connections

There probably are no purely autonomic or somatic centers of integration, and extensive overlap occurs. Somatic responses always are accompanied

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
BuChE: butyrylcholinesterase
CaM: calmodulin
CGRP: calcitonin gene-related peptide
CHT1: choline transporter
COMT: catechol-*O*-methyltransferase
DA: dopamine
DAT: DA transporter
DβH: dopamine β-hydroxylase
DOMA: 3,4-dihydroxymandelic acid
DOPEG: 3,4-dihydroxyphenyl glycol
DOPGAL: dihydroxyphenylglycolaldehyde
ENS: enteric nervous system
ENT: extraneuronal transporter
EPI: epinephrine
EPSP: excitatory postsynaptic potential
ICC: interstitial cells of Cajal
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
5HT: serotonin (5-hydroxytryptamine)
ICC: interstitial cells of Cajal
IP_3: inositol 1,4,5-trisphosphate
IPSP: inhibitory postsynaptic potential
KO: knockout
mAChR: muscarinic acetylcholine receptor
MAO: monoamine oxidase
MAPK: mitogen-activated protein kinase
MOPEG: 3-methyl,4-hydroxyphenylglycol
MOPGAL: monohydroxyphenylglycolaldehyde
nAChR: nicotinic ACh receptor
NE: norepinephrine (noradrenaline)
NET: norepinephrine transporter
NMJ: neuromuscular junction (of skeletal muscle)
NO: nitric oxide
NOS: nitric oxide synthase
NPY: neuropeptide Y
NSF: *N*-ethylmaleamide sensitive factor
PACAP: pituitary adenylyl cyclase–activating peptide
PK_: protein kinase _, as in PKA
PL_: phospholipase _, as in PLA_2, PLC, etc.
PNMT: phenylethanolamine-*N*-methyltransferase
SA: sinoatrial
SLC: solute carrier
SNAP: soluble NSF attachment protein, synaptosome-associated protein
SNARE: SNAP receptor
SST: somatostatin
STN: solitary tract nucleus
TH: tyrosine hydroxylase
VIP: vasoactive intestinal polypeptide
VMA: vanillyl mandelic acid
VMAT2: vesicular uptake transporter

by visceral responses and vice versa. Autonomic reflexes can be elicited at the level of the spinal cord. They clearly are demonstrable in experimental animals or humans with spinal cord transection and are manifested by sweating, blood pressure alterations, vasomotor responses to temperature changes, and reflex emptying of the urinary bladder, rectum, and seminal vesicles. Extensive central ramifications of the autonomic nervous system exist above the level of the spinal cord. For example, integration of the control of respiration in the medulla oblongata is well known. The hypothalamus and the STN generally are regarded as principal loci of integration of autonomic nervous system functions, which include regulation of body temperature, water balance, carbohydrate and fat metabolism, blood pressure, emotions, sleep, respiration, and reproduction. Signals are received through ascending spinobulbar pathways, the limbic system, neostriatum, cortex, and to a lesser extent other higher brain centers. Stimulation of the STN and the hypothalamus activates bulbospinal pathways, which originate in the brainstem, and hormonal output to mediate autonomic and motor responses (Andresen and Kunze, 1994) (see Chapter 16). The hypothalamic nuclei that lie posteriorly and laterally are sympathetic in their main connections and are responsible for myriad responses including body temperature regulation, blood pressure, and pupillary dilation (posterior hypothalamus), and cardiovascular control, feeding, satiety, and insulin release (lateral hypothalamus). Parasympathetic functions evidently are integrated by the midline nuclei in the region of the tuber cinereum and by nuclei lying anteriorly.

Highly integrated patterns of response generally are organized at a hypothalamic level and involve autonomic, endocrine, and behavioral components. More limited patterned responses are organized at other levels of basal forebrain, brainstem, and spinal cord.

Divisions of the Peripheral Autonomic System

On the efferent side, the autonomic nervous system consists of two large divisions: (1) the *sympathetic* or *thoracolumbar outflow*, which includes T1–L2, and (2) the *parasympathetic* or *craniosacral outflow*, which includes cranial nerves III, VII, IX, and X, as well as S2–S4. Figure 10–1 schematically summarizes the arrangement of the principal parts of the peripheral autonomic nervous system.

Neurotransmitters of the Autonomic Nervous System

The neurotransmitter of all preganglionic autonomic fibers, most postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is acetylcholine (Ach). Some postganglionic parasympathetic nerves use nitric oxide (NO) as a neurotransmitter and are termed *nitrergic* (Toda and Okamura, 2003). The majority of the postganglionic sympathetic fibers are *adrenergic,* in which the transmitter is norepinephrine (NE; also called noradrenaline). The terms *cholinergic* and *adrenergic* describe neurons that liberate ACh or NE, respectively. Not all the transmitters of the primary afferent fibers, such as those from the mechano- and chemoreceptors of the carotid body and aortic arch, have been identified conclusively. Substance P and glutamate may mediate many afferent impulses; both are present in high concentrations in the dorsal horn of the spinal cord.

Sympathetic Nervous System

The cells that give rise to the preganglionic fibers of the sympathetic nervous system division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or third lumbar segment. The axons from these cells are carried in the anterior (ventral) nerve roots and synapse, with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in three locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by *rami communicantes*. The white rami are restricted to the segments of the thoracolumbar outflow; they carry the preganglionic myelinated fibers that exit the spinal cord by the anterior spinal roots. The gray rami arise from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number, lie near the organs they innervate, and include ganglia connected with the

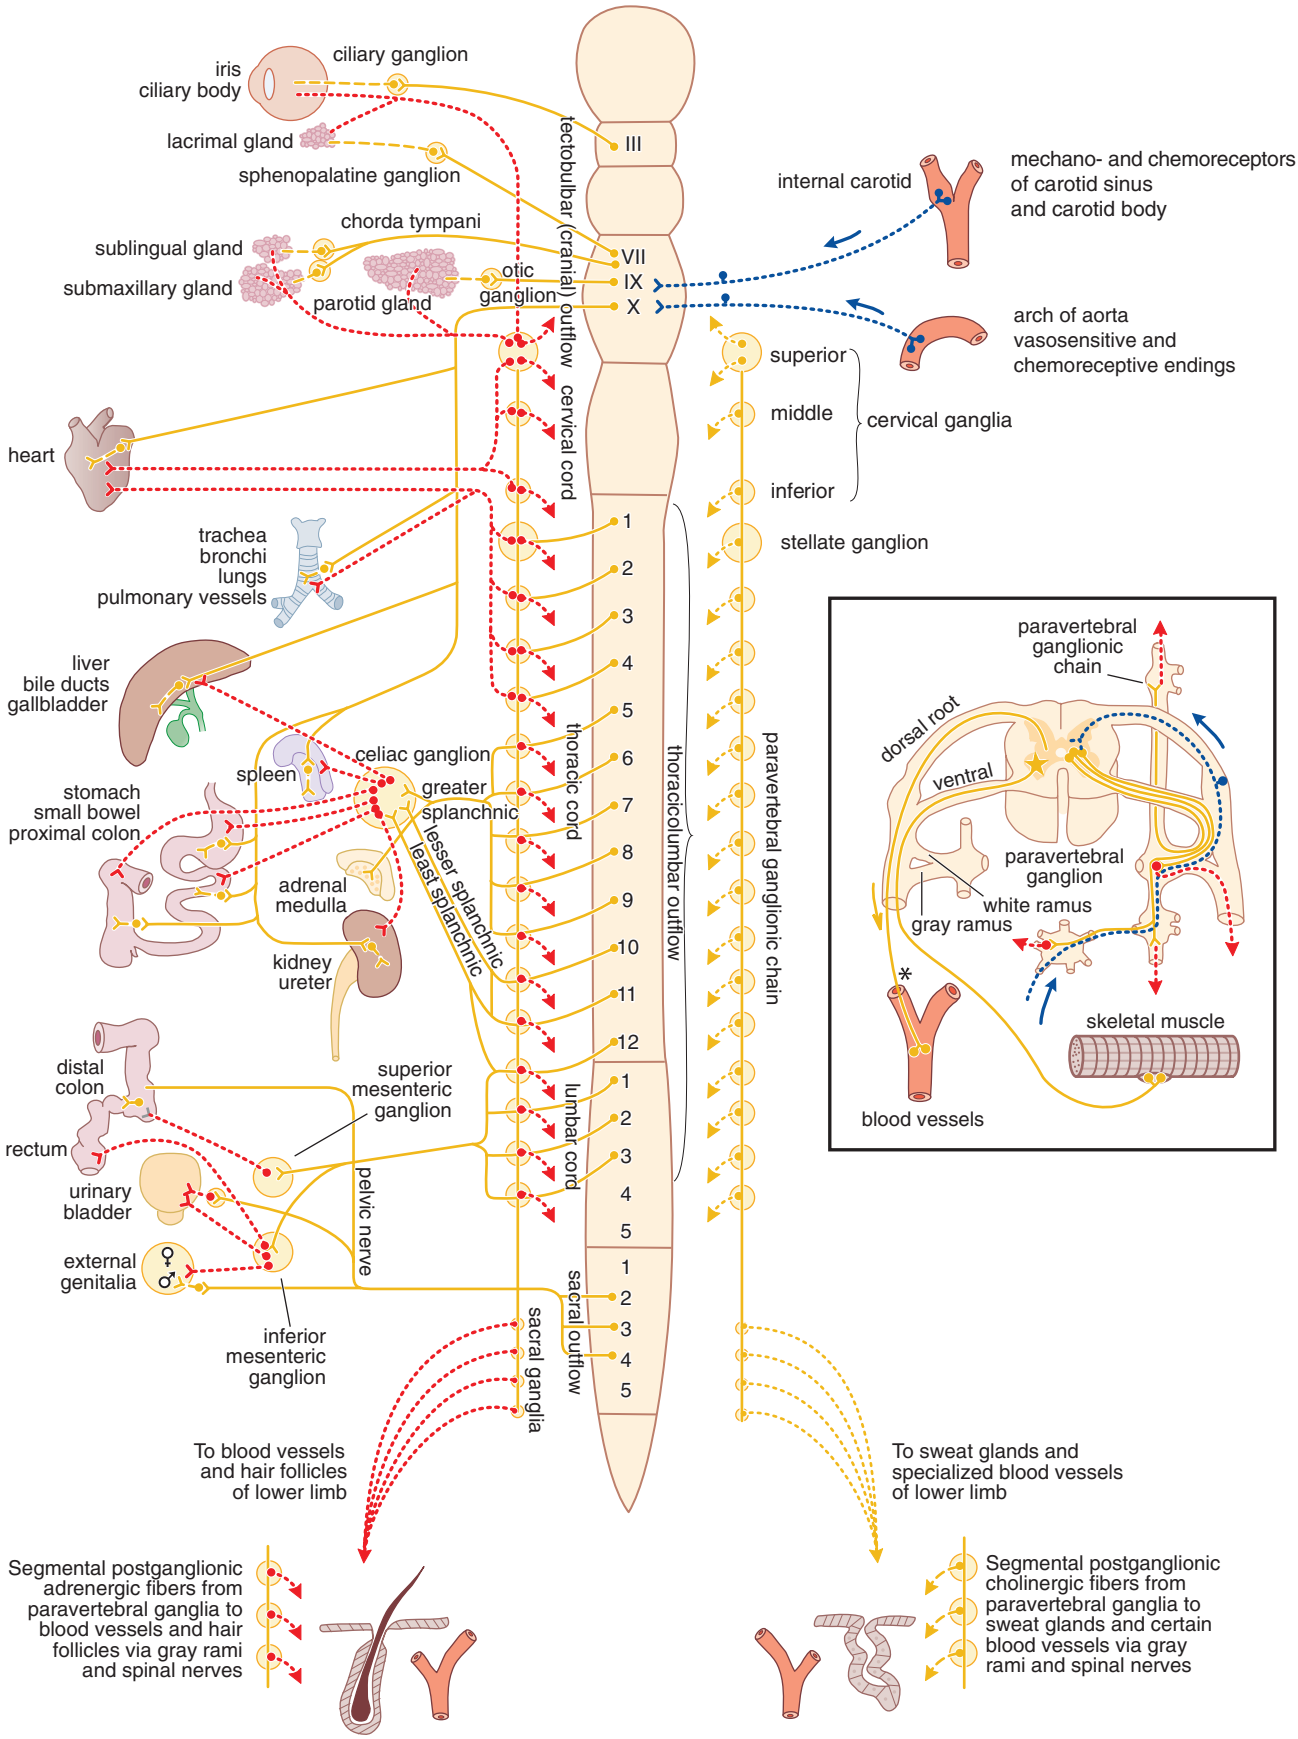

Figure 10–1 *The autonomic nervous system.* Schematic representation of the autonomic nerves and effector organs based on chemical mediation of nerve impulses. Yellow (——), cholinergic; red (——), adrenergic; dotted blue (- - - - -), visceral afferent; solid lines, preganglionic; broken lines, postganglionic. The rectangle at right shows the finer details of the ramifications of adrenergic fibers at any one segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known whether these vasodilator fibers are motor or sensory or where their cell bodies are situated.

urinary bladder and rectum and the cervical ganglia in the region of the neck. In addition, small intermediate ganglia lie outside the conventional vertebral chain, especially in the thoracolumbar region. They are variable in number and location but usually are in proximity to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers issuing from the spinal cord may synapse with the neurons of more than one sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla.

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves. The prevertebral ganglia contain cell bodies whose axons innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillodilator, secretory, and pilomotor) is by means of the cervical sympathetic chain and its three ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia. All preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

Pharmacologically, anatomically, and embryologically, the chromaffin cells of the adrenal medulla resemble a collection of postganglionic sympathetic nerve cells. Typical preganglionic fibers that release ACh innervates these chromaffin cells, stimulating the release of epinephrine (EPI; also called adrenaline), in distinction to the NE released by postganglionic sympathetic fibers.

Parasympathetic Nervous System

The parasympathetic nervous system consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger-Westphal nucleus (accessory oculomotor nucleus) of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow consists of the parasympathetic components of cranial nerves VII, IX, and X.

The fibers in the VII (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the IX (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. Cranial nerve X (vagus) arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. *Thus, in the parasympathetic branch of the autonomic nervous system, preganglionic fibers are very long, whereas postganglionic fibers are very short.* The vagus nerve also carries a far greater number of afferent fibers from the viscera into the medulla. The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (*nervi erigentes*). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs (see Figure 10–1).

Enteric Nervous System

The processes of mixing, propulsion, and absorption of nutrients in the gastrointestinal (GI) tract are controlled locally through a restricted part of the peripheral nervous system called the *enteric nervous system* (ENS). The ENS comprises components of the sympathetic and parasympathetic nervous systems and has sensory nerve connections through the spinal and nodose ganglia (see Figure 54–1 and Furness et al., 2014). The ENS is involved in sensorimotor control and thus consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into two nerve plexuses: the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus. The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of GI smooth muscle, therefore exerting control over peristaltic movements and gastrointestinal motility. The submucosal plexus is involved with secretory and absorptive functions of the GI epithelium, local blood flow, and neuroimmune activities. The microbiota of the gut, the immune system, and their interactions with the ENS inform GI homeostasis and may play a role in the development of neurodegenerative diseases (Obata and Pachnis, 2016).

Parasympathetic preganglionic inputs are provided to the GI tract via the vagus and pelvic nerves. ACh released from *preganglionic neurons* activates nicotinic ACh receptors (nAChRs) on postganglionic neurons within the enteric ganglia. Excitatory preganglionic input activates both excitatory and inhibitory motor neurons that control processes such as muscle contraction and secretion/absorption. *Postganglionic sympathetic nerves* also synapse with intrinsic neurons and generally induce relaxation. Sympathetic input is excitatory (contractile) at some sphincters. Information from afferent and preganglionic neural inputs to the enteric ganglia is integrated and distributed by a network of interneurons. ACh is the primary neurotransmitter providing excitatory inputs between interneurons, but other substances, such as ATP (via postjunctional P2X receptors), substance P (by NK_3 receptors), and serotonin (5HT; via $5HT_3$ receptors), are also important in mediating integrative processing via interneurons.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons, with cell bodies primarily in the myenteric ganglia. ACh is a primary excitatory motor neurotransmitter released from postganglionic neurons. ACh activates M_2 and M_3 receptors in postjunctional cells to elicit motor responses. Pharmacological blockade of muscarinic acetylcholine receptors (mAChRs) does not block all excitatory neurotransmission, however, because neurokinins (neurokinin A and substance P) are also co-released by excitatory motor neurons and contribute to postjunctional excitation. Inhibitory motor neurons in the GI tract regulate motility events such as accommodation, sphincter relaxation, and descending receptive relaxation. Inhibitory responses are elicited by NO and a purine derivative (either ATP or β-nicotinamide adenine dinucleotide) acting at postjunctional $P2Y_1$ receptors. Inhibitory neuropeptides, such as VIP and pituitary adenylyl cyclase–activating peptide, may also be released from inhibitory motor neurons under conditions of strong stimulation.

In general, motor neurons do not directly innervate smooth muscle cells in the GI tract. Nerve terminals make synaptic connections with the interstitial cells of Cajal (ICCs), and these cells make electrical connections (gap junctions) with smooth muscle cells. Thus, the ICCs are the receptive, postjunctional transducers of inputs from enteric motor neurons, and loss of these cells has been associated with conditions that appear to be neuropathies. ICCs have all of the major receptors and effectors necessary to transduce both excitatory and inhibitory neurotransmitters into postjunctional responses (Foong et al., 2020).

Comparison of Sympathetic, Parasympathetic, and Motor Nerves

Differences among somatic motor, sympathetic, and parasympathetic nerves are shown schematically in Figure 10–2. To summarize:

- The *sympathetic* system is distributed to effectors throughout the body, whereas *parasympathetic* distribution is much more limited.
- A *preganglionic sympathetic fiber* may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it

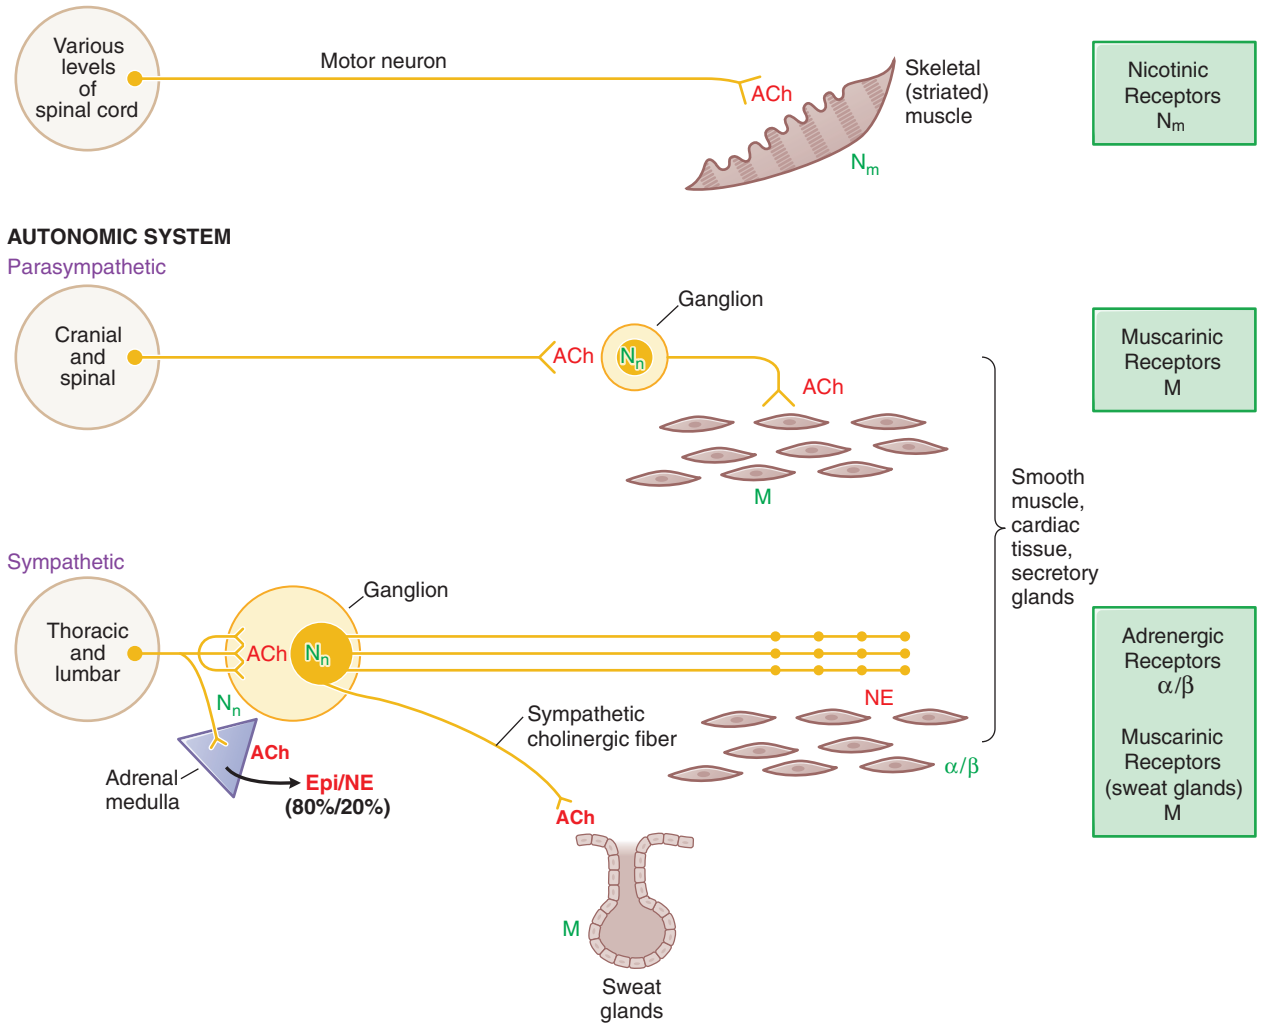

Figure 10–2 *Comparative features of somatic motor nerves and efferent nerves of the autonomic nervous system.* The principal neurotransmitters, ACh and NE, are shown in *red*. The receptors for these transmitters, nicotinic (N) and muscarinic (M) cholinergic receptors, α and β adrenergic receptors, are shown in *green*. Somatic nerves innervate skeletal muscle directly at a specialized synaptic junction, the motor end plate, where ACh activates N_m receptors. Autonomic nerves innervate smooth muscles, cardiac tissue, and glands. Both parasympathetic and sympathetic systems have ganglia, where ACh is released by the preganglionic fibers; ACh acts on N_n receptors on the postganglionic nerves. ACh is also the neurotransmitter at cells of the adrenal medulla, where it acts on N_n receptors to cause release of EPI and NE into the circulation. ACh is the dominant neurotransmitter released by postganglionic parasympathetic nerves and acts on muscarinic receptors. The ganglia in the parasympathetic system are near or within the organ being innervated, with generally a one-to-one relationship between pre- and postganglionic fibers. NE is the principal neurotransmitter of postganglionic sympathetic nerves, acting on α or β adrenergic receptors. Autonomic nerves form a diffuse pattern with multiple synaptic sites. In the sympathetic system, the ganglia are generally far from the effector cells (e.g., within the sympathetic chain ganglia). Preganglionic sympathetic fibers may make contact with a large number of postganglionic fibers.

finally synapses with a postganglionic neuron; also, its terminals make contact with a large number of postganglionic neurons. The *parasympathetic system* has terminal ganglia very near or within the organs innervated and is generally more circumscribed in its influences.

- The cell bodies of *somatic motor neurons* reside in the ventral horn of the spinal cord; the axon divides into many branches, each of which innervates a single muscle fiber; more than 100 muscle fibers may be supplied by one motor neuron to form a motor unit. At each neuromuscular junction (NMJ), the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, termed the *motor end plate* (see Figure 13–4). Reciprocal trophic signals between muscle and nerve regulate the development of the NMJ (Witzemann et al., 2013).
- Ganglionic organization can differ among the different types of nerves and locales. In some organs innervated by the parasympathetic branch, a 1:1 relationship between the number of preganglionic and postganglionic fibers has been suggested. In sympathetic ganglia, one ganglion cell may be supplied by several preganglionic fibers, and the ratio of preganglionic axons to ganglion cells may be 1:20 or more; this organization permits diffuse discharge of the sympathetic system. The ratio of preganglionic vagal fibers to ganglion cells in the myenteric plexus has been estimated as 1:8000.

A Few Details About Innervation

The terminations of the postganglionic autonomic fibers in smooth muscle and glands form a rich plexus, or terminal reticulum. The terminal reticulum (sometimes called the *autonomic ground plexus*) consists of the final ramifications of the postganglionic sympathetic, parasympathetic, and visceral afferent fibers, all of which are enclosed within a frequently interrupted sheath of satellite or Schwann cells. At these interruptions, varicosities packed with vesicles are seen in the efferent fibers. Such varicosities occur repeatedly but at variable distances along the course of the ramifications of the axon.

"Protoplasmic bridges" occur between the smooth muscle fibers themselves at points of contact between their plasma membranes. They are believed to permit the direct conduction of impulses from cell to cell

without the need for chemical transmission. These structures have been termed *nexuses,* or *gap* junctions, and they enable the smooth muscle fibers to function as a syncytial unit.

Sympathetic ganglia are extremely complex anatomically and pharmacologically (see Chapter 13). The preganglionic fibers lose their myelin sheaths and divide repeatedly into a vast number of end fibers with diameters ranging from 0.1 to 0.3 μm; except at points of synaptic contact, they retain their satellite cell sheaths. The vast majority of synapses are axodendritic. Apparently, a given axonal terminal may synapse with multiple dendritic processes.

Responses of Effector Organs to Autonomic Nerve Impulses. *In many instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists* (Table 10–1). Most viscera are innervated by both divisions of the autonomic nervous system, and their activities on specific structures may be either discrete and independent or integrated and interdependent. The effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function. These physiological effects are mediated through negative, and sometimes positive, feedback mechanisms.

From the responses of the various effector organs to autonomic nerve impulses and the knowledge of the intrinsic autonomic tone, one can predict the actions of drugs that mimic or inhibit the actions of these nerves.

General Functions of the Autonomic Nervous System. *The autonomic nervous system is the primary regulator of the constancy of the internal environment of the organism, or the maintenance of homeostasis.*

The *sympathetic system* and its associated adrenal medulla are not essential to life in a controlled environment, but the lack of sympathoadrenal functions becomes evident under circumstances of stress. For example, in the absence of the sympathetic system, body temperature cannot be regulated when environmental temperature varies; the concentration of glucose in blood does not rise in response to urgent need; compensatory vascular responses to hemorrhage, oxygen deprivation, excitement, and exercise are lacking; and resistance to fatigue is lessened. Sympathetic components of instinctive reactions to the external environment are lost, and other serious deficiencies in the protective forces of the body are discernible. The sympathetic system normally is continuously active, the degree of activity varying from moment to moment and from organ to organ, adjusting to a constantly changing environment in order to maintain homeostasis. The sympathoadrenal system can discharge as a unit. Heart rate is accelerated; blood pressure rises; blood flow is shifted from the skin and splanchnic region to the skeletal and cardiac muscles; blood glucose rises; the bronchioles and pupils dilate; and the organism is better prepared for "fight or flight." Many of these effects result primarily from or are reinforced by the actions of EPI secreted by the adrenal medulla.

The *parasympathetic system* is organized mainly for discrete and localized discharge. Although it is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal

HISTORICAL PERSPECTIVE

The earliest concrete proposal of a neurohumoral mechanism was made shortly after the turn of the 20th century. Lewandowsky and Langley independently noted the similarity between the effects of injection of extracts of the adrenal gland and stimulation of sympathetic nerves. In 1905, T. R. Elliott, while a student with Langley at Cambridge, postulated that sympathetic nerve impulses release minute amounts of an EPI-like substance in immediate contact with effector cells. He considered this substance to be the chemical step in the process of transmission. He also noted that long after sympathetic nerves had degenerated, the effector organs still responded characteristically to the hormone of the adrenal medulla. Langley suggested that effector cells have excitatory and inhibitory "receptive substances" and that the response to EPI depended on which type of substance was present. In 1907, Dixon, impressed by the correspondence between the effects of the alkaloid muscarine and the responses to vagal stimulation, advanced the concept that the vagus nerve liberated a muscarine-like substance that acted as a chemical transmitter of its impulses. In the same year, Reid Hunt described the actions of ACh and other choline esters. In 1914, Dale investigated the pharmacological properties of ACh and other choline esters and distinguished its nicotine-like and muscarine-like actions. Intrigued with the remarkable fidelity with which this drug reproduced the responses to stimulation of parasympathetic nerves, he introduced the term *parasympathomimetic* to characterize its effects. Dale also noted the brief duration of action of this chemical and proposed that an esterase in the tissues rapidly splits ACh to acetic acid and choline, thereby terminating its action.

The studies of Loewi, begun in 1921, provided the first direct evidence for the chemical mediation of nerve impulses by the release of specific chemical agents. Loewi stimulated the vagus nerve of a perfused (donor) frog heart and allowed the perfusion fluid to come in contact with a second (recipient) frog heart used as a test object. The recipient frog heart was found to respond, after a short lag, in the same way as the donor heart. It thus was evident that a substance was liberated from the first organ that slowed the rate of the second. Loewi referred to this chemical substance as *Vagusstoff* ("vagus substance," "parasympathin"); subsequently, Loewi and Navratil presented evidence of its identity as ACh. Loewi also discovered that an accelerator substance similar to EPI and called *Acceleranstoff* was liberated into the perfusion fluid in summer, when the action of the sympathetic fibers in the frog's vagus, a mixed nerve, predominated over that of the inhibitory fibers. Feldberg and Krayer demonstrated in 1933 that the cardiac "vagus substance" also is ACh in mammals.

In the same year as Loewi's discovery, Cannon and Uridil reported that stimulation of the sympathetic hepatic nerves resulted in the release of an EPI-like substance that increased blood pressure and heart rate. Subsequent experiments firmly established that this substance is the chemical mediator liberated by sympathetic nerve impulses at neuroeffector junctions. Cannon called this substance "sympathin." In many of its pharmacological and chemical properties, sympathin closely resembled EPI, but also differed in certain important respects. As early as 1910, Barger and Dale noted that the effects of sympathetic nerve stimulation were reproduced more closely by the injection of sympathomimetic primary amines than by that of EPI or other secondary amines. The possibility that demethylated EPI (NE) might be sympathin had been advanced repeatedly, but definitive evidence for its being the sympathetic nerve mediator was not obtained until specific assays were developed for the determination of sympathomimetic amines in extracts of tissues and body fluids. In 1946, von Euler found that the sympathomimetic substance in highly purified extracts of bovine splenic nerve resembled NE by all criteria used (von Euler, 1946).

We now know that NE is the predominant sympathomimetic substance in the postganglionic sympathetic nerves of mammals and is the adrenergic mediator liberated by their stimulation. NE, its immediate precursor dopamine (DA), and its *N*-methylated derivative EPI also are neurotransmitters in the CNS (see Chapter 16). As for ACh, in addition to its role as the transmitter of most postganglionic parasympathetic fibers and of a few postganglionic sympathetic fibers, ACh functions as a neurotransmitter in three additional classes of nerves: preganglionic fibers of both the sympathetic and the parasympathetic systems, motor nerves to skeletal muscle, and certain neurons within the CNS.

TABLE 10–1 ■ RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES

ORGAN SYSTEM	SYMPATHETIC EFFECT[a]	ADRENERGIC RECEPTOR SUBTYPE[b]	PARASYMPATHETIC EFFECT[a]	CHOLINERGIC RECEPTOR SUBTYPE[b]
Eye				
Radial muscle, iris pupillary dilator (dilator pupillae)	Contraction (mydriasis)++	α_1		
Sphincter muscle, iris pupillary constrictor (sphincter pupillae)			Contraction (miosis)+++	M_3, M_2
Ciliary muscle	Relaxation for far vision+	β_2	Contraction for near vision+++	M_3, M_2
Lacrimal glands	Secretion+	α	Secretion+++	M_3, M_2
Heart[c]				
Sinoatrial node	↑ heart rate++	$\beta_1 > \beta_2$	↓ heart rate+++	$M_2 >> M_3$
Atria	↑ contractility and conduction velocity++	$\beta_1 > \beta_2$	↓ contractility++ and shortened AP duration	$M_2 >> M_3$
Atrioventricular node	↑ automaticity and conduction velocity++	$\beta_1 > \beta_2$	↓ conduction velocity; AV block+++	$M_2 >> M_3$
His-Purkinje system	↑ automaticity and conduction velocity	$\beta_1 > \beta_2$	Little effect	$M_2 >> M_3$
Ventricle	↑ contractility, conduction velocity, automaticity, and rate of idioventricular pacemakers+++	$\beta_1 > \beta_2$	Slight ↓ in contractility	$M_2 >> M_3$
Blood vessels				
Arteries and arterioles[d]				
Coronary	Constriction+; dilation[e]++	α_1, α_2; β_2	No innervation[h]	—
Skin and mucosa	Constriction+++	α_1, α_2	No innervation[h]	—
Skeletal muscle	Constriction; dilation[e,f]++	α_1; β_2	Dilation[h] (?)	—
Cerebral	Constriction (slight)	α_1	No innervation[h]	—
Pulmonary	Constriction+; dilation	α_1; β_2	No innervation[h]	—
Abdominal viscera	Constriction+++; dilation+	α_1; β_2	No innervation[h]	—
Salivary glands	Constriction+++	α_1, α_2	Dilation[h]++	M_3
Renal	Constriction++; dilation++	α_1, α_2; β_1, β_2	No innervation[h]	
(Veins)[d]	Constriction; dilation	α_1, α_2; β_2		
Endothelium	—	—	↑ NO synthase[h]	M_3
Lung				
Tracheal and bronchial smooth muscle	Relaxation	β_2	Contraction	$M_2 = M_3$
Bronchial glands	↓ secretion, ↑ secretion	α_1	Stimulation	M_2, M_3
		β_2		
Stomach				
Motility and tone	↓ (usually)[i]+	α_1, α_2, β_1, β_2	↑[i]+++	$M_2 = M_3$
Sphincters	Contraction (usually)+	α_1	Relaxation (usually)+	M_3, M_2
Secretion	Inhibition	α_2	Stimulation++	M_3, M_2
Intestine				
Motility and tone	Decrease[h]+	α_1, α_2, β_1, β_2	↑[i]+++	M_3, M_2
Sphincters	Contraction+	α_1	Relaxation (usually)+	M_3, M_2
Secretion	↓	α_2	↑++	M_3, M_2
Gallbladder and ducts kidney	Relaxation+	β_2	Contraction+	M
Renin secretion	↓+; ↑++	α_1; β_1	No innervation	—
Urinary bladder				
Detrusor	Relaxation	β_2	Contraction++	$M_3 > M_2$

TABLE 10–1 ■ RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES (*CONTINUED*)

ORGAN SYSTEM	SYMPATHETIC EFFECT[a]	ADRENERGIC RECEPTOR SUBTYPE[b]	PARASYMPATHETIC EFFECT[a]	CHOLINERGIC RECEPTOR SUBTYPE[b]
Trigone and sphincter	Contraction++	α_1	Relaxation++	$M_3 > M_2$
Ureter				
Motility and tone	↑	α_1	↑ (?)	M
Uterus	Pregnant contraction	α_1		
	Relaxation	β_2	Variable[j]	M
	Nonpregnant relaxation	β_2		
Sex organs, male skin	Ejaculation+++	α_1	Erection+++	M_3
Pilomotor muscles	Contraction++	α_1	—	
Sweat glands	Localized secretion[k]++	α_1	—	
		—	Generalized secretion+++	M_3, M_2
Spleen capsule	Contraction+++	α_1	—	—
	Relaxation+	β_2	—	
Adrenal medulla	—		Secretion of EPI and NE	N $(\alpha_3)_2(\beta_4)_3$; M (secondarily)
Skeletal muscle	Increased contractility; glycogenolysis; K^+ uptake	β_2	—	—
Liver	Glycogenolysis and gluconeogenesis+++	α_1	—	—
		β_2		
Pancreas				
Acini	↓ secretion+	α	Secretion++	M_3, M_2
Islets (β cells)	↓ secretion+++	α_2	—	
	↑ secretion+	β_2		
Fat cells[l]	Lipolysis+++; thermogenesis	α_1, β_1, β_2, β_3	—	—
	Inhibition of lipolysis	α_2		
Salivary glands	K^+ and water secretion+	α_1	K^+ and water secretion+++	M_3, M_2
Nasopharyngeal glands	—		Secretion++	M_3, M_2
Pineal glands	Melatonin synthesis	β	—	
Posterior pituitary	ADH secretion	β_1	—	
Autonomic nerve endings				
Sympathetic terminal				
Autoreceptor	Inhibition of NE release	$\alpha_{2A} > \alpha_{2C}(\alpha_{2B})$		
Heteroreceptor	—		Inhibition of NE release	M_2, M_4
Parasympathetic terminal				
Autoreceptor	—	—	Inhibition of ACh release	M_2, M_4
Heteroreceptor	Inhibition ACh release	$\alpha_{2A} > \alpha_{2C}$	—	—

[a]Responses are designated + to +++ to provide an approximate indication of the importance of sympathetic and parasympathetic nerve activity in the control of the various organs and functions listed.
[b]Adrenergic receptors: α_1, α_2 and subtypes thereof; β_1, β_2, β_3. Cholinergic receptors: nicotinic (N); muscarinic (M), with subtypes 1–4. The receptor subtypes are described more fully in Chapters 11 and 14 and in Tables 10–2, 10–3, 10–6, and 10–7. When a designation of subtype is not provided, the nature of the subtype has not been determined unequivocally. Only the principal receptor subtypes are shown. Transmitters other than ACh and NE contribute to many of the responses.
[c]In the human heart, the ratio of β_1 to β_2 is about 3:2 in atria and 4:1 in ventricles. While M_2 receptors predominate, M_3 receptors are also present.
[d]The predominant α_1 receptor subtype in most blood vessels (both arteries and veins) is α_{1A}, although other α_1 subtypes are present in specific blood vessels. The α_{1D} is the predominant subtype in the aorta.
[e]Dilation predominates *in situ* owing to metabolic autoregulatory mechanisms.
[f]Over the usual concentration range of physiologically released circulating EPI, the β receptor response (vasodilation) predominates in blood vessels of skeletal muscle and liver; β receptor response (vasoconstriction) predominates in blood vessels of other abdominal viscera. The renal and mesenteric vessels also contain specific dopaminergic receptors whose activation causes dilation.
[g]Sympathetic cholinergic neurons cause vasodilation in skeletal muscle beds, but this is not involved in most physiological responses.
[h]The endothelium of most blood vessels releases NO, which causes vasodilation in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to exogenously added muscarinic agonists in the circulation.
[i]While adrenergic fibers terminate at inhibitory β receptors on smooth muscle fibers and at inhibitory β receptors on parasympathetic (cholinergic) excitatory ganglion cells of the myenteric plexus, the primary inhibitory response is mediated via enteric neurons through NO, P2Y receptors, and peptide receptors.
[j]Uterine responses depend on stages of menstrual cycle, amount of circulating estrogen and progesterone, and other factors.
[k]Palms of hands and some other sites ("adrenergic sweating").
[l]There is significant variation among species in the receptor types that mediate certain metabolic responses. All three β adrenergic receptors have been found in human fat cells. Activation of β_3 receptors produces a vigorous thermogenic response as well as lipolysis. The significance is unclear. Activation of β receptors also inhibits leptin release from adipose tissue.

activity, its elimination is not compatible with life. The parasympathetic system slows the heart rate, lowers the blood pressure, stimulates GI movements and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary bladder and rectum.

The balance of the activity of the sympathetic and parasympathetic systems establishes the basal, homeostatic state of the organism.

Neurochemical Transmission

Nerve impulses elicit responses in smooth, cardiac, and skeletal muscles; exocrine glands; and postsynaptic neurons by liberating specific chemical neurotransmitters.

Evidence for Neurohumoral Transmission

The concept of neurohumoral transmission or chemical neurotransmission was developed primarily to explain observations relating to the transmission of impulses from postganglionic autonomic fibers to effector cells. Evidence supporting this concept includes the following:

- Demonstration of the presence of a physiologically active compound and its biosynthetic enzymes at appropriate sites
- Recovery of the compound from the perfusate of an innervated structure during periods of nerve stimulation but not (or in greatly reduced amounts) in the absence of stimulation
- Demonstration that the compound is capable of producing responses identical to responses to nerve stimulation
- Demonstration that the responses to nerve stimulation and to the administered compound are modified in the same manner by various drugs, usually competitive antagonists

While these criteria are applicable for most neurotransmitters, including NE and ACh, there are now exceptions to these general rules. For instance, NO has been found to be a neurotransmitter in a few postganglionic parasympathetic nerves; in nonadrenergic, noncholinergic neurons in the periphery; in the ENS; and in the CNS. However, NO is not stored in neurons and released by exocytosis. Rather, it is synthesized when needed and readily diffuses across membranes.

Neurotransmission in the peripheral nervous system and CNS once was believed to conform to the hypothesis that each neuron contains only one transmitter substance. However, we now know that synaptic transmission can be mediated by the release of more than one neurotransmitter. Additional peptides, such as enkephalin, substance P, neuropeptide Y (NPY), VIP, and SST; purines such as ATP and adenosine; eicosanoids and endocannabinoids; and small molecules such as NO have been found in nerve endings along with the "classical" biogenic amine neurotransmitters. These additional substances can depolarize or hyperpolarize various nerve terminals and postsynaptic cells. For example, enkephalins are found in postganglionic sympathetic neurons and adrenal medullary chromaffin cells. VIP is localized selectively in peripheral cholinergic neurons that innervate exocrine glands, and NPY is found in sympathetic nerve endings and released along with NE and ATP. These observations suggest that synaptic transmission in many instances may be mediated by the release of more than one neurotransmitter (see the next section).

Steps Involved in Neurotransmission

The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

Axonal Conduction

Conduction refers to the passage of an electrical impulse along an axon or muscle fiber. At rest, the interior of the typical mammalian axon is about 70 mV negative to the exterior. In response to depolarization to a threshold level, an action potential is initiated at a local region of the membrane. The action potential consists of two phases. Following depolarization that induces an open conformation of the channel, the *initial phase* is caused by a rapid increase in the permeability and inward movement of Na^+ through voltage-sensitive Na^+ channels, and a rapid depolarization from the resting potential continues to a positive overshoot. The *second phase* results from the rapid inactivation of the Na^+ channel and the delayed opening of a K^+ channel, which permits outward movement of K^+ to terminate the depolarization. Although not important in axonal conduction, Ca^{2+} channels in other tissues (e.g., L-type Ca^{2+} channels in heart) contribute to the action potential by prolonging depolarization by an inward movement of Ca^{2+}. This influx of Ca^{2+} also serves as a stimulus to initiate intracellular events (Catterall, 2000), and Ca^{2+} influx is important in excitation-exocytosis coupling (transmitter release).

The transmembrane ionic currents produce local circuit currents such that adjacent resting channels in the axon are activated, and excitation of an adjacent portion of the axonal membrane occurs, leading to propagation of the action potential without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state to ensure that depolarization proceeds in the appropriate (forward) direction.

With the exception of the local anesthetics, few drugs modify axonal conduction in the doses employed therapeutically. The puffer fish poison, *tetrodotoxin*, and a close congener found in some shellfish, *saxitoxin*, selectively block axonal conduction by blocking the voltage-sensitive Na^+ channel and preventing the increase in Na^+ permeability associated with the rising phase of the action potential. In contrast, *batrachotoxin*, an extremely potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na^+ channel, which induces a persistent depolarization. Scorpion toxins are peptides that also cause persistent depolarization by inhibiting the inactivation process (Catterall, 2000). Na^+ and Ca^{2+} channels are discussed in more detail in Chapters 13, 16, and 25.

Junctional Transmission

The term *transmission* refers to the passage of an impulse across a synaptic or neuroeffector junction. The arrival of the action potential at the axonal terminals initiates a series of events that trigger transmission of an excitatory or inhibitory biochemical message across the synapse or neuroeffector junction. These events, diagrammed in Figures 10–3, 10–4, and 10–5, are the following:

1. *Storage and release of transmitter*. The nonpeptide (small-molecule) neurotransmitters, such as biogenic amines, are largely synthesized in the region of the axonal terminals and stored there in synaptic vesicles. Neurotransmitter transport into storage vesicles is driven by an electrochemical gradient generated by the vesicular proton pump (vesicular ATPase) (Figures 10–5 and 10–6). Synaptic vesicles cluster in discrete areas underlying the presynaptic plasma membrane, termed *active zones*, often aligning with the tips of postsynaptic folds. Proteins in the vesicular membrane (e.g., synapsin, synaptophysin, synaptogyrin) are involved in development and trafficking of the storage vesicle to the active zone. The processes of priming, docking, fusion, and exocytosis involve the interactions of proteins in the vesicular and plasma membranes and the rapid entry of extracellular Ca^{2+} and its binding to synaptotagmins (Figure 10–4).

Life Cycle of a Storage Vesicle; Molecular Mechanism of Exocytosis. Fusion of the storage vesicle and plasma membrane involves formation of a multiprotein complex that includes proteins in the membrane of the synaptic vesicle, proteins embedded in the inner surface of the plasma membrane, and several cytosolic components. These proteins are referred to as soluble NSF attachment protein (SNAP) receptor (SNARE) proteins. Through the assembly of these proteins, vesicles draw near the membrane (priming, docking), spatially prepared for the next step, which the entry of Ca^{2+} initiates. When Ca^{2+} enters with the action potential, fusion and exocytosis occur rapidly. After fusion, the chaperone ATPase *N*-ethylmaleamide sensitive factor (NSF) and its SNAP adapters catalyze dissociation of the SNARE complex. Figures 10–4 and 10–5 depict this life cycle. Figure 10–4 shows some details of the assembly of the SNARE protein complex leading to fusion and exocytosis of neurotransmitter. The isoforms of the participating proteins may

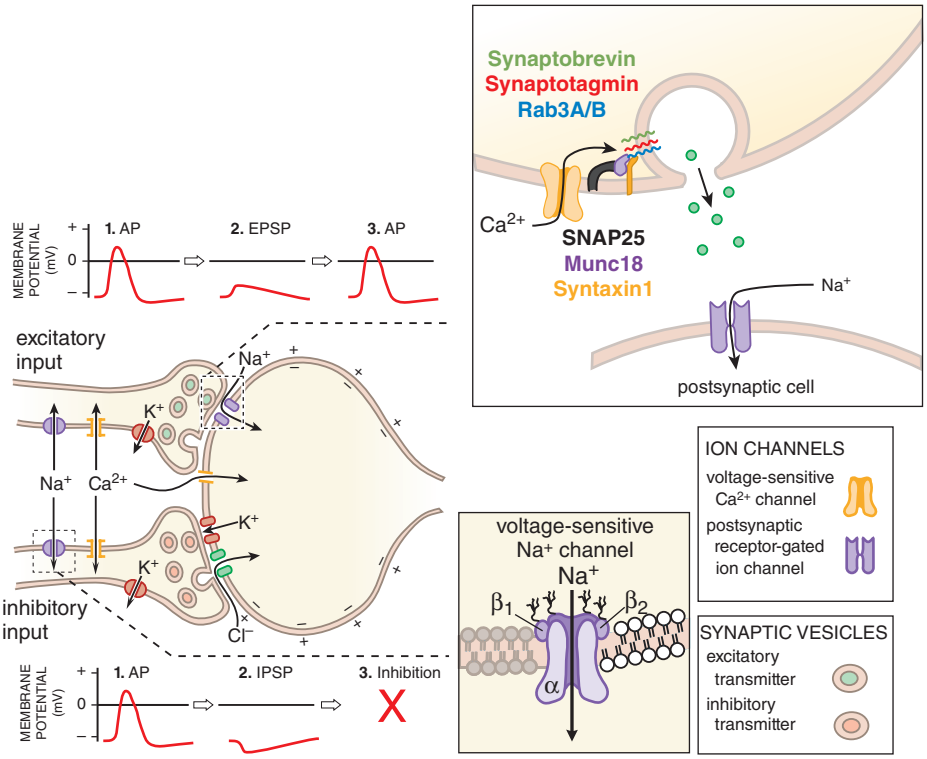

Figure 10–3 *Steps involved in excitatory and inhibitory neurotransmission.* ***1.*** The nerve action potential (AP) consists of a transient self-propagated reversal of charge on the axonal membrane. The membrane potential E_i goes from a negative value, through zero potential, to a slightly positive value, primarily through increases in Na^+ permeability, and then returns to resting values by an increase in K^+ permeability. When the AP arrives at the presynaptic terminal, it initiates release of the excitatory or inhibitory transmitter. Depolarization at the nerve ending and entry of Ca^{2+} initiate docking and then fusion of the synaptic vesicle with the membrane of the nerve ending. Some of the SNARE proteins involved in docking and fusion are shown. Figures 10–4 and 10–5 show additional details of the life cycle of neurotransmitter storage vesicle and exocytosis. ***2.*** Interaction of the excitatory transmitter with postsynaptic receptors produces a localized depolarization, the EPSP, through an increase in permeability to cations, most notably Na^+. The inhibitory transmitter causes a selective increase in permeability to K^+ or Cl^-, resulting in a localized hyperpolarization, the IPSP. ***3.*** The EPSP initiates a conducted AP in the postsynaptic neuron; this can be prevented, however, by the hyperpolarization induced by a concurrent IPSP. The transmitter is dissipated by enzymatic destruction, by reuptake into the presynaptic terminal or adjacent glial cells, or by diffusion. Depolarization of the postsynaptic membrane can permit Ca^{2+} entry if voltage-gated Ca^{2+} channels are present.

differ in different neurotransmitter systems, but the general mechanism seems to be conserved.

During the resting state, there is continual slow release of isolated quanta of the transmitter; this produces electrical responses (*miniature end-plate potentials*) at the postjunctional membrane that are associated with the maintenance of the physiological responsiveness of the effector organ. A low level of spontaneous activity within the motor units of skeletal muscle is particularly important because skeletal muscle lacks inherent tone.

The action potential causes the synchronous release of several hundred quanta of neurotransmitter. In the fusion/exocytosis process, the contents of the vesicles, including enzymes and other proteins, are discharged to the synaptic space. Synaptic vesicles may either fully exocytose with complete fusion or form a transient, nanometer-size pore that closes after transmitter has escaped, "kiss-and-run" exocytosis. In full-fusion exocytosis, the pit formed by the vesicle's fusing with the plasma membrane is clathrin-coated and retrieved from the membrane via endocytosis and transported to an endosome for full recycling. During kiss-and-run exocytosis, the pore closes, and the vesicle is immediately and locally recycled for reuse in neurotransmitter repackaging (Alabi and Tsien, 2013; Südhof, 2014).

Modulation of Transmitter Release. A number of autocrine and paracrine factors may influence the exocytotic process, including the released neurotransmitter itself. Adenosine, DA, glutamate, γ-aminobutyric acid (GABA), prostaglandins, and enkephalins influence neurally mediated release of neurotransmitters. Receptors for these factors exist in the membranes of the soma, dendrites, and axons of neurons (Miller, 1998). *Soma-dendritic receptors*, when activated, primarily modify functions of the soma-dendritic region, such as protein synthesis and generation of action potentials. *Presynaptic receptors*, when activated, modify functions of the terminal region, such as synthesis and release of transmitters.

Two main classes of presynaptic receptors have been identified on most neurons: *Heteroreceptors* are presynaptic receptors that respond to neurotransmitters, neuromodulators, or neurohormones released from adjacent neurons or cells. For example, NE can influence the release of ACh from parasympathetic neurons by acting on α_{2A}, α_{2B}, and α_{2C} receptors, whereas ACh can influence the release of NE from sympathetic neurons by acting on M_2 and M_4 receptors. *Autoreceptors* are receptors located on or close to axon terminals of a neuron through which the neuron's own transmitter can modify transmitter synthesis and release (see Figures 10–6 and 10–8). For example, NE released from sympathetic neurons may interact with α_{2A} and α_{2C} receptors to inhibit neurally released NE. Similarly, ACh released from parasympathetic neurons may interact with M_2 and M_4 receptors to inhibit neurally released ACh.

2. *Interaction of the transmitter with postjunctional receptors and production of a postjunctional potential.* The transmitter diffuses across the synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions (noted in the following discussion), one of three types of permeability change can occur:

- Generalized increase in the permeability to cations (notably Na^+ but occasionally Ca^{2+}), resulting in a localized depolarization of the membrane, that is, an excitatory postsynaptic potential (EPSP).
- Selective increase in permeability to anions, usually Cl^-, resulting in stabilization or actual hyperpolarization of the membrane, which constitutes an inhibitory postsynaptic potential (IPSP).

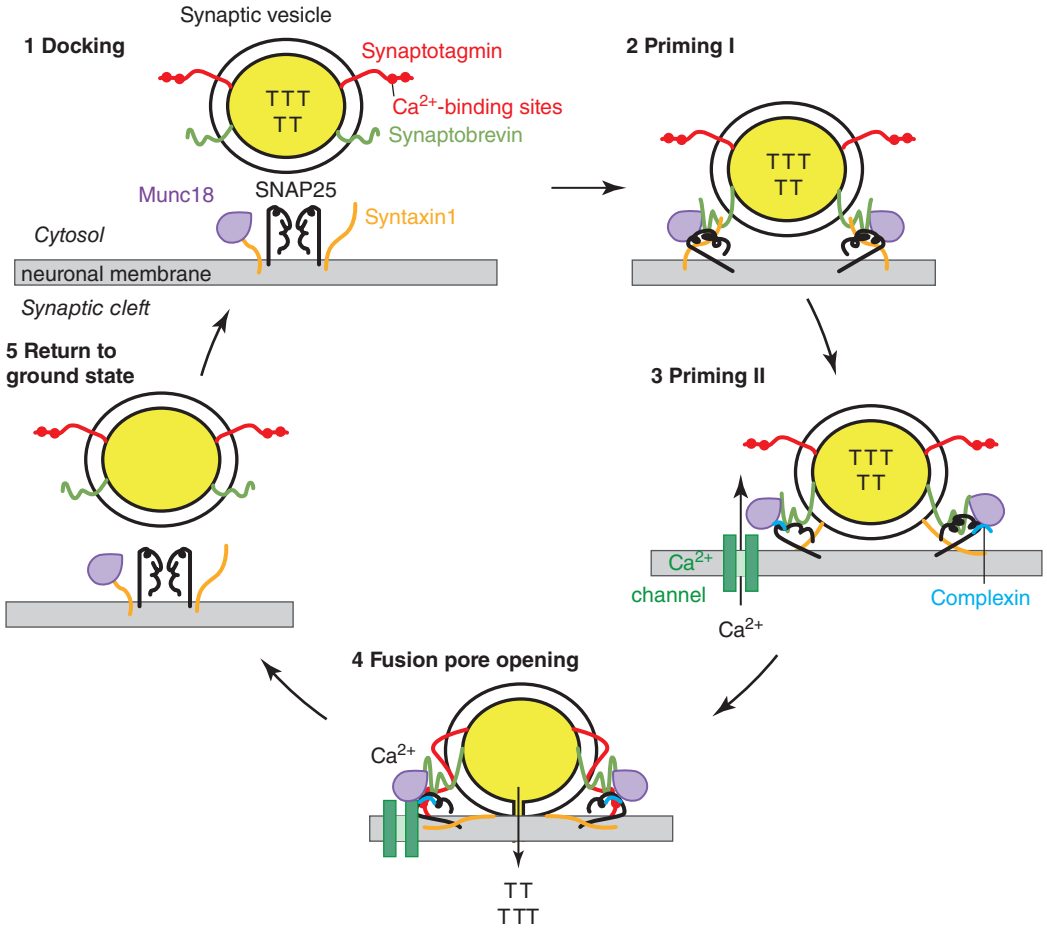

Figure 10–4 *Molecular basis of exocytosis: docking and fusion of synaptic vesicles with neuronal membranes.* **1.** *Vesicular docking in the active zone*: Munc18 binds to syntaxin 1, stabilizing the neuronal membrane SNARE proteins. **2.** *Priming I*: Syntaxin assembles with SNAP25, allowing for the vesicle SNARE protein synaptobrevin to bind to the complex. **3.** *Priming II*: Complexin binds to the SNARE complex and allows for the vesicular synaptotagmin to bind Ca^{2+} that drives the full fusion process. **4.** *Fusion pore opening*: Synaptotagmin interacts with the SNARE complex and binds Ca^{2+}, permitting pore fusion and exocytosis of neurotransmitter. Other components, not shown, are the vesicular GTP-binding Rab3/27; the linking proteins Munc13, RIM, and RIM-BP; and tethering to the Ca^{2+} channel. **5.** *Return to ground state*: After fusion, the chaperone ATPase NSF and its SNAP adapters catalyze dissociation of the SNARE complex. For a more detailed view of this process, see Südhof (2014).

- Increased permeability to K^+. Because the K^+ gradient is directed out of the cell, hyperpolarization and stabilization of the membrane potential occur (an IPSP).

Electric potential changes associated with the EPSP and IPSP at most sites are the results of passive fluxes of ions down their concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional receptors for the neurotransmitter that initiates the response (see Figures 10–4, 10–6, and 10–8 and Chapter 16). These receptors may be clustered on the effector cell surface, as seen at the NMJs of skeletal muscle and other discrete synapses, or distributed more uniformly, as observed in smooth muscle. These *high-conductance, ligand-gated ion channels* usually permit passage of Na^+ or Cl^-; K^+ and Ca^{2+} are involved less frequently. In the presence of an appropriate neurotransmitter, the channel opens rapidly to a high-conductance state, remains open for about a millisecond, and then closes. A short square-wave pulse of current is observed as a result of the channel's opening and closing. The summation of these microscopic events gives rise to the EPSP.

The ligand-gated channels belong to a superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, and certain $5HT_3$ and purine receptors, which conduct primarily Na^+, cause depolarization, and are excitatory; and GABA acid and glycine receptors, which conduct Cl^-, cause hyperpolarization, and are inhibitory. Neurotr ns nitters also can mo du ate the ermeability of K^+ nd Ca^{2+} channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins (see Chapter 3).

The nicotinic, GABA, glycine, and $5HT_3$ receptors are closely related, whereas the glutamate and purinergic ionotropic receptors have distinct structures (see Figure 13–1 and Chapter 16). Neurotransmitters also can modulate the permeability of K^+ and Ca^{2+} channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins. Other receptors for neurotransmitters act by influencing the synthesis of intracellular second messengers and do not necessarily cause a change in membrane potential. The most widely documented examples of receptor regulation of second-messenger systems are the activation or inhibition of adenylyl cyclase to modulate cellular cAMP concentrations and the increase in cytosolic concentrations of Ca^{2+} that results from release of the ion from internal stores by inositol trisphosphate (see Chapter 3).

3. *Initiation of postjunctional activity*. If an EPSP exceeds a certain threshold value, it initiates a propagated action potential in a postsynaptic neuron or a muscle action potential in skeletal or cardiac muscle by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca^{2+} release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca^{2+} mobilization. An IPSP, which is found

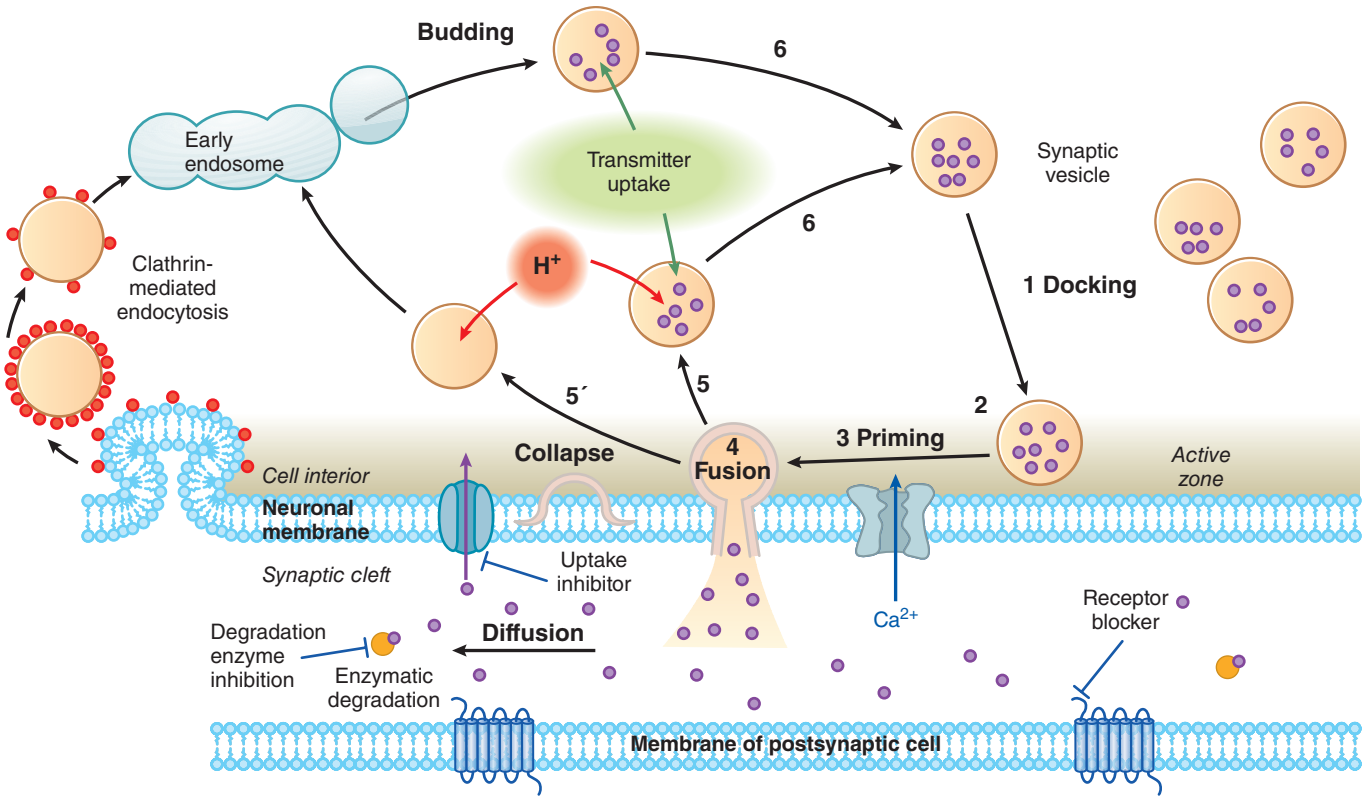

Figure 10–5 *Life cycle of a synaptic vesicle.* A mature storage vesicle, replete with transmitter, is translocated to the perimembrane space (active zone) (1). Once in the active zone (2), the vesicle undergoes docking and priming (see Figure 10–4), as proteins from the cytosol and the vesicular and plasma membranes (SNARE proteins) interact to tether the vesicle in a prefusion stage. The rapid entry of Ca^{2+} via voltage-sensitive channels located in the active zone (3) activates the calcium sensor synaptotagmin and initiates the process of fusion and exocytosis of the vesicular contents into the synaptic space (4). After transmitter release, the vesicle is endocytosed, the SNARE protein complex is disassembled by the action of the chaperone ATPase NSF and its SNAP adapters, and the empty vesicle is recycled, either trafficked directly back into use (5) or routed through an early endosomal pathway (5′). In either event, the vesicular ATPase is at work, promoting H+ uptake to establish the gradient that drives transmitter uptake and repletion of the vesicle (6). Alternatively, full collapse and subsequent endocytosis via a clathrin-mediated process may occur. For a more detailed view of the exocytotic process, see Südhof (2014). Secreted neuropeptides are stored in larger, dense core vesicles (see text). Their secretory process is similar; however, there are no uptake transporters for peptide neurotransmitters; rather, vesicles containing releasable peptides are formed in the trans-Golgi network of the nerve cell body and transported to the release site by molecular motors (kinesins, F-actin, etc.); nonsecreted vesicle components are recycled. Heaslip et al. (2014), Salogiannis and Reck-Peterson (2017), and Milosevic (2018) have reviewed aspects of the transport of such vesicles.

in neurons and smooth muscle but not in skeletal muscle, will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. Whether a propagated impulse or other response ensues depends on the summation of all the potentials.

4. *Destruction or dissipation of the transmitter*. When impulses can be transmitted across junctions at frequencies up to several hundred per second, there must be an efficient means of disposing of the transmitter following each impulse. At cholinergic synapses involved in rapid neurotransmission, high and localized concentrations of acetylcholinesterase (AChE) are available for this purpose. When AChE activity is inhibited, removal of the transmitter is accomplished principally by diffusion. Under these circumstances, the effects of released ACh are potentiated and prolonged (see Chapter 12).

   Rapid termination of NE occurs by a combination of simple diffusion and reuptake by the axonal terminals of most of the released NE. Termination of the action of amino acid transmitters results from their active transport into neurons and surrounding glia. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion.

5. *Nonelectrogenic functions*. The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses are controlled by trophic actions of neurotransmitters and other trophic factors released by the neuron or target cells. The actions of such factors contribute to the plasticity observed in physiological and pathophysiological states.

Cholinergic Transmission

The neurochemical events that underlie cholinergic neurotransmission are summarized in Figure 10–6.

Synthesis and Storage of ACh

Two enzymes, choline acetyltransferase and AChE, are involved in ACh synthesis and degradation, respectively.

Choline Acetyltransferase. *Choline acetyltransferase* catalyzes the synthesis of ACh—the acetylation of choline with acetyl CoA. ChAT is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The final step in the synthesis occurs within the cytoplasm, following which most of the ACh is sequestered within synaptic vesicles. Although moderately potent inhibitors of ChAT exist, they have no therapeutic utility, in part because the rate-limiting step in ACh biosynthesis is the uptake of choline. However, there is a potential for using choline acetyl transferase as an *in vivo* target for biomarkers to enable early diagnosis of Alzheimer's disease and related dementias (Kumar et al., 2017).

Choline and Choline Transport. The availability of choline is critical to the synthesis of ACh. Choline must be derived primarily from the diet (there is little *de novo* synthesis of choline in cholinergic neurons) or, secondarily, from recycling of choline. Once ACh is released from cholinergic

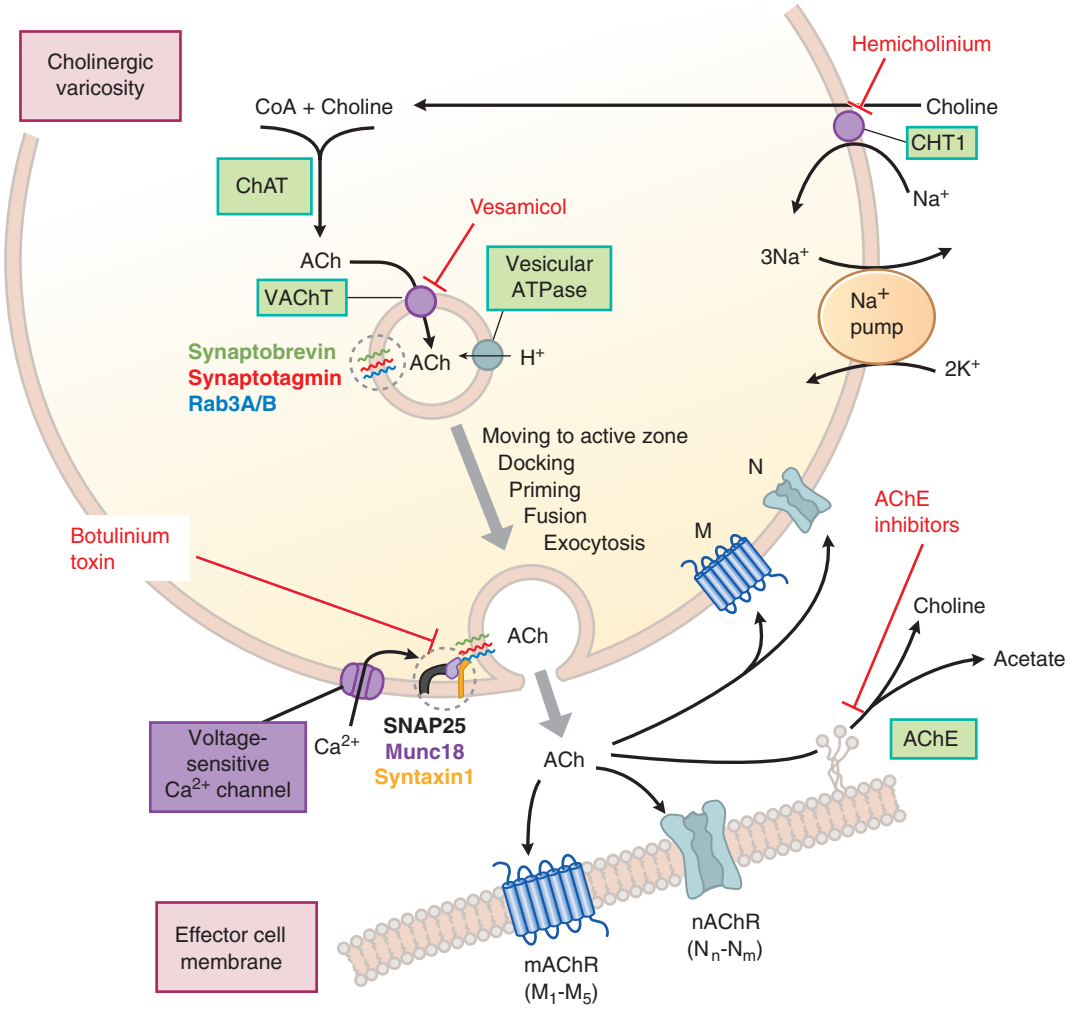

Figure 10–6 *A typical cholinergic neuroeffector junction.* The synthesis of ACh in the varicosity depends on the uptake of choline via a Na^+-dependent carrier, CHT1, that hemicholinium can block. The enzyme choline acetyl transferase catalyzes the synthesis of ACh from choline and the acetyl moiety of acetyl CoA. ACh is transported into the storage vesicle by vesicular ACh transporter (VAChT), which can be inhibited by *vesamicol*. ACh is stored in vesicles (along with other potential cotransmitters, such as ATP and VIP, at certain neuroeffector junctions). Release of ACh and any cotransmitters occurs via exocytosis (the stages are itemized along the gray arrow), triggered by Ca^{2+} entry via a voltage-sensitive Ca^{2+} channel in response to membrane depolarization, as described in Figures 10–3, 10–4, and 10–5. Exocytotic release of ACh at the NMJ can be blocked by botulinum toxins, the active fragments of which are endopeptidases that cleave synaptobrevin, an essential member of the SNARE proteins that mediate docking/priming/exocytosis. Once released, ACh can interact with the muscarinic receptors (M), which are GPCRs, or nicotinic receptors (N), which are ligand-gated ion channels, to produce the characteristic response of the postsynaptic cell. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by extracellular metabolism to choline and acetate by AChE, which is associated with synaptic membranes.

neurons in response to an action potential, ACh is hydrolyzed by AChE to acetate and choline. Much of the choline is taken up at cholinergic nerve terminals and reused for ACh synthesis. Under many circumstances, this reuptake and availability of choline appear to be rate-limiting in ACh synthesis. There are three mammalian transport systems for choline; all three are transmembrane proteins with multiple transmembrane segments; all are inhibited by hemicholinium but at distinct concentrations in the same order as their affinities for choline (Haga, 2014):

- The high-affinity (4 μM) choline transporter CHT1 (SLC5A7) present on presynaptic membranes of cholinergic neurons. This transporter is a member of the SLC5 family of solute carrier proteins that includes Na^+-glucose cotransporters and shares about 25% homology with those transporters (Haga, 2014). Choline transport by CHT1 is Na^+ and Cl^- dependent. This system provides choline for ACh synthesis and is the high-affinity hemicholinium-binding protein (K_i = 0.05 μM).
- A low-affinity (40 μM), Na^+-independent transporter, CTL1 (SLC44A), which is widely distributed and appears to supply choline for phospholipid synthesis (e.g., phosphatidylcholine, sphingomyelin).
- A lower-affinity (100 μM), Na^+-independent transporter, OCT2 (SLC22A2), a nonspecific organic cation secretory transporter found in renal proximal tubules (see Figures 4–8 and 4–9), hepatocytes, the choroid plexus, the luminal membrane of brain endothelium, and synaptic vesicles from cholinergic neurons. Its role in neurons remains to be clarified.

In model systems, CHT1 localizes mainly to intracellular organelles, including transmitter storage vesicles; neural activity increases the fraction of CHT1 in the plasma membrane, and phosphorylation by protein kinase C (PKC) enhances internalization (Haga, 2014).

Storage of ACh. ACh is transported into synaptic vesicles by the vesicular ACh transporter (a solute carrier protein, SLC18A3) using the potential energy of a proton electrochemical gradient that a vacuolar ATPase establishes, such that the transport of protons out of the vesicle is coupled to uptake of ACh into the vesicle and against a concentration gradient. The process is inhibited by the noncompetitive and reversible inhibitor *vesamicol*, which does not affect the vesicular ATPase (Figure 10–6). The gene for choline acetyltransferase and the vesicular transporter are found

at the same locus, with the transporter gene positioned in the first intron of the transferase gene. Hence, a common promoter regulates the expression of both genes.

There appear to be two types of vesicles in cholinergic terminals: electron-lucent vesicles (40–50 nm in diameter) and dense-cored vesicles (80–150 nm). The core of the vesicles contains both ACh and ATP, at a ratio of about 11:1, which are dissolved in the fluid phase with metal ions (Ca^{2+} and Mg^{2+}) and a proteoglycan called vesiculin. Vesiculin, negatively charged and thought to sequester the Ca^{2+} or ACh, is bound within the vesicle, with the protein moiety anchoring it to the vesicular membrane. In some cholinergic terminals, there are peptides, such as VIP, that act as *cotransmitters*. The peptides usually are located in the dense-cored vesicles.

Estimates of the ACh content of synaptic vesicles range from 1000 to over 50,000 molecules per vesicle, with a single motor nerve terminal containing 300,000 or more vesicles. In addition, an uncertain but possibly significant amount of ACh is present in the extravesicular cytoplasm. Recording the electrical events associated with the opening of single channels at the motor end plate during continuous application of ACh has permitted estimation of the potential change induced by a single molecule of ACh (3×10^{-7} V); from such calculations, it is evident that even the lower estimate of the ACh content per vesicle (1000 molecules) is sufficient to account for the magnitude of the miniature end-plate potentials.

Release of ACh. Exocytotic release of ACh and cotransmitters (e.g., ATP, VIP) occurs on depolarization of the nerve terminals. Depolarization of the terminals allows the entry of Ca^{2+} through voltage-gated Ca^{2+} channels and promotes fusion of the vesicular membrane with the plasma membrane, allowing exocytosis to occur, as described previously and shown in Figure 10–6.

Two pools of ACh appear to exist. One pool, the "depot" or "readily releasable" pool, consists of vesicles located near the plasma membrane of the nerve terminals; these vesicles contain newly synthesized transmitter. Depolarization of the terminals causes these vesicles to release ACh rapidly or readily. The other pool, the "reserve pool," seems to replenish the readily releasable pool and may be required to sustain ACh release during periods of prolonged or intense nerve stimulation.

Botulinum toxin blocks ACh release by interfering with the machinery of transmitter release. The active fragments of botulinum toxins are endopeptidases; the SNARE proteins are their substrates. There are eight isotypes of botulinum toxin, each cleaving a specific site on SNARE proteins. Tetanus toxins act similarly, but in the CNS. The active fragments of these toxins cleave synaptobrevin and block exocytosis in specific sets of neurons (inhibitory neurons in the CNS for tetanus, the NMJ for botulinum).

Acetylcholinesterase. At the NMJ, immediate hydrolysis of ACh by AChE reduces lateral diffusion of the transmitter and activation of adjacent receptors. Rapid release of ACh onto the nAChRs of the motor end plate, followed by rapid hydrolysis of the neurotransmitter, spatially limits receptor activation and facilitates rapid control of responses. The time required for hydrolysis of ACh at the NMJ is less than a millisecond. Chapter 12 presents details of the structure, mechanism, and inhibition of AChE.

AChE is found in cholinergic neurons and is highly concentrated at the postsynaptic end plate of the NMJ. Butyrylcholinesterase (BuChE; also called pseudocholinesterase) is virtually absent in neuronal elements of the central and peripheral nervous systems. BuChE is synthesized primarily in the liver and is found in liver and plasma; its likely physiological function is the hydrolysis of ingested esters from plant sources. AChE and BuChE typically are distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (see Chapter 12).

Almost all pharmacological effects of the anti-cholinesterase agents are due to the inhibition of AChE, with the consequent accumulation of endogenous ACh in the vicinity of the nerve terminal. Distinct but single genes encode AChE and BuChE in mammals; the diversity of molecular structure of AChE arises from alternative mRNA processing.

Numerous reports suggest that AChE plays roles in addition to its classical function in terminating impulse transmission at cholinergic synapses. Nonclassical functions of AChE might include hydrolysis of ACh in a nonsynaptic context, action as an adhesion protein involved in synaptic development and maintenance or as a bone matrix protein, involvement in neurite outgrowth, and acceleration of the assembly of Aβ peptide into amyloid fibrils.

Characteristics of Cholinergic Transmission at Various Sites

There are marked differences among various sites of cholinergic transmission with respect to architecture and fine structure, the distributions of AChE and receptors, and the temporal factors involved in normal function. In skeletal muscle, for example, the junctional sites occupy a small, discrete portion of the surface of the individual fibers and are relatively isolated from those of adjacent fibers; in the superior cervical ganglion, about 100,000 ganglion cells are packed within a volume of a few cubic millimeters, and both the presynaptic and the postsynaptic neuronal processes form complex networks.

Skeletal Muscle. At the NMJ, ACh stimulates the nicotinic receptor's intrinsic channel, which opens for about 1 msec, admitting about 50,000 Na^+ ions. The channel-opening process is the basis for the localized depolarizing end-plate potential within the end plate, which triggers the muscle action potential and leads to contraction. The amount of ACh (10^{-17} mol) required to elicit an end-plate potential following its microiontophoretic application to the motor end plate of a rat diaphragm muscle fiber is equivalent to that recovered from each fiber following stimulation of the phrenic nerve.

Following sectioning and degeneration of the motor nerve to skeletal muscle or of the postganglionic fibers to autonomic effectors, there is a marked reduction in the threshold doses of the transmitters and of certain other drugs required to elicit a response; that is, denervation supersensitivity occurs. In skeletal muscle, this change is accompanied by a spread of the receptor molecules from the end-plate region to the adjacent portions of the sarcoplasmic membrane, which eventually involves the entire muscle surface. Embryonic muscle also exhibits this uniform sensitivity to ACh prior to innervation. Hence, innervation represses the expression of the receptor gene by the nuclei that lie in extrajunctional regions of the muscle fiber and directs the subsynaptic nuclei to express the structural and functional proteins of the synapse.

Autonomic Effector Cells. Stimulation or inhibition of autonomic effector cells occurs on activation of muscarinic ACh receptors (discussed below). In this case, the effector is coupled to the receptor by a G protein (see Chapter 3). In contrast to skeletal muscle and neurons, smooth muscle and the cardiac conduction system (sinoatrial [SA] node, atrium, atrioventricular node, and the His-Purkinje system) normally exhibit intrinsic activity, both electrical and mechanical, that is modulated but not initiated by nerve impulses.

In the basal condition, unitary smooth muscle exhibits waves of depolarization or spikes that are propagated from cell to cell at rates considerably slower than the action potential of axons or skeletal muscle. The spikes apparently are initiated by rhythmic fluctuations in the membrane resting potential. Application of ACh (0.1–1 μM) to isolated intestinal muscle causes the membrane potential to become less negative and increases the frequency of spike production, accompanied by a rise in tension. A primary action of ACh in initiating these effects through muscarinic receptors is probably partial depolarization of the cell membrane brought about by an increase in Na^+ and, in some instances, Ca^{2+} conductance. ACh also can produce contraction of some smooth muscles when the membrane has been depolarized completely by high concentrations of K^+, provided that Ca^{2+} is present. Hence, ACh stimulates ion fluxes across membranes or mobilizes intracellular Ca^{2+} to cause contraction.

In the heart, spontaneous depolarizations normally arise from the SA node, enabling it to act as a pacemaker. In the cardiac conduction system, particularly in the SA and atrioventricular nodes, stimulation of the cholinergic innervation or the direct application of ACh causes

inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least in part, to a selective increase in permeability to K^+.

Autonomic Ganglia. The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the NMJ of skeletal muscle. The initial depolarization is the result of activation of nAChRs, which are ligand-gated cation channels with properties similar to those found at the NMJ. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh (see Figure 13–5).

Prejunctional Sites. ACh release is subject to complex regulation by mediators, including ACh itself acting on M_2 and M_4 *autoreceptors*, and activation of *heteroreceptors* (e.g., NE acting on α_{2A} and α_{2C} adrenergic receptors) or substances produced locally in tissues (e.g., NO) (Philipp and Hein, 2004). ACh-mediated inhibition of ACh release following activation of M_2 and M_4 autoreceptors is a physiological negative-feedback control mechanism. At some neuroeffector junctions (e.g., the myenteric plexus in the GI tract or the cardiac SA node), sympathetic and parasympathetic nerve terminals often lie juxtaposed to each other. There, opposing effects of NE and ACh result not only from the opposite effects of the two neurotransmitters on the smooth muscle or cardiac cells but also from the inhibition of ACh release by NE or inhibition of NE release by ACh acting on heteroreceptors on parasympathetic or sympathetic terminals.

Inhibitory heteroreceptors on parasympathetic terminals include adenosine A_1 receptors, histamine H_3 receptors, opioid receptors, and α_{2A} and α_{2C} adrenergic receptors. The parasympathetic nerve terminal varicosities also may contain additional heteroreceptors that could respond by inhibition or enhancement of ACh release by locally formed autacoids, hormones, or administered drugs.

Extraneuronal Sites. All elements of the cholinergic system are functionally expressed independently of cholinergic innervation in numerous nonneuronal cells. These *nonneuronal cholinergic* systems can both modify and control phenotypic cell functions such as proliferation, differentiation, formation of physical barriers, migration, and ion and water movements.

The widespread synthesis of ACh in nonneuronal cells has changed the thinking that ACh acts only as a neurotransmitter. Each component of the cholinergic system in nonneuronal cells can be affected by pathophysiological conditions. Dysfunctions of nonneuronal cholinergic systems may be involved in the pathogenesis of diseases (e.g., inflammatory processes) (Wessler and Kirkpatrick, 2008).

HISTORICAL PERSPECTIVE

Sir Henry Dale noted that the various esters of choline elicited responses that were similar to those of either nicotine or muscarine depending on the pharmacological preparation. A similarity in response also was noted between muscarine and nerve stimulation in those organs innervated by the craniosacral divisions of the autonomic nervous system. Thus, Dale suggested that ACh or another ester of choline was a neurotransmitter in the autonomic nervous system; he also stated that the compound had dual actions, which he termed a "nicotine action" (*nicotinic*) and a "muscarine action" (*muscarinic*).

The capacities of tubocurarine and atropine to block nicotinic and muscarinic effects of ACh, respectively, provided further support for the proposal of two distinct types of cholinergic receptors. Although Dale had access only to crude plant alkaloids of then-unknown structure from *Amanita muscaria* and *Nicotiana tabacum,* this classification remains the primary subdivision of cholinergic receptors. Its utility has survived the discovery of several distinct subtypes of nicotinic and muscarinic receptors.

Cholinergic Receptors and Signal Transduction

Nicotinic receptors are ligand-gated ion channels whose activation always causes a rapid (millisecond) increase in cellular permeability to Na^+ and Ca^{2+}, depolarization, and excitation. *Muscarinic receptors* are G protein-coupled receptors (GPCRs). Responses to muscarinic agonists are slower; they may be either excitatory or inhibitory, and they are not necessarily linked to changes in ion permeability. The muscarinic and nicotinic receptors for ACh belong to two different families whose features are described in Chapters 11 and 13, respectively.

Subtypes of nAChRs. The *nAChRs* exist at the skeletal NMJ, autonomic ganglia, adrenal medulla, and CNS and in nonneuronal tissues. The nAChRs are composed of five homologous subunits organized around a central pore (see Table 10–2 and Figure 13–1). In general, the nAChRs are further divided into two groups:

- *Muscle type* (N_m), found in the vertebrate skeletal muscle, where they mediate transmission at the NMJ
- *Neuronal type* (N_n), found mainly throughout the peripheral nervous system, CNS, and nonneuronal tissues

Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5HT) at diverse sites in the brain (Albuquerque et al., 2009).

Muscle-Type nAChRs. In fetal muscle prior to innervation, in adult muscle after denervation, and in fish electric organs, the nAChR subunit stoichiometry is $(\alpha1)_2\beta1\gamma\delta$, whereas in adult muscle, the γ subunit is replaced by ε to give the $(\alpha1)_2\beta1\varepsilon\delta$ stoichiometry (Table 10–2). The γ/ε and δ subunits are involved together with the α1 subunits in forming the ligand-binding sites and in the maintenance of cooperative interactions between the α1 subunit. Different affinities to the two binding sites are conferred by the presence of different non-α subunits. Binding of ACh to the αγ and αδ sites is thought to induce a conformational change predominantly in the α1 subunits that interacts with the transmembrane region to cause channel opening.

Neuronal-Type nAChRs. Neuronal nAChRs are widely expressed in peripheral ganglia, the adrenal medulla, numerous areas of the brain, and nonneuronal cells, such as epithelial cells and cells of the immune system. To date, nine α (α2–α10) and three β (β2–β4) subunit genes have been cloned. The α7–α10 subunits are found either as homopentamers (of five α7, α8, and α9 subunits) or as heteropentamers of α7, α8, and α9/α10. By contrast, the α2–α6 and β2–β4 subunits form heteropentamers usually with $(\alpha x)_2(\beta y)_3$ stoichiometry. The α5 and β3 subunits do not appear to be able to form functional receptors when expressed alone or in paired combinations with α or β subunits, respectively (Zoli et al., 2018).

The precise function of many of the neuronal nAChRs in the brain is not known; they appear to act more as synaptic modulators, the molecular diversity of the subunits putatively resulting in numerous nAChR subtypes with different physiological properties. Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5HT) at sites throughout the brain (Exley and Cragg, 2008). The synaptic release of a particular neurotransmitter can be regulated by different neuronal-type nAChR subtypes in different CNS regions. For instance, DA release from striatal and thalamic DA neurons can be controlled by the α4β2 subtype or both α4β2 and α6β2β3 subtypes, respectively. In contrast, glutametergic neurotransmission is regulated everywhere by α7 nAChRs.

Subtypes of Muscarinic Receptors. In mammals, there are five distinct subtypes of mAChRs, each produced by a different gene. These variants have distinct anatomic locations in the periphery and CNS and differing chemical specificities. The mAChRs are GPCRs

TABLE 10–2 ■ CHARACTERISTICS OF SUBTYPES OF NICOTINIC ACETYLCHOLINE RECEPTORS (nAChRs)

RECEPTOR (PRIMARY RECEPTOR SUBTYPE)[a]	MAIN SYNAPTIC LOCATION	MEMBRANE RESPONSE	MOLECULAR MECHANISM	AGONISTS	ANTAGONISTS
Skeletal Muscle (N_m) $(\alpha1)_2\beta1\varepsilon\delta$ adult $(\alpha1)_2\beta1\gamma\delta$ fetal	Skeletal neuromuscular junction (postjunctional)	Excitatory; end-plate depolarization; skeletal muscle contraction	Increased cation permeability (Na^+; K^+)	ACh Nicotine Succinylcholine	Atracurium Vecuronium *d*-Tubocurarine Pancuronium α-Conotoxin α-Bungarotoxin
Peripheral neuronal $(N_n)(\alpha3)_2(\beta4)_3$	Autonomic ganglia; adrenal medulla	Excitatory; depolarization; firing of postganglion neuron; depolarization and secretion of catecholamines	Increased cation permeability (Na^+; K^+)	ACh Nicotine Epibatidine Dimethylphenylpiperazinium	Trimethaphan Mecamylamine
CNS neuronal $(\alpha4)_2(\beta4)_3$ (*α-BTX-insensitive*)	CNS; pre- and postjunctional	Pre- and postsynaptic excitation; prejunctional control of transmitter release	Increased cationpermeability (Na^+; K^+)	Cytosine, epibatidine Anatoxin A	Mecamylamine DHbE Erysodine Lophotoxin
$(\alpha7)_5$ (*α-BTX-sensitive*)	CNS; pre- and postsynaptic	Pre- and postsynaptic excitation; prejunctional control of transmitter release	Increased permeability (Ca^{2+})	Anatoxin A	Methyllycaconitine α-Bungarotoxin α-Conotoxin ImI

[a]Nine α (α2–α10) and three β (β2–β4) subunits have been identified and cloned in human brain, which combine in various conformations to form individual receptor subtypes. The structure of individual receptors and the subtype composition are incompletely understood. Only a finite number of naturally occurring functional nAChR constructs have been identified. DHbE, dihydro-β-erythroidine.

(see Table 10–3 and Chapter 11), present in virtually all organs, tissues, and cell types (Table 10–3 and Chapter 11). Most cell types have multiple mAChR subtypes, but certain subtypes often predominate in specific sites. For example, the M_2 receptor is the predominant subtype in the heart and in CNS neurons is mostly located presynaptically, whereas the M_3 receptor is the predominant subtype in the detrusor muscle of the bladder.

In the periphery, mAChRs mediate the classical muscarinic actions of ACh in organs and tissues innervated by parasympathetic nerves, although receptors may be present at sites that lack parasympathetic innervation (e.g., most blood vessels). In the CNS, mAChRs are involved in regulating a large number of cognitive, behavioral, sensory, motor, and autonomic functions. Owing to the lack of specific muscarinic agonists and antagonists that demonstrate selectivity for individual mAChRs and the fact that most organs and tissues express multiple mAChRs, it has been a challenge to assign specific pharmacological functions to distinct mAChRs. The development of gene-targeting techniques in mice has been helpful in defining specific functions (see Table 10–3).

The functions of mAChRs are mediated by interactions with G proteins. The M_1, M_3, and M_5 subtypes couple through $G_{q/11}$ to stimulate the phospholipase (PL) C–inositol 1,4,5-trisphosphate (IP_3)/diacylglycerol-Ca^{2+} pathway, leading to activation of PKC and Ca^{2+}-sensitive enzymes. Activation of M_1, M_3, and M_5 receptors can also cause the activation of PLA_2, leading to the release of arachidonic acid and consequent eicosanoid synthesis; these effects of M_1, M_3, and M_5 mAChRs are generally secondary to elevation of intracellular Ca^{2+}. Stimulated M_2 and M_4 cholinergic receptors couple to G_i and G_o, with resulting inhibition of adenylyl cyclase, leading to a decrease in cellular cAMP, activation of inwardly rectifying K^+ channels, and inhibition of voltage-gated Ca^{2+} channels. The functional consequences of these effects are hyperpolarization and inhibition of excitable membranes. In the myocardium, inhibition of adenylyl cyclase and activation of K^+ conductances account for the negative inotropic and chronotropic effects of ACh. In addition, heterologous systems may produce different receptor-transducer-effector interactions (Zenko and Hislop, 2018).

Following activation by classical or allosteric agonists, mAChRs can be phosphorylated by a variety of receptor kinases and second-messenger regulated kinases; the phosphorylated mAChR subtypes then can interact with β-arrestin and possibly other adapter proteins. As a result, mAChR signaling pathways may be differentially altered. Agonist activation of mAChRs also may induce receptor internalization and downregulation. Muscarinic AChRs can also regulate other signal transduction pathways that have diverse effects on cell growth, survival, and physiology, such as mitogen-activated protein kinase (MAPK), phosphoinositide-3-kinase, RhoA, and Rac1.

Changes in mAChR levels and activity have been implicated in the pathophysiology of numerous major diseases in the CNS and in the autonomic nervous system (see Table 10–3). Phenotypic analysis of mAChR-mutant mice as well as the development of selective agonists and antagonists has led to a wealth of new information regarding the physiological and potential pathophysiological roles of the individual mAChR subtype (Langmead et al., 2008).

Adrenergic Transmission

Norepinephrine (NE) is the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS; DA is the

TABLE 10–3 ■ CHARACTERISTICS OF MUSCARINIC ACETYLCHOLINE RECEPTOR (mAChRs) SUBTYPES

RECEPTOR	CELLULAR AND TISSUE LOCATION[a]	CELLULAR RESPONSE[b]	FUNCTIONAL RESPONSE[c]	DISEASE RELEVANCE
M_1	CNS; most abundant in cerebral cortex, hippocampus, striatum, and thalamus Autonomic ganglia Glands (gastric and salivary) Enteric nerves	Couples by $G_{q/11}$ to activate PLC-IP_3-Ca^{2+}-PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD_2, PLA_2; ↑AA	Increased cognitive function (learning and memory) Increased seizure activity Decrease in dopamine release and locomotion Increase in depolarization of autonomic ganglia Increase in secretions	Alzheimer's disease Cognitive dysfunction Schizophrenia
M_2	Widely expressed in CNS, hindbrain, thalamus, cerebral cortex, hippocampus, striatum, heart, smooth muscle, autonomic nerve terminals	Couples by G_i/G_o (PTX sensitive) Inhibition of AC, ↓ cAMP Activation of inwardly rectifying K^+ channels Inhibition of voltage-gated Ca^{2+} channels Hyperpolarization and inhibition	*Heart:* SA node: slowed spontaneous depolarization; hyperpolarization, ↓ HR AV node: decrease in conduction velocity Atrium: ↓ refractory period, ↓ contraction Ventricle: slight ↓ contraction *Smooth muscle:* ↑ Contraction *Peripheral nerves:* Neural inhibition via autoreceptors and heteroreceptor ↓ Ganglionic transmission. *CNS:* Neural inhibition ↑ Tremors; hypothermia; analgesia	Alzheimer's disease Cognitive dysfunction Pain
M_3	Widely expressed in CNS (<other mAChRs), cerebral cortex, hippocampus Abundant in smooth muscle and glands Heart	Couples by $G_{q/11}$ to activate PLC-IP_3/DAG-Ca^{2+}-PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD_2, PLA_2; ↑AA	*Smooth muscle:* ↑ Contraction (predominant in some, e.g., bladder) *Glands:* ↑ Secretion (predominant in salivary gland) Increases food intake, body weight, fat deposits Inhibition of DA release Synthesis of NO	Chronic obstructive pulmonary disease (COPD) Asthma Urinary incontinence Irritable bowel disease
M_4	Preferentially expressed in CNS, particularly forebrain, also striatum, cerebral cortex, hippocampus	Couples by G_i/G_0 (PTX sensitive) Inhibition of AC, ↓ cAMP Activation of inwardly rectifying K^+ channels Inhibition of voltage-gated Ca^{2+} channels Hyperpolarization and inhibition	Autoreceptor- and heteroreceptor-mediated inhibition of transmitter release in CNS and periphery Analgesia; cataleptic activity Facilitation of DA release	Parkinson's disease Schizophrenia Neuropathic pain Alzheimer's disease
M_5	Substantia nigra Expressed in low levels in CNS and periphery Predominant mAchR in neurons in VTA and substantia nigra	Couples by $G_{q/11}$ to activate PLC-IP_3-Ca^{2+}-PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD_2, PLA_2; ↑AA	Mediator of dilation in cerebral arteries and arterioles (?) Facilitates DA release Augmentation of drug-seeking behavior and reward (e.g., opiates, cocaine)	Drug dependence Parkinson's disease Schizophrenia

[a]Most organs, tissues, and cells express multiple mAChRs.
[b]M_1, M_3, and M_5 mAChRs appear to couple to the same G proteins and signal through similar pathways. Likewise, M_2 and M_4 mAChRs couple through similar G proteins and signal through similar pathways.
[c]Despite the fact that in many tissues, organs, and cells multiple subtypes of mAChRs coexist, one subtype may predominate in producing a particular function; in others, there may be equal predominance.
VTA, ventral tegmentum area.

predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways; and EPI is the major hormone of the adrenal medulla. Collectively, these three amines are called *catecholamines*. Drugs affecting these endogenous amines and their actions are used in the treatment of hypertension, mental disorders, and a variety of other conditions. The details of these interactions and of the pharmacology of the sympathomimetic amines themselves can be found in subsequent chapters. The basic physiological, biochemical, and pharmacological features are presented here.

Synthesis of Catecholamines

The steps in the synthesis of catecholamines and the characteristics of the enzymes involved are shown in Figure 10–7 and Table 10–4. Tyrosine is sequentially 3-hydroxylated and decarboxylated to form DA. DA is β-hydroxylated to yield NE, which is *N*-methylated in chromaffin tissue to give EPI. The enzymes involved have been identified, cloned, and characterized. Table 10–4 summarizes some of the important characteristics of the four enzymes. These enzymes are not completely specific; consequently, other endogenous substances, as well as certain drugs, are also substrates. For example, 5HT can be produced from 5-hydroxy-*L*-tryptophan by aromatic *L*-amino acid decarboxylase (dopa decarboxylase). Dopa decarboxylase also converts dopa into DA (see Chapter 15) and *methyldopa* to α-methyldopamine, which dopamine β-hydroxylase (DβH) converts to methylnorepinephrine.

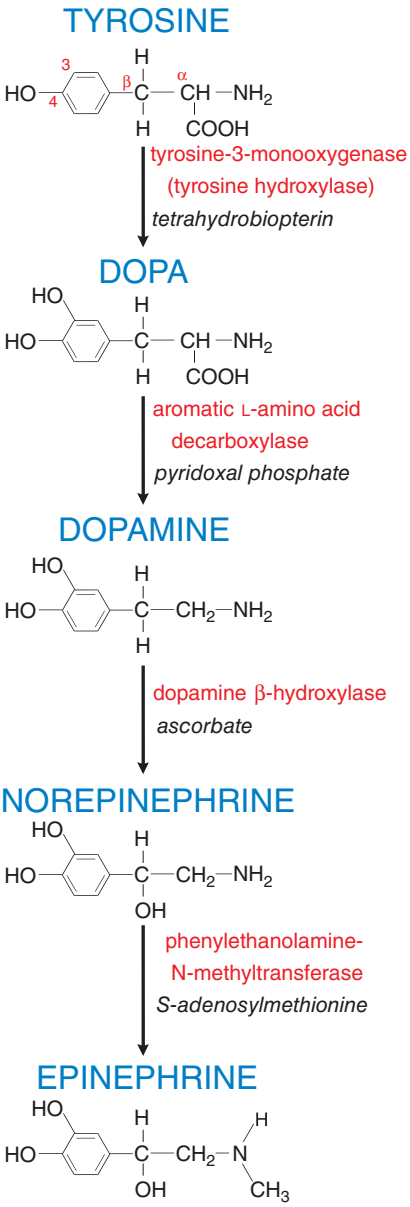

Figure 10–7 *Steps in the enzymatic synthesis of dopamine, norepinephrine, and epinephrine.* The enzymes involved are shown in red; essential cofactors in italics. The final step occurs only in the adrenal medulla and in a few epinephrine-containing neuronal pathways in the brainstem.

The hydroxylation of tyrosine by tyrosine hydroxylase (TH) is the rate-limiting step in the biosynthesis of catecholamines. This enzyme is activated following stimulation of sympathetic nerves or the adrenal medulla. The enzyme is a substrate for PKA, PKC, and calmodulin (CaM) kinase; phosphorylation is associated with increased hydroxylase activity. In addition, there is a delayed increase in TH gene expression after nerve stimulation. These mechanisms serve to maintain the content of catecholamines in response to increased transmitter release. TH also is subject to feedback inhibition by catechol compounds.

Deficiency of TH has been reported in humans and is characterized by generalized rigidity, hypokinesia, and low cerebrospinal fluid levels of NE and DA metabolites homovanillic acid and 3-methoxy-4-hydroxyphenylethylene glycol. TH knockout is embryonically lethal in mice, presumably because the loss of catecholamines results in altered cardiac function. Interestingly, residual levels of DA are present in these mice. Tyrosinase may be an alternate source for catecholamines, although tyrosinase-derived catecholamines are clearly not sufficient for survival (Carson and Robertson, 2002).

Deficiency of DβH in humans is characterized by orthostatic hypotension, ptosis of the eyelids, retrograde ejaculation, and elevated plasma levels of DA. In the case of DβH-deficient mice, there is about 90% embryonic mortality (Carson and Robertson, 2002).

Our understanding of the cellular sites and mechanisms of synthesis, storage, and release of catecholamines derives from studies of sympathetically innervated organs and the adrenal medulla. Nearly all the NE content of innervated organs is confined to the postganglionic sympathetic fibers; it disappears within a few days after section of the nerves. In the adrenal medulla, catecholamines are stored in chromaffin granules. These vesicles contain extremely high concentrations of catecholamines (~21% dry weight), ascorbic acid, and ATP, as well as specific proteins, such as chromogranins, DβH, and peptides, including enkephalin and neuropeptide Y. Chromogranin A fragments reportedly have antibacterial and antifungal activity (Mercer and O'Neil, 2020). Two types of storage vesicles are found in sympathetic nerve terminals: large dense-core vesicles corresponding to chromaffin granules and small dense-core vesicles containing NE, ATP, and membrane-bound DβH.

The main features of the mechanisms of synthesis, storage, and release of catecholamines at an adrenergic neuroeffector junction and their modifications by drugs are summarized in Figure 10–8 and its legend. The *adrenal medulla* has two distinct catecholamine-containing cell types: those with NE and those with primarily EPI. The latter cell population contains the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). In these cells, the NE formed in the granules leaves these structures and is methylated in the cytoplasm to EPI. EPI then reenters the chromaffin granules, where it is stored until released. EPI accounts for about 80% of the catecholamines of the adrenal medulla and NE about 20%.

A major factor that controls the rate of synthesis of EPI, and hence the size of the store available for release from the adrenal medulla, is the level of glucocorticoids secreted by the adrenal cortex. The intra-adrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT (see Figure 10–7). The activities of both TH and DβH also increase in the adrenal medulla when the secretion of glucocorticoids is stimulated. Thus, any stress that persists sufficiently to evoke an enhanced secretion of corticotropin mobilizes the appropriate hormones of both the adrenal cortex (predominantly cortisol in humans) and medulla (EPI). This remarkable relationship is present only in certain mammals, including humans, in which the adrenal chromaffin cells are enveloped entirely by steroid-secreting cortical cells. PMNT is expressed in mammalian tissues such as brain, heart, and lung, leading to extra-adrenal EPI synthesis (Ziegler et al., 2002).

TABLE 10–4 ■ ENZYMES FOR SYNTHESIS OF CATECHOLAMINES

ENZYME	OCCURRENCE	SUBCELLULAR DISTRIBUTION	COFACTORS	SUBSTRATE SPECIFICITY	COMMENTS
TH	Widespread	Cytoplasm	tetrahydrobiopterin (BH_4), O_2, Fe^{2+}	Specific for L-tyrosine	Rate-limiting step. Inhibition can deplete NE.
AAADC	Widespread	Cytoplasm	Pyridoxal PO_4	Nonspecific	Inhibition does not alter tissue NE and EPI appreciably.
DβH	Widespread	Synaptic vesicles	Ascorbate, O_2 (DβH contains Cu)	Nonspecific	Inhibition can ↓ NE and EPI levels.
PNMT	Largely in adrenal gland	Cytoplasm	*S*-adenosyl methionine (SAM) as (CH_3 donor)	Nonspecific	Inhibition can ↓ adrenal EPI/NE; regulated by glucocorticoids.

In addition to *de novo* synthesis, NE stores in the terminal portions of the adrenergic fibers are replenished by reuptake and restorage of NE following its release (see discussion in the following material).

Storage, Release, and Reuptake of Catecholamines; Termination of Action

Storage. NE, ATP, and NPY are stored frequently in the same nerve endings.

Catecholamines. Catecholamines are stored in vesicles, thereby ensuring their regulated release, protecting them from metabolism by cellular enzymes, and preventing their leakage out of the neuron. The vesicular monoamine transporter (VMAT) 2, a vesicular membrane protein, moves NE and other catecholamines from the cytosol into neuronal storage vesicles. VMAT2 is driven by a pH gradient established by an ATP-dependent proton translocase in the vesicular membrane; for each molecule of amine taken up, two H^+ ions are extruded. VMAT2 is a member of the solute carrier (SLC) protein superfamily and is designated SLC18A. Monoamine transporters in the SLC18 family are relatively promiscuous and transport DA, NE, EPI, and 5HT, as well as metaiodobenzylguanidine, which can be used to image chromaffin cell tumors. *Reserpine* and *tetrabenazine* inhibit monoamine transport into storage vesicles; by this action, catecholamines remain in the cytosol where they are vulnerable to degradation, mainly by monoamine oxidase (MAO); ultimately, inhibition of VMAT2 leads to depletion of catecholamine from sympathetic nerve endings and in the brain. *Reserpine*, an irreversible agent, inhibits both VMAT2 and the peripheral isoform, VMAT1. *Tetrabenazine* is a reversible inhibitor with greater specificity for VMAT2.

ATP. ATP is an essential component of catecholamine storage; the capacity of ATP and catecholamines to form relatively stable complexes apparently facilitates accumulation of high concentrations of neurotransmitter within the adrenergic storage granule. The granule accumulates ATP via another vesicular nucleotide carrier, VNUT, a member of the SLC superfamily. VNUT is a Na^+/anion cotransporter, designated as SLC17A9 (see Chapter 4). The frequency and quantal size of exocytotic release mirror VNUT activity (Estévez-Herrera et al., 2016). Thus, vesicular ATP has multiple actions beyond its role as a cellular energy source and energy storage molecule: Vesicular ATP facilitates vesicular storage of high concentrations of catecholamines and, when released with the vesicular contents, acts as a transmitter at purinergic receptors (Burnstock et al., 2015; see Table 16–7).

Neuropeptide Y. NPY, a peptide with 36 amino acids, is synthesized in the endoplasmic reticulum, first as a 97-amino-acid precursor, prepro-NPY, that is processed by three steps of proteolysis and a final C-terminal amidation; the resultant $NPY_{1–36}$ is stored in large, dense-core vesicles that may also contain NE. NE and ATP are more generally stored in smaller dense-core vesicles, but NPY, ATP, and NE are often co-released following nerve stimulation, albeit in proportions that change with the pattern and intensity of stimulation (Westfall, 2004). NPY is abundant in the brain and is a powerful orexigenic. In the peripheral nervous system, NPY occurs in sympathetic nerves and adrenal chromaffin cells; it can also be found in platelets, endothelium, and the GI tract and is inducible in the immune system.

Release. Details of excitation-secretion coupling in sympathetic neurons and adrenal medulla are summarized in Figures 10–3 and 10–8. The triggering event is the entry of Ca^{2+}, which results in the exocytosis of the granular contents, including the catecholamine, ATP, some neuroactive peptides (e.g., NPY) or their precursors, chromogranins, and DβH. The various SNARE proteins (e.g., SNAP-25, syntaxin, and synaptobrevin) described for exocytosis of ACh are also involved here (see Figures 10–3 through 10–6).

Reuptake and Termination of Action. Following its release from a sympathetic nerve varicosity, NE interacts with presynaptic and postsynaptic membrane receptors. Adrenergic fibers can sustain the output of NE during prolonged periods of stimulation without exhausting their supply, provided that synthesis and reuptake of the transmitter are unimpaired. Acute regulation of transmitter synthesis involving activation of TH and DβH has been described previously in this chapter. Recycling of transmitter is also essential, and this is provided by reuptake, restorage, and reuse of transmitter. *The actions of catecholamines are terminated by reuptake into the nerve and postjunctional cells and to a smaller extent by diffusion out of the synaptic cleft.* Two distinct carrier-mediated transport systems are involved in reuptake (see Figure 10–8; Table 10–5):

- NE transporter (NET): This transporter, previously called *uptake 1*, moves NE across the neuronal membrane from the extracellular fluid to the cytoplasm. NET has a higher affinity for NE than for EPI (see Table 10–5). NET is a member of an SLC family of similar transporters and is designated as SLC6A2. This family of proteins transports amino acids and their derivatives into cells using cotransport of extracellular Na^+ as a driving force for substrate translocation against chemical gradients (see Chapter 4). The SLC6A monoamine transporters include NET, DA transporter (DAT) (SLC6A3), and serotonin transporter (SLC6A4).
- Extraneuronal transporter (ENT): This transporter, previously called *uptake 2*, is an organic cation transporter, OCT3, designated as SLC22A3. OCT3 facilitates passive transmembrane movement of organic anions down their electrochemical gradients, including the movement of catecholamines into nonneuronal cells. Compared to NET, it has a lower affinity for catecholamines, favors EPI over NE and DA, has a higher maximum uptake rate for catecholamines, is not Na^+ dependent, and has a different profile for pharmacological inhibition. The synthetic β adrenergic receptor agonist *isoproterenol* is not a substrate for this system. OCT3 activity is altered by MAPK and Ca^{2+}-CaM signaling (Roth et al., 2012). In addition to catecholamines, OCT3 can transport a wide variety of other organic cations, including 5HT, histamine, choline, spermine, guanidine, and creatinine, as can the closely related OCT1 and OCT2. The characteristics and locations of the nonneuronal transporters are summarized in Table 10–5.

