Menopause refers to the permanent cessation of menstrual periods (i.e., for >12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age. The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating, irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and coronary heart disease (CHD) and experience increased memory loss and other cognitive difficulties.

Estrogens

Estrogens are most commonly used to treat vasomotor disturbances ("hot flashes") in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. A variety of preparations, including oral, transdermal, and vaginal, are available. *Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic end point.*

In postmenopausal women with an *intact uterus*, a progestin is included to prevent endometrial cancer. MPA is used in the U.S., but micronized progesterone is preferred; *norethindrone* and *norgestrel/levonorgestrel* are also commonly used. Women *without a uterus* are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

The two major uses of estrogens are for *MHT* and as components of *combination oral contraceptives*, and the pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated equine estrogens have been the most common agents for postmenopausal use (0.625 mg/day). In contrast, most combination oral contraceptives in current use employ 20 to 35 μg/day of *ethinyl estradiol*. These preparations differ widely in their oral potencies (e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5–10 μg of *ethinyl estradiol*). Thus, the "effective" dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, over the past two decades, the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35-μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 50–150 μg of *ethinyl estradiol* or *mestranol*).

Menopausal Hormone Therapy

The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms

The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. MPA may provide some relief of vasomotor symptoms for certain patients, and the α_2 adrenergic agonist *clonidine* diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose, the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

An exciting new approach toward treating vasomotor symptoms involves inhibition of the aforementioned neurokinin 3 receptor. With the postmenopausal absence of estradiol, kisspeptin release from the arcuate nucleus is high, promoting increased GnRH pulsatility and elevated FSH and LH release from the pituitary. This increase in kisspeptin release from the arcuate nucleus may be in part secondary to increased signaling through the neurokinin 3 receptor. Small studies suggest that neurokinin 3 receptor inhibition may improve vasomotor symptoms in peri- or postmenopausal women (Prague et al., 2018).

Osteoporosis

Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (see Chapter 52). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs, such as bisphosphonates, should be considered (see Chapter 52). Most fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Anderson et al., 2004; Rossouw et al., 2002).

Estrogens act primarily to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Belchetz, 1994; Prince et al., 1991). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of Ca^{2+} and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment.

Vaginal Dryness and Urogenital Atrophy

Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered. *Prasterone* is a steroid vaginal insert with an unclear mechanism of action that is indicated for moderate to severe dyspareunia related to vaginal atrophy, although use has been associated with abnormal cervical Pap tests.

Cardiovascular Disease

The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently

showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. However, estrogens promote coagulation and thromboembolic events. Randomized prospective studies unexpectedly have indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time (Grady et al., 2002; Rossouw et al., 2002). Combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

Other Therapeutic Effects

Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes, including headache, fatigue, and difficulty concentrating. Chronic lack of sleep created by hot flashes and other vasomotor symptoms may be contributing factors. Estrogen replacement may help alleviate or lessen some of these via direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994). The Women's Health Initiative (WHI) demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

Menopausal Hormone Regimens

In the 1960s and 1970s, there was an increase in *estrogen replacement therapy* (i.e., estrogens alone) in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. Around 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of *hormone replacement therapy* (HRT), which includes a progestin to limit estrogen-related endometrial hyperplasia. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins.

Conjugated estrogens and MPA historically have been used most commonly in menopausal hormone regimens, although *estradiol*, *estrone*, and *estriol* have been used as estrogens, and *norethindrone*, *norgestimate*, *levonorgestrel*, *norethisterone*, and *progesterone* also have been widely used (especially in Europe). Various "continuous" or "cyclic" regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12 to 14 days of estrogen treatment; and (3) 5 to 6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. Conjugated estrogens plus MPA given as a fixed dose daily and conjugated estrogens given for 28 days plus MPA given for 14 of 28 days are widely used combination formulations. Other combination products available in the U.S. are *ethinyl estradiol* plus *norethindrone acetate*, *estradiol* plus *norethindrone*, *estradiol* and *norgestimate*, and *estradiol* and *drospirenone*. Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration and may increase SHBG, other binding globulins, and angiotensinogen and possibly the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route) (Walsh et al., 1994).

Tibolone is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The effects of this drug on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Finally, a combination of conjugated estrogens and the nonsteroidal SERM *bazedoxifene* can be used for menopausal symptoms. This combination has a neutral effect in the uterus and breast but has been shown to improve hot flashes, reduce vaginal dryness, and prevent (but not treat) bone loss (Parish and Gillespie, 2017).

Regardless of the specific agent or regimen, MHT with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

Untoward Responses

The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is coadministered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen or estrogen-progestin use and breast cancer is of great concern. The results of two large randomized clinical trials of estrogen/progestin and estrogen only (i.e., the two arms of WHI) in postmenopausal women clearly established a small but significant increase in the risk of breast cancer in the conjugated equine estrogens (CEE) plus MPA studies (Anderson et al., 2004; Rossouw et al., 2002). In the WHI study, CEE+MPA was associated with an increased relative risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received CEE alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance. Interestingly, the incidence of colon cancer was reduced by 26% in the WHI trial.

The Million Women Study in the U.K. was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed more than 1 million women; about half had received some type of hormone treatment, and half had never used this type of treatment. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and Million Women Study data are thus consistent with earlier studies indicating that the progestin component (e.g., *medroxyprogesterone*) in combined HRT plays a major role in this increased risk of breast cancer (Ross et al., 2000; Schairer et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, HRT for 5 years or less is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. However, if catechol estrogens, especially the 4-hydroxycatechols, are converted to semiquinones or quinones prior to "inactivation" by catechol-*O*-methyl transferase, the generation of ROSs may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers.

Metabolic and Cardiovascular Effects

Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, addition of progestins may reduce the favorable actions of estrogens. Estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Currently prescribed

doses of estrogens generally do not increase the risk of hypertension, and estrogen engaging the ERβ receptor typically reduces blood pressure.

Postmenopausal women who take HRT have a lower rate of nonalcoholic fatty liver disease and nonalcoholic steatohepatitis development than age-matched men or women not taking HRT. There is also a reduction of the abnormal metabolism in the liver, including excessive liver fat deposition that results in insulin resistance. Furthermore, the development of liver inflammation and fibrosis is attenuated by estrogen in postmenopausal women. The latter likely contributes to preventing progression to hepatocellular carcinoma in some individuals (DiStefano, 2020).

Many studies and clinical trials suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35% to 50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. The Heart and Estrogen/Progestin Replacement Study (HERS) study followed women with established CHD and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, but there was no overall change at 5 years (Hulley et al., 1998). The HERS II follow-up found no overall change in the incidence of CHD after 6.8 years of the treatment (Grady et al., 2002). In women *without* existing CHD (WHI trials) treated with an estrogen plus progestin, protective effects were seen but only when hormone replacement was initiated within 10 years of menopause (Rossouw et al., 2002).

It is clear that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with preexisting cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, for example, an estrogen-progestin combination led to an increase in eight attributable cases of stroke per 10,000 older women and a similar increase in pulmonary embolism (Rossouw et al., 2002). The latter was seen mainly in women who concomitantly smoked cigarettes.

Effects on Cognition

Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer's disease (Green and Simpkins, 2000). However, the WHI Memory Study of a group of women 65 years of age or older found that estrogen-progestin therapy was associated with doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003; Shumaker et al., 2003).

Estrogen and Parkinson's Disease

Based on many animal studies including in primates, estrogen and progesterone were found to have positive effects of preventing apoptosis of basal ganglia, dopamine-secreting neurons (Morissette et al., 2008). In human studies, there are data that estrogen prevents the development of Parkinson's disease, and less estrogen may contribute to the increased incidence of this disease in men (Vegeto et al., 2019).

Other Potential Untoward Effects

Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just before sleep. Fullness and tenderness of the breasts and edema may occur but sometimes can be diminished by lowering the dose.

Drug Therapy in Endometriosis, Fibroids Hirsutism, Gender Transition, and Hypoactive Sexual Desire Disorder

Endometriosis

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside the uterine cavity (Farquhar, 2007). It predominantly affects women during their reproductive years, with a prevalence of 0.5% to 5% in fertile women and 25% to 40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. Although poorly understood, the infertility is thought to reflect involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Because the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment of symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., *medroxyprogesterone, dienogest*) also have been used to promote decidualization of the ectopic endometrial tissue. The *levonorgestrel* IUS, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

Stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include *leuprolide*, *goserelin*, and *nafarelin*; other GnRH agonists also may be used off label for this purpose (see Chapter 46). Due to significant decreases in bone density and symptoms of estrogen withdrawal, "add-back" therapy with either a low-dose synthetic estrogen (e.g., CEE 0.625–1.25 mg) or a high-dose progestin (e.g., *norethindrone* 5 mg) has been used when the duration of therapy has exceeded 6 months (Olive, 2008). Alternatively, an oral GnRH receptor antagonist, *elagolix*, is effective at improving dysmenorrhea and pelvic pain in women with endometriosis, although *elagolix* is associated with hypoestrogenic adverse effects such as hot flashes, increased serum lipids, and a reduction in bone mineral density (Taylor, 2017).

Danazol, a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA-approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin *gestrinone* has been employed. *Danazol* has also been to treat severe forms of hereditary angioedema by increasing expression of esterase inhibitors through yet unknown mechanisms.

Hirsutism

Hirsutism, or increased hair growth in the male distribution, affects about 10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, PCOS, and Cushing syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical (Martin et al., 2008).

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of SHBG, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6 to 9 months. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. *Spironolactone*, a mineralocorticoid receptor antagonist, and *flutamide* (see Chapter 49) inhibit the androgen receptor. In Europe and elsewhere, *cyproterone* (50–100 mg/day) is used as an androgen receptor blocker, often in conjunction with a combination oral contraceptive. *Finasteride*, an inhibitor of the type 2 isozyme of 5α-reductase that blocks the conversion of testosterone to dihydrotestosterone, also is effective. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (fetal risk; contraindicated in pregnancy). The antifungal *ketoconazole*, which inhibits CYP steroid hydroxylases (see Chapters 50 and

61), also can block androgen biosynthesis but may cause liver toxicity. Topical *eflornithine*, an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth.

Nonpharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).

Gender Transition

In the past 10 to 20 years, sex steroids have been used more frequently in transgender patients. Because no significant clinical trials have been performed, a great deal of variability exists in the approaches taken in both male-to-female and female-to-male transgender patients. In general, younger patients in their early teens are often held from natural puberty through the use of GnRH agonists until the individuals are old and mature enough to be certain of their decision. Once the decision is made, whether the patients are younger or older, the approaches can be myriad, although they follow the same principles: (1) suppress endogenous sex steroid production and (2) promote physical and mental features of the desired gender.

Male-to-Female Transitions

The primary medication used for male-to-female transition is some form of estrogen, whether it be oral *estradiol* (2–6 mg/day), transdermal *estradiol* (0.1–0.4 mg every 24 h), or injectable estrogens such as *estradiol valerate* or *estradiol cypionate* (5–10 mg IM every 2 weeks). Side effects with estrogens, including thrombosis and breast cancer (not really established in male-to-female transgender patients), must be discussed with patients. Target serum estradiol levels are usually in the range of 100 to 200 pg/mL. In many patients, estrogen treatment alone will be sufficient to suppress endogenous androgen production and therefore androgen-mediated effects; however, in patients in whom this is not possible, antiandrogens such as *spironolactone* (100–400 mg/d) can be used. Alternatively, endogenous androgen production can be suppressed with GnRH agonists. The advantage of using antiandrogens or GnRH agonists is that the dosages of *estradiol* can often be significantly lower.

Female-to-Male Transitions

The primary medication used in female-to-male transitions is some form of androgen, whether it be injectable, such as *testosterone enanthate* or *cypionate* (50–100 mg IM per week), or androgen gels (25–100 mg/day of testosterone). Target plasma androgen levels should be in the normal male range (300–500 mg/day). Side effects of excess androgens, including polycythemia and lipid abnormalities, should be discussed and monitored with all patients. In general, these doses of androgens are sufficient to suppress endogenous ovarian steroid hormone production; however, if breakthrough uterine bleeding still occurs, patients can be treated with depot *medroxyprogesterone* (150 mg every 3 months) until bleeding no longer occurs.

Hypoactive Sexual Desire Disorder

Hypoactive sexual desire disorder (HSDD) is characterized by deficient or absent sexual fantasies and desire of sexual activity for an extended period of time that causes marked distress or interpersonal difficulty that cannot be attributed to a comorbid medical condition, problems in the relationship, or a drug or substance side effect. As the underlying cause of decreased sexual desire may be multifactorial, an appropriate treatment plan for HSDD may include interventions that target psychosocial, behavioral, and biological causes, sex therapy, and psychotherapy. *Flibanserin*, a centrally acting daily medication, is an FDA-approved therapy for generalized HSDD in premenopausal women. *Flibanserin* is a $5HT_{1A}$ receptor agonist and a $5HT_{2A}$ receptor antagonist, but the mechanism by which the drug improves sexual desire and related distress is not known. *Flibanserin* has been associated with severe hypotension and syncope when taken with alcohol, which should be avoided (USFDA, 2015/2019). *Bremelanotide*, a self-administered injection 45 min prior to anticipated sexual activity, is another FDA-approved medication for the treatment of generalized HSDD in premenopausal women. *Bremelanotide* activates melanocortin receptors, but the mechanism by which it improves sexual desire and related distress is unknown. It is associated with nausea and increased blood pressure and is not recommended in women at high risk for cardiovascular disease (USFDA, 2019). Hormone therapy may benefit select postmenopausal women. Postmenopausal women with vulvovaginal atrophy and/or dyspareunia will benefit from low-dose local vaginal estrogen therapy or a SERM such as *ospemifene* (USFDA, 2019b). Surgically menopausal and postmenopausal women with HSDD who are low risk for cardiometabolic disease may benefit from short-term testosterone therapy that achieves blood concentrations of testosterone that approximate premenopausal physiological concentrations (Davis et al., 2019).

Drug Facts for Your Personal Formulary: *Estrogens, Progestins, GnRH, Gonadotropins*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Estrogens		
Steroidal Estrogen and Derivatives Estradiol Estradiol valerate Estradiol cypionate Ethinyl estradiol Mestranol Estrone sulfate **Nonsteroidal Compounds** Diethylstilbestrol	• Menopause hormone therapy • Components of oral contraceptives • Treatment of transgender individuals • Depending on the preparation, may be available for oral, parenteral, transdermal, or topical administration	• Act via ERα and ERβ • Precaution: prescribe the lowest effective dose for the shortest duration consistent with treatment goals and risks for each individual patient • Increased risk of thromboembolism • Potencies of various oral preparations differ due to differences in first-pass metabolism
Selective Estrogen Receptor Modulators		
Tamoxifen	• Treatment of breast cancer • Antiestrogenic, estrogenic, or mixed activity depending on tissue	• Tissue-selective actions on ERs • Beneficial estrogenic actions in bone, brain, and liver during postmenopausal hormone therapy • Antagonist activity in breast and endometrium • Increased risk of thromboembolism • Hot flashes in premenopausal women
Raloxifene	• Treatment of osteoporosis (estrogen agonist in bone) • Reduces total cholesterol and LDL but does not increase HDL • Reduce risk of breast cancer in high-risk postmenopausal women	• Increased risk of thromboembolism • Neutral or antagonistic in uterus
Toremifene	• Treatment of breast cancer	
Bazedoxifene	• Osteoporosis prevention in postmenopausal women	• Increased risk of thromboembolism • Formulated in combination with conjugated estrogens
Ospemifene	• HSDD and dyspareunia treatment	• Increased risk of thromboembolism • Potential thickening of endometrium
Antiestrogens		
Clomiphene	• Treatment of infertility in anovulatory women	• Primarily a receptor antagonist but also has weak agonist activity
Fulvestrant	• Treatment of breast cancer in women with disease progression after tamoxifen • Used in women with resistance to aromatase inhibitors	• Receptor antagonist in all tissues
Estrogen Synthesis Inhibitors		
Aromatase Inhibitors *Steroidal inhibitors* Exemestane *Nonsteroidal inhibitors* Anastrozole Letrozole, vorozole	• Treatment of breast cancer (exemestane, letrozole, and anastrozole approved in the U.S.)	• *Steroidal inhibitors:* substrate analogues that irreversibly inactivate aromatase • *Nonsteroidal inhibitors:* interact reversibly with the heme groups of CYPs • Risk of osteoporosis with long-term use
Progestins		
Pregnanes Progesterone Medroxyprogesterone acetate Megestrol acetate	• Menopause hormone therapy • Contraception • Assisted reproductive technology • Depot MPA used as a long-acting injectable contraceptive	• Formulations: oral, injection (IM, SC), vaginal gel, vaginal insert • Progesterone: rapid first-pass metabolism • MPA and micronized progesterone are available for oral use
Estranes Norethindrone 19-Norethindrone	• Used in oral and injectable contraceptives • Used in combination with estrogen to treat hypogonadism	• 19-Nortestosterone derivatives • Progestational activity but also some androgenic and other activities
Gonanes Norgestrel Norgestimate	• Used in oral and injectable contraceptives	• 19-Nortestosterone derivatives, ethyl rather than methyl group at position 13 • Progestational components of contraceptives

Drug Facts for Your Personal Formulary: *Estrogens, Progestins, GnRH, Gonadotropins (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Antiprogestins and Progesterone Receptor Modulators		
Mifepristone (RU 38486)	• Termination of early pregnancy	• Competitive receptor antagonist of both progesterone receptors • May have some agonist activity
Ulipristal acetate	• Emergency contraception	• Partial progesterone receptor agonist
GnRH Agonist and Antagonists		
GnRH agonist Leuprolide	• Controlled ovarian hyperstimulation • Endometriosis • Uterine leiomyomas • Precocious puberty • Menstrual suppression in special circumstance (e.g., thrombocytopenia)	• Initial agonist action ("flare effect") results in increase in FSH and LH • After 1–3 weeks, desensitization and pituitary downregulation result in a hypogonadotropic, hypogonadal state • Risk of osteoporosis with long-term use
GnRH antagonist Cetrorelix, ganirelix Goserelin, buserelin Triptorelin, nafarelin	• Controlled ovarian hyperstimulation	• Competitive GnRH receptor antagonist • Immediate decline in LH and FSH levels • Risk of osteoporosis with long-term use
Gonadotropins		
FSH *Recombinant FSH* Follitropin-alpha Follitropin-beta *Human menopausal menotropins* Menotropins Urofollitropins Highly purified urinary FSH	• Ovulation induction • Controlled ovarian hyperstimulation	• Human menopausal gonadotropin may contain FSH, LH, and hCG and purification results in standardization of the FSH and LH activity • Injectable or intravenous
LH Recombinant LH	• Controlled ovarian hyperstimulation in women with LH deficiency due to hypogonadotropic hypogonadism	• Injectable or intravenous
hCG Recombinant hCG Urinary hCG Highly purified urinary hCG	• Promotes meiotic maturation from prophase I to metaphase II in oocytes	• Injectable or intravenous • Also used to stimulate testosterone and sperm production in men

Chapter 49

Androgens and the Male Reproductive Tract

Peter J. Snyder

Testosterone and Other Androgens

In men, *testosterone* is the principal secreted androgen. *Leydig cells* synthesize the majority of testosterone by the pathways shown in Figure 49–1. In women, testosterone also is the principal androgen and is synthesized in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors *androstenedione* and *dehydroepiandrosterone* are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone

Testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, the principal factor in male sexual differentiation, likely stimulated by *human chorionic gonadotropin* (hCG) secreted by the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of midpuberty, about 250 ng/dL (Figure 49–2). Testosterone production then falls by the end of the second trimester, but by birth, the concentration is again about 250 ng/dL, possibly due to stimulation of the fetal Leydig cells by *luteinizing hormone* (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at about 250 ng/dL at 2 to 3 months after birth and falls to less than 50 ng/dL by 6 months, where it remains until puberty. During puberty, from about 12 to 17 years of age, the serum testosterone concentration in males increases so that by early adulthood the serum testosterone concentration is 300 to 800 ng/dL in men, compared to 30 to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

Luteinizing hormone, secreted by the pituitary gonadotroph cells (see Chapter 46), is the principal stimulus of testosterone secretion in men, perhaps potentiated by *follicle-stimulating hormone* (FSH), also secreted by gonadotrophs. The secretion of LH by gonadotrophs is stimulated by hypothalamic *gonadotropin-releasing hormone* (GnRH); testosterone directly inhibits LH secretion in a negative-feedback loop. LH is secreted in pulses, which occur approximately every 2 h and are greater in magnitude in the morning (Crowley et al., 1985). The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Testosterone secretion is likewise pulsatile and diurnal, with the highest plasma concentrations occurring at about 8 AM and the lowest at about 8 PM. The morning peaks diminish as men age. *Sex hormone–binding globulin* binds about 38% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving about 2% unbound or free. In women, LH stimulates the *corpus luteum* (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, *estradiol* and *progesterone*, not testosterone, are the principal inhibitors of LH secretion in women.

Metabolism of Testosterone to Active and Inactive Compounds

Testosterone has many different effects in tissues, both directly and through its metabolism to *dihydrotestosterone* and *estradiol* (Figure 49–3). The enzyme 5α-reductase catalyzes the conversion of testosterone to dihydrotestosterone. Dihydrotestosterone binds to the *androgen receptor*

Abbreviations

AR: androgen receptor
CYP: cytochrome P450
FSH: follicle-stimulating hormone
GnRH: gonadotropin-releasing hormone
hCG: human chorionic gonadotropin
LH: luteinizing hormone
NO: nitric oxide
PDE5: phosphodiesterase type 5
PKG: protein kinase G
sGC: soluble guanylate cyclase

(AR) with higher affinity than testosterone and activates gene expression more efficiently. Two forms of 5α-reductase have been identified: *type I*, which is found predominantly in nongenital skin, liver, and bone; and *type II*, which is found predominantly in urogenital tissue in men and genital skin in men and women. The enzyme complex aromatase, present in many tissues, catalyzes the conversion of testosterone to estradiol. This conversion accounts for about 85% of circulating estradiol in men; the remainder is secreted directly by the testes (MacDonald et al., 1979). Hepatic metabolism converts testosterone to the biologically inactive compounds androsterone and etiocholanolone (see Figure 49–3). Dihydrotestosterone is metabolized to androsterone, androstanedione, and androstanediol.

Physiological and Pharmacological Effects of Androgens

Testosterone is the principal circulating androgen in men. At least three mechanisms contribute to the varied effects of testosterone:

- Direct binding to the AR
- Conversion in certain tissues to dihydrotestosterone, which also binds to the AR
- Conversion to estradiol, which binds to the estrogen receptor (Figure 49–4)

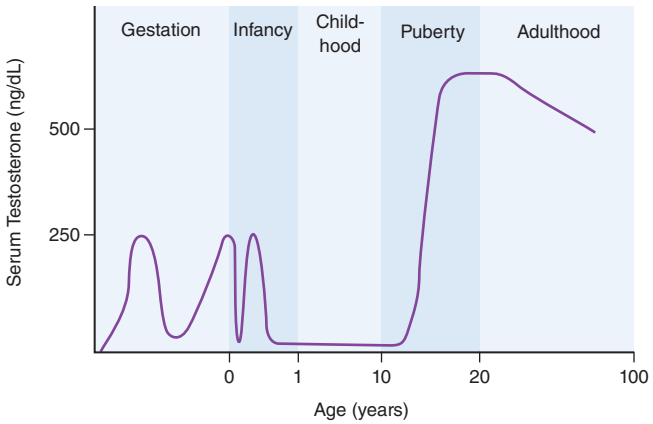

Figure 49–2 *Schematic representation of the serum testosterone concentration from early gestation to old age.*

Effects That Occur via the Androgen Receptor

Testosterone and dihydrotestosterone act as androgens via a single AR, a member of the nuclear receptor superfamily designated as NR3A. The AR has an amino-terminal domain that contains a polyglutamine repeat of variable length, a DNA-binding domain consisting of two Zn finger motifs, and a carboxyterminal ligand-binding domain. The polyglutamine repeat of variable length is unique to the AR; a shorter length appears to increase the receptor's activity.

In the absence of a ligand, the AR is in the cytoplasm associated with a heat shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the AR dissociates from the heat shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes (Agoulnik and Weigel, 2008).

Mutations in the hormone- or DNA-binding regions of the AR result in resistance to the action of testosterone, beginning in utero (McPhaul and Griffin, 1999); consequently, male sexual differentiation and pubertal development are incomplete. Other AR mutations occur in patients with spinal and bulbar muscular atrophy, known as *Kennedy disease*. These patients have an expansion of the CAG (cytosine, adenine, guanine) repeat,

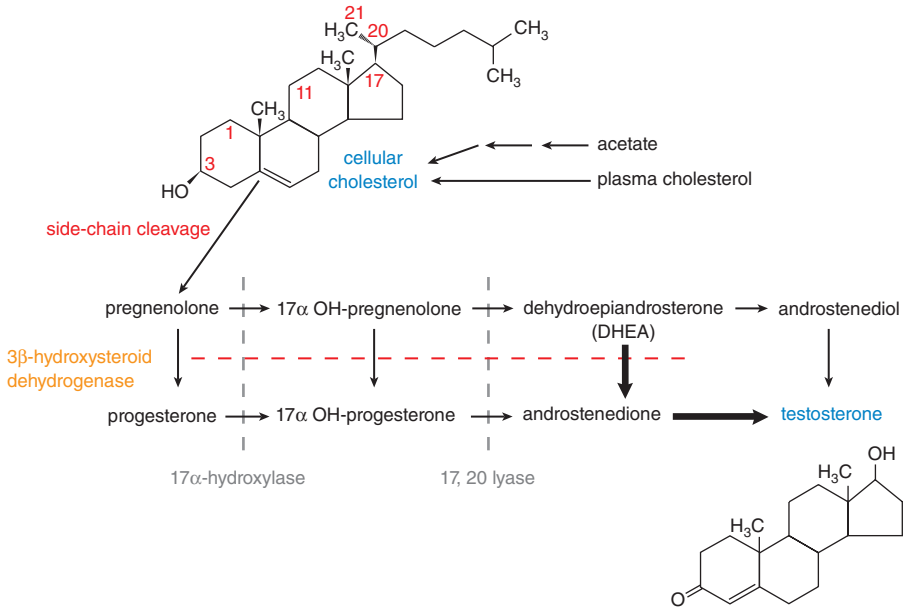

Figure 49–1 *Pathway of testosterone synthesis in Leydig cells of the testes.* In Leydig cells, the 11 and 21 hydroxylases (present in adrenal cortex) are absent, but CYP17 (17α-hydroxylase) is present. Thus, androgens and estrogens are synthesized; corticosterone and cortisol are not formed. Bold arrows indicate favored pathways.

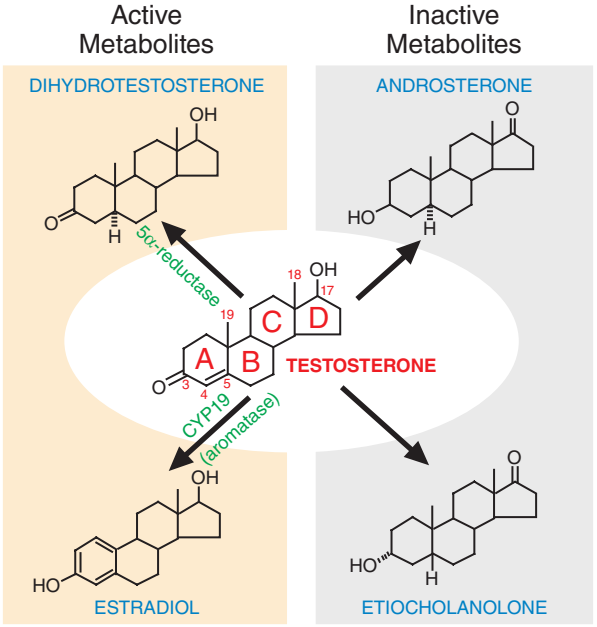

Figure 49–3 *Metabolism of testosterone to its major active and inactive metabolites.*

which codes for glutamine, at the amino terminus of the molecule (Walcott and Merry, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia, and progressively severe motor neuron atrophy (Dejager et al., 2002). The mechanism by which the neuronal atrophy occurs is unknown. Other mutations in AR may explain why metastatic prostate cancer often regresses initially in response to androgen deprivation treatment but then becomes unresponsive to continued deprivation. AR continues to be expressed in androgen-independent prostate cancer, and its signaling remains active. The ligand-independent signaling may result from mutations in the AR gene or changes in AR coregulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as *abiraterone*.

Effects That Occur via the Estrogen Receptor

Certain effects of testosterone are mediated by its conversion to estradiol, catalyzed by *cytochrome P450* (CYP) type 19 (aromatase). In rare cases of males deficient in CYP19 or the estrogen receptor, the epiphyses do not fuse, and long-bone growth continues indefinitely; such patients are also osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the AR (Colvard et al., 1989), testosterone also may act on bone via the AR. Administration of estradiol to a male with CYP19 deficiency can increase libido, suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol (Smith et al., 1994).

Suppression of testosterone production with a GnRH analogue and then replacing testosterone with or without *anastrozole*, an inhibitor of CYP19, also illustrates effects of testosterone that require conversion to estradiol. This paradigm demonstrated that the increase in sexual desire and erectile function and decrease in subcutaneous and abdominal fat require conversion of testosterone to estradiol but that the increase in lean mass and muscle strength do not (Finkelstein et al., 2013).

Effects of Androgens at Different Stages of Life

In Utero

When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. In the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia. The increase in testosterone at the end of gestation may result in further phallic growth.