For NE released by neurons, uptake by NET is more important than uptake by ENT. Sympathetic nerves as a whole remove about 87% of

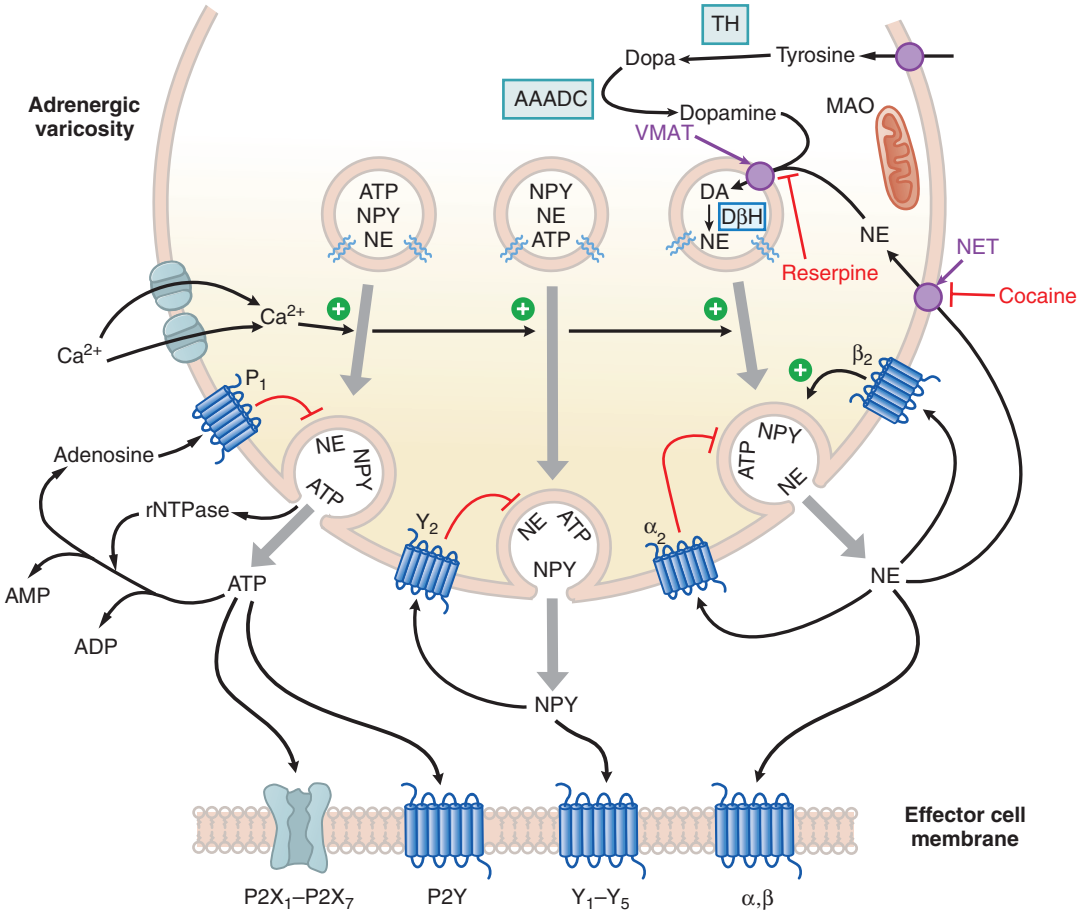

Figure 10–8 *A typical adrenergic neuroeffector junction.* Tyrosine is transported into the varicosity and is converted to DOPA by TH and DOPA to DA by the action of aromatic L-amino acid decarboxylase (AAADC). DA is taken up into the vesicles of the varicosity by a transporter, VMAT2, that can be blocked by *reserpine*. Cytoplasmic NE also can be taken up by this transporter. DA is converted to NE within the vesicle via the action of DβH. NE is stored in vesicles along with other cotransmitters, NPY and ATP, depending on the particular neuroeffector junction. Release of the transmitters occurs via exocytosis, a process activated by depolarization of the varicosity, which allows entry of Ca^{2+} through voltage-dependent Ca^{2+} channels and the interaction of numerous docking and fusion proteins located in the vesicle and the neuronal cell membrane, as described in Figures 10–3, 10–4, and 10–5. In this schematic representation, NE, NPY, and ATP are stored in the same vesicles. Different populations of vesicles, however, may preferentially store different proportions of the cotransmitters. Once in the synapse, NE can interact with α and β adrenergic receptors (GPCRs) to produce the responses characteristic of the particular postsynaptic cell. The α and β receptors also can be located presynaptically, via which NE can either diminish (α_2) or facilitate (β) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a *cocaine*-sensitive neuronal uptake transporter, NET. Once transported into the cytosol, NE can be re-stored in the vesicle or metabolized by MAO. NPY produces its effects by activating NPY receptors (also GCPRs), of which there are at least five types (Y_1 through Y_2). NPY can modify its own release and that of the other transmitters via presynaptic Y_2 receptors. NPY action is terminated by the actions of peptidases. ATP produces its effects by activating P2X receptors (ligand-gated ion channels) or P2Y receptors (GPCRs). There are multiple subtypes of both P2X and P2Y receptors. As with other cotransmitters, ATP can act prejunctionally to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P1 (adenosine) receptors. ATP is cleared from the synapse primarily by releasable nucleotidases (rNTPases) and by cell-fixed ectonucleotidases.

released NE by NET, compared with 5% by extraneuronal uptake (ENT) and 8% by diffusion to the circulation. In contrast, clearance of circulating catecholamines, such as those released from the adrenal medulla, is primarily by nonneuronal mechanisms, with liver and kidney accounting for over 60% of the clearance of circulating catecholamines. Because VMAT2 has a much higher affinity for NE than does MAO, over 70% of recaptured NE is resequestered into storage vesicles (Eisenhofer, 2001).

The NET is also present in the adrenal medulla, the liver, and the placenta, whereas DAT is present in the stomach, pancreas, and kidney (Eisenhofer, 2001). These plasma membrane transporters appear to have greater substrate specificity than does VMAT2. NET and DAT are targets for inhibitors such as cocaine and tricyclic antidepressants (e.g., *imipramine*); selective 5HT reuptake inhibitors such as *fluoxetine* inhibit serotonin transporter. Inhibitors of OCT3 include normetanephrine (an *O*-methylated metabolite of NE; see Figure 10–9). Pharmacological probes of OCT3 include *corticosterone* (an inhibitor) and the substrates *metformin* and *cimetidine*; the interaction of substrates and inhibitors at renal OCT3 can lead to adverse drug effects (see Chapter 4).

The use of selective inhibitors of NET in animal and human studies and data from analysis of mice with targeted deletions (knockout [KO]) of the NET and DAT genes reveal the impact of these uptake systems. The NET-KO and DAT-KO animals exhibit increased extracellular levels and decreased intracellular levels of NE despite increased or unaltered neurotransmitter synthesis. A loss or reduction of NET activity has been implicated in behavior, hemodynamics (e.g., excessive tachycardia and increased blood pressure) during sympathetic activation due to activity, increased central sympatho-inhibition, orthostatic intolerance, posttraumatic stress, and depression.

Certain sympathomimetic drugs (e.g., *ephedrine* and *tyramine*) produce some of their effects indirectly by displacing NE from the nerve terminals to the extracellular fluid, where it then acts at receptor sites of the effector cells. The mechanisms by which these drugs release NE

TABLE 10–5 ■ CHARACTERISTICS OF PLASMA MEMBRANE TRANSPORTERS FOR ENDOGENOUS CATECHOLAMINES

TYPE OF TRANSPORTER	SUBSTRATE SPECIFICITY	TISSUE	REGION/CELL TYPE	INHIBITORS
Neuronal				
NET	DA > NE > EPI	All sympathetically innervated tissue	Sympathetic nerves	Desipramine Cocaine Nisoxetine
		Adrenal medulla	Chromaffin cells	
		Liver	Capillary endothelial cells	
		Placenta	Syncytiotrophoblast	
DAT	DA > NE > EPI	Kidney	Endothelium	Cocaine Imazindol
		Stomach	Parietal and endothelial cells	
		Pancreas	Pancreatic duct	
Nonneuronal				
OCT1	DA > EPI >> NE	Liver	Hepatocytes	Isocyanines Corticosterone
		Intestine	Epithelial cells	
		Kidney (not human)	Distal tubule	
OCT2	DA >> NE > EPI	Kidney	Medullary proximal and distal tubules	Isocyanines Corticosterone
		Brain	Glial cells of DA-rich regions, some nonadrenergic neurons	
ENT (OCT3)	EPI >> NE > DA	Liver	Hepatocytes	Isocyanines Corticosterone *O*-methyl-isoproterenol
		Brain	Glial cells, others	
		Heart	Myocytes	
		Blood vessels	Endothelial cells	
		Kidney	Cortex, proximal and distal tubules	
		Placenta	Syncytiotrophoblasts (basal membrane)	
		Retina	Photoreceptors, ganglion amacrine cells	

from nerve endings are complex. All such agents are substrates for NET. As a result of their uptake by NET, they make carrier proteins available at the inner surface of the membrane for the outward transport of NE ("facilitated exchange diffusion"). In addition, these amines are able to mobilize NE stored in the vesicles by competing for the vesicular uptake process (VMAT2).

The actions of indirect-acting sympathomimetic amines are subject to *tachyphylaxis*. For example, repeated administration of tyramine results in rapidly decreasing effectiveness, whereas repeated administration of NE does not reduce effectiveness and, in fact, reverses the tachyphylaxis to tyramine. These phenomena have not been explained fully. One hypothesis is that the pool of neurotransmitter available for displacement by these drugs is small relative to the total amount stored in the sympathetic nerve ending. This pool is presumed to reside close to the plasma membrane, and the NE of such vesicles may be replaced by the less-potent amine following repeated administration of the latter substance. In any case, neurotransmitter release by displacement is not associated with the release of DβH and does not require extracellular Ca^{2+}; thus, it is presumed not to involve exocytosis.

Prejunctional Regulation of NE Release. The release of the three sympathetic cotransmitters can be modulated by prejunctional autoreceptors and heteroreceptors. Following their release from sympathetic terminals, all three cotransmitters—NE, NPY, and ATP—can feed back on prejunctional receptors to inhibit the release of each other (Westfall, 2004; Westfall et al., 2002). The most thoroughly studied have been prejunctional α_2 adrenergic receptors. The α_{2A} and α_{2C} adrenergic receptors are the principal prejunctional receptors that inhibit sympathetic neurotransmitter release, whereas the α_{2B} adrenergic receptors also may inhibit transmitter release at selected sites. Antagonists of this receptor, in turn, can enhance the electrically evoked release of sympathetic neurotransmitter. NPY, acting on Y_2 receptors, and ATP-derived adenosine, acting on P1 receptors, also can inhibit sympathetic neurotransmitter release. Activation of numerous heteroreceptors on sympathetic nerve varicosities can inhibit the release of sympathetic neurotransmitters; these include M_2 and M_4 muscarinic, 5HT, prostaglandin E_2, histamine, enkephalin, and DA receptors. Enhancement of sympathetic neurotransmitter release can be produced by activation of β_2 adrenergic receptors, angiotensin AT_2 receptors, and nAChRs. All of these receptors can be targets for agonists and antagonists.

Metabolism of Catecholamines. Uptake of released catecholamine terminates the neurotransmitter's effects at the synaptic junction. Following uptake, catecholamines can be metabolized (in neuronal and nonneuronal cells) or re-stored in vesicles (in neurons). Two enzymes are important in the initial steps of metabolic transformation of catecholamines—MAO and catechol-*O*-methyltransferase (COMT).

MAO and COMT. MAO metabolizes transmitter that is released within the nerve terminal or that is in the cytosol as a result of reuptake and has not yet reached the safety of the storage vesicle. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines. The importance of neuronal reuptake of catecholamines is shown by observations that inhibitors of uptake (e.g., *cocaine* and *imipramine*) potentiate the effects of the neurotransmitter; inhibitors of MAO and COMT have less effect.

Both MAO and COMT are distributed widely throughout the body, including the brain; their highest concentrations are in the liver and the kidney. However, little or no COMT is found in sympathetic neurons. In the brain, there is no significant COMT in presynaptic terminals, but it is found in some postsynaptic neurons and glial cells. In the kidney, COMT is localized in proximal tubular epithelial cells, where DA is synthesized and is thought to exert local diuretic and natriuretic effects.

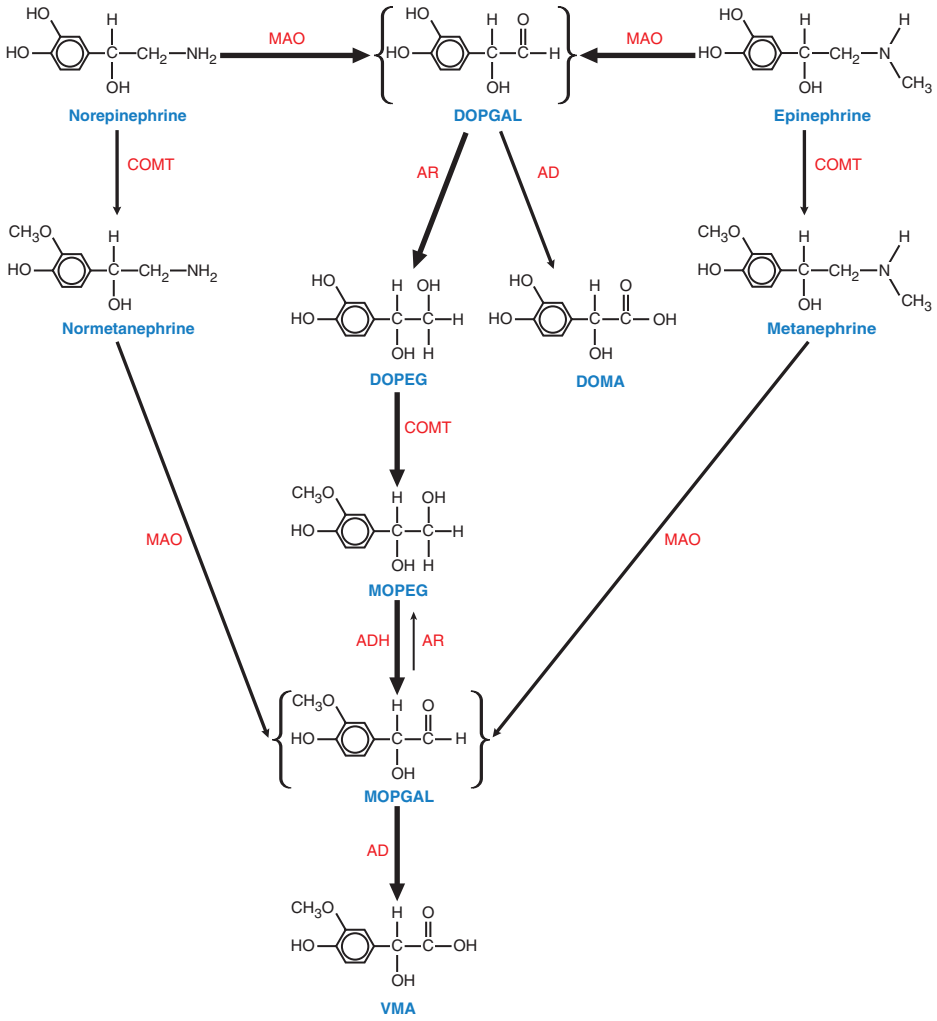

Figure 10–9 *Metabolism of catecholamines.* NE and EPI are first oxidatively deaminated to a short-lived intermediate (DOPGAL) by MAO. DOPGAL then undergoes further metabolism to more stable alcohol- or acid-deaminated metabolites. AD metabolizes DOPGAL to DOMA, while AR metabolizes DOPGAL to DOPEG. Under normal circumstances, DOMA is a minor metabolite, with DOPEG being the major metabolite produced from NE and EPI. Once DOPEG leaves the major sites of its formation (sympathetic nerves; adrenal medulla), it is converted to MOPEG by COMT. MOPEG is then converted to the unstable aldehyde (MOPGAL) by ADH and finally to VMA by AD. VMA is the major end product. Another route for the formation of VMA is conversion of NE or EPI into normetanephrine or metanephrine by COMT in either the adrenal medulla or extraneuronal sites, with subsequent metabolism to MOPGAL and thence to VMA. Catecholamines are also metabolized by *sulfotransferases*.

There are distinct differences in the localizations of the two enzymes; MAO is associated chiefly with the outer surface of mitochondria, including those within the terminals of sympathetic or central noradrenergic neuronal fibers, whereas COMT is largely cytosolic, except in the chromaffin cells of the adrenal medulla, where COMT is membrane bound. These factors are of importance both in determining the primary metabolic pathways followed by catecholamines in various circumstances and in explaining the effects of certain drugs. The physiological substrates for COMT include L-dopa, all three endogenous catecholamines (DA, NE, and EPI), their hydroxylated metabolites, catecholestrogens, ascorbic acid, and dihydroxyindolic intermediates of melanin (Männistö and Kaakkola, 1999).

Two different isozymes of MAO (MAO-A and MAO-B) are found in widely varying proportions in different cells in the CNS and in peripheral tissues. In the periphery, MAO-A is located in the syncytiotrophoblast layer of term placenta and liver, whereas MAO-B is located in platelets, lymphocytes, and liver. In the brain, MAO-A is located in all regions containing catecholamines, with the highest abundance in the locus ceruleus. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store 5HT. MAO-B is most prominent not only in the nucleus raphe dorsalis but also in the posterior hypothalamus and in glial cells in regions known to contain nerve terminals. MAO-B is also present in osteocytes around blood vessels.

Many MAO inhibitors are not selective for MAO-A or MAO-B, and these nonselective agents (e.g., *phenelzine*, *tranylcypromine*, and *isocarboxazid*) enhance the bioavailability of tyramine contained in many foods; tyramine-induced NE release from sympathetic neurons may lead to markedly increased blood pressure (hypertensive crisis). Drugs with selectivity for MAO-B (e.g., *selegiline*, *rasagiline*, *pargyline*) or reversible inhibitors of MAO-A (e.g., *moclobemide*) are less likely to cause this potential interaction.

Inhibitors of MAO activity can cause an increase in the concentration of NE, DA, and 5HT in the brain and other tissues accompanied by a variety of pharmacological effects. No striking pharmacological action in the periphery can be attributed to the inhibition of COMT. COMT inhibitors that are efficacious in the therapy of Parkinson's disease are discussed in Chapter 21.

The Metabolic Pathway (Figure 10–9). There is ongoing passive leakage of catecholamines from vesicular storage granules of sympathetic neurons and adrenal medullary chromaffin cells. As a consequence, most metabolism of catecholamines takes place in the same cells where the amines are synthesized and stored. VMAT2 effectively sequesters about 90% of the amines leaking into the cytoplasm back into storage vesicles; about 10% escapes sequestration and is metabolized (Eisenhofer et al., 2004).

Sympathetic nerves contain MAO but not COMT, and this MAO catalyzes only the first step of a two-step reaction. MAO converts NE or EPI into a short-lived intermediate, dihydroxyphenylglycolaldehyde (DOPGAL), which undergoes further metabolism in a second step catalyzed by another group of enzymes forming more stable alcohol- or acid-deaminated metabolites. Aldehyde dehydrogenase metabolizes DOPGAL to 3,4-dihydroxymandelic acid (DOMA), while aldehyde reductase metabolizes DOPGAL to 3,4-dihydroxyphenyl glycol (DOPEG). In addition to aldehyde reductase, a related enzyme, aldose reductase, can reduce a catecholamine to its corresponding alcohol. This latter enzyme is present in sympathetic neurons and adrenal chromaffin cells. Under normal circumstances, DOMA is an insignificant metabolite of NE and EPI, with DOPEG being the main metabolite produced by deamination in sympathetic neurons and adrenal medullary chromaffin cells.

Once it leaves the sites of formation (sympathetic neurons, adrenal medulla), DOPEG is converted to 3-methyl,4-hydroxyphenylglycol (MOPEG) by COMT. Thus, most MOPEG comes from extraneuronal *O*-methylation of DOPEG produced in and diffusing rapidly from sympathetic neurons into the extracellular fluid. MOPEG is then converted to vanillyl mandelic acid (VMA) by the sequential actions of alcohol and aldehyde dehydrogenases. MOPEG is first converted to the unstable aldehyde metabolite monohydroxyphenylglycolaldehyde (MOPGAL) and then to VMA, with VMA being the major end product of NE and EPI metabolism. Another route for the formation of VMA is conversion by COMT of NE and EPI into normetanephrine and metanephrine, respectively, followed by deamination to MOPGAL and thence to VMA. This is now thought to be only a minor pathway, as indicated by the size of the arrows on Figure 10–9.

In contrast to sympathetic neurons, adrenal medullary chromaffin cells contain both MAO and COMT, the COMT mainly as the membrane-bound form. This isoform of COMT has a higher affinity for catecholamines than does the soluble form found in most other tissues (e.g., liver and kidney). In adrenal medullary chromaffin cells, leakage of NE and EPI from storage vesicles leads to substantial intracellular production of the *O*-methylated metabolites normetanephrine and metanephrine. In humans, over 90% of circulating metanephrine and 25% to 40% of circulating normetanephrine are derived from catecholamines metabolized within adrenal chromaffin cells.

The sequence of cellular uptake and metabolism of catecholamines in extraneuronal tissues contributes only modestly (~25%) to the total metabolism of endogenously produced NE in sympathetic neurons or the adrenal medulla. However, extraneuronal metabolism is an important mechanism for the clearance of circulating and exogenously administered catecholamines.

Classification of Adrenergic Receptors

Adrenergic receptors are broadly classified as either α or β, with subtypes within each group (Table 10–6). The original subclassification was based on the rank order of agonist potency:

- EPI ≥ NE >> *isoproterenol* for α adrenergic receptors.
- *Isoproterenol* > EPI ≥ NE for β adrenergic receptors.

Elucidation of the characteristics of these receptors and the biochemical and physiological pathways they regulate has increased our understanding of the seemingly contradictory and variable effects of catecholamines on various organ systems. Although structurally related (discussed further in the chapter), different receptors regulate distinct physiological processes by controlling the synthesis or mobilization of a variety of second messengers.

Raymond Ahlquist and the Functional Definition of α and β Receptors. Based on studies of the capacities of EPI, NE, and related agonists to regulate various physiological processes, Ahlquist (1948) proposed the existence of more than one adrenergic receptor. It was known that adrenergic agents could cause either contraction or relaxation of smooth muscle depending on the site, the dose, and the agent chosen. For example, NE was known to have potent excitatory effects on smooth muscle and correspondingly low activity as an inhibitor; *isoproterenol* displayed the opposite pattern of activity. EPI could both excite and inhibit smooth muscle. Thus, Ahlquist proposed the designations α and β for receptors on smooth muscle where catecholamines produce excitatory and inhibitory responses, respectively (an exception was the gut, which generally is relaxed by activation of either α or β receptors). He developed the rank orders of potency that define α and β receptor–mediated responses, as noted above. This initial classification was corroborated by the finding that certain antagonists produced selective blockade of the effects of adrenergic nerve impulses and sympathomimetic agents at α receptors (e.g., *phenoxybenzamine*), whereas others produced selective β receptor blockade (e.g., *propranolol*).

α and β Receptor Subtypes. Subsequent to Ahlquist's functional description of α and β receptors, adrenergic pharmacologists used increasingly sophisticated probes, tools, and methods to elucidate subtypes of α and β receptors. The β receptors were subclassified as β_1 (e.g., those in the myocardium) and β_2 (smooth muscle and most other sites), reflecting the finding that EPI and NE essentially are equipotent at β_1 sites, whereas EPI is 10 to 50 times more potent than NE at β_2 sites. Antagonists that discriminate between β_1 and β_2 receptors were subsequently developed (see Chapter 14). Cloning confirmed that these β subtypes are products of different genes, and a human gene that encodes a third β receptor (designated β_3) was isolated (Ahles and Engelhardt, 2014). The β_3 receptor is about 10-fold more sensitive to NE than to EPI and is relatively resistant to blockade by antagonists such as *propranolol*. The β_3 receptor may mediate responses to catecholamine at sites with "atypical" pharmacological characteristics (e.g., adipose tissue, which expresses all three β receptor subtypes). Animals treated with β_3 receptor agonists exhibit a vigorous thermogenic response as well as lipolysis. Polymorphisms in the β_3 receptor gene may be related to risk of obesity or type 2 diabetes in some populations (Ahles and Engelhardt, 2014).

There is also heterogeneity among α adrenergic receptors. The initial distinction was based on functional and anatomic considerations: NE and other α adrenergic agonists profoundly inhibit the release of NE from neurons (see Figure 10–8); conversely, certain α receptor antagonists markedly increase NE release when sympathetic nerves are stimulated. This feedback-inhibitory effect of NE on its release from nerve terminals is mediated by α receptors that are pharmacologically distinct from the classical postsynaptic α receptors. Accordingly, these presynaptic α adrenergic receptors were designated α_2, whereas the postsynaptic "excitatory" α receptors were designated α_1. Compounds such as *clonidine* are more potent agonists at α_2 than at α_1 receptors; by contrast, *phenylephrine* and *methoxamine* selectively activate postsynaptic α_1 adrenergic receptors.

Although there is little evidence to suggest that α_1 adrenergic receptors function presynaptically in the autonomic nervous system, α_2 receptors are present at postjunctional or nonjunctional sites in several tissues. For example, stimulation of postjunctional α_2 receptors in the brain is associated with reduced sympathetic outflow from the CNS and appears to be responsible for a significant component of the antihypertensive effect of drugs such as clonidine (see Chapter 14). Thus, the anatomic concept of prejunctional α_2 and postjunctional α_1 adrenergic receptors has been abandoned in favor of a pharmacological and functional classification (Tables 10–6 and 10–7).

Cloning revealed additional heterogeneity of both α_1 and α_2 adrenergic receptors. There are three pharmacologically defined α_1 receptors (α_{1A}, α_{1B}, and α_{1D}) with distinct sequences and tissue distributions and three cloned subtypes of α_2 receptors (α_{2A}, α_{2B}, and α_{2C}) (see Table 10–6). A fourth type of α_1 receptor, α_{1L}, has been defined on the basis of a low affinity for the selective antagonists *prazosin* and *5-methyl urapidil* but a high affinity for *tamsulosin* and *silodosin*. This phenotype could be of physiological significance; the α_{1L} profile has been identified in myriad tissues across a number of species, where it appears to regulate smooth muscle contractility in the vasculature and lower urinary tract. Despite intense efforts, the α_{1L} adrenergic receptor has not been cloned. Currently, it is viewed as a second phenotype originating from the α_{1A} receptor gene. Distinct pharmacological phenotypes of the α_{1B} receptor have also been described (Yoshiki et al., 2014).

Owing to the lack of sufficiently subtype-selective ligands, the precise physiological functions and therapeutic potential of the subtypes of

TABLE 10–6 ■ CHARACTERISTICS FOR ADRENERGIC RECEPTOR SUBTYPES[a]

	G PROTEIN COUPLING	PRINCIPLE EFFECTORS	TISSUE LOCALIZATION	DOMINANT EFFECTS[b]
α_{1A}	$G\alpha_q$ ($\alpha_{11}/\alpha_{14}/\alpha_{16}$)	↑ PLC, ↑ PLA_2 ↑ Ca^{2+} channels ↑ Na^+/H^+ exchanger Modulation of K^+ channels ↑ MAPK Signaling	Heart, lung Liver Smooth muscle Blood vessels Vas deferens, prostate Cerebellum, cortex Hippocampus	• Dominant receptor for contraction of vascular smooth muscle • Promotes cardiac growth and structure • Vasoconstriction of large resistant arterioles in skeletal muscle

[a]At least three subtypes each of α_1 and α_2 adrenergic receptors are known, but distinctions in their mechanisms of action have not been clearly defined.
[b]In some species (e.g., rat), metabolic responses in the liver are mediated by α_1 adrenergic receptors, whereas in others (e.g., dog) β_2 adrenergic receptors are predominantly involved. Both types of receptors appear to contribute to responses in human beings.
[c]β Receptor coupling to cell signaling can be more complex. In addition to coupling to G_s to stimulate AC, β_2 receptors can activate signaling via a GRK/β-arrestin pathway. β_2 and β_3 receptors can couple to both G_s and G_i in a manner that may reflect agonist stereochemistry. See also Chapter 14.
[d]Metabolic responses in tissues with atypical pharmacological characteristics (e.g., adipocytes) may be mediated by β_3 receptors. Most β receptor antagonists (including propranolol) do not block these responses.

TABLE 10–7 ■ REPRESENTATIVE AGENTS ACTING AT PERIPHERAL CHOLINERGIC AND ADRENERGIC NEUROEFFECTOR JUNCTIONS

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
1. Interference with synthesis of transmitter	Cholinergic	Choline acetyl transferase inhibitors	Minimal depletion of ACh
	Adrenergic	α-Methyltyrosine (inhibition of tyrosine hydroxylase)	Depletion of NE
2. Metabolic transformation by same pathway as precursor of transmitter	Adrenergic	Methyldopa	Displacement of NE by α-methyl-NE, which is an α_2 agonist, similar to clonidine, that reduces sympathetic outflow from CNS
3. Blockade of transport system at nerve terminal membrane	Cholinergic	Hemicholinium	Block of choline uptake with consequent depletion of ACh
	Adrenergic	Cocaine, imipramine	Accumulation of NE at receptors
4. Blockade of transport system of storage vesicle	Cholinergic	Vesamicol	Block of ACh storage
	Adrenergic	Reserpine	Destruction of NE by mitochondrial MAO and depletion from adrenergic terminals
5. Promotion of exocytosis or displacement of transmitter from storage sites	Cholinergic	Latrotoxins	Cholinomimetic followed by anticholinergic
	Adrenergic	Amphetamine, tyramine	Sympathomimetic
6. Prevention of release of transmitter	Cholinergic	Botulinum toxin (BTX, endopeptidase, acts on synaptobrevin)	Anticholinergic (prevents skeletal muscle contraction)
	Adrenergic	Bretylium, guanadrel	Antiadrenergic
7. Mimicry of transmitter at postjunctional sites	Cholinergic		
	Muscarinic[a]	Methacholine, bethanachol	Cholinomimetic
	Nicotinic[b]	Nicotine, epibatidine, cytisine	Cholinomimetic
	Adrenergic		
	α_1	Phenylephrine	Selective α_1 agonist
	α_2	Clonidine	Sympathomimetic (periphery); reduced sympathetic outflow (CNS)
	α_1, α_2	Oxymetazoline	Nonselective α adrenomimetic
	β_1	Dobutamine	Selective cardiac stimulation (also activates α_1 receptors)
	β_2	Terbutaline, albuterol metaproterenol	Selective β_2 receptor agonist (selective inhibition of smooth muscle contraction)
	β_1, β_2	Isoproterenol	Nonselective β agonist
8. Blockade of postsynaptic receptor	Cholinergic		
	Muscarinic[a]	Atropine	Muscarinic blockade
	Nicotinic (N_m)[b]	*d*-Tubucurarine, atracurium	Neuromuscular blockade
	Nicotinic (N_n)[b]	Trimethaphan	Ganglionic blockade
	Adrenergic		
	α_1, α_2	Phenoxybenzamine	Nonselective α receptor blockade (irreversible)
	α_1, α_2	Phentolamine	Nonselective α receptor blockade (reversible)
	α_1	Prazosin, terazosin, doxasozin	Selective α_1 receptor blockade (reversible)
	α_2	Yohimbine	Selective α_2 receptor blockade
	β_1, β_2	Propranolol	Nonselective β receptor blockade
	β_1	Metoprolol, atenolol	Selective β_1 receptor blockade (cardiomyocytes; renal j-g cells)
	β_2	—	Selective β_2 receptor blockade (smooth muscle)

(*Continued*)

TABLE 10–7 ■ REPRESENTATIVE AGENTS ACTING AT PERIPHERAL CHOLINERGIC AND ADRENERGIC NEUROEFFECTOR JUNCTIONS *(CONTINUED)*

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
9. Inhibition of enzymatic breakdown of transmitter	Cholinergic	AChE inhibitors edrophonium, neostigmine, pyridostigmine	Cholinomimetic (muscarinic sites) Depolarization blockade (nicotinic sites)
	Adrenergic	Nonselective MAO inhibitors: pargyline, nialamide	Little direct effect on NE or sympathetic response; potentiation of tyramine
		Selective MAO-B inhibitor: selegeline	Adjunct in Parkinson's disease
		Peripheral COMT inhibitor: Entacapone	Adjunct in Parkinson's disease
		COMT inhibitor:Tolcapone	

The j-g cells are renin-secreting cells in the juxtaglomerular complex of the kidney.
[a]At least five subtypes of muscarinic receptors exist (see Table 10–3). Agonists show little subtype selectivity; several antagonists show partial subtype selectivity (see Chapter 11).
[b]Two subtypes of muscle acetylcholine nicotinic receptors and several subtypes of neuronal receptors have been identified (see Table 10–2).

adrenergic receptors have not been elucidated fully. Genetic approaches using transgenic and receptor knockout experiments in mice (discussed further in the chapter) have advanced our understanding. These mouse models have been used to identify and localize particular receptor subtypes and to describe the pathophysiological relevance of individual adrenergic receptor subtypes (Ahles and Engelhardt, 2014; Philipp and Hein, 2004; Xiao et al., 2006).

Molecular Basis of Adrenergic Receptor Function

Structural Features. All adrenergic receptors are GPCRs that link to heterotrimeric G proteins. Structurally, there are similarities in the regions for ligand binding and modulation by intracellular protein kinases (Figure 10–10). The coding region of each of the three β adrenergic receptor genes and the three α_2 adrenergic receptor genes is contained in a single exon, whereas each of the three α_1 adrenergic receptor genes has a single large intron separating regions that encode the body of the receptor from those that encode the seventh transmembrane domain and carboxy terminus (Dorn, 2010). Each major receptor type shows preference for a particular class of G proteins, that is, α_1 to G_q, α_2 to G_i, and β to G_s (see Table 10–6). The responses that follow receptor activation result from G protein-mediated effects on the generation of second messengers and on the activity of ion channels (see Chapter 3). The signaling pathways overlap broadly with those discussed for muscarinic ACh receptors.

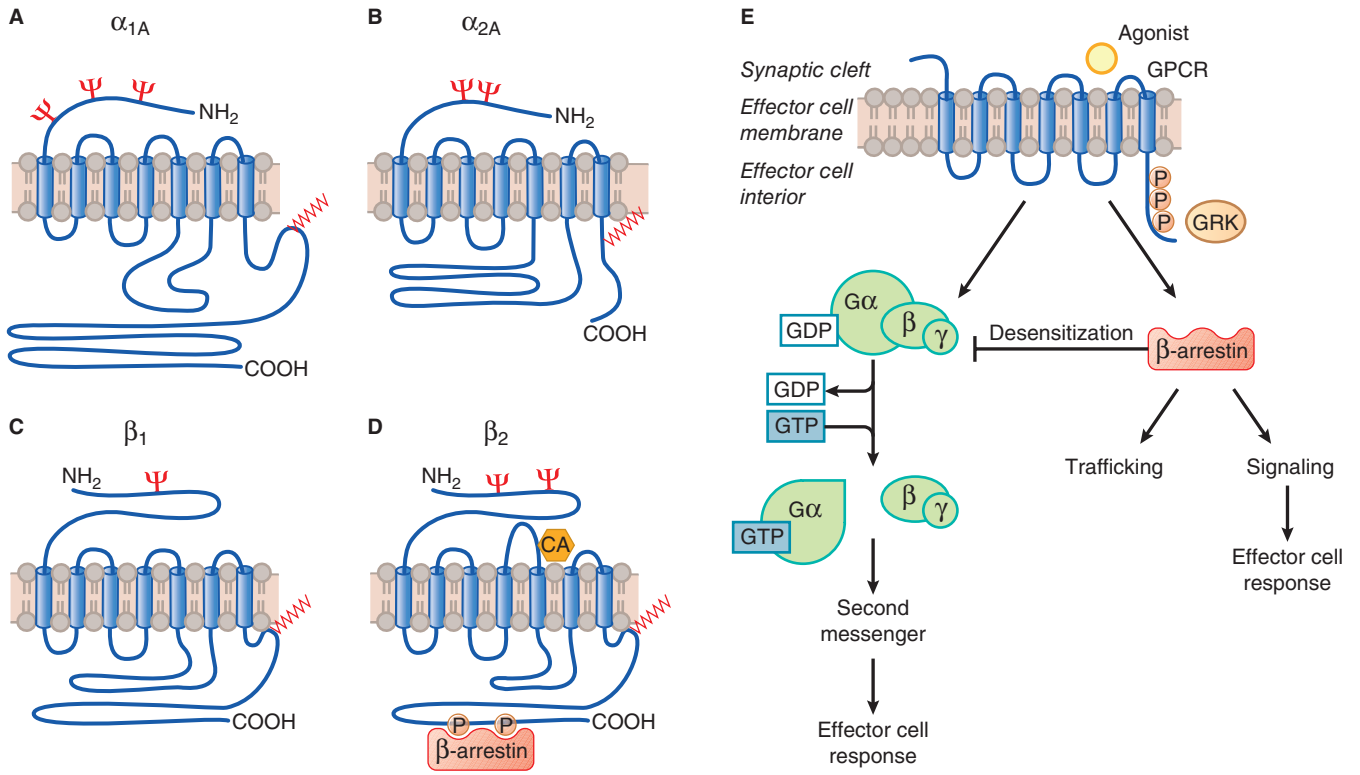

Figure 10–10 *Structural features and functional signaling of adrenergic receptors and subtypes.* All of the adrenergic receptors are hepta-spanning GPCRs. **A–D.** Representatives of each type are shown; each type has three subtypes: α1A, α1B, and α1D; α2A, α2B, and α2C; and β1, β2, and β3. (**E**) shows binding of catecholamine (CA) and β-arrestin. The principal effector systems affected by α1, α2, and β receptors are depicted in Table 10–6. ψ indicates a site for N-glycosylation. **E.** The ligand-receptor complex activates G protein-mediated and β-arrestin–mediated signaling pathways. β-arrestin can act to regulate G protein signaling, desensitization, and trafficking (internalization and translocation), but can also initiate signaling. Biased agonists can act preferentially toward the G protein signaling or β-arrestin–mediated signaling pathways, depending on which arm is favored.

α Adrenergic Receptors. The α_1 receptors (α_{1A}, α_{1B}, and α_{1D}) and the α_2 receptors (α_{2A}, α_{2B}, and α_{2C}) are heptahelical proteins that couple differentially to a variety of G proteins to regulate smooth muscle contraction, secretory pathways, and cell growth (see Table 10–6). Within the membrane-spanning domains, the three α_1 adrenergic receptors share about 75% identity in amino acid residues, as do the three α_2 receptors, but the α_1 and α_2 subtypes are no more similar than are the α and β subtypes (~30%–40%).

α_1 Adrenergic Receptors. Stimulation of α_1 receptors activates the G_q-PLC_β-IP_3/diacylglycerol-Ca^{2+} pathway and results in the activation of PKC and other Ca^{2+} and CaM-sensitive pathways, such as CaM kinases, with sequelae depending on cell differentiation (e.g., contraction of vascular smooth muscle, stimulation of growth in smooth muscles and hypertrophy in cardiac myocytes, and activation of endothelial nitric oxide synthase [NOS] in vascular endothelium) (see Chapter 3). PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ion exchange proteins (e.g., Ca^{2+}-transport ATPase). α_1 Receptor stimulation of PLA_2 leads to the release of free arachidonate, which is then metabolized by cyclooxygenase (yielding prostaglandins) and lipoxygenase (yielding leukotrienes) (see Chapter 41); PLD hydrolyzes phosphatidylcholine to yield phosphatidic acid, which can yield diacylglycerol, a cofactor for PKC activation. PLD is an effector for ADP-ribosylating factor, suggesting that PLD may play a role in membrane trafficking. In most smooth muscles, the increased concentration of intracellular Ca^{2+} causes contraction (see Figure 3–26). In contrast, the increased concentration of intracellular Ca^{2+} following α_1 stimulation of GI smooth muscle causes hyperpolarization and relaxation by activation of Ca^{2+}-dependent K^+ channels. Stimulation of α_1 receptors can activate p38/p42/p44, PI3K, JNK, and others to affect cell growth and proliferation, albeit in receptor subtype-specific and tissue-specific manners.

The α_{1A} receptor is the predominant receptor causing vasoconstriction in many vascular beds, including the following arteries: mammary, mesenteric, splenic, hepatic, omental, renal, pulmonary, and epicardial coronary. It is also the predominant subtype in the vena cava and the saphenous and pulmonary veins. Together with the α_{1B} receptor subtype, it promotes cardiac growth and structure. The α_{1B} receptor subtype is the most abundant subtype in the heart, whereas the α_{1D} receptor subtype is the predominant receptor causing vasoconstriction in the aorta. There is evidence to support the idea that α_{1B} receptors mediate behaviors such as reaction to novelty and exploration and are involved in behavioral sensitizations and in the vulnerability to addiction (see Chapter 28).

In addition to their traditional localization in the plasma membrane, α_1 receptors have nuclear localization signals (as do β receptors and receptors for endothelin and angiotensin) and have been found on the nuclear membrane of adult mouse cardiac myocytes, where they activate intranuclear signaling and appear to play a cardioprotective role (Wu and O'Connell, 2015).

α_2 Adrenergic Receptors. The α_2 adrenergic receptors couple to a variety of effectors. Inhibition of adenylyl cyclase activity was the first effect observed, but in some systems, the enzyme actually is stimulated by α_2 adrenergic receptors, either by G_i βγ subunits or by weak direct stimulation of G_s. The physiological significance of these last processes is unclear. The α_2 receptors activate G protein-gated K^+ channels, resulting in membrane hyperpolarization. In some cases (e.g., cholinergic neurons in the myenteric plexus), this may be Ca^{2+} dependent, whereas in others (e.g., muscarinic ACh receptors in atrial myocytes), it results from direct interaction of βγ subunits with K^+ channels. The α_2 receptors also can inhibit voltage-gated Ca^{2+} channels; this is mediated by G_o. Other second-messenger systems linked to α_2 receptor activation include acceleration of Na^+/H^+ exchange, stimulation of $PLC\beta_2$ activity and arachidonic acid mobilization, increased phosphoinositide hydrolysis, and increased intracellular availability of Ca^{2+}. The last is involved in the smooth muscle–contracting effect of α_2 adrenergic receptor agonists. In addition, the α_2 receptors activate MAPKs via mechanisms dependent on both the α and βγ components of G_i, with involvement of protein tyrosine kinases and small GTPases (Goldsmith and Dhanasekaran, 2007). These pathways are reminiscent of pathways activated by tyrosine kinase activities of growth factor receptors. The α_{2A} and α_{2C} receptors play a major role in inhibiting NE release from sympathetic nerve endings and suppressing sympathetic outflow from the brain, leading to hypotension (Kable et al., 2000).

Thus, depending on subtype, the major biological effects of α_2 adrenergic receptors can be on platelet aggregation, regulation of sympathetic outflow from the CNS, reuptake of NE from within peripheral sympathetic nerve synapses, insulin secretion and lipolysis, or, to a limited extent, vasoconstriction (Gyires et al., 2009). Similar studies with knockout mice have been carried out as was done with α_1 adrenergic receptors.

In the CNS, α_{2A} receptors, which appear to be the dominant adrenergic receptor, probably mediate the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of α_2 agonists. The α_{2C} receptor occurs in the ventral and dorsal striatum and hippocampus. It appears to modulate DA neurotransmission and various behavioral responses. The α_{2B} receptor is the main receptor mediating α_2-induced vasoconstriction, whereas the α_{2C} receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating DA neurotransmission in the brain.

β Adrenergic Receptors

Subtypes. The three β receptor subtypes share about 60% amino acid sequence identity within the putative membrane-spanning domains where the ligand-binding pockets for EPI and NE are found. Based on results of site-directed mutagenesis, individual amino acids in the β_2 receptor that interact with each of the functional groups on the catecholamine agonist molecule have been identified. Figure 10–10 depicts the general hepta-spanning structure of adrenergic receptors and notes some differences in the sizes of the third and fourth intracellular loops.

The β receptors regulate numerous functional responses, including heart rate and contractility, smooth muscle relaxation, and myriad metabolic events in numerous tissues, including skeletal muscle, liver, and adipose tissue (see Table 10–1).

β Receptor Signaling. All three of the β receptor subtypes (β_1, β_2, and β_3) couple to G_s and activate adenylyl cyclase (see Table 10–7). Stimulation of β adrenergic receptors leads to the accumulation of cAMP, activation of the PKA, and altered function of numerous cellular proteins as a result of their phosphorylation (see Chapter 3). In addition, G_s subunits can enhance directly the activation of voltage-sensitive Ca^{2+} channels in the plasma membrane of skeletal and cardiac muscle cells.

The β_1, β_2, and β_3 receptors can differ in their intracellular signaling pathways and subcellular location (Brodde et al., 2006; Violin and Lefkowitz, 2007). While the positive chronotropic effects of β_1 receptor activation are clearly mediated by G_s in myocytes, dual coupling of β_2 receptors to G_s and G_i occurs in myocytes from newborn mice. Stimulation of β_2 receptors causes a transient increase in heart rate that is followed by a prolonged decrease. Following pretreatment with pertussis toxin, which prevents activation of G_i, the negative chronotropic effect of β_2 activation is abolished. These specific signaling properties of β adrenergic receptor subtypes likely result from subtype-selective association with intracellular scaffolding and signaling proteins (Baillie and Houslay, 2005). The β_2 receptors normally are confined to caveolae in cardiac myocyte membranes. The activation of PKA by cAMP and the importance of compartmentation of components of the cAMP pathway are discussed in Chapter 3.

Refractoriness to Catecholamines. Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed *refractoriness, desensitization,* or *tachyphylaxis,* can limit the therapeutic efficacy and duration of action of catecholamines and other agents and is due to phosphorylation of the active receptor by G protein-coupled receptor kinases (GRKs) followed by arrestin binding to receptors, blocking further G protein activation (Chapter 3). An understanding of the mechanisms involved in regulation of G protein-coupled receptor (GPCR) desensitization and the roles of GRKs and β-arrestins has developed over the past two decades due to the efforts of Lefkowitz and colleagues (Violin and Lefkowitz, 2007) and Houslay and colleagues

(Baillie and Houslay, 2005), among others. For a perspective on refractoriness and on the roles of GRKs and β-arrestins in biased agonism, see the discussion that follows.

Desensitization has functional correlates in human health. Long-term exposure to catecholamines can cause cardiac dysfunction and contribute to the course of deterioration in heart failure. Data support the idea that the β_1 receptor is the primary mediator of catecholamine cardiotoxicity (Dorn, 2010). Studies in genetically manipulated mice indicate that β_1 receptor signaling has greater potential than β_2 receptor signaling to contribute to heart failure.

Desensitization, Downregulation, Sustained Signaling. Catecholamines promote β receptor feedback regulation, that is, desensitization, receptor downregulation, and internalization into endosomes. The β receptors differ in the extent to which they undergo such regulation, with the β_2 receptor being the most susceptible, as described in Chapter 3. Poststimulatory interactions of the agonist-liganded β_2 receptor with a GPCR kinase produces a phosphorylated receptor that readily interacts with β-arrestin, which blocks receptor access to the G protein and directs the receptor toward an endocytotic pathway, thereby reducing the number of receptors available at the cell surface. As a scaffolding protein, β-arrestin can also anchor proteins such as phosphodiesterase 4, which can modulate cAMP accumulation. The β receptor–β-arrestin complexes localize to coated pits and are subsequently internalized reversibly into endosomes (where the receptors may be dephosphorylated; such receptors can reenter the plasma membrane to aid resensitization), with some complexes reaching lysosomes, where they are degraded (see Chapter 3). β-Arrestin also serves as an organizing center for the formation of a complex of a phospho-GPCR, a G protein, and β-arrestin, and this complex may provide sustained intracellular signaling from the internalized GPCR (Thomsen et al., 2016).

Biased Agonism and Selective Responsiveness. The original idea that a β adrenergic agonist activates just the G_s–adenylyl cyclase–cAMP-PKA pathway and all else follows is incomplete. What follows the elevation of cAMP depends on the differentiated state of the cell type in question; cells have specialized responses just as they have specialized functions and functional compartmentation of signaling (Steinberg and Brunton, 2001). There are also notable differences in downstream signals activated by the three β receptor subtypes and differences when different ligands activate a single receptor subtype. Ligands can induce receptor conformations that may not activate G protein/adenylyl cyclase signaling or that activate G protein pathways but do not elicit GPCR kinase–β-arrestin actions, generating "biased" responses (see Chapters 3, 14, and 23). This is demonstrated by four findings:

- Signaling resulting from GPCR activation can be complex and involve a host of pathways.
- Ligand-activated GPCRs can adopt a multiplicity of conformations.
- GRKs and β-arrestins are also signal transducers, independently of G proteins.
- Distinct GRKs are recruited to and phosphorylate receptors based on specific ligand-induced receptor conformations, leading to specific signaling mediated by β-arrestin.

A biased agonist stabilizes one or a subset of possible GPCR conformations and thereby activates only a subset of all possible responses (such as G protein only or β-arrestin only); these responses may involve signaling mechanisms mediated by β-arrestins through its myriad scaffolding partners. In work leading to the Nobel Prize in 2012, Lefkowitz and colleagues described this "pluridimensionality of β-arrestin–dependent signaling" at GPCRs (Reiter et al., 2012). This idea raises the possibility that one may design biased agonists that have unusually precise specificity. Advantages of biased agonism include targeting of specific response pathways, improving efficacy while reducing or avoiding side effects, and permitting exploration of signaling pathways previously deemed unattractive targets due to overbroad effects. Biased agonism is discussed at greater length in Chapter 3, in Chapter 14 for adrenergic receptor ligands, and in Chapter 23 with regard to mu opioid agonists.

Adrenergic Receptor Polymorphism

Numerous polymorphisms and splice variants of adrenergic receptors continue to be identified. Such polymorphisms in adrenergic receptors could result in altered physiological responses to activation of the sympathetic nervous system, contribute to disease states, and alter the responses to adrenergic agonists or antagonists (Ahles, 2014; Brodde, 2008). Knowledge of the functional consequences of specific polymorphisms holds the potential for the individualization of drug therapy based on a patient's genetic makeup and could, in part, contribute to the understanding of interindividual variability within the human population, in conjunction with other environmental and societal (nongenetic) factors.

α_1 Adrenergic Receptor Polymorphisms. The α_1 adrenergic receptor is abundant in vascular smooth muscle and is implicated in regulating arterial resistance and blood pressure. The α_1 adrenergic receptor polymorphism most often studied in human hypertension is α_{1A} Arg347Cys; the accumulated data so far suggest only a marginal effect of this polymorphism in cardiovascular responses to sympathetic stimulation or human hypertension. Recent studies suggest adaptive and cardioprotective roles of α_{1A} adrenergic receptor stimulation, including positive inotropy in failing myocytes, protection of the myocardium from ischemia, and physiologic hypertrophy. In addition, it is thought that the pathways that confer these cardioprotective benefits may be selective and operate without affecting blood pressure (Zhang et al., 2021).

α_{2A} Adrenergic Receptor Polymorphisms. As with the α_{1A} adrenergic receptor, there is insufficient evidence supporting a major effect of α_2 receptor polymorphisms in essential hypertension (Dorn, 2010). Although studies suggest an association between α_{2A}, α_{2BA}, and α_{2C} polymorphisms and coronary heart disease, heart failure, and sudden death, these linkages are not yet conclusive and require further study. In contrast, a convincing role for α_{2A} adrenergic receptor polymorphisms in human type 2 diabetes has been elucidated. Moreover, in mice, deletion of the α_{2A} adrenergic receptor results in enhanced insulin secretion, and β-cell–specific overexpression of α_{2A}R mimics diabetes (Lin et al., 2021).

β_1 Adrenergic Receptor Polymorphisms. Evidence supports the notion that increased cardiomyocyte β_1 receptor signaling by chronic agonist stimulation, increased receptor expression, or enhanced receptor signaling can ultimately result in cardiac toxicity and contribute to heart dysfunction and failure (Dorn, 2010). On the other hand, β_1 adrenergic receptor polymorphisms do not seem to be major risk factors in human hypertension.

Biochemical, functional, and structural studies in cultured cell expression systems and genetic mouse models indicate that the Gly389Arg β_1 adrenergic receptor exhibits a gain-of-signaling function that can initially improve cardiac contractility but ultimately predisposes to cardiomyopathic decompensation. This abnormally active Arg389 receptor is more sensitive to pharmacological blockade and exhibits distinctive responses to various β blockers. This polymorphism may affect heart failure risk or progression, but the β blockers currently in use are sufficient to overcome the subtle differences that polymorphic receptor function may have on heart failure survival (Dorn, 2010).

β_2 Adrenergic Receptor Polymorphisms. Data supporting an interaction between β_2 adrenergic receptor polymorphisms and hypertension are inconclusive and suggest that effects of β_2 adrenergic receptor polymorphisms on blood pressure are modest. Similarly, there is no consensus about β_2 adrenergic receptor polymorphisms and heart disease (Dorn, 2010).

β_3 Adrenergic Receptor Polymorphisms. Polymorphisms of the β_3 adrenergic receptor appear to be associated with diabetes phenotypes, but there have been few clinical cardiac studies (Dorn, 2010).

Localization of Adrenergic Receptors

Presynaptic α_2 and β_2 receptors regulate neurotransmitter release from sympathetic nerve endings. Presynaptic α_2 receptors also may mediate inhibition of release of neurotransmitters other than NE in the central and peripheral nervous systems. Both α_2 and β_2 receptors are located at

postsynaptic sites (see Table 10–6), such as on many types of neurons in the brain. In peripheral tissues, postsynaptic α_2 receptors are found in vascular and other smooth muscle cells (where they mediate contraction), adipocytes, and various secretory epithelial cells (intestinal, renal, endocrine). Postsynaptic β_2 receptors can be found in the myocardium (where they mediate contraction) as well as on vascular and other smooth muscle cells (where they mediate relaxation) and skeletal muscle (where they can mediate hypertrophy). Indeed, most normal human cell types express β_2 receptors. Both α_2 and β_2 receptors may be situated at sites that are relatively remote from nerve terminals that release NE. Such extrajunctional receptors typically are found on vascular smooth muscle cells and blood elements (platelets and leukocytes) and may be activated preferentially by circulating catecholamines, particularly EPI.

In contrast, α_1 and β_1 receptors appear to be located mainly in the immediate vicinity of sympathetic adrenergic nerve terminals in peripheral target organs, strategically placed to be activated during stimulation of these nerves. These receptors also are distributed widely in the mammalian brain (see Table 10–6).

The cellular distributions of the three α_1 and three α_2 receptor subtypes still are incompletely understood. Studies using *in situ* hybridization with receptor mRNA and receptor subtype-specific antibodies have allowed subtype identification in some tissues and organs. For example, α_2 receptors in the brain may be both pre- and postsynaptic, and this receptor subtype may function as a presynaptic autoreceptor in central noradrenergic neurons. A similar approach led to the discovery that α_{1A} mRNA is the dominant subtype in prostatic smooth muscle, leading to the development of α blockers as an effective therapeutic approach for treating prostate dysfunction (Akinaga et al., 2019; Gyires et al., 2009).

Pharmacological Considerations

Each step involved in neurotransmission is a potential point of pharmacological intervention. The diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (see Figures 10–6 and 10–8) show these points of intervention. Drugs that affect processes involved in the steps of transmission at both cholinergic and adrenergic junctions are summarized in Table 10–7, which lists representative agents that act through the mechanisms below.

Interference With the Synthesis or Release of the Transmitter

Cholinergic

Hemicholinium, a synthetic compound, blocks the transport system by which choline accumulates in the terminals of cholinergic fibers, thus limiting the synthesis of ACh. *Vesamicol* blocks the transport of ACh into its storage vesicles, thereby preventing repletion of ACh stores following transmitter release and thus reducing ACh available for subsequent release. The site on the presynaptic nerve terminal for block of ACh release by botulinum toxin was discussed previously; death usually results from respiratory paralysis unless patients with respiratory failure receive artificial ventilation. Injected locally, botulinum toxin type A is used in the treatment of certain ophthalmic conditions associated with spasms of ocular muscles (e.g., strabismus and blepharospasm) (see Chapter 74) and for a wide variety of unlabeled uses, ranging from treatment of muscle dystonias and palsy (see Chapter 13) to cosmetic erasure of facial lines and wrinkles (a modern medical testament to the vanity of human wishes; see Chapter 75).

Adrenergic

α-Methyltyrosine (*metyrosine*) blocks the synthesis of NE by inhibiting TH, the enzyme that catalyzes the rate-limiting step in catecholamine synthesis. This drug occasionally may be useful in treating selected patients with pheochromocytoma. On the other hand, *methyldopa*, an inhibitor of aromatic *L*-amino acid decarboxylase, is—like dopa itself—successively decarboxylated and hydroxylated in its side chain to form the putative false neurotransmitter" α-methylnorepinephrine. The use of *methyldopa* in the treatment of hypertension is discussed in Chapter 32. *Bretylium*, *guanadrel*, and *guanethidine* act by preventing the release of NE by the nerve impulse. However, such agents can transiently stimulate the release of NE because of their capacity to displace the amine from storage sites.

Promotion of Release of the Transmitter

Cholinergic

The capacity of pharmacological agents to promote the release of ACh is limited. The latrotoxins from black widow spider venom and stonefish are known to promote neuroexocytosis by binding to receptors on the neuronal membrane.

Adrenergic

Several drugs that promote the release of NE already have been discussed. Based on the rate and duration of the drug-induced release of NE from adrenergic terminals, one of two opposing effects can predominate. *Tyramine*, *ephedrine*, *amphetamine*, and related drugs cause a relatively rapid, brief liberation of the transmitter and produce a sympathomimetic effect.

On the other hand, *reserpine*, by irreversibly blocking the uptake of amines by both VMAT2 and VMAT1, produces a slow, prolonged depletion of the adrenergic transmitter from adrenergic storage vesicles, where the transmitters, trapped in the cytosol, are largely metabolized by intraneuronal MAO. The resulting depletion of transmitter produces the equivalent of adrenergic blockade. *Reserpine* also causes the depletion of 5HT, DA, and possibly other, unidentified, amines from central and peripheral sites; many of its effects may be consequences of the depletion of transmitters other than NE. Another VMAT inhibitor, *tetrabenazine*, acts reversibly and more specifically on VMAT2, avoiding some of the effects of inhibition of VMAT1 that are components of *reserpine*'s actions.

As discussed previously, deficiencies of TH in humans cause a neurologic disorder (Carson and Robertson, 2002) that can be treated by supplementation with the DA precursor *levodopa*.

A syndrome caused by congenital DβH deficiency is characterized by the absence of NE and EPI, elevated concentrations of DA, intact baroreceptor reflex afferent fibers and cholinergic innervation, and undetectable concentrations of plasma DβH activity (Carson and Robertson, 2002). Patients with this syndrome have severe orthostatic hypotension, ptosis of the eyelids, and retrograde ejaculations. *Dihydroxyphenylserine* (L-DOPS) improves postural hypotension in this rare disorder. This therapeutic approach takes advantage of the nonspecificity of aromatic *L*-amino acid decarboxylase, which synthesizes NE directly from this drug in the absence of DβH. Despite the restoration of plasma NE in humans with L-DOPS, EPI levels are not restored, leading to speculation that PNMT may require DβH for appropriate functioning (Carson and Robertson, 2002).

Agonist and Antagonist Actions at Receptors

Cholinergic

The nicotinic receptors of autonomic ganglia and skeletal muscle are not identical; they respond differently to certain stimulating and blocking agents, and their pentameric structures contain different combinations of homologous subunits (see Table 10–2). *Dimethylphenylpiperazinium* (DMPP) and *phenyltrimethylammonium* (PTMA) show some selectivity for stimulation of autonomic ganglion cells and muscle motor end plates. *Trimethaphan* and *hexamethonium* are relatively selective competitive and noncompetitive ganglionic blocking agents, respectively. Although *tubocurarine* effectively blocks transmission at both motor end plates and autonomic ganglia, its action at the former site predominates. *Succinylcholine*, a depolarizing agent, produces selective neuromuscular blockade. Transmission at autonomic ganglia and the adrenal medulla is complicated further by the presence of muscarinic receptors in addition to the principal nicotinic receptors (see Chapter 13).

Various toxins in snake venoms exhibit a high degree of specificity toward cholinergic receptors. The α-neurotoxins from the *Elapidae* family interact with the agonist-binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with

only certain neuronal receptors, such as those containing α7 through α9 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, called the *fasciculins,* inhibits AChE. A third group of toxins, termed the *muscarinic toxins* (MT_1 through MT_4), includes partial agonists and antagonists for muscarinic receptors. Venoms from the *Viperidae* family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Muscarinic ACh receptors, which mediate the effects of ACh at autonomic effector cells, now can be divided into five subclasses. *Atropine* blocks all the muscarinic responses to injected ACh and related cholinomimetic drugs whether they are excitatory, as in the intestine, or inhibitory, as in the heart. Several newer compounds show selectivity as muscarinic-blocking agents: *pirenzepine* for M_1, *tripitramine* for M_2, and *darifenacin* for M_3 receptors. These muscarinic antagonists show sufficient selectivity in the clinical setting to minimize the bothersome side effects seen with the nonselective agents at therapeutic doses (see Chapter 11).

Adrenergic

A vast number of synthetic compounds that bear structural resemblance to the naturally occurring catecholamines can interact with α and β adrenergic receptors to produce sympathomimetic effects (see Chapter 14). *Phenylephrine* acts selectively at α_1 receptors, whereas *clonidine* is a selective α_2 adrenergic agonist. *Isoproterenol* exhibits agonist activity at both β_1 and β_2 receptors. Preferential stimulation of cardiac β_1 receptors follows the administration of *dobutamine*. *Terbutaline* exerts relatively selective action on β_2 receptors; it produces effective bronchodilation with minimal effects on the heart. The main features of adrenergic blockade, including the selectivity of various blocking agents for α and β adrenergic receptors, are considered in detail in Chapter 14. Partial dissociation of effects at β_1 and β_2 receptors has been achieved by subtype-selective antagonists, as exemplified by the β_1 receptor antagonists *metoprolol* and *atenolol*, which antagonize the cardiac actions of catecholamines while causing less antagonism at the β_2 receptors of the bronchioles. *Prazosin* and *yohimbine* are representative of α_1 and α_2 receptor antagonists, respectively; *prazosin* has a relatively high affinity at α_{2B} and α_{2C} subtypes compared with α_{2A} receptors. Several important drugs that promote the release of NE (e.g., *tyramine*) or deplete the transmitter (e.g., *reserpine*) resemble, in their effects, activators or blockers of postjunctional receptors.

Interference With the Destruction of the Transmitter

Cholinergic

The anti-cholinesterase agents (see Chapter 12) constitute a chemically diverse group of compounds, the primary action of which is inhibition of AChE, with the consequent accumulation of endogenous ACh. At the NMJ, accumulation of ACh produces depolarization of end plates and flaccid paralysis. At postganglionic muscarinic effector sites, the response is either excessive stimulation resulting in contraction and secretion or an inhibitory response mediated by hyperpolarization. At ganglia, depolarization and enhanced transmission are observed.

Adrenergic

The reuptake of NE by the adrenergic nerve terminals by means of NET is the major mechanism for terminating NE's transmitter action. Interference with this process is the basis of the potentiating effect of *cocaine* on responses to adrenergic impulses and injected catecholamines. The antidepressant actions and some of the adverse effects of *imipramine* and related drugs may be due to a similar action at adrenergic synapses in the CNS (see Chapter 18).

Entacapone and *tolcapone* are nitro catechol-type COMT inhibitors. *Entacapone* is a peripherally acting COMT inhibitor, whereas *tolcapone* also inhibits COMT activity in the brain. COMT inhibition can attenuate *levodopa* toxicity on dopaminergic neurons and enhance DA's action in the brain of patients with Parkinson's disease (see Chapter 21). On the other hand, nonselective MAO inhibitors, such as *tranylcypromine*, potentiate the effects of *tyramine* and may potentiate effects of neurotransmitters. While most MAO inhibitors used as antidepressants inhibit both MAO-A and MAO-B, selective MAO-A and MAO-B inhibitors are available. *Selegiline* is a selective and irreversible MAO-B inhibitor that also has been used as an adjunct in the treatment of Parkinson's disease.

Other Autonomic Neurotransmitters

ATP and ACh coexist in cholinergic vesicles (Dowdall et al., 1974), and ATP, NPY, and catecholamines are found within storage granules in nerves and the adrenal medulla (see previous discussion). ATP is released along with the transmitters, and it and its metabolites can play significant roles in synaptic transmission in some circumstances (see further discussion). Recently, attention has focused on the growing list of peptides that are found in the adrenal medulla, nerve fibers, or ganglia of the autonomic nervous system or in the structures that are innervated by the autonomic nervous system. This list includes enkephalins, substance P and other tachykinins, SST, gonadotropin-releasing hormone, cholecystokinin, CGRP, galanin, pituitary adenylyl cyclase–activating peptide, VIP, chromogranins, and NPY (Hökfelt et al., 2000). Some of the orphan GPCRs discovered in the course of genome-sequencing projects may represent receptors for undiscovered peptides or other cotransmitters.

Cotransmission in the Autonomic Nervous System

There is a large body of literature on cotransmission in the autonomic nervous system. Much of the research in this area has focused on co-release of ATP by adrenergic and cholinergic nerves. Co-release of NPY, VIP, CGRP, substance P, and NO has also been studied. Whether these co-released factors act as neurotransmitters, neuromodulators, or trophic factors remains a topic of debate (Burnstock, 2013; Burnstock et al., 2015; Mutafova-Yambolieva and Durnin, 2014).

The evidence is substantial that ATP plays a role in sympathetic nerves as a cotransmitter with NE (Westfall et al., 2002). For example, the rodent vas deferens is supplied with dense sympathetic innervation, and stimulation of the nerves results in a biphasic mechanical response that consists of an initial rapid twitch followed by a sustained contraction. The first phase of the response is mediated by ATP acting on postjunctional P2X receptors, whereas the second phase is mediated mainly by NE acting on α_1 receptors (Sneddon and Westfall, 1984). The cotransmitters apparently are released from the same types of nerves because pretreatment with 6-hydroxydopamine, an agent that specifically destroys adrenergic nerves, abolishes both phases of the neurogenically induced biphasic contraction. Whether ATP and NE originate from the same populations of vesicles within a nerve ending is still open to debate and experimentation (Burnstock et al., 2015; Mutafova-Yambolieva and Durnin, 2014).

Once ATP is released into the neuroeffector junction, some of it is metabolized by extracellularly directed membrane-bound nucleotidases to ADP, AMP, and adenosine (Gordon, 1986). However, the majority of its metabolism occurs by the actions of releasable nucleotidases. There is also evidence that ATP and its metabolites exert presynaptic modulatory effects on transmitter release via P2 receptors and receptors for adenosine. In addition to evidence showing that ATP is a cotransmitter with NE, there is evidence that ATP may be a cotransmitter with ACh in certain postganglionic parasympathetic nerves, such as those in the urinary bladder.

The NPY family of peptides is distributed widely in the central and peripheral nervous systems and consists of three members: NPY, pancreatic polypeptide, and peptide YY. NPY is colocalized and co-released with NE and ATP in most sympathetic nerves in the peripheral nervous system, especially those innervating blood vessels (Westfall, 2004). There is also convincing evidence that NPY exerts prejunctional modulatory effects on transmitter release and synthesis. Moreover, there are numerous examples of postjunctional interactions that are consistent with a cotransmitter role for NPY at various sympathetic neuroeffector junctions. Thus, NPY, together with NE and ATP, qualifies as the third

sympathetic cotransmitter of the sympathetic branch of the autonomic nervous system. Functions of NPY include:

- Direct postjunctional contractile effects
- Potentiation of the contractile effects of the other sympathetic cotransmitters
- Inhibitory modulation of the nerve stimulation–induced release of all three sympathetic cotransmitters, including actions on autoreceptors to inhibit its own release

Studies with selective NPY-Y_1 antagonists provided evidence that the principal postjunctional receptor is of the Y_1 subtype, although other receptors are also present at some sites and may exert physiological actions. Studies with selective NPY-Y_2 antagonists suggested that the principal prejunctional receptor is of the Y_2 subtype both in the periphery and in the CNS. There is evidence for a role for other NPY receptors, and clarification awaits the further development of selective antagonists. NPY also can act prejunctionally to inhibit the release of ACh, CGRP, and substance P. In the CNS, NPY exists as a cotransmitter with catecholamine in some neurons and with peptides and mediators in others. A prominent action of NPY is the presynaptic inhibition of the release of various neurotransmitters, including NE, DA, GABA, glutamate, and 5HT, as well as inhibition or stimulation of the release of neurohormones such as gonadotropin-releasing hormone, vasopressin, and oxytocin. Evidence also exists for stimulation of NE and DA release by NPY.

The NPY may use several mechanisms to produce its presynaptic effects, including inhibition of Ca^{2+} channels, activation of K^+ channels, and regulation of the vesicle release complex at some point distal to Ca^{2+} entry. NPY also may play a role in several pathophysiological conditions. The further development of selective NPY agonists and antagonists should enhance understanding about the physiological and pathophysiological roles of NPY.

The pioneering studies of Hökfelt and coworkers, which demonstrated the existence of VIP and ACh in peripheral autonomic neurons, initiated interest in the possibility of peptidergic cotransmission in the autonomic nervous system. Subsequent work has confirmed the frequent association of these two substances in autonomic fibers, including parasympathetic fibers that innervate smooth muscle and exocrine glands and cholinergic sympathetic neurons that innervate sweat glands (Hökfelt et al., 2000).

The role of VIP in parasympathetic transmission has been studied most extensively in the regulation of salivary secretion. The evidence for cotransmission includes the release of VIP following stimulation of the chorda lingual nerve and the incomplete blockade by *atropine* of vasodilation when the frequency of stimulation is raised; the last observation may indicate independent release of the two substances, which is consistent with histochemical evidence for storage of ACh and VIP in separate populations of vesicles. Synergism between ACh and VIP in stimulating vasodilation and secretion also has been described. VIP may be involved in parasympathetic responses in the trachea and in the GI tract, where it may facilitate sphincter relaxation.

Nonadrenergic, Noncholinergic Transmission by Purines

The smooth muscle of many tissues that are innervated by the autonomic nervous system shows inhibitory junction potentials following stimulation by field electrodes. Because such responses frequently are undiminished in the presence of adrenergic and muscarinic cholinergic antagonists, these observations have been taken as evidence for the existence of nonadrenergic, noncholinergic transmission in the autonomic nervous system.

Burnstock and colleagues have compiled compelling evidence for the existence of purinergic neurotransmission in the GI tract, genitourinary tract, and certain blood vessels; ATP fulfills all the criteria for a neurotransmitter. In at least some circumstances, primary sensory axons may be an important source of ATP (Burnstock et al., 2015). Although adenosine is generated from the released ATP by ectoenzymes and releasable nucleotidases, its primary function appears to be modulatory by causing feedback inhibition of transmitter release.

Adenosine can be transported from the cell cytoplasm to activate extracellular receptors on adjacent cells. The efficient uptake of adenosine by cellular transporters and its rapid metabolism to inosine or to adenine nucleotides contribute to its rapid turnover. Several inhibitors of adenosine transport and metabolism can influence concentrations of extracellular adenosine and ATP.

The purinergic receptors found on the cell surface may be divided into the adenosine (P1) receptors and the receptors for ATP (P2X and P2Y receptors). Both P1 and P2 receptors have various subtypes. There are four adenosine receptors (A_1, A_{2A}, A_{2B}, and A_3) and multiple subtypes of P2X and P2Y receptors throughout the body. The adenosine receptors and the P2Y receptors mediate their responses via G proteins, whereas the P2X receptors are a subfamily of ligand-gated ion channels (see Table 16–7) (Burnstock et al., 2015). Methylxanthines such as caffeine and *theophylline* preferentially block P1 adenosine receptors (see Chapter 44).

Signal Integration and Modulation of Vascular Responses by Endothelium-Derived Factors: NO and Endothelin

The contents of adrenergic storage vesicles are not alone in regulating vascular tone. Many other factors modulate vascular contractility, including kinins, angiotensin, natriuretic peptides, substance P, VIP, CGRP, and eicosanoids, all described elsewhere in this volume. There are additional factors generated by the vascular endothelium that influence vascular reactivity: NO and endothelin.

Furchgott and colleagues demonstrated that an intact endothelium is necessary to achieve vascular relaxation in response to ACh (Furchgott, 1999). This inner cellular layer of the blood vessel now is known to modulate autonomic and hormonal effects on the contractility of blood vessels. In response to a variety of vasoactive agents and physical stimuli, endothelial cells release a short-lived vasodilator termed endothelium-derived relaxing factor, now identified as NO. Less commonly, an endothelium-derived hyperpolarizing factor and endothelium-derived contracting factor are released (Vanhoutte, 1996). Formation of endothelium-derived contracting factor depends on cyclooxygenase activity.

Products of inflammation and platelet aggregation (e.g., 5HT, histamine, bradykinin, purines, and thrombin) exert all or part of their action by stimulating the production of NO. Endothelium-dependent mechanisms of relaxation are important in a variety of vascular beds, including the coronary circulation. Activation of specific GPCRs linking to G_q and the mobilization of Ca^{2+} within endothelial cells promotes NO production. NO diffuses readily to the underlying smooth muscle and induces relaxation of vascular smooth muscle by activating the soluble form of guanylyl cyclase, which increases cyclic GMP concentrations (see Figures 3–21 and 3–26). Nitrovasodilating drugs used to lower blood pressure or to treat ischemic heart disease probably act through conversion to or release of NO (see Chapter 31). Certain nerves (termed *nitrergic*) innervating blood vessels and smooth muscles of the GI tract also release NO. NO has a negative inotropic action on the heart.

Alterations in the release or action of NO may affect a number of major clinical situations, such as atherosclerosis (Ignarro et al., 1999; Münzel et al., 2003). Furthermore, there is evidence suggesting that the hypotension of endotoxemia or that induced by cytokines is mediated by induction of NOS2 (the inducible form of NOS) and the enhanced production NO; consequently, increased NO production may have pathological significance in septic shock.

Full contractile responses of cerebral arteries also require an intact endothelium. A family of peptides, termed *endothelins,* is stored in vascular endothelial cells. Endothelin contributes to the maintenance of vascular homeostasis by acting via multiple endothelin receptors that are GPCRs. The release of endothelin-1 (21 amino acids) onto smooth muscle promotes contraction by stimulation of the ET_A receptor. Endothelin antagonists are now employed in treating pulmonary artery hypertension (see Chapter 35).

Chapter 11

Muscarinic Receptor Agonists and Antagonists

Joan Heller Brown, Katharina Brandl, and Jürgen Wess

Acetylcholine and Its Muscarinic Receptor Target

Muscarinic acetylcholine (ACh) receptors in the peripheral nervous system are found primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves. The actions of ACh and related drugs at autonomic effector sites are referred to as *muscarinic*, based on the observation that the alkaloid muscarine acts selectively at those sites and produces the same qualitative effects as ACh. The muscarinic, or parasympathomimetic, actions of the drugs considered in this chapter are practically equivalent to the parasympathetic effects of ACh listed in Table 10–1.

Muscarinic receptors are also present in autonomic ganglia and on some cells (e.g., vascular endothelial cells) that, paradoxically, receive little or no cholinergic innervation. Muscarinic receptors in autonomic ganglia and the adrenal medulla primarily function to modulate the nicotinic actions of ACh at these sites (Chapter 13). In the CNS, muscarinic receptors are widely distributed and have a role in mediating many important responses. Within the CNS, the hippocampus, cortex, and striatum have particularly high densities of muscarinic receptors.

ACh, the naturally occurring neurotransmitter for these receptors, has virtually no systemic therapeutic applications because its actions are diffuse, and its hydrolysis, catalyzed by both acetylcholinesterase (AChE) and plasma butyrylcholinesterase, is rapid. In addition, its penetration to the CNS is limited, and the amount of ACh that reaches peripheral areas with low blood flow is negligible due to its hydrolysis.

Muscarinic agonists mimic the muscarinic receptor–mediated effects of ACh. These agonists typically are longer-acting congeners of ACh or natural alkaloids, some of which stimulate nicotinic as well as muscarinic receptors. The differences between the actions of ACh and other muscarinic agonists at muscarinic receptors are largely quantitative, with limited selectivity for one organ system over another. All of the muscarinic actions of ACh and its congeners can be competitively inhibited by *atropine*.

Properties and Subtypes of Muscarinic Receptors

Muscarinic receptors were characterized initially by analysis of the responses of cells and organ systems in the periphery and the CNS. Differential effects of two muscarinic agonists, *bethanechol* and McN-A-343, on the tone of the lower esophageal sphincter led to the initial designation of muscarinic receptors as M_1 (ganglionic) and M_2 (effector cell) (Goyal and Rattan, 1978). This concept was supplanted by information obtained through molecular cloning of muscarinic receptors, which identified five distinct gene products (Bonner et al., 1987), now designated as M_1 through M_5 muscarinic receptors (Chapter 8). All of the known muscarinic receptors are coupled to heterotrimeric G proteins, which in turn couple to various cellular effectors (Chapter 3). Although selectivity is not absolute, stimulation of M_1, M_3, and M_5 receptors causes activation of G_q and phospholipase C (PLC), hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2), and mobilization of intracellular Ca^{2+} as well as activation of protein kinase C (Figure 11–1), resulting in a variety of cellular responses. In contrast, M_2 and M_4 muscarinic receptors inhibit adenylyl cyclase and regulate specific ion channels via their coupling to the pertussis toxin–sensitive G proteins, G_i and G_o. Recent cryo-electron microscopy studies have revealed the structural basis underlying the G protein-coupling preferences of the individual muscarinic receptor subtypes (Maeda et al., 2019).

Over the past decade, high-resolution X-ray structures have been reported for all five muscarinic receptors (Haga et al., 2012; Kruse et al., 2012, 2013; Thal et al., 2016; Vuckovic et al., 2019), revealing that the structures of the five receptors are very similar (Figure 11–2, A–C). The classical (*orthosteric*) binding site for muscarinic agonists and antagonists is highly conserved among all receptor subtypes (Kruse et al., 2014; Maeda et al., 2019; Thal et al., 2016) (Figure 11–2A). The orthosteric binding site consists of a cleft deeply buried within the membrane, formed by conserved amino acid chains located on several of the receptor's seven transmembrane (TM) helices (TM1–TM7). A key feature shared by other receptors for biogenic amine ligands is the presence of a charge-charge interaction between the tertiary or quaternary nitrogen of the orthosteric ligands and a conserved TM3 aspartic acid side chain. A feature unique to muscarinic receptors is hydrogen bond interactions between the orthosteric ligand and a TM6 asparagine residue. Agonist binding to the receptor leads to considerable contraction of the ligand-binding pocket, reflecting the relatively small size of muscarinic agonists, as compared to muscarinic antagonists. Because the residues that line the orthosteric binding site are highly conserved among all muscarinic receptors (Figure 11–2A), developing orthosteric muscarinic ligands endowed with a high degree of receptor subtype selectivity has proven challenging.

The five muscarinic receptor subtypes are widely distributed in both the CNS and peripheral tissues; most cells express at least two subtypes (Abrams et al., 2006; Lebois et al., 2018; Wess et al., 2007). Identifying the role of a specific subtype in mediating a particular muscarinic response to ACh has been difficult due to the lack of subtype-specific agonists and antagonists. Recent studies with M_1–M_5 receptor knockout mice

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
AV: atrioventricular
eNOS: endothelial NO synthase
GI: gastrointestinal
GIRK channel: G protein-coupled inwardly-rectifying K^+ channel
GRP: gastrin-releasing peptide
HCN: hyperpolarization-activated, cyclic nucleotide–gated channels
5HT: serotonin
I_{Ca-L}: L-type Ca^{2+} current
I_f: cardiac pacemaker current
I_{K-ACh}: ACh-activated K^+ current
IP_3: inositol 1,4,5-trisphosphate
NAM: negative allosteric modulator
NO: nitric oxide
PAM: positive allosteric modulator
PIP_2: phosphatidylinositol 4,5-bisphosphate
PLC: phospholipase C
SA: sinoatrial
TM: transmembrane

(Kruse et al., 2014; Wess et al., 2007) have, however, yielded novel information about the physiological roles of the individual muscarinic receptor subtypes (see Table 10–3) and demonstrated that multiple receptor subtypes are typically involved in mediating specific muscarinic responses. For example, abolishing cholinergic bronchoconstriction, salivation, pupillary constriction, and bladder contraction generally requires deletion of more than one receptor subtype.

Various lines of evidence suggest that muscarinic receptors possess one or more topographically distinct allosteric binding sites formed by amino acid side chains located within the extracellular loops or the outer segments of different TM helices (Birdsall and Lazareno, 2005; May et al., 2007). These regions show a considerable degree of sequence variation among the M_1–M_5 receptors; thus, considerable effort has been directed at developing so-called allosteric modulators that show high selectivity for distinct muscarinic receptor subtypes (Bock et al., 2018; Conn et al., 2014; Gentry et al., 2015; Moran et al., 2019). These agents exert their pharmacological actions by altering the affinity or efficacy of the orthosteric muscarinic ligand (ACh). Positive allosteric modulators (PAMs) enhance orthosteric activity, while negative allosteric modulators (NAMs) inhibit it. Allosteric agents that can directly activate muscarinic receptors are termed *allosteric agonists*. However, these designations are not absolute; they depend on the nature of the orthosteric ligand, receptor subtype under investigation, and assay system used. The recent progress in identifying subtype-selective muscarinic allosteric agents may lead to the development of new therapeutic agents with increased efficacy and reduced side effects. Currently, much research focuses on the potential

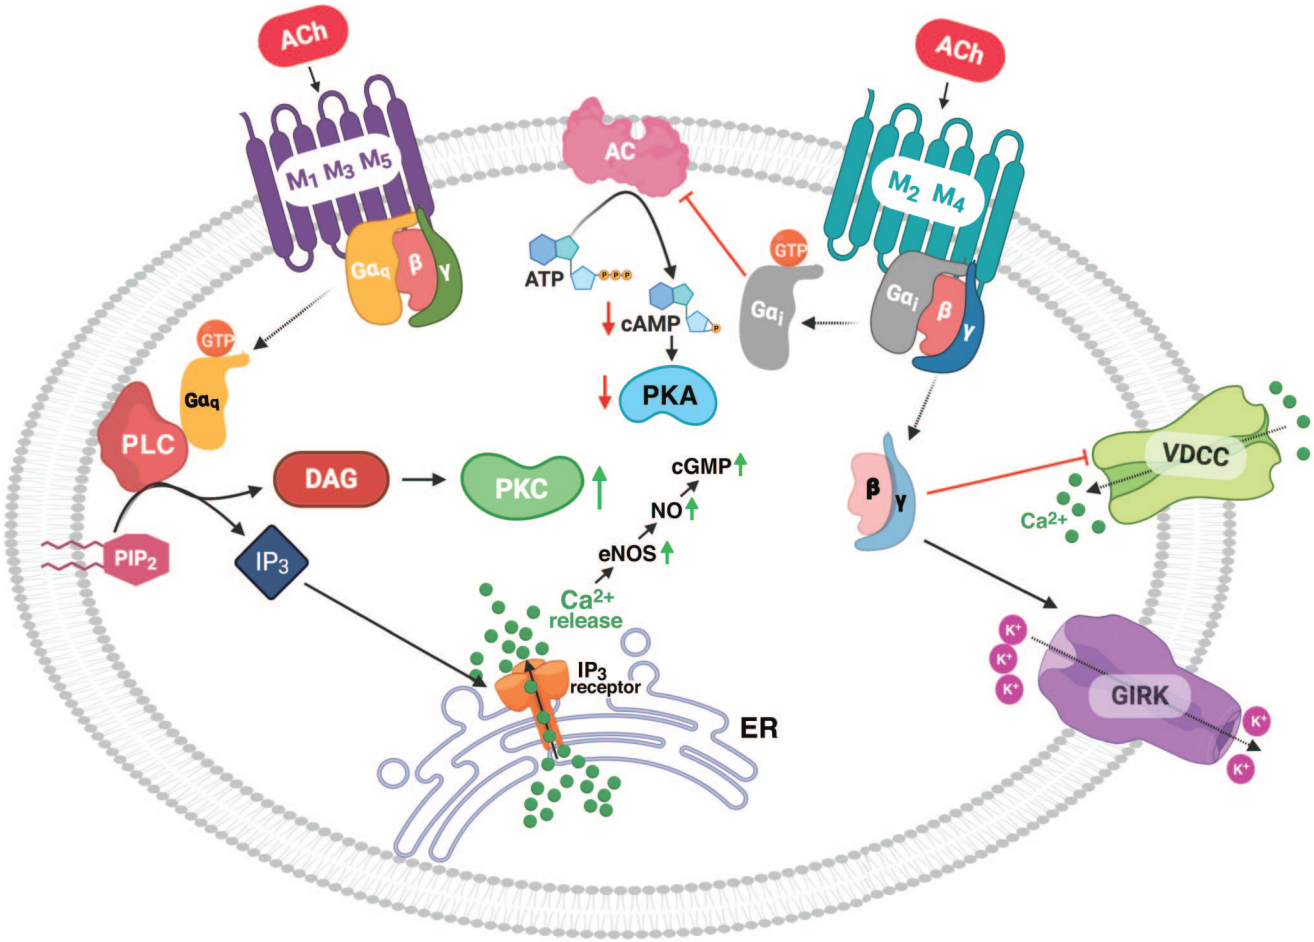

Figure 11–1 *G protein-coupling properties of the M_1–M_5 muscarinic receptors.* Note that the odd-numbered receptors (M_1, M_3, and M_5) selectively couple to G proteins of the G_q family, while the even-numbered receptors (M_2 and M_4) preferentially activate G_i-type G proteins. Some of the major downstream signaling pathways are shown. AC, adenylyl cyclase; DAG, diacylglycerol; IP_3, inositol 1,4,5-trisphosphate; PKA, protein kinase A (cyclic AMP-dependent protein kinase); GIRK channel; G protein-coupled inwardly rectifying K^+ channel; PLC, phospholipase C; PIP_2, phosphatidylinositol 4,5-bisphosphate; VDCC, voltage-dependent Ca^{2+} channel.

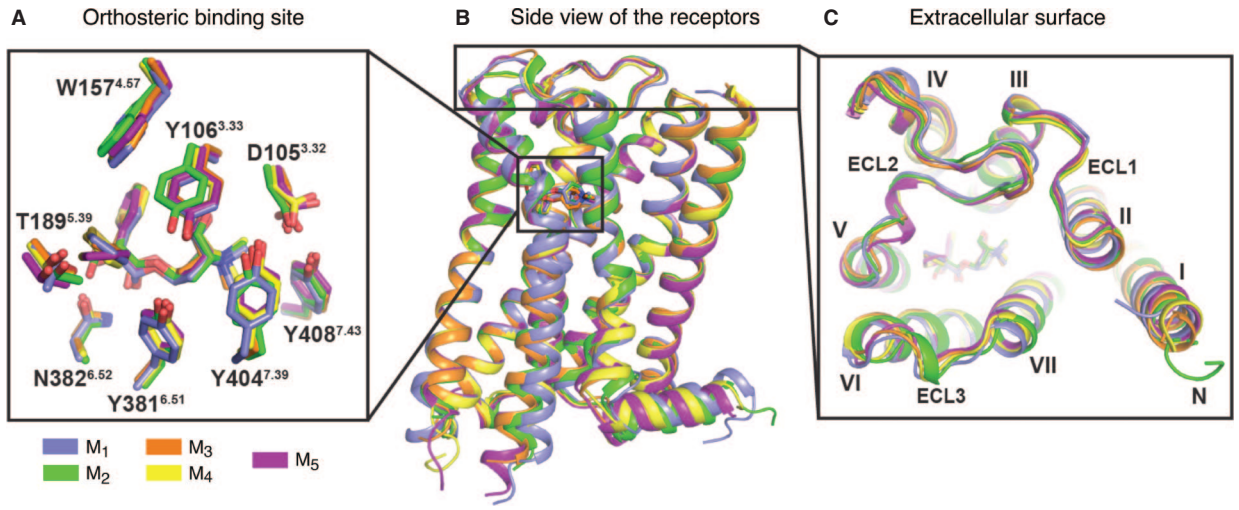

Figure 11–2 *Comparison of the crystal structures of the M1-M5 muscarinic receptors bound to the antagonists tiotropium or N-methylscopolamine (Thal et al., 2016).* **A.** The key amino acids that form the orthosteric binding site. Residues are numbered according to the M1 receptor sequence and the Ballesteros-Weinstein numbering system (superscripts). **B.** Superimposition of all five receptor structures. The orthosteric binding site is located near the middle of the receptors' transmembrane core. **C.** A view of the extracellular surface of the superimposed structures (I -VII, transmembrane helices; N, N-terminal region; ECL, extracellular loop). Note that the positions ECL2 and ECL3 differ slightly from each other among the different receptor subtypes. Additional references: Ballesteros and Weinstein, 1995; Isberg et al., 2015.

of such agents for the treatment of several severe disorders of the CNS, including Alzheimer's disease and schizophrenia (Moran et al., 2019).

An X-ray structure revealed the molecular details of the complex of a positive allosteric modulator (PAM) and the muscarinic receptor; the binding pocket for muscarinic PAMs is located just above the orthosteric binding crevice (Kruse et al., 2013). This structure also illustrates that the bound PAM interferes with the dissociation of the bound orthosteric agonist from the receptor, explaining why the PAM enhances the actions of the orthosteric ligand. Another potential strategy for achieving receptor subtype selectivity is the development of hybrid, bitopic orthosteric/allosteric ligands that interact with both the orthosteric binding cavity and an allosteric site (Bock et al., 2018; Lane et al., 2013). By targeting orthosteric and allosteric sites simultaneously, bitopic ligands achieve both high affinity and receptor subtype selectivity.

Pharmacological Effects of Acetylcholine

The influence of ACh and parasympathetic innervation on various organs and tissues was introduced in Chapter 10. The more detailed description of the effects of ACh presented below provides background for understanding the physiological basis for the therapeutic uses of the muscarinic receptor agonists and antagonists (also see Table 11–1).

Cardiovascular System

ACh has four primary effects on the cardiovascular system:

- Vasodilation
- Decrease in heart rate (negative chronotropic effect)
- Decrease in the conduction velocity in the atrioventricular (AV) node (negative dromotropic effect)
- Decrease in the force of cardiac contraction (negative inotropic effect)

The negative inotropic effect is of lesser significance in the ventricles than in the atria. In addition, some of these effects can be obscured by baroreceptor and other reflexes that dampen the direct responses to ACh.

Cardiac actions of ACh are important because the effects of cardiac glycosides, antiarrhythmic agents, and many other drugs are at least partly due to changes in parasympathetic (vagal) stimulation of the heart; in addition, afferent stimulation of the viscera during surgical interventions can reflexly increase the vagal stimulation of the heart.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation mediated by vascular endothelial nitric oxide (NO). This is usually accompanied by reflex tachycardia. The generalized vasodilation produced by exogenously administered ACh is due to the stimulation of muscarinic receptors, primarily of the M_3 subtype, located on vascular endothelial cells. Occupation of these receptors activates the G_q-PLC-IP_3 pathway, leading to Ca^{2+}-calmodulin–dependent activation of endothelial eNOS (NOS3) and production of NO (endothelium-derived relaxing factor) that diffuses to adjacent vascular smooth muscle cells where it stimulates soluble guanylyl cyclase, thereby promoting relaxation via a cyclic GMP–dependent mechanism (see Figure 3–11; Farah et al., 2018; Harvey, 2012). Baroreceptor or chemoreceptor reflexes or direct stimulation of the vagus can also elicit parasympathetic coronary vasodilation mediated by ACh and the consequent production of NO by the endothelium (Feigl, 1998). If the endothelium is damaged, however, as occurs under various pathophysiological conditions, ACh acts predominantly on M_3 receptors located on the underlying vascular smooth muscle cells, causing vasoconstriction. This capacity to both relax and constrict vessels is shared by many hormones that act via the G_q-PLC-IP_3-Ca^{2+} pathway and for which receptors are present on both endothelial cells and vascular smooth muscle cells. If the agonist can reach both cell types, each cell type will respond in its distinct way to an elevation of intracellular Ca^{2+}—endothelium with a stimulation of NO synthase and smooth muscle with contraction. NO generation in the heart has a multitude of additional effects, and its presence in cholinergic vagal nerves may contribute to vagal dominance (Farah et al., 2018).

ACh has direct effects on cardiac function at doses higher than those required for NO-mediated vasodilation. The cardiac effects of ACh are mediated primarily by M_2 muscarinic receptors (Fisher et al., 2004). Direct effects of ACh include an increase in the ACh-activated K^+ current ($I_{K\text{-}ACh}$) due to activation of K-ACh channels (heterotetrameric proteins consisting of GIRK1 and GIRK4 subunits), a decrease in the L-type Ca^{2+} current ($I_{Ca\text{-}L}$) and L-type Ca^{2+} channel activity due to diminished cyclic AMP generation, and a decrease in the cardiac pacemaker current (I_f) caused by reduced activity of hyperpolarization-activated, cyclic nucleotide–gated (HCN; pacemaker) channels (DiFrancesco and Tromba, 1987; Harvey, 2012). The actions of ACh on M_2 receptors lead to a G_i-mediated decrease in cyclic AMP, which opposes and counteracts the β_1 adrenergic/G_s–mediated increase in cyclic AMP. ACh released from parasympathetic postganglionic nerve terminals also acts on presynaptic M_2 and M_3 receptors on adjacent sympathetic nerve terminals to inhibit the release of norepinephrine (Trendelenburg et al., 2005).

TABLE 11–1 ■ MUSCARINIC RECEPTOR–MEDIATED EFFECTS ON PERIPHERAL EFFECTOR TISSUES

ORGAN	EFFECTOR TISSUE	PREDOMINANT RECEPTOR SUBTYPE	INTRACELLULAR SIGNALING	RESPONSE TO RECEPTOR STIMULATION
GI tract	Gastrointestinal SM SM (internal) sphincters	M_3	$\uparrow IP_3 \rightarrow \uparrow [Ca^{2+}]_i \rightarrow$ SM contraction	Contraction → ↑GI motility Relaxation
Urinary tract	Bladder SM SM (internal) sphincter	M_3		↑Bladder tone, urination
Lungs	Bronchiolar SM	M_3		Bronchoconstriction
Eye	Iris SM: Pupillary sphincter Ciliary muscle	M_3		Pupillary constriction (miosis) Accommodation for near vision
Secretory glands	Salivary glands	M_3	$\uparrow IP_3 \rightarrow \uparrow [Ca^{2+}]_i \rightarrow \uparrow$secretion	Salivation
	Bronchial glands			Bronchial secretion
	Lacrimal glands			Lacrimation
	Sweat glands			Sweating
Heart	Sinoatrial (SA) node Atrioventricular node	M_2 M_2	↓cAMP → ↓activity of HCN channels → ↓SA node automaticity ↓cAMP → ↓activity of PKA → ↓phosphorylation of L-type Ca^{2+} channels → ↓iCa $G_{\beta\gamma}$ → ↑activity of K-ACh channels → ↑iK-ACh → hyperpolarization	↓Heart rate (negative chronotropic effect) ↓Conduction velocity (negative dromotropic effect)
Blood vessels	Vascular endothelial cells	M_3	$IP_3 \rightarrow \uparrow [Ca^{2+}]_i \rightarrow NO \rightarrow \uparrow$ cGMP	Vasodilation

GI, gastrointestinal; SM, smooth muscle.

In addition, there are presynaptic M_2 receptors that inhibit ACh release from parasympathetic postganglionic nerve terminals in the human heart (Oberhauser et al., 2001).

In the sinoatrial (SA) node, each normal cardiac impulse is initiated by the spontaneous depolarization of the pacemaker cells (Chapter 34). At a critical level (the threshold potential), this depolarization initiates an action potential. ACh slows the heart rate primarily by decreasing the rate of spontaneous depolarization; attainment of the threshold potential and the succeeding events in the cardiac cycle are therefore delayed. Until recently, it was widely accepted that β_1 adrenergic and muscarinic cholinergic effects on heart rate resulted from regulation of the cardiac pacemaker current mentioned earlier (I_f). Unexpected findings made through genetic deletion of HCN4 and pharmacological inhibition of I_f have generated an alternative theory involving a pace-making function for an intracellular Ca^{2+} "clock" (Lakatta and DiFrancesco, 2009) that might mediate effects of ACh on heart rate (Lyashkov et al., 2009).

In the atria, ACh causes hyperpolarization and decreased action potential duration by increasing $I_{K\text{-}ACh}$. ACh also inhibits cyclic AMP formation and norepinephrine release, as described above, decreasing atrial contractility. In the AV node, ACh slows conduction and increases the refractory period by inhibiting $I_{Ca\text{-}L}$; the decrement in AV conduction is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically. When parasympathetic (vagal) tone to the resting heart is increased (e.g., by *digoxin*), the prolonged refractory period of the AV node can reduce the frequency with which aberrant atrial impulses are transmitted to the ventricles and thereby decrease the ventricular rate during atrial flutter or fibrillation.

The ventricular myocardium and His-Purkinje system receive only sparse cholinergic (parasympathetic vagal) innervation (Levy and Schwartz, 1994), and the effects of ACh are smaller than those observed in the atria and nodal tissues. The modest negative inotropic effect of ACh in the ventricle is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone (Brodde and Michel, 1999; Levy and Schwartz, 1994; Lewis et al., 2001). Automaticity of Purkinje fibers is suppressed, and the threshold for ventricular fibrillation is increased.

Respiratory Tract

The parasympathetic nervous system plays a major role in regulating bronchomotor tone. A diverse set of stimuli can cause reflexes that increase parasympathetic activity mediating bronchoconstriction. The effects of ACh on the respiratory system include bronchoconstriction, increased tracheobronchial secretion, and stimulation of the chemoreceptors of the carotid and aortic bodies. These effects are mediated primarily by M_3 muscarinic receptors located on bronchial and tracheal smooth muscle (Buels and Fryer, 2012; Fisher et al., 2004) and are most obvious in the case of toxicity from cholinesterase inhibition.

Urinary Tract

Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureteral peristalsis. These responses are difficult to observe with administered ACh because poor perfusion of visceral organs and rapid hydrolysis by plasma butyrylcholinesterase limit access of systemically administered ACh to visceral muscarinic receptors. Muscarinic stimulation of bladder contraction is mediated primarily by M_3 receptors expressed by detrusor smooth muscle cells. Smooth muscle M_2 receptors also seem to make a small contribution to this response by reversing β receptor–cyclic AMP–mediated relaxation of the detrusor muscle and via other indirect effects (Hegde, 2006; Matsui et al., 2002).

GI Tract

Although stimulation of vagal input to the gastrointestinal (GI) tract increases tone, amplitude of contractions, and secretory activity of the stomach and intestine, such responses are inconsistently seen with

administered ACh for the same reasons that urinary tract responses are difficult to observe. As in the urinary tract, M_3 receptors appear to be primarily responsible for mediating cholinergic control of GI motility, but M_2 receptors also contribute (Matsui et al., 2002).

Secretory Effects

In addition to its stimulatory effects on the tracheobronchial and GI secretions, ACh stimulates secretion from other glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, nasopharyngeal, salivary, and sweat glands. All of these effects are mediated primarily by M_3 muscarinic receptors (Caulfield and Birdsall, 1998); M_1 receptors also contribute to the cholinergic stimulation of salivary secretion (Gautam et al., 2004).

Eye

When instilled into the eye, ACh produces miosis by contracting the pupillary sphincter muscle and accommodation for near vision by contracting the ciliary muscle; both of these effects are mediated primarily by M_3 muscarinic receptors, but other subtypes may contribute to the ocular effects of cholinergic stimulation (Mitchelson, 2012).

CNS Effects

All five muscarinic receptor subtypes are expressed in the brain (Lebois et al., 2018), and recent studies suggest that muscarinic receptor–regulated pathways may have an important role in cognitive function, motor control, appetite regulation, nociception, and other processes (Thomsen et al., 2018; Wess et al., 2007). While systemically administered ACh has limited CNS penetration, muscarinic agonists that can cross the blood-brain barrier evoke a characteristic cortical arousal or activation response similar to that produced by injection of cholinesterase inhibitors or by electrical stimulation of the brainstem reticular formation.

Muscarinic Receptor Agonists

Muscarinic cholinergic receptor agonists can be divided into two groups:

- Choline esters, including ACh and several synthetic esters
- The naturally occurring cholinomimetic alkaloids (particularly *pilocarpine, muscarine*, and *arecoline*) and their synthetic congeners

Of several hundred synthetic choline derivatives investigated, only *methacholine*, *carbachol*, and *bethanechol* (Figure 11–3) are in clinical use.

Methacholine (acetyl-β-methylcholine), the β-methyl analogue of ACh, is a synthetic choline ester that differs from ACh chiefly in its greater duration and selectivity of action. Its action is more prolonged because the added methyl group increases its resistance to hydrolysis by cholinesterases. Its selectivity is reflected in a predominance of muscarinic actions manifest most clearly in the cardiovascular system; *methacholine*'s nicotinic actions are minor (Table 11–2).

Carbachol, and its β-methyl analogue, *bethanechol*, are unsubstituted carbamoyl esters that are almost completely resistant to hydrolysis by cholinesterases; their $t_{1/2}$ values are thus sufficiently long that they become distributed to areas of low blood flow. *Carbachol* retains substantial nicotinic activity, particularly on autonomic ganglia. *Bethanechol* has mainly muscarinic actions, with prominent effects on motility of the GI tract and urinary bladder.

The major natural alkaloid muscarinic agonists—*muscarine, pilocarpine*, and *arecoline*—have the same principal sites of action as the choline esters. *Muscarine* acts almost exclusively at muscarinic receptors. *Pilocarpine* has a dominant muscarinic action but is a partial rather than full agonist; the sweat glands are particularly sensitive to *pilocarpine*. *Arecoline* acts on both muscarinic and nicotinic receptors. Although these naturally occurring alkaloids are important pharmacological tools and *muscarine* has toxicological significance (discussed further in the chapter), present clinical use is restricted largely to the employment of *pilocarpine* as a sialagogue and miotic agent (Chapter 74).

HISTORY AND BOTANICAL ORIGINS

The alkaloid *muscarine* was isolated from the mushroom *Amanita muscaria* by Schmiedeberg in 1869. *Pilocarpine* is the chief alkaloid obtained from the leaflets of South American shrubs of the genus *Pilocarpus*. Although the natives had long known that the chewing of leaves of *Pilocarpus* plants caused salivation, the active compound, *pilocarpine*, was isolated only in 1875 and shown to affect the pupil and sweat and salivary glands. *Arecoline* is the main alkaloid of areca or betel nuts, which are consumed as a euphoretic masticatory mixture by the natives of the Indian subcontinent and East Indies. Hunt and Taveau synthesized and studied *methacholine* as early as 1911. *Carbachol* and *bethanechol* were synthesized and investigated in the 1930s.

ADME

The absorption and distribution of these compounds can be predicted from their structures. *Muscarine* and the choline esters are quaternary amines; *pilocarpine* and *arecoline* are tertiary amines (see examples in Figure 11–3). The choline esters, as quaternary amines, are poorly absorbed following oral administration and have limited ability to cross the blood-brain barrier. Even though these drugs resist hydrolysis, the choline esters are short-acting agents due to rapid renal elimination. *Pilocarpine* and *arecoline*, as tertiary amines, are readily absorbed and can cross the blood-brain barrier. While *muscarine* is a quaternary amine and is poorly absorbed, it can still be toxic when ingested and can even have CNS effects. The natural alkaloids are primarily eliminated by the kidneys; excretion of the tertiary amines can be accelerated by acidification of the urine to trap the cationic form in the urine.

Therapeutic Uses of Muscarinic Receptor Agonists

Muscarinic agonists are currently used in the treatment of urinary bladder disorders and xerostomia (dry mouth) and in the diagnosis of bronchial hyperreactivity through a bronchoprovocation test. They are also

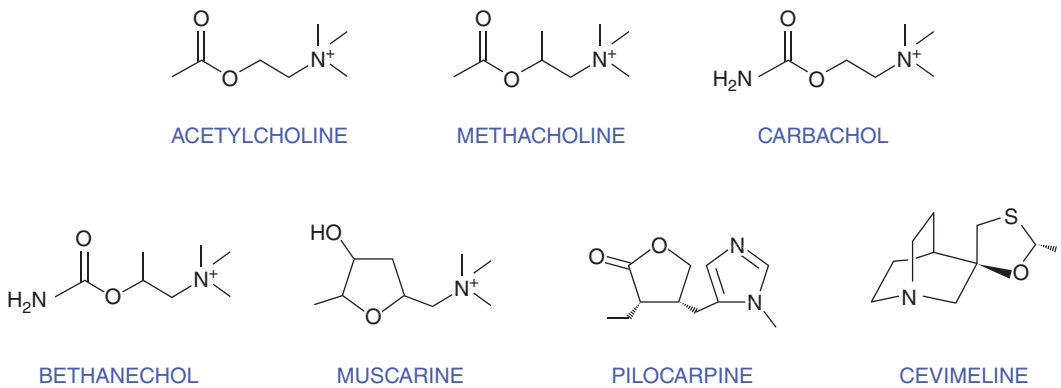

Figure 11–3 *Structural formulas of ACh, choline esters, and natural alkaloids that stimulate muscarinic receptors.*

TABLE 11–2 ■ PHARMACOLOGICAL PROPERTIES OF CHOLINE ESTERS AND NATURAL ALKALOIDS

	HYDROLYSIS BY AChE	NICOTINIC ACTIVITY
Acetylcholine	+++	++
Methacholine	+	+
Carbachol	–	+++
Bethanechol	–	–
Muscarine	–	–
Pilocarpine	–	–

used in ophthalmology as miotic agents and for the treatment of glaucoma. There is growing interest in the use of M_1 agonists in treating the cognitive impairments associated with Alzheimer's disease. Other receptor subtypes, including M_2 and M_5, also appear to be involved in the regulation of cognitive function, at least in animal models (Wess et al., 2007).

Acetylcholine

Although rarely given systemically, ACh is used topically for the induction of miosis during ophthalmologic surgery, instilled into the eye as a 1% solution (Chapter 74).

Methacholine

Methacholine is administered by inhalation for the diagnosis of bronchial airway hyperreactivity in patients who do not have clinically apparent asthma (Crapo et al., 2000). It is available as a powder that is diluted with 0.9% NaCl and administered via a nebulizer. While muscarinic agonists can cause bronchoconstriction and increased tracheobronchial secretions in all individuals, asthmatic patients respond with intense bronchoconstriction and a reduction in vital capacity. The response to *methacholine* may be exaggerated or prolonged in patients taking β adrenergic receptor antagonists. Contraindications to *methacholine* testing include severe airflow limitation, recent myocardial infarction or stroke, uncontrolled hypertension, or pregnancy. Emergency resuscitation equipment, oxygen, and medications to treat severe bronchospasm (e.g., β_2 adrenergic receptor agonists for inhalation) should be available during testing.

Bethanechol

Bethanechol primarily affects the urinary and GI tracts. In the urinary tract, *bethanechol* has utility in treating urinary retention and inadequate emptying of the bladder when organic obstruction is absent, as in postoperative urinary retention, diabetic autonomic neuropathy, and certain cases of chronic hypotonic, myogenic, or neurogenic bladder; catheterization can thus be avoided. When used chronically, 10 to 50 mg of the drug are given orally three or four times daily; the drug should be administered on an empty stomach (i.e., 1 h before or 2 h after a meal) to minimize nausea and vomiting.

In the GI tract, *bethanechol* stimulates peristalsis, increases motility, and increases resting lower esophageal sphincter pressure. *Bethanechol* formerly was used to treat postoperative abdominal distention, gastric atony, gastroparesis, adynamic ileus, and gastroesophageal reflux; more efficacious therapies for these disorders are now available (Chapters 53 and 54).

Carbachol

Carbachol is used topically in ophthalmology for the treatment of glaucoma and the induction of miosis during surgery; it is instilled into the eye as a 0.01% to 3% solution (Chapter 74).

Pilocarpine

Pilocarpine hydrochloride is used for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren syndrome (Porter et al., 2004; Ramos-Casals et al., 2010), an autoimmune disorder occurring primarily in women in whom secretions, particularly salivary and lacrimal, are compromised. Treatment can enhance salivary secretion, ease of swallowing, and subjective improvement in hydration of the oral cavity, provided salivary parenchyma maintains residual function. Side effects typify cholinergic stimulation, with sweating the most common complaint. The usual dose is 5 to 10 mg three times daily; the dose should be lowered in patients with hepatic impairment.

Pilocarpine is used topically in ophthalmology for the treatment of glaucoma and as a miotic agent; it is instilled in the eye as a 1% to 4% solution (Chapter 74).

Cevimeline

Cevimeline is a muscarinic agonist that has a long-lasting sialogogic action on lacrimal and salivary glands and may have fewer side effects and better patient compliance than *pilocarpine* (Noaiseh et al., 2014). *Cevimeline* preferentially activates M_1 and M_3 receptors (Heinrich et al., 2009). The usual dose is 30 mg three times daily.

Contraindications, Precautions, and Adverse Effects

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor stimulation. Thus, important contraindications to the use of muscarinic agonists include asthma, chronic obstructive pulmonary disease, urinary or GI tract obstruction, acid-peptic disease, cardiovascular disease accompanied by bradycardia, hypotension, and hyperthyroidism (muscarinic agonists may precipitate atrial fibrillation in hyperthyroid patients). Common adverse effects include excessive sweating; diarrhea, abdominal cramps, nausea/vomiting, and other GI side effects; a sensation of tightness in the urinary bladder; visual disturbances; and hypotension, which can severely reduce coronary blood flow, especially if it is already compromised. These contraindications and adverse effects are generally of limited concern with topical administration for ophthalmic use.

Toxicology

Poisoning from the ingestion of plants containing *pilocarpine, muscarine*, or *arecoline* is characterized chiefly by exaggeration of their various parasympathomimetic effects. Treatment consists of the parenteral administration of *atropine* in doses sufficient to cross the blood-brain barrier (see Table 11–3) and measures to support the respiratory and cardiovascular systems and to counteract pulmonary edema.

TABLE 11–3 ■ EFFECTS OF ATROPINE IN RELATION TO DOSE

DOSE (mg)	EFFECTS
0.5	Slight cardiac slowing; some dryness of mouth; inhibition of sweating
1	Definite dryness of mouth; thirst; acceleration of heart, sometimes preceded by slowing; mild dilation of pupils
2	Rapid heart rate; palpitation; marked dryness of mouth; dilated pupils; some blurring of near vision
5	Previous symptoms marked; difficulty in speaking and swallowing; restlessness and fatigue; headache; dry, hot skin; difficulty in micturition; reduced intestinal peristalsis
≥10	Previous symptoms more marked; pulse rapid and weak; iris practically obliterated; vision very blurred; skin flushed, hot, dry, and scarlet; ataxia, restlessness, and excitement; hallucinations and delirium; coma

The clinical picture of a high (toxic) dose of atropine may be remembered by an old mnemonic device that summarizes the symptoms: *Red as a beet, Dry as a bone, Blind as a bat, Hot as firestone, and Mad as a hatter.*

Muscarinic Receptor Antagonists

The muscarinic receptor antagonists include:

- The naturally occurring alkaloids *atropine* and *scopolamine*
- Semisynthetic derivatives of these alkaloids, which primarily differ from the parent compounds in their disposition in the body or their duration of action
- Synthetic derivatives, some of which show a limited degree of selectivity for certain muscarinic receptor subtypes

Noteworthy agents in the last two categories are *homatropine* and *tropicamide*, which have shorter durations of action than *atropine*, and *methscopolamine, ipratropium, tiotropium, aclidinium*, and *umeclidinium*, which are quaternary amines that do not cross the blood-brain barrier or readily cross membranes. The synthetic derivatives possessing some degree of receptor subtype selectivity include *pirenzepine*, an M_1 receptor–preferring antagonist, and *darifenacin* and *solifenacin*, two M_3 receptor–preferring agents.