Infancy

The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

Puberty

Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotrophs, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously; the changes in most tissue occur gradually over the course of several years. The phallus enlarges in length and width, the scrotum becomes rugate, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier

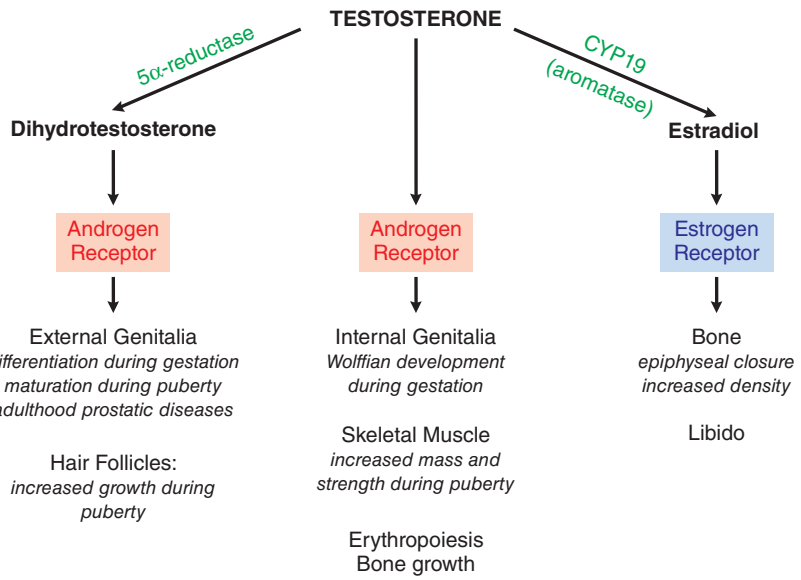

Figure 49–4 *Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.*

due to increased sebum production, which contributes to the development of acne. Male differential sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to slowing and then cessation of growth. Bone also becomes thicker. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops. Other changes may result from the increase in testosterone during puberty; men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

Adulthood

The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples or at the vertex.

Two other conditions are of great medical significance. One is benign *prostatic hyperplasia*, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α-reductase II within prostatic cells (Wilson, 1980). The other change is the development of *prostate cancer*. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

Senescence

As men age, the serum testosterone concentration gradually declines (see Figure 49–2), and the sex hormone–binding globulin concentration gradually increases, so that by age 80, the total testosterone concentration is about 80% and the free testosterone is about 40% of those at age 20 (Harman et al., 2001). This fall in serum testosterone probably results in several other changes that occur with increasing age in men, including decreases in libido, bone mineral density, and hemoglobin, as suggested by improvements in these parameters when testosterone is increased to normal levels for young men (see Therapeutic Uses of Androgens, below).

Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

During Fetal Development

Testosterone deficiency in a male fetus during the first trimester in utero causes incomplete sexual differentiation. Complete deficiency of testosterone secretion results in entirely female external genitalia. Testosterone deficiency at this stage of development also leads to failure of the Wolffian ducts to differentiate into the male internal genitalia, but the Müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete Müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is diminished because of an abnormality of the AR or of the 5α-reductase.

Abnormalities of the AR can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization in utero and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5α-reductase results in incomplete virilization of the external genitalia in utero but normal development of the male internal genitalia, which requires only testosterone (Wilson et al., 1993). Testosterone deficiency during the third trimester impairs phallus growth. The result, microphallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH secretion or action. In addition, with testosterone deficiency, the testes fail to descend into the scrotum; this condition, cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (see Chapter 46).

Before Completion of Puberty

When a boy can secrete testosterone normally in utero but loses the capacity to do so before the anticipated age of puberty, the result is failure to complete puberty. All the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called *gynecomastia*.

After Completion of Puberty

When testosterone secretion becomes impaired after puberty (e.g., castration or antiandrogen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hemoglobin will occur within several months. A decrease in bone mineral density can be detected within a year, but an increase in fracture incidence is not likely to occur for many years. Additionally, loss of sexual hair takes many years.

In Women

Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in decreased libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

Ingestion of testosterone is not an effective means of replacing testosterone deficiency due to its rapid hepatic metabolism following intestinal absorption. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic metabolism of testosterone. Note that all FDA-approved testosterone, *methyltestosterone*, and *oxandrolone* products are Drug Enforcement Administration schedule III controlled substances.

Testosterone Esters

Esterifying a fatty acid to the 17α-hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Table 49–1), is dissolved in oil and administered intramuscularly every 1 to 2 weeks to hypogonadal men, the ester hydrolyzes *in vivo* and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low-normal just before the next injection (Figure 49–5). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone, when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic metabolism. *Testosterone undecanoate* in oil also can be injected and produces stable serum testosterone concentrations for 2 months.

TABLE 49–1 ■ ANDROGENS AVAILABLE FOR THERAPEUTIC USE

Testosterone
Testosterone Esters Testosterone cypionate/enanthate/undecanoate
17α-Alkylated Androgens Methyltestosterone, oxandrolone, stanozolol Fluoxymesterone, danazol

Alkylated Androgens

Several decades ago, chemists found that adding an alkyl group to the 17α position of testosterone retards its hepatic metabolism. Consequently, 17α-alkylated androgens can be administered orally. Table 49–1 lists 17α-alkylated androgens used clinically. However, 17α-alkylated androgens are less androgenic than testosterone and cause hepatotoxicity, whereas native testosterone does not. Some 17α-alkylated androgens show greater anabolic effects than androgenic effects compared to native testosterone in laboratory tests in rats; however, these "anabolic" steroids, so favored by athletes to illicitly improve performance, have not been convincingly demonstrated to have such a differential effect in human beings. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2017a, 2017b).

Transdermal Delivery Systems

To avoid the "first-pass" inactivation of testosterone by the liver, chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. Available preparations include gels or a solution applied to the skin or nasal mucosa, a transdermal patch, and a buccal tablet (see Figure 49–5).

Selective Androgen Receptor Modulators

Attempts have been made to develop selective nonsteroidal AR modulators that exhibit desirable effects of testosterone in some tissues (such as muscle and bone) without the undesirable effects in other tissues, such as prostate. Some molecules with these properties have been developed and have been tested in humans, but unlike selective estrogen receptor modulators (see Chapter 48), none is currently available for clinical use.

Therapeutic Uses of Androgens

Male Hypogonadism

The best-established indication for administration of androgens is testosterone replacement of testosterone deficiency in men. Any of the testosterone preparations or testosterone esters described can be used to treat testosterone deficiency.

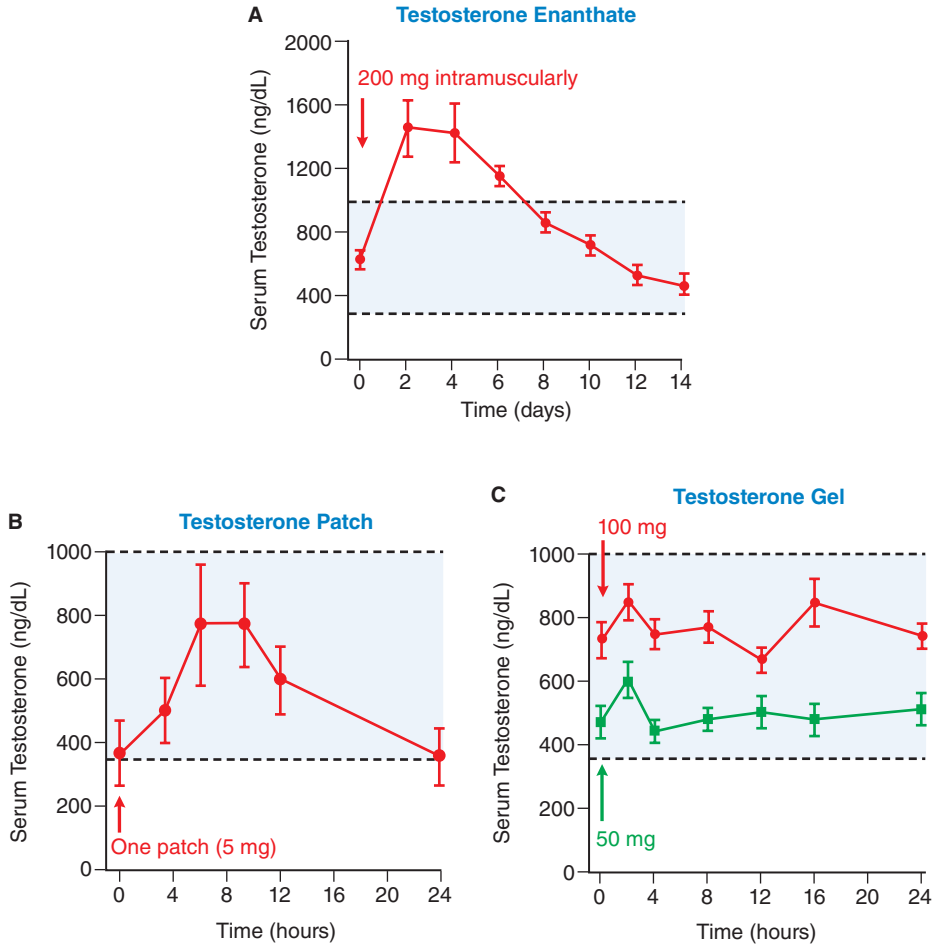

Figure 49–5 *Pharmacokinetic profiles of testosterone preparations during chronic administration to hypogonadal men.* Doses of each were given at time 0. Shaded areas indicate ranges of normal levels (**A.** Data adapted from Snyder and Lawrence, 1980. **B.** Data adapted from Dobs et al., 1999. **C.** Data adapted from Swerdloff et al., 2017.

Monitoring for Efficacy

The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration (see Figure 49–5). Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. With testosterone gels, the serum testosterone concentration is relatively constant from one application to the next (Swerdloff et al., 2000). When the enanthate or cypionate ester of testosterone is administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in adult men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hemoglobin return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density and trabecular connectivity, however, continue to increase for 2 years (Al Mukaddam et al., 2014; Snyder et al., 2000).

Monitoring for Deleterious Effects

Testosterone administered by itself as a transdermal preparation has no "side effects" (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins.

Replacement of physiological levels of testosterone occasionally has undesirable effects in the presence of concomitant illnesses. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions.

When a man is more than 40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer. Modified testosterones, such as the 17α-alkylated androgens, do have side effects even when the doses are targeted to be physiologic. The principal side effects are hepatic, including cholestasis and, uncommonly, peliosis hepatitis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. Additionally, they may lower serum high-density lipoprotein cholesterol, especially at large doses.

Monitoring at the Anticipated Time of Puberty

Testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth hormone status of the boy being treated must be considered. Boys who are short because of growth hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

Male Senescence

Serum testosterone levels decrease as men age, and the parallels between the consequences of aging and those of hypogonadism due to pituitary or testicular disease, such as decreases in sexual function, bone density, and hemoglobin, suggest the possibility that the decrease in testosterone with aging may contribute to these changes of aging. A study of 788 men 65 years or older with low testosterone concentrations demonstrated that testosterone treatment for 1 year, compared to placebo, improved sexual function, mood, depressive symptoms, anemia, and bone density and strength (Roy et al., 2017; Snyder et al., 2016, 2017). Testosterone replacement, however, did not improve cognitive function or glucose or lipid metabolism.

No studies to date have been large enough or long enough to determine whether testosterone treatment of older men will increase the risk of prostate cancer, urinary tract symptoms, or heart disease. The FDA, however, has become sufficiently concerned about the possible risk of cardiovascular disease, based on epidemiological studies and small clinical trials, that it has required a label change for testosterone preparations to indicate that they are approved only for men with "classical hypogonadism," meaning hypogonadism due to discernible pituitary or testicular disease, and not for idiopathic or age-related hypogonadism (Ngyuen et al., 2015).

Female Hypogonadism

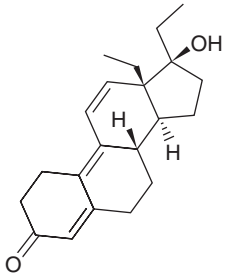
Few data exist regarding whether increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density. In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to high-normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo (Miller et al., 2006).

Enhancement of Athletic Performance

Some athletes take drugs, including androgens, in an attempt to improve their performance. Because androgens for this purpose usually are taken surreptitiously, information about their possible effects is not as complete as that for androgens taken for treatment of male hypogonadism. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2017a, 2017b).

Kinds of Androgens Used

Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When such use by athletes began more than 35 years ago, 17α-alkylated androgens and other compounds (the so-called anabolic steroids) were thought to have greater anabolic effects than androgen effects relative to testosterone and were used most commonly. Because these compounds can be detected readily by organizations that govern athletic competitions, other agents that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone, are also popular because they are treated as nutritional supplements and thus are not regulated by athletic organizations. Selective androgen receptor modulators, although not approved for clinical use, are available on the Internet. *THG*, a potent androgen, appears to have been designed and synthesized to avoid detection by antidoping laboratories on the basis of its novel structure and rapid catabolism.



Tetrahydrogestrinone (THG)

Efficacy

The few controlled studies of the effects of pharmacological doses of androgens suggest a dose-dependent effect of testosterone on muscle strength that acts synergistically with exercise. In one controlled study, 43 normal young men were randomized to one of four groups: strength training with or without 600 mg of testosterone enanthate once a week (more than six times the replacement dose) or no exercise with or without testosterone. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men

who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analogue to reduce endogenous testosterone secretion severely and, in a random blinded fashion, weekly doses of testosterone enanthate from 25 to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001). In contrast, in a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. The treatment also did not increase the mean serum testosterone concentration (King et al., 1999).

Side Effects

All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within 4 months of discontinuation but may take more than a year. High doses of androgens also cause erythrocytosis.

When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia even in high doses.

The 17α-alkylated androgens are the only androgens that cause hepatotoxicity. These androgens, when administered in high doses, affect serum lipid concentrations, specifically to decrease high-density lipoprotein cholesterol and increase low-density lipoprotein cholesterol. Women and children experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

Detection

An androgen other than testosterone can be detected by gas chromatography and mass spectroscopy if the athlete is still taking it when tested. Exogenous testosterone itself can be detected by one of two methods. One is the T/E ratio, the ratio of testosterone glucuronide to its endogenous epimer, epitestosterone glucuronide, in urine. Administration of exogenous testosterone suppresses secretion of both testosterone and epitestosterone and replaces them with only testosterone, so the T/E ratio is higher than normal. This technique is limited, however, by heterozygosity in the UDP-glucuronosyl transferase that converts testosterone to testosterone glucuronide. An athlete who has a deletion of one or both copies of the gene coding for this enzyme and who takes exogenous testosterone will have a much lower T/E ratio than one who has both copies (Schulze et al., 2008).

A second technique for detecting administration of exogenous testosterone employs gas chromatography-combustion-isotope ratio mass spectrometry to detect the presence of ^{13}C and ^{12}C compounds. Urinary steroids with a low $^{13}C/^{12}C$ ratio are likely to have originated from pharmaceutical sources as opposed to endogenous physiological sources (Aguilera et al., 2001).

Catabolic and Wasting States

Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with AIDS, which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

Angioedema

Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it. The 17α-alkylated androgens (e.g., *stanozolol*, *danazol*) stimulate hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes. Alternatively, concentrated C1-esterase inhibitor derived from human plasma may be used for protection in patients with hereditary angioedema.

Blood Dyscrasias

Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as *danazol*, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

Antiandrogens

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antiandrogens and now are used intentionally for this indication. See Chapter 73 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

Inhibitors of Testosterone Secretion

Analogues of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH analogues, given repeatedly, downregulate the GnRH receptor and are available for treatment of prostate cancer.

Some antifungal drugs of the imidazole family, such as *ketoconazole* (see Chapter 61), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis but sometimes are employed in cases of glucocorticoid excess (see Chapter 50).

Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase.

Androgen Receptor Antagonists

Flutamide, Bicalutamide, Nilutamide, Enzalutamide, Apalutamide and Darolutamide. Although relatively potent, these AR antagonists have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analogue in the treatment of metastatic prostate cancer (see Chapter 73). In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogues. *Flutamide* also has been used to treat hirsutism in women; however, its association with hepatotoxicity warrants caution against its use for this cosmetic purpose.

Spironolactone. *Spironolactone* (see Chapter 29) is an inhibitor of aldosterone that also is a weak inhibitor of the AR and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect. In part because of this adverse effect, the selective mineralocorticoid receptor antagonist *eplerenone* was developed. *Spironolactone* can be used in women to treat hirsutism.

Cyproterone Acetate. *Cyproterone acetate* is a progestin and a weak antiandrogen by virtue of binding to the AR. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive but is not approved for use in the U.S.

5α-Reductase Inhibitors

Finasteride and *dutasteride* are antagonists of 5α-reductase. They block the conversion of testosterone to dihydrotestosterone, especially in the male

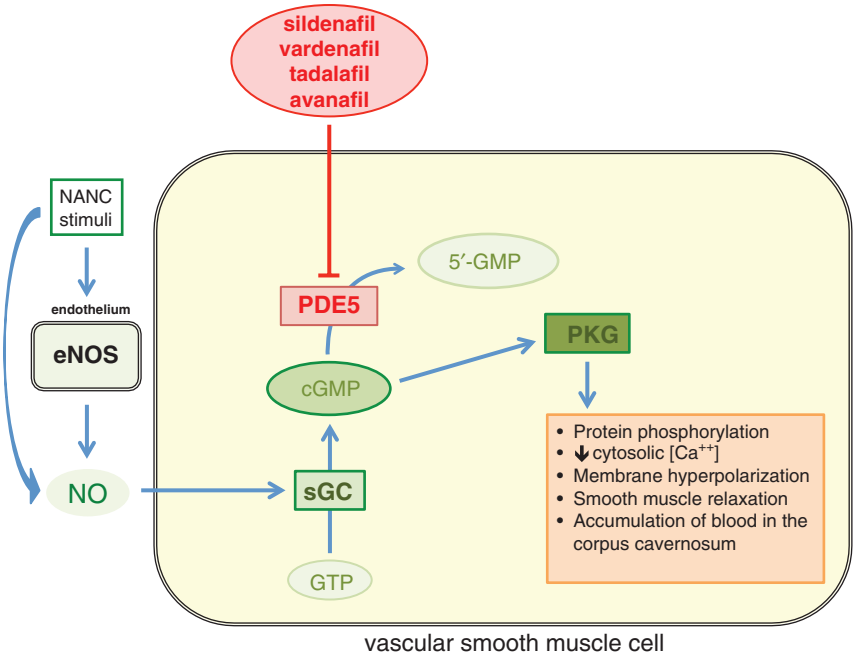


Figure 49–6 *Mechanism of action of PDE5 inhibitors in the corpus cavernosum.* Physiologically, penile erection is initiated by nonadrenergic/noncholinergic (NANC) neural stimulation that results in NO release from neurons and endothelial cells. PDE5 inhibitors enhance signaling through the NO–guanylyl cyclase–cGMP–PKG pathway by inhibiting the degradation of cGMP, thereby enhancing the activation of PKG. PKG activation leads to relaxation of cavernosal smooth muscle, which permits engorgement of the corpus cavernosum with blood, resulting in penile erection. eNOS, endothelial nitric oxide synthase.

external genitalia. These drugs were developed to treat benign prostatic hyperplasia and are approved in the U.S. and many other countries for this purpose. When they are administered to men with moderate-to-severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell et al., 1998). Impotence is a documented, albeit infrequent, side effect of this use. Gynecomastia is a rare side effect. *Finasteride* also is approved for use in the treatment of male pattern baldness and is effective in the treatment of hirsutism.

Pharmacological Treatment of Erectile Dysfunction

Normal erectile function depends on a combination of many factors, including visual, psychological, hormonal, and neurological factors, that act via the common mechanism of increasing the synthesis of NO by vascular endothelium in the arterioles supplying the corpora cavernosa and in the corpora cavernosa. NO diffuses to adjacent smooth muscle cells and causes vasodilation of arterioles and increased compliance of the cavernosal space, permitting its engorgement with blood. This accumulation of blood also restricts the outflow by compressing the veins against the surrounding sheath (*tunica albuginea*). The overall result is penile erection.

Erectile dysfunction can result from psychological, hormonal, and vascular causes, including damage to endothelium and from side effects of various drugs, including some that are used in the therapy of hypertension; it is associated with a variety of disease states, including diabetes (Dean and Lue, 2005).

Erectile Signaling and Erectile Dysfunction

Nitric oxide acts by binding and activating sGC, which catalyzes the production of cyclic GMP from cellular GTP. Cyclic GMP is a second messenger that activates *protein kinase G* (PKG), leading to phosphorylation of contractile proteins and ion channels to decrease the concentration of intracellular Ca^{2+}, resulting in smooth muscle relaxation and increased blood flow to corpora cavernosa. Phosphodiesterase type 5 (PDE5) degrades cyclic GMP; thus, erectile dysfunction can be improved by drugs that retard the degradation of cyclic GMP by inhibiting PDE5 (Goldstein et al., 1998) (Figure 49–6).

PDE5 Inhibitors

Available inhibitors of PDE5 include *sildenafil*, *vardenafil*, *tadalafil*, and *avanafil*. All these agents compete for cyclic GMP binding at the site of cyclic GMP hydrolysis on PDE5. PDE5 inhibitors are also used in treating pulmonary arterial hypertension (see Chapter 35).

ADME

Table 49–2 summarizes pharmacokinetic properties of the available PDE5 inhibitors. These agents are adequately absorbed orally, widely distributed, and act fairly quickly (within ~30 min). Their affinities, time to onset, and half-lives differ somewhat (see Table 49–2), giving patients options for onset and duration of effect. The drugs are metabolized by hepatic CYP3A4, with minor contributions by CYP2C9 (20% for *sildenafil*). Excretion of metabolites is largely via the feces, with urinary excretion playing a secondary role in excretion of *tadalafil* (36%) (Mehrotra et al., 2007).

Clinical Use

All these agents produce satisfactory results in most patients. The starting dose recommendations vary, and patients should start at the lowest recommended dose. This is especially important in patients over 65 years.

Adverse Effects, Precautions

Adverse effects are similar but not identical across this drug class owing to their similar mechanism of action but their differing specificities toward PDE5 compared to other PDE isoforms. Common complaints are headache, flushing, dyspepsia, nasal congestion, dizziness, and back pain. Some patients using *sildenafil* or *vardenafil* may notice blurred vision and a blue-green tinting of vision, referable to inhibition of retinal PDE6, which is involved in phototransduction (see Chapter 74).

TABLE 49–2 ■ PHARMACOKINETIC PROPERTIES OF PDE5 INHIBITORS

	SILDENAFIL	VARDENAFIL	TADALAFIL	AVANAFIL
K_i (nM)	4	0.1	2	4
Plasma $t_{1/2}$ (h)	4	4	17.5	1.3–2
Oral bioavailability (%)	40	15	40	70
Onset of action (min)	30–60	30–60	30–120	15–30
Time to C_{Pmax} (min)	60	60	120	30
Maximum duration of action (h)[a]	12	10	36	6
Optic effects/PDE6	+	+	–	–
Food[b] alters AUC, C_{Pmax}?	+	+	–	±

[a]Duration will vary with dose and rate of clearance.
[b]High-fat meal; generally reduces AUC and C_{Pmax} but, for avanafil, prolongs absorption period and time to C_{Pmax} (by 1 h), decreases C_{Pmax} (−24%), and increases AUC (+14%).
For pharmacokinetic data on PDE5 inhibitors, see FDA, 2012, and Mehrotra et al., 2007.

Concomitant administration of potent CYP3A inducers (e.g., *bosentan*) will generally cause substantial decreases in plasma levels of drugs in this class. CYP3A inhibitors (e.g., protease inhibitors used in human immunodeficiency virus therapy, *erythromycin*, and *cimetidine*) inhibit metabolism of PDE5 inhibitors, thereby prolonging the half-lives and elevating blood levels of these agents. Consistent with their mechanism of action, potentiation of cyclic GMP signaling, PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressures. Thus, the administration of PDE5 inhibitors to patients receiving organic nitrates is contraindicated. The patient's underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrates, α adrenergic antagonists) must be considered prior to use of this class of drugs. Priapism (erection lasting longer than 4 h) induced by PDE5 inhibitors runs the risk of ischemic damage to the cavernosal smooth muscle and sinusoidal epithelium and requires medical attention.

Drug Facts for Your Personal Formulary: *Androgens; Antiandrogens; PDE5 Inhibitors*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Testosterone Esters • Effective for weeks to months. Wide fluctuations in serum concentrations		
Testosterone enanthate, testosterone cypionate	• Treatment of male hypogonadism	• Formulated in oil for injection • Administer as a deep IM injection every 1–2 weeks • Effective in causing and maintaining virilization • Fluctuations in serum concentrations may result in fluctuations in energy, mood, and libido
Testosterone undecanoate	• Treatment of male hypogonadism	• Formulated in oil for injection • Administer as a deep IM gluteal injection. Observe for 30 min after injection for anaphylaxis or pulmonary microembolism • Administer every 10 weeks
Testosterone undecanoate for oral administration	• Treatment of male hypogonadism	• Taken 2–3 times a day with food • Absorbed into lymphatics
Testosterone Transdermal Patch		
One FDA-approved product	• Treatment of male hypogonadism	• Worn without interruption and changed once a day • High rate of skin rash
Transdermal Testosterone Gels		
Several FDA-approved products	• Treatment of male hypogonadism	• Applied once a day • Relatively steady serum testosterone concentration • Effective in causing and maintaining virilization
17α-Alkylated Androgens		
Danazol Methyltestosterone Oxandrolone	• Treatment of angioedema • Treatment of hemolytic anemia • Angioedema prophylaxis • Endometriosis • Fibrocystic breast disease	• Oral administration • Risk of hepatoxicity
GnRH Analogues		
Leuprolide Goserelin Triptorelin Histrelin Buserelin (not available in the U.S.)	• Treatment of metastatic prostate cancer • Leuprolide also approved for endometriosis, precocious puberty, prostate cancer, and uterine leiomyomata • Goserelin also approved for breast cancer, dysfunctional uterine bleeding, and endometriosis • Histrelin also approved for precocious puberty and prostate cancer	• Parenteral administration • Suppresses LH and FSH secretion and thereby causes profound hypogonadism
Androgen Receptor Antagonists		
Flutamide Bicalutamide Nilutamide Enzalutamide	• Adjuvant treatment of metastatic prostate cancer	• Used in conjunction with GnRH agonists
5α-Reductase inhibitors		
Finasteride Dutasteride	• Treatment of lower urinary tract symptoms due to benign prostatic hyperplasia • Finasteride also approved for alopecia	• Shrinks the size of the prostate by decreasing the production of dihydrotestosterone in the prostate • Dutasteride also marketed as fixed-dose combination with tamsulosin
PDE5 Inhibitors		
Sildenafil, vardenafil, tadalafil, avanafil	• Male erectile dysfunction • Pulmonary arterial hypertension	• Contraindicated in patients using nitrate vasodilators (can cause dangerously low blood pressure) • Side effects: headache, flushing, blue-green tinted vision • Erection lasting >4 h requires medical attention

Chapter 50

Adrenocorticotropic Hormone, Adrenal Steroids, and the Adrenal Cortex

Christopher J. Hupfeld and Jorge A. Iñiguez-Lluhí

Corticotropin, also known as adrenocorticotropic hormone (ACTH), is secreted by specialized cells in the anterior pituitary gland known as the *corticotrophs*. They constitute about 20% of the anterior pituitary cells. Besides ACTH, corticotrophs also release melanocyte-stimulating hormone (MSH) and lipotropin. While synthetic derivatives of ACTH are used commonly in the diagnostic assessment of adrenal cortex function, synthetic corticosteroids, rather than ACTH, are used therapeutically.

The adrenal cortex synthesizes and secretes steroid hormones essential for adaptive responses to stress (glucocorticoid) and mineral balance (mineralocorticoid) and for some direct and indirect androgenic functions, particularly in women (adrenal androgens). Glucocorticoids and mineralocorticoids are collectively referred as corticosteroids, with cortisol and aldosterone being the main physiologic forms. Corticosteroids and their biologically active synthetic derivatives may differ individually in their glucocorticoid (metabolic/anti-inflammatory) and mineralocorticoid (electrolyte-regulating) actions. These agents are used as physiological replacement therapy when endogenous production is impaired, as in adrenal insufficiency.

The broad anti-inflammatory and immunosuppressive properties of glucocorticoids are of great therapeutic value in numerous conditions where suppression of inflammation is needed (such as autoimmune diseases and allergic reactions), making them among the most frequently prescribed classes of drugs. Shortly after synthetic *cortisone* became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis, setting the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed in this chapter. Because glucocorticoids exert effects on almost every organ system, their administration and withdrawal may be complicated by severe side effects. Therefore, the decision to institute therapy with systemic glucocorticoids always requires careful consideration of the relative risks and benefits in each patient.

Corticotropin (ACTH)

Human ACTH, a peptide containing 39 amino acids, is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC). In the pituitary, POMC undergoes proteolytic cleavage at dibasic residues by two serine endoproteases, proprotein convertase subtilisin/kexin 1/3 and 2 (PCSK1/3 and 2; Figure 50–1). This process produces ACTH as well as

HISTORICAL PERSPECTIVE

Addison described fatal outcomes in patients with adrenal destruction in 1849. A few years later, Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It became clear that the adrenal cortex, rather than the medulla, was essential for survival in these ablation experiments and that the cortex regulated carbohydrate metabolism and fluid and electrolyte balance. The isolation and identification of the adrenal steroids by Reichstein and Kendall and the effects of these compounds on carbohydrate metabolism (hence the term glucocorticoids) culminated with the synthesis of *cortisone*, the readily available, pharmacologically effective glucocorticoid. Subsequently, Tait and colleagues isolated and characterized aldosterone, which potently affected fluid and electrolyte balance and was termed a mineralocorticoid. That distinct corticosteroids regulated carbohydrate metabolism and fluid/electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors. Kendall, Reichstein, and Hench shared the 1950 Nobel Prize in Physiology/Medicine "for their discoveries relating to the hormones of the adrenal cortex, their structure and biological effects."