Muscarinic antagonists prevent the effects of ACh by blocking its binding to muscarinic receptors on effector cells at parasympathetic (and sympathetic cholinergic) neuroeffector junctions in peripheral ganglia and the CNS. In general, muscarinic antagonists cause little blockade of nicotinic receptors. However, the quaternary ammonium antagonists generally exhibit a greater degree of nicotinic-blocking activity and therefore are more likely to interfere with ganglionic or neuromuscular transmission.

While many effects of muscarinic antagonists can be predicted from an understanding of the physiological responses mediated by muscarinic receptors at parasympathetic and sympathetic cholinergic neuroeffector junctions, paradoxical responses can occur. For example, presynaptic muscarinic receptors of variable subtype are present on postganglionic parasympathetic nerve terminals. Because blockade of presynaptic receptors generally augments neurotransmitter release, the presynaptic effects of muscarinic antagonists may counteract their postsynaptic receptor blockade. Blockade of the modulatory muscarinic receptors in peripheral ganglia represents an additional mechanism for paradoxical responses.

BELLADONNA

The naturally occurring muscarinic receptor antagonists *atropine* and *scopolamine* are alkaloids of the belladonna (*Solanaceae*) plants. Preparations of belladonna were known to the ancient Hindus and have long been used by physicians. During the time of the Roman Empire and in the Middle Ages, the deadly nightshade shrub was frequently used to produce an obscure and often-prolonged poisoning, prompting Linnaeus to name the shrub *Atropa belladonna*, after Atropos, the oldest of the three Fates, who cuts the thread of life. The name *belladonna* derives from the alleged use of this preparation by Italian women to dilate their pupils; modern-day fashion models are known to use this same device for visual appeal. *Atropine* (D,L-hyoscyamine) also is found in *Datura stramonium* (Jamestown or jimson weed). *Scopolamine* (L-hyoscine) is found chiefly in *Hyoscyamus niger* (henbane). In India, the root and leaves of jimson weed were burned and the smoke inhaled to treat asthma. British colonists observed this ritual and introduced the belladonna alkaloids into Western medicine in the early 1800s. *Atropine* was isolated in pure form in 1831. In literature, belladonna sometimes plays the MacGuffin.

An important consideration in the therapeutic use of muscarinic antagonists is the fact that physiological functions in different organs vary in their sensitivity to muscarinic receptor blockade (Table 11–3). Small doses of *atropine* depress salivary and bronchial secretion and sweating. With larger doses, the pupil dilates, accommodation of the lens to near vision is inhibited, and vagal effects on the heart are blocked so that the heart rate increases. Larger doses antagonize parasympathetic control of the urinary bladder and GI tract, thereby inhibiting urination and decreasing intestinal tone and motility. Still higher doses are required to inhibit gastric motility and particularly secretion. Thus, doses of *atropine* and most related muscarinic antagonists that depress gastric secretion also almost invariably affect salivary secretion, ocular accommodation, urination, and GI motility. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of *atropine* for the muscarinic receptors at these sites because *atropine* lacks selectivity toward different muscarinic receptor subtypes. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone, the extent of receptor reserve, the involvement of intramural neurons and reflexes, and the presence of other regulatory mechanisms.

Most clinically available muscarinic antagonists lack receptor subtype selectivity, and their actions differ little from those of *atropine*, the prototype of the group. Notably, the clinical efficacy of some agents may actually depend on antagonistic actions at two or more receptor subtypes.

Structure-Activity Relationships

An intact ester of tropine and tropic acid (Figure 11–4) is essential for antimuscarinic action because neither the free acid nor the basic alcohol exhibits significant antimuscarinic activity. The presence of a free OH group in the acyl portion of the ester also is important for activity. Quaternary ammonium derivatives of *atropine* and *scopolamine* are generally more potent than their parent compounds in both muscarinic- and ganglionic- (nicotinic-) blocking activities when given parenterally. These derivatives are poorly and unreliably absorbed when given orally.

Mechanism of Action

Atropine and related compounds compete with ACh and other muscarinic agonists for the orthosteric ACh binding site on the muscarinic receptor. The antagonism by *atropine* is competitive; thus, it is surmountable by ACh if the concentration of ACh at muscarinic receptors is increased sufficiently. Muscarinic receptor antagonists inhibit responses to postganglionic cholinergic nerve stimulation less effectively than they inhibit responses to injected choline esters. The difference may be explained by the fact that release of ACh by cholinergic nerve terminals occurs in close proximity to the receptors, resulting in very high concentrations of the transmitter at the receptors.

Pharmacological Effects of Muscarinic Antagonists

The pharmacological effects of *atropine*, the prototypical muscarinic antagonist, provide a good background for understanding the therapeutic uses of the various muscarinic antagonists. The effects of other muscarinic antagonists will be mentioned only when they differ significantly from those of *atropine*. The major pharmacological effects of increasing doses of *atropine*, summarized in Table 11–3, offer a general guide to the problems associated with administration of this class of agents.

Cardiovascular System

Heart. The main effect of *atropine* on the heart is to alter the rate. Although the dominant response is tachycardia, there is often a transient bradycardia with average clinical doses (0.4–0.6 mg; Table 11–3). The slowing is modest (4–8 beats/min), occurs with no accompanying changes in blood pressure or cardiac output, and is usually absent after rapid intravenous injection. This unexpected effect has been attributed to the block of presynaptic M_1 muscarinic receptors on parasympathetic postganglionic nerve terminals in the SA node, which normally inhibit ACh release (Wellstein and Pitschner, 1988).

Larger doses of *atropine* cause progressive tachycardia by blocking M_2 receptors on the SA nodal pacemaker cells, thereby antagonizing parasympathetic (vagal) tone to the heart. The resting heart rate is increased by about 35 to 40 beats/min in young men given 2 mg of *atropine* intramuscularly. The maximal heart rate (e.g., in response to exercise) is not altered by *atropine*. The influence of *atropine* is most noticeable in healthy

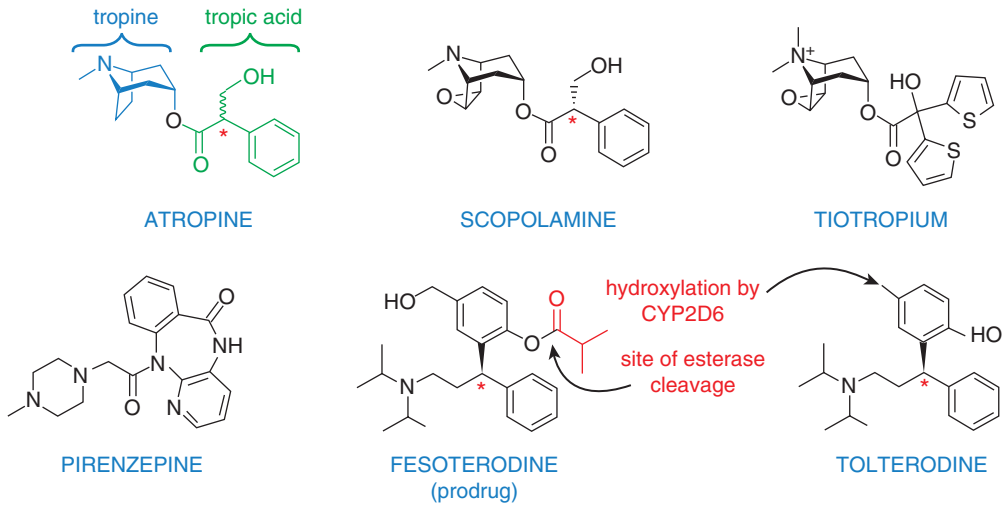

Figure 11–4 *Structural formulas of the belladonna alkaloids and semisynthetic and synthetic analogues.* *Fesoterodine* is converted to an active 5-hydroxymeythyl metabolite by esterase activity. CYP2D6 converts *tolterodine* to the same metabolite. Note that *atropine, scopolamine, tolterodine*, and *fesoterodine* each contain an asymmetric carbon atom (indicated by red asterisk); these compounds therefore exist as racemic mixtures. Clinically, only the (R)-enantiomers of *tolterodine* and *fesoterodine* are used.

young adults, in whom vagal tone is considerable. In infants, the elderly, and patients with heart failure, even large doses of *atropine* may fail to accelerate the heart.

Atropine can abolish many types of reflex vagal cardiac slowing or asystole, such as that occurring from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. *Atropine* also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, AChE inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus.

The removal of vagal tone to the heart by *atropine* may facilitate AV conduction. *Atropine* shortens the functional refractory period of the AV node and can increase the ventricular rate in patients who have atrial fibrillation or flutter. In certain cases of second-degree AV block (e.g., Wenckebach AV block) in which vagal activity is an etiological factor (as with *digoxin* toxicity), *atropine* may lessen the degree of block. In some patients with complete AV block, the idioventricular rate may be accelerated by *atropine*; in others, it is stabilized. *Atropine* may improve the clinical condition of patients with inferior or posterior wall myocardial infarction by relieving severe sinus or nodal bradycardia or AV block.

Circulation. *Atropine* alone has little effect on blood pressure because most vessels lack significant cholinergic innervation. However, in clinical doses, *atropine* completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. In toxic and occasionally in therapeutic doses, *atropine* can indirectly dilate cutaneous blood vessels, especially those in the blush area (*atropine* flush). This may be a compensatory reaction permitting the radiation of heat to offset the *atropine*-induced rise in temperature that can accompany inhibition of sweating.

Respiratory System

Although *atropine* can cause some bronchodilation and decrease in tracheobronchial secretion in normal individuals by blocking parasympathetic (vagal) tone to the lungs, its effects on the respiratory system are most significant in patients with respiratory disease. *Atropine* can inhibit the bronchoconstriction caused by histamine, bradykinin, and the eicosanoids, which presumably reflects the participation of reflex parasympathetic (vagal) activity in the bronchoconstriction elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators forms the basis for the use of muscarinic receptor antagonists, along with β adrenergic receptor agonists, in the treatment of asthma. Muscarinic antagonists also have an important role in the treatment of chronic obstructive pulmonary disease (Chapter 40).

Atropine inhibits the secretions of the nose, mouth, pharynx, and bronchi and thus dries the mucous membranes of the respiratory tract. This action is especially marked if secretion is excessive and formed the basis for the use of *atropine* and other muscarinic antagonists to prevent irritating inhalational anesthetics such as diethyl ether from increasing bronchial secretion; newer inhalational anesthetics are less irritating. Muscarinic antagonists are used to decrease the rhinorrhea ("runny nose") associated with the common cold or with allergic and nonallergic rhinitis. Reduction of mucous secretion and mucociliary clearance can, however, result in mucus plugs, a potentially undesirable side effect of muscarinic antagonists in patients with airway disease.

The quaternary ammonium compounds *ipratropium*, *tiotropium*, *aclidinium*, and *umeclidinium* are used exclusively for their effects on the respiratory tract. Dry mouth is the only frequently reported side effect, as the absorption of these drugs from the lungs or the GI tract is inefficient. In addition, *aclidinium* has been shown to undergo rapid hydrolysis in plasma to inactive metabolites, thus reducing systemic exposure to the drug (Gavalda et al., 2009). The degree of bronchodilation achieved by these agents is thought to reflect the level of basal parasympathetic tone, supplemented by reflex activation of cholinergic pathways brought about by various stimuli. A therapeutically important property of *ipratropium* and *tiotropium* is their minimal inhibitory effect on mucociliary clearance relative to *atropine*. Hence, the choice of these agents for use in patients with airway disease minimizes the increased accumulation of lower airway secretions encountered with *atropine*.

Eye

Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (Chapter 74). Thus, these agents dilate the pupil (mydriasis) and paralyze accommodation (cycloplegia). The wide pupillary dilation results in photophobia; the lens is fixed for far vision, near objects are blurred, and objects may appear smaller than they are. The normal pupillary reflex constriction to light or on convergence of the eyes is abolished. These effects are most evident when the agent is instilled into the eye but can also occur after systemic administration.

Conventional systemic doses of *atropine* have little ocular effect, in contrast to equal doses of *scopolamine*, which cause evident mydriasis and loss of accommodation. Locally applied *atropine* produces ocular effects of considerable duration; accommodation and pupillary reflexes may not fully recover for 7 to 12 days. Other muscarinic receptor antagonists with shorter durations of action are therefore preferred as mydriatics in ophthalmologic practice. *Pilocarpine* and choline esters (e.g., *carbachol*) in sufficient concentrations can reverse the ocular effects of *atropine*.

Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to angle-closure glaucoma, in whom the pressure may occasionally rise dangerously. The rise in pressure occurs when the anterior chamber is narrow and the iris obstructs outflow of aqueous humor into the trabeculae. Muscarinic antagonists may precipitate a first attack in unrecognized cases of this relatively rare condition. In patients with open-angle glaucoma, an acute rise in pressure is unusual. *Atropine*-like drugs generally can be used safely in the latter condition, particularly if the glaucoma is being treated appropriately.

GI Tract

Knowledge of the actions of muscarinic receptor agonists on the stomach and intestine led to the use of muscarinic receptor antagonists as antispasmodic agents for GI disorders and to reduce gastric acid secretion in the treatment of peptic ulcer disease.

Motility. Parasympathetic nerves enhance GI tone and motility and relax sphincters, thereby favoring the passage of gastrointestinal contents. In normal subjects and in patients with GI disease, muscarinic antagonists produce prolonged inhibitory effects on the motor activity of the stomach, duodenum, jejunum, ileum, and colon, characterized by a reduction in tone and in amplitude and frequency of peristaltic contractions. Relatively large doses are needed to produce such inhibition, probably because the enteric nervous system can regulate motility independently of parasympathetic control; parasympathetic nerves serve only to modulate the effects of the enteric nervous system. Although *atropine* can completely abolish the effects of exogenous muscarinic agonists on GI motility and secretion, *atropine* does not completely inhibit the GI responses to vagal stimulation. This difference, particularly striking in the effects of *atropine* on gut motility, can be attributed to the fact that preganglionic vagal fibers innervating the GI tract synapse not only with postganglionic cholinergic fibers but also with a network of noncholinergic intramural neurons that form the plexuses of the enteric nervous system and utilize neurotransmitters (e.g., serotonin (5HT), dopamine, and various peptides) whose effects *atropine* does not block.

Gastric Acid Secretion. Similarly, *atropine* only partially inhibits the gastric acid secretory responses to vagal activity because vagal stimulation of gastrin secretion is mediated not by ACh but by peptidergic neurons in the vagal trunk that release gastrin-releasing peptide (GRP). GRP stimulates gastrin release from G cells; gastrin can act directly to promote acid secretion by parietal cells and to stimulate histamine release from enterochromaffin-like (ECL) cells (see Figure 53–1). Parietal cells (acid secretors) respond to at least three agonists: gastrin, histamine, and ACh. *Atropine* will inhibit only the components of acid secretion that result from muscarinic stimulation of parietal cells and from muscarinic stimulation of ECL cells that secrete histamine.

Secretions. Salivary secretion is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery secretion induced by parasympathetic stimulation. The mouth becomes dry, and swallowing and talking may become difficult. The gastric cells that secrete mucin and proteolytic enzymes are more directly under vagal influence than are the acid-secreting cells, and *atropine* selectively decreases their secretory function. Although *atropine* can reduce gastric secretion, the doses required also affect salivary secretion, ocular accommodation, urination, and GI motility (Table 11–3).

In contrast to most muscarinic receptor antagonists, *pirenzepine*, which shows some degree of selectivity for M_1 receptors, inhibits gastric acid secretion at doses that have little effect on salivation or heart rate. Because parietal cells primarily express M_3 receptors, M_1 receptors in intramural ganglia may be the primary target of *pirenzepine* (Eglen et al., 1996). However, this concept has been brought into question by the observation that *pirenzepine* is still able to inhibit *carbachol*-stimulated gastric acid secretion in M_1 receptor–deficient mice (Aihara et al., 2005). In general, histamine H_2 receptor antagonists and proton pump inhibitors have replaced muscarinic antagonists as inhibitors of acid secretion (Chapter 53).

Other Smooth Muscle

Urinary Tract. Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder and often eliminate drug-induced enhancement of ureteral tone. However, this effect is usually accompanied by reduced salivation and lacrimation and blurred vision (Table 11–3).

Biliary Tract. *Atropine* exerts mild antispasmodic action on the gallbladder and bile ducts in humans. However, this effect usually is not sufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids.

Sweat Glands and Temperature

Small doses of *atropine* inhibit the activity of sweat glands innervated by sympathetic cholinergic fibers, and the skin becomes hot and dry. Sweating may be depressed enough to raise the body temperature, but only notably so after large doses or at high environmental temperatures.

CNS

Atropine has minimal effects on the CNS at therapeutic doses, although mild stimulation of the parasympathetic medullary centers may occur. With toxic doses of *atropine*, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium (see the discussion of *atropine* poisoning further in the chapter). With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma.

In contrast to *atropine*, *scopolamine* has prominent central effects at low therapeutic doses; *atropine* therefore is preferred over *scopolamine* for most purposes. The basis for this difference is probably the greater permeation of *scopolamine* across the blood-brain barrier. *Scopolamine* in therapeutic doses normally causes CNS depression, manifest as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in REM (rapid eye movement) sleep. It also causes euphoria and can therefore be subject to abuse. The depressant and amnesic effects formerly were sought when *scopolamine* was used as an adjunct to anesthetic agents or for preanesthetic medication. However, in the presence of severe pain, the same doses of *scopolamine* can occasionally cause excitement, restlessness, hallucinations, or delirium. These excitatory effects resemble those of toxic doses of *atropine*. *Scopolamine* also is effective in preventing motion sickness, probably by blocking neural pathways from the vestibular apparatus in the inner ear to the emetic center in the brainstem.

ADME

The belladonna alkaloids and the *tertiary* synthetic and semisynthetic derivatives are absorbed rapidly from the GI tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents (e.g., *scopolamine*, allowing delivery by transdermal patch). Systemic absorption of inhaled or orally ingested *quaternary* muscarinic receptor antagonists is limited. The quaternary ammonium derivatives of the belladonna alkaloids also penetrate the conjunctiva of the eye less readily, and central effects are lacking because the quaternary agents do not cross the blood-brain barrier. *Atropine* has a $t_{1/2}$ of about 4 h; hepatic metabolism accounts for the elimination of about half of the dose, and the remainder is excreted unchanged in the urine.

Ipratropium is administered as an aerosol or solution for inhalation, whereas *tiotropium* is administered as a dry powder. As with most drugs administered by inhalation, about 90% of the dose is swallowed. When inhaled, their action is confined almost completely to the mouth and airways. Most of the swallowed drug appears in the feces. After inhalation, maximal responses usually develop over 30 to 90 min, with *tiotropium* having the slower onset. The effects of *ipratropium* last for 4 to 6 h; *tiotropium's* effects persist for 24 h, and the drug is amenable to once-daily dosing.

Therapeutic Uses of Muscarinic Receptor Antagonists

Muscarinic receptor antagonists have been used predominantly to inhibit effects of parasympathetic activity in the respiratory tract, urinary tract, GI tract, eye, and heart. Their CNS effects have resulted in their use in the treatment of Parkinson's disease, the management of extrapyramidal side effects of antipsychotic drugs, and the prevention of motion sickness. The major limitation in the use of drugs that are not receptor subtype selective is often failure to obtain desired therapeutic responses without concomitant side effects. While these usually are not serious, they can be sufficiently disturbing to decrease patient compliance, particularly during long-term administration. To date, selectivity is mainly achieved by local administration (e.g., by pulmonary inhalation or instillation in the eye). The development of allosteric modulators that recognize sites unique to particular muscarinic receptor subtypes is currently considered an important approach to developing receptor subtype–selective drugs for the treatment of specific clinical conditions (Moran et al., 2019).

Respiratory Tract

Ipratropium, tiotropium, aclidinium, and *umeclidinium* are important agents in the treatment of chronic obstructive pulmonary disease (COPD); they are less effective in most patients with asthma (see Chapter 44). These agents often are used with inhaled long-acting β_2 adrenergic receptor agonists, although there is limited evidence of true synergism.

Ipratropium blocks all muscarinic receptor subtypes and accordingly also antagonizes the inhibition of ACh release by presynaptic M_2 receptors on parasympathetic postganglionic nerve terminals in the lung; the resulting increase in ACh release may counteract the drug's blockade of M_3 receptor–mediated bronchoconstriction. In contrast, *tiotropium* shows some selectivity for M_1 and M_3 receptors. In addition, *tiotropium* and *aclidinium* have lower affinities for M_2 receptors and dissociate more slowly from M_3 than from M_2 receptors, thus minimizing the presynaptic effect on ACh release (Alagha et al., 2014).

Ipratropium is administered four times daily via a metered-dose inhaler or nebulizer; *aclidinium* is used twice daily via a dry powder inhaler. *Tiotropium* and *umeclidinium* are once-daily medications that can be used for maintenance therapy via a dry powder inhaler in patients with moderate-to-severe disease.

In normal individuals, inhalation of antimuscarinic drugs can provide virtually complete protection against the bronchoconstriction produced by the subsequent inhalation of such irritants as SO_2, O_3, or cigarette smoke. However, patients with atopic asthma or demonstrable bronchial hyperresponsiveness are less well protected. Although these drugs cause a marked reduction in sensitivity to *methacholine* in asthmatic subjects, inhibition of responses to challenge with histamine, bradykinin, or prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is more modest, and protection against bronchoconstriction induced by 5HT or leukotrienes is slight. The therapeutic uses of *ipratropium* and *tiotropium* are discussed further in Chapter 40.

Ipratropium also is FDA approved for use in nasal inhalers for the treatment of the rhinorrhea associated with the common cold and with allergic or nonallergic perennial rhinitis. The ability of muscarinic antagonists to reduce nasopharyngeal secretions may provide some symptomatic relief. In contrast to *pseudoephedrine* or *phenylephrine*, muscarinic antagonists do not constrict blood vessels and hence they are less efficacious as nasal decongestants. It is probable that the contribution of first-generation antihistamines employed in nonprescription cold medications is due primarily to their antimuscarinic properties, except in conditions with an allergic basis (see Chapters 38 and 43).

Genitourinary Tract

Overactive urinary bladder can be successfully treated with muscarinic receptor antagonists. These agents can lower intravesicular pressure, increase capacity, and reduce the frequency of contractions by antagonizing parasympathetic control of the bladder; they also may alter bladder sensation during filling (Chapple et al., 2008). Muscarinic antagonists can be used to treat enuresis in children, particularly when a progressive increase in bladder capacity is the objective, and to reduce urinary frequency and increase bladder capacity in spastic paraplegia.

The muscarinic receptor antagonists indicated for overactive bladder are *oxybutynin, tolterodine, trospium chloride, darifenacin, solifenacin*, and *fesoterodine*. Although some comparison trials demonstrate small but statistically significant differences in efficacy between these agents (Chapple et al., 2008), the clinical relevance of these differences remains uncertain.

The most important adverse reactions are consequences of muscarinic receptor blockade and include xerostomia, blurred vision, and GI side effects such as constipation and gastrointestinal discomfort. CNS-related antimuscarinic effects including drowsiness, dizziness, and confusion can occur and are particularly problematic in elderly patients. CNS effects appear to be less likely with *trospium*, a quaternary amine, and with *darifenacin* and *solifenacin*; the latter two agents show some preference for M_3 receptors and therefore seem to have minimal effects on M_1 receptors in the CNS are thought to play an important role in memory and cognition (Kay et al., 2006). Adverse effects can limit the tolerability of these drugs with continued use, and patient acceptance declines. Xerostomia is the most common reason for discontinuation.

Oxybutynin, the oldest muscarinic antagonist currently used to treat overactive bladder disorders, is associated with a high incidence of antimuscarinic side effects, particularly xerostomia. In an attempt to increase patient acceptance, *oxybutynin* is marketed as a transdermal system that is associated with a lower incidence of side effects than the oral immediate- and extended-release formulations; a topical gel formulation of *oxybutynin* also appears to offer a more favorable side effect profile. *Oxybutynin* is metabolized by enteric and hepatic CYP3A4; thus, its serum concentration may be increased by concurrent administration of CYP3A4 inhibitors (e.g., grapefruit juice, *ritonavir*, conazoles, *clarithromycin, ciprofloxacin, erythromycin, aprepitant*; see Chapter 5). Because of the extensive metabolism of oral *oxybutynin* by enteric and hepatic CYP3A4, higher doses are used in oral than transdermal administration; the dose may need to be reduced in patients taking drugs that inhibit CYP3A4.

Tolterodine shows some degree of selectivity for the urinary bladder in animal models and in clinical studies, resulting in greater patient acceptance. *Tolterodine* is metabolized by CYP2D6 to 5-hydroxymethyltolterodine, a metabolite that possesses similar activity as the parent drug but differs pharmacokinetically. As CYP2D6 is a polymorphic enzyme, with significant variability of expression, the serum concentration of *tolterodine* and the 5-hydroxymethyl metabolite can vary. Lower initial doses are recommended for patients with low CYP26D activity. *Fesoterodine* is a prodrug that is rapidly hydrolyzed to the active metabolite of *tolterodine* by esterases (Figure 11–4) rather than CYP2D6, thereby providing a less variable source of the 5-hydroxymethyl metabolite of *tolterodine*.

Trospium, a quaternary amine, is as effective as *oxybutynin* but is better tolerated. It is the only antimuscarinic agent used for overactive bladder that is eliminated primarily by the kidneys; 60% of the absorbed *trospium* dose is excreted unchanged in the urine, and dosage adjustment is necessary for patients with impaired renal function. *Trospium* has the potential for pharmacokinetic interaction with other agents that are eliminated by active tubular excretion (see Chapter 4).

Solifenacin shows some preference for M_3 receptors, giving it a favorable efficacy-to-side-effect ratio (Chapple et al., 2004). *Solifenacin* is significantly metabolized by CYP3A4; thus, patients taking drugs that inhibit CYP3A4 should receive lower doses.

Like *solifenacin*, *darifenacin* shows some degree of selectivity for M_3 receptors (Caulfield and Birdsall, 1998). It is metabolized by CYP2D6 and CYP3A4; *darifenacin* doses may need to be reduced in patients taking drugs that inhibit either of these CYPs.

GI Tract

Muscarinic receptor antagonists were once widely used for the management of peptic ulcer. Although they can reduce gastric motility and the secretion of gastric acid, antisecretory doses produce pronounced side effects, such as xerostomia, loss of visual accommodation, photophobia,

and difficulty in urination (Table 11–3). As a consequence, patient compliance in the long-term management of symptoms of acid-peptic disease with these drugs is poor. H_2 receptor antagonists and proton pump inhibitors are the current drugs of choice to reduce gastric acid secretion (Chapter 53).

Pirenzepine, a tricyclic drug similar in structure to *imipramine*, displays a limited degree of selectivity for M_1 receptors (Caulfield and Birdsall, 1998). *Telenzepine*, an analogue of *pirenzepine*, has higher potency and similar selectivity for M_1 receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the U.S. At therapeutic doses of *pirenzepine*, the incidence of xerostomia, blurred vision, and central muscarinic disturbances is relatively low. Central effects are not seen because of the drug's limited penetration into the CNS. Most studies indicate that *pirenzepine* (100–150 mg/day) produces about the same rate of healing of duodenal and gastric ulcers as the H_2 receptor antagonists *cimetidine* or *ranitidine*; *pirenzepine* also may be effective in preventing the recurrence of ulcers (Tryba and Cook, 1997). Side effects necessitate drug withdrawal in less than 1% of patients.

Myriad conditions known or supposed to involve increased tone (spasticity) or motility of the GI tract are treated with belladonna alkaloids (e.g., *atropine, hyoscyamine sulfate*, and *scopolamine*) alone or in combination with sedatives (e.g., *phenobarbital*) or antianxiety agents (e.g., *chlordiazepoxide*). The belladonna alkaloids and their synthetic substitutes can reduce tone and motility when administered in maximally tolerated doses. M_3 receptor–preferring antagonists would theoretically be better tolerated because cardiac and central side effects are mostly avoided. On the other hand, M_3 receptors regulate salivation, bronchial secretion and contraction, and bladder motility; thus, peripheral side effects due to muscarinic antagonism at these sites are to be expected. *Glycopyrrolate*, a muscarinic antagonist that is structurally unrelated to the belladonna alkaloids, is used to reduce GI tone and motility; as a quaternary amine, it is less likely to cause adverse CNS effects than *atropine*, *scopolamine*, and other tertiary amines. Alternative agents for treatment of increased GI motility and its associated symptoms are discussed in Chapter 54.

Diarrhea associated with irritation of the lower bowel, such as mild dysenteries and diverticulitis, may respond to *atropine*-like drugs, an effect that likely involves actions on ion transport as well as motility. However, more severe conditions such as *Salmonella* dysentery, ulcerative colitis, and Crohn's disease respond little, if at all, to muscarinic antagonists.

Dicyclomine hydrochloride is a weak muscarinic receptor antagonist that also has nonspecific direct spasmolytic effects on smooth muscle of the GI tract. It is occasionally used in the treatment of diarrhea-predominant irritable bowel syndrome.

Salivary Secretions

The belladonna alkaloids and synthetic substitutes are effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and Parkinson's disease. *Glycopyrrolate* is a quaternary amine and, as mentioned earlier, is less likely than others to penetrate the CNS. An oral solution of *glycopyrrolate* is indicated to reduce drooling (e.g., in patients with Parkinson's disease).

Eye

Effects limited to the eye are obtained by topical administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia (paralysis of the ciliary muscle resulting in the inhibition of accommodation). Cycloplegia requires higher concentrations or more prolonged application of antagonist and thus cannot be achieved without concomitant mydriasis. Mydriasis often is necessary for thorough examination of the retina and optic disc and in the therapy of iridocyclitis and keratitis. *Homatropine hydrobromide*, a semisynthetic derivative of *atropine* (Figure 11–4), *cyclopentolate hydrochloride*, and *tropicamide* are agents used in ophthalmological practice. These agents are preferred to topical *atropine* or *scopolamine* because of their shorter duration of action. Chapter 74 presents additional information on the ophthalmological properties and preparations of these and other drugs.

Cardiovascular System

The cardiovascular effects of muscarinic receptor antagonists are of limited clinical utility. Generally, these agents are used only in coronary care units for short-term interventions or in surgical settings. They are also sometimes used as an adjunct to stress testing to increase heart rate in the setting of chronotropic incompetence.

Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus bradycardia or AV nodal block. Sinus bradycardia is the most common arrhythmia seen during acute myocardial infarction of the inferior or posterior wall. *Atropine* may prevent further clinical deterioration in cases of high vagal tone or AV block by restoring heart rate to a level sufficient to maintain adequate hemodynamic status and to eliminate AV nodal block. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia (described earlier), while excessive doses will cause tachycardia that may extend the infarct by increasing the demand for O_2.

Atropine occasionally is useful in reducing the severe bradycardia and syncope associated with a hyperactive carotid sinus reflex. It has little effect on most ventricular rhythms. In some patients, *atropine* may eliminate premature ventricular contractions associated with a very slow atrial rate. It also may reduce the degree of AV block when increased vagal tone is a major factor in the conduction defect, such as the second-degree AV block that can be produced by *digoxin*. Selective M_2 receptor antagonists would be of potential utility in blocking ACh-mediated bradycardia or AV block; however, no such agents are currently available for clinical use.

Autonomic control of the heart is known to be abnormal in patients with cardiovascular disease, especially in heart failure. Patients with heart failure typically exhibit increased sympathetic tone accompanied by vagal withdrawal, both of which may contribute to the progression of disease. While β blockers have now emerged as standard of care in heart failure, less is known about whether augmentation of vagal tone may be beneficial. Studies in animals suggested that augmenting vagal tone chronically decreases the inflammatory response and prevents adverse cardiac remodeling associated with heart failure (DeMazumder et al., 2015; Dunlap et al., 2015; Schwartz and De Ferrari, 2011); clinical trials of such therapy have, however, shown limited success (McMurry and Køber, 2016).

CNS

The belladonna alkaloids were among the first drugs to be used in the prevention of motion sickness. *Scopolamine* is the most effective of these agents for short (4- to 6-h) exposures to severe motion and probably for exposures of up to several days. All agents used to combat motion sickness should be given prophylactically; they are much less effective after severe nausea or vomiting has developed. A transdermal preparation of *scopolamine* has been shown to be highly effective when used prophylactically for the prevention of motion sickness. The drug, incorporated into a multilayer adhesive unit, is applied to the postauricular mastoid region, an area where transdermal drug absorption is especially efficient, resulting in the delivery of about 0.5 mg of *scopolamine* over 72 h. Xerostomia is common, drowsiness is not infrequent, and blurred vision occurs in some individuals using the *scopolamine* patch. Mydriasis and cycloplegia can occur by inadvertent transfer of the drug to the eye from the fingers after handling the patch. Rare but severe psychotic episodes have been reported, as have various symptoms following abrupt withdrawal after prolonged use.

Muscarinic receptor antagonists have long been used in the treatment of Parkinson's disease, which is characterized by reduced dopaminergic input into the striatum, resulting in an imbalance between striatal muscarinic cholinergic and dopaminergic neurotransmission (see Chapter 21). The striatum, the major input area of the basal ganglia, contains multiple cell types, including cholinergic interneurons, all of which express one or more muscarinic receptor subtype (Goldberg et al., 2012). Studies with muscarinic receptor mutant mice suggested that the beneficial effects of muscarinic antagonists in the treatment of Parkinson's disease are primarily due to the blockade of M_1 and M_4 receptors, resulting in the activation or inhibition, respectively, of specific striatal neuronal subpopulations (Wess et al., 2007).

Muscarinic antagonists can be effective in the early stages of Parkinson's disease if tremor is predominant, particularly in young patients. Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (Chapter 19). Certain antipsychotic drugs are relatively potent muscarinic receptor antagonists (Roth et al., 2004) and, perhaps for this reason, cause fewer extrapyramidal side effects.

The muscarinic antagonists used for Parkinson's disease and drug-induced extrapyramidal symptoms include *benztropine mesylate, trihexyphenidyl hydrochloride*, and *biperiden* (not marketed in the U.S.); all are tertiary amines that readily gain access to the CNS.

Anesthesia

Atropine is commonly given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. *Atropine* and *glycopyrrolate* are also used to block the parasympathomimetic effects of *neostigmine* when it is administered to reverse skeletal muscle relaxation after surgery. Serious cardiac arrhythmias have occasionally occurred, perhaps because of the initial bradycardia produced by *atropine* combined with the cholinomimetic effects of *neostigmine*.

Anticholinesterase Poisoning

The use of *atropine* in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 12. *Atropine* also may be used to antagonize the parasympathomimetic effects of *pyridostigmine* or other anticholinesterases administered in the treatment of myasthenia gravis. It does not interfere with the salutary effects at the skeletal neuromuscular junction. It is most useful early in therapy, before tolerance to muscarinic side effects of anticholinesterases has developed.

Other Therapeutic Uses

Methscopolamine bromide is a quaternary ammonium derivative of *scopolamine* and therefore lacks the central actions of *scopolamine*. Although formerly used to treat peptic ulcer disease, at present, it is primarily used in certain combination products for the temporary relief of symptoms of allergic rhinitis, sinusitis, and the common cold.

Homatropine methylbromide, the methyl derivative of *homatropine*, is less potent than *atropine* in antimuscarinic activity but four times more potent as a ganglionic blocking agent. Formerly used for the treatment of irritable bowel syndrome and peptic ulcer disease, at present, it is sometimes used with *hydrocodone* as an antitussive combination administered as an oral syrup. This combination must be used with caution and only in adults (>18 years), with full knowledge by patient and physician of the risks associated with opioid use (respiratory depression; necessity to avoid other CNS depressants including ethanol and benzodiazepines; adverse interactions with agents altering CYP3A4 activity), and with refills only after reevaluation of the need for treatment.

Sofpironium and its structural analogue *glycopyrrolate* are both topically used for the treatment of primary axillary hyperhidrosis (excessive sweating). Both drugs reduce sweating locally by inhibiting M_3 receptors at eccrine sweat glands. *Sofpironium* is approved in Japan as a gel; *glycopyrrolate* is available in the U.S. for topical application using a single-use, premoistened, medicated cloth. *Glycopyrrolate* is also used in treating obstructive airway disease (see Chapter 44).

Contraindications and Adverse Effects

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor blockade: dry mouth, constipation, blurred vision, gastrointestinal discomfort, and cognitive impairment. Important contraindications to the use of muscarinic antagonists include urinary tract obstruction, GI obstruction, and uncontrolled (or susceptibility to attacks of) angle-closure glaucoma. Muscarinic receptor antagonists also are contraindicated (or should be used with extreme caution) in patients with benign prostatic hyperplasia. These adverse effects and contraindications generally are of more limited concern with muscarinic antagonists that are administered by inhalation or used topically in ophthalmology.

Toxicology of Drugs With Antimuscarinic Properties

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Moreover, many histamine H_1 receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors and, in sufficient dosage, produce syndromes that include features of *atropine* intoxication. Among the tricyclic antidepressants, *protriptyline* and *amitriptyline* are the most potent muscarinic receptor antagonists, with affinities for muscarinic receptors only an order of magnitude less than that of *atropine*. Because these drugs are administered in therapeutic doses considerably higher than the effective dose of *atropine*, antimuscarinic effects are often observed clinically (Chapter 18). In addition, overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and selective serotonin reuptake inhibitors have more limited anticholinergic properties.

Like the tricyclic antidepressants, many of the older antipsychotic drugs have antimuscarinic effects. These effects are most likely to be observed with the less potent drugs (e.g., *chlorpromazine* and *thioridazine*), which must be given in higher doses. The newer antipsychotic drugs, classified as "atypical" and characterized by their low propensity for inducing extrapyramidal side effects, also include agents that are potent muscarinic receptor antagonists. In particular, *clozapine* binds to human brain muscarinic receptors with high affinity (10 nM, compared to 1–2 nM for *atropine*); *olanzapine* also is a potent muscarinic receptor antagonist (Roth et al., 2004). Accordingly, xerostomia is a prominent side effect of these drugs. A paradoxical side effect of *clozapine* is increased salivation and drooling, possibly resulting from the blockade of other biogenic amine receptors.

Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic refraction and use for other ocular indications. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with *diphenoxylate-atropine*, used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of *scopolamine* used for motion sickness have been noted to cause toxic psychoses, especially in children and in the elderly. Serious intoxication may occur in children who ingest berries or seeds containing belladonna alkaloids. Poisoning from ingestion and smoking of jimson weed is seen with some frequency today.

Table 11–3 shows the oral doses of *atropine* causing undesirable responses or symptoms of overdosage. These symptoms are predictable results of blockade of parasympathetic innervation. In cases of full-blown *atropine* poisoning, the syndrome may last 48 h or longer. Intravenous injection of the anticholinesterase agent *physostigmine* may be used for confirmation. If *physostigmine* does not elicit the expected salivation, sweating, bradycardia, and intestinal hyperactivity, intoxication with *atropine* or a related agent is almost certain. Depression and circulatory collapse are evident only in cases of severe intoxication; the blood pressure declines, convulsions may ensue, respiration becomes inadequate, and death due to respiratory failure may follow after a period of paralysis and coma.

If the poison has been taken orally, begin measures to limit intestinal absorption without delay. For symptomatic treatment, slow intravenous injection of *physostigmine* will rapidly abolish the delirium and coma caused by large doses of *atropine* but carries some risk of overdose in mild *atropine* intoxication. Because *physostigmine* is metabolized rapidly, the patient may again lapse into coma within 1 to 2 h, and repeated doses may be needed (Chapter 12). If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should *not* be used because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary. Ice bags and alcohol sponges can help to reduce fever, especially in children.

Drug Facts for Your Personal Formulary: *Muscarinic Receptor Agonists and Antagonists*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Muscarinic Receptor Agonists		
Methacholine	• Diagnosis of bronchial airway hyperreactivity	• Muscarinic effects: GI cramps, diarrhea, nausea, vomiting; lacrimation, salivation, sweating; urinary urgency; vision problems; bronchospasm • Do not use in patients with GI obstruction, urinary retention, asthma/COPD
Carbachol	• Glaucoma (topical administration)	• Systemic muscarinic effects minimal with proper topical application, otherwise similar to methacholine
Bethanechol	• Ileus (postoperative, neurogenic) • Urinary retention	• Similar to methacholine • Take on empty stomach to minimize nausea/vomiting

Pilocarpine	• Glaucoma (topical administration)
	• Xerostomia due to
	  • Sjögren syndrome
	  • Head and neck irradiation
		• Systemic muscarinic effects minimal with proper topical application, otherwise similar to methacholine

Cevimeline	• Xerostomia due to • Sjögren syndrome	• Similar to methacholine
Muscarinic Receptor Antagonists		
Atropine	• Acute symptomatic bradycardia (e.g., AV block) • Cholinesterase inhibitor intoxication • Aspiration prophylaxis	• Antimuscarinic adverse effects: xerostomia, constipation, blurred vision, dyspepsia, and cognitive impairment • Contraindicated in patients with urinary tract obstruction (especially in benign prostatic hyperplasia), GI obstruction, and angle-closure glaucoma
Scopolamine	• Motion sickness	• CNS effects (drowsiness, amnesia, fatigue)
Homatropine, cyclopentolate, tropicamide	• Ophthalmological examination (cycloplegia and mydriasis induction)	• Antimuscarinic adverse effects are minimal with proper topical application
Ipratropium, tiotropium, aclidinium, umeclidinium	• COPD • Rhinorrhea (ipratropium)	• Minimal absorption as quaternary amine ⇒ fewer antimuscarinic adverse effects, otherwise similar to atropine
Pirenzepine, telenzepine	• Peptic ulcer disease (not in the U.S.)	• Antimuscarinic adverse effects and contraindications similar to atropine
Oxybutynin, trospium, darifenacin, solifenacin, tolterodine, fesoterodine	• Overactive bladder, enuresis, neurogenic bladder	• Antimuscarinic adverse effects and contraindications similar to atropine • CNS-related antimuscarinic effects less likely with trospium (quaternary amine), darifenacin and solifenacin (some selectivity for M_3 receptors), fesoterodine (prodrug of tolterodine), and tolterodine (preference for muscarinic receptors in the bladder)
Glycopyrrolate	• Duodenal ulcer • Sialorrhea • Primary axillary hyperhidrosis	• Antimuscarinic adverse effects and contraindications similar to atropine • Fewer CNS effects as glycopyrrolate is a quaternary amine and therefore unable to cross the blood-brain barrier
Dicyclomine, hyoscyamine	• Diarrhea-predominant irritable bowel syndrome (IBS)	• Antimuscarinic adverse effects and contraindications similar to atropine (including constipation-dominant IBS) • Evidence for efficacy is limited
Trihexyphenidyl, benztropine	• Parkinson's disease	• Antimuscarinic adverse effects and contraindications similar to atropine • Mainly used to treat the tremor in Parkinson's disease • Not recommended for elderly or demented patients

Chapter 12

Anticholinesterase Inhibitors and Reactivators

Palmer Taylor

Acetylcholinesterase

The hydrolytic activity of acetylcholinesterase (AChE) terminates the action of acetylcholine (ACh) at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites (see Chapter 10). Drugs that inhibit AChE are properly termed anti-ChEs or cholinesterase (ChE) inhibitors, since they inhibit both AChE and BChE (butyrylcholinesterase); however, such agents are also referred to as AChE inhibitors. BChE is not abundant in nerve ending synapses but is found in liver and plasma, where it metabolizes circulating esters.

AChE inhibitors cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems. In view of the widespread distribution of cholinergic neurons across animal species and prominence of ACh among neurotransmitters, it is not surprising that the anti-ChE agents have received extensive application as toxic agents, in the form of agricultural insecticides, pesticides, and potential chemical warfare nerve agents or gases. AChE reactivators are particularly useful in treating poisoning by pesticides or agents of terrorism in controlled ventilation facilities. Several anti-ChEs are used therapeutically; others that cross the blood-brain barrier have been approved or are in clinical trials for the treatment of Alzheimer's disease.

Prior to World War II, only the "reversible" anti-ChE agents were generally known, of which *physostigmine* is the prototype (Box 12–1). Shortly before and during World War II, a new class of highly toxic chemicals, the organophosphates, was developed, first as agricultural insecticides and later as potential chemical warfare agents (Everts, 2016). The extreme toxicity of these compounds was found to be due to their "irreversible" inactivation of AChE, which resulted in prolonged enzyme inhibition. Because the pharmacological actions of both the reversible and irreversible anti-ChE agents are qualitatively similar, they are discussed here as a group. Interactions of anti-ChE agents with other drugs acting at peripheral autonomic synapses and the neuromuscular junction are described in Chapters 11 and 13.

Structure of Acetylcholinesterase

Acetylcholinesterase exists in two general classes of molecular forms: simple homomeric oligomers of catalytic subunits (monomers, dimers, and tetramers) and heteromeric associations of catalytic subunits with tructu al subunits (Massoulié, 2(00; Tayl r. 2021: Taylor et a l., 2000).

BOX 12–1 ■ HISTORY AND PERSPECTIVE

Physostigmine, also called *eserine,* is an alkaloid obtained from the Calabar or ordeal bean, the dried, ripe seed of *Physostigma venenosum,* a perennial plant found in tropical West Africa. The Calabar bean once was used by native tribes of West Africa as an "ordeal poison" in trials for witchcraft, in which guilt was judged by death from the poison and innocence by survival after ingestion of a bean. A pure alkaloid was isolated by Jobst and Hesse in 1864 and named *physostigmine*. The first therapeutic use of the drug was in 1877 by Laqueur in the treatment of glaucoma, one of its clinical uses today. Karczmar (1970) and Holmstedt (2000) have presented accounts of the history of *physostigmine*.

After basic research elucidated the chemical basis of the activity of *physostigmine*, scientists began systematic investigations of a series of substituted aromatic esters of alkyl carbamates. *Neostigmine* was introduced in 1931 for its stimulant action on the gastrointestinal (GI) tract and subsequently was reported to be effective in the symptomatic management of myasthenia gravis.

Following the synthesis of about 2000 compounds, Schrader defined the structural requirements for insecticidal activity (and, as learned subsequently, for anti-ChE activity). One compound in this early series, parathion (a phosphorothioate), later became the most widely used insecticide of this class. Malathion also contains the thionophosphorus bond found in parathion. Prior to and during World War II, the efforts of Schrader's group were directed toward the development of chemical warfare agents. The synthesis of several compounds of much greater toxicity than parathion, such as sarin, soman, and tabun, was kept secret by the German government (Everts, 2016). Investigators in the Allied countries also followed Lange and Krueger's lead in 1932 in the search for potentially toxic compounds. DFP (diisopropyl fluorophosphate), synthesized by McCombie and Saunders, was studied extensively by British and American scientists (Giacobini, 2000).

The environmental impact from agricultural and nonagricultural uses of AChE inhibitors has come under scrutiny. For instance, approximately 10^6 pounds of malathion are used annually in the U.S. The U.S. Fish and Wildlife Service has recently concluded that malathion threatens the existence of 78 endangered plant and animal species and adversely affects 23 critical habitats (Environmental Protection Agency, 2021).

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
anti-ChE: anticholinesterase
BChE: butyrylcholinesterase
ChE: cholinesterase
CYPs: cytochrome P450s
DFP: diisopropyl fluorophosphate (diisopropyl phosphorofluoridate)
EPA: Environmental Protection Agency
GI: gastrointestinal
2-PAM: pralidoxime

The homomeric forms are found as soluble species in the cell, presumably destined for export or for association with the outer membrane of the cell, typically through an attached glycophospholipid. One heteromeric form, found mainly in neuronal synapses, is a tetramer of catalytic subunits disulfide-linked to a 20-kDa lipid-linked subunit and localized to the outer surface of the cell membrane. The other heteromeric form consists of tetramers of catalytic subunits, linked by disulfide bonds to each of three strands of a collagen-like structural subunit. This molecular species, whose molecular mass approaches 10^6 Da, is associated with the basal lamina of neuromuscular junctional areas of skeletal muscle.

Molecular cloning revealed that a single gene encodes vertebrate AChEs (Schumacher et al., 1986; Taylor, 2021; Taylor et al., 2000). However, multiple gene products arise from alternative processing of the mRNA that differ only in their carboxyl termini; the portion of the gene encoding the catalytic core of the enzyme is invariant. Hence, the individual AChE species, found in various tissues, can be expected to show identical substrate and inhibitor specificities.

A separate, structurally related gene encodes BChE, which is synthesized in the liver and is found primarily in plasma (Lockridge, 2015; Lockridge et al., 1987). The cholinesterases define a superfamily of proteins that share a common structural motif, the α,β-hydrolase fold (Cygler et al., 1993). The family includes several esterases, other hydrolases not found in the nervous system, and surprisingly, proteins without hydrolase activity, such as thyroglobulin and members of the tactin and neuroligin families (Taylor et al., 2000).

The three-dimensional structures of AChEs show the active center to be nearly centrosymmetric to each subunit, residing at the base of a confining, narrow gorge about 20 Å in depth (Bourne et al., 1995; Sussman et al., 1991). At the base of the gorge lie the residues of the catalytic triad: Ser^{203}, His^{447}, and Glu^{334} in mammals (Figure 12–1). The catalytic mechanism resembles that of other hydrolases; the serine hydroxyl group is rendered highly nucleophilic through a charge-relay system involving the carboxylate anion from the glutamate, the imidazole of histidine, and the hydroxyl of serine (Figure 12–2A).

During enzymatic catalysis of ACh, an ester with trigonal geometry, a tetrahedral intermediate between enzyme and substrate is formed (Figure 12–2A) that collapses to an acetyl enzyme conjugate with the concomitant release of choline. The acetyl enzyme is very labile to hydrolysis, which results in the formation of acetate and active enzyme (Froede and Wilson, 1971; Rosenberry, 1975). AChE is one of the most efficient enzymes known: One molecule of AChE can hydrolyze 6×10^5 ACh molecules per minute; this yields a turnover time of 100 μsec.

Knockout mice lacking the gene encoding AChE can survive under highly supportive conditions and with a special diet, but they exhibit continuous tremors and are stunted in growth (Xie et al., 2000). Mice that selectively lack AChE expression in skeletal muscle but have normal or near-normal expression in brain and organs innervated by the autonomic nervous system can reproduce but have tremors and severely compromised skeletal muscle strength. By contrast, mice with selective reductions of AChE in the CNS by elimination of the exons encoding alternative spliced regions or expression of the structural subunits

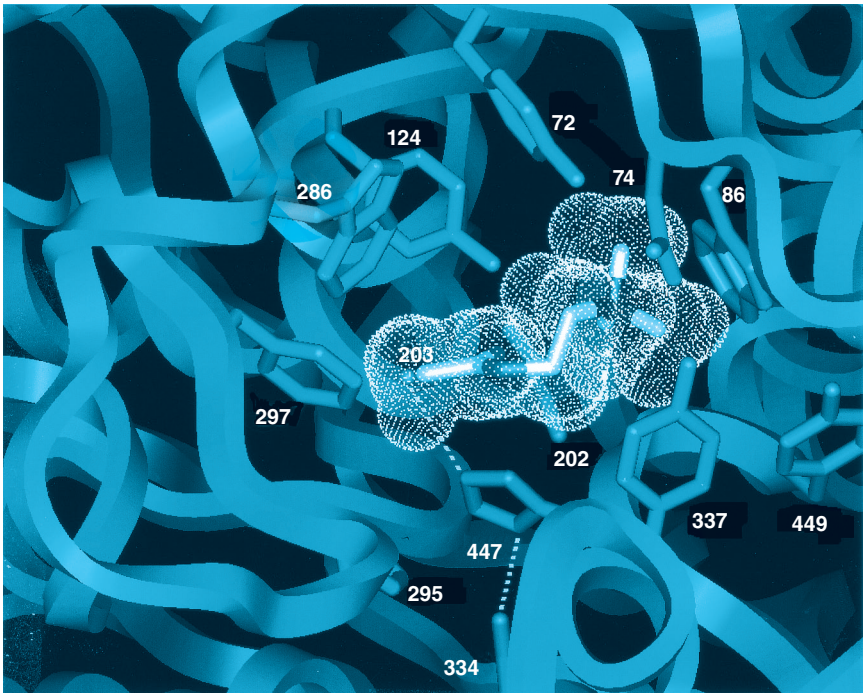

Figure 12–1 *The active center gorge of mammalian AChE, viewed from the portal of substrate entry.* Bound ACh is shown by the dotted structure depicting its van der Waals radii. The crystal structure of mouse cholinesterase active center, which is virtually identical to human AChE, is shown (Bourne et al., 1995). Included are the side chains of (1) the catalytic triad: Glu^{334}, His^{447}, Ser^{203} (hydrogen bonds are denoted by the dotted lines); (2) acyl pocket: Phe^{295} and Phe^{297}; (3) choline subsite: Trp^{86}, Glu^{202}, and Tyr^{337}; and (4) the peripheral site: Trp^{286}, Tyr^{72}, Tyr^{124}, and Asp^{74}. Tyrosines 337 and 449 are further removed from the active center but likely contribute to stabilization of certain ligands. The catalytic triad, choline subsite, and acyl pocket are located at the base of the gorge, while the peripheral site is at the rim of the gorge. The gorge is 18- to 20-Å deep, with its base centrosymmetric to the subunit.

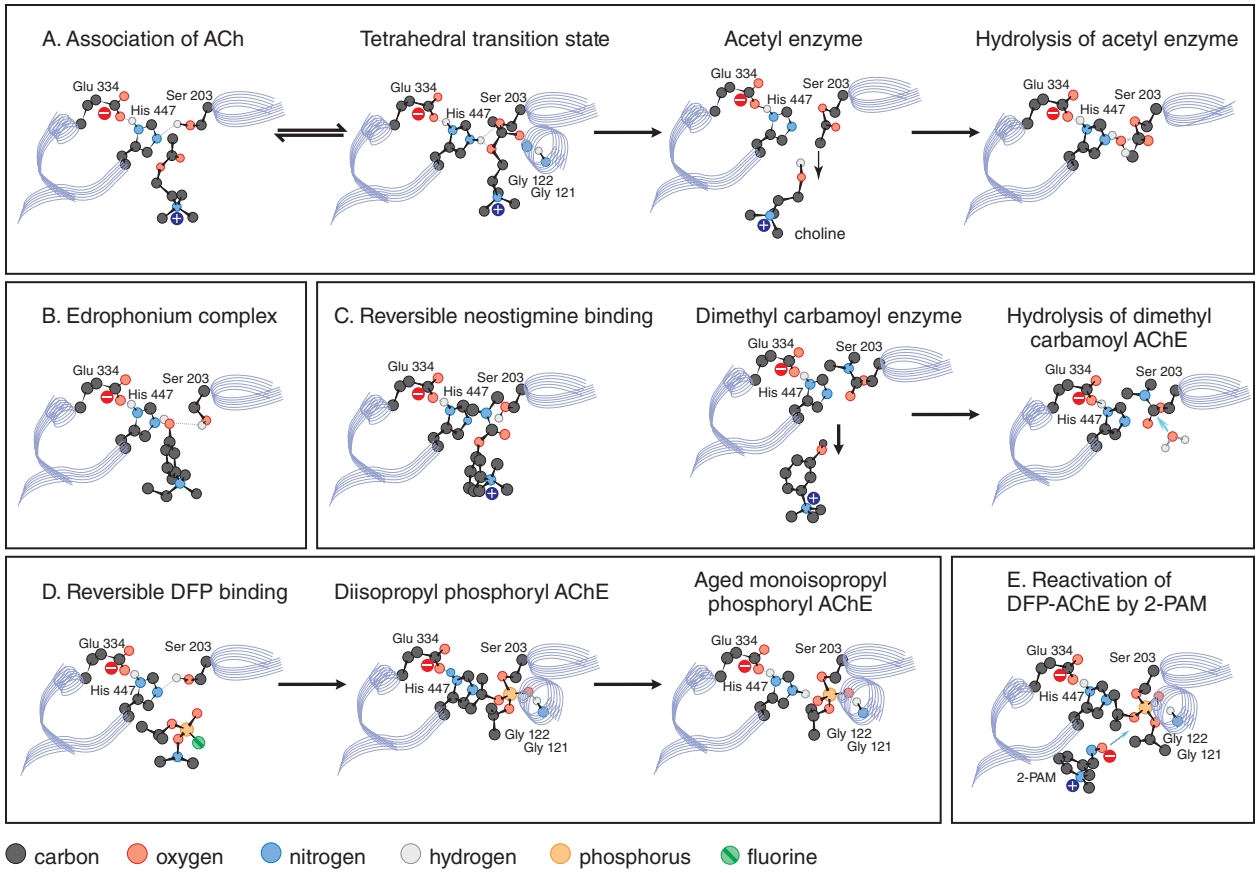

Figure 12–2 *Steps involved in the hydrolysis of ACh by AChE and in the inhibition and reactivation of the enzyme.* Only the three residues of the catalytic triad shown in Figure 12–1 are depicted. Net charge in a region is represented by red and blue circles containing – or + signs, respectively. The associations and reactions shown are as follows: **A.** ACh catalysis: binding of ACh, formation of a tetrahedral transition state, formation of the acetyl enzyme with liberation of choline, rapid hydrolysis of the acetyl enzyme with return to the original state. **B.** Reversible binding and inhibition by *edrophonium*. **C.** *Neostigmine* reaction with and inhibition of AChE: reversible binding of *neostigmine*, formation of the dimethyl carbamoyl enzyme, slow hydrolysis of the dimethyl carbamoyl enzyme. **D.** DFP reaction and inhibition of AChE: reversible binding of DFP, formation of the diisopropyl phosphoryl enzyme, formation of the aged monoisopropyl phosphoryl enzyme. Hydrolysis of the diisopropyl enzyme is very slow and is not shown. The aged monoisopropyl phosphoryl enzyme is virtually resistant to hydrolysis and reactivation. The proposed tetrahedral transition state of ACh hydrolysis resembles the conjugates formed by the tetrahedral phosphate inhibitors and accounts for their potency. Amide bond hydrogens from Gly121 and Gly122 stabilize the carbonyl and phosphoryl oxygens. **E.** Reactivation of the diisopropyl phosphoryl enzyme by 2-PAM. 2-PAM attack of the phosphorus on the phosphorylated enzyme will form a phospho-oxime with regeneration of active enzyme. The individual steps of phosphorylation reaction and oxime reaction have been characterized by mass spectrometry. (Data from Jennings et al., 2003.)

influencing expression in brain yield no obvious phenotype. Presumably, this arises from significant adaptive responses and compensatory reductions of ACh synthesis and storage and receptor responses (Camp et al., 2008; Dobbertin et al., 2009).

Acetylcholinesterase Inhibitors

Molecular Mechanism of Action of AChE Inhibitors

The mechanisms of action of compounds that typify the three classes of anti-ChE agents are also shown in Figure 12–2.

Three distinct domains on AChE constitute binding sites for inhibitory ligands and form the basis for specificity differences between AChE and BChE:

- The acyl pocket of the active center
- The choline subsite of the active center
- The peripheral anionic site (Reiner and Radić, 2000; Taylor and Radić, 1994).

Reversible inhibitors, such as *edrophonium* and *tacrine*, bearing a quaternary cation, bind to the choline subsite in the vicinity of Trp^{86} and Glu^{202} (Silman and Sussman, 2000) (Figure 12–2B). *Edrophonium* has a brief duration of action because its quaternary structure facilitates rapid renal elimination and it binds reversibly to the AChE active center. Additional reversible inhibitors, such as *donepezil*, bind with higher affinity to the active center gorge. Other reversible inhibitors, such as *propidium* and the snake peptidic toxin *fasciculin*, bind to the peripheral anionic site on AChE. This site resides at the rim of the gorge and is defined by Trp^{286}, Tyr^{72}, and Tyr^{124} (see Figure 12–1).

Drugs that have a carbamoyl ester linkage, such as *physostigmine* and *neostigmine*, are hydrolyzed by AChE, but much more slowly than is ACh ester. The quaternary amine in *neostigmine* and the tertiary amine in *physostigmine* exist as cations at physiological pH. By serving as alternate substrates to ACh (Figure 12–2C), their reaction with the active center serine progressively generates the carbamoylated enzyme. The conjugated carbamoyl moiety resides in the acyl pocket outlined by Phe^{295} and Phe^{297}. In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the $t_{1/2}$ for hydrolysis of the dimethylcarbamoyl enzyme is 15–30 min). Sequestration of the enzyme in its carbamoylated form thus precludes the enzyme-catalyzed hydrolysis of ACh for extended periods of time. When administered systemically, the duration of inhibition by the carbamoylating agents is 3 to 4 h.

The organophosphate inhibitors, such as DFP, serve as true hemisubstrates; the resultant conjugate with the active center serine phosphorylated or phosphonylated is extremely stable (Figure 12–2D). Organophosphorus inhibitors are tetrahedral in configuration, a

configuration that resembles the transition state formed in carboxyl ester hydrolysis. Similar to the carboxyl esters, the phosphoryl oxygen binds within the oxyanion hole of the active center. If the alkyl groups in the phosphorylated enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually is not observed. The stability of the phosphorylated enzyme is enhanced through "aging," which results from the loss of one of the alkyl groups. Hence, the return of AChE activity in the aged enzyme conjugate depends largely on biosynthesis of new AChE protein.

Accordingly, the terms *reversible* and *irreversible* as applied to the carbamoyl and organophosphorus anti-ChE agents reflect only quantitative differences in rates of decarbamoylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the active center serine in essentially the same manner as does ACh in forming the transient, short-lived acetyl enzyme.

Chemistry and Structure-Activity Relationships

Structure-activity relationships of anti-ChE agents have been extensively reviewed in the scientific literature. Only agents of general therapeutic or toxicological interest are considered here.

Noncovalent Inhibitors

While these agents interact by reversible and noncovalent association with the active site in AChE, they differ in their disposition in the body and their affinity for the enzyme. *Edrophonium*, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE. Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast, *tacrine* and *donepezil* (Figure 12–3) have higher affinities for AChE, are more hydrophobic, and readily cross the blood-brain barrier to inhibit AChE in the CNS. Partitioning into lipid and higher affinities for AChE may also account for their longer durations of action.

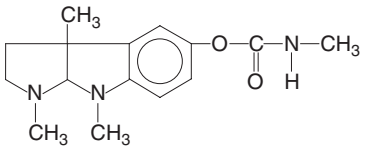
"Reversible" Carbamate Inhibitors

Drugs of this class that are of therapeutic interest are shown in Figure 12–3. Early studies showed that the essential moiety of the *physostigmine* molecule was the methylcarbamate of an amine-substituted phenol. The quaternary ammonium derivative *neostigmine* is a compound of equal or greater potency. *Pyridostigmine*, a close congener, is also used in myasthenia gravis patients.

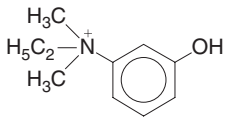
Carbamoylating inhibitors with high lipid solubility (*rivastigmine*) have longer durations of action, cross the blood-brain barrier, and are used as an alternative in the treatment of Alzheimer's disease (Cummings, 2004) (see Chapter 21). The carbamate insecticides carbaryl, propoxur, and aldicarb, used extensively as garden insecticides, inhibit AChE with a mechanism identical to other carbamoylating agents. While more reversible and less toxic, symptoms parallel those of organophosphates (Eddleston and Clark, 2011; King and Aaron, 2015).

Organophosphorus Compounds

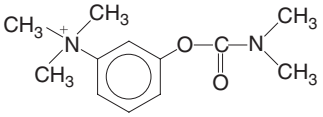
The general formula for the organophosphorus class of ChE inhibitors is shown at the top of Table 12–1. A great variety of substituents is possible:



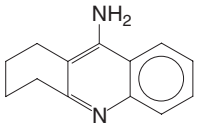
PHYSOSTIGMINE



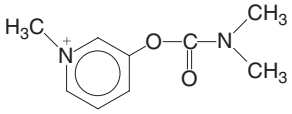
EDROPHONIUM



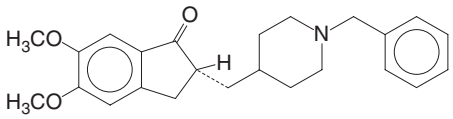
NEOSTIGMINE



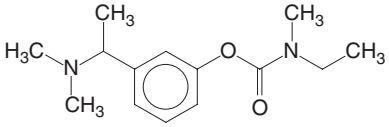
TACRINE



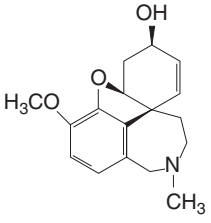
PYRIDOSTIGMINE



DONEPEZIL



RIVASTIGMINE



GALANTAMINE

Figure 12–3 *"Reversible" carbamate and noncovalent AChE inhibitors used clinically.*

TABLE 12–1 ■ CHEMICAL CLASSIFICATION OF REPRESENTATIVE ORGANOPHOSPHORUS AChE INHIBITORS

General formula 
Group **A**, X = halogen, cyanide, or thiocyanate leaving group; group **B**, X = alkylthio, arylthio, alkoxy, or aryloxy leaving group; group **C**, thionophosphorus or thio-thionophosphorus compounds; group **D**, quaternary ammonium leaving group. R_1 can be an alkyl (phosphonates), alkoxy (phosphorates), or an alkylamino (phosphoramidates) group.

GROUP	STRUCTURAL FORMULA	COMMON, CHEMICAL, AND OTHER NAMES	COMMENTS
A		DFP; Isoflurophate; diisopropyl fluorophosphate	Potent, irreversible inactivator
		Tabun Ethyl N-dimethylphosphoramidocyanidate	Extremely toxic "nerve gas"
		Sarin (GB) Isopropyl methylphosphonofluoridate	Extremely toxic "nerve gas"
		Soman (GD) Pinacolyl methylphosphonofluoridate	Extremely toxic "nerve gas"; greatest potential for irreversible action/rapid aging
B		VX *O*-ethyl S [2-(diisopropylamino)ethyl] methyl phosponothioate	Potent, slower onset, skin-penetrating nerve agent
		Malaoxon *O,O*-Dimethyl S-(1,2-dicarboxyethyl)-phosphorothioate	Active metabolite of malathion
C		Parathion *O,O*-Diethyl *O*-(4-nitrophenyl)-phosphorothioate	Agricultural insecticide, resulting in numerous cases of accidental poisoning; phased out in 2003
		Diazinon, Dimpylate *O,O*-Diethyl *O*-(2-isopropyl-6-methyl-4-pyrimidinyl) phosphorothioate	Insecticide; use limited to non-residential agricultural settings
		Chlorpyrifos *O,O*-Diethyl *O*-(3,5,6-trichloro-2-pyridyl) phosphorothioate	Insecticide; use limited to non-residential agricultural settings
		Malathion *O,O*-Dimethyl S-(1,2-dicarbethoxyethyl) phosphorodithioate	Widely employed insecticide of greater safety than parathion or other agents because of rapid detoxification by higher organisms
D		Echothiophate (PHOSPHOLINE IODIDE), MI-217 Diethoxyphosphinylthiocholine iodide	Extremely potent choline derivative; administered locally in treatment of glaucoma; relatively stable in aqueous solution

R_1 and R_2 may be alkyl, alkoxy, aryloxy, amido, mercaptan, or other groups; and X, the leaving group, typically a conjugate base of a weak acid, is a halide, cyanide, thiocyanate, phenoxy, thiophenoxy, phosphate, thiocholine, or carboxylate group. For a compilation of the organophosphorus compounds and their toxicity, see Gallo and Lawryk (1991).

Diisopropyl fluorophosphate produces virtually irreversible inactivation of AChE and other esterases by alkylphosphorylation. Its high lipid solubility, low molecular weight, and volatility facilitate inhalation toxicity, transdermal absorption, and penetration into the CNS. After desulfuration, the insecticides in current use form the dimethoxy or diethoxyphosphoryl conjugate of AChE.

The "nerve gases"—tabun, sarin, soman, and VX—are among the most potent synthetic toxic agents known; they are lethal to laboratory animals in nanogram doses. Insidious employment of these agents occurred in the Matsumoto incident and Tokyo subway terrorism attacks in Japan and against civilians by despotic regimes in the Middle East (Council on Foreign Relations, 2013; Dolgin, 2013; King and Aaron, 2015; Nozaki and Aikawa, 1995). While estimates of lethality in Japan amounted to 8 and 10 people killed, in Syria estimates vary, ranging up to 1000 individuals, with over 3000 showing symptoms of organophosphate toxicity. Attacks continued into 2017 with release of sarin vapor from explosive devices. Toxicity results from inhalation and rapid distribution of sarin to the central and peripheral nervous systems. The slower dermal absorption of VX was used for political assassination in Malaysia in 2017.

Parathion and methylparathion were widely used as insecticides because of their favorable properties of low volatility and stability in aqueous solution. Acute and chronic toxicity has limited their use, and potentially less-hazardous compounds have replaced them for home and garden use throughout the world. These compounds are inactive in inhibiting AChE *in vitro*; they act via the active metabolite, paraoxon. The phosphoryl oxygen for sulfur substitution is carried out predominantly by hepatic cytochrome P450s (CYPs). This reaction also occurs in the insect, typically with more efficiency. Other insecticides possessing the phosphorothioate structure have been widely employed for agricultural use. These include *diazinon* and *chlorpyrifos*. Use of these agents is restricted because of evidence of chronic toxicity in the newborn animal. They have been banned from indoor and outdoor residential use since 2005.

Malathion also requires conversion of a sulfur atom to oxygen *in vivo,* conferring resistance to mammalian species. Also, this insecticide can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases. Plasma carboxylesterase activity dictates species resistance to malathion: The detoxification reaction is much more rapid in mammals and birds than in insects (Costa et al., 2013). In recent years, malathion has been employed in aerial spraying of relatively populous areas for control of citrus orchard–destructive Mediterranean fruit flies and mosquitoes that harbor and transmit viruses harmful to human beings, such as the West Nile encephalitis virus.

Evidence of acute toxicity from malathion arises primarily with suicide attempts or deliberate poisoning. The lethal dose in mammals is about 1 g/kg. Exposure to the skin results in a small fraction (<10%) systemically absorbed. Malathion is used topically in the treatment of pediculosis (lice) infestations in cases of *permethrin* resistance (Centers for Disease Control and Prevention, 2015).

Among the quaternary ammonium organophosphorus compounds (group D in Table 12–1), only *echothiophate* is useful clinically, and its use is limited to ophthalmic administration. As a positively charged quaternary amine, *echothiophate* is not volatile and does not readily penetrate the skin.

Basis for the Pharmacological Effects of ChE Inhibitors

The characteristic pharmacological effects of the anti-ChE agents are due primarily to the prevention of catalytic hydrolysis of ACh by AChE at sites of cholinergic transmission. Transmitter thus accumulates, enhancing the response to ACh that is liberated by cholinergic impulses or that is spontaneously released from nerve endings. Virtually all acute effects of moderate doses of organophosphates are attributable to this action. For example, the characteristic miosis that follows local application of DFP to the eye is not observed after chronic postganglionic denervation of the eye because there is no source from which to release endogenous ACh. The consequences of enhanced concentrations of ACh at motor end plates of skeletal muscle are unique to these sites and are discussed below.

Generally, the pharmacological properties of anti-ChE agents can be predicted by knowing those loci where ACh is released physiologically by nerve impulses, the degree of nerve impulse activity, and the responses of the corresponding effector organs to ACh (see Chapter 10). The anti-ChE agents potentially can produce all the following effects:

- Stimulation of muscarinic receptor responses at autonomic effector organs
- Stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions)
- Stimulation, with occasional subsequent depression, of pre- and postsynaptic cholinergic receptor sites in the CNS

At therapeutic doses, several factors modify the actions of anti-ChE agents. Compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the GI tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. On the other hand, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists (see example of effects of *neostigmine* on denervated skeletal muscle, below, under Neuromuscular Junction). They have comparatively lower effects at autonomic effector sites and ganglia. In contrast, the more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents, such as the chemical warfare agents, are well absorbed through the skin, whereas the volatile agents are transferred readily across the alveolar membranes in the lung (King and Aaron, 2015; Storm et al., 2000).

The actions of anti-ChE agents on autonomic effector cells and on cortical and subcortical sites in the CNS, where ACh receptors are largely of the muscarinic type, are blocked by *atropine*. Likewise, *atropine* blocks some of the excitatory actions of anti-ChE agents on autonomic ganglia, because both nicotinic and muscarinic receptors are involved in ganglionic neurotransmission (see Chapter 13).

Effects on Physiological Systems

The sites of action of anti-ChE agents of therapeutic importance are the CNS, eye, intestine, and neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

Eye

When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. Although the pupil may be "pinpoint" in size, it generally contracts further when exposed to light. The block of the accommodation reflex is more transient and generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (see Chapter 69).

GI Tract

In humans, *neostigmine* enhances gastric contractions and increases the secretion of gastric acid. After bilateral vagotomy, the effects of *neostigmine* on gastric motility are greatly reduced. The lower portion of the esophagus is stimulated by *neostigmine*; in patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis.

Neostigmine also augments locomotor activity of the small and large bowel; the colon is particularly stimulated. Atony produced by muscarinic receptor antagonists or prior surgical intervention may be overcome, propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The total effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the ganglion cells of the Auerbach plexus and at the smooth muscle fibers as a result of the preservation of ACh released by the cholinergic preganglionic and postganglionic fibers, respectively (see Chapter 54).

Neuromuscular Junction

Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained on the basis of their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of *neostigmine* and other quaternary ammonium anti-ChE agents on skeletal muscle. For example, the intra-arterial injection of *neostigmine* into chronically denervated muscle, or muscle in which AChE has been inactivated by prior administration of DFP, evokes an immediate contraction, whereas *physostigmine* does not.

Normally, a single nerve impulse in a terminal motor-axon branch liberates enough ACh to produce a localized depolarization (end-plate potential) of sufficient magnitude to initiate a propagated muscle action potential. The ACh released is rapidly hydrolyzed by AChE, such that the lifetime of free ACh within the nerve-muscle synapse (~200 μsec) is shorter than the decay of the end-plate potential or the refractory period of the muscle. Therefore, each nerve impulse gives rise to a single wave of depolarization. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and cycles of association-dissociation of the released transmitter to multiple receptors. Successive stimulation of neighboring receptors to the release site in the end plate prolongs the decay time of the end-plate potential. Quanta released by individual nerve impulses are no longer isolated. This action destroys the synchrony between end-plate depolarizations and the development of the muscle action potentials. Consequently, asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the endplate predominates, and blockade due to depolarization ensues (see Chapter 13). When ACh persists in the synapse, it also may depolarize the axon terminal, resulting in antidromic firing of the motor neuron; this stimulation contributes to fasciculations that involve the entire motor unit.

Anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents. By contrast, *neostigmine* is not effective against the skeletal muscle paralysis caused by *succinylcholine*, which produces neuromuscular blockade by depolarization; *neostigmine* will enhance depolarization and the resultant blockade.

Cardiopulmonary System

The cardiovascular actions of anti-ChE agents are complex because they reflect both ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels as well as actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually enhance the fall in blood pressure, as a consequence of effects of anti-ChE agents on the medullary vasomotor centers of the CNS.

Anti-ChE agents augment vagal influences on the heart. This shortens the effective refractory period of atrial muscle fibers and increases the refractory period and conduction time at the sinoatrial and atrioventricular nodes. At the ganglionic level, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization of the postsynaptic nerve. The excitatory action on the parasympathetic ganglion cells would tend to reinforce the diminished cardiac output, whereas the opposite sequence results from the action of ACh on sympathetic ganglion cells. Excitation followed by inhibition also is elicited by ACh at the central medullary vasomotor and cardiac centers in the brainstem. These effects are complicated further by the hypoxemia resulting from the bronchoconstrictor and secretory actions of increased ACh on the respiratory system. Hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia probably is a major factor in the CNS depression that appears after large doses of anti-ChE agents.

Actions at Other Sites

Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation, and higher doses actually produce an increase in the resting rate of secretion.

Anti-ChE agents increase contraction of smooth muscle fibers of the bronchioles and ureters, and the ureters may show increased peristaltic activity.

ADME

Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (e.g., pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered *physostigmine* is largely destroyed within 2 to 3 h, mainly by hydrolytic cleavage by plasma esterases.

Neostigmine and *pyridostigmine* are absorbed poorly after oral administration, such that much larger oral doses are needed than by the parenteral route. Whereas the effective parenteral dose of *neostigmine* is 0.5 to 2 mg, the equivalent oral dose may be 15 to 30 mg or more. *Neostigmine* and *pyridostigmine* are also destroyed by plasma esterases; the half-lives of these drugs are about 1 to 2 h (Cohan et al., 1976).

Organophosphate anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; others, such as sarin, have high vapor pressures, augmenting their dispersal and pulmonary absorption. The less volatile agents that are commonly used as agricultural insecticides (e.g., diazinon, chlorpyrifos, malathion) generally are dispersed as aerosols or as dusts adsorbed to an inert, finely particulate material. Consequently, the compounds are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion (Storm et al., 2000).

Following their absorption, most organophosphates are excreted almost entirely as hydrolysis products in the urine. Plasma and liver esterases are responsible for hydrolysis to the corresponding phosphoric and phosphonic acids. However, CYPs are responsible for converting the inactive phosphorothioates containing a phosphorus-sulfur (thiono) bond to phosphorates with a phosphorus-oxygen bond, resulting in their activation. These enzymes also play a role in the inactivation of certain organophosphorus agents, and allelic differences are known to affect rates of metabolism (Furlong, 2007).

The organophosphate anti-ChE agents are hydrolyzed by two families of hepatic enzymes: the carboxylesterases and the paraoxonases (A-esterases). These enzymes are secreted into plasma and scavenge or hydrolyze a large number of organophosphates by cleaving the phosphoester, anhydride, phosphofluoridate, or phosphocyanate bonds. Natural substrates of the paraoxonases appear to be lactones. In addition to catalyzing hydrolysis of organophosphates, the paraoxonase isoform PON1 associates with high-density lipoproteins and appears to play a role in removing oxidized lipids, thereby exerting a protective effect in atherosclerosis and inflammation (Costa et al., 2013; Harel et al., 2004; Mackness and Mackness, 2015). Wide variations in paraoxonase activity exist among animal species. Young animals are deficient in carboxylesterases and paraoxonases, which may account for age-related toxicities seen in newborn animals and suspected to be a basis for organophosphate toxicity in humans (Padilla et al., 2004).

Plasma and hepatic carboxylesterases (aliesterases) and plasma BChE are inhibited irreversibly by organophosphates (Costa et al., 2013; Lockridge, 2015); their scavenging capacity for organophosphates can afford partial protection against inhibition of AChE in the nervous system. The carboxylesterases also catalyze hydrolysis of malathion and other organophosphates that contain carboxyl-ester linkages, rendering them less

active or inactive. Because carboxylesterases are inhibited by organophosphates, toxicity from simultaneous exposure to two organophosphorus insecticides can prove synergistic.

Toxicology

Scope of the Problem

The toxicological aspects of the anti-ChE agents are of practical importance to clinicians. In addition to cases of accidental intoxication from the use and manufacture of organophosphorus compounds as agricultural insecticides, because of their availability, these agents have been used frequently for homicidal and suicidal purposes. Organophosphates account for as many as 80% of pesticide-related hospital admissions. The World Health Organization documents pesticide toxicity as a widespread global problem associated with over 300,000 deaths a year; most poisonings occur in Southeast Asia (Eddleston and Chowdhury, 2015; Eddleston and Clark, 2011). Occupational exposure occurs most commonly by the dermal and pulmonary routes, while oral ingestion is most common in cases of nonoccupational poisoning.

Sources of Information

In the U.S., the Environmental Protection Agency (EPA), by virtue of revised risk assessments and the Food Quality Protection Act of 1996, has placed several organophosphate insecticides, including diazinon and chlorpyrifos, on restricted use and phased-out status in consumer products for home and garden use. A primary concern relates to exposure in pregnancy and to infants and children because the developing nervous system may be particularly susceptible to certain of these agents (Eaton et al., 2008). The National Pesticide Information Center (http://npic.orst.edu/) and the Office of Pesticide Programs of the EPA (https://www.epa.gov/pesticides) provide frequent updates of the status of organophosphate pesticides, their tolerance reassessments, and revisions of risk assessments through their websites.

Acute Intoxication

Acute intoxication by anti-ChE agents is manifested by muscarinic and nicotinic signs and symptoms and, except for quaternary cationic compounds of low lipid solubility, by signs referable to the CNS. Systemic effects appear within minutes after inhalation of vapors or aerosols, while onset of symptoms is delayed after GI and percutaneous absorption. The duration of toxic symptoms is determined largely by the properties of the compound: its lipid solubility, whether it must be activated to form the oxon, the stability of the organophosphate-AChE bond, and whether "aging" of the phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharges in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory responses consist of tightness in the chest and wheezing caused by the combination of bronchoconstriction and increased bronchial secretion. GI symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea. With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of fatigability and generalized weakness, involuntary twitchings, scattered fasciculations, and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles.

A broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

The time of death after a single acute exposure may range from less than 5 min to nearly 24 h, depending on the dose, route, and agent. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Peripheral muscarinic and nicotinic as well as central actions all contribute to respiratory compromise; effects include laryngospasm, bronchoconstriction, increased tracheobronchial and salivary secretions, and compromised voluntary control of the diaphragm and intercostal muscles. Blood pressure may fall to alarmingly low levels, and cardiac arrhythmias may result from hypoxemia.

Delayed symptoms appearing after 1 to 4 days and marked by persistent low blood ChE and severe muscle weakness are termed the *intermediate syndrome* (Lotti, 2002). Delayed neurotoxicity and recurrent seizures also may be evident after severe intoxication (discussed below in Reactivation and Disposition).

Diagnosis and Treatment

The diagnosis of severe, acute anti-ChE intoxication is made readily from the history of exposure and the characteristic signs and symptoms. In suspected cases of milder acute or chronic intoxication, determination of AChE activities in erythrocytes and BChE in plasma generally will establish the diagnosis (Storm et al., 2000). Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident.

Atropine in sufficient dosage (described further in the chapter) effectively antagonizes the actions at muscarinic receptor sites, including increased tracheobronchial and salivary secretion, bronchoconstriction, and bradycardia. Larger doses are required to get appreciable concentrations of *atropine* into the CNS. *Atropine* is virtually without effect against the peripheral neuromuscular compromise, which can be reversed by *pralidoxime* (2-PAM), a cholinesterase reactivator.

In moderate or severe intoxication with an organophosphorus anti-ChE agent, the recommended adult dose of 2-PAM is 1 to 2 g, slowly infused intravenously. If weakness is not relieved or if it recurs after 20 to 60 min, the dose should be repeated. Early treatment is important to ensure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. Many of the alkylphosphates are extremely lipid soluble, and if extensive partitioning into body fat has occurred and desulfuration is required for inhibition of AChE, toxicity will persist.

General supportive measures are important and include:

- Termination of exposure, by removal of the patient or application of a gas mask if the atmosphere remains contaminated, removal and destruction of contaminated clothing, copious washing of contaminated skin or mucous membranes with water, or gastric lavage
- Maintenance of a patent airway, including endobronchial aspiration
- Artificial respiration and administration of O_2, if required
- Alleviation of persistent convulsions with *diazepam* (5–10 mg IV)
- Treatment of shock

Atropine should be given in doses sufficient to cross the blood-brain barrier. Following an initial injection of 2 to 4 mg, given intravenously if possible, otherwise intramuscularly, 2 mg should be given every 5 to 10 min until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. AChE reactivating agents and mild degree of *atropine* block then should be maintained for as long as symptoms are evident.

Although the phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, nucleophilic agents, such as hydroxylamine (NH_2OH), hydroxamic acids (RCONH–OH), and oximes (RCH=NOH), reactivate the enzyme more rapidly than does spontaneous hydrolysis. Froede and Wilson (1971) reasoned that selective reactivation could be achieved by a site-directed nucleophile, wherein interaction of a quaternary nitrogen with the negative subsite of the active center would place the nucleophile in close apposition to the conjugated phosphorus. The oxime is oriented proximally to exert a nucleophilic attack on the phosphorus; a phosphoryloxime is formed, leaving the regenerated enzyme (Figure 12–2E).

Several *bis*-quaternary aldoximes are even more potent as reactivators for insecticide and nerve agent poisoning, for instance, *obidoxime* and HI-6, which are used in Europe as antidotes (Steinritz et al., 2016). However, these compounds do not cross the blood-brain barrier, limiting their effectiveness to peripheral nervous system sites. The oximate ionization state of the oximes is the acting nucleophile. Enhanced penetration of the blood-brain barrier is achieved with amphipathic oximes (Chambers, 2020) or zwitterionic oximes (Shyong et al., 2021; Taylor, 2021), where a neutral species and the cationic, anionic, and zwitterionic ionization species are in rapid equilibrium, allowing both access to the CNS and periphery, in addition to target selectivity (Shyong et al., 2021).

Certain phosphorylated AChE conjugates can undergo a fairly rapid process of "aging," so that within the course of minutes or hours they become completely resistant to the reactivators. Aging is due to the loss of one alkoxy group, leaving a much more stable monoalkyl- or monoalkoxyphosphoryl-AChE (Figure 12–2D and 12–2E). Organophosphorus compounds containing tertiary alkoxy groups, such as soman, are more prone to aging than are congeners containing the secondary or primary alkoxy groups. The oximes are not effective in antagonizing the toxicity of the more rapidly hydrolyzing carbamoyl ester inhibitors; since 2-PAM itself has weak anti-ChE activity, it is not recommended for the treatment of overdosage with *neostigmine* or *physostigmine* or poisoning with carbamoylating insecticides such as carbaryl.

Reactivation and Disposition

The reactivating action of oximes *in vivo* is most marked at the skeletal neuromuscular junction. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS (Eddleston and Clark, 2011; Shyong et al., 2021).

Since high doses or accumulation of oximes inhibit AChE and cause neuromuscular blockade, the offending organophosphate should be identified. Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral *atropine*, an oxime (2-PAM, HI-6, or *obidoxime*), and *diazepam* or *midazolam* as anticonvulsants (King and Aaron, 2015). Oxime entry to the CNS is still limited since the capillary endothelial cell contains extrusion transporters that limit entry into functioning cholinergic synapses. The reactivating oximes are readily eliminated by the kidney, so repetitive dosing is recommended. Hence, a transport inhibitor limiting brain extrusion of the antidote and slowing its renal elimination may constitute improvements in antidote therapy (Shyong et al., 2021).

Parenterally administered human BChE and recombinant DNA-expressed paraoxonases and phosphotriesterases with selected mutations are also under development to scavenge the organophosphate at its portal of entry or in the plasma before it reaches peripheral and central tissue sites (Cerasoli et al., 2005; Mata et al., 2014; Worek et al., 2014). Catalytic enzyme scavengers are limited by their stabilities in the field of use, their slow distribution from intramuscular sites, and costs of production of catalytic proteins with high turnover.

Certain fluorine-containing organophosphorus anti-ChE agents (e.g., DFP, mipafox) may induce a delayed neurotoxicity shared with the triarylphosphates, of which triorthocresyl phosphate (TOCP) is the classic example. The clinical picture is a long-term polyneuropathy manifested initially by sensory disturbances, ataxia, muscle fatigue, and twitching. In severe cases, the weakness may progress to flaccid paralysis and muscle wasting. Toxicity from this organophosphate-induced delayed polyneuropathy is due to a distinct esterase, termed a *neurotoxic esterase* (Johnson, 1993). This enzyme has a specificity for hydrophobic esters, but its natural substrate and function remain unknown (Glynn, 2006; Read et al., 2009).

Therapeutic Uses of AChE Inhibitors

Current use of anti-AChE agents is limited to four conditions in the periphery:

- Atony of the smooth muscle of the intestinal tract and urinary bladder
- Glaucoma, via drop instillation into the eye
- Myasthenia gravis, via parenteral and oral therapy
- Reversal of the paralysis of competitive neuromuscular blocking drugs, via parenteral routes

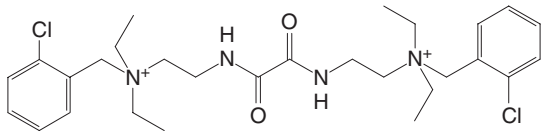
Long-acting and hydrophobic ChE inhibitors are the only inhibitors with documented efficacy, albeit limited, in the treatment of dementia symptoms of Alzheimer's disease. *Physostigmine*, with its shorter duration of action, is used to treat intoxication by *atropine* and several drugs with anticholinergic side effects (discussed further in the chapter); it also is indicated for the treatment of Friedreich or other inherited ataxias. *Edrophonium* has been used for terminating attacks of paroxysmal supraventricular tachycardia.

Available Therapeutic Agents

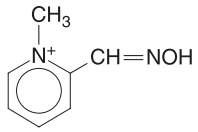
The compounds described here are those commonly used as anti-ChE drugs and ChE reactivators in the U.S. Preparations used solely for ophthalmic purposes are described in Chapter 74. Conventional dosages and routes of administration are given in the further discussion of therapeutic applications.

Physostigmine salicylate is available for injection. *Physostigmine sulfate* ophthalmic ointment and *physostigmine salicylate* ophthalmic solution also are available. *Pyridostigmine bromide* is available for oral or parenteral use. *Neostigmine bromide* is available for oral use. *Neostigmine methylsulfate* is marketed for parenteral injection. *Ambenonium chloride* is available for oral use. *Tacrine, donepezil*, *rivastigmine*, and *galantamine* have been approved for the treatment of Alzheimer's disease.

Pralidoxime chloride is the only AChE reactivator currently available in the U.S. and can be obtained in a parenteral formulation. HI-6 is available in several European and Middle Eastern countries.



AMBENONIUM



PRALIDOXIME (2-PAM)

Paralytic Ileus and Atony of the Urinary Bladder

In the treatment of both paralytic ileus and urinary bladder atony, *neostigmine* generally is preferred among the anti-ChE agents. Directly acting muscarinic agonists (see Chapter 11) are employed for the same purposes.

Neostigmine is used for the relief of abdominal distension and acute colonic pseudo-obstruction from a variety of medical and surgical causes (Ponec et al., 1999). The usual subcutaneous dose of *neostigmine methylsulfate* for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10 to 30 min after parenteral administration, whereas 2 to 4 h are required after oral administration of *neostigmine bromide* (15–30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube.

When *neostigmine* is used for the treatment of atony of the detrusor muscle of the urinary bladder, postoperative dysuria is relieved. The drug is used in a similar dose and manner as in the management of paralytic ileus. *Neostigmine* should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

Glaucoma and Other Ophthalmologic Indications

Glaucoma is a complex disease characterized by an increase in intraocular pressure. If the pressure is sufficiently high and persistent, it will damage the optic disc at the juncture of the optic nerve and the

retina; irreversible blindness can result. Of the three types of glaucoma—primary, secondary, and congenital—anti-AChE agents are of value in the management of the primary as well as of certain categories of the secondary type (e.g., aphakic glaucoma, following cataract extraction); congenital glaucoma rarely responds to any therapy other than surgery. Primary glaucoma is subdivided into narrow-angle (acute congestive) and wide-angle (chronic simple) types, based on the configuration of the angle of the anterior chamber where the aqueous humor is reabsorbed.

Narrow-angle glaucoma is nearly always a medical emergency in which drugs are essential in controlling the acute attack, but the long-range management is often surgical (e.g., peripheral or complete iridectomy). Wide-angle glaucoma, on the other hand, has a gradual, insidious onset and is not generally amenable to surgical improvement; in this type, control of intraocular pressure usually is dependent on continuous drug therapy.

Because the cholinergic agonists and ChE inhibitors also block accommodation and induce myopia, these agents produce transient blurring of far vision, limited visual acuity in low light, and loss of vision at the margin when instilled in the eye. With long-term administration of the cholinergic agonists and anti-ChE agents, these compromises of vision diminish. Nevertheless, other agents without these side effects, such as prostaglandin analogues, β adrenergic receptor antagonists, and carbonic anhydrase inhibitors, have become the primary topical therapies for open-angle glaucoma. AChE inhibitors are held in reserve for the chronic conditions when patients become refractory to the agents mentioned. Topical treatment with long-acting ChE inhibitors such as *echothiophate* gives rise to symptoms characteristic of systemic ChE inhibition. (For a complete account of the use of anti-ChE agents in ocular therapy, see Chapter 74.)

Myasthenia Gravis

Myasthenia gravis is a neuromuscular disease of complex genetic etiology characterized by exacerbations and remissions of weakness and marked fatigability of skeletal muscle (Drachman, 1994; Renton et al., 2015).

The relative importance of prejunctional and postjunctional defects in myasthenia gravis was unknown until Patrick and Lindstrom (1973) found that rabbits immunized with nicotinic receptor slowly developed muscular weakness and respiratory difficulties that resembled the symptoms of myasthenia gravis. This animal model prompted intense investigation into whether the natural disease represented an autoimmune response directed toward the ACh receptor. Antireceptor antibodies are detectable in sera of 90% of patients with the disease, although the clinical status of the patient does not correlate precisely with antibody titers (Drachman, 1994). Sequences in the α_1 ACh receptor subunit constituting the main immunogenic region are well defined (Lindstrom, 2008).

The picture that emerges is that myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the postjunctional end plate. These antibodies reduce the number of receptors detectable either by snake α-neurotoxin–binding assays (Fambrough et al., 1973) or by electrophysiological measurements of ACh sensitivity (Drachman, 1994). Immune complexes along with marked ultrastructural abnormalities appear in the synaptic cleft and enhance receptor degradation through complement-mediated lysis in the end plate.

In a subset of about 10% of patients presenting with a myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis. Characterization of biochemical and genetic bases of the congenital condition has demonstrated mutations in the ACh receptor that affect ligand-binding, channel-opening kinetics and durations; receptor biosynthesis; and synaptic location of receptors (Engel et al., 2012; Sine and Engel, 2006). Other mutations occur as a deficiency in the form of AChE that contains the collagen-like tail unit, in presynaptic transporters involved in the uptake of choline, and in vesicular storage of ACh. In myasthenic patients, identification of the mutation in the complement of synaptic proteins is essential for ascertaining whether a specific pharmacological treatment is warranted.

Diagnosis

Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neurasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. However, in autoimmune myasthenia gravis, the aforementioned deficiencies and enhancement of muscle strength can be improved dramatically by anti-ChE medication. The *edrophonium* test for initial diagnosis relies on these responses. The *edrophonium* test is performed by rapid intravenous injection of 2 mg of *edrophonium chloride*, followed 45 sec later by an additional 8 mg if the first dose is without effect. A positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in nonmyasthenic patients).

An excessive dose of an anti-ChE drug results in a *cholinergic crisis*. The condition is characterized by weakness resulting from generalized depolarization of the motor end plate; other symptoms result from overstimulation of muscarinic receptors. The weakness resulting from depolarization blockade may resemble myasthenic weakness, which is manifest when anti-ChE medication is insufficient. The distinction is of obvious practical importance because the former is treated by withholding, and the latter by administering, the anti-ChE agent. Detection of antireceptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

Treatment of Myasthenia Gravis

Pyridostigmine, *neostigmine*, and *ambenonium* are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of released endogenous ACh. Following AChE inhibition, receptors over a greater cross-sectional area of the end plate presumably are exposed to concentrations of ACh sufficient for channel opening and production of a postsynaptic end-plate potential.

Unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage. *Pyridostigmine* is available in sustained-release tablets containing a total of 180 mg, of which 60 mg are released immediately and 120 mg are released over several hours; this preparation is of value in maintaining patients for 6- to 8-h periods but should be limited to use at bedtime. Muscarinic cardiovascular and GI side effects of anti-ChE agents generally can be controlled by *atropine* or other anticholinergic drugs (see Chapter 11). However, these anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects. Several drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (see Chapter 13); their administration to patients with myasthenia gravis requires proper adjustment of anti-ChE dosage and other precautions.

Other therapeutic measures are essential elements in the management of this disease. Glucocorticoids promote clinical improvement in a high percentage of patients. However, when treatment with steroids is continued over prolonged periods, a high incidence of side effects may result (see Chapter 50). Initiation of steroid treatment augments muscle weakness; however, as the patient improves with continued administration of steroids, doses of anti-ChE drugs can be reduced (Drachman, 1994). Other immunosuppressive agents, such as *azathioprine* and *cyclosporine* and high-dose *cyclophosphamide* (Drachman et al., 2008), have also been beneficial in more refractory cases (see Chapter 39). Thymectomy should be considered in myasthenia associated with a thymoma or when the disease is not controlled adequately by anti-ChE agents and steroids. Because the thymus contains myoid cells with nicotinic receptors (Schluep et al., 1987) and a predominance of patients have thymic abnormalities, the thymus may be responsible for the initial pathogenesis. It also is the source of autoreactive T-helper cells.

Alzheimer's Disease

A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis, has been observed in patients with progressive dementia of the Alzheimer's type (see Chapter 21). Using a rationale similar to that in other CNS degenerative diseases, therapy for enhancing concentrations of cholinergic and other neurotransmitters in the CNS has been investigated.

In 1993, the U.S. Food and Drug Administration (FDA) approved *tacrine* (tetrahydroaminoacridine) for use in mild-to-moderate Alzheimer's disease, but a high incidence of enhanced alanine aminotransferase and hepatotoxicity limited the utility of this drug.

Subsequently, *donepezil* was approved for clinical use and has emerged as the primary agent for treatment in multiple countries (Lee et al., 2015). Initially, 5-mg doses are administered daily, and if tolerated, doses are increased to 10 mg for mild-to-moderate conditions. Recent clinical trials in moderate-to-severe Alzheimer's disease have confirmed benefits for a 23-mg/day sustained-release form. Most studies are carried out for periods of 24 weeks, although treatment periods have been extended, usually extending the treatment baseline, but without further improvement or some decline after 6 months. Adverse side effects, attributed to excessive peripheral cholinergic stimulation, include nasopharyngitis, diarrhea, nausea, and vomiting. Rhabdomyolysis reportedly occurs, requiring discontinuation of the drug. Co-treatment with *memantine* did not result in significant improvement over the higher-dose *donepezil* treatment (Howard et al., 2012).

Rivastigmine, a more lipid-soluble, longer-acting carbamylating inhibitor, is approved for use in the U.S. and Europe in both oral and skin patch forms. While having similar side effects to other cholinesterase inhibitors, *rivastigmine* is reported to have shown a higher incidence of fatalities than other cholinesterase inhibitors used in Alzheimer's dementias (Ali et al., 2015). It has not been determined whether the increase relates to misuse of the transdermal form of administration. *Galantamine* is another FDA-approved agent for Alzheimer's dementias, acting as a reversible AChE inhibitor with a side effect profile similar to that of *donepezil*.

These three cholinesterase inhibitors, which have the requisite affinity and hydrophobicity to cross the blood-brain barrier and exhibit a prolonged duration of action, along with an excitatory amino acid transmitter mimic, *memantine*, constitute current modes of therapy. These agents are not disease modifying and lack well-documented actions on the pathology of disease. However, the bulk of the evidence indicates that they slow the decline in cognitive function and behavioral manifestation for limited intervals of time (see Chapter 21). Associated symptoms, such as depression, may be preferentially delayed (Lu et al., 2009). Current clinical research efforts are directed to synergistic actions of arresting inflammatory processes or neurodegeneration, combining cholinesterase inhibition with selective cholinergic receptor modulation and agents that affect amyloid precursor protein (APP) and tau (see Chapter 21).

Prophylaxis in Cholinesterase Inhibitor Poisoning

Studies in experimental animals have shown that pretreatment with *pyridostigmine* reduces the incapacitation and mortality associated with nerve agent poisoning, particularly for agents such as soman that show rapid aging. The first large-scale administration of *pyridostigmine* to humans occurred in 1990 in anticipation of nerve agent attack in the first Gulf War. At an oral dose of 30 mg every 8 h, the incidence of side effects was around 1%; fewer than 0.1% of the subjects had responses sufficient to warrant discontinuing the drug in the setting of military action (Keeler et al., 1991). Long-term follow-up indicates that veterans of the Gulf War who received *pyridostigmine* showed a low incidence of a neurological syndrome, now termed the *Persian Gulf War syndrome.* It is characterized by impaired cognition, ataxia, confusion, myoneuropathy, adenopathy, weakness, and incontinence (Haley et al., 1997).

Controversy still surrounds the basis of Gulf War syndrome or illness, despite multiple reports and reviews by the U.S. Department of Veterans Affairs in 2008 and the National Academy of Medicine (Committee on Gulf War and Health Reports, 2013; Institute of Medicine, 2013). Although several origins of the syndrome, such as *pyridostigmine* administration, have been ruled out as unlikely, the constellation of symptoms reflect an interplay of chemical toxicants and psychological factors, encompassing widespread pesticide use and exposure from postwar demolition bombing of munitions facilities likely containing chemical warfare agents (sarin and mustards). Psychological factors, emerging as posttraumatic stress disorders, have been documented in prolonged wars since the early 20th century.

Intoxication by Anticholinergic Drugs

In addition to *atropine* and other muscarinic agents, many other drugs, such as the phenothiazines, antihistamines, and tricyclic antidepressants, have central and peripheral anticholinergic activity. *Physostigmine* is potentially useful in reversing the central anticholinergic syndrome produced by overdosage or an unusual reaction to these drugs (Nilsson, 1982). While the effectiveness of *physostigmine* in reversing anticholinergic side effects has been documented, other toxic effects of the tricyclic antidepressants and phenothiazines (see Chapters 18 and 19), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by *physostigmine*. In addition, *physostigmine* may precipitate seizures; hence, its usually small potential benefit must be weighed against these risks. The use of anti-ChE agents to reverse the effects of competitive neuromuscular blocking agents is discussed in Chapter 13.

Drug Facts for Your Personal Formulary: *Anticholinesterase Agents*

Drugs	Therapeutic Uses	Major Toxicity and Clinical Pearls
Noncovalent Reversible Inhibitors		
Edrophonium Tacrine Donepezil Propidium Fasciculin Galantamine	• Edrophonium can be used to diagnose myasthenia gravis • Tacrine, donepezil, and galantamine used for Alzheimer's disease	• Edrophonium, tacrine, and donepezil bind reversibly to the choline subsite in AChE, sterically blocking ACh entry for catalysis • Edrophonium has a short duration of action because of rapid renal elimination; effects are limited to the peripheral nervous system • Donepezil and tacrine: higher affinity for AChE, more hydrophobic, can cross blood-brain barrier • Tacrine: high incidence of hepatotoxicity • Donepezil binds with higher affinity to the active center gorge of AChE • Propidium and fasciculin: bind peripheral anionic site on AChE
Carbamate Inhibitors		
"Reversible" carbamate inhibitors Physostigmine Neostigmine Pyridostigmine Ambenonium Rivastigmine	• Pyridostigmine, neostigmine, and ambenonium are used for treatment of myasthenia gravis • Neostigmine is used for paralytic ileus and atony of the urinary bladder • Rivastigmine is a very lipid-soluble alternative for treating Alzheimer's disease • Pyridostigmine is used prophylactically for protection in nerve agent attacks	• Drugs with carbamoyl ester linkage: AChE substrates that block by carbamylation of AChE active center serine, are hydrolyzed slowly; regarded as hemi-substrate blockers • Neostigmine and pyridostigmine are poorly absorbed after oral administration • Pyridostigmine is available in sustained-release tablets; oral dose >> parenteral dose • Rivastigmine can cross the blood-brain barrier, has longer duration of action, and is available in oral and epidermal patch formulations

Drug Facts for Your Personal Formulary: *Anticholinesterase Agents (continued)*

Drugs	Therapeutic Uses	Major Toxicity and Clinical Pearls
Carbamate insecticides Carbaryl Propoxur Aldicarb	• Garden insecticides	• Symptoms of poisoning resemble those of organophosphates but are more readily reversed and less toxic
Organophosphates		
Echothiophate	• Treatment of glaucoma	• Instilled locally in the eye • Stable in aqueous solution
Nerve agents DFP Tabun Sarin Soman Cyclosarin VX	• Alkylphosphates are the most potent synthetic toxins: typically methylphosphonates • React covalently with the active site serine • Potent and irreversible inactivators of ChE • Recent documented use in terrorism	• Form a stable conjugate with the active site serine by phosphorylation/phosphonylation • Hydrolyzed by hepatic carboxyesterases and paraoxonases • Low molecular weight, hydrophobic, rapidly penetrate into CNS from pulmonary inhalation of the vapor or aerosol • Tabun, sarin, and cyclosarin are volatile and extremely toxic "nerve agents" • VX is absorbed through the skin, has slower onset, but high toxicity • 2-PAM and related aldoximes are used to reactivate organophosphate-ChE conjugates • Resistance to organophosphate-AChE reactivation is enhanced through "aging" that results from loss of one alkyl group of the conjugated organophosphate
Pesticides Parathion Methylparathion Malathion Diazinon Chlorpyrifos	• Insecticides, largely agricultural • Malathion is used topically in the treatment of pediculosis in cases of permethrin resistance • Lethal dose of malathion in mammals is 1 g/kg • Diazinon and chlorpyrifos are used widely in agriculture; indoor use is discouraged	• Metabolism of these *thion* pesticides to the corresponding *oxon* activates pesticide activity and toxicity; thought to occur more rapidly in insects • Malathion: detoxified by plasma carboxylesterases, a reaction that is more rapid in mammals and birds than insects, yielding a further margin of safety
Antidotal therapy for Organophosphate Exposure		
Cholinesterase reactivators 2-PAM HI-6 Obidoxime	• Quaternary pyridinium aldoxime reactivators indicated for insecticide and nerve agent poisoning • Improved reactivators acting centrally and peripherally are in development	• Reactivates organophosphate-AChE conjugate by attacking the conjugated phosphorus to form phospho-oxime and regenerate the active enzyme • Dose is injected IM with autoinjector; dosing should be repeated frequently • Early treatment helps ensure that the oxime reaches the phosphorylated enzyme prior to complete "aging" • Quaternary reactivators do not cross the blood-brain barrier rapidly to reactivate CNS AChE
Anticholinergic agents Atropine	• Blocks symptoms mediated through muscarinic receptors	• Given parenterally in 2- to 4-mg doses every few minutes until muscarinic symptoms subside (see Chapter 11)
Benzodiazepines Diazepam Midazolam (recent FDA approval)	• Minimize seizures and associated neuronal toxicity	• Administered parenterally after exposure

Ryan E. Hibbs and Alexander C. Zambon

The Nicotinic Acetylcholine Receptor

The nicotinic ACh receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the CNS, it plays a major role in modulating the release of neurotransmitters from presynaptic sites. The receptor is called the *nicotinic ACh receptor* because both the alkaloid nicotine and the neurotransmitter ACh can stimulate the receptor. Distinct subtypes of nicotinic receptors, defined by their subunit composition, exist at the neuromuscular junction (N_m), in autonomic ganglia, and in the CNS (the neuronal form, N_n). The binding of ACh to the nicotinic ACh receptor initiates an EPP in muscle or an EPSP in peripheral ganglia by directly mediating cation influx into the postsynaptic cell (see Chapter 10).

Perspective

Classical studies of the actions of curare and nicotine defined the concept of the nicotinic ACh receptor over a century ago and made this the prototypical pharmacological receptor. By taking advantage of specialized structures that have evolved to mediate cholinergic neurotransmission and natural toxins that block motor activity, nicotinic receptors were isolated and characterized (Changeux and Edelstein, 2005). These accomplishments represent historical landmarks in the development of molecular pharmacology.

Cholinergic neurotransmission mediates motor activity in marine vertebrates and mammals, and a large number of peptide, terpenoid, and alkaloid toxins that block the nicotinic receptors have evolved to enhance predation or protect plant and animal species from predation (Taylor et al., 2007; Tsetlin et al., 2021). Among these toxins are the α-toxins: peptides of about 7 kDa from venoms of the krait, *Bungarus multicinctus*, and varieties of the cobra, *Naja naja*. These toxins potently inhibit neuromuscular transmission, are readily radiolabeled, and provide excellent probes for the nicotinic receptor.

The electrical organs from the aquatic species of *Electrophorus* and *Torpedo* are rich sources of nicotinic receptors; up to 40% of the surface of the electric organ's membrane is excitable and contains cholinergic receptors, in contrast to vertebrate skeletal muscle, in which motor end plates occupy 0.1% or less of the cell surface. Using the α-toxin probes, researchers have purified the receptor from *Torpedo*, isolated the cDNAs of the subunits, and cloned the genes for the multiple receptor subunits from mammalian neurons and muscle (Numa et al., 1983). By simultaneously expressing various permutations of the genes that encode the individual subunits in cellular systems and then measuring binding and the electrophysiological events that result from activation by agonists, researchers have been able to correlate functional properties with details of primary structures of the receptor subtypes (Changeux and Edelstein, 2005; Karlin, 2002; Sine et al., 2008).

Structure of Nicotinic Receptors

The nicotinic receptor shares homology with other pentameric ligand-gated ion channels, which include the $5HT_3$ receptors (Chapter 15) and receptors for the inhibitory amino acids (GABA and glycine; Chapter 16). Each of the subunits in the pentameric receptor has a molecular mass of 40 to 60 kDa. In each subunit, around 210 residues of the amino-terminal constitute a large extracellular domain. This is followed by four domains that span the membrane; the region between TM3 and TM4 forms most of the cytoplasmic component (Figure 13–1, A and B).