Studies of adrenocortical steroids also were key in delineating the role of the anterior pituitary. As early as 1912, Cushing described patients with hypercorticism; he later recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was shown to be essential for maintaining the structural integrity and steroidogenic capacity of the adrenal's inner cortical zones. Harris established the role of the hypothalamus in pituitary control and postulated that a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of *corticotropin-releasing hormone* (CRH), a hypothalamic peptide that, together with *arginine vasopressin* (AVP), regulates secretion of ACTH from the pituitary (Miller, 2013).

Abbreviations

ACTH: corticotropin (or adrenocorticotropic hormone)
AngII: angiotensin II
AVP: arginine vasopressin
CAH: congenital adrenal hyperplasia
CBG: corticosteroid-binding globulin
COX: cyclooxygenase
CRH: corticotropin-releasing hormone
CYP: cytochrome P450
CYP11A1: cholesterol side-chain cleavage enzyme
CYP11B1: 11β-hydroxylase
CYP11B2: aldosterone synthase
CYP17A1: 17α-hydroxylase
CYP19A1: aromatase
CYP21A2: steroid 21-hydroxylase
DHEA: dehydroepiandrosterone
DHEAS: dehydroepiandrosterone sulfate
GR: glucocorticoid receptor
HPA: hypothalamic-pituitary-adrenal
3β-HSD: 3β-hydroxysteroid dehydrogenase
11β-HSD1: 11β-hydroxysteroid dehydrogenase (type 1)
11β-HSD2: 11β-hydroxysteroid dehydrogenase (type 2)
5HT: serotonin
IL: interleukin
MCR: melanocortin receptor (5 subtypes; # = 1 to 5)
MR: mineralocorticoid receptor
MSH: melanocyte-stimulating hormone
NF-κB: nuclear factor kappa B
PK: protein kinase
PLC: phospholipase C
POMC: pro-opiomelanocortin
TNF: tumor necrosis factor

other biologically active peptides including endorphins, lipotropins, and MSHs (see also Table 23–1 and Harno et al., 2018).

The actions of the POMC-derived melanocortins (ACTH and MSHs) are mediated by their specific interactions with five melanocortin receptor (MCR) subtypes (MC1R–MC5R) comprising a subfamily of GPCRs (Cone, 2006; Novoselova et al., 2018). The effect of MSH on pigmentation results from interactions with MC1R on melanocytes. ACTH, which is identical to α-MSH in its first 13 amino acids, exerts its effects at the adrenal cortex through MC2R. The affinity of ACTH for MC1R is much lower than for MC2R; however, under pathological conditions in which ACTH levels are persistently elevated (such as primary adrenal insufficiency), ACTH itself may lead to hyperpigmentation through MC1R. In the hypothalamus, activation of MC4R and MC3R by MSH peptides as well as antagonism by agouti signaling protein (ASIP) participate in the regulation of body weight and appetite. The function of MC5R is less well defined, but studies in rodents suggest roles in exocrine secretion, particularly sebogenesis, lacrimal secretion and release of sex pheromones (Morgan and Cone, 2006). Recent translational efforts have focused on developing novel therapies for seborrhea and acne vulgaris based on antagonizing MC5R (Xu et al., 2020).

Actions on the Adrenal Cortex

ACTH, acting via the MC2R, stimulates enzyme activity in the adrenal cortex, regulating production of the main hormones cortisol, aldosterone, and the androgen precursor *dehydroepiandrosterone* (DHEA). The adrenal cortex, both histologically and functionally, can be separated into three zones (Figure 50–2) that produce different steroids under different regulatory influences:

- The outer zona glomerulosa produces aldosterone, the main mineralocorticoid.
- The middle zona fasciculata produces cortisol, the main glucocorticoid.
- The inner zona reticularis produces the androgen precursor DHEA and the much more abundant sulfated derivative DHEAS.

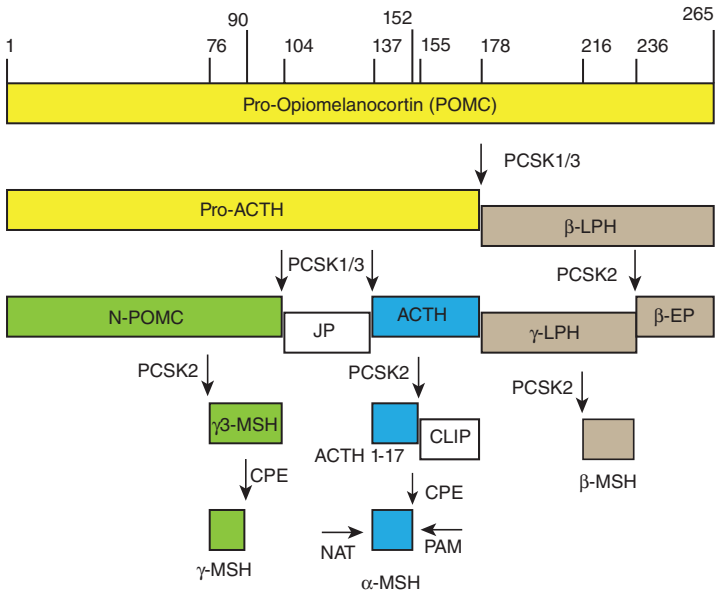

Figure 50–1 *Processing of POMC to ACTH.* POMC is converted to ACTH and other peptides in anterior pituitary, pars intermedia, hypothalamus, and skin. Human peptide cleavage sites are listed above. Anterior pituitary expresses PCSK1/3 only, whereas at other sites, all enzymes are expressed. CLIP, corticotropin-like intermediate peptide; CPE, carboxypeptidase E; JP, joining peptide; MSH, melanocyte-stimulating hormone; NAT, *N*-acetyltransferase; PAM, peptidyl-glycine alpha-amidating monooxygenase; PCSK, prohormone convertase subtilisin/kexin.

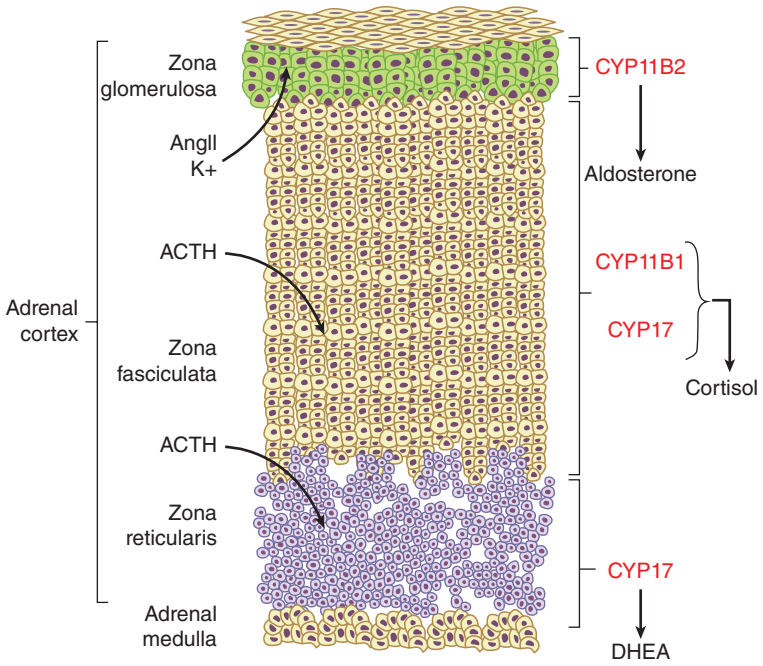

Figure 50–2 *The three anatomically and functionally distinct compartments of the adrenal cortex.* The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiological regulators of steroid production: AngII and K^+ for the zona glomerulosa and ACTH for the zona fasciculata. Although ACTH acutely increases DHEA biosynthesis, the physiological regulators of DHEA production by the zona reticularis are not completely known.

Adrenal steroid hormones are produced from the same precursor, cholesterol, by a set of cytochrome P450 enzymes (CYP11A1, CYP11B1 and CYP11B2, and CYP17A1 and CYP21A2) and the steroid dehydrogenase 3β-HSD. These enzymes are differentially expressed in the three zones of the adrenal cortex giving rise to zone-specific hormone production. Some of the enzymes encoded by these genes can catalyze more than one reaction.

Cells in the zona glomerulosa have receptors for both ACTH and angiotensin II (AngII) and express aldosterone synthase (CYP11B2), the enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production, this zone is regulated primarily by AngII and extracellular K^+ (see Chapter 30) and remains functional in the absence of pituitary function. With persistently elevated ACTH, mineralocorticoid levels initially increase but then return to normal (a phenomenon termed ACTH escape).

Cells of the zona fasciculata have receptors for ACTH and express 17α-hydroxylase (CYP17A1) and 11β-hydroxylase (CYP11B1). These enzymes catalyze the production of glucocorticoids under the control of ACTH. In the zona reticularis, 17α-hydroxylase carries out an additional C17-20 lyase reaction that converts C21 corticosteroids into the C19 androgen precursors.

In the absence of ACTH stimulation (as may occur in hypopituitarism), the zona fasciculata and reticularis undergo atrophy, and production of glucocorticoids and adrenal androgens is severely impaired. Conversely, persistently elevated levels of ACTH induce hypertrophy and hyperplasia of these inner zones, with concomitant overproduction of glucocorticoids and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continually elevated as a secondary response to impaired cortisol biosynthesis.

Mechanism of Action

ACTH stimulates the synthesis and release of the adrenocortical hormones by increasing *de novo* biosynthesis (steroid hormones are hydrophobic and thus cannot be stored). ACTH binding to MC2R activates the G_s–adenylyl cyclase–cyclic AMP–PKA pathway. Cyclic AMP is the second messenger for most effects of ACTH on steroidogenesis.

Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects an increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results from increased transcription of the steroidogenic enzymes.

A number of transcriptional regulators participate in the induction of the steroidogenic enzymes by ACTH. Among these is the nuclear receptor NRSA1 (steroidogenic factor 1), a transcription factor required for the development of the adrenal cortex and for the expression of most of the steroidogenic enzymes (Schimmer and White, 2010). Pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 50–3. The rate-limiting step in steroid hormone production is the translocation of cholesterol across mitochondrial membranes by the steroid acute regulatory (StAR) protein. Cholesterol is then converted to pregnenolone by the side-chain cleavage enzyme CYP11A1, which represents the first enzymatic step in steroid hormone biosynthesis (Miller and Auchus, 2011). Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily (see Chapter 5). To ensure an adequate supply of substrate, the adrenal cortex uses multiple sources of cholesterol, including circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways; endogenous cholesterol liberated from cholesterol ester stores via activation of cholesterol esterase; and endogenous cholesterol from *de novo* biosynthesis.

Regulation of ACTH Secretion

Hypothalamic-Pituitary-Adrenal (HPA) Axis

The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotrophs. These corticotrophs are regulated by CRH and AVP, peptide hormones made by specialized neurons of the hypothalamus and released into the network of portal veins bathing the anterior pituitary (Sheng et al., 2021). This HPA axis forms an integrated system that maintains appropriate levels of glucocorticoids (Figure 50–4). The three characteristic modes of physiological regulation of the HPA axis are:

- Diurnal rhythm in basal steroidogenesis
- Negative-feedback regulation by adrenal corticosteroids
- Marked increases in steroidogenesis in response to stress

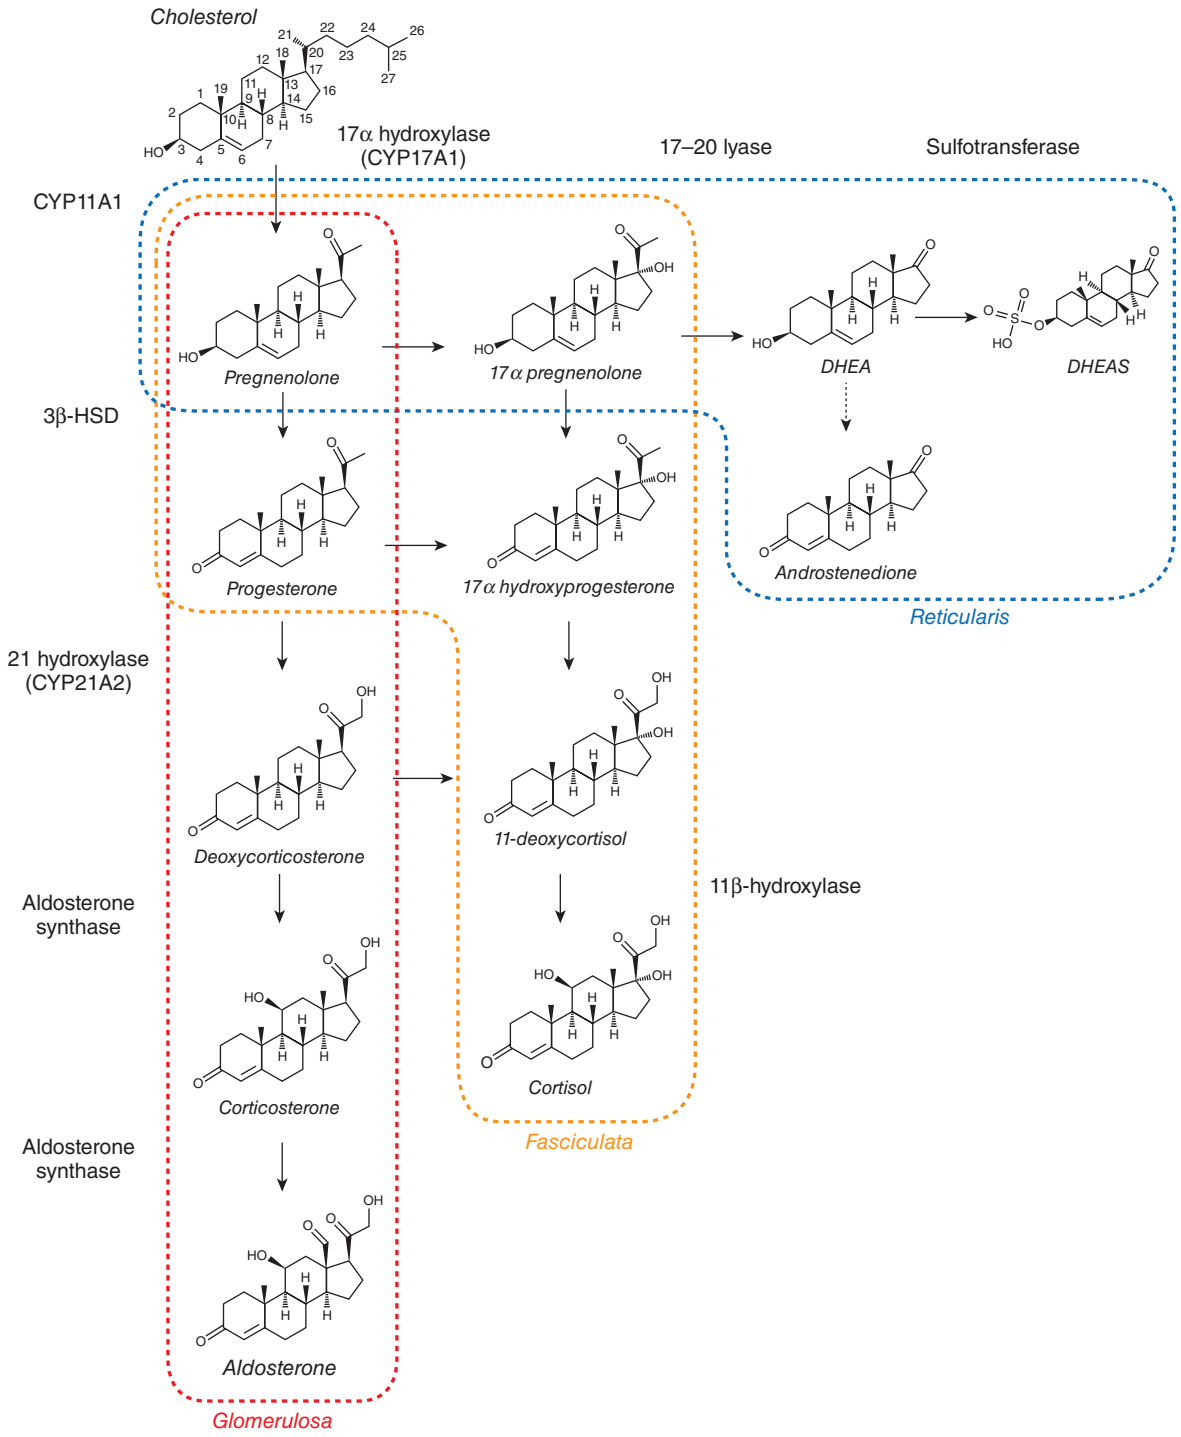

Figure 50–3 *Pathways of corticosteroid synthesis.* The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The reactions in each of the adrenal zones are grouped by dashed lines. The numbering is indicated in the cholesterol structure.

Pathological elevation of steroidogenesis is seen in Cushing disease, in the setting of ectopic secretion of CRH or ACTH (often part of a paraneoplastic syndrome), and in rare conditions as a result of defects in corticosteroid receptor–mediated feedback mechanisms.

The diurnal rhythm is determined by circadian clocks in the hypothalamic suprachiasmatic nucleus and in the adrenal gland itself and is entrained by higher neuronal centers in response to sleep-wake cycles (Oster et al., 2017). Levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at about 8 AM (Leliavski et al., 2015). Negative-feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative-feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Corticotropin-Releasing Hormone

Following release into the hypophyseal plexus, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotrophs. Upon CRH binding, the CRH receptor activates the G_s–adenylyl cyclase–cyclic AMP pathway within corticotrophs, ultimately stimulating both ACTH biosynthesis and secretion.

Arginine Vasopressin

Arginine vasopressin acts as a weak secretagogue for corticotrophs on its own but significantly potentiates the effects of CRH. AVP is produced

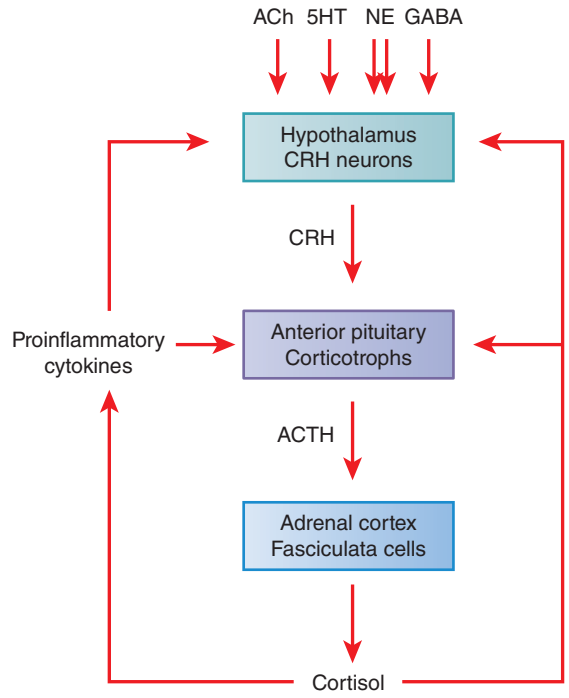

Figure 50–4 *The HPA axis and the immune inflammatory network.* Positive effects are in green, and negative effects are in red. Inputs from higher neuronal centers regulate CRH secretion. In addition, AVP stimulates release of ACTH from corticotrophs. ACh, acetylcholine; GABA, γ-aminobutyric acid; NE, norepinephrine.

in the paraventricular nucleus of the hypothalamus and secreted into the pituitary portal veins from the median eminence. AVP binds to V1b receptors and activates the G_q-PLC-IP_3-Ca^{2+} pathway to enhance the release of ACTH. In contrast to CRH, AVP by itself does not increase *de novo* ACTH synthesis.

Negative Feedback of Glucocorticoids

Glucocorticoid feedback of the HPA axis occurs at both the hypothalamus and the pituitary, and the effects are both rapid (seconds to minutes) and delayed (requiring hours and involving changes in gene transcription) (Keller-Wood, 2015). Glucocorticoids inhibit hypothalamic CRH secretion via direct effects on hypothalamic CRH neurons by decreasing CRH mRNA levels and CRH release. Indirect effects of cortisol on hypothalamic CRH secretion are mediated by both the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) acting on separate CRH neurons in the hippocampus. In the pituitary, glucocorticoids inhibit ACTH secretion through GR by inhibiting corticotroph responsiveness to CRH (rapid response) as well as suppressing POMC expression (delayed response).

The involvement of MR in cortisol feedback mechanisms in the CNS is based on the ability of MR to bind and respond to cortisol in cells lacking 11β-HSD2. Because of the higher intrinsic affinity of MR (relative to GR) for cortisol, the major CNS receptor species occupied during periods of low cortisol levels is MR. At higher blood cortisol levels, MR becomes saturated, and GR occupancy increases. Both MR and GR control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominately occurs via GR.

The Stress Response

Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid levels. Examples of stress signals include trauma, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Different brain regions are involved in the processing of these stimuli. Although the precise mechanisms that underlie this stress response, and the essential functions of corticosteroids during this process, are not fully defined, increased corticosteroid secretion is vital to maintain homeostasis in these settings. As discussed further in the chapter, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response.

Therapeutic Uses and Diagnostic Applications of ACTH and CRH

Except for the treatment of infantile spasms, most proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids. Moreover, therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. ACTH acutely stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. ACTH and CRH, however, have important diagnostic applications.

Infantile Spasms

The mainstay treatment for this rare epileptic disorder of infancy and early childhood is hormonal therapy with ACTH. The mechanism of action is not known but may involve effects independent of adrenal corticosteroid release since ACTH can control spasms in patients with adrenal suppression. Antiepileptic effects involving suppression of CRH in the CNS have been proposed. The formulation used most commonly in the U.S. is measured in units as an injectable gel delivered intramuscularly or subcutaneously. In other countries, a long-acting depot formulation of synthetic ACTH is available (*tetracosactide depot*).

Diagnostic Use

Cosyntropin, a synthetic peptide that corresponds to residues 1–24 of human ACTH, is used in testing the integrity of the HPA axis. At the supraphysiological dose of 0.25 mg, *cosyntropin* maximally stimulates adrenocortical steroidogenesis. An increase in the circulating cortisol level to a level greater than 18 to 20 μg/dL using many of the standard assays indicates a normal response. Newer cortisol assay platforms have higher specificity for cortisol and have corresponding lower normal cutoffs. *Cosyntropin* may also be used diagnostically during adrenal venous sampling, a procedure used to distinguish between unilateral and bilateral aldosterone secretion in primary aldosteronism.

Ovine CRH (*corticorelin*) and human CRH (not available in the U.S.) are used rarely for diagnostic testing of the HPA axis. When evaluating patients with documented ACTH-dependent hypercortisolism, CRH stimulation testing is sometimes used to differentiate pituitary from ectopic sources of ACTH, either alone or more commonly during inferior petrosal sinus sampling. In both cases, pituitary ACTH production is increased by CRH, whereas ectopic ACTH production is not. CRH stimulation testing, after *dexamethasone* suppression, is also occasionally used to assist differentiation of pseudo-Cushing states (as occurs with alcoholism and some neuropsychiatric disorders) from true Cushing syndrome.

Assays for ACTH

Immunoassays that use two separate antibodies directed at distinct epitopes on the ACTH molecule are now widely available. These assays allow differentiation of patients with primary adrenal insufficiency due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from patients with secondary adrenal insufficiency due to low ACTH levels from hypothalamic or pituitary disorders. ACTH immunoassays are also useful during the evaluation of patients with hypercortisolism (Cushing syndrome): normal or high ACTH levels are seen in patients with hypercortisolism from either a pituitary (Cushing disease) or an ectopic (nonpituitary tumor) source, whereas low ACTH levels are invariably seen in patients with hypercortisolism due to an adrenal source. One problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can rarely secrete aberrantly processed forms of ACTH that have biologic activity but do not react in the immunoassays.

Absorption, Fate, and Toxicity

ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans,

the $t_{1/2}$ in plasma is about 15 min, primarily due to rapid enzymatic hydrolysis. Aside from rare hypersensitivity reactions, any toxicity is primarily attributable to the increased secretion of corticosteroids. *Cosyntropin* is generally less antigenic than native ACTH.

Adrenocortical Steroids

Synthesis, Circulating Levels, and Interconversion

The adrenal cortex synthesizes two classes of steroids: the *corticosteroids* (glucocorticoids and mineralocorticoids, which have a 21-carbon pregnane structure) and *androgens*, which have a 19-carbon androstane structure (see Figure 50–3). The actions of corticosteroids historically were described as *glucocorticoid* (reflecting their activity regulating carbohydrate metabolism) and *mineralocorticoid* (reflecting their activity regulating electrolyte balance). In humans, *cortisol* is the main physiological glucocorticoid, and aldosterone is the main physiological mineralocorticoid. Although biosynthetic intermediates such as *corticosterone* and *deoxycorticosterone* have significant glucocorticoid and mineralocorticoid activities, their influence is limited due to their low circulating levels under normal conditions. They can, however, exert important effects when elevated, mainly as the result of rare genetic defects in biosynthetic enzymes or their pharmacological inhibition.

Cortisol is relatively abundant in circulation and is extensively (>95%) bound, primarily to *corticosteroid-binding globulin* (CBG). In contrast, aldosterone circulates mostly in free form at approximately 1000-fold lower levels. Both cortisol and aldosterone are secreted episodically and vary in a similar diurnal manner, with the highest levels reached in the early morning hours and the lowest levels reached several hours after the onset of sleep (Figure 50–5).

In the periphery, cortisol is reversibly converted to the inactive 11-keto derivative cortisone. Quantitatively, the forward inactivating reaction is carried out mainly in the kidney by the enzyme 11β-HSD2. The reverse reactivating reaction is carried out by a different isozyme, 11β-HSD1, mainly but not exclusively in the liver. Therefore, cortisone can be viewed as an inactive circulating reserve for cortisol. Under normal conditions, the circulating levels of cortisone and cortisol are found at an approximately 1:4 ratio. The local availability of cortisol varies greatly and is influenced by the relative activities of the interconverting enzymes, which have distinct tissue expression patterns. The extensive conversion of inactive 11-keto steroids to the active 11-hydroxy forms in the liver forms the basis for the clinical activity of 11 keto prodrug forms of corticosteroid drugs such as *prednisone* (Figure 50–6).

Adrenal Androgens

The adrenal cortex also produces the C19 steroids DHEA and, to a lesser extent, androstenedione. DHEA has limited androgenic potency but serves as the major precursor for most sex steroids. The bulk of DHEA is secreted as its sulfated derivative DHEAS. Although both forms are albumin bound, the interaction of DHEAS is much tighter. Thus, the circulating levels of DHEAS are more than 100-fold higher than those of DHEA.

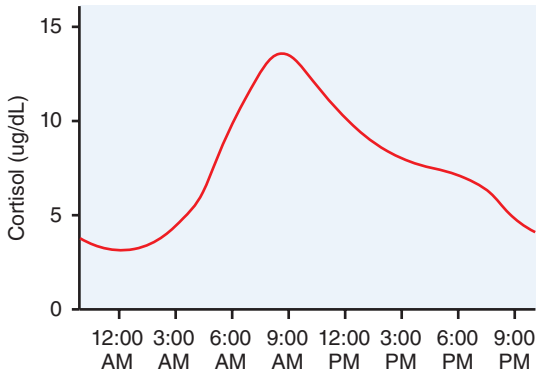

Figure 50–5 *Approximate diurnal pattern of cortisol and aldosterone levels.*

In gonads and other peripheral tissues, steroid sulfatases can convert DHEAS back to DHEA to serve as precursor to more potent androgens and estrogens. Levels of adrenal androgens in circulation rise gradually in childhood, peak in the third decade of life, and decline progressively thereafter in a pattern that reflects the size of the adrenal zona reticularis. Functionally, adrenal androgens drive the first appearance of pubic hair or pubarche and are the precursor source for more than half of the testosterone in women. Patients with adrenal insufficiency do not require adrenal androgen replacement, indicating that these hormones are not essential for survival. Elevated circulating DHEAS levels are associated with hyperandrogenic states, particularly in women. Furthermore, for a number of chronic diseases, affected patients can have very low DHEA levels. Based on this, some have proposed that DHEA treatment might be beneficial in these diseases and could partly alleviate the loss of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. However, studies on the benefits of addition of DHEA to the standard replacement regimen in women with adrenal insufficiency have been inconclusive. Despite the absence of definitive data, DHEA is widely used as an over-the-counter nutritional supplement for its alleged health benefits.

Physiological Functions and Pharmacological Effects

Corticosteroids have numerous effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist stressful and noxious stimuli and environmental changes. In the absence of adequate secretion of corticosteroids from the adrenal cortex, stresses such as infection, trauma, and extremes in temperature can be fatal.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Conversely, in the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed permissive and most likely reflect steroid-induced changes in protein synthesis, which, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are termed either mineralocorticoids or glucocorticoids, according to their relative effects in Na^+ retention and effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis). In general, the potencies of steroids on glucose metabolism closely parallel their potencies as anti-inflammatory agents. The effects on Na^+ retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors. As noted in further discussion (see structure-activity relationships), some steroid derivatives provide relative selectivity as stimulants of Na^+ retention or anti-inflammatory effects.