In vertebrates, the nicotinic receptors of skeletal muscle N_m are pentamers composed of four distinct subunits (α, β, γ, and δ) in a stoichiometric ratio of 2:1:1:1 (Changeux and Edelstein, 2005; Gharpure et al., 2020; Karlin, 2002) (Figure 13–1C). In mature, innervated muscle end plates, the γ subunit is replaced by ε, a closely related subunit. The individual subunits are about 40% identical in their amino acid sequences. The five subunits of the nicotinic ACh receptor are arranged around a pseudo-axis of symmetry to circumscribe a channel. The resulting receptor is an asymmetrical molecule (16 × 8 nm) of 290 kDa, with the bulk of the non-membrane–spanning domain on the extracellular surface. The receptor is present at high densities (10,000/μm^2) in junctional areas (i.e., the motor end plate in skeletal muscle and the ventral surface of the *Torpedo* electrical organ). Agonist-binding sites occur at the subunit interfaces; in muscle, only two of the five subunit interfaces, αγ and αδ, bind agonists (Figures 13–1 and 13–2). Both of the subunits forming the subunit interface contribute to ligand specificity. Neuronal nicotinic N_n receptors found in ganglia and the CNS also exist as pentamers of one or more types of subunits. Subunit types α_2 through α_{10} and β_2 through β_4 are found in neuronal tissues. Although not all pentameric combinations of α and β subunits lead to functional receptors, the diversity in subunit composition is large and exceeds the capacity of ligands to distinguish subtypes on the basis of their selectivity.

Agonist-mediated changes in ion permeability occur through a cation channel intrinsic to the receptor structure. Measurements of membrane conductance demonstrate rates of ion translocation of 5×10^7 ions/sec. The channel is generally nonselective among cations; while highly permeable to Na^+, K^+, and in some cases Ca^{2+}, the majority of the current is carried by

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
anti-ChE: anticholinesterase
AUC: area under the curve
CNS: central nervous system
EPP: end-plate potential
EPSP: excitatory postsynaptic potential
FDA: Food and Drug Administration
GABA: γ-aminobutyric acid
GI: gastrointestinal
5HT: 5-hydroxytryptamine (serotonin)
IPSP: inhibitory postsynaptic potential
MAO: monoamine oxidase
M_x: muscarinic receptor subtype x (x = 1, 2, 3, 4, or 5)
N_m: nicotinic ACh receptor in skeletal muscle
N_n: nicotinic ACh receptor in neurons
NRT: nicotine replacement therapy
SIF: small, intensely fluorescent
TM: transmembrane
VMAT2: vesicular monoamine transporter 2

Na^+ ions (see Figure 13–2). The channel is lined by the five TM_2 α-helices of the channel subunits. The agonist-binding site is intimately coupled with the ion channel; in the N_m, simultaneous binding of two agonist molecules results in a rapid conformational change that opens the channel.

HISTORY Curare

In the mid-19th century, Claude Bernard demonstrated that the locus of action of curare was at or near the neuromuscular junction. Curare is a generic term for various South American arrow poisons. The drug has been used for centuries by Indians along the Amazon and Orinoco Rivers for immobilizing and paralyzing wild animals used for food; death results from paralysis of skeletal muscles. The preparation of curare was long shrouded in mystery and was entrusted only to tribal shamans. Soon after Europeans invaded South American, European explorers and botanists became interested in curare, and late in the 16th century, samples of the native preparations were brought to Europe. Following the pioneering work of scientist/explorer von Humboldt in 1805, the botanical sources of curare became the object of much field research. The curares from eastern Amazonia come from *Strychnos* species, which contain chiefly quaternary neuromuscular blocking alkaloids. The Asiatic, African, and Australian species nearly all contain tertiary strychnine-like alkaloids.

In the mid-19th century, Claude Bernard showed that the locus of curare's action was at or near the neuromuscular junction. Research on curare accelerated when Gill, after prolonged and intimate study of the native methods of preparing curare, brought to the U.S. a sufficient amount of the authentic drug to permit chemical and pharmacological investigations. The modern clinical use of curare apparently dates from 1932, when West employed highly purified fractions in patients with tetanus and spastic disorders. King established the essential structure of tubocurarine in 1935 (see Figure 13–3). Griffith and Johnson reported the first trial of curare for promoting muscular relaxation in general anesthesia in 1942.

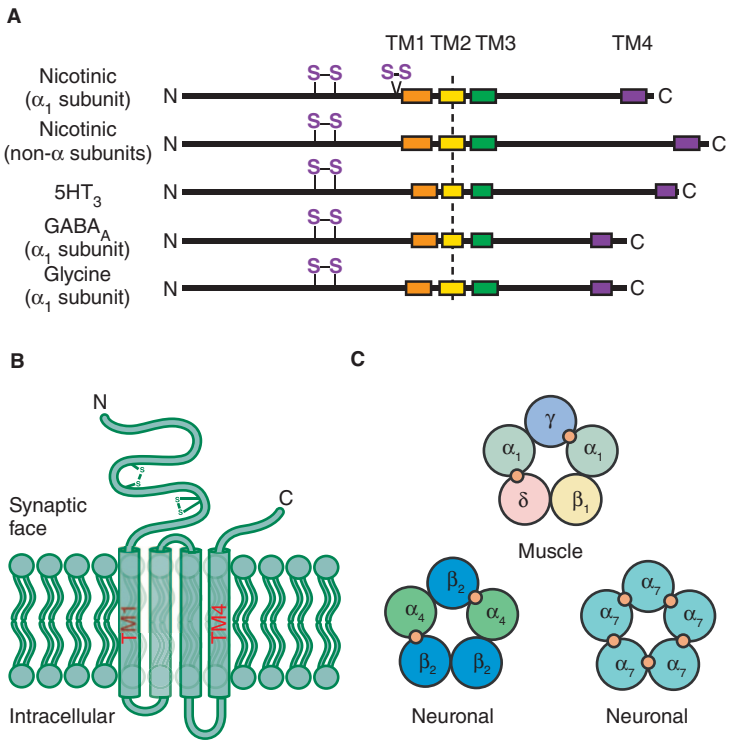

Figure 13–1 *Subunit organization of pentameric ligand-gated ion channels; nicotinic receptor subunit assembly.* **A.** Ligand-gated channels responding to ACh, 5HT, GABA and glycine share a common pentameric architecture. In each subunit, the amino (N)-terminal region of approximately 210 amino acids is found at the extracellular surface. This large extracellular region is followed by the four hydrophobic membrane-spanning regions (TM1 -TM4), leaving the small carboxyl (C) terminus on the extracellular surface. The TM2 region is α-helical, and TM2 regions from each subunit of the pentameric receptor line the internal pore of the receptor. Two disulfide loops at positions 128 to 142 and 192 to 193 are found in the α subunit of the nicotinic receptor. The 128 to 142 motif is conserved in the superfamily of pentameric receptors, whereas the vicinal cysteines at 192 and 193 distinguish α subunits from non-α subunits in the nicotinic receptor. **B.** This diagram illustrates the membrane topology for one of the five subunits of the nicotinic ACh receptor and depicts the regions shown in Panel A. **C.** These transverse sections show representative pentamers for muscle and neuronal nicotinic ACh receptors. Agonist binding sites (small red circles) occur at α subunit-containing interfaces. A total of 16 functional receptor isoforms have been observed in mammals, with different ligand specificities, relative Na^+/ Ca^{2+} permeabilities, and physiological functions as determined by their subunit composition. The only isoform found at the neuromuscular junction is the one shown here, with the caveat that an ε subunit replaces γ in mature muscle. The receptor isoforms found at autonomic ganglia and in the CNS are homo- and hetero-pentamers of α (α_{2-7} and α_{9-10}) and β (β_{2-4}) subunits.

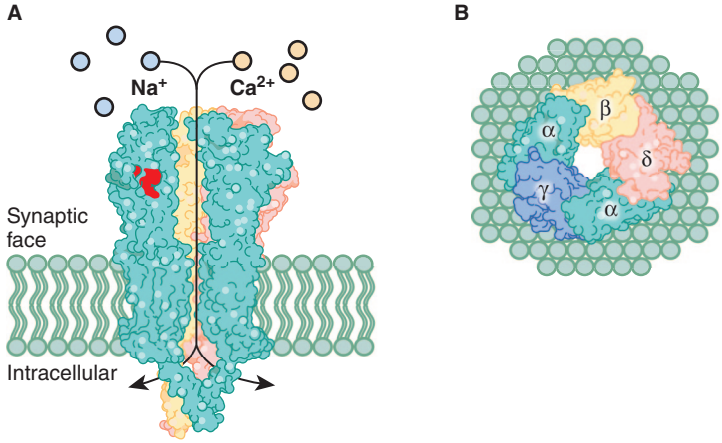

Figure 13–2 *Molecular structure of the nicotinic ACh receptor.* **A.** Longitudinal view of muscle receptor structure recently determined by electron microscopy, with the γ subunit removed (Rahman et al., 2020). The remaining subunits, two copies of α, one of β, and one of δ, are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α-helices form the perimeter of the channel and come from the TM2 region of the linear sequence (Figure 13–1). ACh-binding sites, indicated by red surface, occur at the αγ and αδ (not visible) interfaces. **B.** Muscle nicotinic receptor structure viewed from perspective of neuromuscular junction. Intrinsic channel is down the central axis defined by the pseudosymmetric arrangement of receptor subunits.

Transmission at the Neuromuscular Junction

Neuromuscular Blocking Agents

Modern-day neuromuscular blocking agents fall generally into two classes, depolarizing and competitive/nondepolarizing. At present, only a single depolarizing agent, *succinylcholine*, is in general clinical use; multiple competitive or nondepolarizing agents are available (Figure 13–3). Neuromuscular blocking agents are most commonly used for facilitating endotracheal intubation and to relax skeletal muscle during surgery.

Chemistry

Early structure-activity studies led to the development of the polymethylene bis-trimethyl-ammonium series (referred to as the methonium compounds, or depolarizing blockers). The most potent of these agents at the neuromuscular junction was the compound with 10 carbon atoms between the quaternary nitrogens: *decamethonium* (see Figure 13–3). The compound with 6 carbon atoms in the chain, *hexamethonium*, was found to be essentially devoid of neuromuscular blocking activity but particularly effective as a ganglionic blocking agent (see following discussion).

Several structural features distinguish competitive and depolarizing neuromuscular blocking agents. The competitive agents (e.g., *tubocurarine*, the benzylisoquinolines, the amino steroids, and the asymmetric mixed-onium chlorofumarates) are relatively bulky, rigid molecules, whereas the depolarizing agents (e.g., *decamethonium* [no longer marketed in the U.S.] and *succinylcholine*) generally have more flexible structures that enable free bond rotations.

Mechanism of Action

Competitive antagonists bind the N_m and thereby competitively block the binding of ACh. The depolarizing agents, such as *succinylcholine*, depolarize the membrane by opening channels in the same manner as ACh. However, they persist longer at the neuromuscular junction primarily because of their resistance to AChE. The depolarization is thus longer lasting, resulting in a brief period of repetitive excitation that may elicit transient and repetitive muscle excitation (fasciculations), followed by blocking of neuromuscular transmission and flaccid paralysis (called *phase I block*). The block arises because, after an initial opening, perijunctional Na^+ channels close and will not reopen until the end plate is repolarized. At this point, neural release of ACh results in the binding of ACh to receptors on an already-depolarized end plate. These closed perijunctional channels keep the depolarization signal from affecting downstream channels and effectively shield the rest of the muscle from activity at the motor end plate. This sequence is influenced by such factors as the anesthetic agent used concurrently, the type of muscle, and the rate of drug administration. The characteristics of depolarization and competitive blockade are contrasted in Table 13–1.

Under clinical conditions, with increasing concentrations of *succinylcholine* and over time, the block may convert slowly from a depolarizing phase I block to a nondepolarizing *phase II block* (Durant and Katz, 1982). While the response to peripheral stimulation during phase II block resembles that of the competitive agents, reversal of phase II block by administration of anti-AChE agents (e.g., with *neostigmine*) is difficult to predict and should be undertaken cautiously. Table 13–2 summarizes the characteristics of phase I and phase II blocks.

Many drugs and toxins block neuromuscular transmission by other mechanisms, such as interference with the synthesis or release of ACh (see Figure 10–6), but most of these agents are not employed clinically for neuromuscular blockade. One exception is the group of botulinum toxins, which are administered locally into muscles of the orbit in the management of ocular blepharospasm and strabismus and have been used to control other muscle spasms and to facilitate facial muscle relaxation (see Table 10–7 and Chapter 74). This toxin also has been injected into the lower esophageal sphincter to treat achalasia (Chapter 54). Botulinum toxins are discussed in detail in the later Spasmolytics section. The sites of action and interrelationship of several agents that serve as pharmacological tools are shown in Figure 13–4.

Sequence and Characteristics of Paralysis

Following intravenous injection of an appropriate dose of a *competitive blocking agent*, motor weakness progresses to total flaccid paralysis. Small, rapidly moving muscles such as those of the eyes, jaw, and larynx relax before those of the limbs and trunk. Ultimately, the intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function (Brull and Meistelman, 2020).

After a single intravenous dose (10–30 mg) of the *depolarizing blocking agent succinylcholine*, muscle fasciculations, particularly over the chest and abdomen, occur briefly; then, relaxation occurs within 1 min, becomes maximal within 2 min, and generally disappears within 5 min. Transient apnea usually occurs at the time of maximal effect. Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its efficient hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine.

During prolonged depolarization, muscle cells may lose significant quantities of K^+ and gain Na^+, Cl^-, and Ca^{2+}. In patients with extensive injury to soft tissues, the efflux of K^+ following continued administration of *succinylcholine* can be life-threatening. There are many conditions for which *succinylcholine* administration is contraindicated or should be undertaken with great caution. The change in the nature of the blockade produced by *succinylcholine* (from phase I to phase II) presents an additional complication with long-term infusions.

Effects in CNS and at Ganglia

Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood-brain barrier.

Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Ganglionic blockade by *tubocurarine* and other stabilizing drugs is reversed or antagonized by anti-ChE agents (e.g., *edrophonium, neostigmine, pyridostigmine*).

Clinical doses of *tubocurarine* produce partial blockade both at autonomic ganglia and at the adrenal medulla, resulting in a fall in blood pressure and tachycardia. *Pancuronium* shows less ganglionic blockade at common clinical doses. *Atracurium, vecuronium, doxacurium, pipecuronium, mivacurium*, and *rocuronium* are even more selective, showing less ganglionic blockade (Brull and Meistelman, 2020). The maintenance of cardiovascular reflex responses usually is desired during anesthesia. *Pancuronium* has a vagolytic action, presumably from blockade of muscarinic receptors, which leads to tachycardia.

TABLE 13–1 ■ COMPARISON OF COMPETITIVE (D-TUBOCURARINE) AND DEPOLARIZING (DECAMETHONIUM) BLOCKING AGENTS

	D-TUBOCURARINE	DECAMETHONIUM
Effect of D-tubocurarine administered previously	Additive	Antagonistic
Effect of decamethonium administered previously	No effect or antagonistic	Some tachyphylaxis, but may be additive
Effect of anticholinesterase agents on block	Reversal of block	No reversal
Effect on motor end plate	Elevated threshold to acetylcholine; no depolarization	Partial, persisting depolarization
Initial excitatory effect on striated muscle	None	Transient fasciculations
Character of muscle response to indirect tetanic stimulation during *partial* block	Poorly sustained contraction	Well-sustained contraction

TABLE 13–2 ■ CLINICAL RESPONSES AND MONITORING OF PHASE I AND PHASE II NEUROMUSCULAR BLOCKADE BY SUCCINYLCHOLINE INFUSION

RESPONSE	PHASE I	PHASE II
End-plate membrane potential	Depolarized to –55 mV	Repolarization toward –80 mV
Onset	Immediate	Slow transition
Dose dependence	Lower	Usually higher or follows prolonged infusion
Recovery	Rapid	More prolonged
Train of four and tetanic stimulation	No fade	Fade[a]
Acetylcholinesterase inhibition	Augments	Reverses or antagonizes
Muscle response	Fasciculations → flaccid paralysis	Flaccid paralysis

[a]Posttetanic potentiation follows fade.

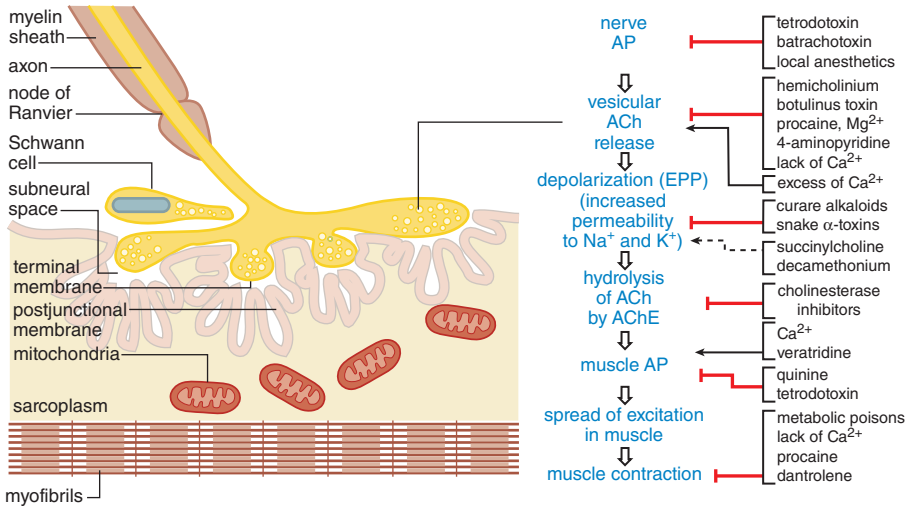

Figure 13–4 *A pharmacologist's view of the motor end plate.* The structures of the motor end plate (left side of figure) facilitate the series of physiological events leading from nerve action potential (AP) to skeletal muscle contraction (center column). Pharmacological agents can modify neurotransmission and excitation-contraction coupling at myriad sites (right-hand column). ⟵, enhancement; ⟝, blockade; ⟵ - - -, depolarization and phase II block.

Of the depolarizing agents, *succinylcholine* at doses producing neuromuscular relaxation rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

ADME

Quaternary ammonium neuromuscular blocking agents are poorly absorbed from the GI tract. Absorption is adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents must be given in lower concentrations, and diffusional requirements slow their rate of onset.

When long-acting competitive blocking agents such as *D-tubocurarine* and *pancuronium* are administered, blockade may diminish after 30 min owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution *as tissues become saturated*. Long-acting agents may accumulate with multiple doses.

The amino steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about one-half the activity of the parent compound and contribute to the total relaxation profile. Amino steroids of intermediate duration of action, such as *vecuronium* and *rocuronium* (Table 13–3), are cleared more rapidly by the liver than is *pancuronium*. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long-duration neuromuscular blocking agent.

Atracurium is converted to less-active metabolites by plasma esterases and by spontaneous degradation in plasma and tissue (Hofmann elimination). *Cisatracurium* is also subject to this spontaneous degradation. Because of these alternative routes of metabolism, *atracurium* and *cisatracurium* do not exhibit an increased $t_{1/2}$ of elimination in patients with impaired renal function and therefore are good choices in this setting (Brull and Meistelman, 2020; Fisher et al., 1986).

The extremely brief duration of action of *succinylcholine* is due largely to its rapid hydrolysis by the butyrylcholinesterase synthesized by the liver and found in the plasma. Among the occasional patients who exhibit prolonged apnea following the administration of *succinylcholine* or *mivacurium*, most have an atypical plasma cholinesterase owing to allelic variations such as the Asp70Gly polymorphism, which can prolong recovery 3 to 8 times longer for heterozygous individuals and up to 60 times longer for homozygous individuals. Additionally, hepatic or renal disease or a nutritional disturbance can also delay recovery (Brull and Meistelman, 2020).

Gantacurium is degraded by two chemical mechanisms, a rapid cysteine adduction and a slower hydrolysis of the ester bond adjacent to the chlorine. Both processes are purely chemical and hence not dependent on enzymatic activities. The adduction process has a $t_{1/2}$ of 1 to 2 min and is likely the basis for the ultrashort duration of action of gantacurium. Administration of exogenous cysteine, which may have excitotoxic side effects, can accelerate the antagonism of gantacurium-induced neuromuscular blockade (Naguib and Brull, 2009).

Clinical Pharmacology

Choice of Agent

Therapeutic selection of a neuromuscular blocking agent should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other side effects, with attention to drug-specific modes of elimination in patients with renal or hepatic failure (see Drug Facts Table).

Two characteristics are useful in distinguishing side effects and pharmacokinetic behavior of neuromuscular blocking agents:

- ***The chemical nature of the agents (Figure 13–3 and Table 13–3).*** Apart from a shorter duration of action, newer agents exhibit greatly diminished frequency of side effects, chiefly ganglionic blockade, block of vagal responses, and histamine release.

TABLE 13–3 ■ NEUROMUSCULAR BLOCKING AGENTS

AGENT Chemical Class *Type of action*	ONSET (min)[a]	DURATION (min)[a]	MODE OF ELIMINATION
Ultrashort and short duration			
Succinylcholine DCE, *depolarizing*	0.8–1.4	6–11	Hydrolysis by plasma cholinesterases
Gantacurium[c] MOCF, *competitive*	1–2	5–10	Cysteine adduction, ester hydrolysis
Mivacurium BIQ, *competitive*	2–3	15–21	Hydrolysis by plasma cholinesterases
Intermediate duration			
Vecuronium AS, *competitive*	2–3	25–40	Hepatic and renal elimination
Atracurium BIQ, *competitive*	3	45	Hofmann elimination; ester hydrolysis
Rocuronium AS, *competitive*	0.5–2	36–73	Hepatic elimination
Cisatracurium BIQ, *competitive*	2–8	45–90	Hofmann elimination; renal elimination
Long duration			
Pipecuronium[b] AS, *competitive*	3–6	30–90	Renal elimination; hepatic metabolism/clearance
D-Tubocurarine[b] CBI, *competitive*	6	80	Renal and hepatic elimination
Pancuronium AS, *competitive*	3–4	85–100	Renal and hepatic elimination
Metocurine[b] BIQ, *competitive*	4	110	Renal elimination
Doxacurium[b] BIQ, *competitive*	4–8	120	Renal elimination

[a]As achieved from dose ranges in Table 11–4.
[b]Not commercially available in the U.S.
[c]Gantacurium is in investigational status.
Abbreviations: AS, aminosteroid; BIQ, benzylisoquinoline; CBI (natural alkaloid), cyclic benzylisoquinoline; DCE, dicholine ester; MOCF, assymetric mixed-onium chlorofumarate.

- ***Duration of drug action.*** These agents are categorized as long-, intermediate-, short-, or ultrashort-acting agents. Often, the long-acting agents are the more potent, requiring the use of low doses (Table 13–4). The necessity of administering potent agents at low concentrations delays their onset.

The prototypical amino steroid *pancuronium* induces virtually no histamine release; however, it blocks muscarinic receptors, an antagonism manifested primarily by vagal blockade and tachycardia. Tachycardia is eliminated in the newer amino steroids *vecuronium* and *rocuronium*. The benzylisoquinolines appear to be devoid of vagolytic and ganglionic blocking actions but show a slight propensity to cause histamine release. The unusual metabolism of the prototype compound *atracurium* and its congener *mivacurium* confers special indications for use of these compounds. For example, *atracurium*'s disappearance from the body depends on hydrolysis of the ester moiety by plasma esterases and by a spontaneous or Hofmann degradation (cleavage of the *N*-alkyl portion in the benzylisoquinoline). Hence, two routes for termination of effect are available, both of which remain functional in renal failure. *Mivacurium* is extremely sensitive to catalysis by cholinesterase or other plasma

TABLE 13–4 ■ DOSING RANGES FOR NEUROMUSCULAR BLOCKING AGENTS

AGENT	INITIATION DOSE (mg/kg)	INTERMITTENT INJECTION (mg/kg)	CONTINUOUS INFUSION (μg/kg/min)
Succinylcholine	0.3–1	0.04–0.07	N/A
D-Tubocurarine[a]	0.6	0.25–0.5	2–3
Metocurine[a]	0.4	0.5–1	N/A
Atracurium	0.3–0.5	0.08–0.2	2–15
Cisatracurium	0.15–0.2	0.03	1–3
Mivacurium	0.15–0.25	0.1	9–10
Doxacurium[a]	0.03–0.06	0.005–0.01	N/A
Pancuronium	0.04–0.1	0.01	1[b]
Rocuronium	0.45–1.2	0.1–0.2	10–12
Vecuronium	0.04–0.28	0.01–0.015	0.8–1.2
Gantacurium[a]	0.2–0.5	N/A	N/A

[a]Not commercially available in the U.S.
[b]Off-label use.

hydrolases, accounting for its short duration of action. Side effects are not yet fully characterized for *gantacurium*, but transient adverse cardiovascular effects suggestive of histamine release have been observed at doses over three times the ED_{95} (Belmont et al., 2004).

Muscle Relaxation

The main clinical use of the neuromuscular blocking agents is as an adjuvant in surgical anesthesia to obtain relaxation of skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations. With muscle relaxation no longer dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices. Thus, the risk of respiratory and cardiovascular depression is minimized, and postanesthetic recovery is shortened. Neuromuscular blocking agents of short duration often are used to facilitate endotracheal intubation and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent. Neuromuscular blocking agents are administered parenterally, nearly always intravenously. These agents may be administered by continuous infusion in the intensive care setting for improving chest wall compliance and eliminating ventilator dyssynchrony.

Measurement of Neuromuscular Blockade in Humans

Assessment of neuromuscular block is usually performed by stimulation of the ulnar nerve. Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission. Rates of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation.

Preventing Trauma During Electroshock Therapy

Electroconvulsive therapy of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents, usually *succinylcholine*, and a short-acting barbiturate, usually *methohexital*, are employed.

Synergisms and Antagonisms

The comparison of interactions between competitive and depolarizing neuromuscular blocking agents is instructive (Table 13–1) and a good test of one's understanding of the drugs' actions. In addition, many other drugs affect transmission at the neuromuscular junction and thus can affect the choice and dosage of neuromuscular blocking agent used.

Because the anti-ChE agents *neostigmine, pyridostigmine*, and *edrophonium* preserve endogenous ACh and also act at the neuromuscular junction, they have been used in the treatment of overdosage with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ *neostigmine* or *edrophonium* to reverse and decrease the duration of competitive neuromuscular blockade. A muscarinic antagonist (*atropine* or *glycopyrrolate*) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid bradycardia. Anti-ChE agents will not reverse depolarizing neuromuscular blockade; instead, they enhance it.

Many inhalational anesthetics exert a stabilizing effect on the postjunctional membrane and therefore potentiate the activity of competitive blocking agents. Consequently, when such blocking drugs are used for muscle relaxation as adjuncts to these anesthetics, their doses should be reduced. The rank order of potentiation is *desflurane* > *sevoflurane* > *isoflurane* > *halothane* > nitrous oxide-barbiturate-opioid or *propofol* anesthesia (Brull and Meistelman, 2020).

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca^{2+}) and to a lesser extent by noncompetitively blocking the receptor. The blockade is antagonized by Ca^{2+} salts but only inconsistently by anti-ChE agents (see Chapter 59). The tetracyclines also can produce neuromuscular blockade, possibly by chelation of Ca^{2+}. Additional antibiotics that have neuromuscular blocking action, through both presynaptic and postsynaptic actions, include *polymyxin B, colistin, clindamycin*, and *lincomycin*. Ca^{2+} channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include *trimethaphan*, *lithium*, opioid analgesics, *procaine*, *lidocaine*, *quinidine*, *phenelzine*, *carbamazepine*, *phenytoin*, *propranolol*, *dantrolene*, *azathioprine*, *tamoxifen*, magnesium salts, corticosteroids, digitalis glycosides, *chloroquine*, catecholamines, and diuretics.

Adverse Effects

The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and, rarely, anaphylaxis. Related factors may include alterations in body temperature; electrolyte imbalance, particularly of K^+; low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of *succinylcholine*; the presence of latent myasthenia gravis or of malignant disease such as small cell carcinoma of the lung with Eaton-Lambert myasthenic syndrome; reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to hepatic dysfunction (*cisatracurium, rocuronium, vecuronium*) or reduced renal function (*pancuronium*). Great care should be taken when administering neuromuscular blockers to dehydrated or severely ill patients. Depolarizing agents can cause rapid release of K^+ from intracellular sites; this may be a factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance. *Succinylcholine*-induced hyperkalemia is a life-threatening complication of that drug.

Malignant Hyperthermia. Malignant hyperthermia is a potentially life-threatening event triggered by the administration of certain anesthetics and neuromuscular blocking agents. The clinical features include contracture, rigidity, and heat production from skeletal muscle, resulting in severe hyperthermia (increases of up to 1°C/5 min), accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca^{2+} from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (e.g., *halothane, isoflurane*, and *sevoflurane*) and *succinylcholine* alone have been reported to precipitate the response, most of the incidents arise

from the combination of depolarizing blocking agent and anesthetic. Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies, such as *central core disease*. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Treatment entails intravenous administration of *dantrolene*, which blocks Ca^{2+} release from the sarcoplasmic reticulum of skeletal muscle (see section on antispasmodics below). Rapid cooling, inhalation of 100% O_2, and control of acidosis should be considered adjunct therapy in malignant hyperthermia.

Respiratory Paralysis. Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent should be by positive-pressure artificial respiration with O_2 and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of *neostigmine methylsulfate* (0.5–2 mg IV) or *edrophonium* (10 mg IV, repeated as required up to a total of 40 mg) (Watkins, 1994). In the case of overdose, a muscarinic cholinergic antagonist (*atropine* or *glycopyrrolate*) may be added to prevent undue slowing of the heart (see Synergisms and Antagonisms).

Histamine Release From Mast Cells. Some clinical responses to neuromuscular blocking agents (e.g., bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. *Succinylcholine*, *mivacurium*, and *atracurium* cause histamine release, but to a lesser extent than *tubocurarine* unless administered rapidly. The amino steroids *pancuronium*, *vecuronium*, *pipecuronium*, and *rocuronium* have even less tendency to release histamine after intradermal or systemic injection (Basta, 1992; Watkins, 1994). Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than anaphylaxis mediated by immunoglobulin E.

Interventional Strategies for Toxic Effects

Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate such side effects as hypotension or induce bronchospasm. In such circumstances, sympathomimetic amines may be given to support the blood pressure. *Atropine* or *glycopyrrolate* is administered to counteract muscarinic stimulation. Antihistamines are beneficial to counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

Reversal of Effects by Chelation Therapy. *Sugammadex*, a modified γ-cyclodextrin, is a chelating agent specific for *rocuronium* and *vecuronium*. *Sugammadex* at doses greater than 2 mg/kg is able to reverse neuromuscular blockade from *rocuronium* within 3 min. *Sugammadex* clearance is markedly reduced in patients with impaired renal function, and use of this agent should be avoided. *Sugammadex* was approved for use in the U.S. in 2015. Side effects include dysgeusia and rare hypersensitivity.

Pediatric and Geriatric Indications and Problems

Because the neuromuscular junction is not fully developed at birth, additional care must be taken in administration of neuromuscular blocking agents to infants and children. *Succinylcholine* is not safe for routine use in pediatric patients, and its use must be reserved for extreme emergency situations where immediate securing of the airway is necessary and other options for neuromuscular blockade are not available. Competitive blocking agents, however, are commonly used in pediatric patients; generally, dosage is similar to adults, but both rate of block onset and clearance are faster. *Atracurium* is an exception: The dosage and duration of action are not significantly different between children older than 2 years and adults, and the same dose (0.25–0.5 mg/kg) can be used among these populations for tracheal intubation. *Vecuronium, cisatracurium, rocuronium*, and *mivacurium* are also commonly administered to children for short procedures where only a single intubating dose is required.

There are normal changes at the neuromuscular junction in elderly patients that may affect pharmacodynamics of neuromuscular blocking agents. With aging, the distance between the terminus of the motor neuron and the end plate increases, the end-plate invaginations become flatter, the amount of transmitter per synaptic vesicle decreases, the vesicle release probability is lower, and the density of receptors at the end plate decreases. The result of these changes is decreased efficiency of neuromuscular transmission. General physiological changes in aging patients, including decreases in body water and muscle, increases in total body fat, and decreases in renal and hepatic function, also contribute to the action of neuromuscular blockers. The dosing of *succinylcholine* is not significantly altered in the geriatric population. Among the competitive blocking agents, initial dose requirements are unchanged; however, the onset of blockade is delayed in an age-related manner, and block is prolonged. For compounds dependent on the kidney, liver, or both for clearance, such as *pancuronium, vecuronium*, and *rocuronium*, plasma clearance times are prolonged by 30% to 50% (Brull and Meistelman, 2020). For compounds such as *atracurium* that are not dependent on hepatic or renal blood flow for their elimination, pharmacodynamics and kinetics are largely unaltered.

Spasmolytics

Centrally Acting Spasmolytics

A variety of clinical manifestations, such as spinal cord injury, stroke, and multiple sclerosis, can cause lesions that disrupt the normal somatic control of skeletal muscle, resulting in muscle spasms, repetitive and uncontrolled contractions of skeletal muscle that are involuntary. The underlying mechanism is the hyperexcitability of the alpha motor neurons in the spinal cord. Spasmolytics are agents that act in the brain and higher centers of the spinal cord to reduce spasms, with the objective of increasing functional capacity and relieving discomfort. Unfortunately, due to significant adverse effects, many of these therapeutic agents are recommended for short-term use only. These orally administered agents include *baclofen*, several anticonvulsants/hypnotics/sedatives (benzodiazepines and *gabapentin*), α_2 adrenergic agonists (*clonidine* and *tizanidine*), and *cyclobenzaprine*.

Baclofen

Baclofen is an orally effective $GABA_B$ receptor agonist that suppresses neurotransmission by multiple mechanisms in both the brain and spinal cord. *Baclofen* acts at pre- and postsynaptic sites to cause membrane hyperpolarization, thereby reducing the probability of membrane depolarization and thus the Ca^{2+} influx necessary to induce release of excitatory transmitter release and inhibiting spinal reflexes.

Benzodiazepines and Gabapentin

Diazepam and other benzodiazepines are effective in treating muscle rigidity but are limited in utility due to high abuse potential and substantial CNS depressant effects. A prominent effect of benzodiazepines is enhancing GABAergic neurotransmission, resulting in enhanced inhibitory signaling in GABA-sensitive synapses.

Gabapentin, a cyclic analogue of GABA (GABA liganded to cyclohexane), interacts not with the GABA receptor but reportedly with two membrane proteins involved in excitation-response coupling: the α_2-δ subunit of Ca_V, the voltage-gated Ca^{2+} channel (Gee et al., 1996), and the voltage-gated K^+ channels KCNQ2/3 (the molecular correlate of neuronal M-currents) and homomeric KCNQ3 and KCNQ5 (Manville and Abbott, 2018). The proposed responses to *gabapentin*'s binding at these sites are the reduction of neuronal Ca^{2+} currents (via interaction with Ca_V) and activation of KCNQ2/3 and homomeric KCNQ3 and KCNQ5 channels, leading to hyperpolarization of susceptible neurons, with concomitant reduction in excitability.

Chapter 22 describes the pharmacology of *diazepam* and other benzodiazepines in detail. Chapter 20 describes the use of both benzodiazepines and *gabapentin* as antiseizure drugs.

α_2 Adrenergic Agonists

Tizanidine is an α_2 adrenergic receptor agonist. It provides effective relief from spasticity due to multiple sclerosis and spinal cord injury. Although

a precise mechanism of action in relieving spasms is not understood, *tizanidine* is thought to have actions similar to those of *clonidine*. The advantage of *tizanidine* over *clonidine* for this indication is *tizanidine*'s lesser effect on lowering blood pressure at an effective concentration to relieve spasm. *Tizanidine* has a short $t_{1/2}$ and is taken at a dose of 2 mg every 6 h for up to three doses daily; the dosage can be gradually ramped up to a daily maximum of 36 mg. In reverse fashion, the drug must be withdrawn slowly, tapering by 2 to 4 mg daily, to avoid a rebound of spasms, tachycardia, and hypertension. Common side effects include dizziness, sedation, and dry mouth. Use of *tizanidine* with a potent CYP1A2 inhibitor (e.g., *fluvoxamine*, *ciprofloxacin*, *cimetidine*) can substantially elevate *tizanidine*'s AUC. *Tizanidine* can interact additively with CNS depressants; its combination with ethanol should be avoided; antibiotics, antiarrhythmics, and hypotensive agents should be used with caution.

Cyclobenzaprine

Cyclobenzaprine is pharmacologically related to tricyclic antidepressants. It can be used for short-term reduction of painful muscle spasms such as those resulting from an acute peripheral injury. It is not useful for spasms resulting from neurological conditions of central origin. *Cyclobenzaprine* acts centrally by a mechanism of action likely related to its activity as a $5HT_2$ receptor antagonist. The drug is administered by mouth, 5 mg three times daily, scheduled or as needed, with one of the doses administered at bedtime, for a duration of only 2 weeks. This agent should not be given concomitantly with MAO inhibitors and should be used with caution with inhibitors of 5HT uptake. *Cyclobenzaprine* can interact with most CNS depressants.

Peripherally Acting Antispasmodics

Botulinum Toxin

Botulinum toxins act peripherally to reduce muscle contraction. There are numerous nonequivalent preparations: *abobotulinumtoxinA, incobotulinumtoxinA, onabotulinumtoxinA, prabotulinumtoxinA-xvfs*, and *rimabotulinumtoxinB*; all work by blocking ACh release. The botulinum toxins bind to cholinergic neurons, enter the cell, and cleave SNARE proteins, thereby inhibiting vesicular release of ACh. The result is flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3 to 4 months, and restoration of function requires nerve sprouting.

Originally approved for the treatment of the ocular conditions of strabismus and blepharospasm and for hemifacial spasms, botulinum toxins have been used to treat spasms and dystonias and spasms associated with the lower esophageal sphincter and anal fissures. Botulinum toxin treatments also have become a popular cosmetic procedure for those seeking a wrinkle-free face. Like the bloom of youth, the reduction of wrinkles is temporary; unlike the bloom of youth, the effect of botulinum toxin can be renewed by readministration.

Botulinum toxins are extremely poisonous and must be administered with great caution. Lethal doses of pure toxin are, roughly, approximately 1 ng/kg when administered IM or IV, approximately 10 ng/kg when inhaled, and approximately 1000 ng/kg when ingested (Arnon et al., 2001). The FDA requires a boxed warning on preparations of botulinum toxin, alerting practitioners and patients to the risk of respiratory paralysis from unexpected spread of the toxin from the site of injection (uses are described in Chapter 75). The FDA requires the highly specific names of the various products to emphasize that different preparations of botulinum toxin are not interchangeable; that is, different preparations' units of biological activity cannot safely be compared. Patients showing signs of botulism should be treated promptly with antitoxin and given long-term supportive therapy.

Dantrolene

Dantrolene inhibits Ca^{2+} release from the sarcoplasmic reticulum of skeletal muscle by limiting the capacity of Ca^{2+} and calmodulin to activate the ryanodine receptor, RYR1. *Dantrolene* is indicated for chronic muscle spasticity associated with upper motor neuron disorders (spinal cord injury, stroke, cerebral palsy, or multiple sclerosis). *Dantrolene* is initiated at 25 mg daily for 7 days and then titrated up every 7 days up to a maximum dose of 400 mg/day. It is also indicated for malignant hyperthermia and used off-label for neuroleptic malignant syndrome. With its peripheral action, it causes generalized weakness. Thus, its use should be reserved to nonambulatory patients with severe spasticity. Hepatotoxicity has been reported with chronic use, requiring frequent liver function tests and use of the lowest possible oral dose.

Miscellaneous Agents

A number of other agents used as muscle relaxants seem to rely on sedative properties and blockade of nociceptive pathways; this group includes *carisoprodol*, which is metabolized to meprobamate (see Chapter 22); *metaxalone*; *methocarbamol*; and *orphenadrine*. *Tetrabenazine* is available for treatment of the chorea associated with Huntington's disease; the drug inhibits VMAT2, resulting in depletion of vesicular stores of dopamine in dopaminergic neurons in the CNS (see Chapters 10, 15, and 16).

Ganglionic Neurotransmission

The Neural Nicotinic Receptor and Postsynaptic Potentials

Neurotransmission in autonomic ganglia involves release of ACh by preganglionic fibers and the rapid depolarization of postsynaptic membranes via the activation of neuronal nicotinic (N_n) receptors by ACh. Unlike the neuromuscular junction, ganglia do not have discrete end plates with focal localization of receptors; rather, the dendrites and nerve cell bodies contain the receptors. The characteristics of nicotinic receptor channels of the ganglia and the neuromuscular junction are similar. There are multiple nicotinic receptor subunits (e.g., α_3, α_5, α_7, β_2, and β_4) in ganglia, with α3 and β4 most abundant and important. The ganglionic nicotinic ACh receptors are sensitive to classical blocking agents such as *hexamethonium* and *trimethaphan* (see discussion that follows). Measurements of single-channel conductance indicate that the characteristics of nicotinic receptor channels of the ganglia and the neuromuscular junction are similar.

Intracellular recordings from postganglionic neurons indicate that at least four different changes in postsynaptic membrane potential can be elicited by stimulation of the preganglionic nerve (Figure 13–5):

- An initial EPSP (via nicotinic receptors) that may result in an action potential
- An IPSP mediated by M_2 (G_i/G_o-coupled) muscarinic receptors
- A secondary slow EPSP mediated by M_1 (G_q/G_{11}-coupled) muscarinic receptors
- A late, slow EPSP mediated by myriad peptides

An action potential is generated in the postganglionic neuron when the initial EPSP achieves a threshold potential. The events that follow the initial depolarization (IPSP; slow EPSP; late, slow EPSP) are insensitive to *hexamethonium* or other N_n antagonists. Electrophysiological and neurochemical evidence suggests that catecholamines participate in the generation of the IPSP. Dopamine and norepinephrine cause hyperpolarization of ganglia; however, in some ganglia, IPSPs are mediated by M_2 muscarinic receptors.

The slow EPSP is generated by ACh activation of M_1 muscarinic receptors and is blocked by *atropine* and M_1-selective antagonists (see Chapter 11). The slow EPSP has a longer latency and greater duration (10–30 sec) than the initial EPSP. Slow EPSPs result from decreased K^+ conductance, the *M current* that regulates the sensitivity of the cell to repetitive fast-depolarizing events. By contrast, the late, slow EPSP lasts for several minutes and is mediated by peptides released from presynaptic nerve endings or interneurons in specific ganglia (see next section). The peptides and ACh may be coreleased at the presynaptic nerve terminals; the relative stability of the peptides in the ganglion extends its sphere of influence to postsynaptic sites beyond those in the immediate proximity of the nerve ending.

Secondary synaptic events modulate the initial EPSP. A variety of peptides, including gonadotropin-releasing hormone, substance P,

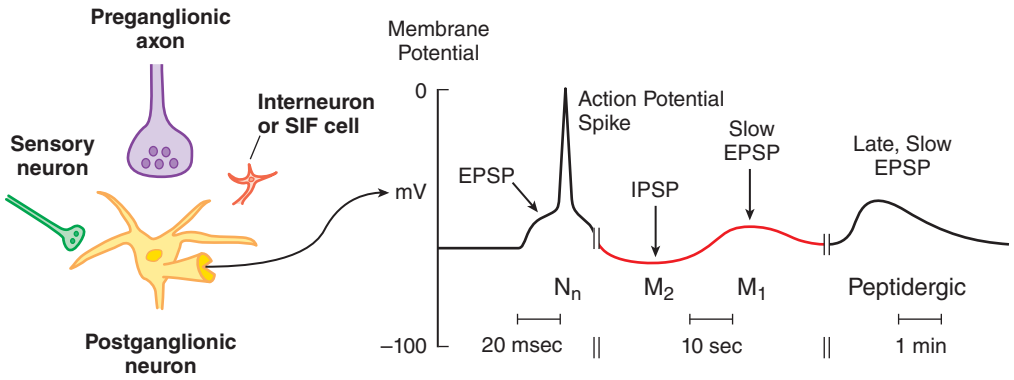

Figure 13–5 *Postsynaptic potentials recorded from an autonomic postganglionic nerve cell body after stimulation of the preganglionic nerve fiber.* The preganglionic nerve releases ACh onto postganglionic cells. The initial EPSP results from the inward Na^+ current (and perhaps Ca^{2+} current) through the nicotinic receptor channel. If the EPSP is of sufficient magnitude, it triggers an action potential spike, which is followed by a slow IPSP, a slow EPSP, and a late, slow EPSP. The slow IPSP and slow EPSP are not seen in all ganglia. The electrical events subsequent to the initial EPSP are thought to modulate the probability that a subsequent EPSP will reach the threshold for triggering a spike. Other interneurons, such as catecholamine-containing SIF cells, and axon terminals from sensory, afferent neurons also release transmitters, which may influence the slow potentials of the postganglionic neuron. A number of cholinergic, peptidergic, adrenergic, and amino acid receptors are found on the dendrites and soma of the postganglionic neuron and the interneurons. The preganglionic fiber releases ACh and peptides; the interneurons store and release catecholamines, amino acids, and peptides; the sensory afferent nerve terminals release peptides. The initial EPSP is mediated through nicotinic (N_n) receptors, the slow IPSP and EPSP through M_2 and M_1 muscarinic receptors, and the late, slow EPSP through several types of peptidergic receptors.

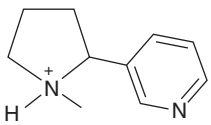
angiotensin, calcitonin gene–related peptide, vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins, have been identified in ganglia. They appear localized to particular cell bodies, nerve fibers, or small, intensely fluorescent (SIF) cells; are released on nerve stimulation; and are presumed to mediate the late, slow EPSP. Other neurotransmitter substances (e.g., 5HT and GABA) can modulate ganglionic transmission.

Ganglionic Stimulating Agents

Drugs that stimulate N_n cholinergic receptors on autonomic ganglia have been essential for analyzing the mechanism of ganglionic function; however, these ganglionic agonists have limited therapeutic use. They can be grouped into two categories. The first group consists of drugs with specificities similar to nicotine: *lobeline*, *tetramethylammonium*, and *dimethylphenylpiperazinium*. Nicotine's excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic receptor antagonists, and mimic the initial EPSP. The second group consists of muscarinic receptor agonists such as *muscarine*, *McN-A-343*, and *methacholine* (see Chapter 11); their excitatory effects on ganglia are delayed in onset, blocked by *atropine*-like drugs, and mimic the slow EPSP.

Nicotine

Nicotine is of considerable medical significance because of its toxicity, presence in tobacco, and propensity for conferring dependence on its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 28. Nicotine is one of the few natural liquid alkaloids. It is a colorless, volatile base (pK_a = 8.5) that turns brown and acquires the odor of tobacco on exposure to air.



NICOTINE

Mechanism of Action. In addition to the actions of nicotine on a variety of neuroeffector and chemosensitive sites, the alkaloid can both stimulate and desensitize receptors, making nicotine's effects complex and unpredictable. The ultimate response of any one system represents the summation of stimulatory and inhibitory effects of nicotine. Nicotine can increase heart rate by excitation of sympathetic ganglia or by paralysis of parasympathetic cardiac ganglia, and it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. The effects of the drug on the chemoreceptors of the carotid and aortic bodies and on regions of the CNS also can influence heart rate, as can the compensatory baroreceptor reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine can stimulate secretion of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.

Effects on Physiological Systems

Peripheral Nervous System. The major action of nicotine consists initially of transient stimulation and then a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. Following larger doses, the initial stimulation is followed by a blockade of transmission. Whereas stimulation of the ganglion cells coincides with their depolarization, depression of transmission by adequate doses of nicotine occurs both during the depolarization and after it has subsided. Nicotine also possesses a biphasic action on the adrenal medulla: Small doses evoke the discharge of catecholamines; larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of high doses of nicotine on the neuromuscular junction are similar to those on ganglia. However, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization. At lower concentrations, such as those typically achieved by recreational tobacco use (~200 nM), nicotine's effects reflect its higher affinity for a neuronal nicotinic receptor ($\alpha_4\beta_2$) than for the neuromuscular junction receptor ($\alpha_1\beta_1\gamma\delta$) (Xiu et al., 2009).

Nicotine, like ACh, stimulates a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of *hexamethonium* prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

Central Nervous System. Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; higher doses cause tremors, leading to convulsions at toxic doses. The excitation of respiration is a prominent action of nicotine: Large doses act directly on the medulla oblongata, whereas smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies. Stimulation of the CNS with large doses is followed by depression, and death results from failure

of respiration owing to both central paralysis and peripheral blockade of the diaphragm and intercostal muscles that facilitate respiration.

Nicotine induces vomiting by both central and peripheral actions. The central component of the vomiting response is due to stimulation of the emetic chemoreceptor trigger zone in the area postrema of the medulla oblongata. In addition, nicotine activates vagal and spinal afferent nerves that form the sensory input of the reflex pathways involved in the act of vomiting. The primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. The stimulatory and pleasure-reward actions of nicotine appear to result from release of excitatory amino acids, dopamine, and other biogenic amines from various CNS centers (Dorostkar and Boehm, 2008).

Chronic exposure to nicotine in several systems causes a marked increase in the density or number of nicotinic receptors, possibly contributing to tolerance and dependence. Nicotine is thought to act as an intracellular pharmacological chaperone; it is uncharged at physiological pH and readily permeates the plasma membrane. Inside the cell, it upregulates receptor expression by stabilizing nascent subunits in pentamers in the endoplasmic reticulum. Chronic low-dose exposure to nicotine also significantly increases the $t_{1/2}$ of nicotinic receptors on the cell surface (Kuryatov et al., 2005; Srinivasan et al., 2014).

Cardiovascular System. In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

GI Tract. The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasionally diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

Exocrine Glands. Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

ADME. Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. As a relatively strong base, nicotine has limited absorption from the stomach. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6 to 11 mg nicotine and delivers about 1 to 3 mg nicotine systemically to the smoker; bioavailability can increase as much as 3-fold with the intensity of puffing and technique of the smoker (Benowitz, 1998).

Approximately 80% to 90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung. Cotinine is the major metabolite. The $t_{1/2}$ of nicotine following inhalation is about 2 h. Nicotine and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.

Acute Adverse Effects. Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably about 60 mg. Smoking tobacco usually contains 1% to 2% nicotine. The gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid; they include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

For treating nicotine poisoning, vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

Ganglionic Blocking Agents

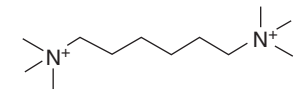
There are two categories of agents that block ganglionic nicotinic receptors. The prototype of the first group, nicotine, initially stimulates the ganglia by an ACh-like action and then blocks them by causing persistent depolarization (Volle, 1980). Compounds in the second category (e.g., *trimethaphan* and *hexamethonium*) impair transmission. *Trimethaphan* acts by competition with ACh, analogous to the mechanism of action of curare at the neuromuscular junction. *Hexamethonium* appears to block the channel after it opens; this action shortens the duration of current flow because the open channel either becomes occluded or closes. Thus, the initial EPSP is blocked, and ganglionic transmission is inhibited. Representative diverse chemicals that block autonomic ganglia without first causing stimulation are shown in Figure 13–6.

Ganglionic blocking agents were the first effective therapy for the treatment of hypertension. However, due to the role of ganglionic transmission in both the sympathetic and parasympathetic branches of the autonomic nervous system, the antihypertensive action of ganglionic blocking agents is accompanied by numerous undesirable side effects (Table 13–5). *Mecamylamine*, a secondary amine with a channel block mechanism similar to *hexamethonium*, is available as an antihypertensive agent with good oral bioavailability for moderate to severe hypertension. Dosing of *mecamylamine* is 2.5 mg twice daily and can be increased in increments of 2.5 mg/day at intervals of 2 or more days until desired blood pressure response is achieved.

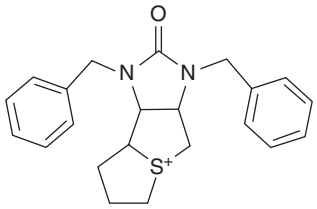
Mechanism of Action

Nearly all the physiological alterations observed after the administration of ganglionic blocking agents can be anticipated with reasonable accuracy by a careful inspection of Figure 10–1 and Table 10–1, and by knowing which division of the autonomic nervous system exercises dominant control of various organs (see Table 13–5). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure.

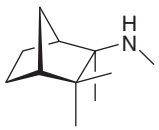
Generalized ganglionic blockade also may result in atony of the bladder and GI tract, cycloplegia, xerostomia, diminished perspiration, and, by abolishing circulatory reflex pathways, postural hypotension. These changes represent the generally undesirable features of ganglionic blockade that severely limit the therapeutic efficacy of ganglionic blocking agents.



HEXAMETHONIUM (C6)



TRIMETHAPHAN



MECAMYLAMINE

Figure 13–6 *Ganglionic blocking agents.*

Cardiovascular Effects

Existing sympathetic tone is a critical determinant of the degree ganglionic blockade will lower blood pressure. Thus, blood pressure may decrease only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension limits the use of ganglionic blockers in ambulatory patients. Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. In humans, only mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete ganglionic blockade. However, a decrease may occur if the heart rate is high initially. Cardiac output often is reduced by ganglionic blocking drugs in patients with normal cardiac function, because of venodilation, peripheral pooling of blood, and the resulting decrease in venous return. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished. Although total systemic vascular resistance is decreased in patients who receive ganglionic blocking agents, changes in blood flow and vascular resistance of individual vascular beds are variable. Reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50 to 60 mmHg. Skeletal muscle blood flow is unaltered, but splanchnic and renal blood flow decrease.

ADME

The absorption of quaternary ammonium and sulfonium compounds from the enteric tract is incomplete and unpredictable. This is due both to the limited ability of these ionized substances to penetrate cell membranes and to the depression of propulsive movements of the small intestine and gastric emptying by parasympathetic blockade. Although the absorption of *mecamylamine* is less erratic, reduced bowel activity and paralytic ileus are a danger. After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. *Mecamylamine* concentrates in the liver and kidney and is excreted slowly in an unchanged form.

Therapeutic Uses; Adverse Effects

Trimethaphan was once used for the induction of controlled hypotension during surgery to reduce bleeding and for the rapid reduction of blood pressure in the treatment of hypertensive emergencies; however, the agent is no longer marketed in the U.S. Adverse reactions are consistent with ganglionic blockade, as shown in Table 13–5.

Nicotine Addiction and Smoking Cessation

As a therapeutic, nicotine is primarily used to aid in smoking cessation. Two goals of the pharmacotherapy of smoking cessation are the reduction of the craving for nicotine and inhibition of the reinforcing effects of smoking. Myriad approaches and drug regimens are used, including NRT, *bupropion* (a CNS-active nicotinic antagonist; see Chapter 18), and partial agonists of the nicotinic ACh receptor (e.g., *varenicline*). More recently, electronic cigarettes (vaping) have been marketed as a safer alternative to combustible cigarettes, a questionable claim in the face of their reported popularity with teenagers smoking flavored tobaccos via vaping.

Current consensus is that NRT, *bupropion*, and *varenicline* all help smokers to quit their smoking habit. *Cytisine* (not approved for use in Europe or the U.S.) also appears effective. The safety and efficacy of NRT are clear. The highest rates of smoking cessation (~30% success at maintaining abstinence from smoking for 6 months) result from the combination of NRT (e.g., patch plus inhaler) and *varenicline* (Cahill et al., 2013). Meta-analysis of clinical studies indicates that behavioral support (e.g., counseling, phone support) in addition to pharmacological treatment increases the likelihood of smoking cessation by about 10% to 25% (Hartman-Boyce et al., 2019).

Nicotine Replacement Therapy

NRT is available in several dosage forms to help achieve abstinence from tobacco use. Nicotine is marketed for over-the-counter use as a gum or lozenge or transdermal patch and by prescription as a nasal spray or vapor inhaler. Different nicotine delivery systems produce different patterns of exposure (see Figure 28–10; St. Helen et al., 2016). The efficacy of these dosage forms in producing abstinence from smoking is enhanced when linked to counseling and motivational therapy (Prochaska and Benowitz, 2016).

Cytisine

Cytisine is a plant alkaloid and a partial agonist at nicotinic ACh receptors, with an affinity for the $\alpha_4\beta_2$ subtype. *Cytisine* is taken orally, has a half-life of about 5 h, and can produce mild GI side effects. In a recent small trial, *cytisine* was effective in producing effects similar to those of NRT and *varenicline* (Walker et al., 2014).

Varenicline

Varenicline is a *cytisine*-based therapeutic for smoking cessation. It is administered initially at 0.5 mg once per day for 3 days then twice daily at the same dose. After 8 days, it is maintained at 1 mg twice daily. The drug interacts with nicotinic ACh receptors. In model systems, *varenicline* is a selective partial agonist at $\alpha_4\beta_2$ receptors, which is thought to be the principal nicotinic receptor subtype involved in nicotine addiction. Binding of *varenicline* to the $\alpha_4\beta_2$ receptors blocks the ability of nicotine to generate the reward experience and, due to its partial agonist activity, does not promote the withdrawal effects as would an antagonist. *Varenicline*

TABLE 13–5 ■ USUAL PREDOMINANCE OF SYMPATHETIC OR PARASYMPATHETIC TONE AT VARIOUS EFFECTOR SITES AND CONSEQUENCES OF AUTONOMIC GANGLIONIC BLOCKADE

SITE	PREDOMINANT TONE	EFFECT OF GANGLIONIC BLOCKADE
Arterioles	Sympathetic (adrenergic)	Vasodilation; increased peripheral blood flow; hypotension
Veins	Sympathetic (adrenergic)	Dilation: peripheral pooling of blood; decreased venous return; decreased cardiac output
Heart	Parasympathetic (cholinergic)	Tachycardia
Iris	Parasympathetic (cholinergic)	Mydriasis
Ciliary muscle	Parasympathetic (cholinergic)	Cycloplegia—focus to far vision
Gastrointestinal tract	Parasympathetic (cholinergic)	Reduced tone and motility; constipation; decreased gastric and pancreatic secretions
Urinary bladder	Parasympathetic (cholinergic)	Urinary retention
Salivary glands	Parasympathetic (cholinergic)	Xerostomia
Sweat glands	Sympathetic (cholinergic)	Anhidrosis
Genital tract	Sympathetic and parasympathetic	Decreased stimulation

is a lower-affinity full agonist at the α_7 subtype and exhibits weak activity toward $\alpha_3\beta_2$- and α_6-containing receptors. *Varenicline* has been shown to be more effective than placebo, nicotine patch, or *bupropion* in helping smokers achieve abstinence (Anthenelli et al., 2016).

ADME

Varenicline has a high oral bioavailability (~90%) and is excreted unchanged in the urine. Reduction in dosage is recommended for those with renal function impairment.

Adverse Effects

Varenicline had previously carried an FDA black-box warning of serious psychiatric adverse effects (e.g., suicide) in some patients with underlying psychiatric disorders; however, recent studies show no significant increase in such events attributable to *varenicline* relative to nicotine patch or placebo (Anthenelli et al., 2016). Nonetheless, patients should be monitored for behavioral or psychiatric changes that typically resolve following discontinuation.

Drug Facts for Your Personal Formulary: *Agents Acting at the Neuromuscular Junction and Autonomic Ganglia; Antispasmodics; Nicotine*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Nicotinic ACh Receptor Agonists		
Succinylcholine[US] (N_m agonist)	Induction of neuromuscular blockade in surgery and during intubation	• Induces rapid depolarization of motor end plate, inducing phase I block • Resistant to and augments AChE inhibition; induces fasciculations, then flaccid paralysis • Influenced by anesthetic agent, type of muscle, and rate of administration • Leads to phase II block after prolonged use • Metabolized by butyrylcholinesterase; not safe for infants and children • Contraindications: history of malignant hyperthermia, muscular dystrophy
Dexamethonium (depolarizer)	• Not used clinically in the U.S.	
Nicotine (N_n agonist)	• Smoking cessation	• Low dose induces postganglionic depolarization • High doses induce ganglionic transmission blockade
Varenicline (N_n [$\alpha_4\beta_2$ subtype])	• Smoking cessation • FDA warning about mood and behavioral changes revised down in 2016	• Partial nicotinic receptor agonist preventing nicotine stimulation and decreasing craving • May cause seizures with alcohol use; excreted largely unchanged in urine
Competitive Nicotinic ACh Receptor Antagonists (Nondepolarizing Neuromuscular Blocking Agents)		
D-Tubocurarine[a,L]	• Induction of neuromuscular blockade in surgery and during intubation • All neuromuscular blocking agents are administered parenterally	• No longer used clinically in the U.S. or Canada • Produces partial blockade of ganglionic ACh transmission that can produce hypertension and reflex tachycardia • Can induce histamine release
Mivacurium[S]		• Short acting due to rapid hydrolysis by plasma cholinesterase • Use with caution in patients with renal or hepatic insufficiency
Pancuronium[L]		• Shows antimuscarinic receptor activity • Renal and hepatic elimination • Vagolytic activity may cause tachycardia, hypertension, and increased cardiac output
Rocuronium[I]		• Amino steroid • Stable in solution • More rapid onset than vecuronium and cisatracurium • Hepatic elimination
Vecuronium[I]		• Amino steroid • Not stable in solution • Hepatic and renal elimination
Metocurine[a,L]		• Three times more potent than tubocurarine • Less histamine release
Atracurium[I]	• Preferred agent for patients with renal failure	• Susceptible to Hofmann elimination and ester hydrolysis • Same dosage for infants >1 month, children, and adults
Cisatracurium[I]		• More potent than atracurium, Hofmann elimination, no histamine release (unlike atracurium)
Doxacurium[a,L]		• Renal elimination
Pipecuronium[a,L]		• Hepatic metabolism, renal elimination

Drug Facts for Your Personal Formulary: *Agents Acting at the Neuromuscular Junction and Autonomic Ganglia; Antispasmodics; Nicotine (continued)*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Competitive Nicotinic ACh Receptor Antagonists (Nondepolarizing Neuromuscular Blocking Agents) (cont.)		
Gantacurium[b,US]		• New compound class; in clinical trial stage • Fastest onset and shortest acting • Metabolism: rapid cysteine adduction, slow ester hydrolysis
Hexamethonium	• Not used therapeutically	• N_n receptor antagonist; blocks ganglionic transmission
Trimethaphan	• Hypertensive crisis • No longer used	• N_n receptor antagonist; blocks ganglionic transmission
CNS-Active Agents		
Baclofen Benzodiazepines Tizanidine Cyclobenzaprine	• Control of muscle spasms	• See Chapter 21
Carisoprodol Metaxalone Methocarbamol Orphenadrine Tetrabenazine	• Muscle relaxants acting in CNS, having, in general, a depressant effect	• CYP2C19 metabolizes carisoprodol to largely to meprobamate • Tetrabenazine is a VCAT2 inhibitor and depletes neuronal monoamine stores
Agents That Block ACh Release		
AbobotulinumtoxinA	• Cervical dystonia • Glabellar lines (moderate to severe)	• Spread of toxin effect may induce paralysis of nontargeted muscle, rarely if administered carefully • Paralysis of swallowing and respiration can be life-threatening
IncobotulinumtoxinA	• Blepharospasm, cervical dystonia • Glabellar lines (moderate to severe)	
OnabotulinumtoxinA	• Botox: axillary hyperhidrosis (severe) • Blepharospasm associated with dystonia; cervical dystonia; migraine (chronic) prophylaxis • Overactive bladder; strabismus; upper limb spasticity (severe); urinary incontinence (due to detrusor overactivity associated with a neurologic condition)	
PrabotulinumtoxinA-xvfs	• Moderate to severe glabellar lines associated with corrugator and/or procerus muscle activity in adult patients	
RimabotulinumtoxinB	• Cervical dystonia	
Inhibitor of Release of Ca^{2+} From the Sarcoplasmic Reticulum		
Dantrolene	• Management and prevention of malignant hyperthermia • Treatment of spasticity associated with upper motor neuron disorders (e.g., spinal cord injury, stroke, cerebral palsy, or multiple sclerosis)	• Hepatic metabolism • Can cause significant hepatotoxicity

Duration of action: [L]long (> ~80 min); [I]intermediate (~20–80 min); [S]short (~15–20 min); [US]ultrashort (< ~15 min).
[a]Not available in the U.S.
[b]Gantacurium is in investigational status.

Chapter 14 Adrenergic Agonists and Antagonists

Douglas G. Tilley, Steven R. Houser, and Walter J. Koch

Introduction

Agents or drugs that act on the adrenergic system may mimic the actions of endogenous catecholamines, block their synthesis or release, or antagonize their effects at the level of adrenergic receptors on cell membranes. Catecholamines are released from neurons within the sympathetic nervous system and adrenal medulla. Norepinephrine (NE) is the primary catecholamine neurotransmitter in the peripheral sympathetic nervous system while epinephrine (EPI) is the primary catecholamine hormone released from the adrenal medulla. NE therefore acts in innervated tissues locally and EPI, secreted into blood circulation, acts as a hormone, with effects dependent upon its circulating concentration. NE and EPI are released and activated by several stimuli including physical and psychological stress. The diversity of their actions accounts for the fact that drugs acting to alter sympathetic and adrenergic responses are used for a myriad of clinical disorders including hypertension, asthma, heart failure, and anaphylactic reactions. Many of these uses are discussed elsewhere (see Chapters 32, 33, and 44). Dopamine is a third endogenous catecholamine; it is predominantly located in the central nervous system (CNS), and its central effects are discussed elsewhere (see Chapter 15), although there are some dopamine receptors in the periphery.

Actions of agents that activate or antagonize adrenergic receptors primarily follow known physiological effects of endogenous catecholamines. Most available adrenergic agonists are structural analogues of EPI and NE. Although EPI and NE are sometimes used, modifications of these parent structures offer therapeutic benefits including improved bioavailability, duration of action, and receptor subtype specificity. The actions of NE and EPI are similar at some sites but quite different at others due to subtypes of adrenergic receptors that are expressed by different organs and tissues. There are nine adrenergic receptor subtypes, and these can dictate specific effects of adrenergic agonists and antagonists throughout the body. Subtype selectivity of newer agonists and antagonists adds to the therapeutic benefits.

Abbreviations

ADHD: attention-deficit/hyperactivity disorder
AV: atrioventricular
BPH: benign prostatic hyperplasia
COMT: catechol-*O*-methyltransferase
COPD: chronic obstructive pulmonary disease
CYP: cytochrome P450
DA: dopamine
ECG: electrocardiogram
EPI: epinephrine
GI: gastrointestinal
HDL: high-density lipoprotein
5HT: 5-hydroxytryptamine (serotonin)
INE: isopropylnorepinephrine, isoproterenol
LDL: low-density lipoprotein
MAO: monoamine oxidase
NE: norepinephrine
SA: sinoatrial
VLABA: very long-acting or ultra β_2 adrenergic receptor agonist

HISTORICAL PERSPECTIVE

The pressor effects of adrenal extracts were first demonstrated by Oliver and Schafer in 1895. The active component was named epinephrine by J.J. Abel in 1899, who isolated the monobenzoyl derivative. Takamine isolated the "pure, stable, crystalline form" and termed it adrenalin (see Arthur, 2015). Henry Dale worked on a series of synthetic amines related to EPI that were termed sympathomimetics (Barger and Dale, 1910). Cannon and Rosenblueth described the actions of the body's "fight and flight" mechanisms, observations that later led to the discovery that NE is the sympathetic neurotransmitter (see Bacq, 1983). In the mid-20th century, Ahlquist hypothesized that the myriad organ-level effects of catecholamines were mediated by activation of two distinct populations of receptors, which he termed distinct α and β receptors. This theory, although not universally embraced at the time (see Lefkowitz, 2018), provided the initial impetus for the synthesis and pharmacological evaluation of β receptor antagonists. The first β-selective agent was dichloroisoproterenol, a partial agonist. James Black and his colleagues initiated a program in the late 1950s to develop additional β blockers, with the resulting synthesis and characterization of *propranolol*. Only in the 1980s were α and β receptors purified, giving physical proof that the receptors were distinct entities. Researchers in the general area of adrenergic signaling have garnered a number of Nobel Prizes: Sutherland (1971) for the discovery of cyclic AMP and a mechanism of transmembrane hormone action; Black, Hitchings, and Elion (1988) for development of β blockers and H_2 antagonists; Krebs and Fischer (1992) for the discovery of cyclic AMP–dependent protein kinase; Rodbell and Gilman (1994) for the discovery of G proteins and their roles in transmembrane signaling; and Lefkowitz and Kobilka (2012) for studies of G protein-coupled receptors, principally the β_2 adrenergic receptor.

Overview: Actions of Catecholamines and Sympathomimetic Drugs

Most of the actions of catecholamines and sympathomimetic agents can be classified into seven broad types:

1. *A peripheral excitatory action* on certain types of smooth muscle, such as those in blood vessels supplying skin, kidney, and mucous membranes; and on gland cells, such as those in salivary and sweat glands
2. *A peripheral inhibitory action* on certain other types of smooth muscle, such as those in the wall of the gut, in the bronchial tree, and in blood vessels supplying skeletal muscle
3. *A cardiac excitatory action* that increases heart rate, force and rate, and extent of contraction, and rate of relaxation
4. *Metabolic actions*, such as an increase in the rate of glycogenolysis in liver and muscle and liberation of free fatty acids from adipose tissue
5. *Endocrine actions*, such as modulation (increasing or decreasing) of the secretion of insulin, renin, and pituitary hormones
6. *Actions in the CNS*, such as respiratory stimulation, an increase in wakefulness and psychomotor activity, and a reduction in appetite
7. *Prejunctional actions* that either inhibit or facilitate the release of neurotransmitters, the inhibitory action being physiologically more important

Not all sympathomimetic drugs show each of the types of action to the same degree; however, many of the differences in their effects are only quantitative. The pharmacological properties of these drugs as a class are described in detail for the prototypical agent, EPI. Appreciation of the pharmacological properties of the drugs described in this chapter depends on an understanding of the classification, distribution, and mechanism of action of α and β adrenergic receptors.

Classification of Sympathomimetic Drugs

Catecholamines and sympathomimetic drugs are classified as *direct-acting, indirect-acting, or mixed-acting sympathomimetics* (Figure 14–1). Direct-acting sympathomimetic drugs act directly on one or more of the adrenergic receptors. These agents may exhibit considerable selectivity for a specific receptor subtype (e.g., *phenylephrine* for α_1, *terbutaline* for β_2) or may have no or minimal selectivity and act on several receptor types (e.g., EPI for α_1, α_2, β_1, β_2, and β_3 receptors; NE for α_1, α_2, and β_1 receptors).

Indirect-acting drugs increase the availability of NE or EPI to stimulate adrenergic receptors by several mechanisms:

- By releasing or displacing NE from sympathetic nerve varicosities
- By inhibiting the transport of NE into sympathetic neurons (e.g., *cocaine*), thereby increasing the dwell time of the transmitter at the receptor
- By blocking the metabolizing enzymes, monoamine oxidase (MAO) (e.g., *pargyline*) or catechol-*O*-methyltransferase (COMT) (e.g., *entacapone*), effectively increasing transmitter supply

Drugs that indirectly release NE and directly activate receptors are referred to as *mixed-acting sympathomimetic drugs* (e.g., *ephedrine*). A feature of *direct-acting sympathomimetic drugs* is that their responses are not reduced by prior treatment with *reserpine* or *guanethidine*, which deplete NE from sympathetic neurons. After transmitter depletion, the actions of direct-acting sympathomimetic drugs may actually increase because the loss of the neurotransmitter induces compensatory changes that upregulate receptors or enhance the signaling pathway. By contrast, the responses of indirect-acting sympathomimetic drugs (e.g., *amphetamine, tyramine*) are abolished by prior treatment with *reserpine* or *guanethidine*. The cardinal feature of mixed-acting sympathomimetic drugs is that their effects are blunted, but not abolished, by prior treatment with *reserpine* or *guanethidine*.

Because *the actions of NE are more pronounced on α and β_1 receptors than on β_2 receptors*, many noncatecholamines that induce the release of NE have predominantly α receptor–mediated and cardiac effects. However, certain noncatecholamines with both direct and indirect effects on adrenergic receptors show significant β_2 activity and are used clinically for these effects. Thus, *ephedrine*, although dependent on release of NE for some of its effects, relieves bronchospasm by its action on β_2 receptors in bronchial smooth muscle, an effect not seen with NE. Moreover, some noncatecholamines (e.g., *phenylephrine*) act primarily and directly on target cells. Thus, it is not possible to predict precisely the effects of noncatecholamines solely on their ability to provoke NE release.

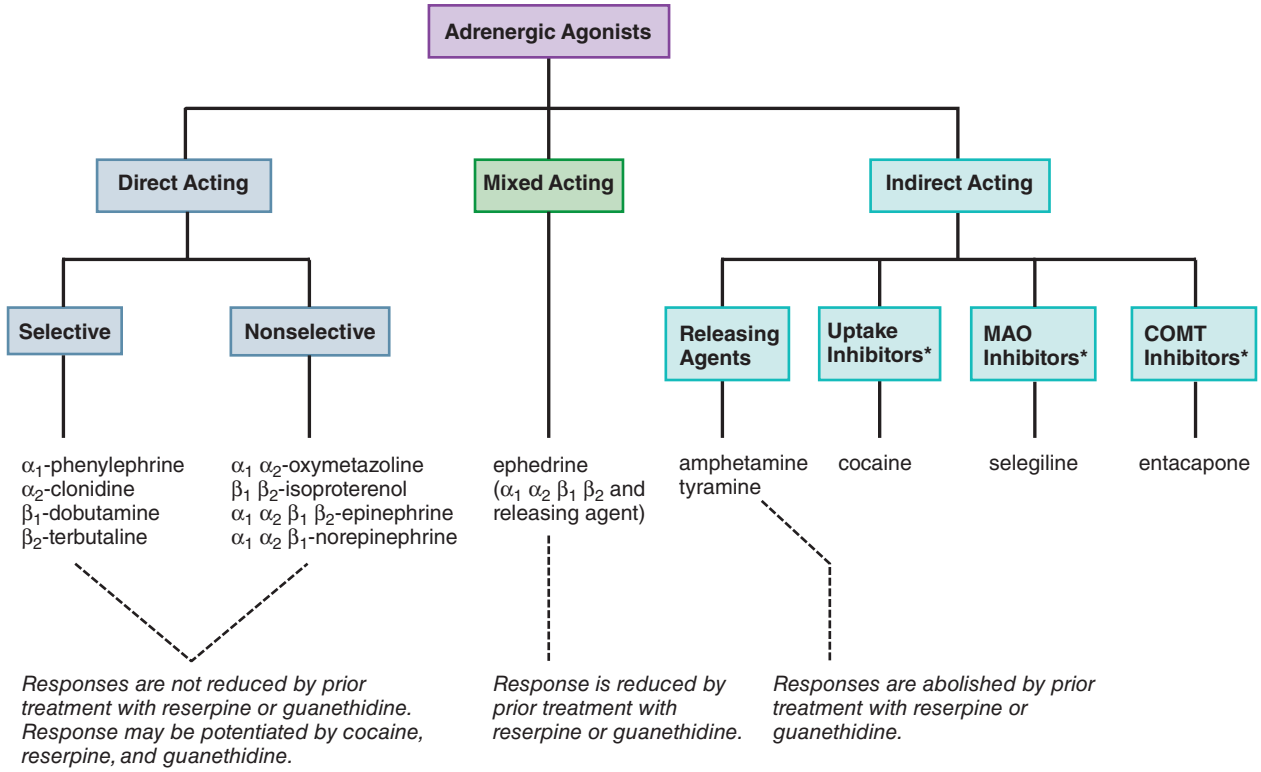

Figure 14–1 *Classification of adrenergic receptor agonists (sympathomimetic amines) or drugs that produce sympathomimetic-like effects.* For each category, a prototypical drug is shown. (*Not actually sympathomimetic drugs but produce sympathomimetic-like effects.)

Structure-Activity Relationship of Sympathomimetic Amines

β-Phenylethylamine, *consisting of a benzene ring and an ethylamine side chain* (parent structure in Table 14–1), can be viewed as the parent compound of the sympathomimetic amines. The structure permits substitutions to be made on the aromatic ring, the α- and β-carbon atoms, and the terminal amino group to yield a variety of compounds with sympathomimetic activity. *NE (norepinephrine), EPI (epinephrine), DA (dopamine), INE (isopropylnorepinephrine, isoproterenol),* and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Because *o-dihydroxybenzene* is also known as *catechol*, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed *catecholamines*. By far the greatest sympathomimetic activity occurs when two carbon atoms separate the ring from the amino group. This rule applies with few exceptions to all types of action.

Many directly acting sympathomimetic drugs influence both α and β receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly α activity (*phenylephrine*) to predominantly β activity (INE). Despite the multiplicity of the sites of action of sympathomimetic amines, several generalizations can be made (Table 14–1).

Substitution on the Amino Group

The effects of amino substitution are most readily seen in the actions of catecholamines on α and β receptors. *Increase in the size of the alkyl substituent increases β receptor activity (e.g., INE).* NE has, in general, rather feeble β_2 activity; this activity is greatly increased in EPI by the addition of a methyl group. A notable exception is *phenylephrine*, which has an *N*-methyl substituent but is an α-selective agonist. β_2-Selective compounds require a large amino substituent but also depend on other substitutions to define selectivity for β_2 over β_1 receptors. *In general, the smaller the substitution on the amino group, the greater is the selectivity for α activity, although N-methylation increases the potency of primary amines. Thus, α activity is maximal in EPI, less in NE, and almost absent in INF*

Substitution on the Aromatic Nucleus

Maximal α and β activity depends on the presence of hydroxyl groups on positions 3 and 4. When one or both of these groups are absent, with no other aromatic substitution, the overall potency is reduced. *Phenylephrine* is thus less potent than EPI at both α and β receptors, with β_2 activity almost completely absent. Studies of the β adrenergic receptor suggest that the catechol hydroxyl groups at positions 3 and 4 can interact with specific hydroxyl groups on serine residues within the ligand binding pocket.

Hydroxyl groups in positions 3 and 5 confer β_2 receptor selectivity on compounds with large amino substituents. Thus, *terbutaline* and similar compounds relax the bronchial musculature in patients with asthma but cause less-direct cardiac stimulation than do the nonselective drugs. The response to noncatecholamines is partly determined by their capacity to release NE from storage sites. These agents thus cause effects that are mostly mediated by α and β_1 receptors because NE is a weak β_2 agonist. Phenylethylamines that lack hydroxyl groups on the ring and the β-hydroxyl group on the side chain act almost exclusively by causing the release of NE from sympathetic nerve terminals.

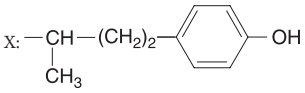
Because substitution of polar groups on the phenylethylamine structure makes the resultant compounds less lipophilic, unsubstituted or alkyl-substituted compounds cross the blood-brain barrier more readily and have more central activity. Thus, *ephedrine*, *amphetamine*, and *methamphetamine* exhibit considerable CNS activity. As noted, the absence of polar hydroxyl groups results in a loss of direct sympathomimetic activity.

Catecholamines have only a brief duration of action and are ineffective when administered orally because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation. Compounds without one or both hydroxyl substituents are not acted on by COMT, and their oral effectiveness and duration of action are enhanced.

Groups other than hydroxyls have been substituted on the aromatic ring. In general, potency at α receptors is reduced, and β receptor activity is minimal; the compounds may even block β receptors. For example, *methoxamine*, with methoxy substituents at positions 2 and 5, has highly

TABLE 14–1 ■ STRUCTURES AND MAIN CLINICAL USES OF IMPORTANT SYMPATHOMIMETIC DRUGS

					MAIN CLINICAL USES							
					α RECEPTOR				β RECEPTOR			
					A	N	P	V	B	C	U	CNS
Phenylethylamine		H	H	H								
Epinephrine Norepinephrine	3-OH, 4-OH 3-OH, 4-OH	OH OH	H H	CH_3 H	A		P P	V	B	C C[a]		
Dopamine Droxidopa	3-OH, 4-OH 3-OH, 4-OH	H OH	H COOH	H H			P P			C[a]		
Dobutamine	3-OH, 4-OH	H	H	X						C		
Isoproterenol	3-OH, 4-OH	OH	H	$CH(CH_3)_2$					B	C		
Terbutaline Metaraminol	3-OH, 5-OH 3-OH	OH OH	H CH_3	$C(CH_3)_3$ H			P		B		U	
Phenylephrine	3-OH	OH	H	CH_3		N	P					
Methoxamine	2-OCH_3, 5-OCH_3	OH	CH_3	H			P					
Albuterol Amphetamine	3-CH_2OH, 4-OH	OH H	H CH_3	$C(CH_3)_3$ H					B		U	 ++
Methamphetamine		H	CH_3	CH_3								++
Ephedrine		OH	CH_3	CH_3		N	P		B	C		



α Activity: A, allergic reactions (includes β action); N, nasal decongestion; P, pressor (may include β action); V, other local vasoconstriction.
β Activity: B, bronchodilator; C, cardiac; U, uterus.
[a]Direct effects reduced by compensatory baroreceptor reflex.

selective α stimulating activity and in large doses blocks β receptors. *Albuterol*, a β_2-selective agonist, has a substituent at position 3 and is an important exception to the general rule of low β receptor activity.

Substitution on the α-Carbon Atom

The substitution on the α-carbon atom blocks oxidation by MAO, greatly prolonging the duration of action of noncatecholamines because their degradation depends largely on the action of this enzyme. The duration of action of drugs such as *ephedrine* or *amphetamine* is thus measured in hours rather than in minutes. Similarly, compounds with an α-methyl substituent persist in the nerve terminals and are more likely to release NE from storage sites. Agents such as *metaraminol* exhibit a greater degree of indirect sympathomimetic activity.

Substitution on the β-Carbon Atom

Substitution of a hydroxyl group on the β-carbon generally decreases actions within the CNS, largely because it lowers lipid solubility. However, such substitution greatly enhances agonist activity at both α and β adrenergic receptors. Although *ephedrine* is less potent than *methamphetamine* as a central stimulant, it is more powerful in dilating bronchioles and increasing blood pressure and heart rate.

Optical Isomerism

Substitution on either α- or β-carbon yields optical isomers. Levorotatory substitution on the β-carbon confers the greater peripheral activity, so that the naturally occurring *l*-EPI and *l*-NE are at least 10 times more potent than their unnatural *d*-isomers. Dextrorotatory substitution on the α-carbon generally results in a more potent compound. *d*-Amphetamine is more potent than *l*-amphetamine in central but not peripheral activity.

Physiological Basis of Adrenergic Responsiveness

Important factors in the response of any cell or organ to sympathomimetic amines are the density and relative proportion of α and β adrenergic receptors. For example, NE has relatively little capacity to increase bronchial airflow because the receptors in bronchial smooth muscle are largely of the β_2 subtype. In contrast, INE and EPI are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively α receptors; thus, NE and EPI cause constriction of such vessels, whereas INE has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both β_2 and α receptors; activation of β_2 receptors causes vasodilation, and stimulation of α receptors constricts these vessels. In such vessels, the threshold concentration for activation of β_2 receptors by EPI is lower than that for α receptors, but when both types of receptors are activated at high concentrations of EPI, the response to α receptors predominates. Physiological concentrations of EPI primarily cause vasodilation.

The ultimate response of a target organ to sympathomimetic amines is dictated not only by the direct effects of the agents but also by the reflex homeostatic adjustments of the organism. One of the most striking effects of many sympathomimetic amines is a rise in arterial blood pressure caused by stimulation of vascular α adrenergic receptors. This stimulation elicits compensatory reflexes that are mediated by the carotid-aortic baroreceptor system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a β_2 agonist) lowers mean blood pressure at the mechanoreceptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart and increasing sympathetic outflow to the heart and vessels. The baroreceptor reflex effect is of special importance for drugs that have little capacity to activate β receptors directly. With diseases such as atherosclerosis, which may impair baroreceptor mechanisms, the effects of sympathomimetic drugs may be magnified.

Inverse and Biased Agonism at Adrenergic Receptors

The observed physiologic effects of adrenergic agonists are broadly attributable to their activation of G proteins, which rapidly initiate downstream cellular responses including generation of the second messenger

cyclic AMP or mobilization of intracellular Ca^{2+}. For instance, EPI stimulation of β_2 adrenergic receptors induces G_s-dependent airway smooth muscle relaxation through the generation of cAMP, while its stimulation of α_1 adrenergic receptors induces G_q-dependent vascular smooth muscle constriction via Ca^{2+} mobilization. The ability of adrenergic receptor ligands (agonists or antagonists) to regulate G protein activation is related to how their chemical structures interact with and alter receptor conformation (Wingler and Lefkowitz, 2020). GPCRs exist within a spectrum of conformations, the stabilization of which by their ligands directs G protein accessibility. While agonists generally promote receptor conformations that increase G protein binding, antagonists stabilize receptor structures that prevent G protein binding. Some receptors have structural arrangements that allow G protein binding and some level of activity in the absence of an agonist. Thus, antagonists for these receptors have the property of *inverse agonism* (see Chapter 3); these drugs can decrease the basal activity of their receptor by shifting the equilibrium of spontaneously active receptors toward an inactive state.

In addition to engagement of G proteins, stimulation of GPCRs for prolonged periods or at high concentrations of agonist results in G protein-coupled receptor kinase–dependent phosphorylation of the receptor's C-terminal tail and subsequent recruitment of β-arrestins, which were originally identified as mediators of receptor desensitization (see Chapter 3). β-Arrestins also orchestrate prolonged GPCR trafficking and signaling events due to their capacity as scaffold proteins that can regulate additional cellular responses (Wingler and Lefkowitz, 2020). The ability of a ligand to elicit a stronger G protein- or β-arrestin–dependent signaling response in comparison to a reference agonist, such as the natural endogenous agonist, is termed *biased agonism* (Kenakin, 2021). The identification of biased adrenergic receptor ligands, including both classically described agonists and antagonists, has demonstrated their ability to differentially engage particular G proteins or β-arrestin scaffolds to induce quantitatively distinct signaling responses. Thus far, the most well-characterized biased adrenergic receptor ligands include β_2 receptor agonists, such as *salmeterol* with bias toward G_s protein activation, and β receptor antagonists, such as *carvedilol* with bias toward β-arrestin–dependent signaling (Ippolito and Benovic, 2021). Whether adrenergic receptor ligands with biased agonist properties exert measurable clinical effects that are attributable specifically to their biased engagement of downstream signaling pathways remains to be determined.

False-Transmitter Concept

Indirectly acting amines are taken up into sympathetic nerve terminals and storage vesicles, where they replace NE in the storage complex. Phenylethylamines that lack a β-hydroxyl group are retained there poorly, but β-hydroxylated phenylethylamines and compounds that subsequently become hydroxylated in the synaptic vesicle by DA β-hydroxylase are retained in the synaptic vesicle for relatively long periods of time. Such substances can produce a persistent diminution in the content of NE at functionally critical sites. When the nerve is stimulated, the contents of a relatively constant number of synaptic vesicles are released by exocytosis. If these vesicles contain phenylethylamines that are much less potent than NE, activation of postsynaptic α and β receptors will be diminished.

This hypothesis, known as the *false-transmitter concept*, is a possible explanation for some of the effects of MAO inhibitors. Phenylethylamines normally are synthesized in the GI (gastrointestinal) tract as a result of the action of bacterial tyrosine decarboxylase. The *tyramine* formed in this fashion usually is oxidatively deaminated in the GI tract and the liver, and the amine does not reach the systemic circulation in significant concentrations. However, when an MAO inhibitor is administered, tyramine may be absorbed systemically and transported into sympathetic nerve terminals, where its catabolism again is prevented because of the inhibition of MAO at this site; the tyramine then is β-hydroxylated to octopamine and stored in the vesicles in this form. As a consequence, NE gradually is displaced, and stimulation of the nerve terminal results in the release of a relatively small amount of NE along with a fraction of octopamine, which has relatively little ability to activate either α or β receptors. Thus, a functional impairment of sympathetic transmission parallels long-term administration of MAO inhibitors.

Despite such functional impairment, patients who have received MAO inhibitors may experience severe hypertensive crises if they ingest cheese, beer, or red wine. These and related foods, which are produced by fermentation, are enriched in tyramine and, to a lesser degree, other phenylethylamines. When GI and hepatic MAO are inhibited, the large quantity of tyramine that is ingested is absorbed rapidly and reaches the systemic circulation in high concentration. A massive and precipitous release of NE can result, causing hypertension severe enough to precipitate a myocardial infarction or a stroke. The properties of various MAO inhibitors are discussed in Chapters 10 and 18.

Endogenous Catecholamines

Epinephrine

Epinephrine (adrenaline) is a potent stimulant of both α and β adrenergic receptors; thus, its effects on target organs are complex (see Table 10–1). Some responses of EPI such as sweating, piloerection, and mydriasis depend on the physiological state of the subject. However, the most prominent actions of EPI are on the heart and on vascular and other smooth muscle.

Actions on Organ Systems

Effects on Blood Pressure. Epinephrine is one of the most potent vasopressor substances known. If a pharmacological dose is given rapidly by an intravenous route, it evokes a characteristic effect on blood pressure, which rises rapidly to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels.

The mechanism of the rise in blood pressure due to EPI is a triad of effects:

- a direct myocardial stimulation that increases the strength of ventricular contraction due to stimulation of β adrenergic receptors (*positive inotropic action*);
- an increased heart rate due to β receptors (*positive chronotropic action*); and
- vasoconstriction in many vascular beds—especially in the *precapillary resistance vessels* of skin, mucosa, and kidney—along with marked constriction of the veins due to net stimulation of α adrenergic receptors.

The pulse rate, at first accelerated, may be slowed markedly at the height of the rise of blood pressure by compensatory vagal discharge (baroreceptor reflex). Small doses of EPI (0.1 μg/kg) may cause the blood pressure to fall. The depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to EPI of vasodilator β_2 receptors than of constrictor α receptors.

Absorption of EPI after subcutaneous injection is slow due to local vasoconstrictor action; the effects of doses as large as 0.5 to 1.5 mg can be duplicated by intravenous infusion at a rate of 10 to 30 μg/min. There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 14–2). Peripheral resistance decreases, owing to a dominant action on β_2 receptors within vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Because the mean blood pressure is not, as a rule, greatly elevated, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and left ventricular work per beat are increased as a result of direct cardiac stimulation and increased venous return to the heart, which is reflected by an increase in right atrial pressure. At slightly higher rates of infusion, there may be no change or a slight rise in peripheral resistance and diastolic pressure, depending on the dose and the resultant ratio of α to β responses in the various vascular beds; compensatory reflexes also may come into play. The details of the effects of intravenous infusion of EPI, NE, and INE in humans are compared in Figure 14–2 and of EPI and NE in Table 14–2.

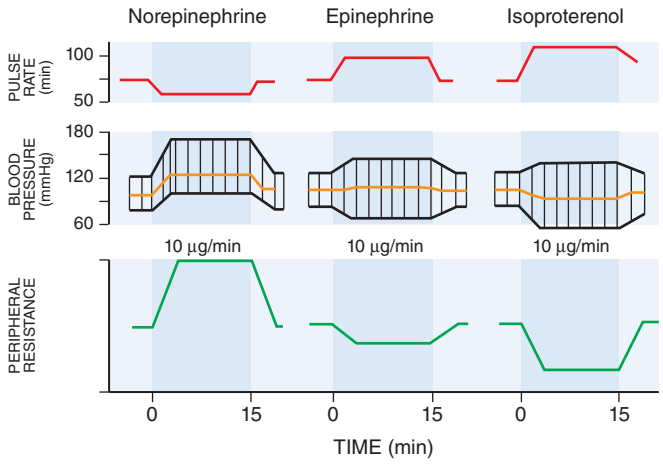


Figure 14–2 *Comparative effects of intravenous infusion of NE, EPI, and INE.* (Reproduced with permission from Allwood MJ, Cobbold AF, Ginsberg J. Peripheral vascular effects of noradrenaline, isopropylnoradrenaline, and dopamine. *Br Med Bull*, **1963**, *19*:132–136. With permission from Oxford University Press.)

Vascular Effects. In the vasculature, *EPI acts chiefly on the smaller arterioles and precapillary sphincters,* although veins and large arteries also respond. Various vascular beds react differently, which results in a substantial redistribution of blood flow. Injected EPI markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules. Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. Blood flow to skeletal muscles is increased by therapeutic doses in humans. This is due in part to a powerful β_2-mediated vasodilator action that is only partially counterbalanced by a vasoconstrictor action on the α receptors that also are present in the vascular bed. The effect of EPI on cerebral circulation is related to systemic blood pressure. In usual therapeutic doses, EPI has relatively little constrictor action on cerebral arterioles. Indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of EPI that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce renal blood flow by as much as 40%. All segments of the renal vascular bed contribute to the increased resistance. Because the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na^+, K^+, and Cl^- is decreased; urine volume may be increased, decreased, or unchanged. Maximal tubular reabsorptive and excretory capacities are unchanged. *The secretion of renin is increased due to the direct action of EPI on β_1 adrenergic receptors in the renal juxtaglomerular cells.*

Arterial and venous pulmonary pressures are raised. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to constriction of the more powerful musculature in the systemic great veins, doubtless plays an important part in the increase in pulmonary pressure. Very high concentrations of EPI may cause pulmonary edema precipitated by elevated pulmonary capillary filtration pressure and possibly by "leaky" capillaries.

Coronary blood flow is enhanced by EPI or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result of two factors. The first is the increased relative duration of diastole at higher heart rates (described later in this chapter); this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by EPI; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial O_2 consumption due to the direct effects of EPI on cardiac myocytes via β_1. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of EPI that results from activation of α receptors in coronary vessels.

Cardiac Effects. *Epinephrine is a powerful cardiac stimulant.* It acts directly on the predominant β_1 adrenergic receptors on cardiomyocytes and on cells within pacemaker and conducting tissues; β_2, β_3, and α receptors also are present in the heart, although there are considerable species differences. The heart rate increases, and the rhythm often is altered by EPI. Cardiac systole is shorter and more powerful, cardiac output is enhanced, and the work of the heart and its oxygen consumption are markedly increased. Cardiac efficiency (work done relative to oxygen consumption) is lessened. *Direct responses to EPI include increases in contractile force (inotropy), accelerated rate of rise of isometric tension, enhanced rate of relaxation (lusitropy), decreased time to peak tension, increased excitability, acceleration of the rate of spontaneous beating (chronotropy), and induction of automaticity in specialized regions of the heart.*

In accelerating the heart, EPI preferentially shortens systole so that the duration of diastole usually is not reduced. Indeed, activation of β receptors increases the rate of relaxation of ventricular muscle. EPI speeds the heart by accelerating the slow depolarization of SA (sinoatrial) nodal cells

that takes place during diastole, that is, during phase 4 of the action potential (see Chapter 34). Consequently, the transmembrane potential of the pacemaker cells rises more rapidly to the threshold level of action potential initiation. The amplitude of the action potential and the maximal rate of depolarization (phase 0) also are increased. A shift in the location of the pacemaker within the SA node often occurs, owing to activation of latent pacemaker cells. In Purkinje fibers, EPI also accelerates diastolic depolarization and may activate latent pacemaker cells. These changes do not occur in atrial and ventricular muscle fibers, where EPI has little effect on the stable, phase 4 membrane potential after repolarization. If large doses of EPI are given, premature ventricular contractions occur and may herald more serious ventricular arrhythmias. This rarely is seen with conventional doses in humans, but ventricular extrasystoles, tachycardia, or even fibrillation may be precipitated by release of endogenous EPI when the heart has been sensitized to this action of EPI by certain anesthetics or by myocardial ischemia. The mechanism of induction of these cardiac arrhythmias is not clear (see Chapter 34 for further details).

Some effects of EPI on cardiac tissues are largely secondary to the increase in heart rate and are small or inconsistent when the heart rate is kept constant. For example, the effect of EPI on repolarization of atrial muscle, Purkinje fibers, or ventricular muscle is small if the heart rate is unchanged. When the heart rate is increased, the duration of the action potential is consistently shortened, and the refractory period is correspondingly decreased. Conduction through the Purkinje system depends on the level of membrane potential at the time of excitation. Excessive reduction of this potential results in conduction disturbances, ranging from slowed conduction to complete block. EPI often increases the membrane potential and improves conduction in Purkinje fibers that have been excessively depolarized.

Epinephrine normally shortens the refractory period of the human atrioventricular (AV) node by direct effects on the heart, although doses of EPI that slow the heart through reflex vagal discharge may indirectly tend to prolong it. EPI also decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Supraventricular arrhythmias are apt to occur from the combination of EPI and cholinergic stimulation. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in EPI-induced ventricular arrhythmias because various drugs that block the vagal effect confer some protection. The actions of EPI in enhancing cardiac automaticity and in causing arrhythmias are effectively antagonized by β receptor antagonists such as *propranolol*. However, α_1 receptors exist in most regions of the heart, and their activation prolongs the refractory period and strengthens myocardial contractions. Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of EPI. Premature ventricular contractions can appear, which may be followed by multifocal ventricular tachycardia or ventricular fibrillation. Pulmonary edema also may occur.

Epinephrine decreases the amplitude of the T wave of the electrocardiogram (ECG) in normal persons. In animals given relatively larger doses, additional effects are seen on the T wave and the ST segment. After decreasing in amplitude, the T wave may become biphasic, and the ST segment can deviate either above or below the isoelectric line. Such ST segment changes are similar to those seen in patients with angina pectoris during spontaneous or EPI-induced attacks of pain. These electrical changes therefore have been attributed to myocardial ischemia. Also, EPI as well as other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes. Recent interest has focused on the possibility that prolonged sympathetic stimulation of the heart, such as in congestive heart failure, may promote apoptosis of cardiomyocytes and replacement by fibrotic tissue that would dampen proper electrical propagation (see Frangogiannis, 2021).

Effects on Nonvascular Smooth Muscles. The effects of EPI on the smooth muscles of different organs and systems depend on the type of adrenergic receptor in the muscle. In general, *EPI relaxes GI smooth muscle* due to activation of both α and β receptors. Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed and the pyloric and ileocecal sphincters are contracted, but these effects depend on the preexisting tone of the muscle. If tone already is high, EPI causes relaxation; if low, contraction.

The responses of *uterine muscle* to EPI vary with species, phase of the sexual cycle, state of gestation, and dose given. During the last month of pregnancy and at parturition, EPI inhibits uterine tone and contractions. Effects of adrenergic agents and other drugs on the uterus are discussed further in this chapter and in Chapter 48. *EPI relaxes the detrusor muscle of the bladder as a result of activation of β receptors and contracts the trigone and sphincter muscles owing to its α agonist activity.* This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

Respiratory Effects. *Epinephrine has a powerful bronchodilator action*, most evident when bronchial muscle is contracted because of disease, as in bronchial asthma, or in response to drugs or various autacoids. The beneficial effects of EPI in asthma also may arise from inhibition of antigen-induced release of inflammatory mediators from mast cells and to a lesser extent from diminution of bronchial secretions and congestion within the mucosa. *Inhibition of mast cell secretion is mediated by β_2 receptors, while the effects on the mucosa are mediated by α receptors*; however, other drugs, such as glucocorticoids and leukotriene receptor antagonists, have much more profound anti-inflammatory effects in asthma (see Chapter 44).

Effects on the CNS. Because EPI is a polar compound, it penetrates poorly into the CNS and thus is not a powerful CNS stimulant. While the drug may cause restlessness, apprehension, headache, and tremor in many persons, these effects in part may be secondary to the effects of EPI on the cardiovascular system, skeletal muscles, and intermediary metabolism; that is, they may be the result of somatic manifestations of anxiety.

Metabolic Effects. Epinephrine elevates the concentrations of glucose and lactate in blood. EPI inhibits secretion of insulin through an interaction with α_2 receptors, whereas activation of β_2 receptors enhances insulin secretions; the predominant effect of EPI is inhibition. Glucagon secretion is enhanced via activation of β receptors of the α cells of pancreatic islets. EPI also decreases the uptake of glucose by peripheral tissues, at least in part not only because of its effects on the secretion of insulin, but also possibly due to direct effects on skeletal muscle. Glycosuria rarely occurs. The effect of EPI to stimulate glycogenolysis in most tissues and in most species involves β receptors. EPI raises the concentration of free fatty acids in blood by stimulating β receptors in adipocytes, primarily β_3 receptors. The result is activation of triglyceride lipase, which accelerates the triglyceride breakdown to free fatty acids and glycerol. The calorigenic action of EPI (increase in metabolism) is reflected in humans by an increase of 20% to 30% in O_2 consumption after conventional doses, an effect due mainly to enhanced breakdown of triglycerides in brown adipose tissue (via β_3 receptors), providing an increase in oxidizable substrate.

Miscellaneous Effects. Epinephrine reduces circulating plasma volume by loss of protein-free fluid to the extracellular space, thereby increasing hematocrit and plasma protein concentration. However, conventional doses of EPI do not significantly alter plasma volume or packed red cell volume under normal conditions, although such doses may have variable effects in the presence of shock, hemorrhage, hypotension, or anesthesia. EPI rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β receptor–mediated demargination of these cells. EPI accelerates blood coagulation and promotes fibrinolysis.

The effects of EPI on secretory glands are not marked; in most glands, secretion usually is inhibited, partly owing to the reduced blood flow caused by vasoconstriction. EPI stimulates lacrimation and scanty mucus secretion from salivary glands. Sweating and pilomotor activity are minimal after systemic administration of EPI but occur after intradermal injection of very dilute solutions of either EPI or NE. Such effects are inhibited by α receptor antagonists.

Mydriasis occurs with physiological sympathetic stimulation but not when EPI is instilled into the conjunctival sac of normal eyes. However, EPI usually lowers intraocular pressure, possibly the result of reduced

production of aqueous humor due to vasoconstriction and enhanced outflow (see Chapter 74).

Although EPI does not directly excite *skeletal muscle, it facilitates neuromuscular transmission*, particularly that following prolonged rapid stimulation of motor nerves. In apparent contrast to the effects of α receptor activation at presynaptic nerve terminals in the autonomic nervous system (α_2 receptors), stimulation of α receptors causes a more rapid increase in transmitter release from the somatic motor neuron, perhaps as a result of enhanced influx of Ca^{2+}. These responses likely are mediated by α_1 receptors. These actions may explain in part the ability of EPI (given intra-arterially) to briefly increase strength of the injected limb of patients with myasthenia gravis. EPI also acts directly on white, fast-twitch muscle fibers to prolong the active state, thereby increasing peak tension. Of greater physiological and clinical importance is the capacity of EPI and selective β_2 agonists to increase physiological tremor, at least in part due to β receptor–mediated enhancement of discharge of muscle spindles.

Epinephrine promotes a fall in plasma K^+, largely due to stimulation of K^+ uptake into cells, particularly skeletal muscle, due to activation of β_2 receptors. This is associated with decreased renal K^+ excretion. These receptors have been exploited in the management of hyperkalemic familial periodic paralysis, which is characterized by episodic flaccid paralysis, hyperkalemia, and depolarization of skeletal muscle. The β_2-selective agonist *albuterol* apparently ameliorates the impairment in the ability of the muscle to accumulate and retain K^+.

The administration of large or repeated doses of EPI or other sympathomimetic amines to experimental animals damages arterial walls and myocardium, even inducing necrosis in the heart that is indistinguishable from myocardial infarction. The mechanism of this injury is not yet clear, but α and β receptor antagonists and Ca^{2+} channel blockers may afford substantial protection against the damage. Similar lesions occur in many patients with pheochromocytoma or after prolonged infusions of NE.

ADME

Epinephrine is not effective after oral administration because it is rapidly conjugated and oxidized in the GI mucosa and liver. Absorption from subcutaneous tissues occurs relatively slowly because of local vasoconstriction. Absorption is more rapid after intramuscular injection. In emergencies, it may be necessary to administer EPI intravenously. When relatively concentrated solutions are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used.

Epinephrine is rapidly inactivated in the liver by COMT and MAO (see Figure 10–9). Although only small amounts appear in the urine of normal persons, the urine of patients with pheochromocytoma may contain relatively large amounts of EPI, NE, and their metabolites.

Epinephrine is available in a variety of formulations geared for different clinical indications and routes of administration, including self-administration for anaphylactic reactions. EPI is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from formation of polymers. Injectable EPI is available in solutions of 1, 0.5, and 0.1 mg/mL. A subcutaneous dose ranges from 0.3 to 0.5 mg. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and injected very slowly. The dose is seldom as much as 0.25 mg, except for cardiac arrest, when larger doses may be required.

Toxicity, Adverse Effects, and Contraindications

Epinephrine may cause restlessness, throbbing headache, tremor, and palpitations. The effects rapidly subside with rest, quiet, recumbency, and reassurance. More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of EPI may result in cerebral hemorrhage from the sharp rise in blood pressure. Ventricular arrhythmias may follow the administration of EPI. Angina may be induced by EPI in patients with coronary artery disease. *The use of EPI generally is contraindicated in patients who are receiving nonselective β receptor antagonists because its unopposed actions on vascular α_1 receptors may lead to severe hypertension and cerebral hemorrhage.*

Therapeutic Uses

A major use of EPI is to provide rapid, emergency relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. EPI also is used to prolong the action of local anesthetics, presumably by decreasing local blood flow and reducing systemic absorption (see Chapter 25). Its cardiac effects may be of use in restoring cardiac rhythm in patients with cardiac arrest due to various causes. It also is used as a topical hemostatic agent on bleeding surfaces, such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Systemic absorption of the drug can occur with dental application. Inhalation of EPI may be useful in the treatment of postintubation and infectious croup.

Norepinephrine

Norepinephrine (*levarterenol*, *l*-noradrenaline, *l*-β-[3,4-dihydroxyphenyl]-α-aminoethanol) is a major chemical mediator liberated by mammalian *postganglionic sympathetic nerves*. It differs from EPI only by lacking the methyl substitution in the amino group (see Table 14–1). NE constitutes 10% to 20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas, which may not express the enzyme phenylethanolamine-*N*-methyltransferase.

Pharmacological Properties

The physiological consequences of pharmacological doses of NE and EPI are compared in Table 14–2. Both drugs are direct agonists on effector cells, and their actions differ mainly in the ratio of their effectiveness in stimulating α and β_2 receptors. *They are approximately equipotent in stimulating β_1 receptors. NE is a potent α agonist and has relatively little action on β_2 receptors*; however, it is somewhat less potent than EPI on the α receptors of most organs.

Cardiovascular Effects

In response to intravenous infusion of NE in humans (see Figure 14–2), *systolic and diastolic pressures, and usually pulse pressure, are increased. Cardiac output is unchanged or decreased, and total peripheral resistance is raised.* Compensatory vagal reflex activity slows the heart, overcoming a direct cardioaccelerator action, and stroke volume is increased. The peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. NE constricts mesenteric vessels and reduces splanchnic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with EPI, and to elevated blood pressure. Although generally a poor β_2 receptor agonist, NE may increase coronary blood flow directly by stimulating β_2 receptors on coronary vessels. Patients with Prinzmetal variant angina may be supersensitive to the α adrenergic vasoconstrictor effects of NE.

Unlike EPI, NE in small doses does not cause vasodilation or lower blood pressure because the blood vessels of skeletal muscle constrict rather than dilate; α adrenergic receptor antagonists therefore abolish the pressor effects but do not cause significant reversal (i.e., hypotension).

Other Effects

Other responses to NE are not prominent in humans. The drug causes hyperglycemia and other metabolic effects similar to those produced by EPI, but these are observed only when large doses are given because NE is not as effective a "hormone" as EPI. Intradermal injection of suitable doses causes sweating that is not blocked by *atropine*.

ADME

Norepinephrine, like EPI, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by COMT and MAO. Small amounts are normally present in the urine; the excretion rate may be greatly increased in patients with pheochromocytoma.

Toxicity, Adverse Effects, and Precautions

The untoward effects of NE are similar to those of EPI, although there typically is greater elevation of blood pressure with NE. Excessive doses can

cause severe hypertension. Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. The infusion should be made high in the limb, preferably through a long plastic cannula extending centrally. Impaired circulation at injection sites, with or without extravasation of NE, may be relieved by infiltrating the area with *phentolamine*, an α receptor antagonist. Blood pressure must be determined frequently during the infusion, particularly during adjustment of the rate of the infusion. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of NE.

Therapeutic Uses

Norepinephrine is used as a vasoconstrictor to raise or support blood pressure under certain intensive care conditions (discussed further in this chapter).

Droxidopa, a Synthetic Prodrug of Norepinephrine

Droxidopa (L-threo-3,4,-dihydroxyphenylserine) is a synthetic prodrug that is converted by L-aromatic amino acid decarboxylase into NE. It is approved by the FDA (Food and Drug Administration) for the treatment of orthostatic dizziness and light-headiness in adults with symptomatic neurogenic orthostatic hypotension associated with primary autonomic failure and impaired compensatory autonomic reflexes (Keating, 2015). The pharmacological effects of *droxidopa* are thought to be mediated through NE rather than through the parent drug or other metabolites. *Droxidopa* can cross the blood-brain barrier, presumably as the substrate of an amino acid transporter.

Dopamine

Dopamine (3,4-dihydroxyphenylethylamine) (see Table 14–1) is the immediate metabolic precursor of NE and EPI; it is a central neurotransmitter particularly important in the regulation of movement (see Chapter 15) and possesses important intrinsic pharmacological properties. In the periphery, it is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. DA is a substrate for both MAO and COMT and, thus, is ineffective when administered orally. Classification of DA receptors, GPCRs structurally similar to adrenergic receptors, is described in Chapter 15.

Pharmacological Properties and Cardiovascular Effects

The cardiovascular effects of DA are mediated by several distinct types of receptors that vary in their affinity for DA (see Chapter 15). At low concentrations, the primary interaction of DA is with vascular D_1 receptors, especially in the renal, mesenteric, and coronary beds. By activating adenylyl cyclase and raising intracellular concentrations of cyclic AMP, D_1 receptor stimulation leads to vasodilation. Infusion of low doses of DA causes an increase in glomerular filtration rate, renal blood flow, and Na^+ excretion. Activation of D_1 receptors on renal tubular cells decreases Na^+ transport by cyclic AMP–dependent and cyclic AMP–independent mechanisms. Increasing cyclic AMP production in the proximal tubular cells and the medullary part of the thick ascending limb of the loop of Henle inhibits the Na^+-H^+ exchanger and the Na^+,K^+-ATPase pump. The renal tubular actions of DA that cause natriuresis may be augmented by the increase in renal blood flow and the small increase in the glomerular filtration rate that follows its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished reabsorption of Na^+ by the proximal tubular cells. Accordingly, DA has pharmacologically appropriate effects in the management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.

At higher concentrations and because of its catecholamine structure, DA exerts a positive inotropic effect on the myocardium, acting on β_1 adrenergic receptors. DA also causes the release of NE from nerve terminals, thereby affecting the heart indirectly via NE. Tachycardia is less prominent during infusion of DA than of INE (discussed further in the chapter). DA usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of DA are given, probably because of the ability of DA to reduce regional arterial resistance in some vascular beds, such as mesenteric and renal, while causing only minor increases in others. At high concentrations, DA activates vascular α_1 receptors, leading to more general vasoconstriction.

CNS Effects

Dopamine is a major neurotransmitter in the CNS; however, injected DA usually has no central effects because it does not readily cross the blood-brain barrier.

Precautions, Adverse Reactions, and Contraindications

Before DA is administered to patients in shock, hypovolemia should be corrected by transfusion of whole blood, plasma, or other appropriate fluid. Untoward effects due to overdosage generally are attributable to excessive sympathomimetic activity (although this also may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during DA infusion. Extravasation of large amounts of DA during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug. DA should be avoided or used at much lower doses if the patient has received a MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

Therapeutic Uses

Dopamine is used in the treatment of severe acute decompensated heart failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug also may improve physiological parameters in the treatment of cardiogenic and septic shock. While DA may acutely improve cardiac and renal function in severely ill patients with chronic heart disease or renal failure, there is relatively little evidence supporting long-term benefit in clinical outcome (Doggrell, 2002).

Dopamine hydrochloride is used only intravenously, preferably into a large vein to prevent perivascular infiltration; extravasation may cause necrosis and sloughing of the surrounding tissue. The use of a calibrated infusion pump to control the rate of flow is necessary. The drug is administered at a rate of 2 to 5 μg/kg per min; this rate may be increased gradually up to 20 to 50 μg/kg per min or more as the clinical situation dictates. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration of action of DA is brief, and hence, the rate of administration can be used to control the intensity of effect.

Fenoldopam and Dopexamine. *Fenoldopam*, a benzazepine derivative, is a rapidly acting vasodilator used for not more than 48 h for control of severe hypertension (e.g., malignant hypertension with end-organ damage) in hospitalized patients. *Fenoldopam* is an agonist for peripheral D_1 receptors and binds with moderate affinity to α_2 adrenergic receptors; it has no significant affinity for D_2 receptors or α_1 or β adrenergic receptors. *Fenoldopam* is a racemic mixture; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries (Murphy et al., 2001). *Fenoldopam* must be administered using a calibrated infusion pump; the usual dose rate ranges from 0.01 to 1.6 μg/kg per min. Less than 6% of an orally administered dose is absorbed because of extensive first-pass formation of sulfate, methyl, and glucuronide conjugates. The elimination $t_{1/2}$ of intravenously infused *fenoldopam* is about 10 min. Adverse effects are related to the vasodilation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine is a synthetic analogue related to DA with intrinsic activity at DA D_1 and D_2 receptors as well as at β_2 receptors; it may have other effects, such as inhibition of catecholamine uptake (Frishman and Hotchkiss, 1996). It has favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, *dopexamine* infusion significantly increases stroke volume with a decrease in systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. *Dopexamine* is not approved for use in the U.S.

α Adrenergic Receptor Agonists

α_1-Selective Adrenergic Receptor Agonists

The major effects of a number of sympathomimetic drugs are due to activation of α_1 adrenergic receptors in vascular smooth muscle. As a result, peripheral vascular resistance is increased, and blood pressure is maintained or elevated. The clinical utility of these drugs is limited to the treatment of some patients with hypotension, including orthostatic hypotension, or shock. *Phenylephrine* and *methoxamine* (discontinued in the U.S.) are direct-acting vasoconstrictors and are selective activators of α_1 adrenergic receptors. *Mephentermine* and *metaraminol* act both directly and indirectly. *Midodrine* is a prodrug that is converted, after oral administration, to *desglymidodrine*, a direct-acting α_1 adrenergic receptor agonist.

Phenylephrine

Phenylephrine is an α_1-selective agonist; it activates β receptors only at much higher concentrations. The pharmacological effects of *phenylephrine* are similar to those of *methoxamine*. The drug causes marked arterial vasoconstriction during intravenous infusion. *Phenylephrine* also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations (see Chapter 74).

Metaraminol

Metaraminol exerts *direct effects* on vascular α_1 adrenergic receptors and acts *indirectly* by stimulating the release of NE. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 34).

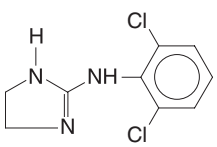
Midodrine

Midodrine is an orally effective α_1 receptor agonist. It is a prodrug, converted to an active metabolite, desglymidodrine, which achieves peak concentrations about 1 h after a dose of *midodrine*. The $t_{1/2}$ of desglymidodrine is about 3 h; its duration of action is about 4 to 6 h. *Midodrine*-induced rises in blood pressure are associated with contraction of both arterial and venous smooth muscle. This is advantageous in the treatment of patients with autonomic insufficiency and postural hypotension (McClellan et al., 1998). A frequent complication in these patients is supine hypertension. This can be minimized by administering the drug during periods when the patient will remain upright, avoiding dosing within 4 h of bedtime, and elevating the head of the bed. Very cautious use of a short-acting antihypertensive drug at bedtime may be useful in some patients. Typical dosing, achieved by careful titration of blood pressure responses, varies between 2.5 and 10 mg three times daily.

α_2-Selective Adrenergic Receptor Agonists

α_2-Selective adrenergic receptor agonists are used primarily for the treatment of systemic hypertension. Their efficacy as antihypertensive agents is somewhat surprising, because many blood vessels contain postsynaptic α_2 adrenergic receptors that promote vasoconstriction. *Clonidine*, an α_2-selective agonist, is an imidazoline derivative that was developed as a vasoconstricting nasal decongestant; it lowers blood pressure by activating α_2 receptors in the CNS, thereby suppressing sympathetic outflow from the brain. The α_2 receptor agonists also reduce intraocular pressure by decreasing the production of aqueous humor. Two derivatives of *clonidine*, *apraclonidine* and *brimonidine*, applied topically to the eye, decrease intraocular pressure with little or no effect on systemic blood pressure.

Clonidine



CLONIDINE

Mechanisms of Action and Pharmacological Effects. Intravenous infusion of *clonidine* causes an acute rise in blood pressure because of activation of postsynaptic α_2 adrenergic receptors in vascular smooth muscle. This transient vasoconstriction (not usually seen with oral administration) is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS. The effect appears to result, at least in part, from activation of α_2 receptors in the lower brainstem region. *Clonidine* also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate. In addition, some of the antihypertensive effects of *clonidine* may be mediated by activation of presynaptic α_2 receptors that suppress the release of NE, ATP, and NPY (neuropeptide Y) from postganglionic sympathetic nerves. *Clonidine* decreases the plasma concentration of NE and reduces its excretion in the urine.

Since *clonidine* is an imidazoline derivative, there are questions about it also acting on imidazoline receptors. Importantly, studies in knockout animals have demonstrated the requirement for a functional α_2 adrenergic receptor for the hypotensive effect of *clonidine*. Imidazoline receptors, of which there are three subtypes (I_1, I_2, and I_3), are widely distributed in the body, including the CNS. Activation of the I_1 receptor appears to reduce sympathetic outflow from the CNS. Whether activation of the CNS I_1 imidazoline receptor also plays a role in the hypotensive effects of *clonidine* and its congeners is a topic of ongoing research. The current hypothesis is that I_1 receptors are upstream from the hypotensive α_2 adrenergic receptors in the CNS and work in tandem with them, such that activation of the I_1 receptors results in catecholamine release onto α_2 receptors (Lowry and Brown, 2014; Nikolic and Agbaba, 2012), thereby reducing sympathetic outflow and reducing blood pressure.

Clonidine does decrease discharges in sympathetic preganglionic fibers in the splanchnic nerve and in postganglionic fibers of cardiac nerves. These effects are blocked by α_2-selective antagonists such as *yohimbine*. *Clonidine* also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate as a consequence of increased vagal tone and diminished sympathetic drive. In addition, some of the antihypertensive effects of *clonidine* may be mediated by activation of presynaptic α_2 receptors that suppress the release of NE, ATP, and NPY from postganglionic sympathetic nerves. *Clonidine* decreases the plasma concentration of NE and reduces its excretion in the urine.

ADME. *Clonidine* is well absorbed after oral administration, with bioavailability about 100%. Peak concentration in plasma and the maximal hypotensive effect are observed 1 to 3 h after an oral dose. The elimination $t_{1/2}$ is 6 to 24 h (mean about 12 h). About half of an administered dose can be recovered unchanged in the urine; the $t_{1/2}$ of the drug may increase with renal failure. A transdermal delivery patch permits continuous administration of *clonidine* as an alternative to oral therapy. The drug is released at an approximately constant rate for a week; 3 to 4 days are required to reach steady-state concentrations in plasma. When the patch is removed, plasma concentrations remain stable for about 8 h and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

Therapeutic Uses. *Clonidine* is used mainly in the treatment of hypertension (see Chapter 32). *Clonidine* also has apparent efficacy in the off-label treatment of a range of other disorders: in reducing diarrhea in some diabetic patients with autonomic neuropathy; in treating and preparing addicted subjects for withdrawal from narcotics, alcohol, and tobacco (see Chapter 28) by ameliorating some of the adverse sympathetic nervous activity associated with withdrawal and decreasing craving for the drug; and in reducing the incidence of menopausal hot flashes (transdermal application). Acute administration of *clonidine* has been used in the differential diagnosis of patients with hypertension and suspected pheochromocytoma. Among the other off-label uses of *clonidine* are atrial fibrillation, attention-deficit/hyperactivity disorder (ADHD), constitutional growth delay in children, *cyclosporine*-associated nephrotoxicity, Tourette syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis, restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

Adverse Effects. The major adverse effects of *clonidine* are dry mouth and sedation, which may diminish in intensity after several weeks of therapy.

Sexual dysfunction also may occur. Marked bradycardia is observed in some patients. These effects of *clonidine* frequently are related to dose, and their incidence may be lower with transdermal administration of *clonidine*. About 15% to 20% of patients develop contact dermatitis when using the transdermal system. Withdrawal reactions follow abrupt discontinuation of long-term therapy with *clonidine* in some hypertensive patients (see Chapter 32).

Apraclonidine

Apraclonidine is a relatively selective α_2 receptor agonist that is used topically to reduce intraocular pressure with minimal systemic effects. This agent does not cross the blood-brain barrier and is more useful than *clonidine* for ophthalmic therapy. *Apraclonidine* is useful as short-term adjunctive therapy in patients with glaucoma whose intraocular pressure is not well controlled by other pharmacological agents. The drug also is used to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (see Chapter 74).

Brimonidine

Brimonidine is a clonidine derivative and α_2-selective agonist that is administered ocularly to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma. Unlike *apraclonidine*, *brimonidine* can cross the blood-brain barrier and can produce hypotension and sedation, although these CNS effects are slight compared to those of *clonidine*.

Guanfacine

Guanfacine is an α_2 receptor agonist that is more selective than *clonidine* for α_2 receptors. Like *clonidine*, *guanfacine* lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. A sustained-release form is FDA approved for treatment of ADHD in children aged 6 to 17 years.

Clinical Use. *Guanfacine* is well absorbed after oral administration. About 50% of the drug appears unchanged in the urine; the rest is metabolized, predominantly by CYP3A4; thus, inhibitors and inducers of CYP3A4 can alter the area under the curve. The $t_{1/2}$ for elimination ranges from 12 to 24 h. *Guanfacine* and *clonidine* appear to have similar efficacy for the treatment of hypertension and a similar pattern of adverse effects. A withdrawal syndrome may occur after the abrupt discontinuation, but it is less frequent and milder than the syndrome that follows *clonidine* withdrawal; this difference may relate to the longer $t_{1/2}$ of *guanfacine*.

Guanabenz

Guanabenz is a centrally acting α_2 agonist that decreases blood pressure by a mechanism similar to those of *clonidine* and *guanfacine*. *Guanabenz* has a $t_{1/2}$ of 4 to 6 h and is extensively metabolized by the liver. Dosage adjustment may be necessary in patients with hepatic cirrhosis. The adverse effects caused by *guanabenz* (e.g., dry mouth and sedation) are similar to those seen with *clonidine*.

Methyldopa

Methyldopa (α-methyl-3,4-dihydroxyphenylalanine) is a centrally acting antihypertensive agent. It is metabolized to α-methylnorepinephrine in the brain, and this compound is thought to activate central α_2 receptors and lower blood pressure in a manner similar to that of *clonidine* (see Chapter 32).

Tizanidine

Tizanidine is a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders (see Chapter 13). It is also an α_2 agonist with some properties similar to those of *clonidine*.

Moxonidine

Moxonidine is a mixed α_2 receptor and imidazole I_1 receptor agonist. It acts to reduce sympathetic outflow from the CNS and thereby reduces blood pressure. *Moxonidine* also has analgesic activity, interacts synergistically with opioid agonists, and is used in treating neuropathic pain.

β Adrenergic Receptor Agonists

β Adrenergic receptor agonists play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or COPD. Minor uses include management of preterm labor, treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction. The development of β_2-selective agonists has resulted in drugs with more valuable characteristics, including adequate oral bioavailability, lack of α adrenergic activity, and relative lack of β_1 adrenergic activity, and thus diminished likelihood of adverse cardiovascular effects. These agents are useful in the treatment of asthma and are more widely used than the nonselective β agonist *isoproterenol* or the primarily β_1-selective agonist *dobutamine*. Emerging β_3-selective adrenergic receptor agonists are being used for overactive bladder syndrome and are in preclinical testing for a host of disorders (Schena and Caplan, 2019).

β Receptor agonists, especially the β_1-selective agonist *dobutamine*, may be used to stimulate the rate and force of cardiac contraction and relaxation. The chronotropic effect is useful in the emergency treatment of arrhythmias such as *torsades de pointes*, bradycardia, or heart block (see Chapter 34), whereas the inotropic effect is useful when it is desirable to augment myocardial contractility.

Nonselective Adrenergic Receptor Agonists

Isoproterenol

Isoproterenol (INE, isopropyl norepinephrine, isoprenaline, isopropylarterenol, isopropyl noradrenaline, *d,l*-β-[3,4-dihydroxyphenyl]-α-isopropylaminoethanol) (see Table 14–1) is a potent, nonselective β adrenergic receptor agonist with very low affinity for α receptors. Consequently, INE has powerful effects on all β receptors and almost no action at α receptors; it is often used experimentally to activate all cellular β receptors.

Pharmacological Actions. The major cardiovascular effects of INE (compared with EPI and NE) are illustrated in Figure 14–2. Intravenous infusion of INE lowers peripheral vascular resistance, primarily in skeletal muscle but also in renal and mesenteric vascular beds. Diastolic pressure falls. Systolic blood pressure may remain unchanged or rise, although mean arterial pressure typically falls. Cardiac output is increased because of the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance. The cardiac effects of INE may lead to palpitations, sinus tachycardia, and more serious arrhythmias; large doses of INE cause myocardial cell death in experimental animals.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, an action that is most pronounced on bronchial and GI smooth muscle. It also prevents or relieves bronchoconstriction. The effects of INE in asthma may be due in part to an additional action to inhibit antigen-induced release of histamine and other mediators of inflammation, an action shared by β_2-selective stimulants.

ADME. *Isoproterenol* is readily absorbed when given parenterally or as an aerosol. It is metabolized by COMT, primarily in the liver but also by other tissues. Of note, INE is a relatively poor substrate for MAO and NET (NE transporter) and is not taken up by sympathetic neurons to the same extent as are EPI and NE. The duration of action of INE therefore may be longer than that of EPI but is still relatively brief.

Therapeutic Uses. *Isoproterenol* may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia torsades de pointes. In disorders such as asthma and shock, INE largely has been replaced by other sympathomimetic drugs (see further in this chapter and in Chapter 44).

Adverse Effects. Palpitations, tachycardia, headache, and flushing are common. Cardiac ischemia and arrhythmias may occur, particularly in patients with underlying coronary artery disease.

β_1-Selective Adrenergic Receptor Agonists

Dobutamine

Dobutamine resembles DA structurally but possesses a bulky aromatic substituent on the amino group (Table 14–1). The pharmacological effects of *dobutamine* are due to direct interactions with α and β receptors; its actions do not appear to result from release of NE from sympathetic

nerve endings, and they are not exerted by dopaminergic receptors. *Dobutamine* possesses a center of asymmetry; both enantiomeric forms are present in the racemate used clinically. The (–) isomer of *dobutamine* is a potent α_1 agonist and can cause marked pressor responses. In contrast, (+)-*dobutamine* is a potent α_1 receptor antagonist, which can block the effects of (–)-*dobutamine* on a receptor and the primary effect is potent β_1 receptor stimulation as both isomers are full agonists at β_1 receptors. The (+) isomer of *dobutamine* is a more potent β agonist than the (–) isomer by approximately 10-fold.

Cardiovascular Effects. The cardiovascular effects of racemic *dobutamine* represent a composite of the distinct pharmacological properties of the (–) and (+) stereoisomers. Compared to INE, *dobutamine* has relatively more prominent inotropic than chronotropic effects on the heart due to its selectivity to the β_1 receptor. Although not completely understood, this useful selectivity may arise because peripheral resistance is relatively unchanged. At equivalent inotropic doses, *dobutamine* enhances automaticity of the sinus node to a lesser extent than does INE; however, enhancement of AV and intraventricular conduction is similar for both drugs. Heart rate increases only modestly when *dobutamine* is administered at less than 20 μg/kg per min. After administration of nonselective or β_1-selective β receptor antagonists, infusion of *dobutamine* fails to increase cardiac output, but total peripheral resistance increases, confirming that *dobutamine* has some modest effects on α adrenergic receptors in the vasculature.

ADME. *Dobutamine* has a $t_{1/2}$ of about 2 min; the major metabolites are conjugates of *dobutamine* and 3-*O*-methyldobutamine. The onset of effect is rapid. Steady-state concentrations generally are achieved within 10 min of initiation of the infusion by calibrated infusion pump. The rate of infusion required to increase cardiac output typically is between 2.5 and 10 μg/kg per min, although higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient.

Therapeutic Uses. *Dobutamine* is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with acute decompensated congestive heart failure requiring hospitalization or acute myocardial infarction. *Dobutamine* increases cardiac output and stroke volume in such patients, usually without a marked increase in heart rate. Alterations in blood pressure or peripheral resistance usually are minor, although some patients may have marked increases in blood pressure or heart rate. An infusion of *dobutamine* in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease.

Adverse Effects. Blood pressure and heart rate may increase significantly during *dobutamine* administration, requiring reduction of infusion rate. Patients with a history of hypertension may exhibit an exaggerated pressor response more frequently. Because *dobutamine* facilitates AV conduction, patients with atrial fibrillation are at risk of marked increases in ventricular response rates; *digoxin* or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. *Dobutamine* may increase the size of a myocardial infarct by increasing myocardial O_2 demand, a property common to inotropic agents. The efficacy of *dobutamine* over a period of more than a few days is uncertain; there is evidence for the development of tolerance, which is due to receptor desensitization mediated by GPCR kinases (Sato et al., 2015).

β_2-Selective Adrenergic Receptor Agonists

β_2-Selective agents have been developed to avoid adverse effects on the heart by INE and *dobutamine* acting on β_1 receptors when used for asthma or COPD (Billington et al., 2017). This selectivity for β_2 receptors, however, is not absolute and is lost at high concentrations of these drugs. Moreover, up to 40% of the β receptors in the human heart are β_2 receptors, activation of which can also cause cardiac stimulation (Rockman et al., 2002).

A second strategy that has increased the usefulness of several β_2-selective agonists in the treatment of asthma and COPD has been structural modification that results in lower rates of metabolism and enhanced oral bioavailability. Modifications have included placing the hydroxyl groups at positions 3 and 5 of the phenyl ring or substituting another moiety for the hydroxyl group at position 3. This has yielded drugs such as *metaproterenol*, *terbutaline*, and *albuterol*, which are not substrates for COMT. Bulky substituents on the amino group of catecholamines contribute to potency at β receptors with decreased activity at α receptors and decreased metabolism by MAO.

A final strategy to enhance preferential activation of pulmonary β_2 receptors is the administration by inhalation of small doses of the drug in aerosol form. This approach typically leads to effective activation of β_2 receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β_1 or β_2 receptors or to stimulate β_2 receptors in skeletal muscle, which can cause tremor and thereby limit oral therapy.

Subcutaneous injection also causes prompt bronchodilation; for an orally administered agent, the peak effect may be delayed for several hours. Administration of β receptor agonists by aerosol (see Chapter 44) typically leads to a very rapid therapeutic response, generally within minutes, although some agonists such as *salmeterol* have a delayed onset of action. Aerosol therapy depends on the delivery of drug to the distal airways. This, in turn, depends on the size of the particles in the aerosol and respiratory parameters such as inspiratory flow rate, tidal volume, breath-holding time, and airway diameter. Only about 10% of an inhaled dose actually enters the lungs; much of the remainder is swallowed and ultimately may be absorbed. Successful aerosol therapy requires that each patient master the technique of drug administration. In some patients, particularly children and the elderly, spacer devices may enhance the efficacy of inhalation therapy.

In the treatment of asthma and COPD, β_2 receptor agonists are used to activate pulmonary receptors that relax bronchial smooth muscle and decrease airway resistance. These drugs also may suppress the release of leukotrienes and histamine from mast cells in lung tissue, enhance mucociliary function, decrease microvascular permeability, and possibly inhibit phospholipase A_2. Airway inflammation also contributes airway hyperresponsiveness; consequently, the use of anti-inflammatory drugs such as inhaled steroids has primary importance. Most authorities recommend that long-acting β_2 agonists should not be used without concomitant anti-inflammatory therapy in the treatment of asthma (see Chapter 44).

Short-Acting β_2 Adrenergic Agonists

Metaproterenol. *Metaproterenol* (called *orciprenaline* in Europe), along with *terbutaline* and *fenoterol,* belongs to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols) (see Table 14–1). Consequently, *metaproterenol* is resistant to methylation by COMT, and a substantial fraction (40%) is absorbed in active form after oral administration. It is excreted primarily as glucuronic acid conjugates. *Metaproterenol* is considered β_2 selective, although it probably is less selective than *albuterol* or *terbutaline* and hence is more prone to cause cardiac stimulation. Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3 to 4 h. *Metaproterenol* is used for the long-term treatment of obstructive airway diseases and asthma and for treatment of acute bronchospasm (see Chapter 44). Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

Albuterol. *Albuterol* is a selective β_2 adrenergic receptor agonist with pharmacological properties and therapeutic indications similar to those of *terbutaline*. It can be administered by inhalation or orally for the symptomatic relief of bronchospasm. When administered by inhalation, it produces significant bronchodilation within 15 min, and effects persist for 3 to 4 h. The cardiovascular effects of *albuterol* are much weaker than those of INE when doses that produce comparable bronchodilation are administered by inhalation. Oral *albuterol* has the potential to delay preterm labor. Although rare, CNS and respiratory side effects are sometimes observed.

Albuterol has been made available in a metered-dose inhaler free of CFCs (chlorofluorocarbons). The alternate propellant, HFA (hydrofluoroalkane), is inert in the human airway, but unlike CFCs, it does not deplete stratospheric ozone.

Levalbuterol. *Levalbuterol* is the *R*-enantiomer of *albuterol*, a racemate used to treat asthma and COPD. Although originally available only as a solution for a nebulizer, it is now available as a CFC-free metered-dose inhaler. *Levalbuterol* is β_2 selective and acts like other β_2 adrenergic agonists. In general, *levalbuterol* has similar pharmacokinetic and pharmacodynamic properties as *albuterol*.

Pirbuterol. *Pirbuterol* is a relatively selective β_2 adrenergic receptor agonist. Its structure differs from that of *albuterol* by the substitution of a pyridine ring for the benzene ring. *Pirbuterol acetate* is available for inhalation therapy; dosing is typically every 4 to 6 h. *Pirbuterol* is the only preparation available in a breath-activated metered-dose inhaler, a device meant to optimize medication delivery by releasing a spray of medication only on the patient's initiation of inspiration.

Terbutaline. *Terbutaline* is a β_2-selective bronchodilator. It contains a resorcinol ring and thus is not a substrate for COMT methylation. It is effective when taken orally or subcutaneously or by inhalation (not marketed for inhalation in the U.S.). Effects are observed rapidly after inhalation or parenteral administration; after inhalation, its action may persist 3 to 6 h. With oral administration, the onset of effect may be delayed 1 to 2 h. *Terbutaline* is used for the long-term treatment of obstructive airway diseases and for treatment of acute bronchospasm; it also is available for parenteral use for the emergency treatment of status asthmaticus (see Chapter 44). It should not be used as a tocolytic (FDA boxed warning).

Fenoterol. *Fenoterol* is a β_2-selective receptor agonist. After inhalation, it has a prompt onset of action, and its effect typically is sustained for 4 to 6 h. A possible association of *fenoterol* use with increased deaths from asthma, although controversial (Billington et al., 2017), has led to its withdrawal from the market. The dysrhythmias and cardiac effects associated with *fenoterol* are likely due to effects on β_1 adrenergic receptors.

Procaterol. *Procaterol* is a β_2-selective receptor agonist. After inhalation, it has a prompt onset of action that is sustained for about 5 h. *Procaterol* is not available in the U.S.

Long-Acting β_2 Adrenergic Agonists (LABAs)

Salmeterol

Mechanism of Action. *Salmeterol* is a lipophilic β_2-selective agonist with a prolonged duration of action (>12 h) and a selectivity for β_2 receptors about 50-fold greater than that of *albuterol*. *Salmeterol* provides symptomatic relief and improves lung function and quality of life in patients with COPD. It is as effective as the cholinergic antagonist *ipratropium*, more effective than *theophylline*, and has additive effects when used in combination with inhaled *ipratropium* or oral *theophylline*. *Salmeterol* also may have anti-inflammatory activity and has been reported to be a G_s-biased agonist at β_2 receptors, although the impact of these characteristics on its clinical effects are not known.

ADME. The onset of action of inhaled *salmeterol* is relatively slow, so it is not suitable monotherapy for acute attacks of bronchospasm. *Salmeterol* is metabolized by cytochrome P450 (CYP) 3A4 to α-hydroxy-salmeterol, which is eliminated primarily in the feces.

Clinical Use, Precautions, and Adverse Effects. *Salmeterol* and *formoterol* (below) are the agents of choice for nocturnal asthma in patients who remain symptomatic despite anti-inflammatory agents and other standard management. *Salmeterol* is generally well tolerated but has the potential to increase heart rate and plasma glucose concentration, to produce tremors, and to decrease plasma K^+ concentration through effects on extrapulmonary β_2 receptors. *Salmeterol* should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting β_2 agonist (e.g., *albuterol*) when breakthrough symptoms occur.

Patients with moderate or severe persistent asthma or COPD benefit from the use of LABAs like *salmeterol* in combination with an inhaled corticosteroid. For that reason, *salmeterol* is available in a single formulate combination with the corticosteroid *fluticasone*. These benefits must be counterbalanced against data, oft-criticized, showing that the addition of a LABA to "usual therapy" was associated with an increased risk of fatal or near-fatal asthmatic attacks, as compared with usual therapy alone. On the other hand, there is a lack of reports of increased asthma mortality among patients taking both a LABA and an inhaled corticosteroid (Fanta, 2009). Nevertheless, the FDA has placed a **black-box warning** in the labeling information for *salmeterol, formoterol*, and *arformoterol*. Expert panels (Fanta, 2009) recommend the use of LABAs only for patients in whom inhaled corticosteroids alone either failed to achieve good asthma control or for initial therapy.

Formoterol. *Formoterol* is a long-acting β_2-selective receptor agonist that induces significant bronchodilation that may persist for up to 12 h, with effects starting within minutes of inhalation of a therapeutic dose. It is highly lipophilic and has high affinity for β_2 receptors. Its major advantage over many other β_2-selective agonists is this prolonged duration of action, which may be particularly advantageous in settings such as nocturnal asthma. *Formoterol*'s sustained action is due to its insertion into the lipid bilayer of the plasma membrane, from which it gradually diffuses to provide prolonged stimulation of β_2 receptors. It is FDA approved for treatment of asthma and bronchospasm, prophylaxis of exercise-induced bronchospasm, and COPD. It can be used concomitantly with short-acting β_2 agonists, glucocorticoids (inhaled or systemic), and *theophylline* (Billington et al., 2017). *Formoterol* is also available as a single formulaic combination with the glucocorticoids *mometasone* or *budesonide* for treatment of COPD.

Arformoterol. *Arformoterol*, an enantiomer of *formoterol*, is a selective LABA that has twice the potency of racemic *formoterol*. It is FDA approved for the long-term treatment of bronchoconstriction in patients with COPD, including chronic bronchitis and emphysema (Matera and Cazzola, 2007). Systemic exposure to *arformoterol* is due to pulmonary absorption, with plasma levels reaching a peak in 0.25 to 1 h. It is primarily metabolized by direct conjugation to glucuronide or sulfate conjugates and secondarily by O-demethylation by CYP2D6 and CYP2C19. It does not inhibit any of the common CYPs (Fanta, 2009).

Very Long-Acting β_2 Adrenergic Agonists (VLABAs)

Very long-acting or ultra β_2 adrenergic receptor agonists have been developed primarily for treating COPD. These drugs are not recommended for treating asthma.

Indacaterol, the first once-daily VLABA approved for COPD, is a potent β_2 agonist with high intrinsic efficacy. It has a fast onset of action, appears well tolerated, and is effective in COPD with little tachyphylaxis on continued use. In contrast to *salmeterol*, *indacaterol* does not antagonize the bronchorelaxant effect of short-acting β_2 adrenergic agonists.

Olodaterol is also a once-daily VLABA approved for use in COPD. It is also offered in combination with *tiotropium bromide*, an antagonist at M_3 muscarinic receptors.

Vilanterol is a VLABA approved for use in combination with *fluticasone*. *Vilanterol* is available in Europe in combination with the long-acting muscarinic antagonist *umeclidinium*.

Other β_2-Selective Agonists

Ritodrine. *Ritodrine* is a β_2-selective agonist that was developed specifically for use as a uterine relaxant. Its pharmacological properties closely resemble those of the other agents in this group. The pharmacokinetic properties of *ritodrine* are complex and incompletely defined, especially in pregnant women. *Ritodrine* is rapidly but incompletely (30%) absorbed following oral administration: The drug may be administered intravenously to selected patients to arrest premature labor. β_2-Selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. *Ritodrine* is not available in the U.S.

Adverse Effects of β_2-Selective Agonists

The major adverse effects of β_2 receptor agonists occur as a result of excessive activation of β adrenergic receptors. Patients with underlying

cardiovascular disease are particularly at risk for significant reactions. However, the likelihood of adverse effects can be greatly decreased in patients with lung disease by administering the drug by inhalation rather than orally or parenterally. Tremor is a relatively common adverse effect of the β_2-selective adrenergic receptor agonists. Tolerance generally develops to this effect; it is not clear whether tolerance reflects desensitization of the β_2 receptors of skeletal muscle or adaptation within the CNS. This adverse effect can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops. Feelings of restlessness, apprehension, and anxiety may limit therapy with these drugs, particularly oral or parenteral administration.

Tachycardia is a common adverse effect of systemically administered β receptor agonists. Stimulation of heart rate occurs primarily with higher doses via activation of β_1 adrenergic receptors. It is uncertain to what extent the increase in heart rate also is due to activation of cardiac β_2 receptors or to reflex effects that stem from β_2 receptor–mediated peripheral vasodilation. During a severe asthma attack, heart rate actually may decrease during therapy with a β_2 agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β_2 agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects also is increased in patients who are receiving MAO inhibitors. In general, at least 2 weeks should elapse between the use of MAO inhibitors and administration of β_2 agonists or other sympathomimetics.

When given parenterally, these drugs also may increase the concentrations of glucose, lactate, and free fatty acids in plasma and decrease the concentration of K^+. The decrease in K^+ concentration may be especially important in patients with cardiac disease, particularly those taking *digoxin* and diuretics. In some diabetic patients, hyperglycemia may be worsened by these drugs, and higher doses of insulin may be required. Side effects of LABAs and VLABAs include nasopharyngitis and increase in incidence of pneumonia. As a result of these side effects, postmarketing safety studies are under way.

β_3 Adrenergic Receptor Agonists

The existence of the β_3 adrenergic receptor subtype was first proposed in the 1970s but was not confirmed until the receptor was cloned in 1989 (Emorine et al., 1989). The β_3 adrenergic receptor couples to the G_s-cyclic AMP pathway and has a much stronger affinity for NE than EPI. There is also significant coupling to the G_i pathway that leads to activation of nitric oxide (NO) synthases, accumulation of NO, and cyclic GMP (Cannavo and Koch, 2017; Schena and Caplan, 2019). The β_3 receptor displays much lower affinities for classic β antagonists (such as *propranolol* or *atenolol*) that are better at blocking β_1 and β_2 receptors. In humans, the β_3 adrenergic receptor is expressed in brown adipose tissue, gallbladder, and ileum and to a lesser extent in white adipose tissue and the detrusor muscle of the bladder; however, there is appreciable expression in myocardium (Cannavo and Koch, 2017). To date, the major therapeutic target that has emerged from this field has been the development of β_3 receptor agonists for use in urinary incontinence (Schena and Caplan, 2019). β_3 Receptors are prominent in brown and white adipose tissues where, in rodents, their activation can increase brown fat and stimulate lipolysis. Such observations have made these receptors an attractive target for weight loss, with clinical trials proceeding in this area. The absence of cardioprotective NO-dependent signaling in β_3 receptor knockout mice (Cannavo and Koch, 2017) has led to preclinical studies and clinical trials of β_3 agonists for cardiovascular indications. In addition to the current indication for β_3 agonists for overactive bladder disease, there are ongoing clinical trials testing their efficacy in irritable bowel syndrome.

Mirabegron is a β_3-selective adrenergic receptor agonist approved for use against incontinence due to overactive bladder. Activation of this receptor in the bladder leads to detrusor muscle relaxation and increased bladder capacity. This action prevents voiding and provides relief for those with an overactive bladder and urinary incontinence. Side effects include increased blood pressure, increased incidence of urinary tract infection, and headache. *Mirabegron* is also a moderate CYP2D6 inhibitor, so care must be taken when prescribing with other drugs metabolized by CYP2D6, such as *digoxin*, *metoprolol*, and *desipramine*. *Mirabegron* is being used in clinical trials for induction of brown fat in humans and also heart failure.

Vibegron is another β_3-selective adrenergic receptor agonist also approved for overactive bladder syndrome and being tested preclinically and clinically for other indications.

Miscellaneous Sympathomimetic Agonists

Amphetamine

Amphetamine, racemic β phenylisopropylamine (see Table 14–1), has powerful CNS stimulant actions in addition to the peripheral α and β receptor actions common to indirect-acting sympathomimetic drugs. Unlike EPI, it is effective after oral administration, and its effects last for several hours.

Cardiovascular System

Amphetamine given orally raises both systolic and diastolic blood pressure. Heart rate often is slowed via reflex mechanisms; with large doses, cardiac arrhythmias may occur. Cardiac output is not enhanced by therapeutic doses, and cerebral blood flow does not change much. The *l*-isomer is slightly more potent than the *d*-isomer in its cardiovascular actions.

Other Smooth Muscles

In general, smooth muscles respond to *amphetamine* as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason, *amphetamine* has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. The GI effects of *amphetamine* are unpredictable. If enteric activity is pronounced, *amphetamine* may cause relaxation and delay the movement of intestinal contents; if the gut already is relaxed, the opposite effect may occur. The response of the human uterus varies, but there usually is an increase in tone.

CNS

Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center, lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation. In eliciting CNS excitatory effects, the *d*-isomer (dextroamphetamine) is three to four times more potent than the *l*-isomer. The psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10 to 30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often, elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved, but, although more work may be accomplished, the number of errors may increase. Physical performance (e.g., in athletes) is improved, and the drug often is abused for this purpose. These effects are variable and may be reversed by overdosage or repeated usage. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given *amphetamine* experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue.

Fatigue and Sleep. In general, *amphetamine* prolongs the duration of adequate performance before fatigue appears, and the effects of fatigue are at least partly reversed, most strikingly when performance has been reduced by fatigue and lack of sleep. Such improvement may be partly due to alteration of unfavorable attitudes toward the task. However, *amphetamine* reduces the frequency of attention lapses that impair performance after prolonged sleep deprivation and thus improves execution of tasks requiring sustained attention. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

Analgesia. *Amphetamine* and some other sympathomimetic amines have a small analgesic effect that is not sufficiently pronounced to be therapeutically useful. However, *amphetamine* can enhance the analgesia produced by opiates.

Respiration. *Amphetamine* stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally acting drugs, *amphetamine* may stimulate respiration.

Appetite. *Amphetamine* and similar drugs have been used for the treatment of obesity, although the wisdom of this use is at best questionable. Weight loss in obese humans treated with *amphetamine* is almost entirely due to reduced food intake and only in small measure to increased metabolism. The site of action probably is in the lateral hypothalamic feeding center; injection of *amphetamine* into this area, but not into the ventromedial region, suppresses food intake. Neurochemical mechanisms of action are unclear but may involve increased release of NE or DA. In humans, tolerance to the appetite suppression develops rapidly. Hence, continuous weight reduction usually is not observed in obese individuals without dietary restriction.

Mechanisms of Action in the CNS

Amphetamine exerts most or all of its effects in the CNS by releasing biogenic amines from their storage sites in nerve terminals. The neuronal dopamine transporter (DAT) and the vesicular monoamine transporter (VMAT2) appear to be two of the principal targets of *amphetamine*'s action (Fleckenstein, 2007; Sitte and Freissmuth, 2015). These mechanisms include *amphetamine*-induced exchange diffusion, reverse transport, channel-like transport phenomena, and effects resulting from the weakly basic properties of *amphetamine*. *Amphetamine* analogues affect monoamine transporters through phosphorylation, transporter trafficking, and the production of reactive oxygen and nitrogen species. These mechanisms may have potential implications for neurotoxicity as well as dopaminergic neurodegenerative diseases (discussed further in the chapter).

The alerting effect of *amphetamine*, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of NE from central noradrenergic neurons. These effects can be prevented in experimental animals by inhibiting tyrosine hydroxylase and thus catecholamine synthesis. Some aspects of locomotor activity and the stereotyped behavior induced by *amphetamine* probably are a consequence of the release of DA from dopaminergic nerve terminals, particularly in the neostriatum. Higher doses are required to produce these behavioral effects, and this correlates with the higher concentrations of *amphetamine* required to release DA from brain slices or synaptosomes *in vitro*. With still higher doses of *amphetamine*, disturbances of perception and overt psychotic behavior occur. These effects may be due to release of 5HT [(5-hydroxytryptamine (serotonin)] from serotonergic neurons and of DA in the mesolimbic system. In addition, *amphetamine* may exert direct effects on CNS receptors for 5HT (see Chapter 15).

Toxicity and Adverse Effects

The acute toxic effects of *amphetamine* usually are extensions of its therapeutic actions and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of *amphetamine* are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. GI symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma, and cerebral hemorrhages are the main pathological findings.

The toxic dose of *amphetamine* varies widely. Toxic manifestations occasionally occur as an idiosyncratic reaction after as little as 2 mg but are rare with doses less than 15 mg. Severe reactions have occurred with 30 mg, yet doses of 400 to 500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug. Treatment of acute *amphetamine* intoxication may include acidification of the urine by administration of ammonium chloride; this enhances the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of sodium nitroprusside or an α adrenergic receptor antagonist.

Chronic intoxication with *amphetamine* causes symptoms similar to those of acute overdosage, but abnormal mental conditions are more common. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery usually is rapid after withdrawal of the drug, but occasionally the condition becomes chronic. In these persons, *amphetamine* may act as a precipitating factor hastening the onset of incipient schizophrenia.

The abuse of *amphetamine* as a means of overcoming sleepiness and of increasing energy and alertness should be discouraged. The drug should be used only under medical supervision. All *amphetamines* are schedule II drugs under federal regulations. The additional contraindications and precautions for the use of *amphetamine* generally are similar to those described for EPI. *Amphetamine* use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

Dependence and Tolerance

Psychological dependence often occurs when *amphetamine* or *dextroamphetamine* is used chronically, as discussed in Chapter 28. Tolerance almost invariably develops to the anorexigenic effect of *amphetamines* and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients. Tolerance is striking in individuals who are dependent on the drug; a daily intake of 1.7 g without apparent ill effects has been reported. Development of tolerance is not invariable, and cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

Therapeutic Uses

Amphetamine is used chiefly for its CNS effects. *Dextroamphetamine*, with greater CNS action and less peripheral action, is FDA approved for the treatment of narcolepsy and ADHD (see discussion later in this chapter).

Methamphetamine

Methamphetamine is closely related chemically to *amphetamine* and *ephedrine* (see Table 14–1). The drug acts centrally to release DA and other biogenic amines and to inhibit neuronal and VMATs as well as MAO. Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly to cardiac stimulation. Cardiac output is increased, although the heart rate may be slowed via reflex action. Venous constriction causes peripheral venous pressure to increase. These factors tend to increase the venous return and thus cardiac output; pulmonary arterial pressure is raised.

Methamphetamine is widely abused as a cheap, accessible recreational drug. Illegal production of *methamphetamine* in clandestine laboratories throughout the U.S. is common. It is used principally for its central effects, which are more pronounced than those of *amphetamine* and are accompanied by less-prominent peripheral actions.

Methylphenidate

Methylphenidate is a piperidine derivative that is structurally related to *amphetamine*. *Methylphenidate* is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation that may lead to convulsions. The effects of *methylphenidate* resemble those of the *amphetamines*.

Methylphenidate also shares the abuse potential of the *amphetamines* and is listed as a schedule II controlled substance in the U.S. *Methylphenidate* is effective in the treatment of narcolepsy and ADHD (described below). *Methylphenidate* is readily absorbed after oral administration, reaching a peak C_p in about 2 h. The drug is a racemate; its more potent (+) enantiomer has a $t_{1/2}$ of about 6 h; the less-potent (–) enantiomer has a $t_{1/2}$ of approximately 4 h. Concentrations in the brain exceed those in plasma. The main urinary metabolite is a de-esterified product, ritalinic acid, which accounts for 80% of the dose. The use of *methylphenidate* is contraindicated in patients with glaucoma.

Dexmethylphenidate

Dexmethylphenidate is the *d*-threo enantiomer of racemic *methylphenidate*. It is FDA approved for the treatment of ADHD and is listed as a schedule II controlled substance in the U.S.

Pemoline

Pemoline is structurally dissimilar to *methylphenidate* but elicits similar changes in CNS function with minimal effects on the cardiovascular system. It is employed in treating ADHD. It can be given once daily because of its long $t_{1/2}$. Clinical improvement may require treatment for 3 to 4 weeks. Use of *pemoline* has been associated with severe hepatic failure. The drug was discontinued in the U.S. in 2006.

Lisdexamphetamine

Lisdexamphetamine is a therapeutically inactive prodrug that is converted primarily in the blood to lysine and D-amphetamine, the active component (Childress and Berry, 2012). It is approved for the treatment of ADHD in children, adolescents, and adults. The drug produces mild-to-moderate side effects, including decreased appetite, dizziness, dry mouth, fatigue, headache, insomnia, irritability, nasal congestion, nasal pharyngitis, upper respiratory infection, vomiting, and decreased weight.

Ephedrine

Ephedrine is an agonist at both α and β receptors; in addition, it enhances release of NE from sympathetic neurons and thus is a mixed-acting sympathomimetic (see Table 14–1 and Figure 14–1). Only *l*-ephedrine and racemic ephedrine are used clinically.

ADME and Pharmacological Actions

Ephedrine is effective after oral administration; effects may persist for several hours. *Ephedrine* is eliminated in the urine largely as unchanged drug, with a $t_{1/2}$ of 3 to 6 h. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, *ephedrine* usually increases blood pressure. Stimulation of the α adrenergic receptors of smooth muscle cells in the bladder base may increase the resistance to the outflow of urine. Activation of β adrenergic receptors in the lungs promotes bronchodilation. *Ephedrine* is a potent CNS stimulant.

Therapeutic Uses and Untoward Effects

The use of *ephedrine* as a bronchodilator in asthmatic patients is less common with the availability of β_2-selective receptor agonists. *Ephedrine* has been used to promote urinary continence. Indeed, the drug may cause urinary retention, particularly in men with benign prostatic hyperplasia (BPH). *Ephedrine* also has been used to treat the hypotension that may occur with spinal anesthesia.

Untoward effects of *ephedrine* include hypertension and insomnia. Tachyphylaxis may occur with repetitive dosing. Usual or higher-than-recommended doses may cause important adverse effects in susceptible individuals, especially in patients with underlying cardiovascular disease that might be unrecognized. Large amounts of herbal preparations containing *ephedrine* (ma huang, ephedra) are utilized around the world. There can be considerable variability in the content of *ephedrine* in these preparations, which may result in inadvertent consumption of higher-than-usual doses of *ephedrine* and its isomers, leading to significant toxicity and death. Thus, the FDA has banned the sale of dietary supplements containing *ephedra*. In addition, the Combat Methamphetamine Epidemic Act of 2005 regulates the sale of *ephedrine*, *phenylpropanolamine*, and *pseudoephedrine*, which can be used as precursors in the illicit manufacture of *amphetamine* and *methamphetamine*.

Other Sympathomimetic Agents

Several sympathomimetic drugs (e.g., *propylhexedrine, naphazoline, oxymetazoline*, and *xylometazoline*) are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the eye.

Phenylephrine, *pseudoephedrine* (a stereoisomer of *ephedrine*), and *phenylpropanolamine* are the sympathomimetic drugs that have been used most commonly in oral preparations for the relief of nasal congestion. *Pseudoephedrine* is available without a prescription in a variety of solid and liquid dosage forms. *Phenylpropanolamine* shares the pharmacological properties of *ephedrine* and is approximately equal in potency except that it causes less CNS stimulation. Due to concern about the possibility that *phenylpropanolamine* increases the risk of hemorrhagic stroke, the drug is no longer licensed for marketing in the U.S.

Therapeutic Uses of Sympathomimetic Drugs

Shock

Shock is a clinical syndrome characterized by inadequate perfusion of tissues; it usually is associated with hypotension and ultimately with the failure of organ systems. Shock is an immediately life-threatening impairment of delivery of O_2 and nutrients to the organs of the body. Causes of shock include hypovolemia; cardiac failure; obstruction to cardiac output (due to pulmonary embolism, pericardial tamponade, or aortic dissection); and peripheral circulatory dysfunction (sepsis or anaphylaxis). The treatment of shock consists of specific efforts to reverse the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. The accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock, these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis.

The initial therapy of shock involves basic life support measures. It is essential to maintain blood volume, which often requires monitoring of hemodynamic parameters. Specific therapy (e.g., antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities in blood pressure and flow. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β adrenergic receptor agonists increase heart rate and force of contraction, α adrenergic receptor agonists increase peripheral vascular resistance, and DA promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors.

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. A number of sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: INE is a powerful chronotropic agent and can greatly increase myocardial O_2 demand; NE intensifies peripheral vasoconstriction; and EPI increases heart rate and may predispose the heart to dangerous arrhythmias. DA is an effective inotropic agent that causes less increase in heart rate than does INE. DA also promotes renal arterial dilation; this may be useful in preserving renal function. When given in high doses (>10–20 μg/kg per min), DA activates α receptors,

causing peripheral and renal vasoconstriction. *Dobutamine* has complex pharmacological actions that are mediated by its stereoisomers; the clinical effects of the drug are to increase myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients in shock, hypotension is so severe that vasoconstricting drugs are required to maintain a blood pressure that is adequate for CNS perfusion. The α agonists such as NE, *phenylephrine*, *metaraminol*, *mephentermine*, *midodrine*, *ephedrine*, EPI, DA, and *methoxamine* all have been used for this purpose. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (e.g., after spinal anesthesia or injury). However, in patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Indeed, vasodilating drugs such as *nitroprusside* are more likely to improve blood flow and decrease cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or barely normal peripheral vascular resistance, possibly owing to excessive effects of endogenously produced NO as well as normal or increased cardiac output. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Therapy with drugs such as DA or *dobutamine* is guided by hemodynamic monitoring.

Hypotension

Drugs with predominantly α adrenergic receptor agonist activity can be used to raise blood pressure in patients with decreased peripheral resistance in conditions such as spinal anesthesia or intoxication with antihypertensive medications. However, hypotension per se is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension.

Patients with orthostatic hypotension (excessive fall in blood pressure with standing) often represent a pharmacological challenge. There are diverse causes for this disorder, including the Shy-Drager syndrome and idiopathic autonomic failure. Therapeutic approaches include physical maneuvers and a variety of drugs (*fludrocortisone*, prostaglandin synthesis inhibitors, somatostatin analogues, caffeine, vasopressin analogues, and DA antagonists). A number of sympathomimetic drugs also have been used in treating this disorder. The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction to avoid supine hypertension. No such agent currently is available. Drugs used in this disorder to activate α_1 receptors include both direct- and indirect-acting agents. *Midodrine* shows promise in treating this challenging disorder.

Hypertension

Centrally acting α_2 adrenergic receptor agonists such as *clonidine* are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 32.

Cardiac Arrhythmias

Cardiopulmonary resuscitation in patients with cardiac arrest due to ventricular fibrillation, electromechanical dissociation, or asystole may be facilitated by drug treatment. EPI is an important therapeutic agent in patients with cardiac arrest; EPI and other α agonists increase diastolic pressure and improve coronary blood flow. The α receptor agonists also help to preserve cerebral blood flow during resuscitation. Cerebral blood vessels are relatively insensitive to the vasoconstricting effects of catecholamines, and perfusion pressure is increased. Consequently, during external cardiac massage, EPI facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. The optimal dose of EPI in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock.

In patients with paroxysmal supraventricular tachycardias, particularly those associated with mild hypotension, careful infusion of an α agonist (e.g., *phenylephrine*) to raise blood pressure to about 160 mmHg may end the arrhythmia by increasing vagal tone. However, this method of treatment has been replaced largely by Ca^{2+} channel blockers with clinically significant effects on the AV node, β antagonists, adenosine, and electrical cardioversion (see Chapter 34). A β adrenergic receptor agonist such as INE may be used as adjunctive or temporizing therapy with *atropine* in patients with marked bradycardia who are compromised hemodynamically; if long-term therapy is required, a cardiac pacemaker usually is the treatment of choice.

Congestive Heart Failure

At first glance, sympathetic stimulation of β receptors in the heart would appear to be an important compensatory mechanism for maintenance of cardiac function in patients with congestive heart failure. However, the failing heart does not respond well to excess sympathetic stimulation. *Dobutamine* and other β_1-selective agonists are used acutely in hospitalized decompensated heart failure patients and do improve short-term cardiac contractility; their long-term effects are deleterious in congestive heart failure (Butta et al., 2020). In chronic heart failure, *dobutamine* can add to the already toxic nature of increased catecholamines; moreover, β adrenergic receptors are also desensitized and downregulated in part to increased GPCR kinase activity (Sato et al., 2015). Further, β agonists may increase cardiac output in acute emergency settings such as shock but, again, are indicated only for short-term use. Chronically, β adrenergic receptor antagonists are now part of the standard of care in the treatment of patients with congestive heart failure, a topic covered in detail in Chapter 33.

Local Vascular Effects

Epinephrine is used in surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of EPI with local anesthetics retards their absorption and increases the duration of anesthesia (see Chapter 25). Injection of α adrenergic receptor agonists into the penis may be useful in reversing priapism, a complication of the use of α receptor antagonists or phosphodiesterase 5 (PDE5) inhibitors (e.g., *sildenafil*) in the treatment of erectile dysfunction. Both *phenylephrine* and *oxymetazoline* are efficacious vasoconstrictors when applied locally during sinus surgery.

Nasal Decongestion

α Adrenergic receptor agonists are used as nasal decongestants in patients with allergic or vasomotor rhinitis and in acute rhinitis in patients with upper respiratory infections. These drugs probably decrease resistance to airflow by decreasing the volume of the nasal mucosa; this may occur by activation of α receptors in venous capacitance vessels in nasal tissues that have erectile characteristics. The receptors that mediate this effect appear to be α_1 adrenergic receptors. The use of α_2 adrenergic receptor agonists may mediate contraction of arterioles that supply nutrition to the nasal mucosa. Intense constriction of these vessels may cause structural damage to the mucosa. A major limitation of therapy with nasal decongestants is loss of efficacy, "rebound" hyperemia, and worsening of symptoms with chronic use or when the drug is stopped. Although mechanisms are uncertain, possibilities include receptor desensitization and damage to the mucosa. Agonists that are selective for α_1 receptors may be less likely to induce mucosal damage.

In general, α adrenergic receptor agonists for nasal decongestion may be administered either orally or topically. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement; these agents are contraindicated in patients who are taking MAO inhibitors. Topical decongestants are particularly useful in acute rhinitis because of their more selective site of action, but they are apt to be used excessively by patients, leading to

rebound congestion. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Patients with uncontrolled hypertension or ischemic heart disease generally should avoid the oral consumption of over-the-counter products or herbal preparations containing sympathomimetic drugs.

Asthma

Use of β adrenergic agonists in the treatment of asthma and COPD is discussed in Chapter 44.

Allergic Reactions

Epinephrine is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from food, bee sting, or drug allergy). A subcutaneous injection of EPI rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of EPI may be required to ensure prompt pharmacological effects. This treatment may be life-saving when edema of the glottis threatens airway patency or when there is hypotension or shock in patients with anaphylaxis. In addition to its cardiovascular effects, EPI is thought to activate β receptors that suppress the release from mast cells of mediators such as histamine and leukotrienes. Although glucocorticoids and antihistamines frequently are administered to patients with severe hypersensitivity reactions, EPI remains the mainstay. EPI autoinjectors are employed widely for the emergency self-treatment of anaphylaxis.

Ophthalmic Uses

Ophthalmic uses are discussed in Chapter 74.

Narcolepsy and Sleep/Wake Imbalance

Hypocretin neurons activate wake-promoting pathways in the CNS. A deficiency of hypocretin, likely due to autoimmune destruction of hypocretin neurons, produces narcolepsy, a condition of hypersomnia, including excessive daytime sleepiness and attacks of sleep that may occur suddenly under conditions that are not normally conducive to sleep. Hypocretin agonists will likely be available in the future. At present, treatment relies on the fact that monoamine pathways promote wakefulness; thus, current treatments utilize CNS stimulants, including those that enhance transmission in monoamine pathways (Black et al., 2017).

The CNS stimulants *modafinil* (a mixture of *R*- and *S*-enantiomers) and *armodafinil* (the *R*-enantiomer of modafinil) are first-line agents for narcolepsy. In the U.S., *modafinil* is a schedule IV controlled substance. Its mechanism of action in narcolepsy is unclear. *Methylphenidate* and *amphetamines* are also used. Therapy with *amphetamines* is complicated by the risk of abuse and the likelihood of the development of tolerance. Depression, irritability, and paranoia also may occur. *Amphetamines* may disturb nocturnal sleep, which increases the difficulty of avoiding daytime attacks of sleep in these patients. *Armodafinil* is also indicated to improve wakefulness in shift workers and to combat excessive sleepiness in patients with obstructive sleep apnea-hypopnea syndrome. See previous sections for more details on these agents.

Sodium γ-hydroxybutyrate (Na^+-oxybate) is FDA approved for treating the sleep/wake imbalance and cataplexy of narcolepsy. The mechanism of action of *oxybate* is unknown but likely relates to its structural similarity to glutamate and GABA and to actions on NE and DA neurons mediated by $GABA_B$ receptors. *Oxybate* is a schedule III controlled substance, available through a special program with the manufacturer. *Oxybate* carries an FDA boxed warning about severe CNS depressants and must be used with great caution (see FDA, 2012).

Weight Reduction

Amphetamine promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorexic drugs include *methamphetamine*, *dextroamphetamine* (and a prodrug form, *lisdexamfetamine*), *phentermine*, *benzphetamine*, *phendimetrazine*, *phenmetrazine*, *diethylpropion*, *mazindol*, *phenylpropanolamine*, and *sibutramine* (a mixed adrenergic/serotonergic drug). *Phenmetrazine*, *mazindol*, and *phenylpropanolamine* have been discontinued in the U.S. Available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and modification of diet under medical supervision.

Preclinical data show that β_3-selective adrenergic receptor agonists have remarkable antiobesity and antidiabetic effects in rodents, and the drug *mirabegron* (above) has some promising effects in humans (Cypess et al., 2015). β_3 Agonists are being studied in humans, but their use for the treatment of obesity in humans remains a possibility for the future (Dehvari et al., 2018).

Attention-Deficit/Hyperactivity Disorder

The ADHD syndrome, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. Children with this disorder frequently are troubled by difficulties in school, impaired interpersonal relationships, and excitability. Academic underachievement is an important characteristic. A substantial number of children with this syndrome have characteristics that persist into adulthood. Behavioral therapy may be helpful in some patients.

Catecholamines may be involved in the control of attention at the level of the cerebral cortex. A variety of stimulant drugs have been utilized in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases (Cortese, 2020). *Dextroamphetamine* has been demonstrated to be more effective than placebo. *Methylphenidate* is effective in children with ADHD and is the most common intervention. Treatment may start with a dose of 5 mg of *methylphenidate* in the morning and at lunch; the dose is increased gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg; because of its short duration of action, most children require two or three doses of *methylphenidate* each day. The timing of doses is adjusted individually in accordance with rapidity of onset of effect and duration of action.

Methylphenidate, *dextroamphetamine*, and *amphetamine* probably have similar efficacy in ADHD and are the preferred drugs in this disorder (Cortese, 2020). Sustained-release preparations of *dextroamphetamine*, *methylphenidate*, *dexmethylphenidate*, and *amphetamine* may be used once daily in children and adults. *Lisdexamfetamine* can be administered once daily, and a transdermal formulation of *methylphenidate* is marketed for daytime use. Potential adverse effects of these medications include insomnia, abdominal pain, anorexia, and weight loss, which may be associated with suppression of growth in children. Minor symptoms may be transient or may respond to adjustment of dosage or administration of the drug with meals. Other drugs that have been utilized include tricyclic antidepressants, antipsychotic agents, and *clonidine*. A sustained-release formulation of guanfacine, an α_{2A} adrenergic receptor agonist, is also being used for ADHD (Cortese, 2020).

Adrenergic Receptor Antagonists

Many types of drugs interfere with the function of the sympathetic nervous system and thus have profound effects on the physiology of sympathetically innervated organs. Several of these drugs are important in clinical medicine, particularly for the treatment of cardiovascular diseases.

The remainder of this chapter focuses on the pharmacology of adrenergic receptor antagonists, drugs that inhibit the interaction of NE, EPI, and other sympathomimetic drugs with α and β adrenergic receptors throughout peripheral tissues (Figure 14–3). Most of these agents are competitive antagonists; an important exception is *phenoxybenzamine*, an irreversible antagonist that binds covalently to α adrenergic receptors.

There are important structural differences among adrenergic receptors, differences that have permitted development of compounds with substantially different affinities for the various receptors. Thus, it is possible to interfere selectively with responses that result from stimulation of the sympathetic nervous system. The selectivity is relative, not absolute.

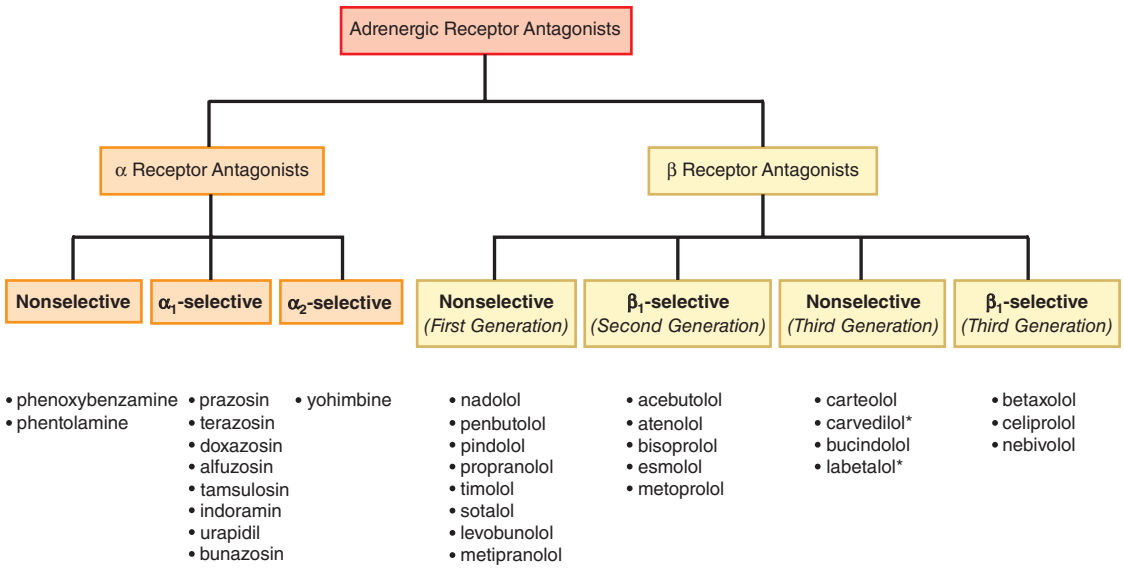


Figure 14–3 *Classification of adrenergic receptor antagonists.* Drugs marked by an asterisk (*) also block α_1 receptors.

Nonetheless, selective antagonists of β_1 adrenergic receptors block most actions of epinephrine and NE on the heart, while having less effect on β_2 receptors in bronchial smooth muscle and no effect on responses mediated by α_1 or α_2 adrenergic receptors. Accordingly, detailed knowledge of the autonomic nervous system and the sites of action of drugs that act on adrenergic receptors is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs (see Chapter 10). Agents that block dopaminergic receptors are considered in Chapter 15.

α Adrenergic Receptor Antagonists

Overview

The α adrenergic receptors mediate many of the important actions of endogenous catecholamines as detailed above. α_1 Adrenergic receptors mediate contraction of arterial, venous, and visceral smooth muscle, while the α_2 receptors are involved in suppressing sympathetic output, increasing vagal tone, facilitating platelet aggregation, inhibiting the release of NE and acetylcholine from nerve endings, and regulating metabolic effects (e.g., suppression of insulin secretion and inhibition of lipolysis). α_2 Adrenergic receptors also mediate contraction of some arteries and veins.

Some of the most important effects of α receptor antagonists observed clinically are on the cardiovascular system. Actions in both the CNS and the periphery are involved; the outcome depends on the cardiovascular status of the patient at the time of drug administration and the relative selectivity of the agent for α_1 and α_2 receptors.

Antagonists against α adrenergic receptors have a wide spectrum of pharmacological specificities and are chemically heterogeneous. Some of these drugs have markedly different affinities for α_1 and α_2 adrenergic receptors. For example, *prazosin* is much more potent in blocking α_1 than α_2 receptors (i.e., α_1 selective), whereas *yohimbine* is α_2 selective; *phentolamine* has similar affinities for both of these receptor subtypes and is considered a nonselective α-adrenergic receptor antagonist. More recently, agents that discriminate among the various subtypes of a particular receptor have become available; for example, *tamsulosin* has higher potency at α_{1A} than at α_{1B} receptors (Docherty, 2019).

Catecholamines increase the output of glucose from the liver; in humans, this effect is mediated predominantly by β adrenergic receptors, although α adrenergic receptors may contribute. Thus, α receptor antagonists may reduce glucose release. Receptors of the α_{2A} subtype facilitate platelet aggregation; the effect of blockade of platelet α_2 receptors *in vivo* is not clear. Activation of α_2 receptors in the pancreatic islets suppresses insulin secretion; conversely, blockade of pancreatic α_2 adrenergic receptors may facilitate insulin release (see Chapter 51).

Nonselective α Adrenergic Antagonists

Phenoxybenzamine and Phentolamine

Phenoxybenzamine and *phentolamine* are nonselective α adrenergic receptor antagonists. *Phenoxybenzamine*, a haloalkylamine, produces an irreversible antagonism, while *phentolamine*, an imidazaline, produces a competitive antagonism. Both of these drugs cause a progressive decrease in peripheral resistance due to antagonism of α adrenergic receptors in the vasculature and an increase in cardiac output that is due in part to reflex sympathetic nerve stimulation. The cardiac stimulation is accentuated by enhanced release of NE from cardiac sympathetic nerve due to antagonism of presynaptic α_2 adrenergic receptors by these nonselective α blockers. Postural hypotension is a prominent feature with these drugs, and this, accompanied by reflex tachycardia that can precipitate cardiac arrhythmias, severely limits the use of these drugs to treat essential hypertension. The α_1-selective receptor antagonists, such as *prazosin*, have replaced the "classical" α-blockers in the management of essential hypertension. However, *phenoxybenzamine* and *phentolamine* are still marketed for several specialized uses.

Therapeutic Uses. *Phenoxybenzamine* is used in the treatment of pheochromocytomas, tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines into the circulation. The usual result is hypertension, which may be episodic and severe. The vast majority of pheochromocytomas are treated surgically; *phenoxybenzamine* is often used in preparing the patient for surgery. The drug controls episodes of severe hypertension and minimizes other adverse effects of catecholamines, such as contraction of plasma volume and injury of the myocardium. A conservative approach is to initiate treatment with *phenoxybenzamine* (at a dosage of 10 mg twice daily) 1 to 3 weeks before the operation. The dose is increased every other day until the desired effect on blood pressure is achieved. The usual daily dose of *phenoxybenzamine* in patients with pheochromocytoma is 40 to 120 mg given in two or three divided portions. Prolonged treatment with *phenoxybenzamine* may be necessary in patients with inoperable or malignant pheochromocytoma. In some patients, particularly those with malignant disease, administration of *metyrosine*, a competitive inhibitor of tyrosine hydroxylase (the rate-limiting enzyme in the synthesis of catecholamines), may be a useful adjunct. β Adrenergic receptor antagonists also are used to treat pheochromocytoma, but only after the administration of an α receptor antagonist (described later in the chapter). *Phenoxybenzamine* has been

used off-label to control the manifestations of autonomic hyperreflexia in patients with spinal cord transection.

Phentolamine can also be used in short-term control of hypertension in patients with pheochromocytoma. Rapid infusions of *phentolamine* may cause severe hypotension, so the drug should be administered cautiously. *Phentolamine* may be useful in relieving pseudo-obstruction of the bowel in patients with pheochromocytoma.

Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an α receptor agonist. The drug also may be useful for the treatment of hypertensive crises that follow the abrupt withdrawal of *clonidine* or that may result from the ingestion of tyramine-containing foods during the use of nonselective MAO inhibitors. Although excessive activation of α receptors is important in the development of severe hypertension in these settings, there is little information about the safety and efficacy of *phentolamine* compared with those of other antihypertensive agents in the treatment of such patients. Buccally or orally administered *phentolamine* may have efficacy in some men with sexual dysfunction.

Phentolamine is FDA approved for reversing or limiting the duration of soft tissue local anesthesia. Sympathomimetics are frequently administered with local anesthetics to slow the removal of the anesthetic by causing vasoconstriction. When the need for anesthesia is over, *phentolamine* can help reverse it by antagonizing the α receptor–induced vasoconstriction.

Toxicity and Adverse Effects. Hypotension is the major adverse effect of *phenoxybenzamine* and *phentolamine*. In addition, reflex cardiac stimulation may cause alarming tachycardia, cardiac arrhythmias, and ischemic cardiac events, including myocardial infarction. Reversible inhibition of ejaculation may occur due to impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. *Phentolamine* stimulates GI smooth muscle, an effect antagonized by *atropine*, and enhances gastric acid secretion due in part to histamine release. Thus, *phentolamine* should be used with caution in patients with a history of peptic ulcer. *Phenoxybenzamine* is mutagenic in the Ames test, and repeated administration of this drug to experimental animals causes peritoneal sarcomas and lung tumors.

α_1-Selective Adrenergic Receptor Antagonists

General Pharmacological Properties

Blockade of α_1 adrenergic receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance. The magnitude of such effects depends on the activity of the sympathetic nervous system at the time the antagonist is administered and thus is less in supine than in upright subjects and is particularly marked if there is hypovolemia. For most α_1 adrenergic receptor antagonists, the fall in blood pressure is opposed by baroreceptor reflexes that cause increases in heart rate and cardiac output, as well as fluid retention. These reflexes are exaggerated if the antagonist also blocks α_2 adrenergic receptors on peripheral sympathetic nerve endings, leading to enhanced release of NE and increased stimulation of postsynaptic β_1 adrenergic receptors in the heart and on juxtaglomerular cells (Gilsbach and Hein, 2008). Although stimulation of α_1 receptors in the heart may cause an increased force of contraction, the importance of blockade at this site in humans is uncertain.

Blockade of α_1 adrenergic receptors also inhibits vasoconstriction and the increase in blood pressure produced by the administration of a sympathomimetic amine. The pattern of effects depends on the adrenergic agonist that is administered: Pressor responses to *phenylephrine* can be completely suppressed; those to NE are only incompletely blocked because of residual stimulation of cardiac β_1 receptors; and pressor responses to EPI may be transformed to vasodepressor effects because of residual stimulation of β_2 adrenergic receptors in the vasculature with resultant vasodilation.

Blockade of α_1 adrenergic receptors can alleviate some of the symptoms of BPH. The symptoms of BPH include a resistance to urine outflow. This results from mechanical pressure on the urethra due to an increase in smooth muscle mass and an α adrenergic receptor–mediated increase in smooth muscle tone in the prostate and neck of the bladder. Antagonism of α_1 receptors permits relaxation of the smooth muscle and decreases the resistance to the outflow of urine.

Prazosin. *Prazosin* is the prototypical α_1-selective adrenergic receptor antagonist; accordingly, it and several similar agents exhibit greater clinical utility and have largely replaced the nonselective haloalkylamine (e.g., *phenoxybenzamine*) and imidazoline (e.g., *phentolamine*) α receptor antagonists. The affinity of *prazosin* for α_1 adrenergic receptors is about 1000-fold greater than that for α_2 adrenergic receptors. *Prazosin* has similar potencies at α_{1A}, α_{1B}, and α_{1D} subtype. *Prazosin* and the related α receptor antagonists *doxazosin* and *tamsulosin* frequently are used for the treatment of hypertension (see Chapter 32).

Pharmacological Effects. The major effects of *prazosin* result from its antagonism of α_1 adrenergic receptors in arterioles and veins. This leads to a fall in peripheral vascular resistance and in venous return to the heart. Unlike other vasodilating drugs, administration of *prazosin* usually does not increase heart rate. Because *prazosin* has little or no α_2 receptor–blocking effect, it probably does not promote the release of NE from sympathetic nerve endings in the heart. *Prazosin* decreases cardiac preload and has little effect on cardiac output and rate, in contrast to vasodilators such as *hydralazine* that have minimal dilating effects on veins. Although the combination of reduced preload and selective α_1 adrenergic receptor blockade might be sufficient to account for the relative absence of reflex tachycardia, *prazosin* also may act in the CNS to suppress sympathetic outflow. *Prazosin* appears to depress baroreflex function in hypertensive patients. *Prazosin* and related drugs in this class decrease LDLs and triglycerides and increase concentrations of HDLs.

ADME. *Prazosin* is well absorbed after oral administration, and bioavailability is about 50% to 70%. Peak concentrations of *prazosin* in plasma generally are reached 1 to 3 h after an oral dose. The drug is tightly bound to plasma proteins (primarily α_1-acid glycoprotein), and only 5% of the drug is free in the circulation; diseases that modify the concentration of this protein (e.g., inflammatory processes) may change the free fraction. *Prazosin* is extensively metabolized in the liver, and little unchanged drug is excreted by the kidneys. The plasma $t_{1/2}$ is about 3 h (may be prolonged to 6–8 h in congestive heart failure). The duration of action is approximately 7 to 10 h in the treatment of hypertension.

The initial dose should be 1 mg, usually given at bedtime so that the patient will remain recumbent for at least several hours to reduce the risk of syncopal reactions that may follow the first dose of *prazosin*. The dose is titrated upward depending on the blood pressure. A maximal effect generally is observed with a total daily dose of 20 mg in patients with hypertension. In the off-label treatment of BPH, doses from 1 to 5 mg twice daily typically are used.

Terazosin. *Terazosin,* a close structural analogue of *prazosin*, is less potent than *prazosin* but retains high specificity for α_1 adrenergic receptors; *terazosin* does not discriminate among α_{1A}, α_{1B}, and α_{1D} receptors. The major distinction between the two drugs is in their pharmacokinetic properties. *Terazosin* is more soluble in water than is *prazosin*, and its bioavailability is high (>90%). The $t_{1/2}$ of elimination of *terazosin* is about 12 h, and its duration of action usually extends beyond 18 h. Consequently, the drug may be taken once daily to treat hypertension and BPH in most patients. *Terazosin* and *doxazosin* induce apoptosis in prostate smooth muscle cells. This apoptosis may lessen the symptoms associated with chronic BPH by limiting cell proliferation. The apoptotic effect of *terazosin* and *doxazosin* appears to be related to the quinazoline moiety rather than α_1 receptor antagonism; *tamsulosin*, a nonquinazoline α_1 receptor antagonist, does not produce apoptosis (Kyprianou, 2003). Only about 10% of *terazosin* is excreted unchanged in the urine. An initial first dose of 1 mg is recommended. Doses are slowly titrated upward depending on the therapeutic response. Doses of 10 mg/day may be required for maximal effect in BPH.

Doxazosin. *Doxazosin* is another congener of *prazosin* and a highly selective antagonist at α_1 adrenergic receptors. It is nonselective among α_1 receptor subtypes and differs from *prazosin* in its pharmacokinetic

profile. The $t_{1/2}$ of *doxazosin* is about 20 h, and its duration of action may extend to 36 h. The bioavailability and extent of metabolism of *doxazosin* and *prazosin* are similar. Most *doxazosin* metabolites are eliminated in the feces. The hemodynamic effects of *doxazosin* appear to be similar to those of *prazosin*. *Doxazosin* should be given initially as a 1-mg dose in the treatment of hypertension or BPH. *Doxazosin* also may have beneficial actions in the long-term management of BPH related to apoptosis that are independent of α_1 receptor antagonism. *Doxazosin* is typically administered once daily. An extended-release formulation marketed for BPH is not recommended for the treatment of hypertension.

Alfuzosin. *Alfuzosin* is a quinazoline-based α_1 receptor antagonist with similar affinity at all of the α_1 receptor subtypes. It has been used extensively in treating BPH; it is not approved for treatment of hypertension. Alfuzosin has a $t_{1/2}$ of 3 to 5 h. *Alfuzosin* is a substrate of CYP3A4, and the concomitant administration of CPY3A4 inhibitors (e.g., *ketoconazole*, *clarithromycin*, *itraconazole*, *ritonavir*) is contraindicated. *Alfuzosin* should be avoided in patients at risk for prolonged QT syndrome. The recommended dosage is one 10-mg extended-release tablet daily to be taken after the same meal each day.

Tamsulosin. *Tamsulosin*, a benzenesulfonamide, is an α_1 receptor antagonist with some selectivity for α_{1A} (and α_{1D}) subtypes over the α_{1B} subtype (Kenny et al., 1996). This selectivity may favor blockade of α_{1A} receptors in the prostate. *Tamsulosin* is efficacious in the treatment of BPH with little effect on blood pressure (Beduschi et al., 1998) and is not approved for the treatment of hypertension. *Tamsulosin* is well absorbed and has a $t_{1/2}$ of 5 to 10 h. It is extensively metabolized by CYPs. *Tamsulosin* may be administered at a 0.4-mg starting dose; a dose of 0.8 mg ultimately will be more efficacious in some patients. Abnormal ejaculation is an adverse effect of *tamsulosin*, experienced by about 18% of patients receiving the higher dose.

Silodosin. *Silodosin* exhibits selectivity for the α_{1A}, over the α_{1B}, adrenergic receptor. The drug is metabolized by several pathways; the main metabolite is a glucuronide formed by UGT2B7; coadministration with inhibitors of this enzyme (e.g., *probenecid*, *valproic acid*, *fluconazole*) increases systemic exposure to *silodosin*. The drug is approved for the treatment of BPH and has lesser effects on blood pressure than the non–α_1-subtype selective antagonists. Nevertheless, dizziness and orthostatic hypotension can occur. The chief side effect of *silodosin* is retrograde ejaculation (in 28% of those treated). *Silodosin* is available as 4- and 8-mg capsules.

Adverse Effects

A major potential adverse effect of *prazosin* and its congeners is the first-dose effect: Marked postural hypotension and syncope sometimes are seen 30 to 90 min after an initial dose of *prazosin* and 2 to 6 h after an initial dose of *doxazosin*. Syncopal episodes also have occurred with a rapid increase in dosage or with the addition of a second antihypertensive drug to the regimen of a patient already taking a large dose of *prazosin*. The risk of the first-dose phenomenon is minimized by limiting the initial dose (e.g., 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously.

Because orthostatic hypotension may be a problem during long-term treatment with *prazosin* or its congeners, it is essential to check standing as well as recumbent blood pressure. Nonspecific adverse effects such as headache, dizziness, and asthenia rarely limit treatment with *prazosin*.

Therapeutic Uses

Hypertension. *Prazosin* and its congeners have been used successfully in the treatment of essential hypertension (see Chapter 32). Pleotropic effects of these drugs include improved lipid profiles and glucose-insulin metabolism in patients with hypertension who are at risk for atherosclerotic disease (Deano and Sorrentino, 2012). Catecholamines are also powerful stimulators of vascular smooth muscle hypertrophy, acting by α_1 adrenergic receptors. To what extent these effects of α_1 antagonists have clinical significance in diminishing the risk of atherosclerosis is not known.

Congestive Heart Failure. Although α adrenergic receptor antagonists have been used in the treatment of congestive heart failure, they are not the drugs of choice. Short-term effects of α adrenergic receptor blockade in these patients are due to dilation of both arteries and veins, resulting in a reduction of preload and afterload, which increases cardiac output and reduces pulmonary congestion. In contrast to results obtained with inhibitors of angiotensin-converting enzyme or a combination of *hydralazine* and an organic nitrate, *prazosin* has not been found to prolong life in patients with congestive heart failure.

Benign Prostatic Hyperplasia (BPH). In a significant percentage of older men, BPH produces symptomatic urethral obstruction that leads to weak stream, increased urinary frequency, and nocturia. These symptoms are due to a combination of mechanical pressure on the urethra due to the increase in smooth muscle mass and the α_1 adrenergic receptor–mediated increase in smooth muscle tone in the prostate and neck of the bladder (Kyprianou, 2003). α_1 Receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine. *Prazosin* reduces this resistance in some patients with impaired bladder emptying caused by prostatic obstruction or parasympathetic decentralization from spinal injury.

Finasteride and *dutasteride*, two drugs that inhibit conversion of testosterone to dihydrotestosterone (see Chapter 49) and can reduce prostate volume in some patients, are approved as monotherapy and in combination with α receptor antagonists. Drugs that are α_1-selective antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. These agents rapidly improve urinary flow, whereas the actions of *finasteride* are typically delayed for months. Combination therapy with *doxazosin* and *finasteride* reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug alone (McConnell et al., 2003). *Tamsulosin* at the recommended dose of 0.4 mg daily and *silodosin* at 0.8 mg are less likely to cause orthostatic hypotension than are the other drugs. The predominant α_1 subtype expressed in the human prostate is the α_{1A} receptor (Kenny et al., 1996). Developments in this area will provide the basis for the selection of α receptor antagonists with specificity for the relevant subtype of α_1 receptor. However, the possibility remains that some of the symptoms of BPH are due to α_1 receptors in other sites, such as bladder, spinal cord, or brain.

Other Disorders. Some studies indicated that *prazosin* can decrease the incidence of digital vasospasm in patients with Raynaud syndrome; however, its relative efficacy as compared with Ca^{2+} channel blockers is not known. *Prazosin* may have some benefit in patients with other vasospastic disorders. *Prazosin* may be useful for the treatment of patients with mitral or aortic valvular insufficiency, presumably by reducing afterload.

α_2-Selective Adrenergic Receptor Antagonists

Activation of presynaptic α_2 adrenergic receptors inhibits the release of NE and other co-transmitters from peripheral sympathetic nerve endings. Activation of α_2 receptors in the pontomedullary region of the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure; these receptors are a site of action for drugs such as *clonidine*. Blockade of α_2 adrenergic receptors with selective antagonists such as *yohimbine* thus can increase sympathetic outflow and potentiate the release of NE from nerve endings, leading to activation of α_1 and β_1 adrenergic receptors in the heart and peripheral vasculature with a consequent rise in blood pressure. Antagonists that also block α_1 receptors give rise to similar effects on sympathetic outflow and release of NE, but the net increase in blood pressure is prevented by inhibition of vasoconstriction.

Although certain vascular beds contain α_2 adrenergic receptors that promote contraction of smooth muscle, it is thought that these receptors are preferentially stimulated by circulating catecholamines, whereas α_1 receptors are activated by NE released from sympathetic nerve fibers. In other vascular beds, α_2 adrenergic receptors reportedly promote vasodilation by stimulating the release of NO from endothelial cells. The physiological role of vascular α_2 receptors in the regulation of blood flow within various vascular beds is uncertain. α_2 Receptors contribute to smooth muscle contraction in the human saphenous vein, whereas α_1 receptors are more prominent in dorsal hand veins. The effects of α_2 adrenergic

receptor antagonists on the cardiovascular system are dominated by actions in the CNS and on sympathetic nerve endings.

Yohimbine

Yohimbine is a competitive antagonist that is selective for α_2 adrenergic receptors. The compound is an indolealkylamine alkaloid and is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; its structure resembles that of *reserpine*, an alkaloid also found in *Rauwolfia*. *Yohimbine* readily enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. These actions are opposite to those of *clonidine*, a selective α_2 adrenergic receptor agonist. *Yohimbine* also antagonizes effects of 5HT. In the past, it was used extensively to treat male sexual dysfunction; however, the efficacies of PDE5 inhibitors (e.g., *sildenafil*, *vardenafil*, and *tadalafil*) and *apomorphine* (off-label) have been much more conclusively demonstrated in oral treatment of erectile dysfunction. Some studies suggested that *yohimbine* may be useful for diabetic neuropathy and in the treatment of postural hypotension. In the U.S., *yohimbine* can be legally sold as a dietary supplement; however, labeling claims that it will arouse or increase sexual desire or improve sexual performance are prohibited. *Yohimbine* is approved in veterinary medicine for the reversal of xylazine anesthesia.

Additional α Adrenergic Receptor Antagonists

Ergot Alkaloids

The ergot alkaloids were the first adrenergic receptor antagonists to be discovered. Ergot alkaloids exhibit a complex variety of pharmacological properties. To varying degrees, these agents act as partial agonists or antagonists at α adrenergic receptors, DA receptors, and 5HT receptors. Chapter 15 presents additional information about the ergot alkaloids.

Indoramin

Indoramin is a selective, competitive, α_1-selective receptor antagonist that also antagonizes H_1 and 5HT receptors. *Indoramin* lowers blood pressure with minimal tachycardia. The drug is not available in the U.S.; outside the U.S., *indoramin* is used for the treatment of hypertension and BPH and in the prophylaxis of migraine. The drug also decreases the incidence of attacks of Raynaud syndrome. Some of the adverse effects of *indoramin* include sedation, dry mouth, and failure of ejaculation.

Ketanserin

Although developed as a 5HT receptor antagonist, *ketanserin* also blocks α_1 receptors. *Ketanserin* (not available in the U.S.) is discussed in Chapter 15.

Urapidil

Urapidil is a selective α_1 receptor antagonist that has a chemical structure distinct from those of *prazosin* and related compounds; the drug is not commercially available in the U.S. Blockade of peripheral α_1 adrenergic receptors appears to be primarily responsible for the hypotension produced by *urapidil*, although it has actions in the CNS as well.

Bunazosin

Bunazosin is an α_1-selective antagonist of the quinazoline class that can lower blood pressure in patients with hypertension. *Bunazosin* is not available in the U.S.

Neuroleptic Agents

Chlorpromazine, *haloperidol*, and other neuroleptic drugs of the phenothiazine and butyrophenone types produce significant blockade of both α adrenergic and dopaminergic D_2 receptors in humans.

β Adrenergic Receptor Antagonists

Overview

Competitive antagonists of β adrenergic receptors, or β blockers, have received enormous clinical attention because of their efficacy in the treatment of hypertension, ischemic heart disease, congestive heart failure, and certain arrhythmias.

The myriad β antagonists can be distinguished by the following properties:

- Relative affinity for β_1 and β_2 receptors (and to some extent β_3 receptors)
- Intrinsic sympathomimetic activity
- Blockade of α receptors
- Differences in lipid solubility (CNS penetration)
- Capacity to induce vasodilation
- Pharmacokinetic parameters

Propranolol is a competitive nonselective β adrenergic receptor antagonist and remains the prototype to which other β blockers are compared. *Propranolol* has equal affinity for β_1 and β_2 adrenergic receptors and a lower affinity for β_3 receptors. Agents such as *metoprolol*, *atenolol*, *acebutolol*, *bisoprolol*, and *esmolol* have somewhat greater affinity for β_1 than for β_2 receptors; and are examples of β_1-selective antagonists, even though the selectivity is not absolute and higher concentrations will block β_2 receptors. There currently are no selective β_2 or β_3 adrenergic receptor antagonists used clinically, but there are some for experimental use (Schena and Caplan, 2019).

Several β blockers (e.g., *pindolol* and *acebutolol*) can actually activate β adrenergic receptors partially in the absence of catecholamines; however, the intrinsic activities of these drugs are less than that of a full agonist such as INE. These partial agonists have *intrinsic sympathomimetic activity*; this slight residual activity may prevent profound bradycardia or negative inotropy in a resting heart. The potential clinical advantage of this property, however, is unclear and may be disadvantageous in the context of secondary prevention of myocardial infarction. *Propranolol* is a pure antagonist, and it has no capacity to activate β adrenergic receptors.

Several β adrenergic receptor antagonists also have local anesthetic or membrane-stabilizing activity, independent of β blockade. Such drugs include *propranolol*, *acebutolol*, and *carvedilol*. *Pindolol*, *metoprolol*, *betaxolol*, and *labetalol* have slight membrane-stabilizing effects. Although most β adrenergic receptor antagonists do not block α adrenergic receptors, *labetalol*, *carvedilol*, and *bucindolol* block both α_1 and β adrenergic receptors. In addition to *carvedilol*, *labetalol*, and *bucindolol*, other β receptor antagonists have vasodilating properties due to mechanisms discussed in the following material. These include *celiprolol*, *nebivolol*, *nipradilol*, *carteolol*, *betaxolol*, *bopindolol*, and *bevantolol* (Toda, 2003).

Pharmacological Properties

The pharmacological properties of β adrenergic receptor antagonists can be deduced and explained largely from knowledge of the responses elicited by the receptors in the various tissues and the activity of the sympathetic nerves that innervate these tissues (see Chapter 10, especially Table 10–1). For example, β adrenergic receptor blockade has relatively little effect on the normal heart of an individual at rest but has profound effects when sympathetic control of the heart is dominant, as during exercise or stress.

The β adrenergic receptor antagonists are generally classified as non–subtype-selective ("first generation"), β_1 selective ("second generation"), and non–subtype- or subtype-selective *with additional cardiovascular actions* ("third generation"). These last drugs have additional cardiovascular properties (especially vasodilation) that seem unrelated to β receptor blockade. Table 14–3 summarizes the pharmacological and pharmacokinetic properties of β receptor antagonists.

Cardiovascular System. The major therapeutic effects of β adrenergic receptor antagonists are on the cardiovascular system. It is important to distinguish these effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia. As discussed above, catecholamines have positive chronotropic and inotropic actions; therefore, β adrenergic receptor antagonists have the converse actions including slowing heart rate and decreasing myocardial contractility, but only if there is sympathetic tone, which normally is present. When tonic stimulation of β adrenergic receptors is low, the effect of β blockade is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise, during stress, or in disease states, β receptor antagonists produce more robust cardiac depressant effects.

TABLE 14–3 ■ PHARMACOLOGICAL/PHARMACOKINETIC PROPERTIES OF β ADRENERGIC RECEPTOR BLOCKING AGENTS

DRUG	MEMBRANE STABILIZING ACTIVITY	INTRINSIC AGONIST ACTIVITY	LIPID SOLUBILITY	EXTENT OF ABSORPTION (%)	ORAL AVAILABILITY (%)	PLASMA $t_{1/2}$ (HOURS)	PROTEIN BINDING (%)
Classical nonselective β blockers: First generation							
Nadolol	0	0	Low	30	30–50	20–24	30
Penbutolol	0	+	High	~100	~100	~5	80–98

Nebivolol	0	0	Low	NA	NA	11–30	98

NA, not applicable.
[a]Detectable only at doses much greater than required for β blockade.

Short-term administration of β adrenergic receptor antagonists decreases cardiac output; peripheral resistance increases in proportion to maintain blood pressure as a result of blockade of vascular β_2 adrenergic receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular α adrenergic receptors. However, with long-term use of β antagonists, total peripheral resistance returns to initial values or decreases in patients with hypertension (Man in't Veld et al., 1988). With β adrenergic receptor antagonists that also are α_1 receptor antagonists, such as *labetalol*, *carvedilol*, and *bucindolol*, cardiac output is maintained with a greater fall in peripheral resistance. This also is seen with β receptor antagonists that are direct vasodilators.

The β adrenergic receptor antagonists have significant effects on cardiac rhythm and automaticity. Although it had been thought that these effects were due exclusively to blockade of β_1 receptors, β_2 receptors likely also regulate heart rate in humans (Altschuld and Billman, 2000). As discussed above, β_3 adrenergic receptors also have been identified in normal myocardial tissue (Schena and Caplan, 2019). Signal transduction for β_3 adrenergic receptors is complex and includes not only G_s but also G_i/G_o stimulation and signaling through NO and cyclic GMP (Cannavo and Koch, 2017). While β_3 receptor agonists are being explored as possible treatments for heart failure, the potential utility of β_3-adrenergic receptor antagonists in human heart disease is unknown.

Antagonizing β adrenergic receptors reduces the sinus rate, decreases the rate of spontaneous depolarization of ectopic pacemakers, slows conduction in the atria and in the AV node, and increases the functional refractory period of the AV node. Although high concentrations of many β blockers exert a membrane-stabilizing activity, it is doubtful that this is significant at usual therapeutic doses. However, this effect may be important when there is overdosage. *d*-Propranolol may suppress ventricular arrhythmias independently of β receptor blockade.

The cardiovascular effects of β adrenergic receptor antagonists are most evident during dynamic exercise when there is more sympathetic tone and higher levels of catecholamines. In the presence of β blockade, exercise-induced increases in heart rate and myocardial contractility are attenuated. However, the exercise-induced increase in cardiac output is less affected because of an increase in stroke volume. The effects of β adrenergic receptor antagonists on exercise are somewhat analogous to the changes that occur with normal aging. In healthy elderly persons, catecholamine-induced increases in heart rate are smaller than in younger individuals; however, the increase in cardiac output in older people may be preserved because of an increase in stroke volume during exercise. β Blockers tend to decrease work capacity, as assessed by their effects on intense short-term or more prolonged steady-state exertion. Exercise performance may be impaired to a lesser extent by β_1-selective agents than by nonselective antagonists. Blockade of β_2 receptors blunts the increase in blood flow to active skeletal muscle during submaximal exercise and may attenuate catecholamine-induced activation of glucose metabolism and lipolysis.

Coronary artery blood flow increases during exercise or stress to meet the metabolic demands of the heart. By increasing heart rate, contractility, and systolic pressure, catecholamines increase myocardial O_2 demand. However, in patients with coronary artery disease, fixed narrowing of these vessels attenuates the expected increase in flow, leading to myocardial ischemia. β Adrenergic receptor antagonists decrease the effects of catecholamines on the determinants of myocardial O_2 consumption.

TABLE 14–4 ■ THIRD-GENERATION β RECEPTOR ANTAGONISTS WITH PUTATIVE ADDITIONAL MECHANISMS OF VASODILATION

Nipradilol[a]		Labetalol			

[a]Not currently available in the U.S.

However, these agents may tend to increase the requirement for O_2 by increasing end-diastolic pressure and systolic ejection period. Usually, the net effect is to improve the relationship between cardiac O_2 supply and demand; exercise tolerance generally is improved in patients with angina, whose capacity to exercise is limited by the development of chest pain (see Chapter 31).

Antihypertensive Activity. β Adrenergic receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure. However, these drugs lower blood pressure in patients with hypertension, but the mechanisms responsible for this important clinical effect are not fully understood. The release of renin from the juxtaglomerular cells is stimulated by the sympathetic nervous system by means of β_1 adrenergic receptors, and this effect is blocked by β receptor antagonists (see Chapter 30). Some investigators have found that the antihypertensive effect of β blockade is most marked in patients with elevated concentrations of plasma renin, compared to patients with low or normal concentrations of renin. However, β adrenergic receptor antagonists are effective even in patients with low plasma renin.

Presynaptic β adrenergic receptors (primarily β_2 receptors) enhance the release of NE from sympathetic neurons, and diminished release of NE from β blockade is a possible response. Although β blockers would not be expected to decrease the contractility of vascular smooth muscle, long-term administration of these drugs to hypertensive patients ultimately leads to a fall in peripheral vascular resistance (Man in't Veld et al., 1988). The mechanism for this effect is not known, but this delayed fall in peripheral vascular resistance in the face of a persistent reduction of cardiac output appears to account for much of the antihypertensive effect of these drugs.

Some β adrenergic receptor antagonists have additional effects that may contribute to their capacity to lower blood pressure. These drugs all produce peripheral vasodilation; at least six properties have been proposed to contribute to this effect, including production of NO, partial activation of β_2 adrenergic receptors, blockade of α_1 adrenergic receptors, blockade of Ca^{2+} entry, opening of K^+ channels, and antioxidant activity (see Table 14–4). These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload. *Celiprolol* and *nebivolol* also have been observed to produce vasodilation and thereby reduce preload (see below).

Nonselective β adrenergic receptor antagonists inhibit the vasodilation caused by INE and augment the pressor response to EPI. This is particularly significant in patients with pheochromocytoma, in whom β receptor antagonists should be used only after adequate α receptor blockade has been established. This avoids uncompensated α adrenergic receptor–mediated vasoconstriction caused by EPI secreted from the tumor.

Pulmonary System. Nonselective β receptor antagonists such as *propranolol* block β_2 receptors in bronchial smooth muscle. This usually has little effect on pulmonary function in normal individuals. However, in patients with COPD, such blockade can lead to life-threatening bronchoconstriction. Although β_1-selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than *propranolol* to increase airway resistance in patients with asthma, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases. Drugs such as *celiprolol*, with β_1 receptor selectivity and β_2 receptor partial agonism, are of potential promise, although clinical experience is limited.

Metabolic Effects. The β adrenergic receptor antagonists modify the metabolism of carbohydrates and lipids. Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Nonselective β blockers may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. In addition to blocking glycogenolysis, β receptor antagonists can interfere with the counterregulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor, tachycardia, and nervousness. Thus, β adrenergic receptor antagonists should be used with great caution in patients with labile diabetes and frequent hypoglycemic reactions. If such a drug is indicated, a β_1-selective antagonist is preferred because these drugs are less likely to delay recovery from hypoglycemia (Dunne et al., 2001).

The β receptors mediate activation of hormone-sensitive lipase in fat cells, leading to release of free fatty acids into the circulation. This increased flux of fatty acids is an important source of energy for exercising muscle. β Receptor antagonists can attenuate the release of free fatty acids from adipose tissue. Nonselective β receptor antagonists consistently reduce HDL (high-density lipoprotein) cholesterol, increase LDL (low-density lipoprotein) cholesterol, and increase triglycerides. In contrast, β_1-selective antagonists, including *celiprolol*, *carteolol*, *nebivolol*, and *bevantolol*, reportedly improve the serum lipid profile of dyslipidemic patients. While drugs such as *propranolol* and *atenolol* increase triglycerides, plasma triglycerides are reduced with chronic use of *celiprolol*, *carvedilol*, and *carteolol* (Toda, 2003).

In contrast to classical β blockers, which decrease insulin sensitivity, the vasodilating β receptor antagonists (e.g., *celiprolol*, *nipradilol*, *carteolol*, *carvedilol*, and *dilevalol*) increase insulin sensitivity in patients with insulin resistance. Together with their cardioprotective effects, improvement in insulin sensitivity from vasodilating β adrenergic receptor antagonists may partially counterbalance the hazard from worsened lipid abnormalities associated with diabetes.

When β blockers are required, β_1-selective or vasodilating β receptor antagonists are preferred. In addition, it may be necessary to use β receptor antagonists in conjunction with other drugs (e.g., 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) to ameliorate adverse metabolic effects (Dunne et al., 2001).

The β receptor agonists decrease the plasma concentration of K^+ by promoting its uptake, predominantly into skeletal muscle. At rest, an infusion of EPI causes a decrease in the plasma concentration of K^+. The marked increase in the concentration of EPI that occurs with stress (such as myocardial infarction) may cause hypokalemia, which could predispose to cardiac arrhythmias. In preclinical studies, the hypokalemic effect of EPI is blocked by an experimental antagonist, ICI 118551, which has a high affinity for β_2 and, to a lesser degree, β_3 receptors. Exercise causes an increase in the efflux of K^+ from skeletal muscle. Catecholamines tend to buffer the rise in K^+ by increasing its influx into muscle. β Blockers negate this buffering effect.

Other Effects. β Adrenergic receptor antagonists block catecholamine-induced tremor. They also block inhibition of mast cell degranulation by catecholamines.

Adverse Effects and Precautions

Cardiovascular System. β Adrenergic receptor blockade, although initially contraindicated in chronic heart failure, is now standard of care, and the β_1-selective antagonist *metoprolol* and nonselective β blocker *carvedilol* have been shown to improve the mortality and morbidity of heart failure patients (Rockman et al., 2002). The use of β blockers in congestive heart failure is discussed in more detail in Chapter 33.

Bradycardia is a normal response to β adrenergic receptor blockade; however, in patients with partial or complete AV conduction defects, β antagonists may cause life-threatening bradyarrhythmias. Particular caution is indicated in patients who are taking other drugs, such as *verapamil* or various antiarrhythmic agents, which may impair sinus node function or AV conduction.

Some patients complain of cold extremities while taking β receptor antagonists. Symptoms of peripheral vascular disease may occasionally worsen, or Raynaud syndrome may develop.

Abrupt discontinuation of β receptor antagonists after long-term treatment can exacerbate angina and may increase the risk of sudden death. There is enhanced sensitivity to β adrenergic receptor agonists in patients who have undergone long-term treatment with certain β receptor antagonists after the blocker is withdrawn abruptly. This increased sensitivity is evident several days after stopping a β receptor antagonist and may persist for at least 1 week. Such enhanced sensitivity can be attenuated by tapering the dose of the β blocker for several weeks before discontinuation. Super-sensitivity to INE also has been observed after abrupt discontinuation of *metoprolol*, but not of *pindolol*. This enhanced β responsiveness may result from upregulation of β receptors and downregulation of GPCR kinases (Sato et al., 2015). The number of β adrenergic receptors on circulating lymphocytes is increased in subjects who have received *propranolol* for long periods; *pindolol*, with its slight agonist activity, has the opposite effect. For discontinuation of β blockers, it is prudent to decrease the dose gradually and to restrict exercise during this period.

Pulmonary Function. A major adverse effect of β adrenergic receptor antagonists is caused by blockade of β_2 receptors in bronchial smooth muscle. These receptors are particularly important for promoting bronchodilation in patients with bronchospastic disease, and β_2 receptor blockade may cause a life-threatening increase in airway resistance in such patients. Drugs with selectivity for β_1 adrenergic receptors or those with intrinsic sympathomimetic activity at β_2 adrenergic receptors seem less likely to induce bronchospasm. β Blockers should be avoided if at all possible in patients with asthma. However, in selected patients with COPD and cardiovascular disease, the advantages of using β_1 receptor antagonists may outweigh the risk of worsening pulmonary function (Salpeter et al., 2005).

CNS. The adverse effects of β adrenergic receptor antagonists that enter the CNS may include fatigue, sleep disturbances (including insomnia and nightmares), and depression. Interest has focused on the relationship between the incidence of the adverse effects of β adrenergic receptor antagonists and their lipophilicity; however, no clear correlation has emerged.

Metabolism. β Adrenergic receptor blockade may blunt recognition of hypoglycemia by patients; it also may delay recovery from insulin-induced hypoglycemia. β Receptor antagonists should be used with great caution in patients with diabetes who are prone to hypoglycemic reactions; β_1-selective agents may be preferable for these patients.

Sexual Function and Reproduction. The incidence of sexual dysfunction in men with hypertension who are treated with β adrenergic receptor antagonists is not clearly defined. Although experience with the use of β adrenergic receptor antagonists in pregnancy is increasing, information about the safety of these drugs during pregnancy still is limited.

Overdosage. The manifestations of poisoning with β adrenergic receptor antagonists depend on the pharmacological properties of the ingested drug, particularly its β_1 selectivity, intrinsic sympathomimetic activity, and membrane-stabilizing properties. Hypotension, bradycardia, prolonged AV conduction times, and widened QRS complexes are common manifestations of overdosage. Seizures and depression may occur. Hypoglycemia and bronchospasm can occur. Significant bradycardia should be treated initially with *atropine*, but a cardiac pacemaker often is required. Large doses of INE or an α adrenergic receptor agonist may be necessary to treat hypotension. *Glucagon*, acting through its own GPCR and independently of the β adrenergic receptor, has positive chronotropic and inotropic effects on the heart, and the drug has been useful in some patients who have an overdose of a β receptor antagonist.

Drug Interactions. Aluminum salts, *cholestyramine*, and *colestipol* may decrease the absorption of β blockers. Drugs such as *phenytoin*, *rifampin*, and *phenobarbital*, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of β adrenergic receptor antagonists that are metabolized extensively (e.g., *propranolol*). *Cimetidine* and *hydralazine* may increase the bioavailability of agents such as *propranolol* and *metoprolol* by affecting hepatic blood flow. β Receptor antagonists can impair the clearance of *lidocaine*.

Additive effects on blood pressure by β blockers and other antihypertensive agents often are employed to clinical advantage. However, the antihypertensive effects of β adrenergic receptor antagonists can be opposed by *indomethacin* and other nonsteroidal anti-inflammatory drugs (see Chapter 42).

Therapeutic Uses

Cardiovascular Diseases. β Adrenergic receptor antagonists are used extensively in the treatment of hypertension, angina and acute coronary syndromes, and congestive heart failure (see Chapters 31–33). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (see Chapter 34). β Receptor antagonists are used in the treatment of hypertrophic obstructive cardiomyopathy, relieving angina, palpitations, and syncope in patients with this disorder. Efficacy probably is related to partial relief of the pressure gradient along the outflow tract. β Blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

β Blockers are used frequently in the medical management of acute dissecting aortic aneurysm; their usefulness comes from reduction in the force of myocardial contraction and the rate of development of such force. *Nitroprusside* is an alternative, but when given in the absence of β adrenergic receptor blockade, it causes an undesirable reflex tachycardia. Chronic treatment with β receptor antagonists may be efficacious in slowing the progression of aortic dilation and its complications in patients with Marfan syndrome, although surgical aortic repair is still warranted as aortic diameter expands; *losartan*, an angiotensin-converting enzyme inhibitor, is showing promise as a more effective treatment (Hiratzka et al., 2010).

Glaucoma. The β adrenergic receptor antagonists are used in the treatment of chronic open-angle glaucoma (see Chapter 74). These agents decrease the production of aqueous humor, which appears to be the mechanism for their clinical effectiveness.

Other Uses. Many of the signs and symptoms of hyperthyroidism are reminiscent of the manifestations of increased sympathetic nervous system activity. β Adrenergic receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuncts to more definitive therapy. In addition, *propranolol* inhibits the peripheral conversion of thyroxine to triiodothyronine, an effect that may be independent of β receptor blockade (see Chapter 47).

Propranolol, *timolol*, and *metoprolol* are effective for the prophylaxis of migraine; these drugs are not useful for treatment of acute attacks of migraine.

Propranolol and other β blockers are effective in controlling acute panic symptoms in individuals who are required to perform in public or in other anxiety-provoking situations. Tachycardia, muscle tremors, and other evidence of increased sympathetic activity are reduced.

β Adrenergic receptor antagonists may be of some value in the treatment of patients undergoing withdrawal from alcohol or those with

akathisia. *Propranolol* and *nadolol* are efficacious in the primary prevention of variceal bleeding in patients with portal hypertension caused by cirrhosis of the liver (Bosch, 1998).

Clinical Selection of a β Adrenergic Receptor Antagonist

The various β receptor antagonists that are used for the treatment of hypertension and angina appear to have similar efficacies. Selection of the most appropriate drug for an individual patient should be based on pharmacokinetic and pharmacodynamic differences among the drugs, cost, and whether there are concurrent medical problems. β_1-Selective antagonists are preferable in patients with bronchospasm, diabetes, peripheral vascular disease, or Raynaud syndrome. Although no clinical advantage of β adrenergic receptor antagonists with intrinsic sympathomimetic activity has been clearly established, such drugs may be preferable in patients with bradycardia. In addition, third-generation β antagonists that block α_1 adrenergic receptors, stimulate β_2 adrenergic receptors, enhance NO production, block Ca^{2+} entry, open K^+ channels, or possess antioxidant properties may offer therapeutic advantages.

Nonselective β Adrenergic Receptor Antagonists

Propranolol

Propranolol (Table 14–5) interacts with β_1 and β_2 receptors with equal affinity, lacks intrinsic sympathomimetic activity, does not block α receptors, and has lower affinity for β_3 adrenergic receptors.

ADME. *Propranolol* is highly lipophilic and almost completely absorbed after oral administration. Much of the drug is metabolized by the liver during its first passage through the portal circulation; only about 25% reaches the systemic circulation. In addition, there is great interindividual variation in the presystemic clearance of *propranolol* by the liver; this contributes to enormous variability in plasma concentrations (~20-fold) after oral administration of the drug and to the wide dosage range for clinical efficacy. The degree of hepatic extraction of *propranolol* declines as the dose is increased. The bioavailability of *propranolol* may be increased by the concomitant ingestion of food and during long-term administration of the drug.

Propranolol readily enters the CNS. Approximately 90% of the drug in the circulation is bound to plasma proteins. It is extensively metabolized, with most metabolites appearing in the urine. One product of hepatic metabolism is 4-hydroxypropranolol, which has some β adrenergic antagonist activity. Analysis of the distribution of *propranolol*, its clearance by the liver, and its activity is complicated by the stereospecificity of these processes (Walle et al., 1988). The (–) enantiomers of *propranolol* and other β blockers are the active forms. The (–) enantiomer of *propranolol* appears to be cleared more slowly from the body than is the inactive enantiomer. The clearance of *propranolol* may vary with hepatic blood flow and liver disease and also may change during the administration of other drugs that affect hepatic metabolism.

Despite its short $t_{1/2}$ in plasma (~4 h), twice-daily administration suffices to produce the antihypertensive effect in some patients. Sustained-release formulations of *propranolol* maintain therapeutic concentrations of *propranolol* in plasma throughout a 24-h period. For the treatment of hypertension and angina, the initial oral dose of *propranolol* generally is 40 to 80 mg/day. The dose may then be titrated upward until the optimal response is obtained. For the treatment of angina, the dose may be increased at intervals of less than 1 week, as indicated clinically. In hypertension, the full blood pressure response may not develop for several weeks. Typically, doses are less than 320 mg/day. If *propranolol* is taken twice daily for hypertension, blood pressure should be measured just prior to a dose to ensure that the duration of effect is sufficiently prolonged. Adequacy of β adrenergic receptor blockade can be assessed by measuring suppression of exercise-induced tachycardia (see Table 14–5).

Propranolol may be administered intravenously for the management of life-threatening arrhythmias or to patients under anesthesia. Under these circumstances, the usual dose is 1 to 3 mg, administered slowly (<1 mg/min) with careful and frequent monitoring of blood pressure, ECG, and cardiac function. If an adequate response is not obtained, a second dose may be given after several minutes. If bradycardia is excessive, *atropine* should be administered to increase heart rate. A change to oral therapy should be initiated as soon as possible.

Nadolol

Nadolol is a long-acting antagonist with equal affinity for β_1 and β_2 adrenergic receptors. It is devoid of both membrane-stabilizing and intrinsic sympathomimetic activity. A distinguishing characteristic of *nadolol* is its relatively long $t_{1/2}$. It can be used to treat hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension.

ADME. *Nadolol* is very soluble in water and is incompletely absorbed from the gut; its bioavailability is about 35%. Interindividual variability is less than with *propranolol*. The low lipid solubility of *nadolol* may result in lower concentrations of the drug in the brain. *Nadolol* is not extensively metabolized and is largely excreted intact in the urine. The $t_{1/2}$ of the drug in plasma is about 20 h; consequently, it generally is administered once daily. *Nadolol* may accumulate in patients with renal failure, and dosage should be reduced in such individuals.

Timolol

Timolol is a potent, nonselective β adrenergic receptor antagonist with no intrinsic sympathomimetic or membrane-stabilizing activity. It is used for hypertension, congestive heart failure, acute myocardial infarction, and migraine prophylaxis. In ophthalmology, *timolol* has been used in the treatment of open-angle glaucoma and intraocular hypertension. The drug appears to reduce aqueous humor production through blockade of β receptors on the ciliary epithelium.

ADME. *Timolol* is well absorbed from the GI tract. It is metabolized extensively by CYP2D6 in the liver. Only a small amount of unchanged drug appears in the urine. The $t_{1/2}$ in plasma is about 4 h. The ocular formulation of *timolol* may be absorbed systemically (see Chapter 74) and produce adverse effects in susceptible patients, such as those with asthma or congestive heart failure. The systemic administration of *cimetidine* with topical ocular *timolol* increases the degree of β adrenergic receptor blockade, resulting in a reduction of resting heart rate, intraocular pressure, and exercise tolerance (Ishii et al., 2000). For ophthalmic use, *timolol* is available combined with other medications (e.g., with *dorzolamide* or *travoprost*). *Timolol* also provides benefits to patients with coronary heart disease: In the acute period after myocardial infarction, *timolol* produced a 39% reduction in mortality in the Norwegian Multicenter Study.