General Mechanisms for Corticosteroid Effects

Corticosteroids exert their effects principally by causing both positive and negative changes in the transcription of corticosteroid-responsive genes leading to changes in the protein composition and thus function of target cells and tissues. These effects are mediated by GR and MR, two closely related members of the nuclear receptor superfamily of ligand regulated transcription factors. Although some genes are regulated in most target cells, the array of responsive genes and the extent and pattern of regulation are tissue and cell type specific. The effects are governed by the expression and intrinsic function of the receptors, their relative affinities, local availability of the ligands, and the array of other transcription factors present in a particular cell. It is also becoming recognized that in addition to protein-coding genes, the receptors regulate the expression of noncoding RNAs, the physiological function

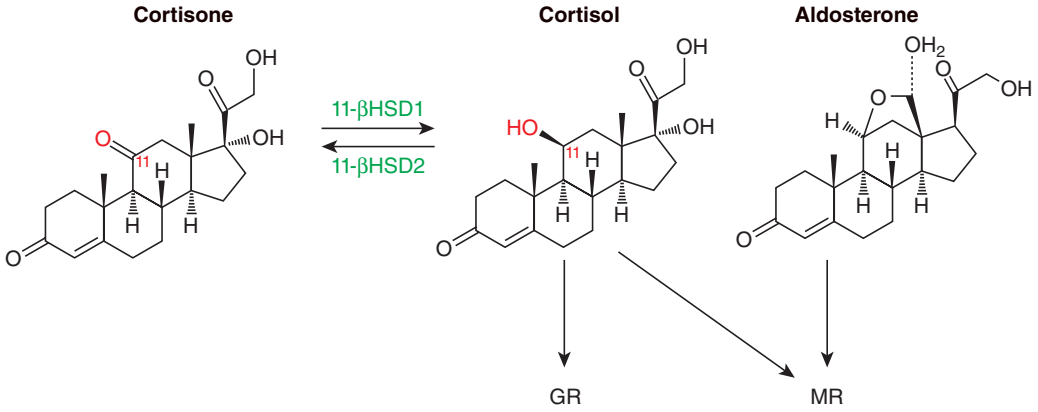

Figure 50–6 *Corticosteroid conversion and receptor specificity.* Cortisol and aldosterone bind to the MR with equally high affinity; cortisol binds with more modest affinity to the GR, which binds aldosterone only marginally. Cortisol is converted to the inactive cortisone by 11β-HSD2, and cortisone is activated to cortisol by 11β-HSD1.

of which remains largely unexplored. Given the multistep process of transcription and translation leading to net changes in protein levels, many effects of corticosteroids are not immediate but become apparent after several hours. In many cases, but not invariably, the therapeutic effects of corticosteroids become clinically apparent only after a time delay. Corticosteroids also have more rapid effects that are unlikely to be dependent on gene regulation. The exact mechanisms are not fully understood, although in some circumstances, GR and MR have been implicated.

Glucocorticoid and Mineralocorticoid Receptors. GR (gene name *NR3C1*, nuclear receptor subfamily 3, group C, member 1) and MR (*NR3C2*) share with other members of the nuclear receptor family of transcription factors a common architecture composed of a central DNA binding domain (DBD), a C-terminal ligand binding domain (LBD), and an N-terminal region harboring transcriptional regulatory functions (AF-1) (Figure 50–7A). GR and MR reside predominately in the cytoplasm in an inactive form complexed with molecular chaperones that maintain the receptor in a ligand binding competent state (Kirschke et al., 2014). Steroid binding to the LBD results in receptor activation and translocation to the nucleus where the receptors exert both positive and negative effects on transcription (see Figure 50–7B for GR).

Determinants of Specificity and Action. The receptor responsible for the effects of a given corticosteroid depend not only on receptor affinity but also on local availability of the ligand such that different combinations of receptors and ligands occur in distinct tissues and conditions. In terms of affinities, the mineralocorticoid receptor binds comparably and with very high affinity to cortisol, aldosterone, precursors such as deoxycorticosterone (which act as agonists), and progesterone and 17α-progesterone (which act as antagonists). In contrast, GR binds with more modest affinity to both cortisol and the precursors corticosterone and deoxycorticosterone as agonists (and to a lesser extent to progesterone as antagonist) while having very low affinity for aldosterone. Neither receptor binds appreciably to 11-keto forms such as cortisone.

In epithelial cells of the kidney, colon, and salivary glands, aldosterone specifically activates MR in the face of much higher circulating levels of glucocorticoids due to the co-expression of 11β-HSD2. As mentioned above, this enzyme metabolizes glucocorticoids such as cortisol to inactive 11-keto derivatives such as cortisone. Aldosterone escapes this inactivation and maintains mineralocorticoid activity because it exists predominantly in the hemiacetal form that is resistant to 11β-HSD action. In the absence of 11β-HSD2, as occurs in the inherited disease *syndrome of apparent mineralocorticoid excess*, MR is inappropriately activated by cortisol, leading to severe hypokalemia and hypertension. A similar state is elicited acutely when 11β-HSD2 is inhibited by *glycyrrhizic acid*, a component of licorice implicated in licorice-induced hypertension.

MR is also expressed in cells not involved in Na^+ reabsorption, including endothelial cells, vascular smooth muscle cells, cardiomyocytes, certain neuronal populations, and inflammatory cells. When examined, many cells lack 11β-HSD2, and thus, MR likely responds physiologically to cortisol.

Similarly, in cells that express 11β-HSD1 such as hepatocytes and adipocytes, GR is exposed to higher levels of cortisol relative to the circulation due to local activation of cortisone to cortisol (see Figure 50–6).

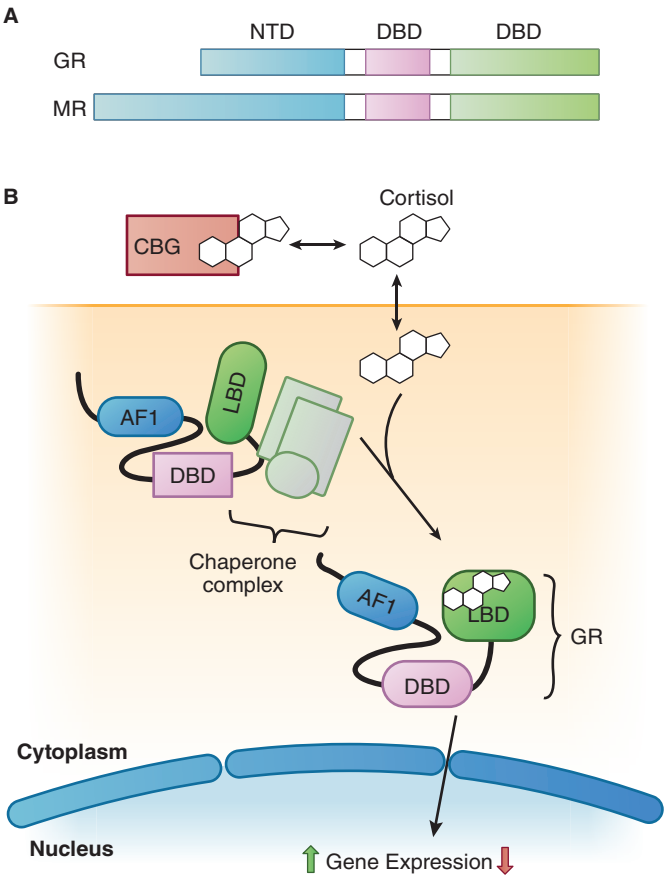

Figure 50–7 *Domain organization of GR and MR and mechanism of action of GR.* **A.** GR and MR share a common organization composed of a central DNA binding domain (DBD), a C-terminal ligand binding domain (LBD), and a more variable N-terminal domain (NTD). **B.** Cortisol circulates mostly bound to CBG. Free cortisol enters cells and interacts with GR, inducing a conformational change that activates the receptor and allows for translocation to the nucleus where it causes both positive and negative changes in gene expression.

Regulation of Gene Expression by the Glucocorticoid Receptor. After ligand binding and nuclear translocation, GR is recruited to specific sites on the genome. The location and extent of recruitment vary extensively between cell types (John et al., 2011). At these sites, GR nucleates or modifies the assembly of transcriptional regulatory complexes through interactions with both sequence-specific factors and coregulator complexes and exerts positive or negative effects on transcription (Sacta et al., 2016). At most positive sites, GR homodimers bind directly to specific DNA sequences termed glucocorticoid-response elements and recruit coregulators that enhance transcription by altering chromatin structure or contacting the basal RNA polymerase II transcription apparatus (Figure 50–8A). Genes regulated in this manner include metabolism genes such as phosphoenolpyruvate carboxykinase (*PEPCK*) and tyrosine aminotransferase as well as anti-inflammatory genes such as the inhibitory subunit of NF-κB. GR repression at negative sites can occur through multiple mechanisms. A frequent pattern involves recruitment of GR monomers to DNA-bound positively acting transcription factors such as AP-1 or NF-κB. The resulting complexes interfere with successful transcriptional initiation or elongation (Figure 50–8B). This type of mechanism mediates GR repression of genes for multiple proinflammatory cytokines such as IL-6 and IL-2, as well as for collagenase and stromelysin. GR inhibition of POMC gene transcription illustrates a different mechanism of repression. In this case, direct binding of GR to DNA sequences that overlap and occlude the binding of basal transcriptional machinery components interferes with transcription, thereby contributing to the negative-feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase 2 (COX-2) and inducible nitric oxide synthase.

Several GR isoforms result from alternative RNA splicing and from translation initiation at alternative sites. Of these, GRα is the prototypical glucocorticoid-responsive isoform. GRγ is a splice variant with a single amino acid insertion in the DNA binding domain that has altered DNA binding specificity. GRβ has a truncated C terminus that is unable to bind ligands and has been implicated in decreased responsiveness to glucocorticoids. Multiple polymorphisms in the human GR are associated with differences in GR function, but they appear to account for only a small fraction of clinical variability to glucocorticoid responsiveness.

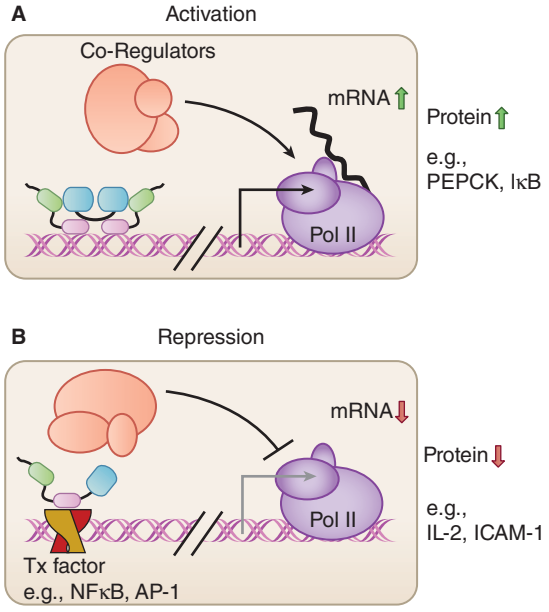

Figure 50–8 *Mechanisms of transcriptional regulation by GR.* **A.** At activated genes, GR binds directly to specific sequences (glucocorticoid-response element [GRE]) as a dimer and regulates the assembly of coregulator complexes that enhance mRNA transcription by RNA polymerase II (Pol II). **B.** Gene repression often involves GR monomers binding to other transcription (Tx) factors and recruiting repressive coregulator complexes that inhibit Pol II.

Regulation of Gene Expression by the Mineralocorticoid Receptor. Like GR, the MR is also a ligand-activated transcription factor and binds to similar specific DNA sequences. MRs also associate with molecular chaperone proteins and regulate the transcription of discrete sets of genes in target tissues. MR and GR also differ in their ability to interact functionally with other transcription factors and this may in part underly the contrasting pro-inflammatory effects of MR relative to the anti-inflammatory effects of GR. In contrast to the essentially ubiquitous expression of GR, MR is expressed in a much more restricted manner in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands, and sweat glands) and in some nonepithelial tissues (e.g., hippocampus, heart, vasculature, and adipose tissue).

Aldosterone exerts its effects on Na^+ and K^+ homeostasis via MR primarily through its actions on the principal cells of the distal renal tubules and collecting ducts, whereas effects on H^+ secretion largely are exerted in the intercalated cells. The binding of aldosterone to MR in the kidney initiates a sequence of events that includes the prompt induction of serum and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na^+ channels (also called ENaC) in the apical membrane. Thereafter, increased Na^+ influx stimulates the Na^+/K^+-ATPase in the basolateral membrane (see Chapter 29). In addition to these rapid genomic effects, aldosterone increases the synthesis of these membrane proteins as part of a more delayed effect.

Carbohydrate and Protein Metabolism

Glucocorticoids markedly effect carbohydrate and protein metabolism. Glucocorticoids stimulate the liver to form glucose from amino acids (gluconeogenesis) while also promoting glucose storage as glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Through their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patient with diabetes mellitus and can precipitate the new onset of hyperglycemia in susceptible patients.

Lipid Metabolism

Two effects of glucocorticoids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in hypercortisolism, as in patients with Cushing syndrome. In this setting, there is increased fat in the back of the neck ("buffalo hump"), face ("moon facies"), and supraclavicular area, coupled with a loss of fat in the extremities. The molecular mechanisms underlying these depot-specific effects remain incompletely understood. The other effect of glucocorticoids on lipid metabolism is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

Electrolyte and Water Balance

Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na^+ from the tubular fluid; they also increase the urinary excretion of K^+ and H^+. These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids and are the result of selective activation of MR by aldosterone in tissues expressing 11β-HSD2. Thus, the primary features of hyperaldosteronism are positive Na^+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na concentration, normal or low K^+, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na^+ wasting and contraction of extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that

maintain the glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney. In addition to their effects on monovalent cations and water, glucocorticoids exert multiple effects on Ca^{2+} metabolism, lowering Ca^{2+} uptake from the gut, increasing mobilization from bone, and increasing Ca^{2+} excretion by the kidney, collectively leading to decreased total body Ca^{2+} stores.

Cardiovascular System

The most striking effects of corticosteroids on the cardiovascular system result from MR-mediated changes in renal Na^+ retention, as evident in primary hyperaldosteronism. MR activation also has direct effects on the heart and vessel walls; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The clinical efficacy of MR antagonists in heart failure at doses that do not alter blood pressure argue for a direct effect on the heart. These effects are thought to reflect at least in part MR occupancy by cortisol since cardiomyocytes are devoid of 11β-HSD2 (Richardson et al., 2016). A third major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as norepinephrine and AngII, perhaps due to decreased expression of receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

Skeletal Muscle

Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary hyperaldosteronism, muscle weakness results primarily from hypokalemia rather than from a direct effect of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods causes skeletal muscle wasting, likely reflecting the need for precursor mobilization to sustain glucocorticoid-induced gluconeogenesis (see Carbohydrate and Protein Metabolism above). Glucocorticoid-induced myopathy accounts in part for weakness and fatigue in patients with glucocorticoid excess.

CNS

Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose, and electrolyte concentrations. Corticosteroids also have direct effects on the CNS that involve both GR and MR with effects on the latter likely due to cortisol occupancy in regions devoid of 11β-HSD2 such as the hippocampus. Corticosteroids affect mood, behavior, cognition, memory, and brain excitability. Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, irritability, and even psychosis. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing syndrome. These abnormalities usually, but not always, improve or disappear after cessation of glucocorticoid therapy or treatment of endogenous Cushing syndrome.