Pindolol

Pindolol is a nonselective β receptor antagonist *with intrinsic sympathomimetic activity*. It has low membrane-stabilizing activity and low lipid solubility. It is used to treat angina pectoris and hypertension. β Blockers with slight partial agonist activity may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia. Nonetheless, the clinical significance of partial agonism has not been substantially demonstrated in controlled trials but may be of importance in individual patients.

ADME. *Pindolol* is almost completely absorbed after oral administration; the drug has a moderately high bioavailability and plasma $t_{1/2}$ of about 4 h. Approximately 50% of *pindolol* ultimately is metabolized in the liver; the remainder is excreted unchanged in the urine. Clearance is reduced in patients with renal failure.

β_1-Selective Adrenergic Receptor Antagonists

Metoprolol

Metoprolol is a β_1-selective adrenergic receptor antagonist that is devoid of intrinsic sympathomimetic activity and membrane-stabilizing activity.

ADME. *Metoprolol* is almost completely absorbed after oral administration, but bioavailability is relatively low (~40%) due to first-pass metabolism. Plasma concentrations of the drug vary widely (up to 17-fold), possibly due to genetically determined differences in the rate of metabolism in the liver by CYP2D6. Only 10% of the administered drug is recovered unchanged in the urine. The $t_{1/2}$ of *metoprolol* is 3 to 4 h, but can increase to 7 to 8 h in CYP2D6 poor metabolizers who have a

TABLE 14–5 ■ SUMMARY OF ADRENERGIC AGONISTS AND ANTAGONISTS

SUBCLASS	DRUGS	PROMINENT PRINCIPAL PHARMACOLOGICAL ACTIONS	THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
Direct-acting nonselective agonists					
	Epinephrine (α_1, α_2, β_1, β_2, β_3)	↑ Heart rate; ↑ blood pressure; ↑ contractility; slight ↓ in PVR; ↑ cardiac output; vasoconstriction (viscera); vasodilation (skeletal muscle); ↑ blood glucose and lactate	Open-angle glaucoma With local anesthetics to prolong action Anaphylactic shock Complete heart block or cardiac arrest Bronchodilator in asthma	Palpitation Cardiac arrhythmias Cerebral hemorrhage Headache Tremor Restlessness	Not given orally Life saving in anaphylaxis or cardiac arrest
	Norepinephrine (α_1, α_2, β_1 >> β_2)	↑ Systolic and diastolic blood pressure; vasoconstriction; ↑ PVR; direct ↑ in heart rate and contraction; reflex ↓ in heart rate	Hypotension	Similar to EPI Hypertension	Not absorbed orally
β Receptor agonists					
Nonselective (β_1 + β_2)	Isoproterenol	↓ PVR; ↑ cardiac output; bronchodilation	Bronchodilator in asthma Complete heart block or cardiac arrest Shock	Palpitations Tachycardia Tachyarrhythmias Headache Flushed skin Cardiac ischemia in patients with coronary artery disease	Intravenous administration Administered by inhalation in asthma
β_1 Selective	Dobutamine	↑ Contractility; some ↑ heart rate; ↑ AV conduction	Short-term treatment of cardiac decompensation after surgery or patients with congestive heart failure or myocardial infarction	↑ Blood pressure and heart rate	Intravenous only Use with caution in patients with hypertension or cardiac arrhythmias
β_2 Selective (intermediate acting)	Albuterol Bitolterol Fenoterol Isoetharine Levalbuterol Metaproterenol Pirbuterol Procaterol Terbutaline	Relaxation of bronchial smooth muscle Relaxation of uterine smooth muscle Activation of other β_2 receptors after systemic administration	Bronchodilators for treatment of asthma and COPD Short-/intermediate-acting drugs for acute bronchospasm	Skeletal muscle tremor Tachycardia and other cardiac effects seen after systemic administration (much less with inhalational use)	Use with caution in patients with cardiovascular disease (reduced by inhalational administration) Minimal side effects

(*Continued*)

TABLE 14–5 ■ SUMMARY OF ADRENERGIC AGONISTS AND ANTAGONISTS (*CONTINUED*)

SUBCLASS	DRUGS	PROMINENT PRINCIPAL PHARMACOLOGICAL ACTIONS	THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
(Long acting)	Formoterol Salmeterol Arformoterol Carniterol Indacaterol Ritodrine	Relaxation of bronchial smooth muscle Relaxation of uterine smooth muscle	Bronchodilators for treatment of COPD Best choice for prophylaxis due to long action Ritodrine, to stop premature labor	Contraindicated in asthma	Long action, favored for prophylaxis
β_3 Selective	Mirabegron Vibegron	Increases nitric oxide Relaxes nonvascular smooth muscle	Urinary incontinence Overactive bladder syndrome	May increase levels of drugs that are metabolized by CYP2D6	Clinical trials being conducted for heart failure and irritable bowel syndrome Potential use for obesity
α Receptor agonists					
α_1 Selective	Methoxamine Phenylephrine Mephentermine Metaraminol Midodrine	Vasoconstriction	Nasal congestion (used topically) Postural hypotension	Hypertension Reflex bradycardia Dry mouth, sedation, rebound hypertension on abrupt withdrawal	Mephentermine and metaraminol also act indirectly to release NE Midodrine, a prodrug activated *in vivo*
α_2 Selective	Clonidine Apraclonidine Guanfacine Guanabenz Brimonidine α-Methyldopa	↓ Sympathetic outflow from brain to periphery resulting in ↓ PVR and blood pressure ↓ Nerve-evoked release of sympathetic transmitters ↓ Production of aqueous humor	Adjunctive therapy in shock Hypertension To reduce sympathetic response to withdrawal from narcotics, alcohol, and tobacco Glaucoma		Apraclonidine and brimonidine used topically for glaucoma and ocular hypertension Methyldopa is converted in CNS to α-methyl NE, an effective α_2 agonist
Indirect acting	Amphetamine Methamphetamine Methylphenidate (releases NE peripherally; NE, DA, 5HT centrally)	CNS stimulation ↑ Blood pressure Myocardial stimulation	Treatment of ADHD Narcolepsy Obesity (rarely)	Restlessness Tremor Insomnia Anxiety Tachycardia Hypertension Cardiac arrhythmias	Schedule II drugs Marked tolerance occurs Chronic use leads to dependence Can result in hemorrhagic stroke in patients with underlying disease Long-term use can cause paranoid schizophrenia

Mixed acting	Dopamine (α_1, α_2, β_1, D_1; releases NE)	Vasodilation (coronary, renal mesenteric beds) ↑ Glomerular filtration rate and natriuresis ↑ Heart rate and contractility ↑ Systolic blood pressure	Cardiogenic shock Congestive heart failure Treatment of acute renal failure	High doses lead to vasoconstriction Restlessness	Important for its ability to maintain renal blood flow Administered intravenously
	Ephedrine (α_1, α_2, β_1, β_2; releases NE)	Similar to epinephrine but longer lasting CNS stimulation	Bronchodilator for treatment of asthma Nasal congestion Treatment of hypotension and shock	Tremor Insomnia Anxiety Tachycardia Hypertension	Administered by all routes Not commonly used
α Blockers					
Nonselective (classical α blockers)	PBZ Phentolamine Tolazoline	↓ PVR and blood pressure Venodilation	Treatment of catecholamine excess (e.g., pheochromocytoma)	Postural hypotension Failure of ejaculation	Cardiac stimulation due to initiation of reflexes and to enhanced release of NE via α_2 receptor blockade PBZ produces long-lasting α receptor blockade, can block neuronal and extraneuronal uptake of amines
α_1 Selective	Prazosin Terazosin Doxazosin Trimazosin Alfuzosin Tamsulosin Silodosin	↓ PVR and blood pressure Relax smooth muscles in neck of urinary bladder and in prostate	Primary hypertension Increase urine flow in BPH	Postural hypotension when therapy instituted	Prazosin and related quinazolines are selective for α_1 receptors Tamsulosin exhibits some selectivity for α_{1A} receptors
β Blockers					
Nonselective (first generation)	Nadolol Penbutolol Pindolol Propranolol Timolol	↓ Heart rate ↓ Contractility ↓ Cardiac output Slow conduction in atria and AV node ↑ Refractory period, AV node Bronchoconstriction Prolonged hypoglycemia ↓ Plasma free fatty acids ↓ HDL cholesterol ↑ LDL cholesterol and triglycerides Hypokalemia	Angina pectoris Hypertension Cardiac arrhythmias Congestive heart failure Pheochromocytoma Glaucoma Hypertrophic obstructive cardiomyopathy Hyperthyroidism Migraine prophylaxis Acute panic symptoms Substance abuse withdrawal Variceal bleeding in portal hypertension	Bradycardia Negative inotropy ↓ Cardiac output Bradyarrhythmias ↓ AV conduction Bronchoconstriction Fatigue Sleep disturbances (insomnia, nightmares) Prolongation of hypoglycemia Sexual dysfunction in men Drug interactions	Effects depend on sympathoadrenal tone Bronchoconstriction (do not use in asthma and COPD) Hypoglycemia (of concern in hypoglycemics and diabetics) Membrane-stabilizing effect (propranolol, and betaxolol) ISA (strong for pindolol; weak for penbutolol, carteolol, and betaxolol)

(*Continued*)

TABLE 14–5 ■ SUMMARY OF ADRENERGIC AGONISTS AND ANTAGONISTS (*CONTINUED*)

SUBCLASS	DRUGS	PROMINENT PRINCIPAL PHARMACOLOGICAL ACTIONS	THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
β_1 Selective (second generation)	Acebutolol Atenolol Bisoprolol Betaxolol Esmolol Metoprolol	Similar to above but with less adverse effect on bronchial constriction	Similar to above	Similar to above	Effects depend on sympathoadrenal tone Bronchoconstriction effect is less than for nonspecific agents but use only with great caution in asthma and COPD
Nonselective (third-generation) vasodilators	Carteolol Carvedilol Bucindolol Labetalol	See text. These agents affect multiple receptor types and signaling pathways. They are used to treat hypertension; carvedilol is also used to treat heart failure. Effects and applications generally resemble those of other β blockers with some α blocking properties: • α_1 adrenergic receptor blockade (labetalol, carvedilol, bucindolol) • increased production of NO (celiprolol, nebivolol, carteolol) • β_2 agonist properties (celiprolol, carteolol) • Ca^{2+} entry blockade (carvedilol) • antioxidant action (carvedilol)			Vasodilation seen in third-generation drugs; multiple mechanisms (see Figure 14–4) Weak ISA for labetalol Receptor polymorphisms affect response to bucindolol's anti-arrhythmic properties
β_1 Selective (third-generation) vasodilators	Celiprolol Nebivolol				

ISA, intrinsic sympathomimetic activity; NO, nitric oxide; PBZ, phenoxybenzamine; PVR, pulmonary vascular resistance.

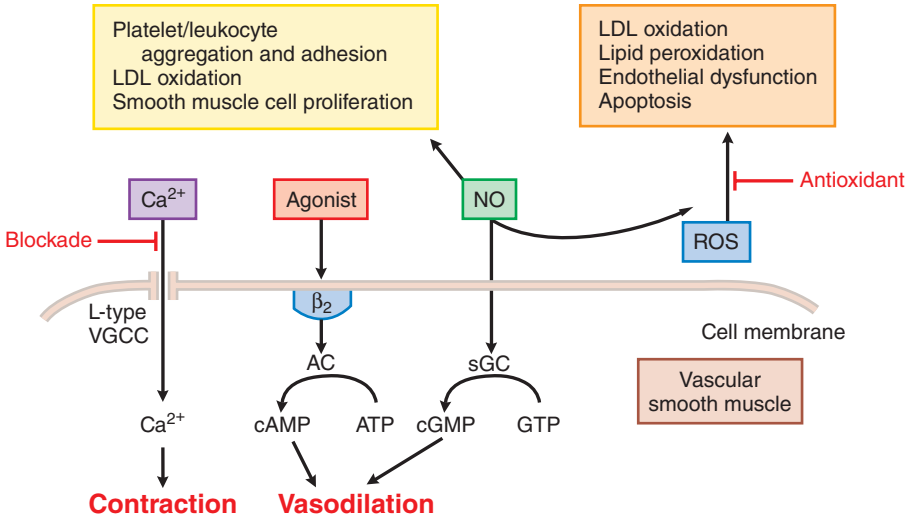

Figure 14–4 *Mechanisms underlying actions of vasodilating ß blockers in blood vessels.* Multiple mechanisms contribute to the vasodilating effects of the newer β antagonists. See Table 14–4 for details. AC: adenylyl cyclase; sGC: soluble guanylyl cyclase; NO: nitric oxide; ROS: reactive oxygen species; VGCC: voltage-gated Ca^{2+} channel. (Modified with permission from Toda, 2003. Copyright © Elsevier.)

5-fold higher risk for developing adverse effects (Wuttke et al., 2002). An extended-release formulation is available for once-daily administration.

Therapeutic Uses. *Metoprolol* has been used to treat essential hypertension, angina pectoris, tachycardia, heart failure, and vasovagal syncope and as secondary prevention after myocardial infarction, an adjunct in treatment of hyperthyroidism, and for migraine prophylaxis. For the treatment of hypertension, the usual initial dose is 100 mg/day. The drug sometimes is effective when given once daily, although it frequently is used in two divided doses. Dosage may be increased at weekly intervals until optimal reduction of blood pressure is achieved. *Metoprolol* generally is used in two divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of *metoprolol tartrate* is available; oral dosing is initiated as soon as the clinical situation permits. *Metoprolol* generally is contraindicated for the treatment of acute myocardial infarction in patients with heart rates of less than 45 beats/min, heart block greater than first-degree (PR interval ≥0.24 sec), systolic blood pressure less than 100 mmHg, or moderate-to-severe heart failure.

Atenolol

Atenolol is a β_1-selective antagonist that is devoid of intrinsic sympathomimetic and membrane-stabilizing activity. *Atenolol* is very hydrophilic and appears to penetrate the CNS only to a limited extent.

ADME. *Atenolol* is available in 25-, 50-, and 100-mg oral tablets (initial dose is 50 mg/day). It is incompletely absorbed (~50%) and is excreted largely unchanged in the urine, with elimination $t_{1/2}$ of 5 to 8 h. The drug accumulates in patients with renal failure, and dosage should be adjusted for patients whose creatinine clearance is less than 35 mL/min.

Therapeutic Uses. *Atenolol* can be used to treat hypertension, coronary heart disease, arrhythmias, and angina pectoris and to treat or reduce the risk of heart complications following myocardial infarction. Recent meta-analysis and clinical trials demonstrated a lack of benefit compared with placebo or other antihypertensive agents for reduction of stroke, cardiovascular and all-cause, despite similar blood pressure reduction compared to other antihypertensive agents (Ripley and Saseen, 2014). Compared with other active treatments, *atenolol* was associated with increased risk of all-cause mortality, cardiovascular mortality, and stroke and had a neutral effect on myocardial infarction. *Atenolol* is also used to treat the hypertension that can accompany Graves disease until antithyroid medication can take effect. The initial dose of *atenolol* for the treatment of hypertension usually is 50 mg/day, given once daily. If an adequate therapeutic response is not evident within several weeks, the daily dose may be increased to 100 mg. *Atenolol* has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension. *Atenolol* causes fewer CNS side effects (depression, nightmares) than most β blockers and few bronchospastic reactions due to its pharmacological and pharmacokinetic profile (Varon, 2008).

Esmolol

Esmolol is a β_1-selective antagonist with a rapid onset and a very short duration of action. It has little if any intrinsic sympathomimetic activity and lacks membrane-stabilizing actions. *Esmolol* is administered intravenously and is used when β blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. It is a class II antiarrhythmic agent (see Chapter 34).

ADME. *Esmolol* is given by slow intravenous injection. Because *esmolol* is used in urgent settings where immediate onset of β receptor blockade is warranted, a partial loading dose (500 µg/kg over 1 min) typically is administered, followed by a continuous infusion of the drug (maintenance dose of 50 µg/kg/min for 4 min). If an adequate therapeutic effect is not observed within 5 min, the same loading dose is repeated, followed by a maintenance infusion at a higher rate. This may need to be repeated until the desired end point (e.g., lowered heart rate or blood pressure) is approached. The drug is hydrolyzed rapidly by esterases in erythrocytes and has a $t_{1/2}$ of about 8 min. The $t_{1/2}$ of the carboxylic acid metabolite of *esmolol* is far longer (~4 h) and will accumulate during prolonged infusion of *esmolol*. However, this metabolite has very low potency as a β receptor antagonist (1/500 of the potency of *esmolol*); it is excreted in the urine.

Therapeutic Uses. *Esmolol* is commonly used in patients during surgery to prevent or treat tachycardia and in the treatment of supraventricular tachycardia. The onset and cessation of β receptor blockade with *esmolol* are rapid: Peak hemodynamic effects occur within 6 to 10 min of administration of a loading dose, and there is substantial diminution of β blockade within 20 min of stopping an infusion. *Esmolol* is particularly useful in severe postoperative hypertension and is a suitable agent in situations where cardiac output, heart rate, and blood pressure are increased. The American Heart Association/American College of Cardiology guidelines recommend against using *esmolol* in patients already on β blocker therapy, bradycardic patients, and patients with decompensated heart failure, as the drug may compromise their myocardial function (Varon, 2008). *Esmolol* is generally tolerated well, but it is associated with an increased risk of hypotension that is rapidly reversible (Garnock-Jones, 2012).

Acebutolol

Acebutolol is a β_1-selective adrenergic antagonist with some intrinsic sympathomimetic and membrane-stabilizing activity.

ADME. *Acebutolol* is administered orally (starting dose 200 mg twice daily titrated up to 1200 mg/day). It is well absorbed and undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug's activity. Overall bioavailability is 35% to 50%. The elimination $t_{1/2}$ of *acebutolol* typically is approximately 3 h, but the $t_{1/2}$ of diacetolol is 8 to 12 h; it is excreted largely in the urine. *Acebutolol* is lipophilic and crosses the blood-brain barrier. It has no negative impact on serum lipids (cholesterol, triglycerides, or HDL).

Therapeutic Uses. *Acebutolol* has been used to treat hypertension, ventricular and atrial cardiac arrhythmias, acute myocardial infarction in high-risk patients, and Smith-Magenis syndrome. The initial dose of *acebutolol* in hypertension usually is 400 mg/day; it may be given as a single dose, but two divided doses may be required for adequate control of blood pressure. Optimal responses usually occur with doses of 400 to 800 mg/day (range 200–1200 mg).

Bisoprolol

Bisoprolol is a highly selective β_1 adrenergic receptor antagonist that lacks intrinsic sympathomimetic or membrane-stabilizing activity (McGavin and Keating, 2002). It has a higher degree of β_1 selectivity than *atenolol*, *metoprolol*, or *betaxolol* but less than *nebivolol*. It is approved for the treatment of hypertension.

Bisoprolol generally is well tolerated; side effects include dizziness, bradycardia, hypotension, and fatigue. *Bisoprolol* is well absorbed following oral administration, with bioavailability of about 90%. It is eliminated by renal excretion (50%) and liver metabolism to pharmacologically inactive metabolites (50%). *Bisoprolol* has a plasma $t_{1/2}$ of approximately 11 to 17 h. *Bisoprolol* can be considered a standard treatment option when selecting a β blocker for use in combination with angiotensin-converting enzyme inhibitors and diuretics in patients with stable, moderate-to-severe chronic heart failure and in treating hypertension (McGavin and Keating, 2002; Simon et al., 2003). It has also been used to treat arrhythmias and ischemic heart disease. *Bisoprolol* was associated with a 34% mortality benefit in the CIBIS-II (Cardiac Insufficiency Bisoprolol Study-II).

Betaxolol

Betaxolol is a selective β_1 adrenergic receptor antagonist with no partial agonist activity and slight membrane-stabilizing properties. *Betaxolol* is used to treat hypertension, angina pectoris, and glaucoma. The drug is well absorbed with high bioavailability; its elimination $t_{1/2}$ varies from 14 to 22 h. It is usually well tolerated; side effects are mild and transient.

β Adrenergic Receptor Antagonists With Additional Cardiovascular Effects ("Third-Generation" β Blockers)

In addition to the classical nonselective and β_1-selective adrenergic receptor antagonists, there are drugs that possess vasodilating actions (Toda, 2003). These effects are produced through a variety of mechanisms, including the following:

- *α_1 Adrenergic receptor blockade* (*labetalol, carvedilol, bucindolol, bevantolol, nipradilol*)
- *Increased production of NO* (*celiprolol, nebivolol, carteolol, bopindolol, nipradilol*)
- *β_2 Agonist properties* (*celiprolol, carteolol, bopindolol*)
- *Ca^{2+} entry blockade* (*carvedilol, betaxolol, bevantolol*)
- *Opening of K^+ channels* (*tilisolol*)
- *Antioxidant action* (*carvedilol*)

These actions are summarized in Table 14–4. Some third-generation β adrenergic receptor antagonists are not available in the U.S. but have undergone clinical trials and are available elsewhere.

Labetalol

Labetalol acts as a competitive antagonist at both α_1 and β receptors. *Labetalol* has two optical centers, and the formulation used clinically contains equal amounts of the four diastereomers. The pharmacological properties of the drug are complex because each isomer displays different relative activities. The properties of the mixture include selective blockade of α_1 adrenergic receptors (as compared with the α_2 subtype), blockade of β_1 and β_2 adrenergic receptors, partial agonist activity at β_2 receptors, and inhibition of neuronal uptake of NE (cocaine-like effect). The potency of the mixture for β adrenergic receptor blockade is 5- to 10-fold that for α_1 receptor blockade.

The pharmacological effects of *labetalol* have become clearer since the four isomers were separated and tested individually.

- *The R,R isomer* is about four times more potent as a β receptor antagonist than is racemic *labetalol* and accounts for much of the β blockade produced by the mixture of isomers. As an α_1 antagonist, this isomer is less than 20% as potent as the racemic mixture. The *R,R* isomer has some intrinsic sympathomimetic activity at β_2 adrenergic receptors; this may contribute to vasodilation.
- *The R,S isomer* is almost devoid of both α- and β-blocking effects.
- *The S,R isomer* has almost no β-blocking activity, yet is about five times more potent as an α_1 blocker than is racemic *labetalol*.
- *The S,S isomer* is devoid of β-blocking activity and has a potency similar to that of racemic *labetalol* as an α_1 receptor antagonist.

The actions of *labetalol* on both α_1 and β adrenergic receptors contribute to the fall in blood pressure observed in patients with hypertension. α_1 Receptor blockade leads to relaxation of arterial smooth muscle and vasodilation, particularly when the patient is upright. The β_1 blockade also contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. In addition, the intrinsic sympathomimetic activity of *labetalol* at β_2 adrenergic receptors may contribute to vasodilation, and the drug may have some direct vasodilating capacity.

Labetalol is available in oral form for therapy of chronic hypertension and as an intravenous formulation for use in hypertensive emergencies. *Labetalol* has been associated with hepatic injury in a limited number of patients. *Labetalol* has been recommended as treatment of acute severe hypertension (hypertensive emergency). Its hypotensive action begins within 2 to 5 min after intravenous administration, reaching its peak at 5 to 15 min and lasting about 2 to 4 h. Heart rate is either maintained or slightly reduced, and cardiac output is maintained. *Labetalol* reduces systemic vascular resistance without reducing total peripheral blood flow. Cerebral, renal, and coronary blood flow is maintained. It can be used in the setting of pregnancy-induced hypertensive crisis because little placental transfer occurs due to the poor lipid solubility of *labetalol*.

ADME. Although *labetalol* is completely absorbed from the gut, there is extensive first-pass clearance; bioavailability is about 20% to 40% but may be increased by food intake. The drug is rapidly metabolized in the liver; very little unchanged drug is found in the urine. The rate of metabolism of *labetalol* is sensitive to changes in hepatic blood flow. The elimination $t_{1/2}$ of the drug is about 8 h. The $t_{1/2}$ of the *R,R* isomer of *labetalol* is approximately 15 h.

Carvedilol

Carvedilol is a third-generation β receptor antagonist that has a unique pharmacological profile. It blocks β_1, β_2, and α_1 receptors similarly to *labetalol* but also has antioxidant and anti-inflammatory properties (DiNicolantonio et al., 2015), features that may be beneficial in treating congestive heart failure (see below). The drug has membrane-stabilizing activity but lacks intrinsic sympathomimetic activity. *Carvedilol* has also been demonstrated to be a β-arrestin–biased ligand that promotes β-arrestin recruitment to β_1 and β_2 receptors in the absence of G_s activation, the clinical relevance of which has yet to be determined.

Carvedilol reduces arterial blood pressure by decreasing vascular resistance and maintaining cardiac output while decreasing sympathetic vascular tone (DiNicolantonio et al., 2015; Zepeda et al., 2012). The hemodynamic effect exerted by *carvedilol* is similar to that of angiotensin-converting enzyme inhibitors and superior to that of traditional β blockers such as *propranolol*. *Carvedilol* is renoprotective and has favorable effects in patients with diabetes or metabolic syndrome. The drug is FDA approved for use in hypertension, congestive heart failure, and left ventricular dysfunction following myocardial infarction.

Carvedilol possesses two distinct antioxidant properties: It is a chemical antioxidant that can scavenge reactive oxygen species (ROS), and it can suppress the biosynthesis of ROS and oxygen radicals. *Carvedilol* is extremely lipophilic and protects cell membranes from lipid peroxidation. It prevents LDL oxidation, which in turn induces the uptake of LDL into the coronary vasculature. *Carvedilol* also inhibits ROS-mediated loss of myocardial contractility, stress-induced hypertrophy, apoptosis, and the accumulation and activation of neutrophils. At high doses, *carvedilol* exerts Ca^{2+} channel–blocking activity.

Numerous controlled trials have shown that *carvedilol* improves ventricular function and reduces mortality and morbidity in patients with mild-to-severe congestive heart failure (Chatterjee et al., 2013; Poole-Wilson et al., 2003). Several experts recommend it as the standard treatment option in this setting. In addition, *carvedilol*, in combination with conventional therapy, reduces mortality and attenuates myocardial infarction. In patients with chronic heart failure, *carvedilol* reduces cardiac sympathetic drive, but it is not clear whether blockade of α_1 adrenergic receptor–mediated vasodilation is maintained over long periods of time.

ADME. *Carvedilol* is rapidly absorbed following oral administration, with peak plasma concentrations occurring in 1 to 2 h. It is highly lipophilic and more than 95% protein bound. Hepatic CYPs 2D6 and 2C9 metabolize *carvedilol*, yielding a $t_{1/2}$ of 7 to 10 h. Stereoselective first-pass metabolism results in more rapid clearance of S(−)-carvedilol than R(+)-carvedilol. No significant changes in the pharmacokinetics of *carvedilol* are seen in elderly patients with hypertension, and no change in dosage is needed in patients with moderate-to-severe renal insufficiency (Keating and Jarvis, 2003). Because of extensive hepatic metabolism, *carvedilol*'s pharmacokinetics can be profoundly affected by drugs that induce or inhibit CYPs 2D6 and 2C9. These include the inducer *rifampin* and inhibitors such as *cimetidine, quinidine, fluoxetine*, and *paroxetine*.

Bucindolol

Bucindolol is a third-generation nonselective β adrenergic receptor antagonist with weak α_1 receptor–blocking properties. *Bucindolol* increases left ventricular systolic ejection fraction and decreases peripheral resistance, thereby reducing afterload. It increases plasma HDL cholesterol but does not affect plasma triglycerides. A large comprehensive clinical trial, BEST (β Blocker Evaluation of Survival Trial), was terminated early because of a lack of a demonstrable survival benefit with *bucindolol* versus placebo. Further analysis has demonstrated that polymorphisms in β_1 and α_{2c} adrenergic receptors predict the effect of *bucindolol* to prevent new-onset atrial fibrillation and ventricular arrhythmias (Cooper-DeHoff and Johnson, 2016; O'Connor et al., 2012).

Celiprolol

Celiprolol is a third-generation, cardioselective β adrenergic receptor antagonist used for treatment of hypertension and angina. It has low lipid solubility, is devoid of membrane-stabilizing activity, and possesses weak vasodilating and bronchodilating effects attributed to partial selective β_2 agonist activity and possibly *papaverine*-like relaxant effects on smooth muscle (including bronchial smooth muscle). It also has been reported to antagonize peripheral α_2 adrenergic receptor activity, to promote NO production, and to inhibit oxidative stress. Weak α_1 adrenergic receptor antagonistic properties are present but are not considered clinically significant at therapeutic doses (Toda, 2003). *Celiprolol* reduces heart rate and blood pressure and can increase the functional refractory period of the AV node. Oral bioavailability ranges broadly (30%–70%); peak plasma levels occur 2 to 4 h after oral administration. It is predominantly excreted in the urine, largely unchanged, and to a lesser extent in the feces.

Nebivolol

Nebivolol is a third-generation, long-acting, and highly selective β_1 adrenergic receptor antagonist that stimulates NO-mediated vasodilation via β_3 receptor agonism (Fongemie and Felix-Getzik, 2015). *Nebivolol* is devoid of intrinsic sympathomimetic effects as well as membrane-stabilizing activity and α_1 receptor–blocking properties.

ADME. *Nebivolol* is administered as the racemate containing equal amounts of the *d*- and *l*-enantiomers. The *d*-isomer is the active β-blocking component; the *l*-isomer is responsible for enhancing production of NO. *Nebivolol* is lipophilic, and concomitant administration of *chlorthalidone*, *hydrochlorothiazide*, *theophylline*, or *digoxin* with *nebivolol* may reduce its extent of absorption.

Nebivolol undergoes extensive first-pass metabolism, primarily by CYP2D6, with a mean terminal $t_{1/2}$ of about 10 h. Active metabolites (e.g., 4-OH nebivolol) contribute to the β-blocking effect of *nebivolol*. Polymorphisms in the CYP2D6 gene affect *nebivolol*'s metabolism but not its efficacy due to the production of active hydroxylated metabolites (Lefebvre et al., 2007).

Therapeutic Uses. *Nebivolol* is approved for treatment of hypertension and may be associated with better outcomes than first- and second-generation β receptor antagonists with reduced risk of hospitalization due to cardiovascular events (Olawi et al., 2019). *Nebivolol* lowers blood pressure by reducing peripheral vascular resistance and significantly increases stroke volume with preservation of cardiac output to maintain systemic blood flow to target organs. *Nebivolol* also reduces endothelial dysfunction and oxidative stress and may have favorable effects on both carbohydrate and lipid metabolism. These benefits are also observed in the presence of metabolic syndrome, which often presents along with hypertension (Ignarro, 2008). The NO-dependent vasodilating action of *nebivolol* and its high β_1 adrenergic receptor selectivity likely contribute to the drug's efficacy and comparative tolerability as an antihypertensive agent (e.g., less fatigue and sexual dysfunction in men) (Olawi et al., 2019). While *nebivolol* has potential utility in the treatment of heart failure with reduced ejection fraction, it may not reduce mortality to the same degree as *carvedilol*, *metoprolol*, or *bisoprolol* (Chatterjee et al., 2013).

Chapter 15

5-Hydroxytryptamine (Serotonin) and Dopamine

Charles D. Nichols, Susan G. Amara, and David R. Sibley

Introduction

5-Hydroxytryptamine (5HT, serotonin) and dopamine (DA) are neurotransmitters in the central nervous system (CNS) that also have prominent peripheral actions. Although high concentrations of 5HT are present in the CNS, about 95% of all 5HT in the human body is located in the periphery, with high levels in enterochromaffin cells throughout the gastrointestinal (GI) tract and in storage granules in platelets. The highest concentrations of DA are found in the brain, but DA stores are also present peripherally in the adrenal medulla, in the plexuses of the GI tract, and in the enteric nervous system. Fourteen mammalian 5HT receptor subtypes, categorized into seven subfamilies, and five DA receptor subtypes, categorized into two subfamilies, have been delineated by structural and pharmacological analyses and are encoded by separate genes. For some receptors, alternative RNA splicing or editing creates additional heterogeneity; for example, over 30 isoforms of the $5HT_{2C}$ receptor subtype arise from RNA editing. The identification of individual receptor subtypes has facilitated development of subtype-selective drugs and elucidation of actions of 5HT and DA at a molecular level. Increasingly, therapeutic goals are being achieved by using drugs that selectively target one or more of the subtypes of 5HT or DA receptors or that act on a combination of both 5HT and DA receptors.

5-Hydroxytryptamine

HISTORICAL PERSPECTIVE

In the 1930s, Vittorio Erspamer began to study the distribution of enterochromaffin cells, which were stained with a reagent for indoles. The highest concentrations of these cells were found in GI mucosa, followed by platelets and the CNS. Subsequently, Irving Page and colleagues at the Cleveland Clinic isolated and characterized a vasoconstrictor substance released from platelets in clotting blood. This substance, named serotonin by Page, was identical to the indole, enteramine, isolated by Erspamer. Both enteramine and serotonin proved to be 5-hydroxytryptamine. Subsequent discovery of the biosynthetic and degradative pathways for 5HT and clinical presentation of patients with carcinoid tumors of intestinal enterochromaffin cells spurred interest in 5HT. In the mid-1950s, Betty Tvorog discovered that 5HT was also present in the brain. Subsequent discoveries that the pronounced behavioral effects of *reserpine* are accompanied by a profound decrease in brain 5HT led to the proposal that 5HT might be a neurotransmitter in the mammalian CNS. Numerous congeners of 5HT have pharmacological activity (see Figure 15–1). Many of the *N*- and *O*-methylated indoleamines have psychedelic or hallucinogenic properties. A close relative of 5HT, melatonin, is formed by sequential *N*-acetylation and *O*-methylation (Figures 15–1 and 15–2). Melatonin, not to be confused with the pigment melanin, is the principal indoleamine in the pineal gland, where it modulates circadian rhythms , especially those relating to sleep preparation, hence its use in the treatmnt of jet lag and insomnia.

Synthesis and Metabolism of 5-Hydroxytryptamine (Serotonin)

Synthesis of 5HT (5-hydroxytryptamine, serotonin) occurs by a two-step pathway from the essential amino acid tryptophan (Figure 15–2). Tryptophan is actively transported into the brain by L-type amino acid transporter 1 (LAT1), a heteromeric carrier protein that also transports other large neutral and branched-chain amino acids as well as some drugs.

Abbreviations

AADC: aromatic L-amino acid decarboxylase
ADHD: attention-deficit/hyperactivity disorder
BBB: blood-brain barrier
COMT: catechol-*O*-methyl transferase
CGRP: calcitonin gene-related peptide
CSF: cerebrospinal fluid
DA: dopamine
DAG: diacylglycerol
DAT: dopamine transporter
L-DOPA: 3,4-dihydroxyphenylalanine
DOPAC: 3,4-dihydroxyphenylacetic acid
EPI: epinephrine
EPS: extrapyramidal symptoms
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
GSK-3: glycogen synthase kinase 3
5-HIAA: 5-hydroxyindole acetic acid
HSDD: hypoactive sexual desire disorder
5HT: 5-hydroxytryptamine, serotonin
HVA: homovanillic acid
LSD: lysergic acid diethylamide
MAO: monoamine oxidase
MPP^+: 1-methyl-4-phenylpyridinium
MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MSAA: multifunctional serotonin agonists and antagonists
NE: norepinephrine
NET: norepinephrine transporter
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
NSS: neurotransmitter–sodium symporter
6-OHDA: 6-hydroxydopamine
PD: Parkinson's disease
PFC: prefrontal cortex
PKC: protein kinase C
PLC: phospholipase C
RLS: restless leg syndrome
SERT: serotonin transporter
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TAAR1: trace amine-associated receptor 1
TCA: tricyclic antidepressants
VMAT2: vesicular monoamine transporter 2
VNTR: variable number of tandem repeat

Levels of tryptophan in the brain are influenced not only by its plasma concentration but also by the plasma concentrations of other amino acids that compete for the transporter. Tryptophan hydroxylase 1 (TPH1) is a mixed-function oxidase that requires molecular O_2 and a reduced pteridine cofactor for activity and is the rate-limiting enzyme in the synthetic pathway. TPH2, a brain-specific isoform of TPH1, is entirely responsible for the synthesis of brain 5HT. 5HT itself does not cross the blood-brain barrier (BBB) and thus must be synthesized locally within the CNS. Brain TPH2 is not generally saturated with substrate; consequently, the concentration of tryptophan in the brain influences the synthesis of 5HT.

L-5-hydroxytryptophan is converted to 5HT by aromatic L-amino acid decarboxylase (AADC). AADC is widely distributed and has broad substrate specificity. The synthesized product, 5HT, is transported into secretory granules by the vesicular monoamine transporter, VMAT2. *Reserpine* depletes vesicular stores of 5HT and other monoamines by selectively inhibiting VMAT2. Based on its ability to deplete norepinephrine (NE) or DA, *reserpine* was once used as an antihypertensive or antipsychotic agent, respectively; however, it is no longer used for these purposes. In the CNS, stored vesicular 5HT is released by exocytosis from serotonergic neurons in response to an action potential. 5HT signaling is either terminated through neuronal reuptake by the serotonin transporter (SERT), localized in the membrane of serotonergic axon terminals, or degraded by monoamine oxidase A (MAO-A). SERT is also found on the cellular membranes of platelets and is crucial for regulating and maintaining serotonin concentrations within platelets, which lack the ability to synthesize 5HT. Localized on the plasma membrane, SERT serves a function distinct from VMAT2, a vesicular monoamine transporter that concentrates monoamines into intracellular storage vesicles. SERT can be inhibited by selective serotonin reuptake inhibitors (SSRIs) that are used to treat depression and other mood disorders.

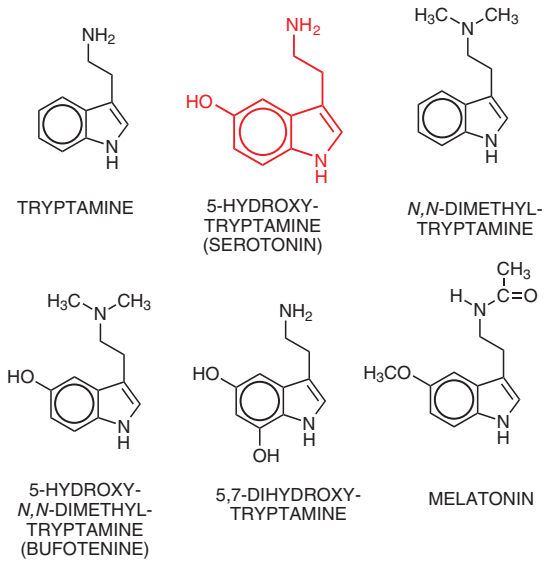

Figure 15–1 *Structures of representative indolealkylamines.*

The principal route of metabolism of 5HT involves oxidative deamination by monoamine oxidase (MAO). The aldehyde intermediate formed is converted to 5-hydroxyindole acetic acid (5-HIAA) by aldehyde dehydrogenase (see Figure 15–2). An alternative route, reduction of the acetaldehyde to an alcohol to generate 5-hydroxytryptophol, is normally insignificant. 5-HIAA is actively transported out of the brain by a process that is sensitive to the nonspecific transport inhibitor *probenecid*. 5-HIAA produced from metabolism of 5HT is excreted in the urine along with small amounts of 5-hydroxytryptophol sulfate or glucuronide conjugates.

Of the two isoforms of MAO (see Chapter 10), MAO-A preferentially metabolizes 5HT and NE. Selective MAO-A inhibitors increase stores of 5HT and NE and are considered first-generation antidepressant agents (see Chapter 15). MAO-B prefers β-phenylethylamine and benzylamine as substrates. DA and tryptamine are metabolized equally well by both isoforms. Neurons contain both isoforms of MAO, which are found primarily in the outer membrane of mitochondria. MAO-B is the principal isoform in platelets, which contain large amounts of 5HT.

Serotonergic Projection Pathways in the Brain

In the CNS, 5HT is almost entirely synthesized by cells located in the raphe nuclei in the brainstem. These neurons exhibit extensive projections throughout the brain and spinal cord. These projections are so extensive that it has been hypothesized that every neuron in the brain may be in synaptic contact with a serotonergic projection fiber (Figure 15–3). Individual cell types both in the brain and body, however, produce small amounts of 5HT. The role of this intracellular 5HT is unclear, but it may be necessary for posttranslational modifications of intracellular proteins by "serotonylation" where 5HT is covalently attached to glutamine residues of proteins via the enzyme transglutaminase.

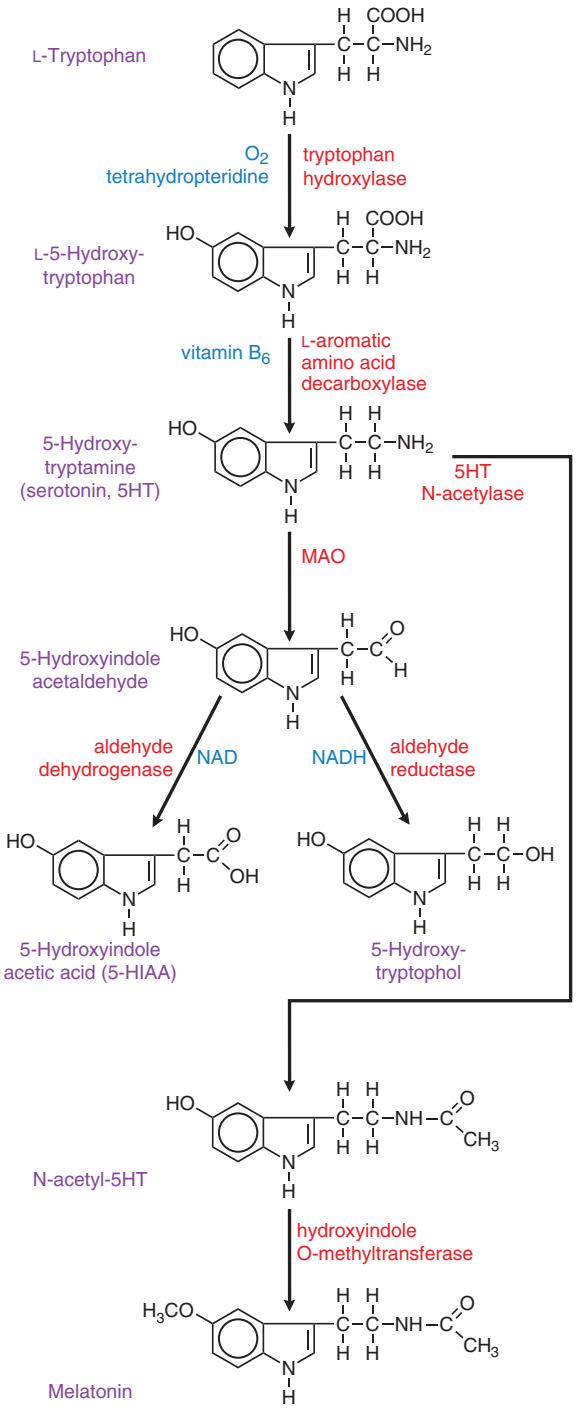

Figure 15–2 *Synthesis and inactivation of serotonin.* Enzymes are identified in red lettering, and cofactors are shown in *blue*.

A model of a serotonergic synapse is depicted in Figure 15–4. 5HT released from the nerve terminal activates cell-specific postsynaptic receptors, leading to activation of effectors and signal transduction. Presynaptic 5HT receptors (autoreceptors) also exist on the nerve terminal where they can act to modulate 5HT release via negative feedback. Reuptake of 5HT by the SERT transporter is the primary mechanism for termination of 5HT action and allows for either vesicular repackaging of transmitter or metabolism.

The 5HT Receptors

Multiple 5HT receptor subtypes and their splice and edited isoforms mediate serotonin's diverse array of physiological effects and comprise the largest known neurotransmitter/hormone receptor family (Barnes et al., 2020). The 5HT receptor subtypes are expressed in distinct but often overlapping patterns and couple with differing efficiencies to different transmembrane signaling mechanisms (Table 15–1). With the exception of the $5HT_3$ receptor, which is a ligand-gated ion channel, all of the 5HT receptor subtypes are G protein-coupled receptors (GPCRs) (see Figures 16–7 and 16–8).

The $5HT_1$ Receptor Subfamily

- The $5HT_1$ receptor family comprises five members, all of which preferentially couple to $G_{i/o}$ and inhibit adenylyl cyclase and cyclic AMP accumulation. $5HT_1$ receptors are also known to modulate K^+ and Ca^{2+} channels.
- The $5HT_{1A}$ and $5HT_{1B/1D}$ receptors can act as autoreceptors, either on the cell bodies ($5HT_{1A}$) or on the axon terminals ($5HT_{1B/1D}$) (Figure 15–5). The density of $5HT_{1A}$ receptors is high in the brain, where they have been implicated in depression and anxiety. $5HT_{1B}$ and $5HT_{1D}$ receptors are predominantly expressed in the brain, and these two receptors share significant co-localization in the CNS. Antimigraine triptan drugs are $5HT_{1B/1D}$ agonists (see further discussion).
- The $5HT_{1E}$ and $5HT_{1F}$ receptors are predominantly found in the brain; however, their precise functions remain unclear. A $5HT_{1F}$ receptor–selective agonist, *lasmiditan*, has been recently approved as a clinical therapeutic for migraines.

The $5HT_2$ Receptor Subfamily

- The three subtypes of $5HT_2$ receptors preferentially couple to G_q/G_{11} proteins and activate PLC-DAG/IP_3-Ca^{2+}-PKC pathways (see Table 15–1). $5HT_2$ receptor stimulation can also lead to activation of phospholipase A_2, promoting the release of arachidonic acid.
- $5HT_{2A}$ receptors are the most widespread of the 5HT receptors and expressed in nearly every type of tissue and cell type throughout the body. In the CNS, they are found at high densities in several brain structures including the prefrontal, parietal, and somatosensory cortices. In the periphery, they are found at high levels in blood platelets and smooth muscle cells, among other tissues. Many antipsychotic drugs inhibit $5HT_{2A}$ receptors, and psychedelics activate $5HT_{2A}$ receptors.
- The $5HT_{2B}$ receptor is not as widely expressed but is found at low levels in the brain and peripheral tissues. It is found at higher levels in vascular smooth muscle and certain immune cells.
- The $5HT_{2C}$ receptor is the only GPCR whose activity is regulated by RNA editing. Multiple $5HT_{2C}$ receptor isoforms generated by RNA editing exhibit modified G protein-coupling efficiencies (Barnes et al., 2020). The $5HT_{2C}$ receptor has been implicated in the control of cerebrospinal fluid (CSF) production, feeding behavior, and mood and is expressed most highly in the brain and choroid plexus.

$5HT_3$ Receptors

- The $5HT_3$ receptor is the only monoamine neurotransmitter receptor that functions as a ligand-gated ion channel.
- The functional $5HT_3$ receptor forms pentameric complexes consisting of three distinct subunits, and activation of these ligand-gated channels elicits a rapidly desensitizing depolarization, mediated by the gating of cations.
- $5HT_3$ receptors are located on parasympathetic terminals in the GI tract, including vagal and splanchnic afferents. In the CNS, a high density of $5HT_3$ receptors occurs in the solitary tract nucleus, the area postrema, and the vomiting center of the brainstem. $5HT_3$ receptors in both the GI tract and the CNS participate in the emetic response, providing a basis for the antiemetic property of FDA-approved $5HT_3$ receptor antagonists like *ondansetron*. The functional $5HT_3$ receptor is not the product of a single gene but can be composed of subunits expressed from one of five separate gene products ($5HT_{3A-E}$).

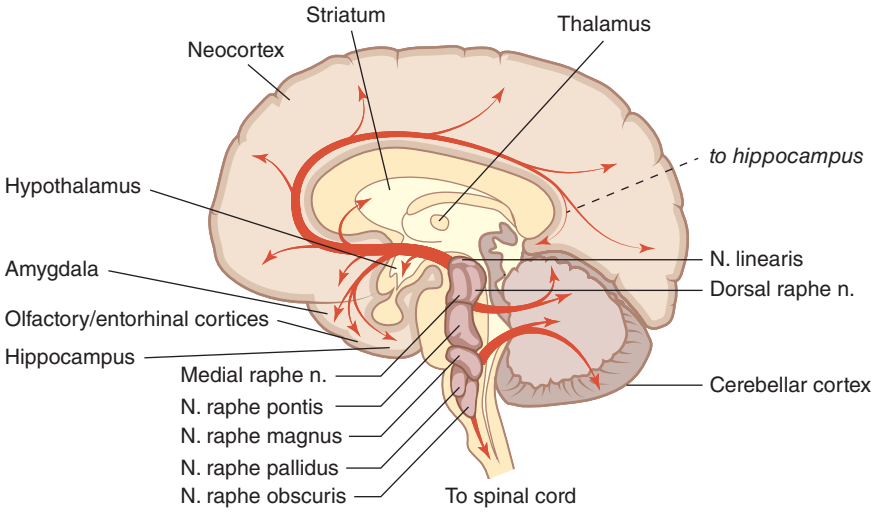

Figure 15–3 *Serotonergic pathways in the brain.* Serotonin is produced by several discrete brainstem nuclei, shown here in rostral and caudal clusters. The rostral nuclei, which include the nucleus, dorsal raphe, medial raphe, and raphe pontis, innervate most of the brain, including the cerebellum. The caudal nuclei, which comprise the raphe magnus, raphe pallidus, and raphe obscuris, have more limited projections that terminate in the cerebellum, brainstem, and spinal cord. Together, the rostral and caudal nuclei innervate most of the CNS. (Modified with permission from Nestler EJ et al., eds. *Molecular Neuropharmacology: A Foundation for Clinical Neuroscience*, 3rd ed. McGraw Hill, New York, **2015**.)

$5HT_4$ Receptors

- The $5HT_4$ receptor subtype couples to G_s to activate adenylyl cyclase and increase cyclic AMP production.
- In the CNS, high densities of $5HT_4$ receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, $5HT_4$ receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. Stimulation of the $5HT_4$ receptor is thought to evoke secretion and to facilitate the peristaltic reflex. The latter effect may explain the utility of prokinetic benzamide drugs in GI disorders (see Chapter 54).
- Effects of pharmacological manipulation of $5HT_4$ receptors on memory and feeding behaviors in animal models suggest possible clinical applications in the future.

$5HT_5$ Receptors

- The $5HT_5$ subfamily preferentially couples to $G_{i/o}$ to inhibit adenylyl cyclase.
- Humans express a single functional $5HT_{5A}$ receptor, whereas rodents express both $5HT_{5A}$ and $5HT_{5B}$ receptors. The human $5HT_{5B}$ gene is interrupted by a stop codon and several other polymorphisms, leading to a nonfunctional gene.
- The $5HT_{5A}$ receptor has high constitutive activity and is expressed widely in the CNS where it is linked to anxiety, circadian rhythms, and cognition. There is little to no expression of $5HT_5$ receptors in the periphery.

$5HT_6$ Receptors

- The $5HT_6$ receptor preferentially couples to G_s to activate adenylyl cyclase and increase intracellular cyclic AMP levels.
- The $5HT_6$ receptor is almost exclusively found in the CNS; its abundance in cortical, limbic, and extrapyramidal regions suggests that it is important for motor control and cognition. It is one of the few GPCRs found in primary neuronal cilia.
- $5HT_6$ receptor antagonists are currently in clinical trials as a therapeutic modality for cognitive decline in patients with Alzheimer's disease and dementia.

$5HT_7$ Receptors

- The $5HT_7$ receptor preferentially couples to G_s to activate adenylyl cyclase and increase intracellular cyclic AMP. It is widely distributed throughout the CNS, including the trigeminal nerve. It is also found in the periphery at high levels in several tissues including the spleen, GI tract, and arteries.
- $5HT_7$ receptors play a role in thermoregulation, sleep, nociception, cognitive function, and the relaxation of smooth muscle in the GI tract and the vasculature. Blockade of $5HT_7$ receptor activity may play a role in the therapeutic action of some antipsychotic and antidepressant medications.
- There is a $5HT_7$ receptor pseudogene in humans whose mRNA is widely expressed throughout the body but is not translated into a functional receptor.

The 5HT Transporter (SERT)

- The actions of 5HT are primarily terminated by SERT (SLC6A4), the transport protein responsible for the reuptake of 5HT into serotonergic neurons.
- Encoded by a single gene, SERT possesses 12 membrane-spanning domains and is a member of the neurotransmitter–sodium symporter (NSS) family that includes the transporters for DA, NE, γ-aminobutyric acid (GABA), and glycine. SERT is expressed prominently in central serotonergic neurons that originate in the raphe nucleus, but is also found in platelets, placenta, lung, gut, enteric nervous system, and the adrenal gland.
- SERT is a secondary active transporter that couples 5HT transport to the movement of sodium into the cell.
- SSRIs such as *fluoxetine*, *paroxetine*, *citalopram*, and *sertraline* bind to the SERT and inhibit serotonin transport. Tricyclic antidepressants (TCAs) and the newer class of serotonin-norepinephrine reuptake inhibitors (SNRIs) that includes *venlafaxine* and *duloxetine* block SERT, the NE transporter (NET), or both with varying degrees of selectivity.
- SSRIs and SNRIs are prescribed for major depressive disorder, obsessive-compulsive disorder, panic disorder, generalized anxiety disorder, fibromyalgia, and neuropathic pain, among others.

Actions of 5HT in Physiological Systems

Platelets

Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and exocytotic release of 5HT. 5HT is not synthesized in platelets but is taken up from the circulation via the SERT and

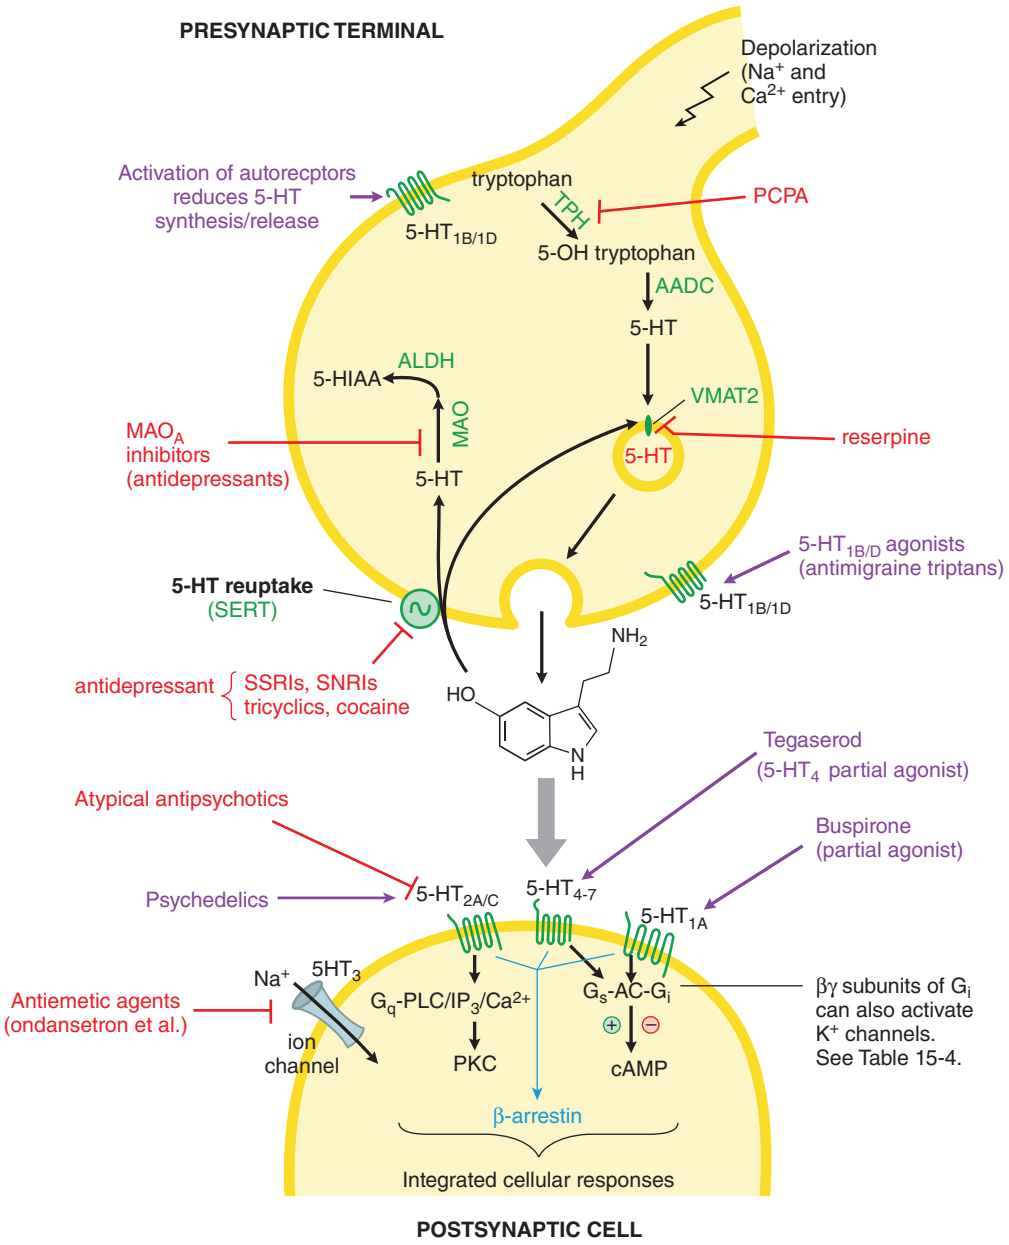

Figure 15–4 *A serotonergic synapse.* Presynaptic and postsynaptic molecular entities involved in the synthesis, release, signaling, and reuptake of serotonin are shown. MAO is in mitochondria within serotonergic nerve terminals.

stored in secretory granules by active transport, similar to the uptake and storage of serotonin by serotonergic nerve terminals. When platelets make contact with injured endothelium (see Chapter 36), they release substances that promote platelet aggregation; secondarily, they release 5HT (Figure 15–6). 5HT binds to platelet $5HT_{2A}$ receptors and elicits a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autocoids (thromboxane A_2 [TxA_2], kinins, and vasoactive peptides). Conversely, 5HT may interact with endothelial cells to stimulate production of nitric oxide (NO) and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

Cardiovascular System

The classical response of blood vessels to 5HT is contraction, particularly in the splanchnic, renal, pulmonary, and cerebral vasculatures. 5HT also induces a variety of responses in the heart that are the result of activation of multiple 5HT receptor subtypes, stimulation or inhibition of autonomic nerve activity, or dominance of reflex responses to 5HT. Thus, 5HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. Activation of $5HT_3$ receptors on vagal nerve endings elicits the Bezold-Jarisch reflex, causing extreme bradycardia and hypotension. The local response of arterial blood vessels to 5HT also may be inhibitory, the result of the stimulation of endothelial NO production and prostaglandin synthesis and blockade of NE release from sympathetic nerves. Conversely, 5HT amplifies the local constrictor actions of NE, angiotensin II, and histamine, which reinforce the hemostatic response to 5HT.

Gastrointestinal Tract

Enterochromaffin cells in the gastric mucosa are the site of the synthesis and most of the storage of 5HT in the body and are the source of circulating 5HT. Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited via signaling mediated by at least five subtypes of 5HT receptors (Table 15–2).

TABLE 15–1 ■ SEROTONIN RECEPTOR SUBTYPES[a]

SUBTYPE	SIGNALING EFFECTOR	LOCALIZATION	FUNCTION	AGONISTS	ANTAGONISTS
5-HT_{1A}	↓ AC	Raphe nuclei, cortex, hippocampus	Somatodendritic autoreceptor in raphe Postsynaptic in cortex and hippocampus	8-OH-DPAT, buspirone	WAY 100135
5-HT_{1B}	↓ AC	Cortex, subiculum, globus pallidus, substantia nigra	Presynaptic autoreceptor	Sumatriptan, CP94253	GR-55562
5-HT_{1D}	↓ AC	Cranial vessels, globus pallidus, substantia nigra	Presynaptic autoreceptor, vasoconstriction	Sumatriptan, PNU142633	SB 714786
5-HT_{1E}	↓ AC	Cortex, striatum	—	—	—
5-HT_{1F}	↓ AC	Dorsal raphe, hippocampus, periphery	—	Lasmiditan	—
5-HT_{2A}	↑ PLC, PLA_2	Widespread, including platelets, smooth muscle, cerebral cortex, immune cells	Platelet aggregation, smooth muscle contraction, neuronal excitation	DOI, 25CN-NBOH	M100907, pimivanserin
5-HT_{2B}	↑ PLC	Stomach fundus	Smooth muscle contraction	BW723C86, DOI	LY266097
5-HT_{2C}	↑ PLC, PLA_2	Choroid plexus, substantia nigra, basal ganglia	CSF production, neuronal excitation	1-methylpsilocin, Ro-60-0175, DOI	RS102221,
5-HT_3	Cations	Parasympathetic nerves, solitary tract, area postrema, GI tract	Neuronal excitation	SR57227, quipazine	Ondansetron, palonosetron
5-HT_4	↑ AC	Hippocampus, striatum, GI tract	Neuronal excitation	BIMU8, tegaserod	GR 113808
5-HT_{5A}	↓ AC	Cortex, hippocampus	Unknown	—	SB-699551
5-HT_{5B}	Unknown	—	Pseudogene in humans	—	—
5-HT_6	↑ AC	Hippocampus, striatum, nucleus accumbens	Neuronal excitation	WAY-181187	SB-271046
5-HT_7	↑ AC	Hypothalamus, SCN, hippocampus, GI tract	Smooth muscle relaxation	AS-19, LP-12	SB-269970

[a]For further information on the pharmacological properties of the 5HT subtypes, see IUPHAR/BPS Guide to Pharmacology: http://www.guidetopharmacology.org/index.jsp.
Abbreviations: AC, adenylyl cyclase; PLA_2, phospholipase A_2; PLC, phospholipase C; 5-CT, 5-carboxamino-tryptamine; DOI, 1-(2,5-dimethoxy-4-iodophenyl) isopropylamine; 8-OH-DPAT, 8-hydroxy-(2-*N*,*N*-dipropylamino)-tetraline; MCPP, metachlorphenylpiperazine; others are manufacturers' designations.

Mechanical stretching augments basal release of enteric 5HT, such as that caused by food and by efferent vagal stimulation. Released 5HT enters the portal vein and is metabolized by hepatic MAO-A. 5HT that survives hepatic oxidation may be captured by platelets or rapidly removed by the endothelium of lung capillaries and inactivated. 5HT released from enterochromaffin cells also acts locally to regulate GI function. $5HT_3$ receptors in the GI tract and the vomiting center of the CNS participate in the emetic response, providing a basis for the antiemetic property of $5HT_3$ receptor antagonists (see Figure 54–5 and Table 54–6). $5HT_3$ receptor antagonists are highly efficacious in the treatment of nausea, with *ondansetron* being the most widely used as an antiemetic. The $5HT_3$ receptor antagonist *alosetron* is approved for the treatment of inflammatory bowel syndrome in women whose main symptom is diarrhea.

Inflammation

In inflammation-related disease, 5HT exerts a proinflammatory influence primarily via activation of $5HT_{2A}$ receptors. Activation of this receptor subtype contributes to maturation of T cells, recruitment of other types of immune-related cells to sites of inflammation, and secretion of proinflammatory molecules. Although 5HT itself is proinflammatory, activation of $5HT_{2A}$ receptors with certain psychedelics can have potent

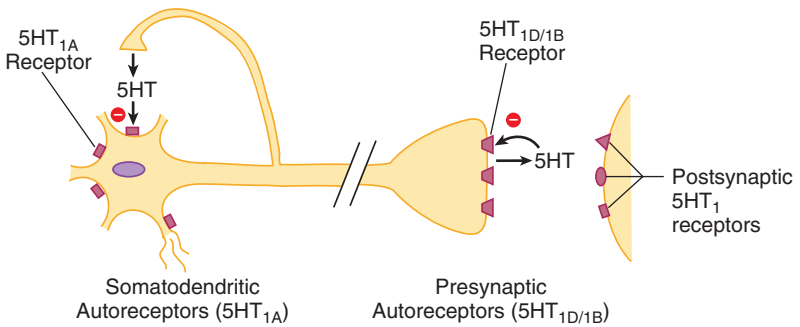

Figure 15–5 *Two classes of 5HT autoreceptors with differential localizations.* Somatodendritic $5HT_{1A}$ autoreceptors decrease raphe cell firing when activated by 5HT released from axon collaterals of the same or adjacent neurons. The receptor subtype of the presynaptic autoreceptor on axon terminals in the forebrain has different pharmacological properties and has been classified as $5HT_{1D}$ (in humans) or $5HT_{1B}$ (in rodents). This receptor modulates the release of 5HT. Postsynaptic $5HT_1$ receptors are also indicated.

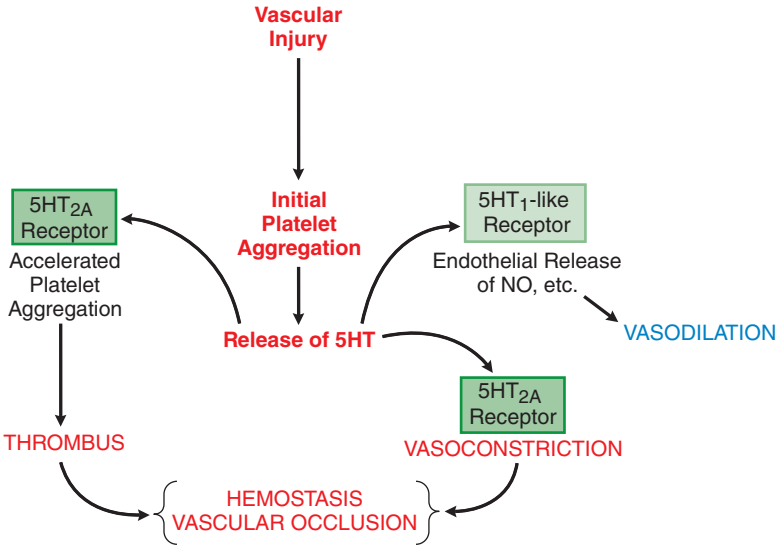

Figure 15–6 *The local influences of platelet 5HT.* The release of 5HT stored in platelets is triggered by aggregation. The local actions of 5HT include feedback actions on platelets (shape change and accelerated aggregation) mediated by interaction with platelet $5HT_{2A}$ receptors, stimulation of NO production mediated by $5HT_1$-like receptors on vascular endothelium, and contraction of vascular smooth muscle mediated by $5HT_{2A}$ receptors. These influences act in concert with many other mediators to promote thrombus formation and hemostasis. See Chapter 36 for details of adhesion and aggregation of platelets and factors contributing to thrombus formation and blood clotting.

anti-inflammatory effects in animal models of human disease (Flanagan and Nichols, 2018).

CNS

All 5HT receptor subtypes are expressed in the brain, where 5HT influences a multitude of functions, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. The principal cell bodies of 5HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord (see Figure 15–3). In addition to release at discrete synapses, serotonin release also occurs at sites of axonal varicosities that do not form distinct synaptic contacts. 5HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets, perhaps acting as a neuromodulator as well as a neurotransmitter (see Chapter 16).

Sleep-Wake Cycle

Control of the sleep-wake cycle is one of the first behaviors in which a role for 5HT was identified. Depletion of 5HT with *p*-chlorophenylalanine, a tryptophan hydroxylase inhibitor, elicits insomnia that is reversed by the 5HT precursor, 5-hydroxytryptophan. Conversely, treatment with L-tryptophan or with nonselective 5HT agonists accelerates sleep onset and prolongs total sleep time. 5HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep following administration of a selective $5HT_{2A/2C}$ receptor antagonist such as *ritanserin*. Selective $5HT_{2A}$ receptor antagonists like *pimavanserin* were found to have positive effects on sleep consolidation in late-stage clinical trials but have not been further developed for this indication.

TABLE 15–2 ■ ACTIONS OF 5HT IN ACT

SITE	RESPONSE	RECEPTOR
Enterochromaffin cells	Release of 5HT Inhibition of 5HT release	$5HT_3$ $5HT_4$

Aggression and Impulsivity

Serotonin serves a critical role in aggression and impulsivity. Human studies reveal a correlation between low CSF 5-HIAA and violent impulsivity and aggression. A human genetic study identified a point mutation in the gene encoding MAO-A that was associated with extreme aggressiveness and mental impairment (Brunner et al., 1993); this has been confirmed in knockout mice lacking MAO-A (Cases et al., 1995). Pharmacological activation of $5HT_{1A}$ or $5HT_{1B}$ receptors has been demonstrated to have antiaggressive effects, and gene knockout of the $5HT_{1B}$ receptor results in enhanced aggression (Olivier and van Oorschot, 2005). Several serotonin receptors have been implicated in impulsivity, including $5HT_{1A}$, $5HT_{1B}$, and $5HT_{2C}$.

Appetite and Obesity

Lorcaserin is a preferential $5HT_{2C}$ receptor agonist that was approved for weight loss; however, it is no longer on the U.S. market due to the FDA's concerns over an increased risk of certain cancers. The drug is thought to decrease food consumption and promote satiety by activating $5HT_{2C}$ receptors on anorexigenic proopiomelanocortin neurons in the arcuate nucleus of the hypothalamus. Halogenated amphetamines, which are known to promote the release of 5HT and block its reuptake, are valuable experimental tools; two of them, *fenfluramine* and *dexfenfluramine*, were used clinically to reduce appetite. The once-popular diet drug regimen, "fen-phen," combined *fenfluramine* and *phentermine*. *Fenfluramine* and *dexfenfluramine* were withdrawn from the U.S. market in the late 1990s after reports of life-threatening heart valve disease and pulmonary hypertension associated with their use. This toxicity was the result of $5HT_{2B}$ receptor activation promoting hyperproliferation of cells within the heart valves (Hutcheson et al., 2011). Subsequent to this finding, other drugs

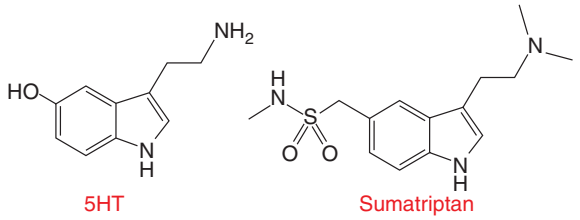
(e.g., some ergot alkaloids) with demonstrated agonist activity at the $5HT_{2B}$ receptor have been withdrawn from the market.

Drugs Affecting 5HT Signaling

Direct-acting 5HT receptor agonists have widely different chemical structures and diverse pharmacological properties and are used in the pharmacotherapy of a number of disorders (Table 15–3), including anxiety, depression, nausea, disorders of GI motility, and migraine. 5HT is a key mediator in the pathogenesis of migraine. Consistent with the 5HT hypothesis of migraine, 5HT receptor agonists are a mainstay for acute treatment of migraine headaches, although the newer calcitonin gene-related peptide (CGRP) antagonist class of drug is quite effective in the treatment of migraine. The efficacy of serotonergic antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors.

$5HT_{1B/1D}$ Receptor Agonists: The Triptans

The triptans are indole derivatives that are effective, acute antimigraine agents. Their capacity to decrease nausea and vomiting of migraine is an important advance in the treatment of this condition. Some examples include *almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan*, and *zolmitriptan*. *Sumatriptan* for migraine headaches is also marketed in a fixed-dose combination with the nonsteroidal anti-inflammatory drug (NSAID) *naproxen*. The triptans are effective in the acute treatment of migraine (with or without aura) but are not intended for use in prophylaxis of migraine. Treatment with triptans should begin as soon as possible after the onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use, but they may not be practical in patients experiencing migraine-associated nausea and vomiting.



Migraine

Migraine headache afflicts 10% to 20% of the population. Although migraine is a specific neurological syndrome, the manifestations vary widely. The principal types are migraine without aura (common migraine), migraine with aura (classic migraine, which includes subclasses of migraine with typical aura, migraine with prolonged aura, migraine aura without headache, and migraine with acute-onset aura), and several rarer types. Premonitory aura may begin as long as 24 h before the onset of pain and often is accompanied by photophobia, hyperacusis, polyuria, and diarrhea and by disturbances of mood and appetite. A migraine attack may last for hours or days and be followed by prolonged pain-free intervals. The frequency of migraine attacks is extremely variable. Therapy of migraine headaches is complicated by the variable responses among and within individual patients and by the lack of a firm understanding of the pathophysiology of the syndrome. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and possibly undefined environmental and genetic factors.

The pathogenesis of migraine headache is complex, involving both neural and vascular elements. Evidence suggesting that 5HT is a key mediator in the pathogenesis of migraine includes the following:

- Plasma and platelet concentrations of 5HT vary with the different phases of the migraine attack.
- Urinary concentrations of 5HT and its metabolites are elevated during most migraine attacks.
- Migraine may be precipitated by agents (e.g., *reserpine* and *fenfluramine*) that release 5HT from intracellular storage sites.

Consistent with the 5HT hypothesis, 5HT receptor agonists have become a mainstay for *acute* treatment of migraine headaches. Treatments for the *prevention* of migraines, such as β adrenergic antagonists and newer antiepileptic drugs, have mechanisms of action that are, presumably, unrelated to 5HT (Mehrotra et al., 2008).

Mechanism of Action

The pharmacological effects of the triptans appear to be limited to the $5HT_1$ family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans interact potently with $5HT_{1B}$ and $5HT_{1D}$ receptors and have low or no affinity for other subtypes of 5HT receptors or for α_1 and α_2 adrenergic, β adrenergic, dopaminergic, muscarinic cholinergic, and benzodiazepine receptors. Clinically effective doses of the triptans correlate well with their affinities for both $5HT_{1B}$ and $5HT_{1D}$ receptors, supporting the hypothesis that $5HT_{1B}$ and $5HT_{1D}$ receptors are the most likely receptors involved in the mechanism of action of acute antimigraine drugs.

The mechanism of the efficacy of $5HT_{1B/1D}$ agonists in migraine is not resolved. One hypothesis of migraine suggests that unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head and shunting of carotid arterial blood flow, producing cerebral ischemia and hypoxia perceived as migraine pain; activation of $5HT_{1B/1D}$ receptors may cause constriction of intracranial blood vessels, including arteriovenous anastomoses, closing the shunts and restoring blood flow to the brain. An alternative hypothesis proposes that both $5HT_{1B}$ and $5HT_{1D}$ receptors serve as presynaptic autoreceptors that block the release of neurotransmitter or proinflammatory neuropeptides at nerve terminals in the perivascular space, which could account for the efficacy of agonists at those receptors in the acute treatment of migraine. Successful treatment of migraine with *sumatriptan* was shown to correlate with lower blood

TABLE 15–3 ■ EXAMPLES OF SEROTONERGIC DRUGS: PRIMARY ACTIONS AND CLINICAL INDICATIONS

RECEPTOR	ACTION	DRUG EXAMPLES	CLINICAL DISORDER
$5HT_{1A}$	Partial agonist	Buspirone, ipsaperone	Anxiety, depression
$5HT_{1D}$	Agonist	Sumatriptan	Migraine
$5HT_{2A/2C}$	Antagonist	Risperidone	Schizophrenia, depression
$5HT_{2A/2C}$	Agonist	Psilocybin	Depression
$5HT_3$	Antagonist	Ondansetron	Chemotherapy-induced emesis
$5HT_4$	Agonist	Tegaserod, cisapride	GI disorders
SERT (5HT transporter)	Inhibitor	Fluoxetine, sertraline	Depression, obsessive-compulsive disorder, panic disorder, social phobia, posttraumatic stress disorder

levels of a CGRP, a potent vasodilatory and proinflammatory neuropeptide. Along these lines, a new class of migraine drugs has been developed that blocks signaling by CGRP. These include the small-molecule CGRP receptor antagonist drug *rimegepant*, and the CGRP-blocking monoclonal antibodies *erenumab*, *fremanezumab*, and *galcanezumab*.

Clinical Use

The triptans are effective in the acute treatment of migraine (with or without aura) but are not intended for prophylaxis of migraine. Treatment with triptans should begin as soon as possible after the onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use but may not be practical in patients experiencing migraine-associated nausea and vomiting, for whom injectable and nasal spray formulations are useful. Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of *sumatriptan*, a dose that may be repeated once within a 24-h period if the first dose does not relieve the headache. The other triptans have distinct dosing requirements as summarized on their FDA-approved package inserts. A recent meta-analysis concluded that *eletriptan* is the most likely triptan to produce a favorable outcome at the 2-h and 24-h time points after administration (Thorlund et al., 2014). No triptan should be used concurrently with (or within 24 h of) an ergot derivative (described in the next section) or another triptan.

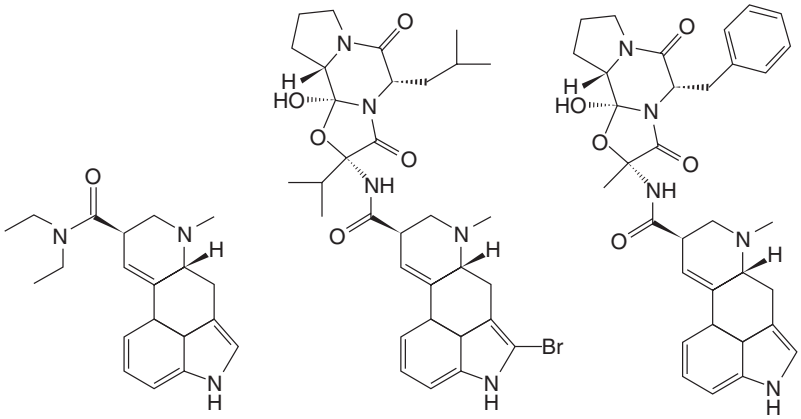
Adverse Effects and Contraindications

In general, only minor side effects are seen with the triptans in the acute treatment of migraine. After subcutaneous injection of *sumatriptan*, patients often experience irritation at the site of injection (transient mild pain, stinging, or burning sensations). The most common side effect of *sumatriptan* nasal spray is a bitter taste. Triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating. In the extreme, these agents can cause serotonin syndrome, a consequence of a generalized excess of 5HT receptor stimulation, especially when used in combination with SSRIs, SNRIs, TCAs, and MAO inhibitors.

Rare but serious cardiac events have been associated with the administration of triptans, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. The triptans are contraindicated in patients with a history of ischemic or vasospastic coronary artery disease (including history of stroke or transient ischemic attacks), cerebrovascular or peripheral vascular disease, hemiplegic or basilar migraines, other significant cardiovascular diseases, or ischemic bowel diseases. Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. *Lasmiditan*, a nontriptan $5HT_{1F}$ receptor–selective agonist, has been approved for the treatment of migraine and has fewer adverse cardiovascular effects associated with its use than the $5HT_{1B/D}$ activating triptans and is particularly indicated in patients with preexisting cardiovascular risk factors. *Naratriptan* is contraindicated in patients with severe renal or hepatic impairment; *rizatriptan* should be used with caution in such patients. *Eletriptan* is contraindicated in hepatic disease. *Almotriptan, rizatriptan, sumatriptan*, and *zolmitriptan* are contraindicated in patients who have taken an MAO inhibitor within the preceding 2 weeks, and all triptans are contraindicated in patients with near-term prior exposure to ergot alkaloids, other triptans or 5HT agonists, SSRIs, and SNRIs. With respect to the use of triptans in pregnancy, there are no adequate and well-controlled studies in pregnant women. The FDA recommends the use of triptans during pregnancy only if the potential benefit justifies a potential risk to the fetus; evidence of safety in pregnancy is best with *sumatriptan*. These agents should also be used with caution in nursing mothers. Källén and Reis (2016) have reviewed drugs for managing pain, including migraine, during pregnancy.

The Ergot Alkaloids

Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The elucidation of the constituents of ergot and their complex actions was an important chapter in the evolution of modern pharmacology, even though the multiplicity of their actions limits their therapeutic uses. The pharmacological effects of the ergot alkaloids result from their actions as partial agonists or antagonists at serotonergic, dopaminergic, and adrenergic receptors. Ergot alkaloids can be subdivided into smaller molecular weight ergolines, such as *d-lysergic acid diethylamide* (LSD), a potent psychedelic, and larger molecular weight ergots that incorporate a cyclic peptide moiety, such as *bromocriptine*, which is used to control the secretion of prolactin, a property derived from its effect as a DA agonist. Other ergot alkaloids employed therapeutically include *methysergide* and *ergonovine* (and *methyl ergonovine*), which were historically used to treat migraine and postpartum hemorrhage, respectively.

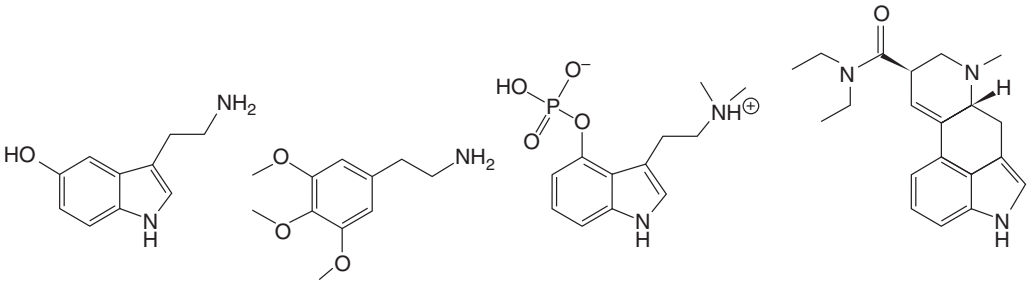


Ergots in the Treatment of Migraine

The multiple pharmacological effects of ergot alkaloids have complicated the determination of their precise mechanism of action in the acute treatment of migraine. The actions of ergot alkaloids at $5HT_{1B/1D}$ receptors likely mediate their *acute* antimigraine effects, and potentially at $5HT_{2A}$ receptors to mediate prophylactic effects. Due to their numerous adverse side effects including pleuropulmonary fibrosis and coronary and endocardial fibrosis, ergots such as *dihydroergotamine* and *methysergide* are no longer prescribed frequently and their use has for the most part been supplanted by triptans. The European Medicines Agency has recommended that ergot derivatives no longer be used to treat migraine. Ergot alkaloids with demonstrated agonist activity at the $5HT_{2B}$ receptor resulting in cardiac valvopathy have been withdrawn from the market.

Psychedelics

Psychedelics are a class of hallucinogenic drugs whose primary effects are mediated by activation of $5HT_{2A}$ receptors. Although able to elicit somewhat similar behavioral effects, other hallucinogens like 3,4-Methyl enedioxy methamphetamine (MDMA), ketamine, phencyclidine (PCP), and cannabinoids are not pharmacologically considered psychedelics. Classic psychedelics include those that occur naturally in nature and fall into three structurally distinct superfluous families: phenethylamine (e.g., *mescaline*), tryptamine (e.g., *psilocybin*), and ergot alkaloid derivatives (e.g., LSD). Novel psychedelics include synthetic derivatives of the classic psychedelics such as 2C-B and 4-OH-DIPT. Some are highly selective for the $5HT_2$ receptor family (e.g., 2,5-dimethoxy-4-iodoamphetamine; DOI), whereas others have affinity and activity at nearly all serotonin receptors (e.g., *psilocin*), and dopamine and adrenergic receptors as well (e.g., LSD). The shared effects of psychedelics, which have been shown in both animal models and humans to be mediated by activation of $5HT_{2A}$ receptors, include profound sensory alterations and detachment from reality. One of the most potent psychedelics, LSD, is behaviorally active at doses as low as 25 μg in humans. Although ignored and little researched due to restrictive controlled substance scheduling and societal misperceptions for 30 years, psychedelics have recently shown promise in several areas as new therapeutics. Clinical trials using primarily *psilocybin*, but also others such as LSD, have shown promise in the treatment of depression, anxiety, substance use disorder, obsessive-compulsive disorder, and migraines (Bogenschutz et al., 2018; Davis et al., 2021; Moreno et al., 2006; Reiff et al., 2020; Schindler et al., 2021). Remarkably, these trials have shown that only a single treatment can have persistent effects lasting months to years. The physiological mechanisms underlying these effects are currently unknown but may involve increases in synaptic connectivity (Jones et al., 2009; Ly et al., 2018; Shao et al., 2021). Preclinical studies of psychedelics in animal models have also shown promise for treating inflammation-related disorders such as asthma and ocular and cardiovascular disease, with effects mediated through activation of $5HT_{2A}$ receptors (Flanagan and Nichols, 2018).



Serotonin Receptor Agonists, Inverse Agonists, SSRIs, and MSAAs

Anxiolytic and Antidepressant Agents

Buspirone, *gepirone*, and *ipsapirone* are selective partial agonists at $5HT_{1A}$ receptors. *Buspirone* has been effective in the treatment of anxiety (see Chapter 18). *Buspirone* mimics the antianxiety properties of benzodiazepines but does not interact with $GABA_A$ receptors or display the sedative and anticonvulsant properties of benzodiazepines. The effects of 5HT-active drugs in anxiety and depressive disorders, like the effects of SSRIs, strongly suggest a role for 5HT in the neurochemical mediation of these disorders. Inhibition of neuronal reuptake of 5HT via the 5HT transporter prolongs the dwell time of 5HT in the synapse. SSRIs, such as *citalopram*, potentiate and prolong the action of 5HT released by neuronal activity. When coadministered with L-5-hydroxytryptophan, SSRIs elicit profound activation of serotonergic responses. However, the capacity to enhance serotonergic neurotransmission alone does not explain the antidepressant effectiveness: Uptake inhibition occurs immediately, whereas weeks of treatment are required to achieve clinical efficacy. This has led to the proposal that long-term homeostatic adaptations in brain function underlie the therapeutic effects of this class of antidepressants. SSRIs (*citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine*, and *sertraline*) are the most widely used treatment of major depressive disorder (see Chapter 18).

Vilazodone is an SSRI and a partial agonist at the $5HT_{1A}$ receptor, which has a faster time of therapeutic onset than traditional SSRIs due to direct activation of $5HT_{1A}$ receptors.

Viloxazine is a medication that is used in the treatment of attention-deficit/hyperactivity disorder (ADHD) in children and depression. It was marketed for more than two decades as an antidepressant in Europe before being repurposed as a treatment for ADHD and recently launched in the United States. While its mechanism of action was originally thought to be blockade of NET, more recently, it has been determined to act as an antagonist of the $5HT_{2B}$ receptor and as an agonist of the $5HT_{2C}$ receptor, actions that may be involved in its therapeutic effects.

5HT and Sexual Dysfunction

One of the most common side effects of SSRIs and SNRIs is sexual dysfunction, such as anorgasmia, erectile dysfunction, diminished libido, and sexual anhedonia. Poor sexual function is one of the most common reasons that patients discontinue taking these medications. The mechanism by which SSRIs/SNRIs cause sexual side effects is not well understood. In contrast, the serotonergic drug *flibanserin*, which is an agonist of cortical $5HT_{1A}$ receptors and an antagonist of $5HT_{2A}$ receptors, is approved to treat hypoactive sexual desire disorder (HSDD) in premenopausal women. This disorder is also referred to as female sexual interest/arousal disorder. Clinical trials showed that *flibanserin* can increase the number of satisfying sexual events in some, but not all, women with this disorder by about one episode compared to placebo during the trial duration (Fisher et al., 2017). Administration of *flibanserin* leads to decreases of 5HT levels in the cortex and increases in DA and NE. This redistribution of monoamine levels has been speculated to be the mechanism of the observed response of increased sexual function.

Psychosis

Recently, *pimavanserin* has been introduced to treat hallucinations and delusions associated with psychosis experienced by some people with Parkinson's disease (PD). This drug is a potent and selective inverse agonist at $5HT_{2A}$ with 40-fold selectivity over $5HT_{2C}$ receptors and no appreciable affinity for the $5HT_{2B}$ or other monoaminergic receptors. Typically, patients with PD cannot tolerate other antipsychotics on the market because this drug class functions through blocking dopamine receptors, which results in a worsening of the motor symptoms of this disease. The efficacy of *pimavanserin* in treating psychosis observed in other disease states, such as schizophrenia, has not yet been determined.

Clinical Manipulation of 5HT Levels: Serotonin Syndrome

Excessive elevation of 5HT levels in the body can cause *serotonin syndrome*, a constellation of symptoms sometimes observed in patients

starting new or increased antidepressant therapy or combining an SSRI with an NE reuptake inhibitor or a triptan (for migraine). Serotonin syndrome is largely mediated by activation of $5HT_{2A}$ and $5HT_{1A}$ receptors, and symptoms may include restlessness, confusion, shivering, tachycardia, diarrhea, muscle twitches/rigidity, fever, seizures, loss of consciousness, and even death. Serotonin syndrome and its treatment are discussed in Chapter 18.

Dopamine

Dopamine consists of a catechol moiety linked to an ethyl amine, leading to its classification as a catecholamine (Figure 15–7). DA is a polar molecule that does not readily cross the BBB. It is closely related to melanin, a pigment that is formed by oxidation of DA, tyrosine, or 3,4-dihydroxyphenylalanine (L-DOPA). Melanin exists in the skin and cuticle and gives the substantia nigra brain region its namesake dark color. Both DA and L-DOPA are readily oxidized by nonenzymatic pathways to form cytotoxic reactive oxygen species and quinones. DA- and dopa-quinones form adducts with α-synuclein, a major constituent of Lewy bodies in PD (see Chapter 21).

HISTORICAL PERSPECTIVE

Dopamine was first synthesized in 1910. Later that year, Henry Dale characterized the biological properties of DA in the periphery and described it as a weak, adrenaline-like substance. In the 1930s, DA was recognized as a transitional compound in the synthesis of NE and EPI but was believed to be little more than a biosynthetic intermediate. Not until the early 1950s were stores of DA identified in tissues, suggesting that DA had a signaling function of its own. Soon thereafter, Oleh Hornykiewicz discovered the DA deficit in parkinsonian brains, fueling interest in the role of DA in neurological diseases and disorders (Hornykiewicz, 2010).

Synthesis and Metabolism

The biosynthesis and metabolism of DA are summarized in Figure 15–8. Phenylalanine and tyrosine are the precursors of DA. For the most part, mammals convert dietary phenylalanine to tyrosine by phenylalanine hydroxylase. Diminished levels of phenylalanine hydroxylase lead to high levels of phenylalanine, producing a condition known as phenylketonuria, which must be controlled by dietary restrictions to avoid intellectual impairment. Tyrosine crosses readily into the brain through uptake; normal brain levels of tyrosine are typically saturating. Conversion of tyrosine to L-DOPA by the tyrosine hydroxylase is the rate-limiting step in the synthesis of DA (as in NE synthesis; see Chapter 10). Once generated, L-DOPA is rapidly converted to DA by AADC, the same enzyme that generates 5HT from L-5-hydroxytryptophan. Unlike DA, L-DOPA readily crosses the BBB and is converted to DA in the brain, which explains its utility in therapy for PD (see Chapter 21).

Metabolism of DA occurs primarily by MAO in both pre- and postsynaptic elements. MAO acts on DA to generate an inactive aldehyde derivative by oxidative deamination; the aldehyde is subsequently metabolized by aldehyde dehydrogenase to form 3,4-dihydroxyphenylacetic acid (DOPAC). DOPAC can be further metabolized by catechol-*O*-methyl transferase (COMT) to form homovanillic acid (HVA). In humans, HVA is the principal metabolite of DA. DOPAC, HVA, and DA are excreted in the urine, where they are readily

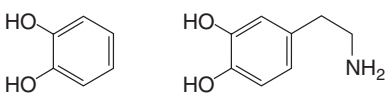


Figure 15–7 *The catechol nucleus of catecholamines.*

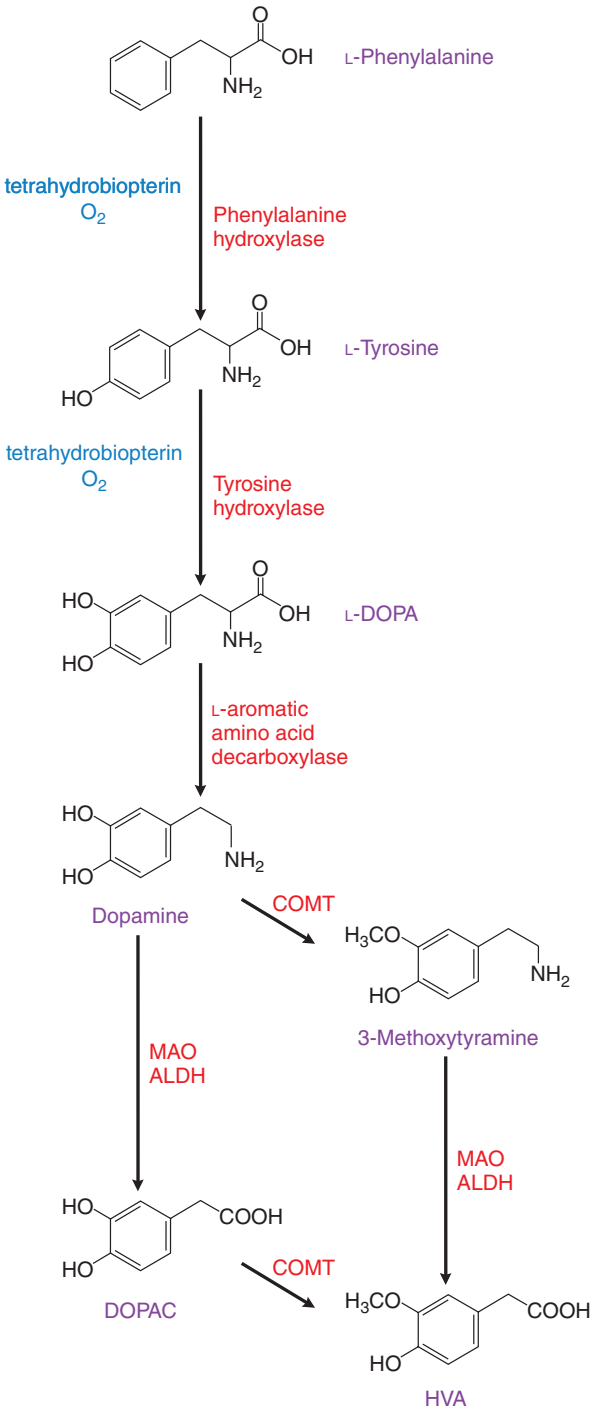

Figure 15–8 *Synthesis and inactivation of DA.* Enzymes are identified in red lettering, and cofactors are shown in blue letters.

measured. Levels of DOPAC and HVA are reliable indicators of DA turnover; ratios of these metabolites to DA in CSF serve as accurate representations of brain dopaminergic activity. In addition to metabolizing DOPAC, COMT acts on DA to generate 3-methoxytyramine, which is subsequently converted to HVA by MAO. MAO-B–selective inhibitors, such as *selegiline*, *rasagiline*, or *safinamide*, can increase DA levels and are currently used to treat PD (see Chapter 21). COMT in the periphery also metabolizes L-DOPA to 3-*O*-methyldopa, which then competes with L-DOPA for uptake into the CNS (see Figure 21–4). Consequently, L-DOPA given in the treatment of PD must be coadministered with peripheral COMT inhibitors, such as *entacapone*, *tolcapone*, or *opicapone*, to preserve L-DOPA and allow sufficient entry into the CNS.

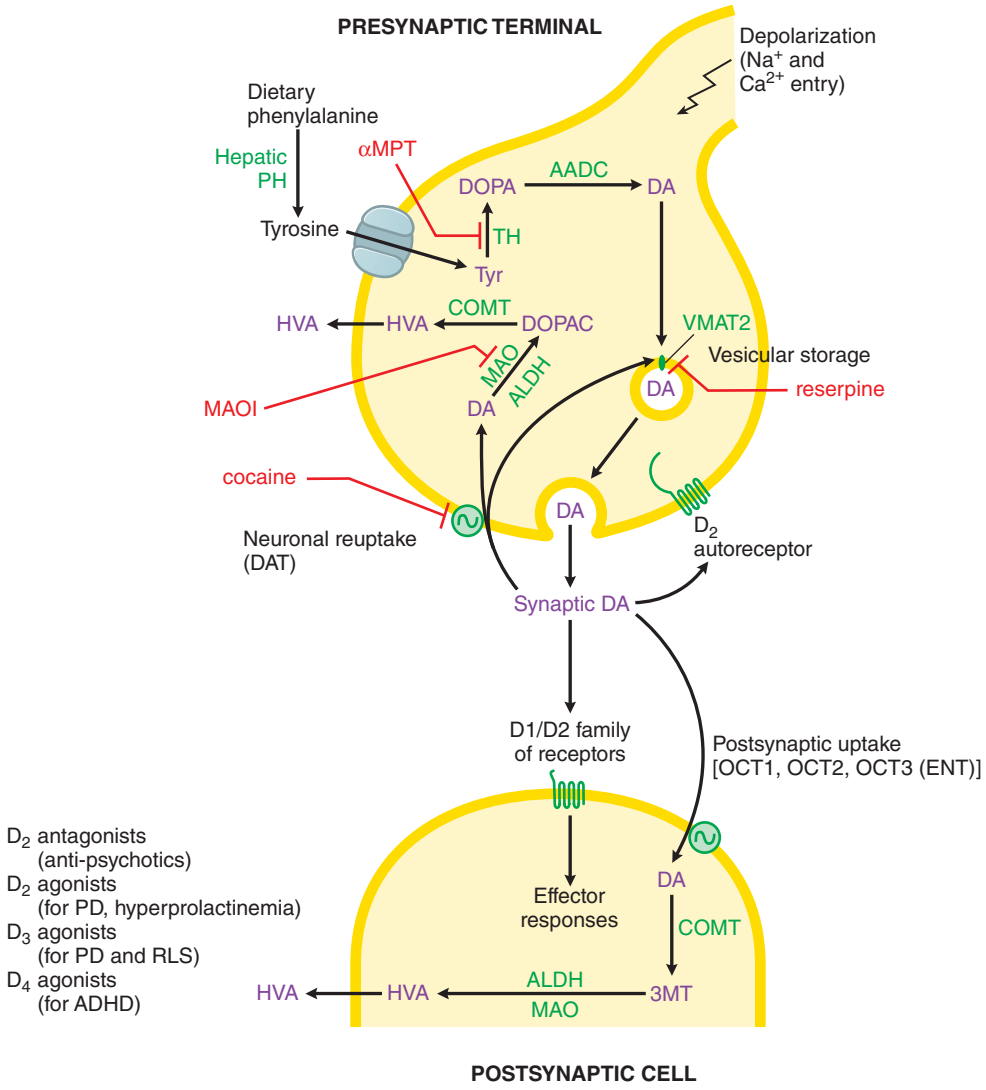

Figure 15–9 *A dopaminergic synapse.* DA is synthesized from tyrosine in the nerve terminal by the sequential actions of TH and AADC. DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D_1-like and D_2-like receptors. Synaptic DA may be taken up into the neuron via the DA transporter (DAT) or removed by postsynaptic uptake via an organic cation transporter (OCT). Cytosolic DA is subject to degradation by MAO/ALDH in the neuron and by COMT in nonneuronal cells; the final metabolic product is HVA. See structures in Figure 15–8. ALDH, aldehyde dehydrogenase; MAOI, monoamine oxidase inhibitor; αMPT, α-methylphenyltyrosine; TH, tyrosine hydroxylase.

Figure 15–9 summarizes the neurochemical events that underlie DA neurotransmission. In dopaminergic neurons, synthesized DA is packaged into secretory vesicles by the vesicular monoamine transporter (VMAT2). Drugs such as *reserpine*, which inhibit VMATs and deplete DA levels, were once used to treat psychosis. Recently, a VMAT2-selective inhibitor, *valbenazine*, has been introduced for the treatment of tardive dyskinesia, a neurological disorder characterized by involuntary movements. Although the exact cause tardive dyskinesia is unknown, it is hypothesized to be due to DA hypersensitivity, and valbenazine causes a reversible reduction in DA release. Notably, the presynaptic vesicular packaging of DA allows it to be stored in readily releasable quanta and protects the transmitter from further anabolism or catabolism. By contrast, in adrenergic and noradrenergic cells, DA is not packaged; instead, it is converted to NE by DA β-hydroxylase and, in adrenergic cells, methylated to epinephrine (EPI) in cells expressing phenylethanolamine *N*-methyltransferase (see Chapter 10).

Synaptically released DA activates postsynaptic receptor subtypes, the expression of which is cell specific, leading to signal transduction via G protein-mediated pathways, although in some cases, G protein-independent signaling occurs (see further discussion). DA receptor subtypes are also the targets of many therapeutically employed drugs and pharmacological tool compounds. Specific receptor subtypes of the D_2-like category can also be expressed on the presynaptic nerve terminal, where they regulate the release of DA, or on the cell bodies and dendrites, where they regulate DA synthesis. Reuptake of released DA by the DA transporter is the primary mechanism for termination of DA action and allows for either vesicular repackaging of transmitter or metabolism.

The DA transporter, DAT, localizes to dendrites, axons, and soma of mesencephalic DA neurons and is also found peripherally in the stomach, pancreas, and lymphocytes. Psychostimulants, such as *cocaine*, *amphetamine*, and *methamphetamine*, induce euphoria and hyperactivity by increasing extracellular DA. *Cocaine* is not a substrate of the DAT but rather acts as an antagonist to block DA reuptake, thereby potentiating DA signaling. However, the actions of *amphetamines* are more complex: *Amphetamines* are competitive substrates for both the DATs and the VMATs. *Amphetamines* enter the cell through the DAT, where they displace DA from vesicular stores, causing an accumulation of DA within the neuronal cytoplasm. This resulting increase in cytosolic DA drives the release of DA by a nonvesicular mechanism that involves efflux through the DAT (Sitte et al., 2015). Newer studies also support the idea that *amphetamines* also target the trace amine-associated receptor 1 (TAAR1), an intracellular receptor within DA neurons, to activate

cellular signaling pathways. *Amphetamines* activate G_s-dependent pathways coupled to increases in cyclic AMP and G_{13}-dependent pathways coupled to the activation of the small GTPase, RhoA (Underhill et al., 2021). Agonists for TAAR1 include *amphetamines*, DA, trace amines, and a variety of drugs. TAAR1 has been proposed to mediate some of the actions of *amphetamines* (Gainetdinov et al., 2018).

The DA transporter can also serve as a molecular entryway for some neurotoxins, including 6-OHDA (6-hydroxydopamine) and MPP^+ (1-methyl-4-phenylpyridinium), the neurotoxic metabolite of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). Following uptake into dopaminergic neurons, MPP^+ and 6-OHDA facilitate intra- and extracellular DA release and generate reactive oxygen species such as superoxide radicals (O_2^-) that cause neuronal death. This selective dopaminergic degeneration mimics PD and serves as an animal model for this disorder.

Dopamine Receptors

Early investigations found that DA increases cyclic AMP levels in both the brain and retina, presumably by activating a DA-sensitive adenylyl cyclase. Subsequent studies revealed the existence of DA receptors not linked to adenylyl cyclase activation, thus implying the existence of multiple DA receptor subtypes. It was then hypothesized that there were D_1 and D_2 receptors that could be distinguished on the basis of their pharmacological properties and signaling mechanisms. Subsequent molecular biological studies identified not only genes corresponding to the originally defined D_1 and D_2 receptor subtypes but also genes for additional DA receptors. We now recognize that there are five distinct DA receptors in mammals that are members of the GPCR superfamily and categorized into two D_1-like and D_2-like subfamilies (Sibley and Monsma, 1992). The D_1-like subfamily consists of the D_1 and D_5 receptors, whereas the D_2, D_3, and D_4 subtypes compose the D_2-like subfamily. Receptors in the D_1-like subfamily (D_1 and D_5) couple to heterotrimeric G_s or G_{olf} proteins to stimulate the adenylyl cyclase–cyclic AMP–protein kinase A (PKA) pathway. In contrast, the D_2-like receptors (D_2, D_3, and D_4) couple to G_i, G_o, or G_z proteins to inhibit adenylyl cyclase and diminish cyclic AMP production (Figure 15–10). Activation of $G_{i/o/z}$ proteins can also directly modulate the activity of certain K^+ and Ca^{2+} channels.

It is now recognized that GPCRs can signal independently from G proteins via interactions with β-arrestin proteins (Shukla et al., 2011). Agonist-activated GPCRs typically recruit β-arrestins to their intracellular surface as part of a homeostatic mechanism that turns off G protein-mediated signaling and facilitates receptor internalization. However, the GPCR-β-arrestin dimer can serve as a signaling complex that leads to the activation of downstream protein kinase–mediated signaling pathways. Among DA receptors, this process has been best described for the D_2 receptor subtype. When the agonist-activated D_2 receptor binds β-arrestin, two other proteins are recruited to this complex, namely protein phosphatase 2A (PP2A) and protein kinase B (also known as Akt). As a result, Akt is dephosphorylated and inactivated by PP2A. Since Akt constitutively phosphorylates and inhibits glycogen synthase kinase 3β (GSK-3β), D_2 receptor activation ultimately results in increased GSK-3β–mediated signaling (see Figure 15–10), which is thought to play a role in the actions of antipsychotics and mood stabilizers (Urs et al., 2012).

Pharmacological agents targeting DA receptors are used in the treatment of numerous neuropsychiatric disorders, including PD, schizophrenia, bipolar disorder, Huntington's disease, ADHD, and Tourette's syndrome. Like many GPCRs, DA receptors may form homo- and hetero-oligomers and also oligomerize with other GPCRs as well as ligand-gated ion channels (Fuxe et al., 2015). Notably, the D_2 and A_{2A} adenosine receptors form heteromers, and this complex provides a drug target for the treatment of PD (Chen and Cunha, 2020). Within a heteromeric complex, the D_2 and A_{2A} adenosine receptors mutually inhibit each other's signaling through allosteric mechanisms. However, the A_{2A} adenosine receptor antagonist *istradefylline* can enhance D_2 receptor signaling through blocking D_2 receptor inhibition by the A_{2A} receptor. *Istradefylline* has recently been approved as adjunctive therapy with L-DOPA for the treatment of PD (see Chapter 21). For further information on DA receptor signaling, see Beaulieu and Gainetdinov (2011) and Beaulieu et al. (2015).

The D_1 Receptor

- The D_1 receptor is the most highly expressed of the DA receptors; the highest levels of D_1 receptor protein are found within the CNS, but it is also located in the kidney, retina, and cardiovascular system.
- The neostriatum expresses the highest levels of D_1 receptor in the CNS but does not express any detectable G_s. In this region, the D_1 receptor appears to couple to G_{olf} to increase levels of cyclic AMP and its downstream effectors. In contrast, the D_1 receptor couples to G_s in the cerebral cortex to regulate cognition.
- In addition to activating G proteins, the D_1 receptor can form hetero-oligomers with ionotropic *N*-methyl-D-aspartate (NMDA) glutamate receptors (see Chapter 16) to modulate glutamatergic signaling.

The D_2 Receptor

- The D_2 receptor is the second most highly expressed DA receptor and consists of short (D_{2S}) and long (D_{2L}) isoforms that arise from alternative messenger RNA splicing. The D_{2S} isoform is missing 29 amino acids in the third intracellular loop that are present in the D_{2L} variant.
- The D_{2S} and D_{2L} receptors are pharmacologically identical; both couple to G_i, G_o, or G_z to decrease cyclic AMP production. The D_{2L} receptor is more prevalent and postulated to function postsynaptically. In contrast, the D_{2S} isoform functions as a putative presynaptic autoreceptor that regulates DA synthesis and release.

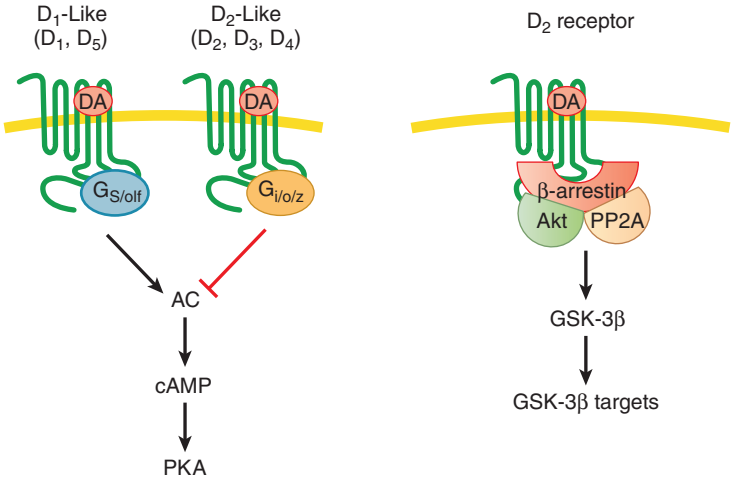

Figure 15–10 *The two subfamilies of DA receptors and their signaling pathways.* **Left:** D_1-like and D_2-like DA receptors differentially regulate G protein-mediated signaling pathways. **Right:** The D_2 receptor enhances GSK-3β signaling by recruiting β-arrestin and inactivating Akt. AC, adenylyl cyclase.

- The D_2 receptors can signal through $G_{\beta\gamma}$ subunits to regulate a variety of functions, including inwardly rectifying K^+ channels (GIRKs), N-type Ca^{2+} channels, and L-type Ca^{2+} channels.
- The D_2 receptor can signal through recruitment of the scaffolding protein, β-arrestin, thereby coupling to downstream signaling through the protein kinases B (Akt) and GSK-3β.

The D_3 Receptor

- The D_3 receptor is less abundant than the D_2 receptor and is mainly expressed in the limbic regions of the brain. The highest levels of the D_3 receptor are found in the islands of Calleja, nucleus accumbens, substantia nigra pars compacta, and ventral tegmental area.
- The D_3 receptor signals through pertussis toxin–sensitive $G_{i/o/z}$ proteins, although not as effectively as the D_2 receptor.
- The D_3 receptor may function as a drug target for the treatment of substance use disorders, particularly for those involving opioids (Galaj et al., 2020).

The D_4 Receptor

- The D_4 receptor is expressed in the retina, hypothalamus, prefrontal cortex (PFC), amygdala, and hippocampus.
- The D_4 receptor is highly polymorphic, containing variable number of tandem repeat (VNTR) encoding sequences within the third intracellular loop. In humans, the four-repeat variant is the most common. Association between a seven-repeat VNTR variant of the D_4 receptor and ADHD has been suggested.
- The D_4 receptor couples to $G_{i/o/z}$ to inhibit adenylyl cyclase activity and depress intracellular cyclic AMP levels.

The D_5 Receptor

- The D_5 receptor is the least abundant DA receptor but is found in the hippocampus, substantia nigra, hypothalamus, striatum, cerebral cortex, nucleus accumbens, and olfactory tubercle. It is also expressed in the kidney.
- The D_5 receptor activates G_s and G_{olf} to increase cyclic AMP production and can also modulate Na^+ currents and N-, P-, and L-type Ca^{2+} currents via PKA-dependent pathways. The D_5 receptor can also directly interact with $GABA_A$ receptors to decrease Cl^- flux.
- Along with the D_1 receptor, the D_5 receptor regulates neuronal circuitry controlling learning and memory.

The Dopamine Transporter

- DAT (SLC6A3) clears extracellular DA released during neurotransmission and is a major target for both therapeutic and addictive psychostimulant drugs.
- Like SERT, the DAT is a member of the NSS family (see Chapter 4, section on *Transporters and Pharmacodynamics: Drug Action in the Brain*), which couples neurotransmitter transport across the plasma membrane to the movement of Na^+ ions into the cell.
- The DAT has 12 membrane-spanning domains; a recent high-resolution X-ray structure of a *Drosophila* DAT has been determined (Penmatsa et al., 2015).
- The DAT protein is abundantly expressed in mesostriatal, mesolimbic, and mesocortical DA pathways, where it can be found on cell bodies, dendrites, and axons of DA neurons (Ciliax et al., 1999). However, the DAT is not readily detected within synapses, suggesting that rather than regulating synaptic neurotransmitter concentrations, it is poised to regulate spillover and diffusion of DA away from sites of release.
- The DAT is the therapeutic target of *methylphenidate* and *amphetamine*, the two major drugs used to treat attention-deficit disorders. The DAT inhibitor *bupropion* is used to treat depression and to support smoking cessation.

Actions of Dopamine in Physiological Systems

Heart and Vasculature

At low concentrations, circulating DA primarily stimulates vascular D_1 receptors (see below), causing vasodilation and reducing cardiac load. The net result is a decrease in blood pressure and an increase in cardiac contractility. As circulating DA concentrations rise, DA is able to activate β adrenergic receptors to further increase cardiac contractility. At very high concentrations, circulating DA activates α adrenergic receptors in the vasculature, thereby causing vasoconstriction; thus, high concentrations of DA increase blood pressure. Clinically, DA administration is used to treat severe congestive heart failure, sepsis, or cardiogenic shock. It is only administered intravenously and is not considered a long-term treatment.

Kidney

Dopamine is a paracrine/autocrine transmitter in the kidney and binds to receptors of both the D_1 and D_2 subfamilies. Renal DA primarily serves to increase natriuresis, although it can also increase renal blood flow and glomerular filtration. Under basal sodium conditions, DA regulates Na^+ excretion by inhibiting the activity of various Na^+ transporters, including the apical Na^+/H^+ exchanger and the basolateral Na^+/K^+-ATPase. Activation of D_1 receptors increases renin secretion, whereas DA, acting on D_3 receptors, reduces renin secretion. Abnormalities in the DA system and its receptors have been implicated in human hypertension.

Pituitary Gland

Dopamine is the primary regulator of prolactin secretion from the pituitary gland. DA released from the hypothalamus into the hypophyseal portal blood supply acts on lactotroph D_2 receptors to decrease prolactin secretion (see Chapter 46). The ergot-based DA agonists *bromocriptine* and *cabergoline* are used in the treatment of hyperprolactinemia. Both have a high affinity for D_2 receptors, with a lower affinity for D_1, 5HT, and adrenergic receptors; both activate D_2 receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease in ergot therapy is not associated with the lower doses used in treating hyperprolactinemia. The use of *bromocriptine* and *cabergoline* in the management of hyperprolactinemia is described in Chapter 46.

Catecholamine Release

Both D_1 and D_2 receptors modulate the release of NE and EPI. The D_2 receptor provides tonic inhibition of EPI release from chromaffin cells of the adrenal medulla and of NE release from sympathetic nerve terminals. In contrast, activation of the D_1 receptor promotes the release of catecholamines from the adrenal medulla.

CNS

There are three major groups of DA projections in the brain (Figure 15–11): mesocortico/mesolimbic (originating in the ventral tegmental area), nigrostriatal (originating in the substantia nigra pars compacta), and tuberoinfundibular (originating in the hypothalamus). The physiological processes under dopaminergic control include reward, emotion, cognition, memory, and motor activity. Dysregulation of the dopaminergic system is critical in a number of disease states, including PD, Tourette's syndrome, bipolar depression, schizophrenia, ADHD, and addiction/substance abuse.

The mesolimbic pathway is associated with reward and, less so, with learned behaviors. Dysfunction in this pathway is associated with addiction, schizophrenia, and psychoses (including bipolar depression) and learning deficits. The mesocortical projections are important for "higher-order" cognitive functions, including motivation, reward, emotion, and impulse control; they are also implicated in psychoses, including schizophrenia, and in ADHD. The nigrostriatal pathway is a key regulator of movement. Impairments in this pathway are involved in PD and underlie detrimental motor side effects associated with dopaminergic

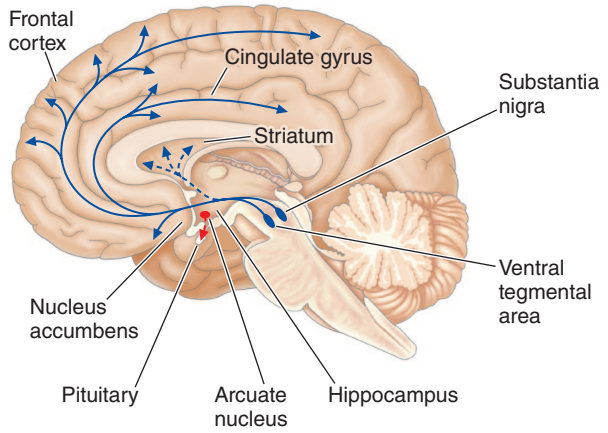

Figure 15–11 *Major dopaminergic projections in the CNS.*

- The nigrostriatal (or mesostriatal) pathway. Neurons in the substantia nigra compacta project to the dorsal striatum (*upward dashed blue arrows*); this is the pathway that degenerates in Parkinson's disease.
- The mesocortico/mesolimbic pathway. Neurons in the ventral tegmental area project to the ventral striatum (nucleus accumbens), olfactory bulb, amygdala, hippocampus, orbital and medial prefrontal cortex, and cingulate gyrus (*solid blue arrows*).
- The tuberoinfundibular pathway. Neurons in the arcuate nucleus of the hypothalamus project by the tuberoinfundibular pathway in the hypothalamus, from which DA is delivered to the anterior pituitary (*red arrows*).

therapy, including tardive dyskinesia (see Chapter 21). As noted previously, DA released in the tuberoinfundibular pathway is carried by the hypophyseal blood supply to the pituitary, where it regulates prolactin secretion.

Dopaminergic neurons are strongly influenced by excitatory glutamate and inhibitory GABA input. In general, glutamate inputs enable burst-like firing of dopaminergic neurons, resulting in high concentrations of synaptic DA. GABA inhibition of DA neurons causes a tonic, basal level of DA release into the synapse. DA release also modulates GABA and glutamate neurons, thus providing an additional level of interaction between DA and other neurotransmitters.

Motor Control and Parkinson's Disease

In the early 1980s, several young people in California developed rapid-onset parkinsonism. All of the affected individuals had injected a synthetic analogue of *meperidine* that was contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPTP is metabolized by MAO-B to the neurotoxin 1-methyl-4-phenylpyridinium (MPP^+). Because of the high specificity of MPP^+ for the DA transporter, neuronal death is largely restricted to the substantia nigra and ventral tegmental area, resulting in a phenotype remarkably similar to PD. 6-OHDA is similar to MPTP in both mechanism of action and utility in animal models. Administration of MPTP or 6-OHDA to animals results in tremor, grossly diminished locomotor activity, and rigidity. As with PD, these motor deficits are alleviated with L-DOPA therapy or dopaminergic agonists.

Other pharmacological agents that act on the DAT are known to potentiate locomotor activity via dopaminergic actions, including *cocaine* and *amphetamine*. The accumulation of extracellular DA increases stimulation of DA receptors and results in heightened locomotor activity. Mice lacking DAT are hyperactive and do not display increased locomotion in response to *cocaine* or *amphetamine* treatment.

Reward: Implications for Addiction

In general, drugs of abuse increase DA levels in the *nucleus accumbens*, an area critical for rewarded behaviors. This role for mesolimbic DA in addiction has led to numerous studies of abused drugs in DA receptor "knockout" mice in which the genes expressing specific receptors have been disrupted. Studies of D_1 receptor knockout mice showed a reduction in the rewarding properties of ethanol, suggesting that the rewarding and reinforcing properties of ethanol are dependent, at least in part, on the D_1 receptor. D_2 receptor knockout mice also display reduced preference for ethanol consumption. *Morphine* lacks rewarding properties in D_2 knockout mice when measured by conditioned place-preference or self-administration paradigms. However, mice lacking the D_2 receptor exhibit enhanced self-administration of high doses of *cocaine*. These data suggest a complex and drug-specific role for the D_2 receptor in rewarding and reinforcing behaviors. The D_3 receptor, highly expressed in the limbic system, has also been implicated in the rewarding properties of several drugs of abuse. However, D_3 knockout mice display drug-associated place preference similar to wild-type mice following *amphetamine* or *morphine* administration. Recently developed D_3 receptor–preferring ligands implicate a role for the D_3 receptor in motivation for drug seeking and in drug relapse, rather than in the direct reinforcing effects of the drugs (Keck et al., 2015; Newman et al., 2021).

Cognition and Memory

Seminal work by Goldman-Rakic, Arnsten, and their colleagues (Arnsten et al., 2017) showed that an optimum level of D_1 receptor activity in the PFC is required for optimum performance in learning and memory tasks. Either too little or too much D_1 receptor stimulation, due to disease or aging, impairs PFC function in rats, monkeys, and humans. Thus, low doses of D_1 agonists improve working memory and attention, whereas high levels of DA release, such as during stress, impair PFC function. These observations have led to the "inverted U" hypothesis of the relationship between D_1 receptor stimulation and normal physiological functioning of the PFC (Figure 15–12). Interestingly, suboptimal levels of D_1 receptor stimulation have been suggested to underlie age-associated learning deficits and to contribute to the decreased cognition observed in various pathophysiological states, especially schizophrenia. Not surprisingly, the D_1 receptor provides an attractive drug target for the treatment of disorders involving cognitive decline, including schizophrenia, PD, and Alzheimer's disease. Unfortunately, agonists that directly stimulate the D_1 receptor have failed clinically as cognitive enhancers mainly due to hypotensive side effects originating from D_1 receptor stimulation in the kidney. Recently, it has been hypothesized that positive allosteric modulators (PAMs) of the D_1 receptor, which have more limited effects on D_1 receptor stimulation (Hall et al., 2019), may prove successful as cognitive enhancers in patients without hypotensive side effects (Hao et al., 2019). Another approach is to use noncatechol D_1-like partial agonists that have good brain penetrability and D_1-like receptor selectivity without the hypotensive side effects seen with full D_1 agonists (Hall et al., 2019).

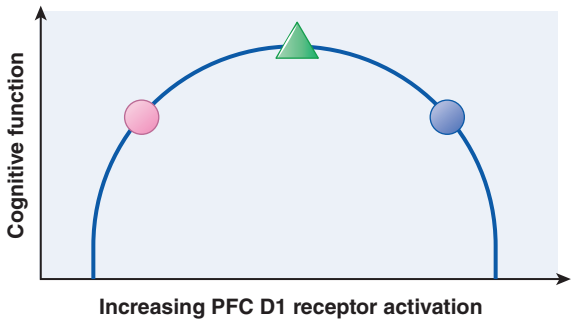

Figure 15–12 *Inverted U relationship between D_1 receptor signaling in the PFC and cognition.* The *green triangle* shows an optimum level of signaling/cognition, whereas the *pink ball* shows less than optimal levels due to disease/aging and the *blue ball* shows less than optimal levels due to stress.

Drugs Affecting Dopamine Signaling

Dopamine Receptor Agonists

Dopamine receptor agonists that target D_2-like receptors are mainly used in the treatment of PD, restless leg syndrome (RLS), and hyperprolactinemia. One limitation to the therapeutic use of dopaminergic agonists is the lack of receptor subtype selectivity. However, advances in receptor-ligand structure-function relationships have enabled the development of drugs that can fully distinguish between D_1-like and D_2-like receptor subfamilies and, in some cases, show selectivity for individual receptor subtypes, particularly for the D_3 and D_4 receptors. Many of these compounds have already proven to be useful experimental tools (Table 15–4), and this remains an active area of research.

Parkinson's Disease

Dopamine does not cross the BBB; thus, the principal pharmacotherapy for PD is to administer the precursor to DA, L-DOPA, which crosses the BBB and is converted to DA in the brain. Commonly, L-DOPA is formulated with a decarboxylase inhibitor to prevent the peripheral conversion of L-DOPA to DA, which can result in adverse side effects. While the response to L-DOPA by patients with PD is usually quite favorable, longer-term treatment can result in a loss of effectiveness and the emergence of dyskinetic syndromes referred to as L-DOPA–induced dyskinesias. These limitations to the therapeutic effects of L-DOPA have generated interest in developing alternative therapies for PD, with the intent of either delaying the use of L-DOPA or alleviating its side effects. DA receptor agonists can be used in conjunction with lower doses of L-DOPA in a combined therapy approach or as monotherapy. Historically, two general classes of dopaminergic agonists have been used in the treatment of PD: ergots and nonergots. The pharmacological management of PD is detailed in Chapter 21.

Ergot derivatives (see above) act on several different neurotransmitter systems, including DA, 5HT, and adrenergic receptors. *Bromocriptine* and *pergolide* have been used for the treatment of PD; however, their use is associated with risk for serious cardiac complications, specifically, the promotion of valvular heart disease due to $5HT_{2B}$ serotonin receptor stimulation (Hutcheson et al., 2011). *Bromocriptine* is a potent D_2 receptor agonist and a weak D_1 antagonist. *Pergolide* is a partial agonist of D_1 receptors and a strong D_2 family agonist with high affinity for both D_2 and D_3 receptor subtypes. *Pergolide* was removed from the U.S. market as therapy for PD after it was associated with an increased risk for valvular heart disease. *Bromocriptine* remains on the market primarily for the treatment of hyperprolactinemia or prolactin-secreting adenomas, where lower (D_2-selective) doses can be employed to avoid cardiac complications.

Several nonergot alkaloids are also employed in the management of PD. *Apomorphine* is a pan-DA receptor agonist most commonly used in the acute treatment of sudden "off" periods (bradykinesia, freezing) that can occur after long-term L-DOPA treatment. *Pramipexole* and *ropinirole*, widely used in the treatment of PD, are agonists at all D_2-like receptors but have the highest affinities for the D_3 receptor subtype. However, these agents are less effective than L-DOPA in the early stages of PD treatment, and both are associated with the development of impulse control disorders, such as compulsive gambling or hypersexuality; notably, fewer drug-induced dyskinesias are observed. The mechanisms underlying the impulse control disorders are currently unknown. *Rotigotine* is a DA agonist with preference for the D_2-like subfamily and is offered in a transdermal patch that is approved for the treatment of PD.

TABLE 15–4 ■ EXPERIMENTAL TOOLS AT DA RECEPTORS

RECEPTOR	AGONIST	ANTAGONIST
D_1-like[a]	SKF-81297 PF-06412562	SCH-23390 SCH-39166 (Ecopipam)
D_2-like[b]	Quinpirole	Spiperone Sulpiride
D_2	Sumanirole	L-741626 ML-321
D_3	PD128907 ML-417	SB-277011 VK4-40
D_4	PD168077 A412997	L-745870 L-741742

[a]These compounds are selective for D_1-like versus D_2-like receptors. There are no useful tool compounds that can differentiate D_1 from D_5 receptors.
[b]These compounds are selective for D_2-like versus D_1-like receptors.

Hyperprolactinemia

Despite the contraindications for PD, ergot-based DA agonists are still used in the treatment of hyperprolactinemia. Like *bromocriptine*, *cabergoline* is a strong agonist at D_2 receptors and has lower affinity for D_1, 5HT, and α adrenergic receptors. The therapeutic utility of *bromocriptine* and *cabergoline* in hyperprolactinemia is derived from their properties as DA receptor agonists: They activate D_2 receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease from ergot therapy is associated with higher doses of drug (necessary for PD treatment) but not with the lower doses used in treating hyperprolactinemia (see Chapter 46).

Restless Leg Syndrome

Restless leg syndrome is a neurological deficit characterized by abnormal sensations in the legs that are alleviated by movement. Decreased DA receptor expression and mild dopaminergic hypofunction are noted in patients with RLS. *Rotigotine*, *ropinirole*, and *pramipexole* are FDA approved as pharmacotherapies for both PD and RLS.

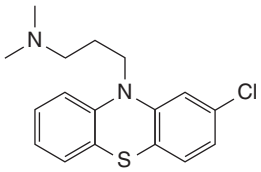
Dopamine Receptor Antagonists

Just as enhancing DA neurotransmission can be clinically important, so can inhibiting dopaminergic signaling be useful in certain disease states. Clinically, most DA antagonists are used to treat schizophrenia and bipolar disorders (see below). However, some antagonists, such as *metoclopramide* and *domperidone*, have been used to treat nausea and vomiting (see Chapter 54). As with the DA receptor agonists, a lack of subtype-specific antagonists has limited the therapeutic utility of this group of ligands. Recent advances in elucidating GPCR structures and modeling ligand binding have advanced drug design, and subtype-selective antagonists are beginning to emerge as experimental tools (see Table 15–4). Some receptor subtype-selective antagonists are in early stages of preclinical testing for therapeutic utility.

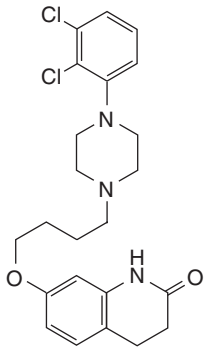
Schizophrenia

Dopamine receptor antagonists of the D_2-like subfamily are a mainstay in the pharmacotherapy of schizophrenia. While many neurotransmitter systems likely contribute to the complex pathology of schizophrenia (see Chapter 19), modulating DA signaling is considered the basis of treatment. The DA hypothesis of schizophrenia has its origins in the characteristics of the drugs used to treat this disorder: All antipsychotic compounds used clinically have high affinity for DA receptors, especially for the D_2 receptor subtype. Moreover, psychostimulants that increase extracellular DA levels can induce or worsen psychotic symptoms in schizophrenic patients. The advent of neuroimaging techniques for visualization of DA in human brain regions has led to new insights in the role of specific DA systems. DA hyperfunction in subcortical regions, most notably the striatum, has been associated with the positive symptoms of schizophrenia, which respond well to antipsychotic treatment. In contrast, the PFC of schizophrenic patients exhibits dopaminergic hypofunction, which has been associated with the more treatment-refractory negative/cognitive symptoms. The drugs currently used to treat schizophrenia are classified as either typical (or first-generation) or atypical (second-generation) antipsychotics. This nomenclature stems from the fewer extrapyramidal symptoms (EPS), or parkinsonian-like side effects, observed with atypical antipsychotics.

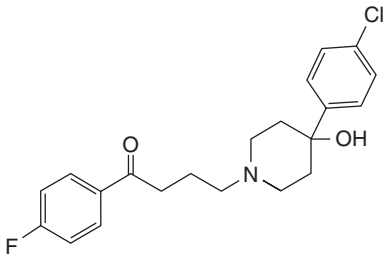
Typical Antipsychotics. The first antipsychotic drug used to treat schizophrenia was *chlorpromazine*. Its antipsychotic properties were attributed to its antagonism of DA receptors, especially the D_2 receptor. More D_2-selective ligands (e.g., *haloperidol*) were developed to improve the antipsychotic properties (see Chapter 19). Notably, drugs that are completely selective for the D_2 receptor subtype, without overlapping with affinity for the D_3 or D_4 receptor subtypes, are currently unavailable. While all typical antipsychotics markedly improve positive symptoms (e.g., hallucinations), they are not very beneficial in the treatment of negative or cognitive symptoms of this disease.



CHLORPROMAZINE



ARIPIPRAZOLE



HALOPERIDOL

Atypical Antipsychotics. This class of antipsychotic drugs originated with *clozapine* and is distinguished by lower EPS than typical antipsychotics. Atypical agents are also less likely to stimulate prolactin production. The lack of extrapyramidal side effects has been partly attributed to a much lower affinity for the D_2 receptor compared to typical antipsychotics. This frequently results from a slower association and faster dissociation of the drug to/from the D_2 receptor, resulting in a lower receptor occupancy time. It has been hypothesized that this allows for more receptor occupancy by dopamine and a higher dopaminergic "tone" leading to fewer EPS (Sykes et al., 2017). Although atypical antipsychotics are considered safer than many of the older drugs, they can also have serious metabolic side effects that include weight gain, type 2 diabetes, and hyperlipidemia, as well as cardiovascular actions that can result in arrhythmias and stroke. Most, but not all, atypical antipsychotics are also high-affinity antagonists or inverse agonists at the $5HT_{2A}$ receptor. While the precise role of $5HT_{2A}$ receptor blockade in the atypical effects of antipsychotics remains unclear, dual DA–5HT receptor blockade has contributed to the development of many atypical antipsychotics (see Chapter 19). Atypical antipsychotics have also proven useful as adjunctive therapeutics in both major depression and bipolar disorder (see Chapters 18 and 19).

Partial D_2-Like Receptor Agonists. *Aripiprazole* has even fewer side effects than earlier atypical antipsychotics. *Aripiprazole* diverges from the traditional atypical profile in several ways: First, it has higher affinity for D_2 receptors than for $5HT_{2A}$ receptors; second, it is a partial agonist at D_2 receptors. As a partial agonist, *aripiprazole* may diminish subcortical (striatal) DA hyperfunction by competing with DA for receptor binding, while simultaneously enhancing dopaminergic neurotransmission in the PFC by acting as an agonist. The dual mechanism afforded by a partial agonist may thus treat both the positive and negative symptoms associated with schizophrenia. *Aripiprazole* also exhibits functional selectivity at the D_2 receptor in that it exhibits higher efficacy for β-arrestin–mediated signaling than for G protein-mediated signaling. How this property may contribute to the unique effects of *aripiprazole* is not yet clear.

Recently, a derivative of *aripiprazole*, *brexpiprazole*, has been approved for the treatment of schizophrenia and as an adjunctive treatment of depression. The pharmacological properties of *brexpiprazole* are similar to those of *aripiprazole* except that *brexpiprazole* has lower D_2 receptor agonist efficacy and high partial agonist effects at the $5HT_{1A}$ receptor; perhaps this latter property underlies its effectiveness in treating depression.

Another partial agonist of the D_2 receptor, *cariprazine*, has recently been approved for treating schizophrenia and bipolar disorder. Interestingly, *cariprazine* is also a partial agonist at the D_3 receptor and exhibits higher affinity for the D_3 versus the D_2 receptor. In some studies, *cariprazine* has been shown to exhibit procognitive effects, suggesting that it may be useful for treating negative as well as positive symptoms of schizophrenia.

D_3 Receptor Antagonists and Drug Addiction

Although much work remains to determine their clinical utility, D_3-selective antagonists show promise in the treatment of addiction (Newman et al., 2012, 2021). This interest stems from the high expression of the D_3 receptor in the limbic system, the reward center of the brain, and from animal studies of D_3-selective antagonists that suggest a role for the D_3 receptor in the motivation to abuse drugs and in the potential for drug-abuse relapse (Keck et al., 2015). Preclinical research has suggested that D_3-selective antagonists may be particularly effective in treating opioid use disorders, and several such agents are currently under development (Galaj et al., 2020; Newman et al., 2021).

Drug Facts for Your Personal Formulary: *Serotonergic Ligands*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
$5HT_3$ Receptor Antagonists • Antiemetic agents • Additional detail in Chapters 54 and 55		
Ondansetron Dolasetron Granisetron Palonosetron	• Antiemetics • Treatment of nausea	• Associated with asymptomatic electrocardiogram changes, including prolongation of PT and QTc intervals
Alosetron	• Irritable bowel syndrome	• Most useful in women with irritable bowel syndrome when diarrhea is the principal symptom
$5HT_{2A}$ Receptor Agonists • Psychedelics		

Psilocybin
Mescaline
LSD
	• In clinical trials for:
	  • Depression
	  • Substance use disorder
	  • Migraine
	  • Obsessive-compulsive disorder
		• Produce profound hallucinations, which may be relevant to therapeutic mechanisms
		• Efficacy in preclinical models as an anti-inflammatory

Drug Facts for Your Personal Formulary: *Serotonergic Ligands (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
$5HT_{2A}$ Receptor Inverse Agonists • Psychosis		
Pimavanserin	• Treatment of psychosis	• Currently restricted to psychosis occurring within PD
The Triptans: $5HT_{1B/1D}$ Receptor Agonists • Migraine		
Almotriptan[a] Eletriptan Frovatriptan Naratriptan Rizatriptan Sumatriptan[b] Zolmitriptan	• Acute treatment of migraine	• Most effective in acute settings; should be used as soon as possible after onset of attack • Usually dosed orally; onset, 1–3 h • Use with caution in patients with cardiovascular issues; contraindicated in patients with ischemic heart disease and coronary artery vasospasm • Drug interactions: CYP3A4 inhibitors ↑ C_p and $t_{1/2}$ of eletriptan, naratriptan; MAO inhibitors ↑ levels of almo-, riza-, suma-, and zolmitriptan • Side effects: dizziness, somnolence, neck and chest pain • May cause fetal harm; not recommended during pregnancy and nursing; reduce dose in renal and hepatic impairment; do not administer within 24 h of other triptans, ergots, SSRIs/SNRIs • Beware serotonin syndrome, especially in combination with SSRIs and SNRIs
$5HT_{1F}$ Receptor Agonists • Migraine		
Lasmiditan	• Acute treatment of migraine	• Fewer adverse cardiovascular events than triptans
The Ergot Alkaloids • Interact with multiple 5HT receptor isoforms • Broad therapeutic utility		
LSD	• No longer employed clinically • Potent hallucinogen	• Positron emission tomographic imaging reveals similar activation patterns between schizophrenic patients experiencing hallucinations and LSD-induced hallucinations • $5HT_{2A}$ receptor activation is believed to mediate the hallucinogenic effect of LSD
Methysergide	• Acute treatment of migraine • Treatment of vascular headaches	• Restricted to use in patients with frequent, moderate, or infrequent, severe migraine attacks • Erratic drug absorption • Potential for inflammatory fibrosis with prolonged use, including pleuropulmonary and endocardial fibrosis
Ergonovine Methylergonovine	• Prevention of postpartum hemorrhage	• Increasing dose results in prolonged duration and increased force of uterine contraction • Sustained contracture can result at high doses • Hallucinations at supratherapeutic levels
$5HT_{1A}$ Receptor Partial Agonists and SSRIs • Anxiolytics and antidepressants • Additional detail in Chapter 18		
Buspirone	• Treatment of anxiety	• Mimics antianxiety effects of benzodiazepines but does not interact with $GABA_A$ receptors • Partial agonist of the $5HT_{1A}$ receptor
Fluoxetine Fluvoxamine Paroxetine Citalopram Escitalopram Sertraline Vilazodone	• Antidepressants • Also used to treat anxiety, panic disorder, obsessive-compulsive disorder, fibromyalgia, and neuropathic pain	• Selectively inhibit the serotonin transporter (SSRIs) • Most widely used treatments for major depressive disorder • Sexual dysfunction is a common side effect with SSRIs • Precaution: serotonin syndrome
Multifunctional Serotonin Agonists and Antagonists (MSAAs) • Treatment of sexual dysfunction • Activity at multiple receptor isoforms		
Flibanserin	• Treatment of HSDD/FSIAD[c] in premenopausal women	• Potent $5HT_{1A}$ receptor agonist and $5HT_2$ receptor family antagonist • Exerts both agonist and antagonist activity at 5HT receptors → MSAA designation
Dopamine Receptor Agonists • Some with subfamily specificity		
Dopamine	• Congestive heart failure • Sepsis • Cardiogenic shock	• Only used acutely via intravenous administration
Bromocriptine Cabergoline	• PD (see Chapter 21) • Hyperprolactinemia	• Ergot derivatives with D_2 agonist activity and D_1 antagonist activity • Limited utility for PD due to high potential for cardiac valvulopathies via $5HT_{2B}$ stimulation • Bromocriptine and cabergoline can be used at low doses to treat hyperprolactinemia
Apomorphine Pramipexole Ropinirole Rotigotine	• PD (see Chapter 21 for more details) • RLS	• Nonergot alkaloids with broader DA receptor agonist activity • Less efficacious than L-DOPA in PD; often used as adjunct therapy in advanced PD • Use in early PD can lead to poor impulse control • Pramipexole, ropinirole, and rotigotine are used to treat RLS

Drug Facts for Your Personal Formulary: *Serotonergic Ligands* (*continued*)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Dopamine Receptor Antagonists • Antipsychotics • Emerging subtype specificity of ligands (see also Chapter 19)		
Chlorpromazine Haloperidol	• Schizophrenia (see Chapter 19)	• Classified as typical antipsychotics • Agents block D_2 receptors but are not completely selective • Improvements are most notable in positive symptoms of schizophrenia
Clozapine Risperidone Olanzapine	• Schizophrenia (see Chapter 19)	• Classified as atypical antipsychotics • Mixed $5HT_{2A}$–D_2 receptor blockade • Fewer extrapyramidal side effects than typical antipsychotics, but can have greater effects on metabolism and weight gain
Aripiprazole Brexpiprazole Cariprazine	• Schizophrenia (see Chapter 19)	• D_2 partial agonists with varied profiles at 5HT receptors • Improved side effect profile over many other antipsychotics
DAT Ligands • High potential for abuse • Interact with the dopamine transporter		
Bupropion	• Depression • Smoking cessation	• Also inhibits NET • ↑ risk of suicidal ideation in pediatric/young adult patients taking this medication
Cocaine	• Rarely used therapeutically	• Schedule II classification • Limited clinical utility as a topical anesthetic in eye and nasal surgeries
Methylphenidate Methamphetamine Amphetamine	• ADHD, ADD[d] • Narcolepsy • Obesity	• Can worsen psychosis; use with extreme caution in patients with bipolar disorder • Schedule II drug classification due to psychostimulant properties if misused

[a]Fewest side effects.
[b]Has best evidence for safety in pregnancy.
[c]Female sexual interest/arousal disorder.
[d]Attention-deficit disorder.

Chapter 16

Neurotransmission in the Central Nervous System

R. Benjamin Free, Suzanne M. Underhill, Susan G. Amara, and David R. Sibley

The brain is a complex assembly of interacting cells that regulate many of life's activities in a dynamic fashion, generally through a communication process termed neurotransmission. Because the CNS drives so many physiological responses, it stands to reason that centrally acting drugs are invaluable for a plethora of conditions. CNS-acting drugs are used not only to treat anxiety, depression, mania, and schizophrenia, but also to target diverse pathophysiological conditions such as pain, fever, movement disorders, insomnia, eating disorders, nausea, vomiting, and migraine. However, as the CNS dictates such diverse physiology, the recreational use of some CNS-acting drugs can and does lead to physical dependence (see Chapter 28) with enormous societal impacts. The sheer breadth of physiological and pathological activities mediated by drug molecules acting in the CNS makes this class of therapeutics both wide-ranging and important.

The identification of CNS targets and the development of drug molecules for those targets present extraordinary scientific challenges. While years of investigation have begun to dissect the cellular and molecular bases for many aspects of neuronal signaling, complete understanding of the functions of the human brain remains in its infancy. Complicating the effort is the fact that a CNS-active drug may act at multiple sites with disparate and even opposing effects. Furthermore, many CNS disorders likely involve multiple brain regions and pathways, which can frustrate efforts that focus on a single therapeutic agent.

The pharmacology of CNS-acting drugs is primarily driven by two broad and overlapping goals:

- To develop/use drugs as biochemical probes to both elucidate and manipulate the normal CNS; and
- To develop drugs to correct pathophysiological changes in the abnormal CNS.

Modern advances in molecular biology, neurophysiology, structural biology, epigenetics, biomarkers, immunology, and an array of other fields have facilitated both our understanding of the brain and the development of an ever-expanding repertoire of drugs that can selectively treat diseases of the CNS. An important goal in drug discovery is to determine receptor structure at the atomic level and understand how neurotransmitters and drug molecules interact with receptors to stimulate or inhibit receptor-mediated signaling. This has spurred the use of complex techniques such as x-ray crystallography and cryo-electron microscopy to solve receptor structures to a high degree of accuracy, followed by computer-aided molecular dynamic simulations and modeling as essential components to understand how neurotransmitters and drug molecules affect signaling. As more atomic level structures of receptors, transporters, ion channels, and other relevant drug targets are elucidated, such structural biology techniques will likely become even more prevalent in drug discovery and development.

This chapter introduces fundamental principles and guidelines for the comprehensive study of drugs that affect the CNS. Specific therapeutic approaches to neurological and psychiatric disorders are discussed in subsequent chapters. For further detail, see specialized texts such as Sibley et al. (2007), Brady et al. (2012), Nestler et al. (2020), and Kandel et al. (2021). Detailed information on nearly all specific receptors and ion channels can be found at the official databases of the International Union of Basic and Clinical Pharmacology (IUPHAR) Guide to Pharmacology (http://www.guidetopharmacology.org).

Cellular Organization of the CNS

The CNS is made up of several types of specialized cells that are physiologically integrated to form complex functional brain tissue. The primary communicating cell is the neuron, which is strongly influenced and sustained by a variety of important supporting cells. Specific connections between neurons, both within and across the macro-divisions of the brain, are essential for neurological function. Through patterns of neuronal circuitry, individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain. Under these guidelines, present understanding of the cellular organization of the CNS can be viewed from the perspective of the size, shape, location, and interconnections between neurons (Shepherd, 2004; Squire, 2013).

Neurons

Neurons are the highly polarized signaling cells of the brain and are subclassified into types based on factors including function (sensory, motor, or interneuron), location, morphology, neurotransmitter phenotype, or the class(es) of receptors expressed. Neurons are electrically active cells that express a variety of ion channels and ion transport proteins that

Abbreviations

ACh: acetylcholine
ADHD: attention-deficit/hyperactivity disorder
AMPA: α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
BBB: blood-brain barrier
CFTR channel: cystic fibrosis transmembrane conductance regulated channel
CGRP: calcitonin gene–related peptide
ClC: chloride channel
CNG channel: cyclic nucleotide–gated channel
CSF: cerebrospinal fluid
CYP: cytochrome P450
DA: dopamine
DAT: dopamine transporter
EAAT: excitatory amino acid transporter
EPI: epinephrine
GABA: γ-aminobutyric acid
GABA-T: GABA transaminase
GAT: GABA transporter
GluR: AMPA/kainate type of glutamate receptor
GPCR: G protein-coupled receptor
HCN channel: hyperpolarization-activated, cyclic nucleotide–gated channel
HP loop: hairpin loop
5HT: 5-hydroxytryptamine, serotonin
IP_3: inositol 1,4,5-trisphosphate
IUPHAR: International Union of Basic and Clinical Pharmacology
KA: kainic acid
L-DOPA: levodopa
MGL: monoacylglycerol lipase
mGluR: metabotropic glutamate receptor
NADA: *N*-arachidonoyl-dopamine
NAM: negative allosteric modulator
NE: norepinephrine
NET: norepinephrine transporter
NMDA: *N*-methyl-D-aspartate
NO: nitric oxide
OCT: organic cation transporter
PAM: positive allosteric modulator
PK_: protein kinase _, as in PKA, PKC
PL_ : phospholipase_, as in PLA, PLC
PMAT: plasma membrane monoamine transporter
SERT: serotonin transporter
TAAR: trace amine–associated receptors
TRP channel: transient receptor potential channel
VAChT: vesicular acetylcholine transporter
VGAT: vesicular GABA and glycine transporter
VGLUT: vesicular glutamate transporter
VMAT: vesicular monoamine transporter

allow them to conduct nerve impulses or action potentials that ultimately trigger release of neurotransmitters during chemical neurotransmission. Neurons also exhibit the cytological characteristics of highly active secretory cells with large nuclei, large amounts of smooth and rough endoplasmic reticulum, and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex) in which secretory products of the cell are packaged into membrane-bound organelles for transport from the perikaryon/soma to the axon or dendrites (Figure 16–1). The sites of interneuronal communication in the CNS are termed *synapses*. Although synapses are functionally analogous to "junctions" in the somatic motor

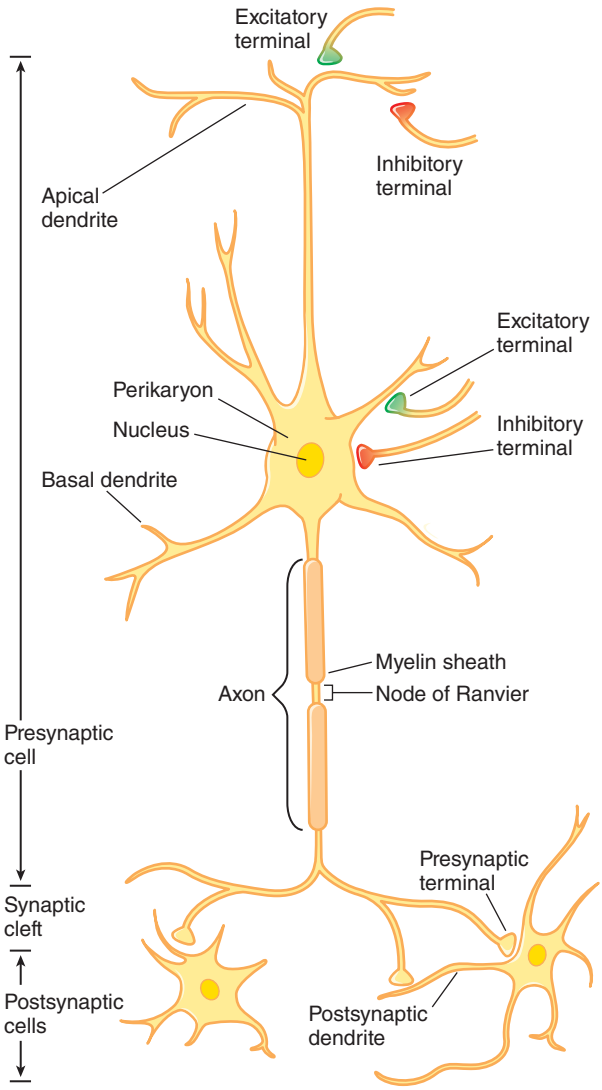

Figure 16–1 *Principal features of a neuron.* Dendrites, including apical dendrites, receive synapses from presynaptic terminals. The cell body (~50 μm in diameter) contains the nucleus and is the site of transcription and translation. The axon (0.2–20 μm wide, 100 μm to 2 m in length) carries information from the perikaryon to the presynaptic terminals, which form synapses (up to 1000) with the dendrites of other neurons. Axo-somatic synapses also occur. Many CNS-active pharmacological agents act at the presynaptic and postsynaptic membranes of the synaptic clefts and at areas of transmitter storage near the synapses. (Adapted with permission from Kandel ER, Schwartz JH, Jessell TM (eds). *Principles of Neural Science*, 4th ed. McGraw-Hill, New York, **2000**, p 22.)

and autonomic nervous systems, central synapses contain an array of specific proteins presumed to be the active zone for transmitter release and response. Like peripheral "junctions," central synapses are denoted by accumulations of tiny (50–150 nm) *synaptic vesicles*. The proteins of these vesicles have specific roles in neurotransmitter storage, vesicle docking, secretion, and reaccumulation of neurotransmitter. The release of these neurotransmitters and their action on the neighboring cells via specific receptors, through mechanisms discussed below, underlie the ability of these specialized cells to communicate with each other to dictate complex physiological actions.

Nonneuronal Cells

A diverse cast of support cells outnumber neurons in the CNS. These include neuroglia, vascular elements, the cerebrospinal fluid (CSF)-forming cells found within the intracerebral ventricular system, and the meninges that cover the surface of the brain and comprise the CSF-containing envelope. *Neuroglia* (often referred to simply as glia) are the

most abundant support cells. They are nonneuronal cells that maintain important brain functions such as holding neurons in place, supplying oxygen and nutrients to neurons, insulating signaling between neurons, and destroying potential pathogens. Traditionally it was thought that neuroglia acted only in a supporting role; however, newer studies have demonstrated that they may also be involved in some signaling processes.

Neuroglia are classified as either *micro-* or *macro*glia. In the CNS, the macroglia consist of *astrocytes, oligodendroglia, ependymal cells*, and *radial glia. Astrocytes* (cells interposed between the vasculature and the neurons) are the most abundant of these and often surround individual compartments of synaptic complexes. They play a variety of metabolic support roles including furnishing energy intermediates, anchoring neurons to their blood supply, and regulating the external environment of the neuron by active removal of neurotransmitters and excess ions following release. The *oligodendroglia* produce myelin—multilayer compacted membranes that electrically insulate segments of axons and permit nondecremental propagation of action potentials. Ependymal cells line the spinal cord and ventricular system and are involved in the creation of CSF, while radial cells act as neuroprogenitors and scaffolds. *Microglia* consist of specialized immune cells found within the CNS. Although the brain is immunologically protected by the blood-brain barrier (BBB), these microglia act as macrophages to protect the neurons and are therefore mediators of immune response in the CNS. Microglia respond to neuronal damage and inflammation, and many diseases are associated with deficient microglia. In some instances, such as in chronic neuroinflammation, the balance between the numbers of microglia and astrocytes can determine whether there will be resulting cell damage or protection. Thus, in addition to neurons, support cells such as glia are key players in facilitating most aspects of neuronal function and CNS signaling.

Blood-Brain Barrier

The BBB is an important boundary separating the periphery (capillaries carrying blood) from the CNS. This barrier consists of *endothelial cells, astrocytes,* and *pericytes* on a *noncellular basement membrane*. The BBB diminishes the rate of access of many chemicals in plasma, thus preventing unencumbered access to the brain by circulating blood components. The BBB evolved as a mechanism to protect the brain from toxins in the environment. In terms of CNS therapeutics, the BBB represents a substantial obstacle to overcome for drug delivery to the site of action. An exception exists for lipophilic molecules, which diffuse freely across the BBB and accumulate in the brain. In addition to its relative impermeability to charged molecules such as neurotransmitters, the BBB can be viewed as a combination of the partition of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (see Chapter 4). However, the cells within the barrier also have the capacity to actively transport molecules such as glucose and amino acids that are critical for brain function (see Chapter 17). One of these transport systems that is selective for large amino acids catalyzes the movement across the BBB and thus contributes to the therapeutic utility of L-DOPA in the treatment of Parkinson's disease. Furthermore, for some compounds, including metabolites of neurotransmitters (e.g., homovanillic acid and 5-hydroxyindoleacetic acid), the acid transport system of the choroid plexus provides an important route for clearance from the brain. The BBB is covered in detail in Chapter 17.

Neuronal Excitability and Ion Channels

As noted above, neurons, the primary signaling cells of the brain, release neurotransmitters in response to a rapid rise and fall in membrane potential known as an action potential. Voltage-dependent ion channels within the plasma membrane open when the membrane potential increases to a threshold value, thus regulating the electrical excitability of neurons. Action potentials are the signals by which the brain and neurons receive and transmit information to one another through pathways determined by their connectivity.

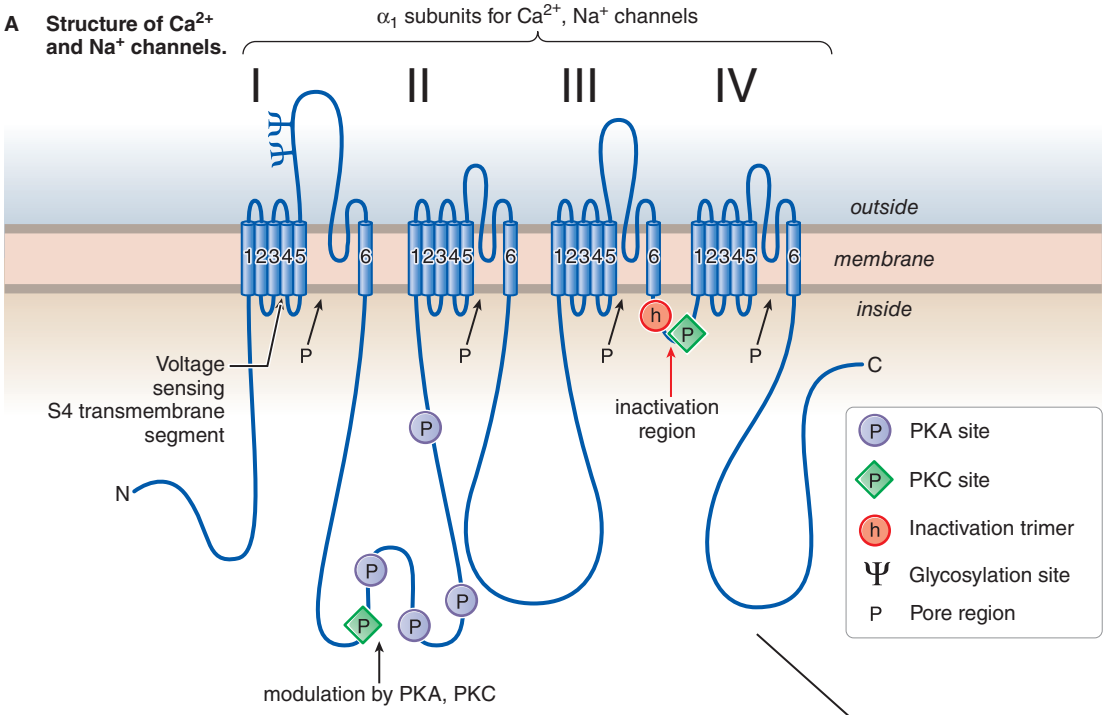
We now understand in considerable detail how three major cations, Na^+, K^+, and Ca^{2+}, as well as Cl^- anions, are regulated via their flow through highly discriminative ion channels (Figures 16–2 and 16–3). Active transmembrane countertransport of Na^+ and K^+ and the intracellular sequestration and mobilization of Ca^{2+} permit resting cells to maintain a steady-state concentration of ions that enable electrical depolarization. Voltage-sensitive ion channels permit the flow of Na^+ and K^+ ions that mediate depolarization and repolarization, while homeostatic mechanisms (e.g., Na^+/K^+-ATPase, Na^+/Ca^{2+} exchanger, Ca^{2+}-ATPases) restore the transmembrane ionic gradients to their resting conditions. The relatively high extracellular concentration of Na^+ (~140 mM) compared to its intracellular concentration (~14 mM) means that increases in permeability to Na^+ cause cellular depolarization, ultimately leading to the generation of an action potential. In contrast, the intracellular concentration of K^+ is relatively high (~120 mM, vs. 4 mM outside the cell), and increased permeability to K^+ results in hyperpolarization. Changes in the concentration of intracellular Ca^{2+} (100 nM to 1 μM) affect multiple processes in the cell and are critical in the release of neurotransmitters. Electrical excitability thus generates the action potential through changes in the distribution of charged ions across the neuronal cell membrane.

The principal anion involved in neuronal excitability is Cl^-, and its flux is also regulated by membrane channels and transporters. Cl^- channels are a superfamily of ion channels that are important for maintaining resting potential and are also responsible for the inhibitory postsynaptic potentials that dampen neuronal excitability. In most neurons, the Cl^- gradient across the plasma membrane is inwardly driven (~116 mM outside vs. 20 mM inside the cell), and as a result, inactivation of these Cl^- channels leads to hyperexcitability. There are several families of both voltage-gated and ligand-gated Cl^- channels (Figure 16–3). Ligand-gated Cl^- channels are linked to inhibitory transmitters including γ-aminobutyric acid (GABA) and glycine (discussed in detail below). A class of secondary active transporters, the cation-chloride cotransporters, plays an essential role in establishing the electrochemical Cl^- gradient that is required for the hyperpolarizing postsynaptic inhibition mediated by both GABA receptors and glycine receptors. During brain development, changes in the expression of neuronal cation-chloride cotransporter isoforms can result in shifts in the direction of the chloride gradient such that activation of a ligand-gated chloride channel becomes excitatory.

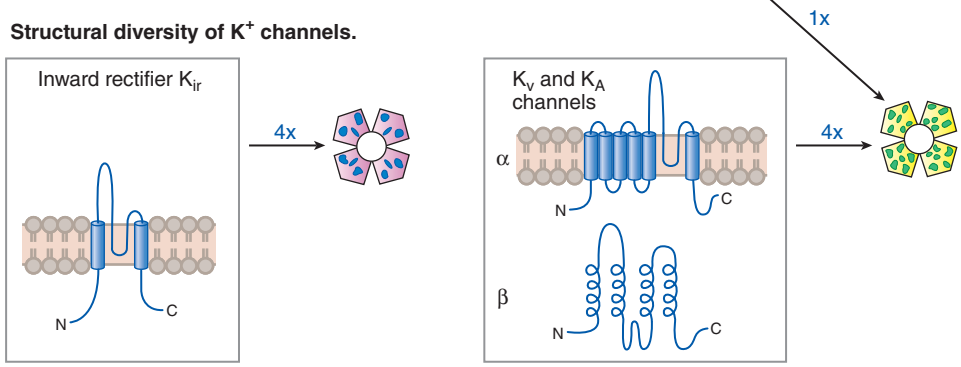
The chloride channel (ClC) family of Cl^- channels consists of plasma membrane channels that affect Cl^- flux and membrane potential as well as channels that function as Cl^-/H^+ antiporters. ClC Cl^- channels can also influence the pH of intracellular vesicles. Cystic fibrosis transmembrane conductance regulated (CFTR) channels are gated by ATP and activated by PKA; CFTR channels mediate the conductance of certain anions, mainly Cl^- and HCO_3^-. Overall, these channels are responsible for a variety of important neurophysiological roles including regulation of membrane potential, volume homeostasis, and regulation of pH on internal extracellular compartments.

Cyclic nucleotide–gated (CNG) channels are nonselective cation channels that regulate ion flux in neurons. CNG channels are activated by cyclic nucleotide binding, and their primary function involves sensory transduction, especially in the retina and olfactory neurons. Since CNG channels are nonselective and also allow alkali ions to flow, they can result in either depolarization or hyperpolarization. These channels consist of four subunits assembled around a central pore and are subclassified into α (four genes) and β (two genes) subunits. Another type of CNG channel is the *hyperpolarization-activated, cyclic nucleotide–gated (HCN)* channel. HCN channels are nonselective ligand-gated cation channels that are encoded by four genes and are expressed in the heart as well as in the brain, where they are thought to influence the way neurons respond to synaptic input. HCN channels have been implicated in epilepsy and neuropathic pain. These channels open with hyperpolarization and close with depolarization; upon direct binding of cyclic AMP or cyclic GMP, the activation curves for the channels are shifted to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and in rhythmic and oscillatory activity as they are finely tuned to respond to activation thresholds in the CNS.

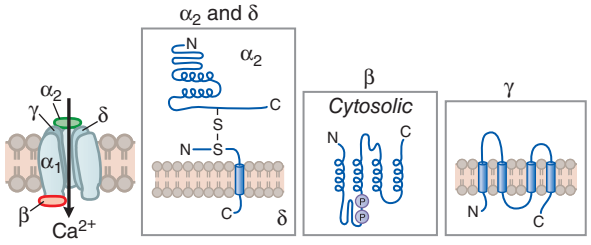
A Structure of Ca^{2+} and Na^+ channels.



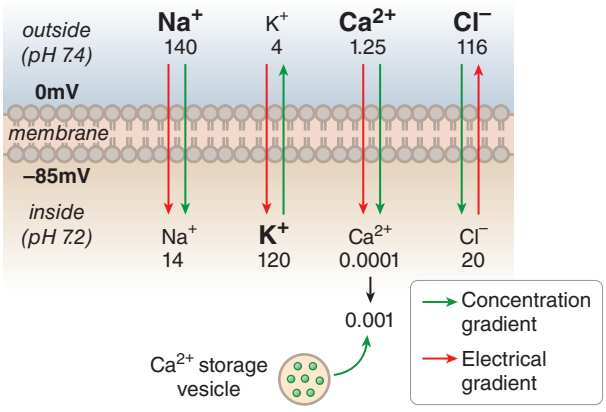
B Structural diversity of K^+ channels.



C Multisubunit assembly of Ca^{2+} channels.



D Ionic gradients across a mammalian nerve cell membrane



Transient receptor potential (TRP) channels are a large family of around 28 ion channels that are nonselectively permeable to cations including Na^+, Ca^{2+}, and Mg^{2+}. The name *transient receptor potential channel* is unfortunate and does not describe the function of these channels, which is to respond to multiple types of stimuli to allow cation entry into the cell. They are broadly grouped into six receptor subfamilies with diverse structures and functions and possessing four subunits with a cation-permeable pore: ankyrin (TRPA), canonical (TRPC), melastatin (TRPM), mucolipin (TRPML), polycystin (TRPP), and vanilloid (TRPV). These channels can have diverse modes of activation and permeation and respond to multiple stimuli and function in sensory physiology, including thermosensation, osmosensation, and taste. Importantly some TRP channels are also mediators of pain as they function as detectors of thermal and chemical stimuli that activate sensory neurons. Spices such as garlic, chili powder, and wasabi activate certain subtypes. Others respond to such diverse chemicals as menthol, peppermint, and camphor. Mutations in TRP channels have been associated with neurodegenerative diseases as well as cancer. The diversity of their physiology has led to their investigation as drug targets. The capsaicin receptor, TRPV1, is the most thoroughly characterized TRP channel, and both agonists and antagonists are being investigated, particularly for the treatment of chronic pain. Reviews of TRP channels and drug development are available (Moran, 2018; Zhao et al., 2021). The 2021 Nobel Prize in Physiology or Medicine was awarded to David Julius for his work on TRP channels and to Ardem Patapoutian for his work on the mechanosensitive ion channels, piezos (https://www.nobelprize.org/prizes/medicine/2021/summary/).

Chemical Communication in the CNS

A central concept of neuropsychopharmacology is that drugs that improve the functional status of patients with neurological or psychiatric diseases typically act by enhancing or blunting neurotransmission in the CNS. Therapeutic targets typically include *ion channels* (discussed above) that mediate changes in excitability induced by neurotransmitters, *neurotransmitter receptors* that physiologically respond to activation by neurotransmitters, and *transport proteins* that clear released transmitter from the extracellular space.

Identification of Central Neurotransmitters

Neurotransmitters are endogenous chemicals in the brain that act to enable signaling across a chemical synapse. They carry, boost, and modulate signals between neurons or other cell types and act on a variety of targets to elicit a host of biological functions. An essential step in understanding the functional properties of neurotransmitters within the context of the circuitry of the brain is to identify substances that are transmitters at specific interneuronal connections. The precise number of transmitters is unknown, but more than 100 chemical messengers have been identified to date. The criteria for identification of central transmitters are similar to those used to establish the transmitters of the autonomic nervous system (see Chapter 14):

- The transmitter must be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals arise.
- The transmitter must be released from the presynaptic nerve concomitantly with nerve activity in high enough quantity to have an effect.
- The effects of experimental application of the putative transmitter should mimic the effects of stimulating the presynaptic pathway.
- If available, specific pharmacological agonists and antagonists should stimulate and block, respectively, the measured functions of the putative transmitter.
- There should be a mechanism present (either reuptake or enzymatic) that stops the actions of the transmitter.

Many neurons contain multiple transmitter substances either packaged together in the same vesicles or in adjacent active zones that may act jointly on the postsynaptic membrane(s) or may act presynaptically to affect release of transmitter from the presynaptic terminal. In the setting of concurrent release of multiple signaling molecules, mimicking or fully antagonizing the action of a given transmitter with a single drug compound is difficult. This complexity in identifying signaling molecules has been partially overcome by use of defined *in vitro* cell culture systems and conditional transgenic animal models that can then be extrapolated to the human CNS.

Cell Signaling and Synaptic Transmission

Cellular signaling links neurotransmitter receptor activation to downstream biological effects. A number of mechanisms have been identified, and these can be broadly classified into two main types of signaling: fast and slow neurotransmission. The most common postreceptor events are fast transmission resulting from rapid changes in ion flux through ion channels. Slow neurotransmission is primarily the role of a second major group of receptors, the G protein-coupled receptors (GPCRs), which interact with heterotrimeric GTP-binding proteins. Additional mechanisms are seen with growth factor receptors and a distinct class of nuclear receptors that transduce steroid hormone signaling. Since the majority of cell-to-cell communication in the CNS involves chemical transmission, neurons require specialized cellular functions to mediate these actions including (Figure 16–4):

Figure 16–2 *Voltage-dependent Na^+, Ca^{2+} and K^+ channels.* Voltage-dependent channels provide for rapid changes in ion permeability along axons and within dendrites and for excitation-secretion coupling that causes neurotransmitter release from presynaptic sites. **A.** *Structure of Ca^{2+} and Na^+ channels.* The α subunit in both Ca^{2+} and Na^+ channels consists of four sub-subunits or segments (labeled **I** through **IV**), each with six transmembrane (TM) hydrophobic domains (blue cylinders). The hydrophobic regions that connect TM5 and TM6 in each segment associate to form the pore of the channel. Segment 4 in each domain includes the voltage sensor. (Adapted with permission from Catterall W. *Neuron* **2000**, *26*:13–25. © Elsevier.) **B.** *Structural diversity of K^+ channels. Inward rectifier, K_{ir}.* The basic subunit of the inwardly rectifying K^+ channel protein K_{ir} has the general configuration of TM5 and TM6 of a segment of the α subunit shown in panel **A**. Four of these subunits assemble to create the pore. *Voltage-sensitive K^+ channel, K_v.* The α subunits of the voltage-sensitive K^+ channel K_v and the rapidly activating K^+ channel K_A share a hexaspanning structure resembling in overall configuration a single segment of the Na^+ and Ca^{2+} channel structure, with six TM domains. Four of these assemble to form the pore. Regulatory β subunits (cytosolic) can alter K_v channel functions. **C.** *Multisubunit assembly of Ca^{2+} channels.* Ca^{2+} channels variably require several auxiliary small proteins (α_2, β, γ, and δ); α_2 and δ subunits are linked by a disulfide bond. Likewise, regulatory subunits also exist for Na^+ channels. **D.** *Ionic gradients across a mammalian nerve cell membrane.* The kidney is the primary regulator of the extracellular ionic environment. Active transport of cations and the relatively selective permeabilities of ion channels maintain the intracellular milieu. In this figure, the numbers below the various ions are resting state concentrations in mM; the large bold lettering of the elements indicates the location of the higher concentration of the ion; the red and green arrows indicate the direction of the electrical and concentration gradients. In the resting state, Na^+ channels are closed, K^+ channels are open, and the membrane potential approaches the Nernst potential for K^+. The opening of Na^+ channels results in depolarization. In contrast, the K^+ gradient is such that increased permeability to K^+ results in *hyperpolarization*. Changes in the concentration of intracellular Ca^{2+} (entry via Ca^{2+} channels and mobilization of Ca^{2+} sequestered in the cell) affect multiple cellular processes and are critical for the release of neurotransmitters. Cl^- flows through membrane channels, a large fraction of which are gated by GABA or glycine. Activation of neuronal $GABA_A$ receptors generally leads to a net influx of Cl^-, resulting in membrane hyperpolarization and inhibition of depolarization. The equilibrium potential for Cl^- is relatively close to the membrane resting potential, and small changes in cellular Cl^-, the membrane potential, and the activities of Cl^- transporters (e.g., KCC2 and NKCC1) can influence transmembrane Cl^- movements.

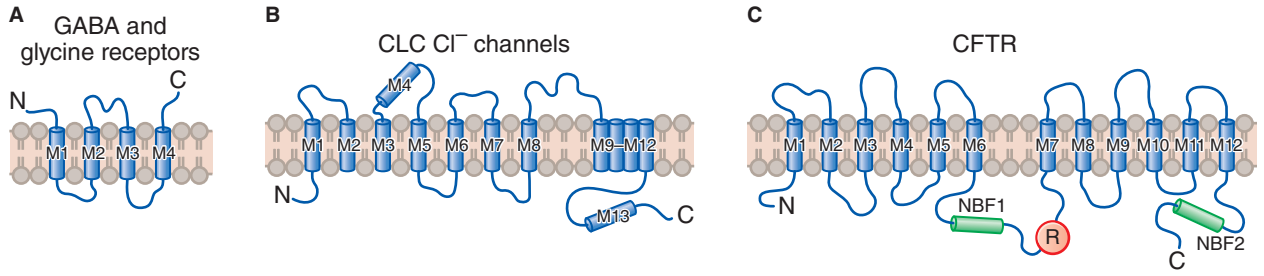


Figure 16–3 *Families of Cl⁻ channels.* Due to the Cl^- gradient across the plasma membrane (~116 mM outside vs. 20 mM inside the cell), activation of Cl^- channels causes an inhibitory postsynaptic potential (IPSP) that dampens neuronal excitability; inactivation of these channels can lead to hyperexcitability. There are three distinct types of Cl^- channels. **A.** *Ligand-gated channels* are linked to inhibitory transmitters, including GABA and glycine. These channels are pentamers that are composed of differing subunits that each have four transmembrane domains as shown (discussed below). **B.** *CLC Cl^- channels* affect Cl^- flux, membrane potential, and the pH of intracellular vesicles. **C.** *CFTR channels* bind ATP and are regulated by phosphorylation of serine residues. M, transmembrane domains; NBF, nucleotide-binding fold; R, regulatory (phosphorylation) domain. (Adapted with permission from Jentsch J. Chloride channels: a molecular perspective. *Curr Opin Neurobiol,* **1996**, *6*:303-310. Copyright Elsevier.)

- Neurotransmitter synthesis. Small-molecule neurotransmitters are synthesized in nerve terminals, whereas others, such as peptides, are synthesized in cell bodies and transported to nerve terminals.
- Neurotransmitter storage. Synaptic vesicles store transmitters, often in association with various proteins and frequently with ATP.

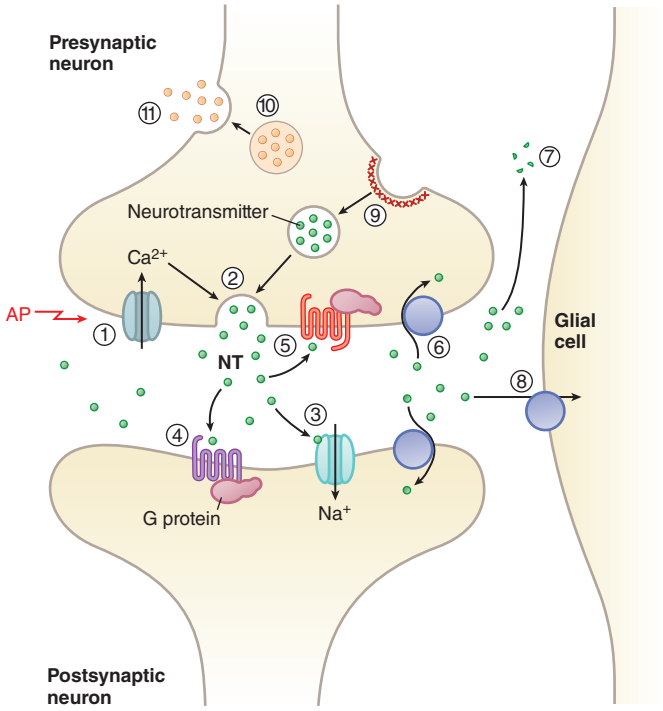

Figure 16–4 *Transmitter release, action, and inactivation.* Depolarization opens voltage-dependent Ca^{2+} channels in the presynaptic nerve terminal (1). The influx of Ca^{2+} during an action potential (AP) (2) triggers the exocytosis of small synaptic vesicles that store neurotransmitter (NT). Released neurotransmitter interacts with receptors in the postsynaptic membranes that either couple directly with ion channels (3) or act through second messengers, such as GPCRs (4). Neurotransmitter receptors in the presynaptic nerve terminal membrane (5) can inhibit or enhance subsequent exocytosis. Released neurotransmitter is inactivated by reuptake into the nerve terminal by (6) a transport protein coupled to the Na^+ gradient (e.g., for DA, NE, or GABA), which can also be found in the postsynaptic membrane, or by (7) degradation (ACh, peptides), or by (8) transporter-facilitated uptake and metabolism by glial cells (glutamate). The synaptic vesicle membrane is recycled by (9) clathrin-mediated endocytosis. Neuropeptides and proteins are sometimes stored in (10) larger, dense core granules within the nerve terminal. These dense core granules can be released from sites (11) distinct from active zones after repetitive stimulation.

- Neurotransmitter release. Release of transmitter into the synaptic cleft occurs by exocytosis. Depolarization of the presynaptic neuron results in a complex initiation of stimulus-secretion coupling, which involves vesicle docking at the plasma membrane, followed by the formation of membrane fusion/release complexes, and culminates in the Ca^{2+}-dependent release of vesicle contents.
- Neurotransmitter recognition. Neurotransmitters diffuse from sites of release and bind selectively to receptor proteins to initiate intracellular signaling events within the postsynaptic cell.
- Termination of action. A variety of mechanisms terminate the action of synaptically released transmitters, including diffusion from the synapse, enzymatic inactivation (for acetylcholine and peptides), and uptake into neurons and/or glial cells by specific transporters.

Fast Neurotransmission

Responses to activation of receptors consisting of an ion channel as part of its structure tend to be very rapid (milliseconds) since the effects are direct and generally do not require multiple steps leading to second messenger activation. In fast neurotransmission (also called directly gated transmission), neurotransmitters bind directly to ligand-gated ion channels on the postsynaptic membrane to rapidly open the channel and change the permeability of the postsynaptic site leading to depolarization or hyperpolarization. Depolarization results in continuation of the nerve impulse, whereas hyperpolarization leads to diminished signaling (see Figure 13–5).

Ligand-gated ion channels mediating fast transmission (also called ionotropic receptors) are composed of multiple subunits, each usually having four transmembrane domains (Figure 16–5). Receptors with this structure include nicotinic cholinergic receptors, normally activated by acetylcholine (ACh; one subtype of which is responsible for muscle contraction via the neuromuscular junction); the receptors for the amino acids GABA, glycine, glutamate, and aspartate; and the serotonin $5HT_3$ receptor. The nicotinic ACh receptor provides a good example of receptor structure and how subunit composition varies with anatomic location and affects function (Figure 16–6).

Slow Neurotransmission

Slower transmission (although still relatively fast, often on a time scale of seconds) is mediated by neurotransmitters that do not bind to ion channels but to receptors with a very different architecture that generate second messengers upon activation (also called metabotropic receptors). This major group of receptors are the GPCRs that contain seven transmembrane spanning domains (Figure 16–7). GPCRs typically contain sites for N-linked glycosylation on their extracellular amino tail and sometimes on their second extracellular loop. There are also multiple potential sites for phosphorylation, often by PKA and PKC, on the third intracellular loop and the carboxyl tail. Phosphorylation can regulate GPCR–G protein-effector coupling and provide docking sites for arrestins and scaffolding proteins. Some GPCRs are palmitoylated on the carboxyl tail (see Figure 16–7). There are more

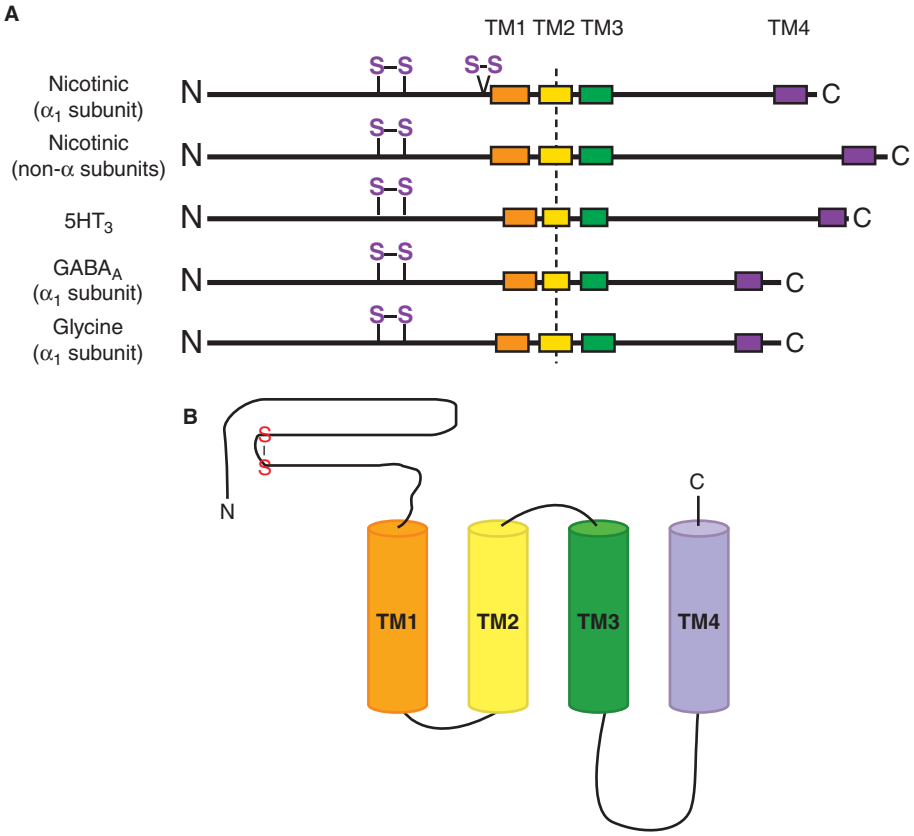

Figure 16–5 *Pentameric ligand-gated ion channels.* The subunits of these channels, which mediate fast synaptic transmission, are embedded in the plasma membrane to form a roughly cylindrical structure with a central pore. In response to binding of transmitter, the receptor proteins change conformation; the channel gate opens, and ions diffuse along their concentration gradient across the membrane through a hydrophilic opening in the otherwise-hydrophobic membrane. **A.** *Subunit organization.* For each subunit of these pentameric receptors, the amino terminal region of approximately 210 amino acids is extracellular. It is followed by four hydrophobic regions that span the membrane (TM1–TM4); a small carboxyl terminus is on the extracellular surface. The TM2 region is α helical, and TM2 regions from each subunit line the internal pore of the pentameric receptor. Two disulfide loops at positions 128–142 and 192–193 are found in the α subunit of the nicotinic receptor. The 128–142 motif is conserved in the family of pentameric receptors; the vicinal cysteines at 192–193 occur only in α subunit of the nicotinic receptor. **B.** *Schematic rendering of a nicotinic ACh receptor α subunit.* Five such subunits form a pentameric receptor. See Figure 16–6 for an example.

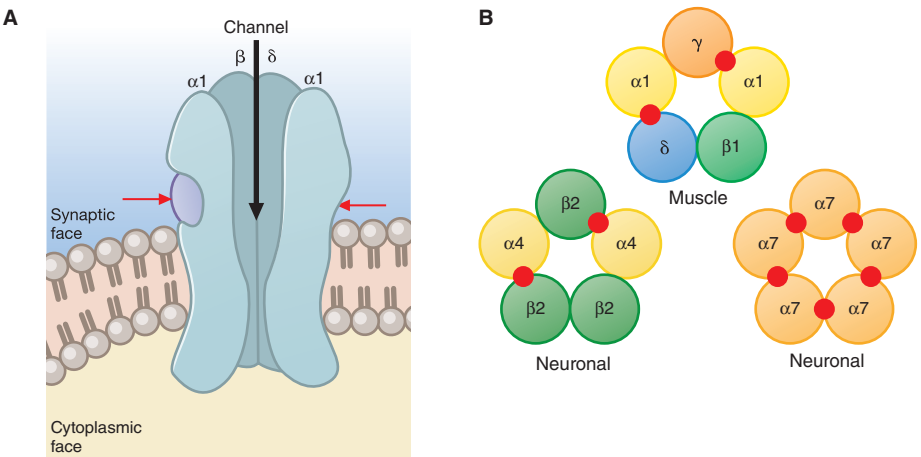

Figure 16–6 *Subunit arrangement: the nicotinic ACh receptor.* **A.** *Longitudinal view of receptor schematic with the γ subunit removed.* The remaining subunits, two copies of α, one of β, and one of δ, are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α helices with slightly bowed structures form the perimeter of the channel and come from the TM2 region of the linear sequence (see Figure 16–5). ACh-binding sites, indicated by red arrows, occur at the αγ and αδ (not visible) interfaces. **B.** *Nicotinic receptor subunit arrangements.* Agonist-binding sites (red circles) occur at α subunit–containing interfaces. At least 17 functional receptor isoforms have been observed *in vivo*, with different ligand specificity, relative Ca^{2+}/Na^{+} permeability, and physiological function determined by their subunit composition. The only isoform found at the neuromuscular junction is shown for comparison. The neuronal receptor isoforms found at autonomic ganglia and in the CNS are homomeric or heteromeric pentamers of α (α_2–α_{10}) and β (β_2–β_4) subunits.

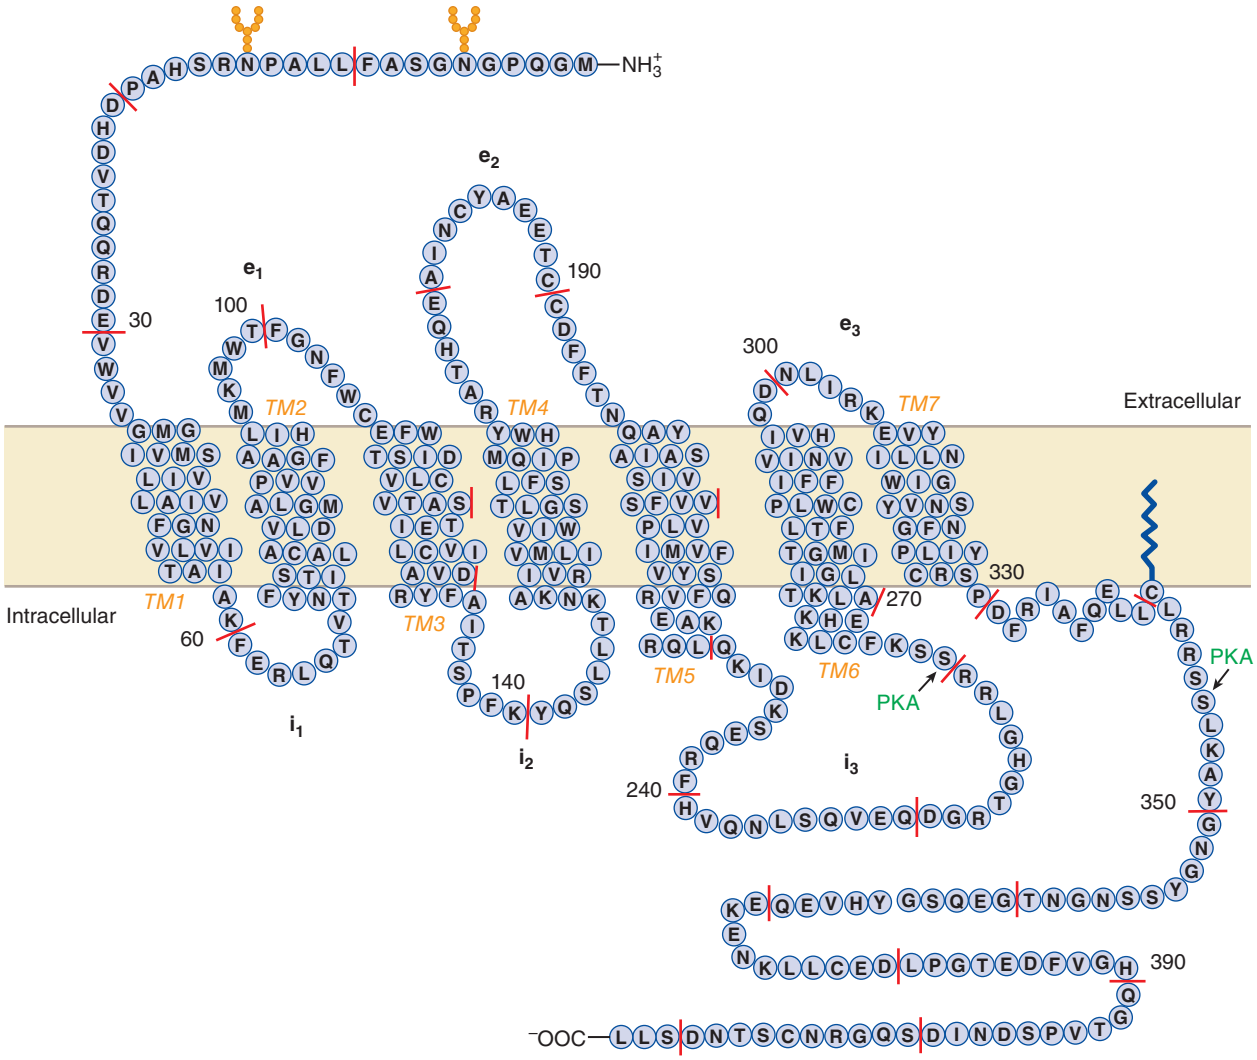

Figure 16–7 *The β adrenergic receptor as a model for GPCRs.* This two-dimensional model illustrates features common to most GPCRs. Red lines mark 10–amino acid regions. The amino terminus (N) is extracellular and the carboxyl terminus (C) is intracellular; in between are seven hydrophobic transmembrane (TM) domains and alternating intracellular and extracellular loops (e_{1-3} and i_{1-3}). Glycosylation sites are found near the N terminus; consensus sites for phosphorylation by PKA (*arrows*) are found in the i_3 loop and the carboxyl terminal tail. An aspartate residue in TM_3 (Asp^{113}) interacts with the nitrogen of catecholamine agonists while two serines (Ser^{204}, Ser^{207}) in TM_5 interact with the hydroxyl groups on the phenyl ring of catecholamine agonists. A cysteine residue (Cys^{341}) is a substrate for palmitoylation. Interaction of the palmitoyl group with membrane lipids reduces the flexibility of the carboxyl tail. (Figure modified with permission from Rasmussen SGF et al. Crystal structure of the human β_2 adrenergic G-protein-coupled receptor. *Nature*, **2007**, *450*:383. Copyright © 2007.)

than 800 human GPCRs, which can be classified into five major families in vertebrates: rhodopsin (class A); secretin (class B); glutamate (class C); adhesion; and frizzled/taste receptor 2 (TAS2) (class F) (Stevens et al., 2013). These families can be further divided into subfamilies based on amino acid sequence similarities (see Figure 3–14).

GPCRs are associated with a broad spectrum of physiological effects including activation of K^+ channels, activation of phospholipase (PL) C–inositol 1,4,5-trisphosphate (IP_3)–Ca^{2+} pathways, and modulation of adenylyl cyclase activity and downstream systems affected by cyclic AMP. These effects are typically mediated through the activation of specific G proteins, each a heterotrimer of α, β, and γ subunits where the β and γ units are constitutively associated. The GTP-binding α subunits can modulate the activities of numerous effectors (e.g., adenylyl cyclase, PLC). The βγ subunits are also active in mediating signaling, especially in the regulation of ion channels. Table 16–1 shows examples of the variety of physiological functions mediated by G proteins. Notably, GPCRs can also signal to downstream pathways through other intermediary proteins, such as the β-arrestins (Shukla et al., 2011; van Gastel et al., 2018). Drugs targeting GPCRs represent a core of modern medicine and comprise over one-third of all pharmaceuticals.

Central Neurotransmitters

CNS transmitters are classified by chemical structure into various categories including amino acids, acetylcholine, monoamines, neuropeptides, purines, and gases. This section describes each category and examines some prominent members and their receptors.

Amino Acids

The CNS contains high concentrations of certain amino acids that potently alter neuronal firing. They are ubiquitously distributed within the brain and produce rapid and readily reversible effects on neurons. The dicarboxylic amino acids, glutamate and aspartate, produce excitation, while the monocarboxylic amino acids, γ-aminobutyric acid (GABA), glycine, β-alanine, and taurine, cause inhibition. The effects of glutamate and GABA are especially notable. Following the emergence of selective agonists and antagonists, the identification of pharmacologically distinct amino acid receptor subtypes became possible (see below). Figure 16–8 shows these amino acid transmitters and their drug congeners.

TABLE 16–1 ■ G PROTEIN-MEDIATED SIGNALING

FAMILY	α SUBUNITS	SIGNALS TRANSDUCED
Family Members		
G_s family		
G_s	α_s	Activation of AC
G_{olf}	α_{olf}	Activation of AC
G_i family		
G_i/G_o	α_i, α_o	Inhibition of AC
G_z	α_z	Inhibition of AC
G_{gust} (gustducin)	α_{gust}	Activation of PDE6
G_t (transducin)	α_t	Activation of PDE6
G_q family		
G_q	α_q, α_{11}, α_{14}, α_{15}, α_{16}	Activation of PLC
$G_{12/13}$ family		
$G_{12/13}$	α_{12}, α_{13}	Activation of Rho GTPases
βγ Subunits (acting as a heterodimer)		
G_β	β1, β2, β3, β4, β5	↓ AC, ↑ Ca^{2+} and K^+ channels, ↑ PI3K, ↑ PLC_β, ↑AC2 and AC4, ↑ Ras-dependent MAPK activation, ↑ recruitment of GRK2 and GRK3
G_γ	γ1, γ2, γ3, γ4, γ5, γ7, γ8, γ9, γ10, γ11, γ12, γ13	

Glutamate and Aspartate

Glutamate and aspartate are found in high concentrations in brain, and both amino acids have powerful excitatory effects on neurons in virtually every region of the CNS. Glutamate is the most abundant excitatory neurotransmitter and serves as the principal fast excitatory neurotransmitter. Glutamate acts through receptors that are classed as either *ligand-gated ion channels (ionotropic)* or *metabotropic GPCRs* (Table 16–2). A well-characterized phenomenon involving glutamate transmission is the induction of long-term potentiation and its converse, long-term depression. These phenomena are known for strengthening and weakening synapses and have long been hypothesized to be important mechanisms in learning and memory and other processes that depend on adaptive changes within the brain.

Ionotropic glutamate receptors are ligand-gated ion channels that were historically divided into three classes, including *N*-methyl-D-aspartate (NMDA) receptors, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, and kainic acid (KA) receptors, which are named for their preferred synthetic ligands. With the discovery of an increasing number of subunits comprising these receptor categories, the classification has recently been refined (see Table 16–2).

NMDA receptors consist of heteromers that are made up of multiple subunit combinations (termed GluN*x*) with the minimal receptor being a dimer of the GluN1 subunit and at least one GluN2 subunit; more complex heteromeric complexes are generated by incorporating multiple subunits. The NMDA receptors have relatively high permeability to Ca^{2+} and are blocked by Mg^{2+} in a voltage-dependent manner. NMDA receptors are unique in that their activation requires the simultaneous binding of two different agonists; in addition to glutamate, glycine binding is necessary for activation (Figure 16–9). While NMDA receptors are involved in normal synaptic transmission, their activation is more closely associated with the induction of various forms of synaptic plasticity rather than fast point-to-point signaling in the brain.

Aspartate is also a selective NMDA receptor agonist. Other NMDA receptor ligands include open-channel blockers such as *phencyclidine* (PCP or "angel dust") and *ketamine*; antagonists include 5,7-dichlorokynurenic acid, which acts at an allosteric glycine-binding site, and *ifenprodil*, which selectively inhibits NMDA receptors containing GluN2B subunits. *Ketamine*, which is a racemic mixture of *R* and *S* enantiomers, has attracted interest for the treatment of drug-resistant depression. In fact, the *S* enantiomer of *ketamine* (*esketamine*) has recently been introduced to the marketplace, although controversy exists as to whether *esketamine* is clinically more efficacious than the *R* isomer of *ketamine* or the racemic mixture itself. The clinical effects of *ketamine* are thought to be due in part to its NMDA receptor antagonism; see Figure 18–2 for a schematic of possible effects of *ketamine* at a glutamatergic synapse.

The activity of NMDA receptors is sensitive to pH and to modulation by a variety of endogenous agents including Zn^{2+}, some neurosteroids, arachidonic acid, redox reagents, and polyamines such as spermine (see Figure 16–9).

AMPA receptors exist predominantly as heterotetramers and contain multiple subunits (termed GluA*x*) (see Table 16–2). In addition, there are transmembrane AMPA receptor regulatory proteins (TARPs), which, together with a variety of scaffolding and regulatory proteins, modulate channel properties and alter the trafficking of receptors to and from perisynaptic and postsynaptic regions. AMPA receptors open and close rapidly, making them well-suited to mediate the majority of excitatory synaptic transmission in the brain and, like NMDA receptors, they are involved in synaptic plasticity. AMPA receptors can be selectively antagonized by NBQX (2,3-dioxo-6-nitro-7-sulfamoyl-benzo[f]quinoxaline); and CNQX (6-cyano-7-nitroquinoxaline-2,3-dione), and similar antagonists are being explored as neuroprotective drugs for the treatment of stroke.

KA receptors are composed of a distinct array of subunits (termed GluK*x*) that assemble as homo- or heterotetramers to form functional receptors. An important difference between KA and AMPA receptors is that KA receptors require extracellular Na^+ and Cl^- for activation. KA receptors differ functionally from AMPA and NMDA receptors in other important ways. KA receptors do not reside predominantly within postsynaptic signaling complexes and are positioned to modulate neuronal excitability and synaptic transmission by altering the likelihood that the postsynaptic cell will fire in response to subsequent stimulation. Presynaptic KA receptors have also been implicated in modulating GABA release through presynaptic mechanisms.

Glutamate-mediated excitotoxicity may underlie the damage that occurs when ischemia or hypoglycemia in the brain leads to a massive release and impaired reuptake of glutamate resulting in excess stimulation of glutamate receptors and subsequent cell death. The cascade of events leading to neuronal death seems to be triggered by excessive activation of NMDA or AMPA/KA receptors, allowing an excessive influx and mobilization of Ca^{2+} in neurons. A general picture of glutamate-mediated excitotoxicity is emerging. In overview, the influx of Ca^{2+} is thought to promote oxidation within the cell (↑ nitric oxide/peroxynitrite, ↓ glutathione, ↑ reactive oxygen species), resulting in lipid peroxidation, destabilization of lysosomes, and damage to mitochondria and ultimately leading to cell death via apoptosis and by cathepsin- and calpain-dependent pathways (Kritis et al., 2015). NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors. Glutamate receptors have become targets for diverse therapeutic interventions. For example, a role for disordered glutamatergic transmission in the etiology of chronic neurodegenerative diseases has been postulated (see Chapter 21).

Metabotropic glutamate receptors (mGluRs) are GPCRs structurally defined by the presence of a large N-terminal domain that is linked via a cysteine-rich region to a seven-transmembrane spanning domain that is typical of other GPCRs (Nasrallah et al., 2021). Like all class C GPCRs, these receptors function as obligate dimers. Orthosteric agonists, including glutamate, and antagonists bind to the N-terminal domain, whereas allosteric modulators typically interact within the seven-transmembrane spanning domain. G proteins and β-arrestins engage the cytoplasmic surface of the activated mGluR (Figure 16–10). There are eight unique mGluRs organized into three subgroups (see Table 16-2). mGluRs bind glutamate and function to fine-tune excitatory and inhibitory transmission by presynaptic, postsynaptic, and glial mechanisms, including the

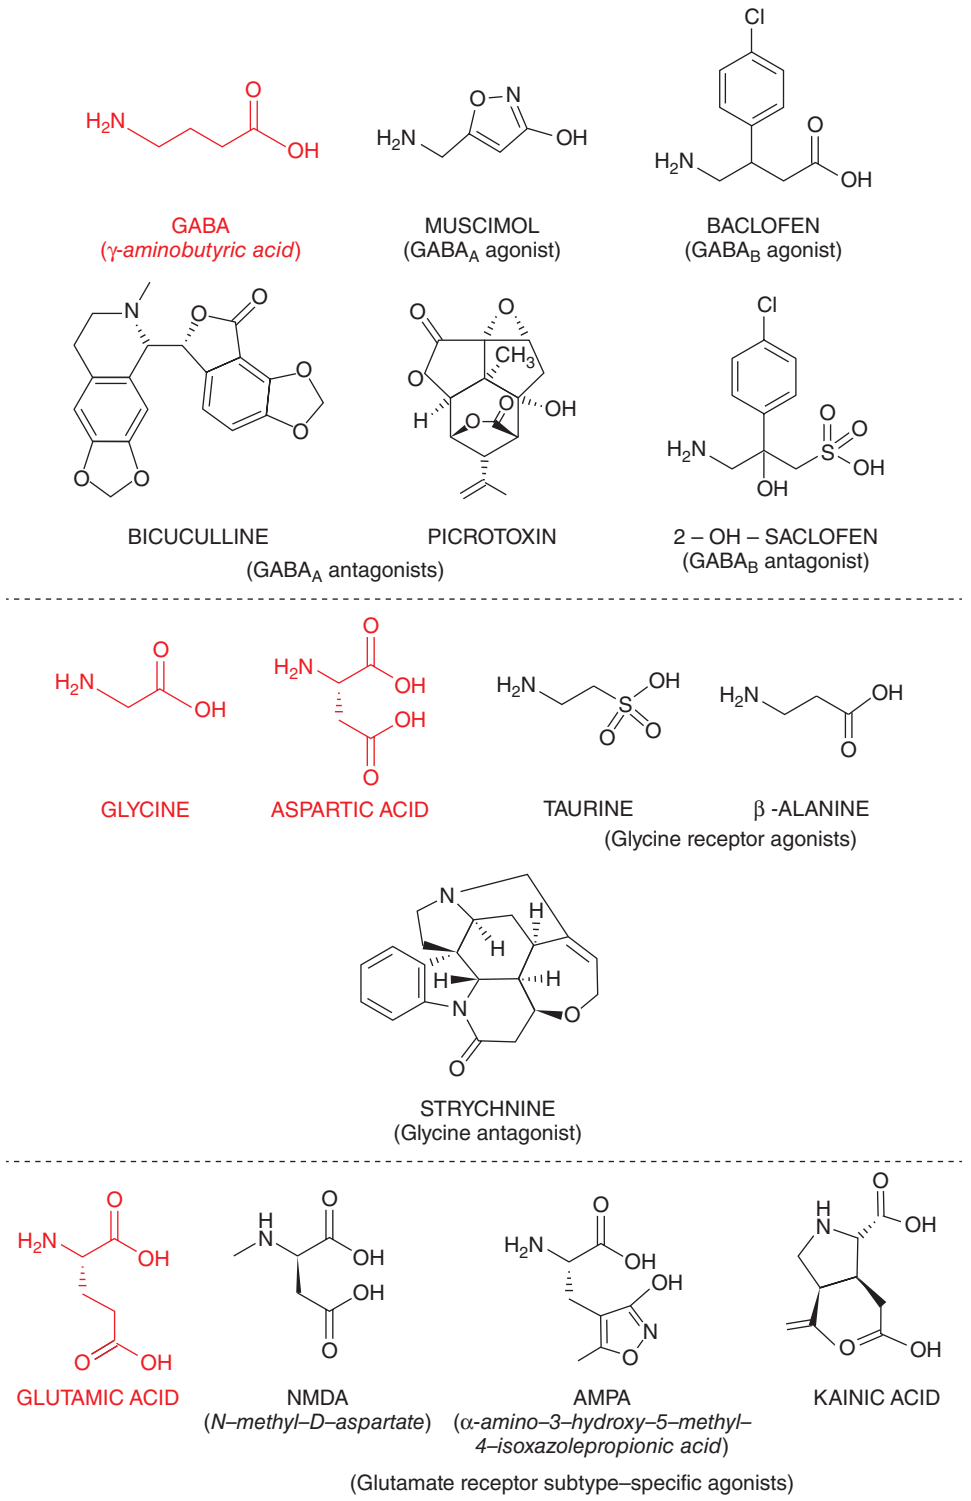

Figure 16–8 *Amino acid transmitters (red) and congeners (black).*

modulation of release and signaling of other neurotransmitters including GABA, purines, dopamine, serotonin (5-hyroxytryptamine [5HT]), and neuropeptides. Group I mGluRs couple to G_q activation, while groups II and III are known to couple to G_i/G_o. mGluRs are located in a variety of brain regions and sometimes linked to opposing functional responses. In general, group I receptors increase neuronal excitability, whereas both group II and group III suppress excitability. They are known to play a role in the modulation of other receptors and to function in synaptic plasticity.

In the past few years, researchers have made significant progress in determining the mechanisms of mGluR activation and the proteins mGluRs interact with and in developing both orthosteric and allosteric ligands to modulate receptor activity. Widespread expression of mGluRs, their capacity to modulate presynaptic neurotransmission in a dynamic and activity-dependent manner, and the availability of subtype-selective and pharmacologically novel *negative* and *positive allosteric modulators* (NAMs and PAMs) make these receptors attractive targets for the treatment of cognitive impairment related to several psychiatric and neurodegenerative diseases. Studies now suggest that ligands for specific mGluR subtypes have potential for the treatment of multiple CNS disorders, including anxiety disorders, schizophrenia, Alzheimer's disease, and Parkinson's disease. For example, studies have shown high involvement of $mGluR_5$ in anxiety disorders as this receptor increases neuronal

TABLE 16–2 ■ CLASSIFICATION OF GLUTAMATE RECEPTORS

FAMILY	SUBTYPE	AGONISTS	ANTAGONISTS	
Ionotropic				
NMDA	GluN1, GluN2A, GluN2B, GluN2C, GluN2D, GluN3A, GluN3B	NMDA, aspartate	D-AP5, 2R-CPPene, MK-801, ketamine, phencyclidine, D-aspartate	
AMPA	GluA1, GluA2, GluA3, GluA4	AMPA, kainate, (s)-5-fluorowillardiine	CNQX, NBQX, GYK153655

Metabotropic				
				SIGNALING
Group I	$mGlu_1$, $mGlu_5$	3,5-DHPG, quisqualate	AIDA S-(+)-CBPG	Activation of PLC (G_q)
Group II	$mGlu_2$, $mGlu_3$	APDC, MGS0028 DCG-IV, LY354740	EGLU PCCG-4	Inhibition of AC (G_i/G_o)
Group III	$mGlu_4$, $mGlu_6$, $mGlu_7$, $mGlu_8$	L-AP4, (RS)-PPG	CPPG, MPPG, MSOP, LY341495	Inhibition of AC (G_i/G_o)

AIDA, 1-aminoindan-1,5-dicarboxylic acid; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; L-AP4, L-2-amino-4-phosphonobutiric acid; ATPA, 2-amino-3(3-hydroxy-5-tert-butylisoxa-zol-4-yl)propanoic acid; CBPG, (S)-(+)-2-(3-carboxybicyclo(1.1.1)pentyl)-glycine; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; D-AP5, D-2-amino-5-phosphonovaleric acid; DCG-IV, (2S,2′R,3′R)-2-(2′,3′-Dicarboxycyclopropyl)glycine; (S)-3,4-DCPG, (S)-3,4-dicarboxyphenylglycine; 3,5-DHPG, 3,5-dihydroxyphenylglycine; EGLU, (2S)-α-ethylglutamic acid; MPPG, (RS)-α-methyl-4-phosphonophenylglycine; MSOP, (RS)-α-methylserine-O-phosphate; NBQX, 1,2,3,4-tetrahydro-6-nitro-2,3-dioxo-benzo[f] quinoxaline-7-sulfonamide; NMDA, *N*-methyl-D-aspartate; PCCG-4, phenylcarboxycyclopropylglycine; (RS)-PPG, (RS)-4-phosphonophenylglycine.
Glutamate is the principal agonist at both ionotropic and metabotropic receptors for glutamate and aspartate.

excitability and NMDA receptor currents, leading to the hypothesis that an antagonist of $mGluR_5$ might dampen the hyperactivity. Consistent with this, $mGluR_5$ NAMs have robust efficacy in several animal models of anxiolytic activity, and the clinically validated anxiolytic agent *fenobam* acts as a selective $mGluR_5$ NAM. In addition, group III mGluRs (i.e., $mGluR_4$, $mGluR_7$, and $mGluR_8$) are expressed in GABAergic and glutamatergic terminals, and agonists and PAMs for these receptors can inhibit the release of both glutamate and GABA in Parkinson's disease, thereby opposing glutamate hyperactivity in this disorder. $mGluR_4$ PAMs reduce motor symptoms in animal models of Parkinson's disease and may play a role in neuroprotection and enrichment of motor responses to low doses of L-DOPA. Similarly, inhibition of presynaptic glutamate release has been implicated as a target for other excitation-toxicity–associated disorders such as Huntington's disease. There is also growing evidence that group II mGluRs may play a role in the cognitive decline seen with schizophrenia. Together these findings highlight the diverse roles that this receptor family can play in the modulation of CNS signaling while providing an opportunity for the development of novel therapeutics for the treatment of neurodegenerative and neuropsychiatric conditions (Crupi et al., 2019).

Gamma-Aminobutyric Acid

GABA (see Figure 16–8) is the main inhibitory neurotransmitter in the CNS. GABA is synthesized in the brain beginning with the Krebs cycle at the point where α-ketoglutarate is transaminated to glutamate by GABA transaminase (GABA-T). GABA is subsequently formed from glutamate by glutamic acid decarboxylase; the presence of glutamic acid decarboxylase in a neuron therefore delineates a neuron that uses GABA as a transmitter. Interestingly, intraneuronal GABA is also inactivated by GABA-T to succinic semialdehyde, but only in the presence of α-ketoglutarate. This GABA shunt serves to maintain levels of GABA, making GABA-T both a synthesis and degradative enzyme (Brady et al., 2012). There is a vesicular GABA transporter (VGAT) that is involved in vesicular storage of GABA for release into the synaptic cleft. The action of GABA is primarily terminated by reuptake by one of four different GABA transporters (GATs) present on both neurons and glia. GABA acts by binding to and activating specific ionotropic or metabotropic receptors on both pre- and postsynaptic membranes. *$GABA_A$ receptors*, the most prominent GABA receptor subtype, are ionotropic ligand-gated Cl^- channels. The *$GABA_B$ receptors* are metabotropic GPCRs. One subtype formerly known

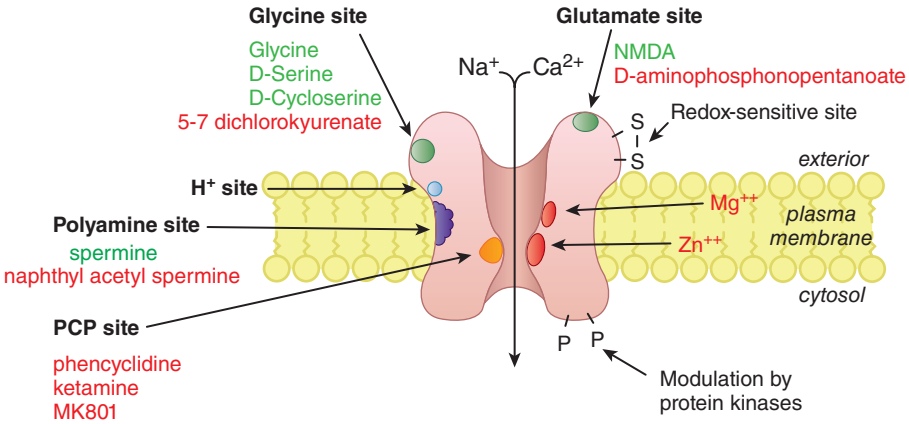

Figure 16–9 *Pharmacological binding sites on the NMDA receptor.* Agents that promote receptor function are shown in green. Those that inhibit receptor function appear in red. Binding of both glutamate and glycine is necessary for activation.

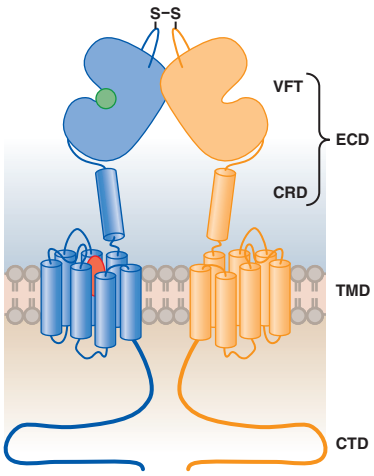

Figure 16–10 *General structure of metabotropic glutamate receptors.* Functional metabotropic glutamate receptors (mGluRs) are GPCRs that exist as obligate dimers, both homodimers and heterodimers. Each monomer possesses a large extracellular N-terminal domain (ECD) comprising the Venus flytrap domain (VFT) that contains the orthosteric binding site for glutamate (green dot in the cleft of the VFT) and a cysteine-rich domain (CRD) that links the VFT to the seven-transmembrane domain (TMD). Disulfide bonds between regions of adjacent VFTs facilitate dimerization. The TMD contains binding sites for allosteric modulators (red dot). The TMD and the C-terminal domain (CTD) together regulate G protein coupling. The long CTD (40–380 amino acids) may also facilitate regulatory interactions with protein kinases and scaffolding proteins. (Reproduced with permission from McCullock TW, Kammermeier PJ. The evidence for and consequences of metabotropic glutamate receptor heterodimerization. *Neuropharmacology,* **2021**, *199*:108801. Copyright © Elsevier Ltd.)

as the *$GABA_C$ receptor* is now classified as a type of $GABA_A$ receptor based on structural and functional criteria.

$GABA_A$ receptors have been extensively characterized as important drug targets and are the site of action of many neuroactive drugs, notably benzodiazepines (such as *diazepam*), barbiturates, ethanol, anesthetic steroids, and volatile anesthetics among others (Figure 16–11). These drugs are used to treat various neuropsychiatric disorders including epilepsy, Huntington's disease, addictions, sleep disorders, and more. The $GABA_A$ receptors are pentamers of subunits that each contain four transmembrane domains and assemble around a central ion-permeable pore (Figures 16–3 and 16–5), which is selective for Cl^- in the case of the $GABA_A$ receptor. The major forms of the $GABA_A$ receptor contain

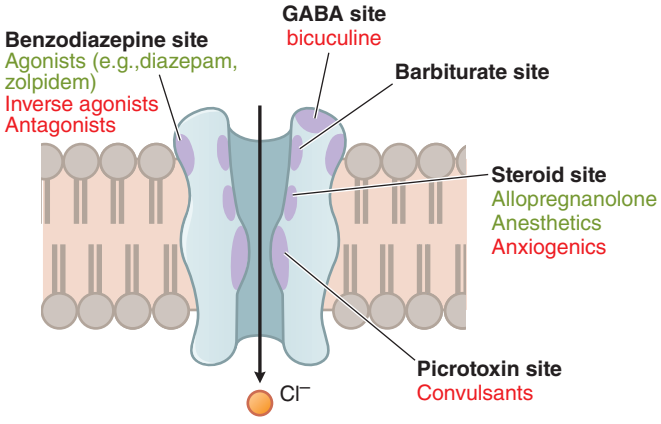

Figure 16–11 *Pharmacologic binding sites on the $GABA_A$ receptor.* GABA binds at the orthosteric site on the $GABA_A$ receptor. Other sites noted are modulatory in nature, at which allosteric agonists or antagonists may promote (green) or inhibit (red) receptor function. (Reproduced with permission from Nestler EJ, Hyman SE, Holtzman DM, Malenka RC, eds. *Molecular Neuropharmacology: A Foundation for Clinical Neuroscience,* 3rd ed. McGraw Hill, New York, **2015**.)

at least three different types of subunits: α, β, and γ, with a likely stoichiometry of 2α, 2β, 1γ. The IUPHAR/British Pharmacological Society recognizes 19 unique subunits that are known to form 11 native $GABA_A$ receptors that can be pharmacologically differentiated. Of interest is that the particular combination of the α and γ subunits can affect the efficacy of benzodiazepine binding and channel modulation. Many drugs, such as benzodiazepines and volatile anesthetics, act as positive allosteric modulators of the $GABA_A$ receptor (i.e., act at a site distinct from the GABA binding site to positively modulate the function of the receptor). The high-resolution cryo-electron microscopy structures of the α1β3γ2L $GABA_A$ receptor bound to the agonist GABA and the classical benzodiazepines, *alprazolam* and *diazepam*, have been solved and utilized to further deduce signaling mechanisms of this group of receptors (Masiulis et al., 2019). *Brexanolone* is a neuroactive steroid that is a PAM at $GABA_A$ receptors and is approved to treat postpartum depression. The interaction of various drugs with the $GABA_A$ receptor and their therapeutic uses are presented in Chapter 18.

$GABA_B$ receptors are metabotropic GPCRs that function as obligate heterodimers of two subunits named $GABA_{B1}$ and $GABA_{B2}$. $GABA_B$ receptors are widespread in the CNS and regulate both pre- and postsynaptic activity. These receptors interact with G_i to inhibit adenylyl cyclase, activate K^+ channels, and reduce Ca^{2+} conductance, and with G_q to enhance PLC activity. Presynaptic $GABA_B$ receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. A number of $GABA_B$ agonists have been identified, including *baclofen* (see Figure 16–8), a skeletal muscle relaxant, and the psychoactive drug *gamma-hydroxybutyric acid* (GHB), which is sometimes used to treat narcolepsy and also used recreationally as an intoxicant.

Glycine

Glycine (see Figure 16–8) is an amino acid normally incorporated into proteins that can also act as an inhibitory neurotransmitter, particularly in the spinal cord and brainstem. Glycine is synthesized primarily from serine by the enzyme serine hydroxymethyltransferase. Glycine enters synaptic vesicles via VGAT, the same vesicular transport system used by GABA. The action of glycine in the synaptic cleft is terminated by reuptake through specific transporters (GLYT1 and GLYT2) located on presynaptic nerve terminals and glial cells. These transporters can be pharmacologically differentiated and present an attractive therapeutic target for the modulation of glycine levels; this is an active area of research, especially considering that there are glycine binding sites on NMDA receptors. Glycine acts as a co-agonist at NMDA receptors such that both glutamate and glycine must be present for activation to occur (see above). In addition to the NMDA receptor site, there are specific ionotropic glycine receptors that contain many of the structural features described for other ligand-gated ion channels (pentamers of subunits containing four transmembrane domains). These function as hyperpolarizing Cl^- channels and are prominent in the brainstem and spinal cord. There are four known α subunits and a single β subunit that assemble into a variety of glycine receptor subtypes. Taurine and β-alanine are agonists of glycine receptors; strychnine, a potent neurotoxin, is a selective antagonist (see Figure 16–8).

Acetylcholine

Acetylcholine (ACh), the first neurotransmitter discovered, occurs throughout the nervous system and functions as a neurotransmitter. It plays a primary role in the autonomic nervous system in ganglionic transmission and in innervation of autonomic effector cells by parasympathetic postganglionic fibers; ACh is also the neurotransmitter of the somatic motor nerves that innervate skeletal muscle in vertebrates (see Figure 10–2). In the CNS, ACh is found primarily in interneurons. ACh is synthesized by choline acetyltransferase and stored in vesicles in the nerve endings (see Figure 10–6). Following release and receptor activation, it is degraded by acetylcholinesterase (see Chapter 12). The effects of ACh result from interaction with two broad classes of receptors: ionotropic ligand-gated ion channels termed nicotinic receptors and metabotropic

TABLE 16–3 ■ SUBTYPES OF MUSCARINIC RECEPTORS IN THE CNS

SUBTYPE	TRANSDUCER EFFECTOR	AGONISTS (EXAMPLES)	ANTAGONISTS (EXAMPLES)
M_1	G_q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine, McN-A-343	Pirenzepine, telenzepine, 4-DAMP, xanomeline
M_2	$G_{i/}G_o$ Inhibition of AC	Acetylcholine, carbachol, oxotremorine	AF-DX 116, AF-DX 384, AQ-RA 741, tolterodine, (S)-(+)-dimethindene maleate, methoctramine
M_3	G_q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine, cevimeline	Darifenacin, 4-DAMP, DAU 5884, J-104129, tropicamide, tolterodine
M_4	$G_{i/}G_o$ Inhibition of AC	Acetylcholine, carbachol oxotremorine	AF-DX384, 4-DAMP, PD 102807, xanomeline
M_5	G_q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine	4-DAMP, xanomeline, VU-0488130 (ML381)

Acetylcholine is the endogenous transmitter for all muscarinic receptors. Nonselective antagonists include atropine, scopolamine, and ipratropium. 4-DAMP, 1,1-dimethyl-4-diphenylacetoxypiperidinium iodide.

GPCRs called muscarinic receptors. In the CNS, the degeneration of cholinergic pathways is a hallmark of Alzheimer's disease.

Nicotinic ACh receptors are found in skeletal muscle (see Figure 16–6) as well as in autonomic ganglia, the adrenal gland, and the CNS. Their activation by ACh results in a rapid increase in the influx of Na^+, depolarization, and the influx of Ca^{2+}. Nicotinic receptors are pentamers consisting of various combinations of five of the 17 known subunits [$\alpha_{(1-10)}$ and $\beta_{(1-4)}$, γ, δ, ε] that can form the ion channel. In the CNS, nicotinic receptors are assembled as combinations of $\alpha_{(2-10)}$ and $\beta_{(2-4)}$ subunits. Pairwise combinations of α and β (e.g., $\alpha_3\beta_4$ and $\alpha_4\beta_2$) and, in at least one case, a homomeric α_7 are sufficient to form a functional receptor *in vitro*; however, more complex isoforms have been identified *in vivo* (see Figure 13–1). The subunit composition strongly influences the biophysical and pharmacological properties of the receptor. Comprehensive listings of nicotinic receptor subunit combinations and brain locations can be found in Zoli et al. (2015). These receptors have high therapeutic value, not only in the treatment of smoking cessation (as they are the primary receptors for nicotine; see Chapter 13), but also for other neurological pathologies (Papke and Horenstein, 2021).

Muscarinic ACh receptors are GPCRs consisting of five subtypes, all of which are expressed in the brain. M_1, M_3, and M_5 couple to G_q, while the M_2 and M_4 receptors couple to G_i/G_o (Table 16–3). Chapter 11 covers the physiology and pharmacology of muscarinic receptors and their agonist and antagonist ligands in detail.

Monoamines

Monoamines are neurotransmitters whose structure contains an amino group connected to an aromatic ring by a two-carbon chain. All are derived from aromatic amino acids and regulate neurotransmission that underlies cognitive processes, including emotion. Drugs that affect monoamine receptors and signaling are used to treat a variety of conditions such as depression, schizophrenia, and anxiety, as well as movement disorders like Parkinson's disease. Monoamines include dopamine (DA), norepinephrine (NE), epinephrine (EPI), histamine (H), serotonin (5HT), and the trace amines. Each system is anatomically distinct and serves separate functional roles within its field of innervation.

Dopamine

DA along with NE and EPI are catecholamine neurotransmitters (see Chapters 14 and 15). In contrast to its presence in the periphery, DA is the predominant catecholamine in the CNS. Its synthesis and degradation are discussed in Chapter 15.

There are three major DA-containing pathways in the CNS: the nigrostriatal, the mesocortical/mesolimbic, and the tuberoinfundibular (see Figure 15–3). These pathways mediate DA signaling and play a role in motivation and reward (most drugs of abuse increase DA signaling), motor control, and the release of various hormones. These effects are mediated by five distinct GPCRs grouped into two subfamilies: D1-like receptors (D_1 and D_5) that stimulate adenylyl cyclase activity via coupling to G_s or G_{olf} and D2-like receptors (D_2, D_3, and D_4) that couple to G_i/G_o to inhibit adenylyl cyclase activity and modulate various voltage-gated ion channels (see Figure 15–10). Dopamine receptor subtypes are discussed extensively in Chapter 15. DA-containing pathways and receptors have been implicated in the pathophysiology of schizophrenia and Parkinson's disease and in the side effects following the pharmacotherapy of these disorders (see Chapters 19 and 21).

Norepinephrine

Both α and β adrenergic receptor subtypes are present in the CNS; all are GPCRs (Table 16–4; see also Chapter 14). β Adrenergic receptors couple to G_s to activate adenylyl cyclase. α_1 Adrenergic receptors are coupled

TABLE 16–4 ■ ADRENERGIC RECEPTORS IN THE CNS

FAMILY	SUBTYPES	TRANSDUCER	AGONIST	ANTAGONIST
α_1 Adrenergic	α_{1A} α_{1B} α_{1D}	$G_{q/11}$	Epinephrine, phenylephrine, oxymetazoline, dabuzalgron (α_{1A}), A61603 (α_{1B})	Prazosin, doxazosin, terazosin, tamsulosin, alfuzosin, S(+)-niguldipine (α_{1A}), L-765314 (α_{1B}), BMY-7378 (α_{1D})
α_2 Adrenergic	α_{2A} α_{2B} α_{2C}	G_i/G_o	Epinephrine, norepinephrine, dexmedetomidine, clonidine, guanfacine	Yohimbine, rauwolscine
β Adrenergic	β_1 β_2 β_3	G_s	Epinephrine, norepinephrine, prenalterol (β_1), fenoterol (β_2), salbutamol (β_2), mirabegron (β_3), BRL37344 (β_3)	Carvedilol, bupranolol, levobunolol, metoprolol, propranolol, betaxolol (β_1), ICI118554 (β_2), SR 59230A (β_3)

to G_q, resulting in stimulation of the PLC-IP_3/diacylglycerol-Ca^{2+}-PKC pathway, and are associated predominantly with neurons. α_1 Adrenergic receptors on noradrenergic target neurons respond to NE with *depolarizing responses* because of decreases in K^+ conductance. α_2 Adrenergic receptors are found on glial and vascular elements, as well as on neurons. They are prominent on noradrenergic neurons, where they couple to G_i, inhibit adenylyl cyclase, and mediate a *hyperpolarizing response* due to enhancement of an inwardly rectifying K^+ channel (via βγ heterodimer). α_2 Adrenergic receptors are also located presynaptically where they function as inhibitory autoreceptors to diminish the release of NE. The antihypertensive effects of *clonidine* may result from stimulation of such autoreceptors.

There are relatively large amounts of NE within the hypothalamus and in certain parts of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. NE also is present in significant amounts in most brain regions. Mapping studies indicate that noradrenergic neurons of the locus coeruleus innervate specific target cells broadly throughout cortical, subcortical, and spinomedullary fields.

Epinephrine

Most EPI in the brain is contained in vascular elements. Neurons in the CNS that contain EPI were recognized only after the development of sensitive enzymatic assays and immunocytochemical staining techniques for phenylethanolamine-*N*-methyltransferase, the enzyme that converts NE into EPI. EPI-containing neurons are found in the medullary reticular formation and make restricted connections to pontine and diencephalic nuclei, eventually coursing as far rostrally as the paraventricular nucleus of the thalamus. Their physiological properties have not been unambiguously identified.

Histamine

In addition to its well-known physiological functions in immune and digestive responses, histamine is a monoamine neurotransmitter in the CNS. Histaminergic neurons are located in the ventral posterior hypothalamus; they give rise to long ascending and descending tracts similar to other monoaminergic systems. The histaminergic system is thought to affect arousal, body temperature, and vascular dynamics. The biosynthesis of histamine is described in Chapter 43. Vesicular monoamine transporter (VMAT) 2 facilitates vesicular histamine storage. There does not appear to be a specific transport process for the reuptake of histamine after its release. Rather, histamine reuptake can occur via the facilitative organic cation transporters OCT2 (SLC22A2) and OCT3 (SLC22A3) and, to a lesser degree, by the plasma membrane monoamine transporter (PMAT) (SLC24A4). Histamine is metabolized by histamine-*N*-methyltransferase and, in the periphery, also by diamine oxidase. Histamine signals through four GPCR subtypes (H_1–H_4) that regulate either adenylyl cyclase or PLC (Figure 16–12).

H_1 receptors are widely distributed in the brain where high densities are found in regions linked to neuroendocrine, behavioral, and nutritional state control. H_1 receptor activation excites neurons in most brain regions, and genetic knockout of the H_1 receptor results in behavioral state abnormalities, consistent with a major role for H_1 receptors in cortical control of the sleep-wake cycle. This is evident in the well-known sedative actions of H_1 receptor blockers that are used as antihistamines in the treatment of allergies. The development of H_1 antagonists with low CNS penetration has reduced the incidence of sedation in the treatment of allergy-related disorders (see Chapter 43), although in some

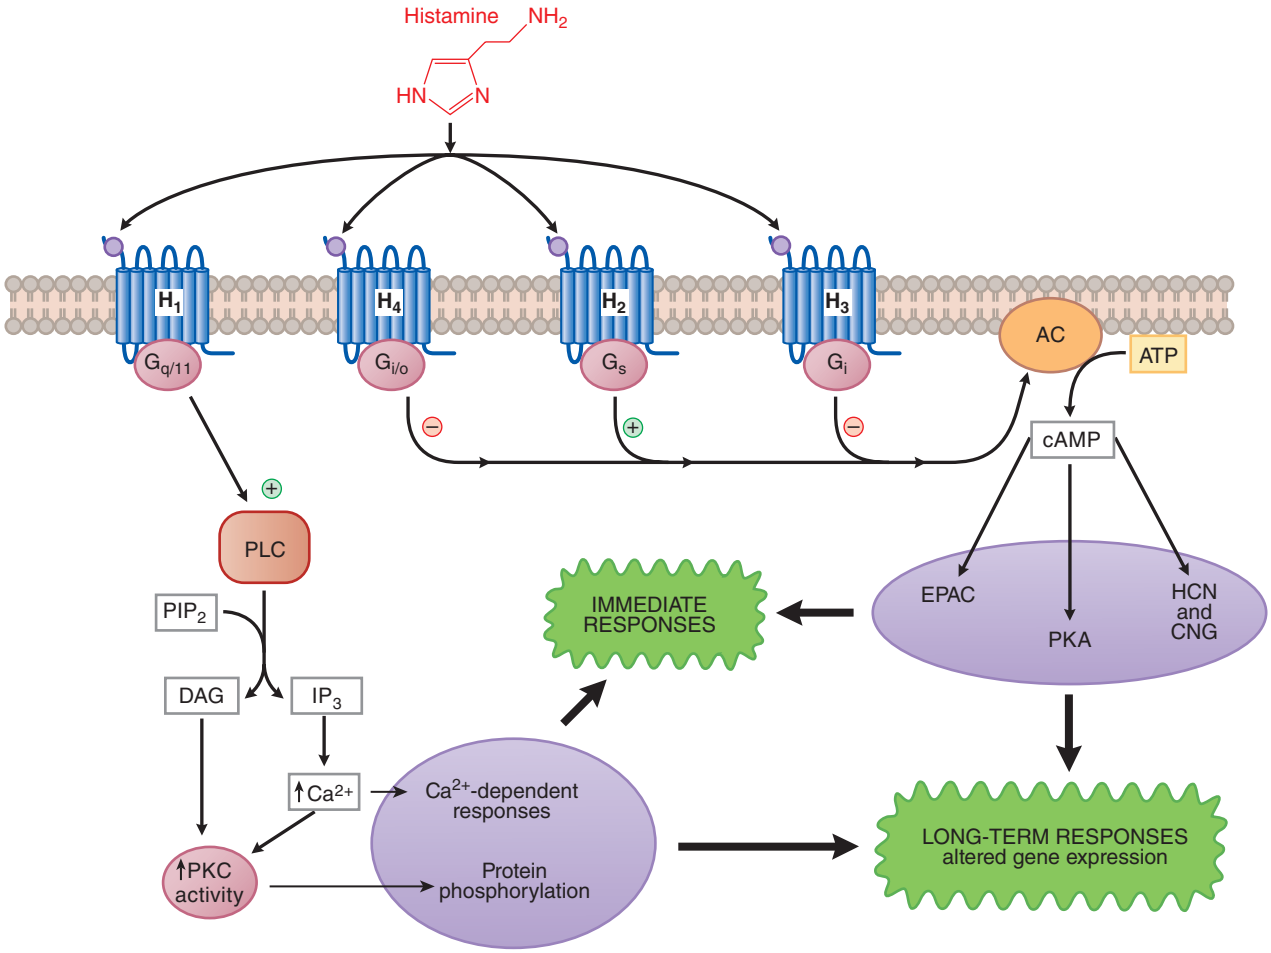

Figure 16–12 *Main signal transduction pathways for histamine receptors.* Histamine can couple to a variety of G protein-linked signal transduction pathways via four different receptors. The H_1 receptors activate phosphatidylinositol turnover via $G_{q/11}$. The other receptors couple either positively (H_2 receptor) or negatively (H_3 and H_4 receptor) to adenylyl cyclase activity via G_s and $G_{i/o}$, respectively.

conditions, the sedative effect of antihistamines can be beneficial in inducing sleep.

H_2 receptors activate adenylyl cyclase and are primarily involved in gastric acid secretion and smooth muscle relaxation. H_2 receptor antagonists are a mainstay of treatment for dyspepsia and acid reflux, as discussed in detail in Chapter 43. H_2 receptors are also highly expressed in the brain where they regulate neuronal physiology and plasticity. Mice lacking H_2 receptors show cognitive defects and impaired hippocampal long-term potentiation along with abnormalities in nociception. Systemic inhibition of the H_2 receptor has antinociceptive effects. To date, no H_2 receptor (or other histamine antagonist) has been approved for pain management.

H_3 receptors are also present in the CNS and can act as autoreceptors on histaminergic neurons to inhibit histamine synthesis and release. These receptors act to inhibit adenylyl cyclase as well as modulate N-type voltage-gated calcium channels. While it is known that H_3 receptors function as autoreceptors for histamine, they are not confined to histaminergic neurons and have been found to regulate serotonergic, cholinergic, noradrenergic, and dopaminergic neurotransmitter release. As a consequence of its ability to modulate other neurotransmitters, the H_3 receptor has become a therapeutic target for treating various conditions such as obesity, movement disorders, schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and wakefulness. A wide array of compounds have been developed that interact with the H_3 receptor. They are useful pharmacological tools both *in vitro* and *in vivo*, and one compound, *pitolisant*, an inverse agonist at the H_3 receptor, is FDA approved for the treatment of narcolepsy.

H_4 receptors are expressed on cells of hematopoietic origin—eosinophils, T cells, mast cells, basophils, and dendritic cells—and are involved in eosinophil shape and mast cell chemotaxis. More recent evidence suggests that they have limited expression in the CNS and on microglia, where they may indirectly affect neurons. Regardless, most of the information about this subtype is related to allergy, asthma, and the antipruritic properties of H_4 antagonists. These functions are discussed further in Chapter 43.

Serotonin (5HT)

The synthesis and metabolism of 5HT are summarized in Figure 15–2. There are diverse pathways mediating serotonin signaling that play a role in modulating mood, depression, anxiety, and phobia, as well as GI motility (Tables 15–1 and 15–2). These effects are mediated by 13 distinct GPCRs and one ligand-gated ion channel, which have characteristic ligand-binding profiles, couple to different intracellular signaling systems, and exhibit subtype-specific distribution within the CNS. The 5HT receptors, their pharmacology, and their therapeutic utility are discussed in detail in Chapter 15.

Trace Amines

Trace amines have only recently been appreciated as neurotransmitters. As the name implies, these compounds are detected only at trace levels; they have very short half-lives due to their rapid metabolism by monoamine oxidase. Some trace amines act as neuromodulators/neurotransmitters interacting with specific receptors. Trace amines are structurally related to catecholamines and consist of the phenethylamines (phenethylamine, *N*-methylphenethylamine [an endogenous amphetamine isomer]), phenylethanolamine, tyramine, tryptamine, *N*-methyltyramine, octopamine, synephrine, and 3-methoxytyramine. These trace amines are thought to act through GPCRs that were originally termed *trace amine receptors* but are now called *trace amine–associated receptors* (TAARs) since not all members have very high affinity for trace amines. The first receptor was identified in 2001 (Borowsky et al., 2001; Bunzow et al., 2001), and to date, six human genes (*TAAR1, TAAR2, TAAR5, TAAR6, TAAR8*, and *TAAR9*) have been identified along with several potential pseudo-genes. Multiple TAAR-related receptor genes have been identified in other species, and several are expressed prominently in the olfactory epithelium, where they may serve as olfactory receptors for volatile amines. Only one TAAR (TAAR1) has been recognized by IUPHAR as a trace amine receptor, TA_1. TA_1 is a GPCR that couples to G_s and G_{13} and possibly to other G protein α-subunits, depending on the cell type and cellular location. TA_1 has the highest affinity for the trace amines tyramine, β-phenylephrine, and octopamine. In neurons, TA_1 is predominantly intracellular and activates downstream signaling pathways from an intracellular membrane compartment. TA_1 modulates monoaminergic activity in the CNS and is activated by amphetamine and related psychostimulants, as well as the endogenous thyronamines (Gainetdinov et al., 2018). Agonists for the TAAR1 receptors have been shown to have favorable effects in animal models of addiction and schizophrenia, though human therapeutics targeting TAAR1 have yet to be further developed.

Regulation of Neurotransmission

Peptides

Neuropeptides in the CNS typically behave as modulators of neurotransmission rather than direct agents of excitation or inhibition (Mains and Epper, 2012). The growing number of neuropeptides (Table 16–5) are involved in a wide array of brain functions, ranging from analgesia to social behaviors, learning, and memory. In contrast to the biosynthesis of monoamines and amino acids, peptide synthesis requires transcription of DNA into mRNA and translation of mRNA into protein. This takes place primarily in perikarya, after which the resulting peptide is transported to nerve terminals. Single genes can, through transcriptional and posttranslational modifications, give rise to multiple neuropeptides. For example, proteolytic processing of proopiomelanocortin (POMC) gives rise to, among other peptides, adrenocorticotropic hormone (ACTH; corticotropin), α-, γ-, and β-melanocyte-stimulating hormones (MSH), and β-endorphin (Figure 16–13). In addition, alternative splicing of RNA transcripts in different tissues may produce distinct mRNA species (e.g., calcitonin and calcitonin gene–related peptide [CGRP]). Furthermore, while some CNS peptides function independently, most are thought to act in concert with coexisting neurotransmitters. They are often packaged into vesicles and released along with other neurotransmitters to modulate their actions. While classical neurotransmitters generally signal to neurons by depolarizing or hyperpolarizing, neuropeptides have more diverse mechanisms of action and can also affect gene expression. Their action is not terminated by rapid reuptake into the presynaptic cell, but rather they are enzymatically inactivated by extracellular peptidases. As a result, their effects on neuronal signaling can be prolonged in nature (Mains and Epper, 2012).

Most neuropeptide receptors are GPCRs in which the extracellular domains of the receptors play a primary role in peptide ligand binding. As with other transmitter systems, there are often multiple receptor subtypes for the same peptide transmitter (Table 16–6). Neuropeptide receptors can exhibit different affinities for the nascent neuropeptide and for peptide analogues. As peptides are typically inefficient as drugs, particularly at CNS targets behind the BBB due to difficulties with their delivery, major efforts have been made to develop small-molecule drugs that are effective as either agonists or antagonists. Through a combination of structural biology, chemistry, high-throughput screening, and drug development, there are now small-molecule ligands for many neuropeptide receptors. Some of these compounds are listed in Table 16–6. Natural products have not typically been good sources of drugs that affect peptidergic transmission. One notable exception is the plant alkaloid *morphine*, which acts selectively at opioid receptor subtypes. The actions of neuropeptides have been targeted in other ways. Several approaches have been used to disrupt the actions of CGRP, a neuropeptide that plays a key role in the development of migraine. Small-molecule antagonists, antibodies against CGRP itself, and antibodies against the CGRP receptor have all been approved as effective treatments for the prevention of migraine. The use of antibody-based therapeutics provides a new avenue

TABLE 16–5 ■ EXAMPLES OF NEUROPEPTIDES

Calcitonin Family
- Calcitonin
- Calcitonin gene-related peptide (CGRP)

Hypothalamic Hormones
- Oxytocin, vasopressin

Hypothalamic Releasing and Inhibitory Hormones
- Corticotropin-releasing factor (CRF or CRH)
- Gonadotropin-releasing hormone (GnRH)
- Growth hormone-releasing hormone (GHRH)
- Somatostatin (SST)
- Thyrotropin-releasing hormone (TRH)

Neuropeptide Y Family
- Neuropeptide Y (NPY)
- Neuropeptide YY (PYY)
- Pancreatic polypeptide (PP)

Opioid Peptides
- β-Endorphin (also pituitary hormone)
- Dynorphin peptides
- *Leu*-enkephalin
- *Met*-enkephalin

Pituitary Hormones
- Corticotropin (formerly adrenocorticotropic hormone; ACTH)
- α-Melanocyte-stimulating hormone (α-MSH)
- Growth hormone (GH)
- Follicle-stimulating hormone (FSH)
- β-Lipotropin (β-LPH), luteinizing hormone (LH)

Tachykinins
- Neurokinins A and B
- Neuropeptide K, substance P

VIP-Glucagon Family
- Glucagon, glucagon-like peptide (GLP-1)
- Pituitary adenylyl cyclase–activating peptide (PACAP)
- Vasoactive intestinal polypeptide (VIP)

Other Peptides
- Agouti-related peptide (ARP)
- Bombesin, bradykinin (BK)
- Cholecystokinin (CCK)
- Cocaine/amphetamine-regulated transcript (CART)
- Galanin, ghrelin
- Melanin-concentrating hormone (MCH)
- Neurotensin, nerve growth factor (NGF)
- Orexins, orphanin FQ (nociceptin)
- Hemopressin (CB_1 inverse agonist)

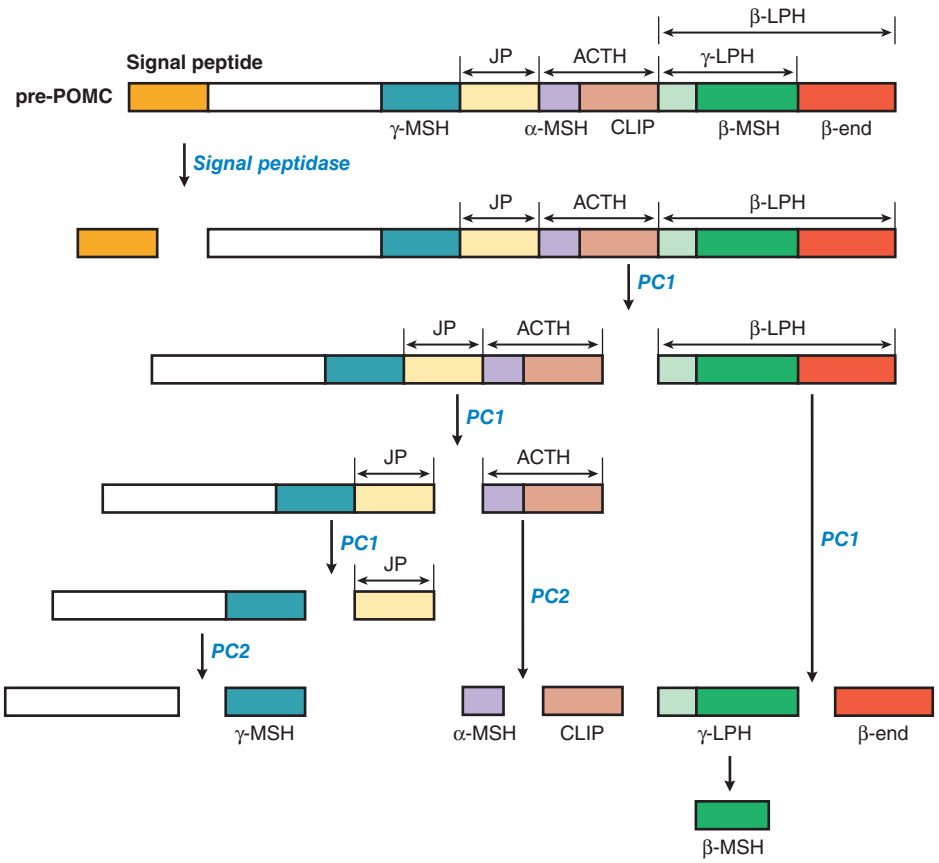

Figure 16–13 *Proteolytic processing of proopiomelanocortin (POMC).* After removal of the signal peptide from pre-POMC, the remaining propeptide undergoes endoproteolysis by prohormone convertases 1 and 2 (PC1 and PC2) at dibasic residues. PC1 liberates the bioactive peptides adrenocorticotropic hormone (ACTH), β-endorphin (β-end), and γ-LPH (lipotrophic hormone). PC2 cleaves ACTH into CLIP (corticotropin-like intermediate peptide) and α-melanocyte-stimulating hormones (MSH) and also releases γ-MSH from the N-terminal portion of the propeptide. The JP (joining peptide) is the region between ACTH and γ-MSH. β-MSH is formed by cleavage of γ-LPH. Some of the resulting peptides are amidated or acetylated before they become fully active.

TABLE 16–6 ■ PEPTIDE TRANSMITTERS AND RECEPTORS

for targeting peptidergic systems within both central and peripheral nervous systems (Lu et al., 2020).

Purines

Adenosine, ATP, UDP, and UTP have roles as extracellular signaling molecules. ATP is also a component of many neurotransmitter storage vesicles and is released along with transmitters. Intracellular nucleotides may also reach the cell surface by other means, and extracellular adenosine can result from cellular release and metabolism of ATP. These released nucleotides can be hydrolyzed extracellularly by ectonucleotidases. Adenosine is reaccumulated by transport into neighboring cells unless extracellular adenosine deaminase is present. Extracellular nucleotides and adenosine can act on a family of diverse purinergic receptors, which have been implicated in a variety of functions including memory and learning, locomotor behavior, and feeding.

There are three classes of *purinergic receptors*: adenosine receptors (also called P1), P2Y, and P2X (Table 16–7). *Adenosine receptors* are GPCRs that consist of four subtypes (A_1, A_{2A}, A_{2B}, and A_3) activated endogenously by adenosine. A_1 and A_3 couple to G_i, whereas A_2 receptors couple to G_s. Activation of A_1 receptors is associated with inhibition of adenylyl cyclase, activation of K^+ currents, and in some instances, activation of PLC; stimulation of A_2 receptors activates adenylyl cyclase. In the CNS, both A_1 and A_{2A} receptors are involved in regulating the release of other neurotransmitters such as glutamate and dopamine, making the A_{2A} receptor a potential therapeutic target for disorders such as Parkinson's disease. Recently, the A_{2A} receptor antagonist istradefylline was approved as adjunctive therapy with L-DOPA for the treatment of Parkinson's disease (see Chapters 15 and 21).

P2Y receptors are also GPCRs and are activated by ATP, ADP, UTP, UDP, and UDP-glucose. There are eight known subtypes of P2Y receptors that couple to a variety of G proteins as indicated in Table 16–7. The $P2Y_{12}$ receptor is expressed in the CNS, where it is stimulated by UDP-glucose and may play a role in neuroimmune functions. The $P2Y_{12}$ receptor is important clinically: Antagonism of this receptor in platelets inhibits platelet aggregation.

ATP-sensitive *P2X receptors* are ligand-gated cation channels that are expressed throughout the CNS on presynaptic and postsynaptic nerve terminals and on glial cells. P2X receptors have been found on nociceptive sensory neurons, where they primarily gate Na^+, K^+, and Ca^{2+}, and have been implicated in mediating sensory transduction. There are seven subtypes of P2X receptors with varying sensitivities to their endogenous agonist, ATP (see Table 16–7). Functional P2X receptors have a trimeric topology, existing either as homopolymers or heteropolymers with other P2X receptors. Following the first crystal structure that confirmed this arrangement in 2009 (Kawate et al., 2009), more than 20 crystal structures of P2X receptors from different subtypes and in different states have been described and have added to our understanding of how these receptors interact with agonists and antagonists (Schmid and Evans, 2019). The study of compounds that are selective for P2X subtypes suggests that targeting these receptors may be useful in the therapy of neurological disorders such as neuropathic and inflammatory pain, epilepsy, memory, and alcohol use disorders. The first P2X drug to come to clinical fruition (approved in Japan in 2022) is *gefapixant*, a $P2X_3$ receptor antagonist for refractory cough. The release of ATP from irritated bronchial cells can stimulate $P2X_3$ receptors on sensory nerve fibers in the airway, initiating an action potential that can lead to coughing. *Gefapixant* inhibits ATP binding to $P2X_3$ receptors, thereby reducing the stimulation that leads to coughing. Among the notable features of *gefapixant* is that it is named after the late Geof Burnstock, a pioneer of purinergic signaling (North and Costa, 2021).

Cannabinoids

Delta-9-tetrahydrocannabinol (THC) was identified as a psychoactive substance in marijuana in the 1960s (Figure 16–14). This led to the

[a]NECA is a nonselective agonist of P1 receptors.

[b]$P2Y_{14}$ binds UDP-glucose, UDP-galactose, or UDP-acetylglucosamine.

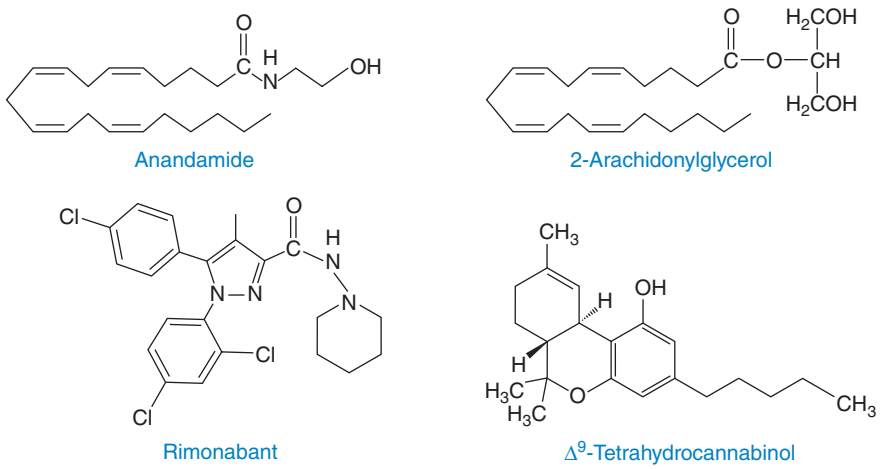

Figure 16–14 *Cannabinoid (CB) receptor ligands.* Anandamide and 2-arachidonylglycerol are endogenous agonists. *Rimonabant* is a synthetic CB receptor antagonist. Δ^9-Tetrahydrocannabinol is a CB agonist derived from marijuana.

discovery of two cannabinoid receptors and the identification of endogenous compounds that modulate them. The two receptor subtypes (CB_1 and CB_2) are GPCRs that couple to G_i/G_o to inhibit adenylyl cyclase and, in some cell types, inhibit voltage-gated Ca^+ channels or stimulate K^+ channels. The receptors share relatively low overall homology and are found in differing locations, although both are found in the CNS. CB_1 receptors are found in high levels throughout the brain, whereas CB_2 receptors are prominent in immune cells. Within the CNS, CB_2 receptors are less abundant than CB_1 receptors and are thought to occur primarily on microglia. The finding of endogenous cannabinoids responsible for signaling to these receptors, along with a host of clinical data from marijuana use, has fueled interest in this signaling system and has greatly expanded our understanding of its physiology.

The endogenous cannabinoid system consists of the cannabinoid receptors, endogenous cannabinoids, and the enzymes that synthesize and degrade endocannabinoids (see Figure 26–5). The endocannabinoids are lipid molecules and include anandamide (*N*-arachidonoylethanolamine) and 2-arachidonoylglycerol (2-AG), as well as other compounds that have been putatively identified to serve as endogenous endocannabinoids, including *O*-arachidonoylethanolamine (virodhamine), *N*-dihomo-γ-linolenoylethanolamine, *N*-docosatetraenoic-ethanolamine, oleamide, 2-arachidonyl-glyceryl-ether (2-AGE), *N*-arachidonoyl-dopamine (NADA), and *N*-oleoyl-dopamine. The actions of endocannabinoids are terminated by their uptake into cells, followed by hydrolysis. Two enzymes known to break down anandamide and 2-AG are fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MGL), respectively. Although a few studies suggested the existence of a specific transport system for endocannabinoids, no molecular entity that mediates such a carrier-mediated process has been identified. Obviously, drugs that inhibit the transport or degradation of endocannabinoids would prolong their physiological actions. Chapter 26 reviews the pharmacology of endo- and over-the-counter cannabinoids, cannabinoid receptor signaling, and associated therapeutic developments.

Other Lipid Mediators

Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A_2, C, and D). Arachidonic acid can be converted to highly reactive modulators by three major enzymatic pathways (see Chapter 41): *cyclooxygenases* (leading to prostaglandins and thromboxane), *lipoxygenases* (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and *CYP450s* (which are inducible and expressed at low levels in brain). Arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, possibly involved with the formation of long-term potentiation and other forms of neuronal plasticity.

Gases: Nitric Oxide and Carbon Monoxide

Both constitutive and inducible forms of nitric oxide (NO) synthase are expressed in the brain. The application of inhibitors of NO synthase (e.g., *methylarginine*) and of NO donors (e.g., *nitroprusside*) suggests the involvement of NO in a host of CNS phenomena, including long-term potentiation, activation of soluble guanylyl cyclase, neurotransmitter release, and enhancement of glutamate (NMDA)-mediated neurotoxicity. Another diffusible gas, carbon monoxide, is generated in neurons or glia and may act as an intracellular messenger stimulating soluble guanylyl cyclase through nonsynaptic actions.

Termination of Neurotransmitter Action

It is essential that there are mechanisms to terminate the actions of released neurotransmitters to maintain the balance of neuronal signaling. There are two primary mechanisms for terminating the signaling of released transmitters. One is the conversion of the transmitter into an inactive compound via an enzymatic reaction. The best example of enzymatic inactivation is for the transmitter ACh, the action of which is terminated via hydrolysis by acetylcholinesterase to choline and acetate (see Chapter 12). A second mechanism involves the clearance of the neurotransmitter by transport proteins present on neuronal or glial membranes, so that it can no longer act on the target receptors; reuptake of DA by the dopamine transporter (DAT) is a good example. In addition to the above, slow diffusion of the transmitter away from the synapse and subsequent degradation also play a role for both conventional neurotransmitters and neuropeptides.

Neurons and glial cells express *specific transporter proteins* such as those for the monoamines norepinephrine (NE transporter [NET]), serotonin (5HT transporter [SERT]), and dopamine (DAT), which remove NE, 5HT, and DA from the extracellular space by transporting it back into the presynaptic neuron (see Chapters 10 and 15). These plasma membrane carriers serve as a major mechanism for limiting the extent and duration of neurotransmitter signaling. To accomplish this task, they couple the movement of neurotransmitters to the influx of multiple sodium ions, which provides a strong thermodynamic driving force for inward transport. The carriers for NE, 5HT, DA, GABA, and glycine have 12 hydrophobic membrane-spanning domains with their amino- and carboxyl-termini located within the cytoplasm (Figure 16–15). These transporters are generally glycosylated within an extracellular loop and possess sites for phosphorylation and binding to intracellular regulatory proteins, primarily on their amino- and carboxyl-termini.

A second family of plasma membrane neurotransmitter transporters mediates the clearance of glutamate and aspartate released during synaptic transmission. In humans, five subtypes of glutamate transporters (referred to as excitatory amino acid transporters [EAATs] 1–5) clear

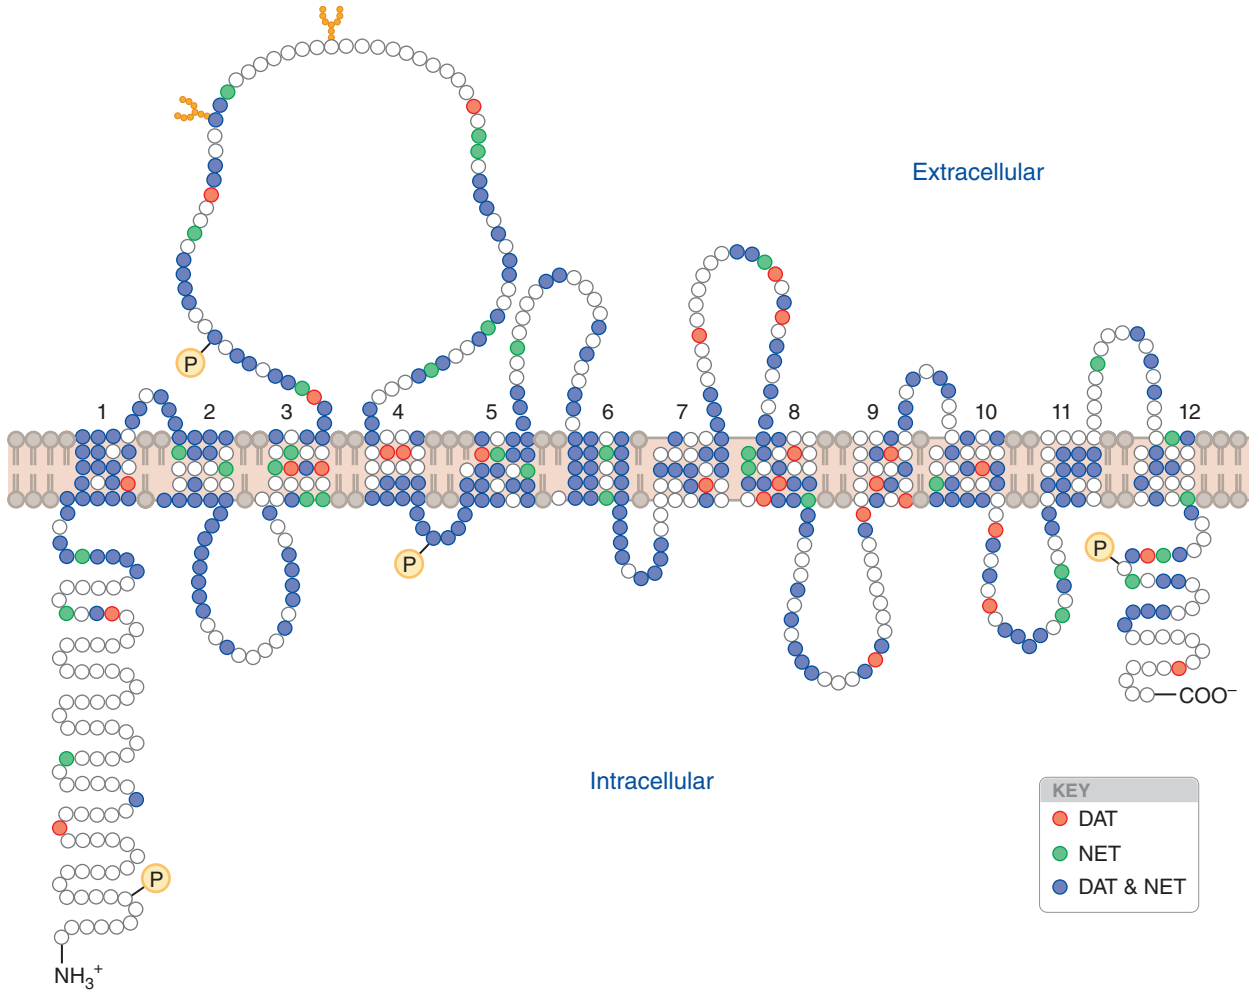

Figure 16–15 *Structure of the rat 5HT transport protein.* Both the amino and carboxyl termini are intracellular. These transport proteins typically have 12 hydrophobic, membrane-spanning domains with intervening extracellular and intracellular loops. The second extracellular loop is the largest and contains several potential glycosylation sites (indicated with tree-like symbols). Amino acid residues that are homologous to those in the DAT and the NET are colored, as noted. The most highly conserved regions of these transporters are located in the transmembrane domains; the most divergent areas occur in the N and C termini. (Used with permission from Dr. Beth J. Hoffman, San Diego, CA.)

glutamate into neurons and glial cells. The two glial carriers, EAAT1 and EAAT2, are responsible for the bulk of glutamate transport activity in the CNS and are critical for limiting excitotoxic actions of glutamate. These transporters assemble as homotrimers within the membrane with each protomer possessing eight transmembrane domains (TM1–8) and two re-entrant hairpin loops (HP1 and HP2) that appear to serve as intracellular and extracellular gates during the transport process (Jiang and Amara, 2011; Yernool et al., 2004) (Figure 16–16).

There are also at least three distinct gene families of vesicular neurotransmitter transporters that sequester the neurotransmitters within synaptic vesicles for storage and, ultimately, for release during neuronal signaling. These include the vesicular monoamine and ACh transporters (VMAT1, VMAT2, and VAChT), a vesicular carrier for both GABA and glycine (VGAT), and three vesicular glutamate carriers, VGLUT1, VGLUT2, and VGLUT3. These transporters ensure that vesicles fill rapidly during neurotransmission and provide a means for reducing cytoplasmic concentrations of neurotransmitter in areas where rates of reuptake are high. Three structurally related VMAT2 inhibitors, *tetrabenazine*, *deutetrabenazine*, and *valbenazine*, have been shown to effectively lower the vesicular storage and release of DA and are now used clinically in the treatment of involuntary movement disorders such as Huntington's chorea and tardive dyskinesia (Koch et al., 2020).

The monoamine transporters, DAT, NET, and SERT, are well-established targets for therapeutic antidepressants and for addictive drugs including *cocaine* and amphetamines. Selective inhibitors of these carriers can increase the duration and spatial extent of the actions of neurotransmitters. Inhibitors of the uptake of NE and/or 5HT are used to treat depression and other behavioral disorders, as described in Chapter 18. The psychostimulants *methylphenidate* and *amphetamine* are the major drugs used to treat ADHD in children and in adults. Although the two drugs have stimulant actions in healthy individuals, in ADHD patients, they reduce hyperactivity and increase attention by inhibiting DAT and NET and enhancing DA and NE neurotransmission. These transporters are discussed in further detail in Chapters 4, 10, and 15.

CNS Drug Discovery and Development

After determining a CNS target site for which modulation would prove helpful for treating a disorder, the next step involves the discovery of a compound suitable for targeting that site that can be developed into a drug. Four core approaches are typically used to identify and develop small-molecule compounds for targeting neuronal signaling:

- Synthesis of structural analogues of known neurotransmitters or modulators of receptors/channels to generate structure-activity relationship information for determining how chemical structure can lead to greater target specificity.
- Use of natural products that exist in nature (e.g., toxins or plant extracts) that have shown efficacy for treating a particular disease, either as drugs themselves or as templates for drug design.

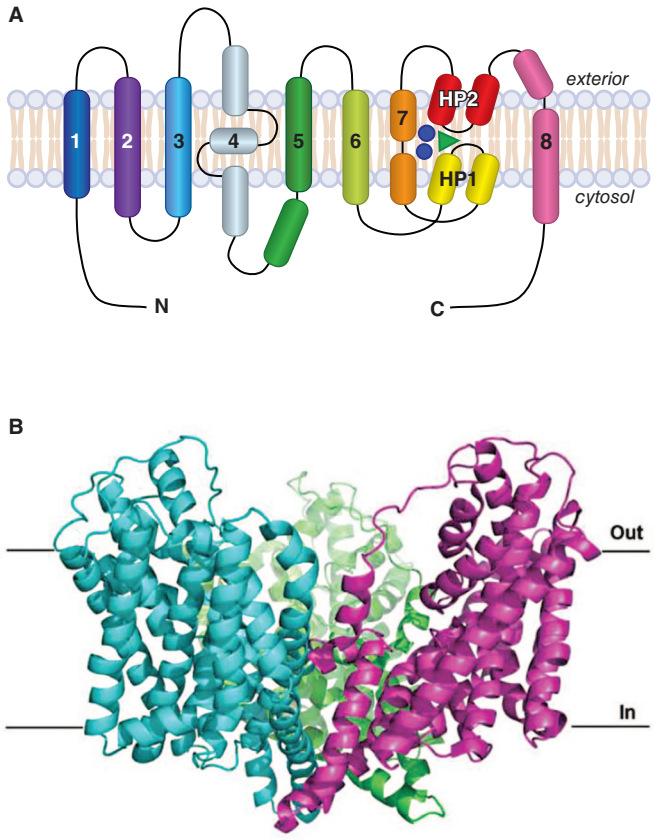

Figure 16–16 *Structure of the excitatory amino acid transporters.* The mammalian EAAT family includes the plasma membrane transporters EAAT1 to EAAT5. **A.** Membrane topology of a single EAAT family subunit: transmembrane domains (colored oblongs) are labeled 1–8. Approximate binding sites occupied by Na^+ (blue dots) and substrate (green triangle) are formed by the nonhelical segments at the tips of two hairpin loops, HP1 and HP2. **B.** Crystal structure (protein data base ID: 1XFH) of the archaeal glutamate transporter ortholog, Glt_{Ph}, from *Pyrococcus horikoshii*. Individual subunits have been colored distinctively to illustrate their trimeric organization within the membrane. (Reproduced, with permission, from Jiang J, Amara SG. New views of glutamate transporter structure and function: advances and challenges. *Neuropharmacology*, **2011**, *60*:172–181. Copyright © Elsevier Ltd.)

- The development of a signaling assay that is amenable for the screening of large (thousands to millions) compound libraries with diverse chemical structures to identify novel scaffolds with promising functional profiles for drug development.
- Use of atomic-level (x-ray or cryo-electron microscopy) structures of targets to rationally design new compounds or use structure-based virtual (*in silico*) screening to identify chemical scaffolds that likely bind to the target.

Each approach has benefits and pitfalls, but together, these types of approaches have been successful in discovering and developing many new drugs for targeting CNS signaling processes.

Chapter 17

The Blood-Brain Barrier and Its Influence on Drug Transport to the Brain

Richard Daneman, Margareta Hammarlund-Udenaes, and Eric V. Shusta

Brain Barriers

For a drug to be active, it must reach a certain concentration in the target tissue. The central nervous system (CNS) possesses a series of barriers that separate the neural tissue from the periphery. These barriers act to stringently regulate the movement of ions, molecules, and cells between peripheral fluids (i.e., blood) and the CNS, thus tightly regulating the extracellular environment of the CNS, which is critical to maintain homeostasis. The barriers not only control the influx of glucose and essential nutrients but also greatly limit the entry of many exogenous compounds, including drugs. The pharmaceutical industry has struggled with developing drugs that can cross these barriers and enter the brain without requiring high doses that give unwanted peripheral side effects or are too costly. For large-molecule drugs like antibodies, this problem is greater since larger molecules have an even lower ability to cross brain barriers.

The brain barriers include the blood vessels that vascularize the CNS parenchyma, the meningeal covering of the brain, and the choroid plexus within the ventricles (Figure 17–1).

The barriers are especially important to insulate the neurons from ionic fluctuations, such that the neurons can maintain appropriate ion gradients required for neural circuit function. The brain barriers also protect the CNS from toxins, pathogens, and even the body's own immune system, which is crucial because the CNS fails to regenerate after many injuries and diseases. The importance of the barriers is highlighted by the severe pathology of diseases in which the barriers are disrupted, such as multiple sclerosis, stroke, traumatic brain injury, meningitis, and other neurological injuries and disease. When intact, these barriers also create obstacles for drug delivery, as they greatly impede the entry of most blood-borne molecules from entering the brain.

The most studied barrier is the BBB, an endothelial barrier formed by the blood vessels that vascularize the parenchyma of the CNS. The BBB makes up most of the surface area of the brain barriers and hence is most important for drug delivery to the CNS. The meningeal coverings of the brain have two distinct barriers that restrict the movement of solutes from the periphery into the brain. The first barrier is the arachnoid barrier, which stringently regulates the passage of molecules and cells between the outer dura mater, which contains fenestrated "leaky" blood vessels, and the inner subarachnoid space, which contains the cerebrospinal fluid (CSF). This barrier is an epithelial barrier made up of arachnoid barrier cells that physically separate the dura mater and the subarachnoid space. The second barrier is an endothelial barrier possessed by the blood vessels within the subarachnoid space, which restrict the movement of molecules and cells between the blood and the CSF within the subarachnoid space. The choroid plexuses, which secrete CSF into the ventricles, also contain a barrier that is formed by choroid plexus epithelial cells that surround fenestrated "leaky" blood vessels within the plexuses. These epithelial cells act to tightly regulate the composition of the CSF that they are secreting into the ventricles, forming what is termed the blood-CSF barrier (BCSFB).

This chapter focuses on describing the cellular and molecular composition of the BBB, how the barrier properties are regulated, the role of the BBB in CNS pharmacology, and how the BBB is being targeted for CNS drug delivery.

The Blood-Brain Barrier

Cellular Composition of the BBB: The Neurovascular Unit

The BBB is a term used to describe the unique properties of the blood vessels that vascularize the CNS, which allows them to tightly regulate the movement of ion molecules and cells between the blood and the brain. Endothelial cells that form the walls of the blood vessels provide most the BBB properties, greatly restricting the passage of nonspecific molecules, while transporting specific nutrients into the CNS. Critical to the function of the BBB is also the interaction of the endothelial cells with other cells within the neurovascular unit including mural cells, fibroblasts, astrocytes, and immune cells (Figure 17–2).

Endothelial cells are thin cells that form the inner walls of all blood vessels, generating a lumen for blood to flow. In larger vessels, arteries and veins, the circumference of the vessel can be made up of dozens of endothelial cells, whereas the smallest capillaries can consist of a single endothelial cell folding upon itself to form a lumen of 6 to 8 μm in diameter.

Abbreviations

Apo: apolipoprotein
ATP: adenosine triphosphate
AUC: area under the concentration-time curve
BBB: blood-brain barrier
BCRP: breast cancer resistance protein
BCSFB: blood–cerebrospinal fluid barrier
CSF: cerebrospinal fluid
$f_{u,brain}$: unbound fraction of drug in brain homogenate
$f_{u,plasma}$: unbound fraction of drug in plasma
FUS: focused ultrasound
IR: insulin receptor
ISF: interstitial fluid
$K_{p,uu,brain}$: partition coefficient of unbound drug in brain interstitial fluid to that in plasma
$K_{p,uu,cell}$: partition coefficient of unbound drug between intracellular and interstitial fluids
LDLRf: low-density lipoprotein receptor family
MRP: multidrug resistance protein
PET: positron emission tomography
PS: permeability surface area product
RMT: receptor-mediated transcytosis
Tf: transferrin
TfR: transferrin receptor
$V_{u,brain}$: unbound volume of distribution in the brain; i.e., partitioning of total drug to that unbound in the brain interstitial fluid

The vascular network of the human brain is roughly 600 km long, with a thickness of 200 to 400 nm of the endothelial cells and a surface area of 15 to 25 square meters (Wong et al., 2013). Thus, the endothelial cells make up the primary cellular interface between the blood and the tissue and thus regulate permeability, transport, coagulation, and immune cell infiltration.

Mural cells are vascular support cells that sit on the abluminal surface of the endothelial cells, embedded in the vascular basement membrane, and regulate vascular parameters. On large vessels, *vascular smooth muscle cells* form concentric rings around the vessels and, through their contraction, control vessel diameter and thus blood flow. On capillaries and postcapillary venules, *pericytes* form incomplete layers, extending processes that interact with endothelial cells through peg-and-socket junctions. Pericytes regulate vascular permeability, endothelial immune activation, and blood flow (Armulik et al., 2011).

Fibroblasts are found embedded in the vascular smooth muscle layer of large vessels (Vanlandewijck et al., 2018b), sensing vascular stretch and regulating wound healing through the deposition of extracellular matrix.

A *basement membrane* consisting of extracellular matrix proteins including type IV collagens, laminins, nidogen, and heparan sulfate proteoglycans surrounds the CNS blood vessels. The basement membrane can be divided into two layers, the inner vascular basement membrane secreted by endothelial cells, mural cells, and fibroblasts, and the outer parenchymal basement membrane secreted primarily by astrocytes. These two basement membranes are separated in larger vessels but fuse around capillaries (Xu et al., 2019).

Astrocytes are a major glial cell population that extends polarized cellular processes; one set of processes ensheathes either synapses in the gray matter or nodes of Ranvier in the white matter, whereas the other process extends end feet that ensheathe more than 95% of the abluminal surface of the blood vessels, separated from the vessels by the basement membrane (Sofroniew and Vinters, 2010). Therefore, astrocytes are situated to sense and respond to both neural activity and vascular function and have been shown to regulate blood flow, vascular permeability, and CNS fluid dynamics as part of the glymphatic system (Hablitz and Nedergaard, 2021). In addition, neural progenitors, neurons, oligodendrocyte progenitors, and oligodendrocytes have been shown to interact with endothelial cells, regulating different aspects of vascular function.

Immune cells, both within the brain and within the blood, interact with CNS blood vessels. *Perivascular macrophages* are found in the perivascular spaces of draining venules where the glial lamina separates from the vascular basement membrane and survey this Virchow-Robin space as the first line of immunity in the CNS. *Microglia*, the CNS resident myeloid cells, extend highly motile ramified processes that survey the parenchyma and also poke between astrocyte end feet to inspect the vascular space (Li and Barres, 2018). These microglia have been shown to regulate vascular repair following injury (Lou et al., 2016).

Properties of the BBB

The BBB is not one entity, but a series of properties that allow the blood vessels to limit the passage of nonspecific molecules while delivering specific nutrients to the underlying neural tissue. Many of these properties are possessed by the endothelial cells that form the walls of the blood vesssels, such that CNS endothelial cells have distinct properties compared to endothelial cells in other tissues.

Glycocalyx

The *glycocalyx* is the carbohydrate-rich matrix that lines the luminal surface (blood side) of the endothelial cells and forms the first barrier to blood-borne molecules and cells. The vascular glycocalyx is made up of glycoproteins, proteoglycans, and glycolipids that can protrude several microns into the lumen of the vessel. Two-photon imaging in rodents has shown that this acts as the first barrier to large molecules, limiting their diffusion and ability to reach the endothelial cell (Kutuzov et al., 2018). It is currently unclear how the composition of the glycocalyx is different in CNS vessels compared to peripheral vessels and how the sieve-like barrier properties of the vascular glycocalyx are different in different tissues.

Tight Junctions

CNS endothelial cells are held together by *tight junctions* that form a tight paracellular barrier that polarizes the cell into distinct luminal and abluminal membrane compartments. Tight junctions, primarily studied in epithelial cells, are intercellular adhesions formed by transmembrane proteins including claudin family members, occludin, and junctional adhesion molecules that are linked to the cytoskeleton by adapters including zona occludens (Kniesel and Wolburg, 2000). The composition of claudins appears to determine the permeability of the paracellular pore, with claudin 5 being the most prominent claudin in CNS endothelial cells, creating a barrier that is greatly restrictive to ions with an electrical resistance of 1000 to 4000 ohms/cm^2. Genetic deletion of claudin 5 in mice results in a size-specific leakiness of the BBB to molecules less than 1000 Da (Nitta et al., 2003).

Transcellular Permeability

CNS endothelial cells restrict the transcellular movement of solutes with a *lack of fenestra* (pores in the membranes) and *low rates of transcytosis* (transcellular vesicle trafficking) compared to other vascular beds. Transcytosis in the endothelial cells can be divided into two mechanisms: (1) nonspecific transcytosis mediated through caveolin-coated vesicles and (2) receptor-mediated transcytosis of specific substrates through clathrin-coated vesicles. The tight paracellular barrier and low amounts of nonspecific transcytosis allow CNS endothelial cells to control the passage of molecules through transport. The receptor-mediated transport allows for the uptake of specific molecules including transferrin, insulin, and leptin (Yang et al., 2020).

Efflux Transport

The physical barrier properties restrict the passage of hydrophilic molecules across the endothelial cells; however, many small lipophilic molecules can passively diffuse across the endothelial cell membrane into the parenchyma. To regulate movement of lipophilic molecules across the BBB, CNS endothelial cells express a variety of *efflux transporters*

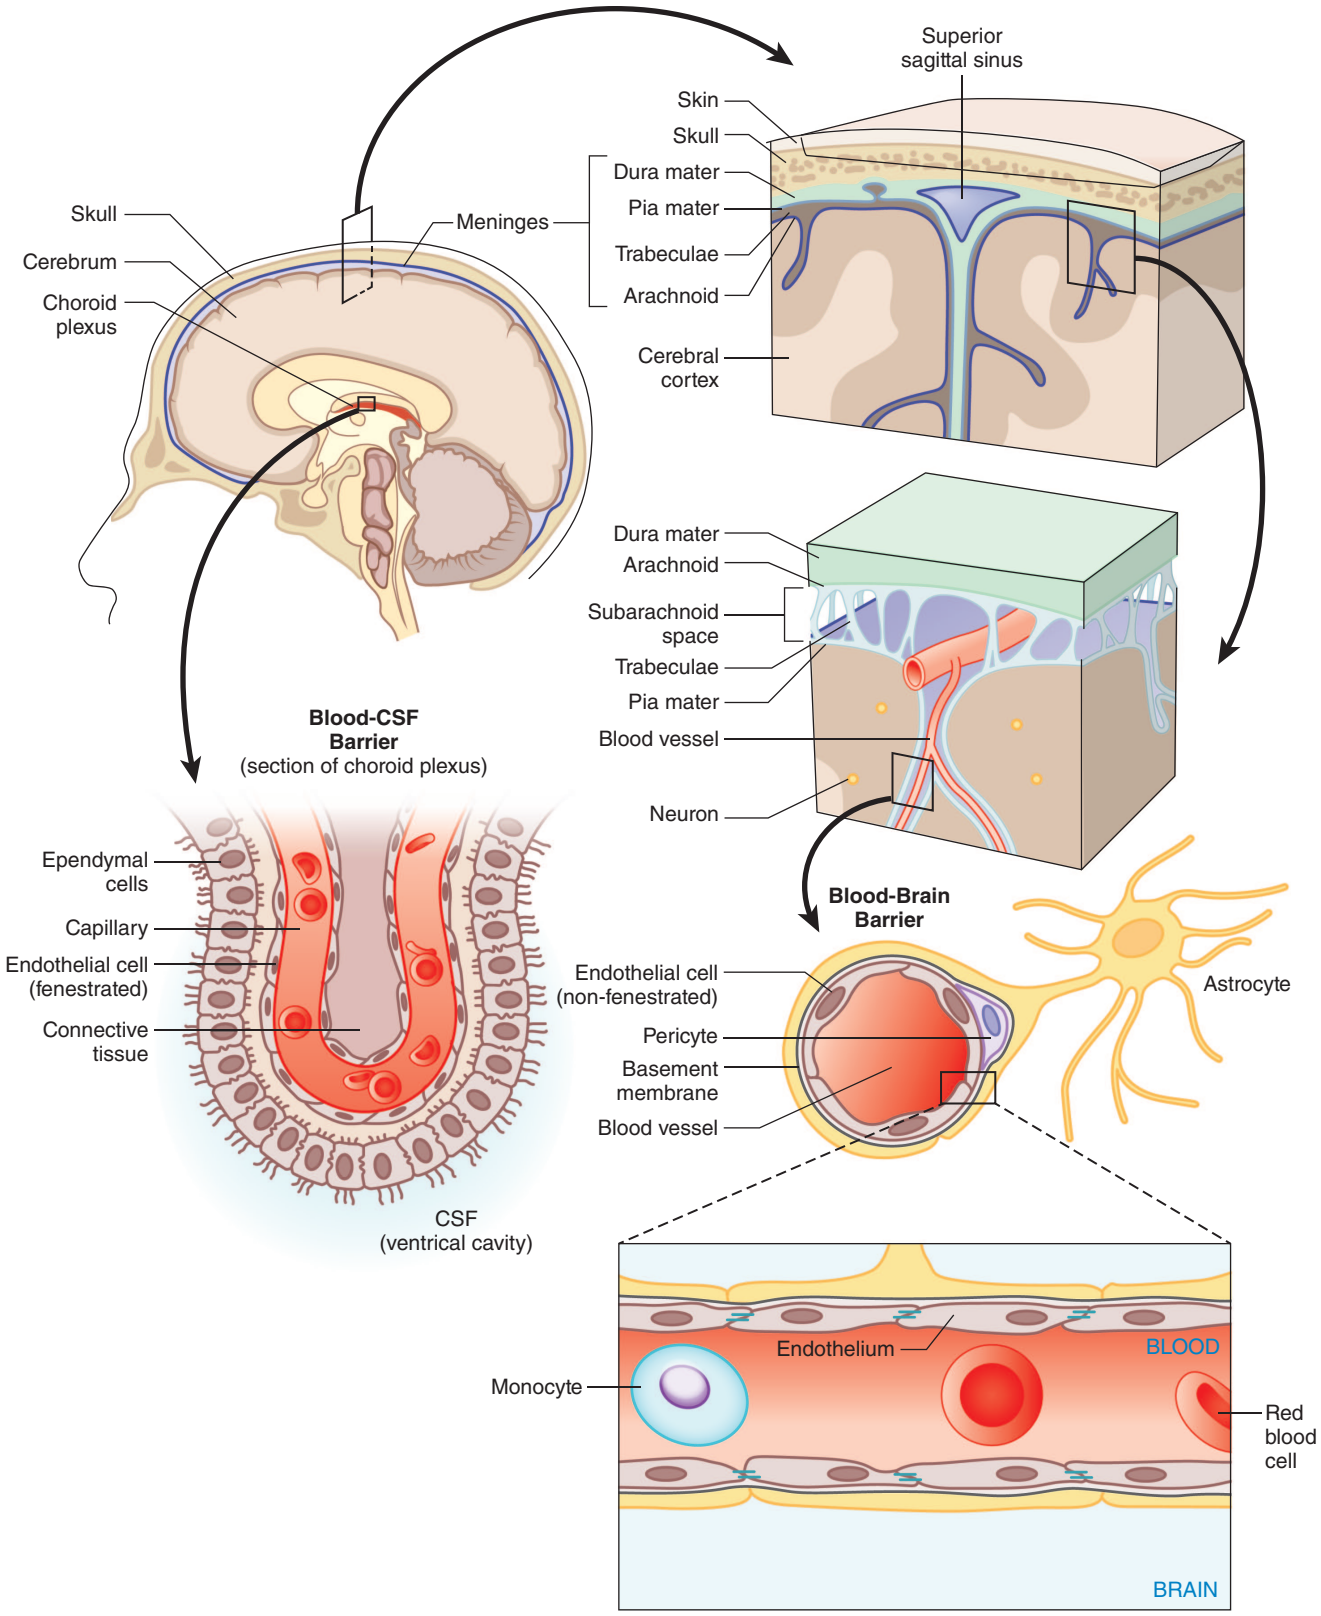

Figure 17–1 *Schematic representation of the major brain barriers.* Top right is a schematic of a cross-section through the meningeal coverings of the brain depicting the major meningeal barrier sites including the arachnoid barrier between the dura and the subarachnoid space and the vascular barrier possessed by the blood vessels within the subarachnoid space. Bottom left is a schematic of a cross-section through the choroid plexus that sits within the brain ventricles, depicting the choroid plexus epithelial cells that form the blood-CSF barrier between the leaky fenestrated vessels within the choroid plexus and the CSF within the ventricles. Bottom right depicts a cross-section of a parenchymal capillary that forms the BBB.

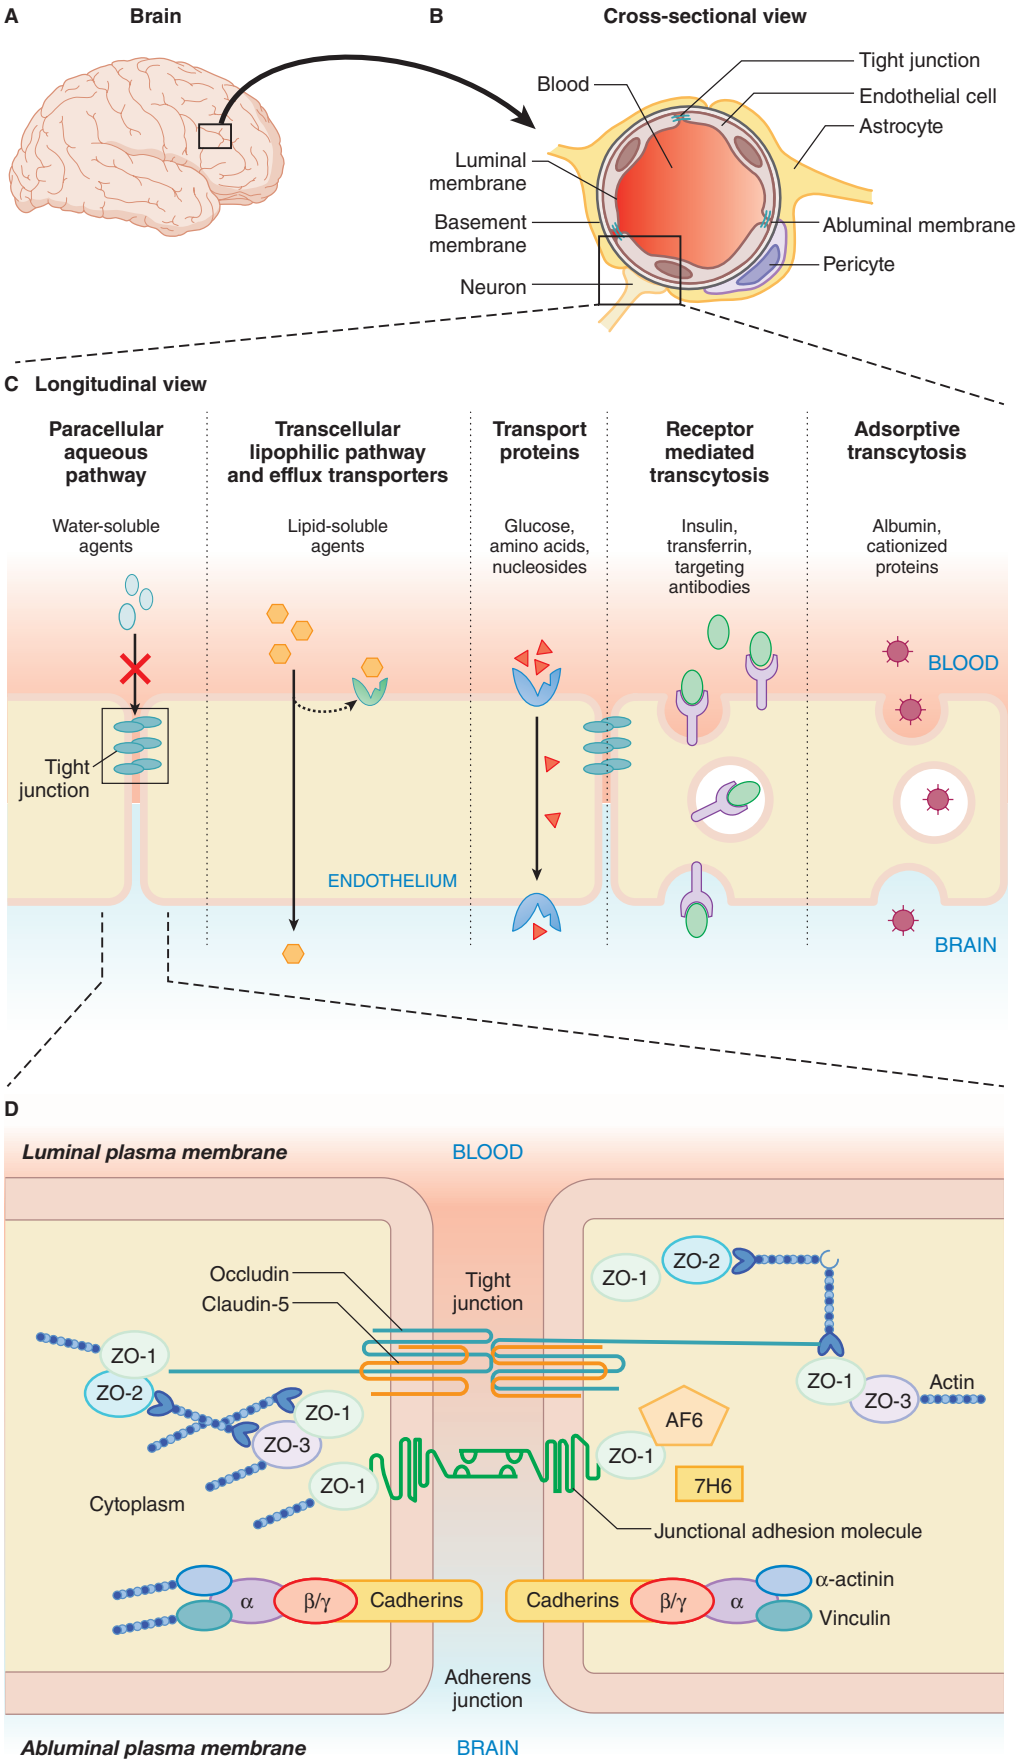

Figure 17–2 *Cellular and molecular anatomy of the BBB.* The vasculature of the brain (**A**) possesses specialized barrier properties that are induced and maintained by perivascular cells of the neurovascular unit (**B**). The BBB has a specialized network of transporters and properties to support selective transport of nutrients and metabolites into and out of the CNS (**C**). Brain endothelial cell adherens junctions and tight junctions are comprised of a complex network of cytoskeletal and transmembrane proteins (**D**).

including P-glycoprotein (ABCB1/MDR1) and breast cancer resistance protein (ABCG2/BRCP) (Loscher and Potschka, 2005) (Figure 17–2). These ABC transporters are present on the luminal membrane and use energy derived from the hydrolysis of adenosine triphosphate (ATP) to pump a wide array of substrates that would otherwise passively diffuse across the membrane, up their concentration gradient, and back into the blood. These transporters are critical modulators of drug delivery as they limit the entry of many small-molecule therapeutics into the brain.

Solute Transporters

The paracellular and transcellular barrier properties allow CNS endothelial cells to greatly restrict the movement of nonspecific molecules; however, the underlying neural tissue still requires specific nutrients for cell survival and physiological function. Therefore, CNS endothelial cells express a variety of *solute transporters* that facilitate the transport of specific substrates into the brain, including GLUT1 (glucose), LAT1 (amino acids), MCT1 (lactate), MCT8 (thyroid hormone), and others. Although peripheral tissues also require these nutrients, these transporters are largely lacking on the surface of peripheral vascular beds since these small molecules can easily access the tissues through paracellular routes. Lack of specific transporters in the BBB can lead to distinct neurological syndromes including De Vivo disease (GLUT1 deficiency) (De Vivo et al., 1991), an autistic syndrome (LAT1 deficiency) (Tarlungeanu et al., 2016), and psychomotor retardation (MCT8 deficiency) (Vatine et al., 2017). In addition, CNS endothelial cells express a variety of unique metabolic and signaling systems that act to regulate the extracellular composition of the CNS.

Immune Modulation

CNS endothelial cells also have much lower levels of *leukocyte adhesion molecules* compared to endothelial cells in other tissues. Binding of immune cells to leukocyte adhesion molecules is a critical step in their entry into a tissue. This is a multiple-step process that involves initial binding to the endothelium through selectins (e.g., E-selectin, P-selectin), rolling on the endothelium, firm adhesion through binding of immunoglobulin superfamily members (e.g., ICAM1, VCAM1), followed by transendothelial migration (see Figure 38–5). The low levels of these adhesion molecules on CNS endothelial cells correlate with very low amounts of immune cell infiltration across a healthy BBB, as most CNS immune surveillance occurs in CSF compartments including the ventricles and subarachnoid space. However, in many neuroinflammatory diseases, such as stroke, encephalitis, and multiple sclerosis, the endothelial cells can become activated and upregulate these adhesion molecules, leading to immune cell infiltration into the CNS. Inhibition of immune cell interactions with VCAM1 using *natalizumab*, an anti-VlA4 antibody, is effective at limiting new neuroinflammatory lesion formation in patients with relapsing-remitting multiple sclerosis (Polman et al., 2006).

Regulation of the BBB

To improve CNS drug delivery, it is critical to understand how the properties of the BBB are regulated within brain endothelial cells. Although many properties of the BBB are possessed by the endothelial cells, these properties can be induced and maintained by interactions with other cells within the neurovascular unit. This was first identified in transplantation studies, where blood vessels gained barrier properties upon vascularizing transplanted brain tissue, whereas brain blood vessels were found to lose barrier properties upon vascularizing the gut (Stewart and Wiley, 1981).

BBB Induction

Genetic manipulations in rodent models have identified that Wnt/β-catenin signaling drives CNS angiogenesis, but not angiogenesis in peripheral tissues, as well as the induction of tight junctions and solute transporter expression in the newly formed CNS vessels, indicating that specific barrier properties are induced as part of the CNS-specific angiogenic program (Daneman et al., 2009; Liebner et al., 2008; Stenman et al., 2008). Wnt/β-catenin signaling is also required for maintenance of the BBB, as genetic inhibition of this pathway in endothelial cells in adults leads to a cell-intrinsic reduction in tight junction proteins and leakage of blood vessels to nonspecific molecules (Wang et al. 2012). The cellular source of Wnt signals appears to be neural stem cells and progenitors during the initial invasion of blood vessels into the CNS and other cells, including astrocytes and oligodendrocytes, later in development and through adulthood.

Pericytes and Astrocytes

Pericytes are also critical regulators of BBB properties, acting to limit the activated state of the endothelial cells. Genetic manipulations in mice that reduce pericyte coverage of CNS vessels lead to BBB leakage through an increase in nonspecific caveolin-mediated transcytosis as well as an increase in the expression of leukocyte adhesion molecules and thus the inflammatory state of the vessels (Armulik et al., 2010; Daneman et al., 2010). Astrocytes are also critical regulators of the barrier properties in endothelial cells: astrocyte-conditioned media can decrease paracellular permeability and increase endothelial efflux, and reactive astrocytes can regulate BBB repair following disease (Abbott et al., 2006; Bush et al., 1999). Therefore, BBB function is induced and maintained through a series of complex and coordinated cellular signals derived from neural progenitors, astrocytes and pericytes.

Heterogeneity of the BBB

Although the BBB is largely a property of the capillaries in the CNS, barrier properties are present throughout the vascular trees from the invading arterioles to the draining venules. It is critical that each branch possesses barrier properties, as leakage at any level of the vascular tree would disrupt CNS homeostasis. There is both molecular and functional heterogeneity along the different segments of the vascular tree with regulation of blood flow most prominent in the arterioles, transport properties most prominent in the capillaries, and immune cell interactions most prominent in the postcapillary venules (Aird, 2007a, 2007b; Vanlandewijck et al., 2018a).

In addition, there is regional heterogeneity of the BBB to differentially control the local environment of different brain regions. For example, the area postrema, the subfornical organ, the vascular organ of lamina terminalis, the median eminence, the pituitary neural lobe, and the pineal gland, together termed the circumventricular organs, lack BBB properties. Instead, the fenestrated vessels in these regions allow for diffusion of molecules between the blood and the neural tissue, which is critical to the neurosensory and neurosecretory function of these brain regions (Kaur and Ling, 2017). Tanycytes are cells that create borders around these regions providing a cellular barrier restricting the blood-derived molecules from entering neighboring brain regions. Less is known about whether there is heterogeneity of the BBB in brain regions that contain a functional BBB to meet the unique requirements of different brain regions. Interestingly, there are 6-fold differences in the uptake of *paliperidone*, a strong P-glycoprotein substrate, among different brain regions, indicating that regional heterogeneity of the BBB may be a critical modulator of drug uptake (Loryan et al., 2016).

Plasticity of the BBB in Health

Blood-brain barrier function is not static but can change at different stages of life and in response to different stimuli. During embryonic development, the earliest invading vessels have immature junctions, large amounts of transcytosis, and high levels of leukocyte adhesion molecules, and thus are leakier than mature blood vessels (Siegenthaler et al., 2013). In aging, there is a decrease in specific receptor-mediated transcytosis and an increase in nonspecific caveolin-mediated transcytosis; thus, the BBB less stringently regulates the extracellular environment of aged brains (Yang et al., 2020). The properties of the BBB can also be dynamically regulated by signals coming from both the brain and periphery. For example, neural activity can decrease barrier efflux (Pulido et al., 2020), likely coordinating detoxification of the brain during rest periods with other brain exit routes including the glymphatic system. Furthermore, diet has been shown to alter the components of brain endothelial cell tight junctions, thus modulating the paracellular permeability (Salameh et al., 2019). Hence, the BBB is not simply a static wall that protects that brain, but a dynamic component of the neural circuitry, changing in response to different stimuli. These are important principles for understanding how the BBB regulates brain homeostasis and acts as an obstacle for drug delivery.

BBB in Disease

Blood-brain barrier dysfunction is observed in many neurological diseases, including stroke, multiple sclerosis, traumatic brain injury, epilepsy, and other neuroinflammatory and neurodegenerative diseases. This dysfunction can involve an increase in transcytosis, a loss of tight junction integrity, alterations in transporter expression, and an increase in the inflammatory state of the endothelial cells, which can lead to massive leakage of the BBB (Profaci et al., 2020). This leakage is often localized spatially to the region insult and temporally to specific pathophysiological stages of the injury and disease. For instance, in patients with multiple sclerosis, there is a leakage of the BBB, as measured by gadolinium enhancement on magnetic resonance imaging, at the location of neuroinflammatory lesions specifically at the onset of lesion formation. This leakage can be harnessed to target drug delivery to specific injured regions of the CNS within the specific time window of leakage (Miller et al., 1988).

Drug Delivery Across the BBB

Given the unique properties the BBB possesses, drug delivery across the BBB is a challenge. A circulating drug first encounters the endothelial glycocalyx, which reduces drug penetration by binding and sequestering molecules as they diffuse to the endothelial cell surface. If a drug molecule can penetrate the glycocalyx, it next needs to cross the barrier-forming endothelial cells of the BBB. There are several possible modalities for the trans-BBB passage of drug molecules (see Figure 17–2).

1. *Paracellular transport by diffusion between adjacent endothelial cells:* This process works for water-soluble molecules in peripheral vascular beds but is negligible at the BBB because of the high resistance tight junctions. Indeed, the introduction of small hydrophilic tracers into the bloodstream is often used as a measure of BBB integrity given their extremely low brain penetration. As a result of this physical barrier, drug penetration through the endothelial tight junctions does not result in therapeutic concentrations in the brain.
2. *Crossing plasma membranes:* Drug molecules can diffuse serially through the endothelial cell plasma membranes. For this process, drugs need to be small (<500–1200 Da) and rather lipophilic. In many cases, however, drugs having more lipophilic physiochemical properties are substrates for the efflux transporters P-glycoprotein, breast cancer resistance protein (BCRP), or members of the multidrug resistance protein (MRP) family. Thus, despite the cell-penetrable physiochemical properties, lipophilic drugs may not reach the brain because the active barrier of efflux transporters pumps drugs back to the bloodstream.
3. *Co-opting nutrient transporters:* For drugs that are large and/or hydrophilic, other delivery routes must be identified. One strategy takes advantage of the nutrient transporters expressed at the BBB. If a drug molecule is structurally similar to a nutrient, it may be possible for it to transport across the BBB using the endogenous transporter. For instance, the prodrug *levodopa* is structurally similar to phenylalanine, allowing it to enter brain endothelial cells via the large neutral amino acid transporter, after which it is subsequently metabolically converted to dopamine (Wade and Katzman, 1975). Unfortunately, steric limitations on such membrane carriers prevent their use with many drug cargoes. It is also important to note that since brain endothelial cells are polarized, the influx and efflux transporters can be found with differential abundance on the blood and brain side endothelial membranes, and this polarization may also impact the efficiency of trans-BBB delivery.
4. *Co-opting receptor-mediated transporters:* The endosomal trafficking network of brain endothelial cells can be targeted for drug delivery. Nonspecific fluid-phase endocytosis or pinocytosis and subsequent transcytosis are very limited at the BBB in healthy conditions, so drug uptake solely through this pathway is insufficient. However, the endosomal trafficking network of brain endothelial cells can be co-opted with carefully designed drug delivery constructs. For instance, protein cationization can lead to interactions with the brain endothelial cell surface and trigger the process known as adsorptive-mediated transcytosis. Alternatively, endothelial cell surface receptors that interact with endogenous large-molecule ligands like transferrin can be targeted using a variety of strategies, allowing conjugated drug molecules to cross the BBB and enter the brain.
5. *BBB opening:* Another option for crossing the BBB involves chemical or physical disruption of the tight junctions such that paracellular diffusion through the spaces between endothelial cells is enhanced. While this can increase drug uptake into the brain, it is inherently nonspecific in that other blood components can also enter the brain upon BBB disruption, potentially resulting in detrimental side effects.

Diffusion Into Brain

Once a drug leaves the brain endothelial cell, it also encounters the vascular basement membrane that surrounds endothelial cells and their associated pericytes and the glial limitans, an additional barrier formed by the extracellular matrix proteins secreted by astrocyte foot processes that wrap the brain vasculature. To reach neuronal or glial therapeutic targets, drugs must therefore diffuse through both the basal lamina and glial limitans before they can diffuse through the brain extracellular space. The brain extracellular space is estimated to have an average pore size of about 40 to 60 nm (Thorne and Nicholson, 2006), which could limit the transport of antibodies and nanoparticulate therapeutics.

Taken together, several routes exist for drug entry into the brain. The delivery of small-molecule therapeutics to the CNS by crossing plasma membranes is by far the most clinically advanced approach. With the continued development of protein and gene medicines (biologics) that are too large to transport through the endothelial cell membranes, there have also been significant recent efforts in the co-opting of receptor-mediated transport systems and leveraging of BBB opening to deliver biologics. The principles governing small-molecule transport into the brain are discussed below, followed by parallel efforts in developing brain delivery paradigms for biologics.

Small Molecules

When a drug is administered, independent of being given orally, intravenously, subcutaneously, or intramuscularly, it will first distribute into the bloodstream and from there out in the whole body. In all tissues and organs, there is further a distribution across the capillaries into the tissue and further into cells. As the brain constitutes around 2% of whole-body weight, most of the administered drug will distribute to the rest of the body, although clinically relevant concentrations can be obtained in the brain.

To enter the brain, the drug must cross the BBB. It is only the unbound drug molecules that can transverse the BBB. The molecules that are bound to plasma proteins cannot. Once inside the brain, it is only the unbound molecules that can interact with the target. Thus, what is nonspecifically bound to tissue components or to plasma proteins in the blood can be considered as an inactive reservoir in rapid equilibrium with the unbound, freely moving molecules. Therefore, measuring the unbound concentration is the most important way to understand membrane transport and drug action, without confounding the measurement with binding in plasma or to tissue components.

Drug distribution can be considered as a series of equilibria across barriers and between bound and unbound moieties of the drug. There is also an equilibrium between unionized and ionized drugs that is dependent on the pK_a of the drug and the pH at the specific site. In Figure 17–3, the equilibria relevant for drug transport across the BBB are depicted.

Rate and Extent of Transport Across the BBB

Transport across the BBB can have different rates depending on the drug's physicochemical properties in relation to those of the membrane. Also, different relationships can exist between the unbound concentrations in brain interstitial fluid (ISF) and plasma, due to the efflux and uptake transporter's efficiency. Thus, the rate and the extent of transport are two important aspects of transport across the BBB. These are two independent properties governing the pharmacodynamics of drug action in the brain. For anesthesia before surgery, drugs with rapid transport are sought after. It is also optimal that the anesthesia goes away quickly after surgery. For

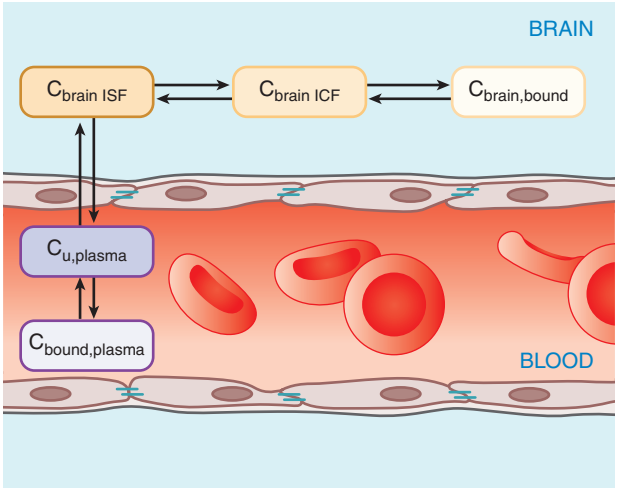

Figure 17–3 *Drug transport and equilibration across the BBB and into the brain parenchyma.* Drugs distribute in blood plasma between what is free and what is bound to plasma proteins. Only the free, unbound molecules can transverse the endothelial cell layer of the brain capillaries and reach the interstitial fluid (ISF) and go back into blood. Once inside the brain parenchyma, the drug equilibrates into cell intracellular fluid (ICF) and binds to cellular components. C describes the concentration.

other drugs that are taken daily for chronic diseases, the rate is not as important as the extent (i.e., how much drug enters the brain). Instead, we want high enough concentrations in the brain for action over time. Therefore, even though the transport across the BBB may be slow, a drug may still enter in enough quantities to be valuable. The extent of transport is therefore the most relevant property for drugs given chronically.

From Figure 17–3, it is clear that if a drug has a constant concentration in plasma and the passage across the BBB is passive (i.e., not influenced by any transporters either hindering or helping uptake into the brain [influx clearance = efflux clearance]), the unbound concentrations will be the same on both sides of the BBB at steady state. If transporters at the BBB hinder uptake (influx clearance < efflux clearance), the concentration in brain ISF will never reach as high levels as those in plasma. Conversely, if transporters in the BBB pick up drug from plasma (influx clearance > efflux clearance), the brain ISF concentration will become higher than those in plasma. This is illustrated in Figure 17–4. The ratio between brain ISF and unbound plasma concentrations is named $K_{p,uu,brain}$ (the

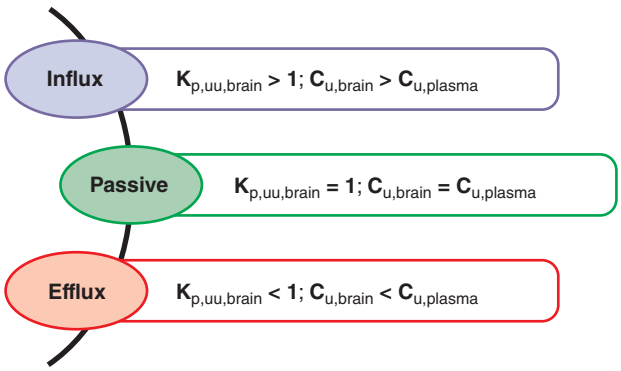

Figure 17–4 *Drugs equilibrate across the BBB in three ways depending on the activity of transporters, as described with $K_{p,uu,brain}$, the partition coefficient of drug concentrations across the BBB between unbound in brain ISF and unbound in plasma at steady state.* When efflux transporters like P-glycoprotein hinder transport into the brain, the unbound brain ISF concentration ($C_{u,brain}$) will never reach the same concentration as that in plasma ($C_{u,plasma}$) and $K_{p,uu,brain}$ will be lower than unity. When drug can transverse the BBB freely, the unbound concentrations will be similar in brain ISF and plasma, and when there are active uptake transporters acting on the drug, the concentration in brain ISF will be higher than that in plasma, and $K_{p,uu,brain}$ will be above unity.

partition coefficient of unbound drug across the BBB or, expressed differently, the concentration ratio of unbound drug between brain ISF and plasma) (Gupta et al., 2006; Hammarlund-Udenaes et al., 2008). Depending on the efficiency of an efflux transporter to hinder uptake, the ratio can be somewhat or much smaller than unity. The most potent efflux transporter for small molecular drugs is P-glycoprotein. Conversely, if a drug is actively taken up into the brain at the BBB, the higher the efficiency of uptake transport, the higher is the brain ISF concentration. Glucose enters the brain using the glucose uptake transporter GLUT1, but as glucose is rapidly consumed in the brain, the concentration is not generally higher than in plasma. Drugs are normally not metabolized in brain tissue. Therefore, their transport properties will more directly influence their concentration in the brain versus that in plasma.

$K_{p,uu,brain}$ can be expressed as a concentration ratio and as a ratio of clearances across the BBB:

$$K_{p,uu,brain} = \frac{C_{u,brain}}{C_{u,plasma}} = \frac{CL_{in}}{CL_{out}} \qquad \text{(Equation 17–1)}$$

where CL_{in} is the net influx clearance at the BBB from plasma to brain ISF and CL_{out} is the net efflux clearance from brain ISF to plasma (see Figure 17–4). The unit for clearance is µL/min/g brain.

In general, many more drugs are effluxed at the BBB than taken up actively. Examples of drugs on the market and their $K_{p,uu,brain}$ values are depicted in Figure 17–5. Measuring $K_{p,uu,brain}$ is so far done only in preclinical studies (Loryan et al., 2014). The values given in Figure 17–5 are therefore mainly from rat studies. Humans have a less "efficient" P-glycoprotein function at the BBB; thus, drug delivery to the brain may be higher in humans than in rodents (Syvanen et al., 2009; Uchida et al., 2020).

$K_{p,uu,brain}$ values of drugs provide important information for determining drug action in the CNS. For therapeutic targets in the CNS, drug developers should aim at higher $K_{p,uu,brain}$ values. To minimize CNS side effects, it should be low. At the same time, drug potency needs to be considered.

$K_{p,uu,brain}$ values can vary drastically within a drug class and can determine their therapeutic actions. Opioids are a good example: *Loperamide* is a strong P-glycoprotein substrate that is very efficiently effluxed. Its $K_{p,uu,brain}$ is less than 0.01, indicating that less than 1% equilibrates across the BBB. In other words, more than 99% is kept out of the brain by the BBB. On the other hand, *morphine* is only mildly effluxed out of the brain ($K_{p,uu,brain}$ = 0.3), and *oxycodone* is actively taken up at the BBB ($K_{p,uu,brain}$ = 3), reaching 3-fold higher concentration in the brain than plasma. Hence, the BBB actions determine the clinical use of these opioids: *Loperamide* can be used for diarrhea without effects from the CNS, while *morphine* and *oxycodone* are centrally acting analgesics. *Oxycodone* also shows much faster uptake into the brain than *morphine* (Bostrom et al., 2006, 2008). Although *morphine* and *oxycodone* have a 10-fold difference in their extent of BBB transport, they are both active in the CNS, as other pharmacokinetic factors are also contributing, including the dose that is used to give a clinically relevant effect.

Another class of drugs with varying brain delivery is the antihistamines. The newer generation antihistamines, like *cetirizine* or *loratadine*, are all significantly effluxed, thereby causing much less central side effects such as sedation. On the other hand, *diphenhydramine* is actively taken up at the BBB with a $K_{p,uu,brain}$ of 5 (i.e., five times higher concentrations in brain ISF than unbound in blood), explaining why it causes much more sedation. *Diphenhydramine* in fact has the highest active brain uptake of all drugs measured thus far.

Intrabrain Distribution

After traversing the BBB, the drug enters the brain parenchyma and distributes in the ISF and cells (Figure 17–6). The concentration in brain ISF is the driving force for further distribution. The distribution can involve passive diffusion and binding as well as active uptake into or efflux from cells. Intrabrain distribution can be described as the ratio of total amount of drug in the brain parenchyma to unbound drug concentration in brain

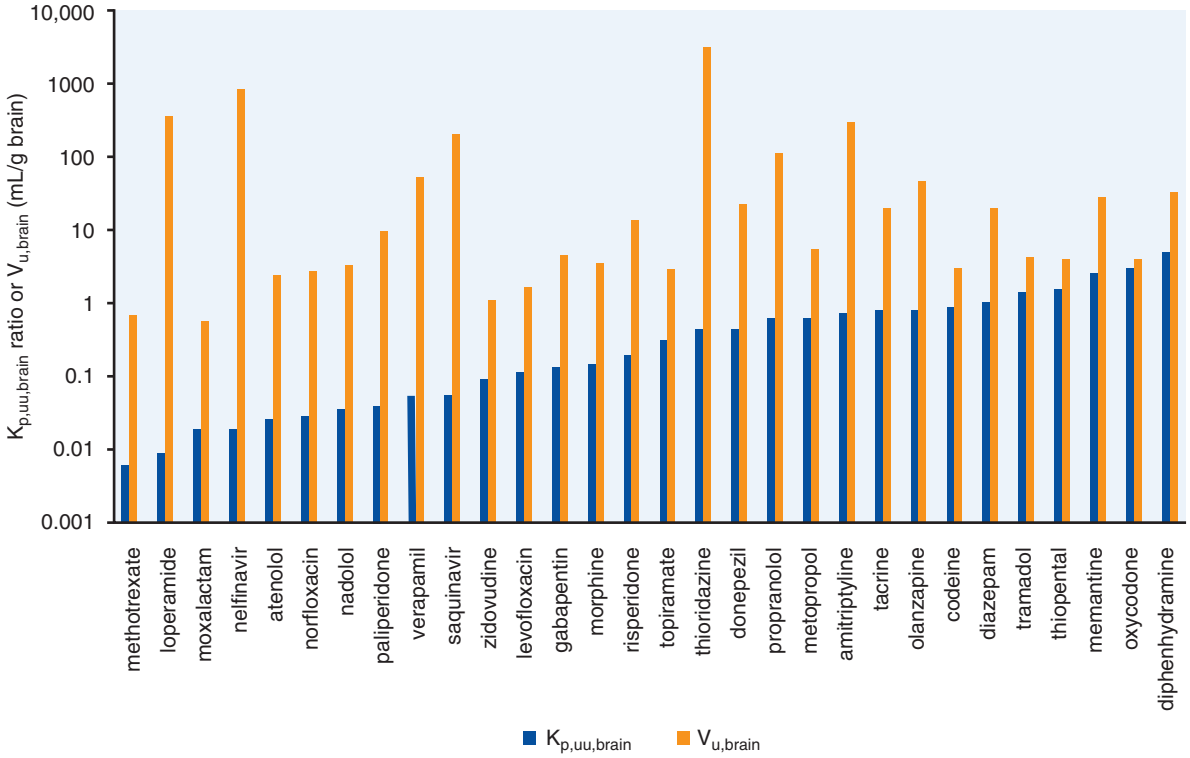

Figure 17–5 *Examples of how different drugs partition across the BBB and how they distribute in the brain parenchyma, showing that the two properties are not at all related.* This is described by the partition coefficient of unbound drug in brain ISF to that in plasma $K_{p,uu,brain}$ (blue) and the intrabrain distribution parameter $V_{u,brain}$ (orange), the unbound volume of distribution of drug in the brain, estimated as the ratio of the total amount of drug per gram of brain divided by the unbound concentration in brain ISF (mL/g) (describing both binding and/or intracellular distribution).

ISF, also called $V_{u,brain}$ (the unbound volume of distribution in the brain, expressed in mL/g brain). Approximating that 1 g brain equals 1 mL, this can be considered as a ratio, where the unbound volume of distribution in the brain $V_{u,brain}$ (mL/g brain) is described as:

$$V_{u,brain} = \frac{A_{tot,brain} - V_{blood\ in\ brain} \cdot C_{tot,blood}}{C_{u,brainISF}} \qquad \text{(Equation 17–2)}$$

$A_{tot,brain}$ is the total amount of drug in the brain per gram of brain. As there is also blood in the brain capillaries, this amount needs to be subtracted from the total amount in the brain to obtain a correct value. Therefore, $V_{blood\ in\ brain}$ is the physiological volume of blood in the brain, and $C_{tot,blood}$ is the total concentration of drug in the blood present in the brain. The blood volume in brain is 3% or less, depending on the sampling technique. $C_{u,brainISF}$ is the unbound concentration of drug in the brain ISF.

The values found so far of $V_{u,brain}$ range from 0.6 mL/g brain for *moxalactam* to 3300 mL/g brain for *thioridazine* (see Figure 17–5). The higher the value, the more the drug is bound to or distributed into cells than what is present in brain ISF. Some drugs, generally the more lipophilic ones, distribute and bind extensively to brain tissue components, as the brain parenchyma is also lipophilic in nature. Thus, BBB transport and brain drug binding are two independent parameters. A drug can have a very low BBB transport but quite extensive distribution and binding in the brain parenchyma (see Figure 17–5). The opposite is also possible (i.e., a drug can have a rather high BBB transport but not so extensive binding in brain). For example, the antiarrhythmic agent *verapamil* has a $K_{p,uu,brain}$ of 0.05 and a $V_{u,brain}$ of 54 mL/g brain, the antiviral drug *nelfinavir* has a $K_{p,uu,brain}$ of 0.02 and a $V_{u,brain}$ of 860 mL/g brain, while *diazepam* has a $K_{p,uu,brain}$ of unity, thus being mainly passively transported, and a $V_{u,brain}$ of 20 mL/g brain (i.e., 20 times more bound and/or distributed than unbound in brain). Drugs that do not enter cells to any significant degree have $V_{u,brain}$ values below unity. This is the case for *methotrexate* due to its high hydrophilicity.

Thus, when only total brain concentrations are measured, a candidate for further development may erroneously be selected that has high total brain concentrations but much lower unbound concentrations. Thus, if the high concentration is due to high binding, the part that is active (i.e., the unbound part) is much lower. Over the last decades, this has resulted in selection of many unsuccessful candidate drugs.

Intracellular Distribution

Drugs are taken up into cells due to pH partitioning as well as active uptake or efflux from the brain parenchymal cells (see Figure 17–6). In this context, cells of different types are averaged to a "typical" cell, independent of whether they are neuronal cells or glial cells. Of course, the distribution into these different cell types may differ, something that can be studied in cell cultures. The purpose here is to obtain an overview of how drugs are generally distributed.

Due to a lower intracellular pH, especially in lysosomes and other acidic organelles, basic drugs tend to accumulate in brain parenchymal cells, whereas acidic drugs do not. Basic drugs therefore tend to cause more side effects due to their accumulation in lysosomes, so-called lysosomotropism.

The ratio of unbound drug between intracellular and interstitial fluids is called $K_{p,uu,cell}$ (see Equation 17–3). As for the BBB, a ratio around unity indicates mainly passive transport, values below unity indicate reduced uptake into cells, and values above unity indicate accumulation into the brain parenchymal cell.

$$V_{p,uu,cell} = \frac{C_{u,cell}}{C_{u,brainISF}} \qquad \text{(Equation 17–3)}$$

where $C_{u,cell}$ is the average unbound concentration in cells and $C_{u,brainISF}$ is the concentration in brain ISF.

The equilibration of drug between the brain ISF and the average brain intracellular compartment, $K_{p,uu,cell}$, is a separate property from the overall binding and distribution to brain parenchyma ($V_{u,brain}$) (Figure 17–7).

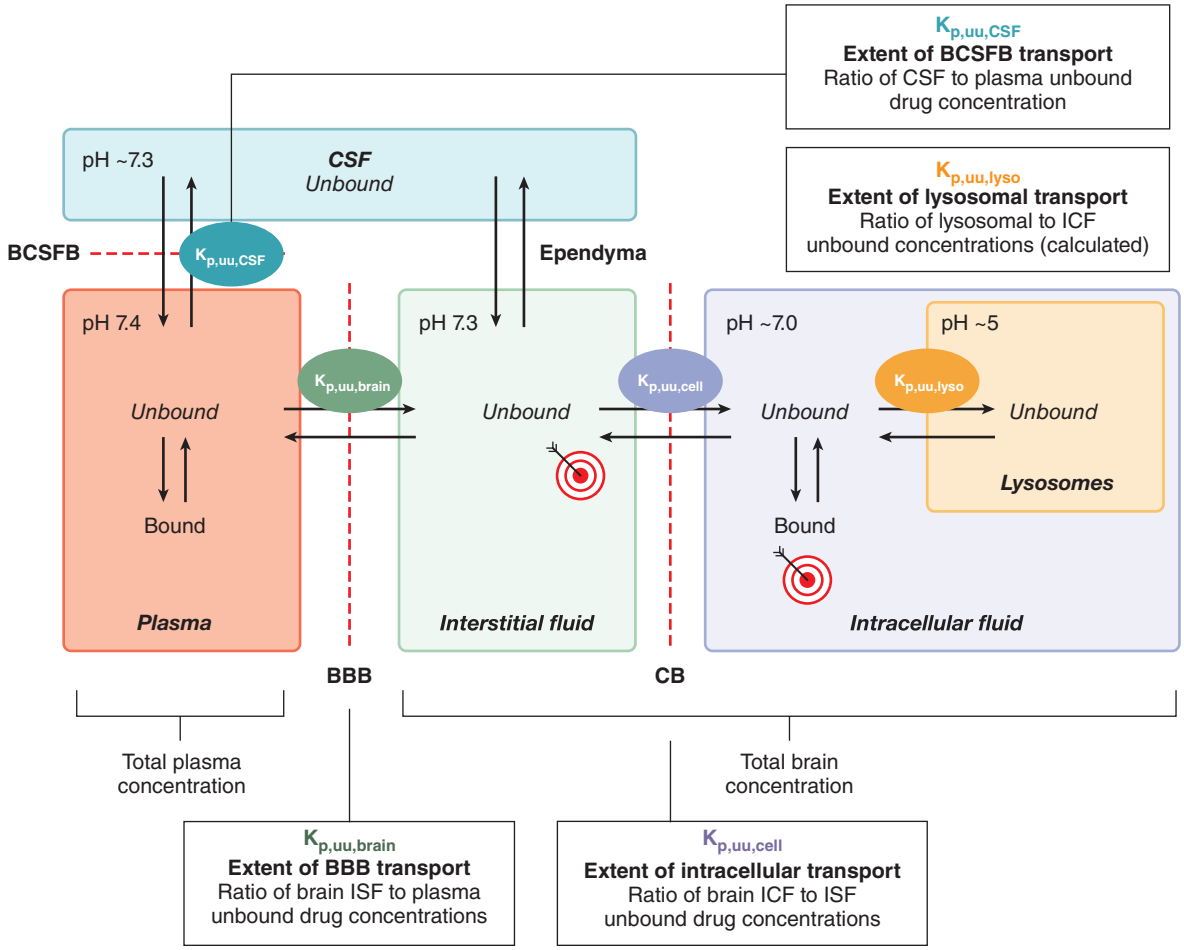

Figure 17–6 *Schematic representation of the equilibration of drug across the brain and cellular barriers (CB) and their representative parameters.* To be noted is the pH difference between the different compartments, influencing basic and acidic drugs to distribute differently, with basic drugs tending to accumulate into acidic lysosomes. ICF, intracellular fluid.

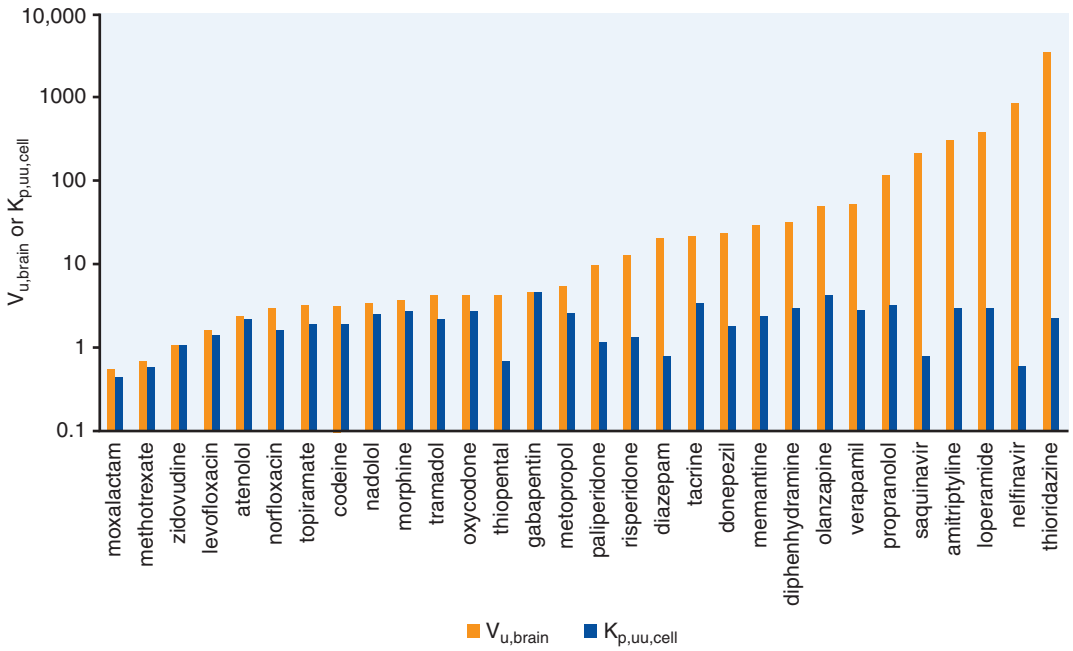

Figure 17–7 *Examples of how drugs distribute and bind in the brain parenchyma on average ($V_{u,brain}$) and their cellular partitioning ($K_{p,uu,cell}$), showing no relationship between the two.* This indicates that they are independent properties, where some drugs are accumulating into cells ($K_{p,uu,cell} > 1$) and others are not ($K_{p,uu,cell} = 1$ or < 1).

The binding is more governed by lipophilicity, while the cellular distribution, as described with $K_{p,uu,cell}$, is governed by other processes including pH partitioning. For example, compared to *methotrexate* with a $K_{p,uu,cell}$ of 0.6, the antidepressant *amitriptyline* with a $K_{p,uu,cell}$ of 2.9 accumulates intracellularly to much higher levels (Figure 17–7). A special case is *gabapentin*, which does not bind to cellular components, as shown by a $V_{u,brain}$ of close to unity, but exhibits a $K_{p,uu,cell}$ of 5. The likely explanation is the presence of an active uptake mechanism for *gabapentin* at the cellular barrier.

Whether drug concentrations in a given brain compartment are relevant for drug effects is dependent on the potency of the drug together with where the target is situated, be it toward brain ISF or cytosol or in the nucleus (see Figure 17–6). The same goes for side effects, as mentioned earlier with lysosomotropism.

CSF Versus Brain ISF Concentrations of Drugs

Cerebrospinal fluid is used as a surrogate site for measuring unbound drug brain concentrations in humans, as there is no other way of measuring unbound brain concentrations directly. Lumbar puncture is used to collect CSF. CSF has very little protein in healthy individuals, meaning that CSF drug concentrations are largely unbound. However, in disease, the protein concentration in CSF may increase. To understand the relationship of drug concentrations in CSF versus brain ISF, anatomical and physiological comparison of CSF versus brain ISF production and relation to plasma concentrations of the drugs must be considered. As discussed earlier, CSF is mainly produced at the BCSFB, in the choroid plexus (see Figure 17–1), while the main origin of brain ISF comes from the BBB. Transporter expression and hence active transport at the BBB are somewhat different than at the BCSFB. Thus, CSF drug concentrations may differ from those in brain ISF. For example, the transporter MRP2 is present at the BCSFB but not at the BBB (Gazzin et al., 2008). Nevertheless, the few studies that have been performed *in vivo* indicate that CSF concentrations are a reasonable estimate of ISF concentrations for most drugs (Friden et al., 2009).

Drug Interactions at the BBB

Drug-drug interactions could be expected since the transporter activity is high at the BBB. One might envision that two drugs that are both substrates for P-glycoprotein may compete with each other, resulting in higher brain concentrations of both drugs. However, to date, no such interaction has been reported. A likely explanation is that the plasma concentrations that the BBB "sees" are quite low in relation to the capacity of the transporters to handle the drug transport (i.e., the transport is not saturated). This contrasts to the liver and the gastrointestinal tract, where often much higher drug concentrations are present that can saturate transport systems (see Chapters 2 and 5 for details). In that regard, *in vitro* cell studies using much higher concentrations than those attained *in vivo* may suggest potential drug-drug interactions that are not observed *in vivo*.

Methods to Study BBB Transport

To measure BBB transport of drugs, the gold standard is microdialysis, where a microdialysis catheter is placed in a specific brain region and concentrations there are compared with unbound plasma concentrations (Chaurasia et al., 2007). Unfortunately, the method cannot be used for many drugs that bind avidly to plastic material in the catheter. Useful for those drugs is a combination of several methods, called the "combinatory mapping approach" (Loryan et al., 2014). Here, the total brain and plasma concentrations are measured at steady state, combined with plasma protein binding and brain tissue binding with the brain slice and brain homogenate techniques. These three measurements together will give the $K_{p,uu,brain}$:

$$K_{p,uu,brain} = \frac{C_{tot,brain}}{C_{tot,plasma} \cdot V_{u,brain} \cdot f_{u,plasma}} \qquad \text{(Equation 17–4)}$$

$C_{tot,brain}$ and $C_{tot,plasma}$ are the corresponding total concentrations at steady state, and $f_{u,plasma}$ is the unbound fraction of drug in plasma, measured with equilibrium dialysis of plasma versus buffer at pH 7.4. $V_{u,brain}$ is measured with the brain slice technique (Loryan et al., 2013), alternatively as a surrogate with the brain homogenate method, where $f_{u,brain}$ (unbound fraction of drug in brain homogenate) ≈ $1/V_{u,brain}$. However, the brain homogenate lacks pH partitioning and active membrane transport due to the homogenization of the tissue cells, which reduce the quality of the measurement.

To measure intrabrain distribution, the brain slice and the brain homogenate methods can be combined, resulting in $K_{p,uu,cell}$ (Equation 17–5). If the pK_a of a drug is known, it is also possible to estimate the partitioning between lysosomal and intracellular compartments, resulting in $K_{p,uu,lyso}$ (Figure 17–6).

$$K_{p,uu,cell} = \frac{C_{u,cell}}{C_{u,brain\ ISF}} = V_{u,brain} \cdot f_{u,brain} \qquad \text{(Equation 17–5)}$$

Positron emission tomography (PET) is a noninvasive method that can measure brain concentrations in humans. However, it measures total radioactivity and thereby both bound and unbound drug, as well as metabolites. Ongoing research attempts to translate PET measurements to unbound drug concentrations, which would give much more information on how humans are handling drugs at the BBB (Gustafsson et al., 2019).

Biologics

The BBB properties of tight junctions and limited pinocytosis severely restrict the uptake of large-molecule biologics into the brain. For example, only 0.03% to 0.1% of monoclonal antibodies administered intravenously reach the brain (Jones and Shusta, 2009), and thus, therapeutic concentrations are rarely achievable even under high dosing regimens (e.g., 20–50 mg/kg). Hence, biologics such as protein, DNA, and nanoparticles must use alternative routes for brain entry. Such routes include targeting the endosomal trafficking network of brain endothelial cells via adsorptive or receptor-mediated transcytosis where appropriately targeted drug cargo can engage with an endothelial cell receptor and piggyback across the BBB into the brain. For adsorptive or receptor-mediated processes, the steps for crossing the BBB include (1) binding to the endothelial cell surface via nonspecific charge interactions (adsorptive) or by targeting a specific BBB receptor (receptor-mediated); (2) inducing the formation and endocytosis of vesicles; (3) trafficking through the endothelial cell; (4) exocytosis; and (5) therapeutic release at the basolateral membrane (Figure 17–8). Alternatively, pathological BBB disruption or BBB disruption through chemical or physical means can be leveraged to increase brain entry of blood-borne biologics.

Quantifying Brain Uptake of Biologics

The critical measurement to understand potential therapeutic efficacy is the drug concentration that can be achieved in brain tissue. Initial rate pharmacokinetic analyses can allow the comparison of biologic delivery strategies as they relate to BBB permeability, the property that ultimately determines drug concentrations reached in brain. As is the situation for biologics, where the BBB permeability is relatively low compared with blood flow (Bickel, 2005), initial rate pharmacokinetics indicate that the brain uptake (%ID/g) is a function of the BBB permeability surface area (PS) product and the area under the plasma concentration curve (AUC):

$$\%\frac{ID}{g} = PS \times AUC \qquad \text{(Equation 17–6)}$$

where %ID/g is the percentage of the injected dose delivered to brain per gram of brain, PS is the BBB permeability surface area product (μL/min•g), and AUC is the area under the plasma concentration curve (%ID•min/μL).

As seen from Equation 17–6, the brain uptake will be directly proportional to the BBB permeability of the biologic through the PS product.

Thus, the PS product is instructive for comparing various strategies for crossing the BBB. The PS product is a lumped parameter describing the entire BBB transport process from binding to the brain endothelial cell to release into the brain (steps 1–5 in Figure 17–8). Importantly, the PS products for different targeting approaches and transport systems are not equivalent due to differences in receptor density and the percentage of internalized receptors that undergo transendothelial transport rather than recycling or being targeted to the lysosome (see Figure 17–8). In addition, brain uptake depends on the dose and systemic clearance properties of the molecule, quantified as the area under the brain concentration curve (AUC). Importantly, the AUC can be influenced by the brain specificity of the biologic targeting strategy. An ideal biologic delivery system would combine high trans-BBB transport that approaches or exceeds the natural ligand (Table 17–1) with high brain specificity and reduced clearance

TABLE 17–1 ■ TRANSPORT OF ANTIBODIES AND NATURAL LIGANDS AT THE BBB

(increased AUC). Thus, throughout the sections below, PS product and AUC are used as means for comparison of different strategies for biologic delivery to brain.

Confirming Brain Exposure of Biologics

Although kinetic approaches are accurate measures for brain delivery, they are based on whole-brain uptake assays that include both the vasculature and the brain components. Hence, any biologic that is bound to or internalized into brain endothelial cells (e.g., Figure 17–8) but not yet transported fully into brain will be included in these measures. Importantly, when using transcytosis-based delivery approaches, the fraction of delivered therapeutic that can be "trapped" in the vasculature and not available for brain exposure can be substantial. Several measurement methods have been introduced to circumvent this challenge.