Formed Elements of Blood

Glucocorticoids exert minor effects on hemoglobin and the erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing syndrome and of normochromic, normocytic anemia in adrenal insufficiency. Corticosteroids also affect circulating white blood cells. Addison disease is associated with an increased mass of lymphoid tissue and lymphocytosis; in contrast, Cushing syndrome is characterized by lymphocytopenia and a decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of *hydrocortisone* leads to a decline of these circulating cells within 4 to 6 h; this effect persists for 24 h and results from the redistribution of cells rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, glucocorticoids are effective in the treatment of certain lymphoid malignancies, in large part due to the capacity of glucocorticoids to induce lymphocyte apoptosis.

Anti-inflammatory and Immunosuppressive Actions

In addition to their effects on lymphocyte number, glucocorticoids profoundly alter the immune responses of lymphocytes. These effects are important facets of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Although the use of glucocorticoids as anti-inflammatory agents for the most part does not address the underlying cause of the disease, the suppression of inflammation is of vital clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of great value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominately result from humoral immunity, such as urticaria (see Chapter 75), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (see Chapter 39). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte function.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids induce the expression of lipocortin proteins, which inhibit phospholipase A2 and thus arachidonic acid–derived leukotriene mediators (see Chapter 41). In numerous cell types, glucocorticoids inhibit the production of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractant factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of proinflammatory cytokines, COX-2, and inducible nitric oxide synthase. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 50–1.

Among the proinflammatory cytokines, IL-1, IL-6, and TNF-α stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. The increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites as discussed previously. Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Turnbull and Rivier, 1999).

Pharmacokinetics

Absorption

Hydrocortisone (cortisol) and numerous congeners, including the synthetic analogues, are orally effective. Certain water-soluble esters of *hydrocortisone* and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in systemic or targeted body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of *hydrocortisone*, its esters, and congeners. Minor changes in chemical structure markedly alter the rate of absorption, time of onset of effect, and duration of action. Glucocorticoids are also absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is

TABLE 50–1 ■ INHIBITORY EFFECTS OF GLUCOCORTICOIDS ON INFLAMMATORY/IMMUNE RESPONSES

CELL TYPE	FACTOR INHIBITED	COMMENTS
Macrophages and monocytes	Arachidonic acid, PGs, and LTs Cytokines: IL-l, IL-6, and TNF-α Acute-phase reactants	Mediated by glucocorticoid inhibition of COX-2 and PLA_2 Production and release are blocked; cytokines exert multiple effects on inflammation (e.g., ↑ T cells, ↑ fibroblast proliferation) Including the third component of complement
Endothelial cells	ELAM-1 and ICAM-1 Acute-phase reactants Cytokines (e.g., IL-1) Arachidonic acid derivatives	ELAM-1 and ICAM-1 are critical for leukocyte localization Same as above for macrophages and monocytes
Basophils	Histamine, LTC_4	IgE-dependent release ↓ by glucocorticoids
Fibroblasts	Arachidonic acid metabolites	Same as above for macrophages and monocytes Glucocorticoids ↓ growth factor–induced DNA synthesis and fibroblast proliferation
Lymphocytes	Cytokines (IL-1, IL-2, IL-3, IL-6, TNF-α, GM-CSF, interferon γ)	Same as above for macrophages and monocytes

ELAM-1, endothelial-leukocyte adhesion molecule 1; ICAM-1, intercellular adhesion molecule 1; LT, leukotriene; PG, prostaglandin; PL, phospholipase.

prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Distribution, Metabolism, and Excretion

After absorption of cortisol into plasma, 90% or more is reversibly bound to protein under normal circumstances. In most tissues, only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all the corticosteroid-binding capacity: CBG and albumin. CBG is an α globulin secreted by the liver that has relatively high affinity for glucocorticoids (dissociation constant of ~1 nM) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of 1 mM). In tissues with prolonged capillary transit time (e.g., liver, spleen), corticosteroid released from albumin is available for delivery. At high corticosteroid concentrations, the capacity of CBG binding is exceeded, and a slightly greater fraction of the corticosteroid exists in the free state. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these last steroids are found in the free form. A special state of physiological hypercortisolism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol levels increase several-fold, with only small increases in free cortisol. The physiological significance of these changes remains to be established. Similar effects on CBG and total cortisol levels are seen in women taking estrogen-containing contraceptives. The aldosterone levels also rise 3- to 10-fold during pregnancy, in part reflecting the marked elevations of progesterone and 17α-progesterone, which are effective MR and, to a lesser extent, GR antagonists. GR antagonism may also contribute to the mild elevation in free cortisol.

As a general rule, the metabolism of steroid hormones involves sequential additions of O or H atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond (see Figure 50–6) occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced compounds are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver and, to a lesser extent, in the kidney. The resultant sulfate esters and glucuronides are water soluble and are excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto group, such as *cortisone* and *prednisone*, must be enzymatically reduced to the corresponding 11β-hydroxy derivative before they are biologically active. The type 1 isoenzyme of 11β-HSD (11β-HSD1) catalyzes this reduction, predominately in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin (see Figure 50–6). In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., *hydrocortisone* or *prednisolone* rather than *cortisone* or *prednisone*). Such settings include individuals with severe hepatic failure and patients with rare mutations causing cortisone reductase deficiency.

Structure-Activity Relationships

Chemical modifications of the cortisol molecule have generated derivatives with greater separation of glucocorticoid and mineralocorticoid activity (Table 50–2); for several synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used. In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these are summarized in Table 50–3. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism or from suppressive effects on the HPA axis.

Estimates of Na^+-retaining and anti-inflammatory potencies of representative steroids are listed in Table 50–2. Some steroids that are classified predominately as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these "glucocorticoids" are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid is needed. In contrast, aldosterone is exceedingly potent with respect to Na^+ retention but has only minimal effects on carbohydrate metabolism. Even at levels that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of glucocorticoids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.

Withdrawal of Therapy

The most frequent problem with steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe,

TABLE 50–2 ■ RELATIVE POTENCIES AND EQUIVALENT DOSES OF REPRESENTATIVE CORTICOSTEROIDS

COMPOUND	ANTI-INFLAMMATORY POTENCY	NA^+-RETAINING POTENCY	DURATION OF ACTION[a]	EQUIVALENT DOSE (mg)[b]

[d]This agent is used for its mineralocorticoid effects, not for glucocorticoid effects.

acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals, the time to full recovery can be a year or longer.

Most protocols for discontinuing glucocorticoid therapy in patients receiving long-term treatment involve gradual reduction in daily dosage or transition to an alternate-day regimen before gradual taper. If signs of acute adrenal insufficiency develop, immediate return to a higher dose is warranted. Patients who have received supraphysiological doses of glucocorticoids for a period of 2 to 4 weeks within the preceding year or with cushingoid appearance should be considered to have some degree of HPA impairment until proven otherwise. A characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgias, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, pseudotumor cerebri, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

Chronic Use of Supraphysiologic Glucocorticoid Doses

Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with glucocorticoids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, peptic ulcers, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Fluid and Electrolyte Handling. Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis and hypertension, particularly in patients treated concomitantly with mineralocorticoids. Similarly, hypertension is a relatively common manifestation of exogenous glucocorticoid administration, even in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

Metabolic Changes. The effects of glucocorticoids on intermediary metabolism were described previously. Hyperglycemia usually can be managed with diet and antidiabetes medications, including *insulin*. With proper management, this effect should not be a major factor in the decision to initiate or continue glucocorticoid therapy in diabetic patients.

Immune Responses. Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections, glucocorticoids should be administered only if necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy. Whenever possible, it is generally advised to provide appropriate vaccination before initiation of long courses of glucocorticoids, especially in vulnerable populations. The efficacy of some vaccines is reduced in patients already on glucocorticoids.

Gastrointestinal Effects. Glucocorticoids alone mildly increase the risk of gastritis, ulcer formation, and gastrointestinal bleeding; however, combination with nonsteroidal anti-inflammatory drugs leads to a synergistic increase in incidence. Glucocorticoids can also mask the symptoms of serious gastrointestinal disease, which may account for the associated increased risk of perforated sigmoid diverticular abscesses.

Myopathy. Myopathy, characterized by weakness of proximal limb muscle, can occur in patients taking large doses of corticosteroids and is also part of the clinical picture in patients with endogenous Cushing syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (see Chapter 44); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of high-dose corticosteroids and in patients with endogenous Cushing syndrome; these disturbances may take many forms, including anxiety, insomnia, depression, and overt psychosis.

Cataracts. Cataracts are a well-established complication of glucocorticoid therapy and are related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of cataracts, which may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at *prednisone* doses of 10 to 15 mg/day or greater should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

Osteoporosis. Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of both genders and all ages and is related to dosage and duration of therapy. About 30% to 50% of all patients who receive chronic glucocorticoid therapy ultimately develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormone production via lowering gonadotropin release, diminished GI absorption of Ca^{2+} both via inhibition of vitamin D action and via decreased intestinal calcium channel expression, and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption by osteoclasts via changes in the production of osteoprotegerin and receptor

TABLE 50–3 ■ SOME AVAILABLE PREPARATIONS OF ADRENOCORTICAL STEROIDS AND THEIR SYNTHETIC ANALOGUES

NONPROPRIETARY NAME	TYPE OF PREPARATION
Alclometasone dipropionate	Topical
Amcinonide	Topical
Beclomethasone dipropionate	Inhaled, nasal, topical
Betamethasone acetate	Injectable
Betamethasone sodium phosphate	Oral, injectable
Betamethasone valerate	Topical
Budesonide	Oral, inhaled, nasal, rectal
Ciclesonide	Inhaled, nasal
Clobetasol propionate	Topical, shampoo
Clocortolone pivalate	Topical
Desonide	Topical
Desoximetasone	Topical
Dexamethasone	Oral, ophthalmic, intravitreal implant, ophthalmic insert, intraocular
Dexamethasone sodium phosphate	Ophthalmic, otic, injectable
Diflorasone diacetate	Topical
Fludrocortisone acetate[a]	Oral
Flunisolide	Inhaled, nasal
Fluocinolone acetonide	Topical, shampoo, otic, intravitreal implant
Fluocinonide	Topical, otic
Fluorometholone	Ophthalmic
Fluorometholone acetate	Ophthalmic
Flurandrenolide	Impregnated dressing, topical
Halcinonide	Topical
Hydrocortisone	Topical, oral, rectal
Hydroxycortisone acetate	Topical, rectal
Hydroxycortisone butyrate	Topical
Hydrocortisone probutate	Topical
Hydrocortisone sodium succinate	Injectable
Hydrocortisone valerate	Topical
Methylprednisolone	Oral
Methylprednisolone acetate	Injectable
Methylprednisolone sodium succinate	Injectable
Mometasone furoate	Inhaled, nasal, topical
Prednisolone	Oral
Prednisolone acetate	Oral, ophthalmic
Prednisolone sodium phosphate	Oral, ophthalmic
Prednisone	Oral
Triamcinolone acetonide	Nasal, topical, injectable, dental
Triamcinolone hexacetonide	Injectable

Note: *Topical* preparations include agents for application to skin or mucous membranes in creams, foams, solutions, ointments, gels, pastes (for oral lesions), oils, tape, and aerosols; *ophthalmic* preparations include solutions, suspensions, and ointments; *inhalation* preparations include agents for nasal or oral inhalation.
[a]Fludrocortisone acetate is intended for use as a mineralocorticoid.

for activating NF-κB ligand (see Chapter 52). In addition, glucocorticoid inhibition of intestinal Ca^{2+} uptake and increased renal calcium excretion may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The initiation of glucocorticoid therapy at 5 mg/day or more of *prednisone* (or its equivalent) for 3 months or longer is an indication for bone densitometry to detect abnormalities in trabecular bone. Importantly, bone loss associated with glucocorticoids predominantly occurs within the first 6 months of therapy, and preventive treatment, if indicated, should be promptly initiated. Calcium (to provide 1200 mg/day from dietary or supplemental sources) and vitamin D (800 IU/day) are typically provided to all patients. In patients clinically determined to be at higher risk, bisphosphonate treatment has been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 48 and 52.

Osteonecrosis. Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy, particularly with prolonged therapy using higher doses. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of times. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

Regulation of Growth and Development. Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by (off-label) treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. In experimental animals, antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. The actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in late gestation and in the neonatal period (e.g., production of pulmonary surfactant and induction of hepatic gluconeogenic enzymes); those actions notwithstanding, antenatal steroids may lead to subtle abnormalities in fetal development. Babies born to women receiving large doses of corticosteroids during pregnancy should be monitored for signs of adrenal insufficiency and appropriate therapy initiated, if necessary.

Therapeutic Uses and Diagnostic Applications in Endocrine Diseases

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the optimal dose to achieve a therapeutic effect must be determined by trial and error and periodic reevaluation as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

When glucocorticoids are to be given over long periods, the dose, determined empirically, must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control a potentially life threatening condition, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies empiric administration to critically ill patients suspected of having adrenal insufficiency. This is lifesaving in cases of previously undiagnosed adrenal insufficiency. If the treated patient turns out not to have adrenal insufficiency, the single dose will not cause harm. Long courses of therapy at high doses are typically reserved for life-threatening conditions.

To diminish HPA axis suppression with longer-term treatment of an underlying condition responsive to glucocorticoids, the intermediate-acting steroid preparations (e.g., *prednisone* or *prednisolone*) should be given in the morning as a single dose. Alternate-day therapy with these glucocorticoids can often be used in patients who have achieved adequate therapeutic responses on the daily regimen. Pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1–1.5 g/day IV of *methylprednisolone* for 3 days) can be used as initial therapy in patients with fulminant, immunologically related disorders and with acute exacerbations of conditions such as multiple sclerosis, acute transplant rejection, necrotizing glomerulonephritis, and lupus nephritis.

Replacement Therapy for Adrenal Insufficiency

Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency, or Addison disease) or from structural or functional lesions of the anterior pituitary of hypothalamus (secondary adrenal insufficiency). In resource rich regions, primary adrenal insufficiency is most commonly caused by autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in resource limited regions. Other causes of primary adrenal insufficiency include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, AIDS, inherited disorders of steroidogenic enzymes, and X-linked adrenoleukodystrophy. Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency. This life-threatening condition is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It is more commonly associated with disorders of the adrenal rather than with disorders of the pituitary or hypothalamus, although it can also occur following abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic NaCl solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload, such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, *hydrocortisone* should be given by continuous infusion at a rate of 50 to 100 mg every 8 h, a dose that confers sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the *hydrocortisone* dose may be decreased to 75 mg every 6 to 8 h. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency. For the initial management of unconfirmed acute adrenal insufficiency, 4 mg *dexamethasone sodium phosphate* can be substituted for *hydrocortisone*; *dexamethasone* does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the *cosyntropin* [ACTH] stimulation test). Failure to respond to *cosyntropin* in this setting is diagnostic of adrenal insufficiency.

Chronic Adrenal Insufficiency. Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids. The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter of glucocorticoid dosing in primary and secondary disease. Overtreatment with glucocorticoid may cause manifestations of Cushing syndrome in adults and decreased linear growth in children. The plasma ACTH levels are not typically used to monitor therapy in patients with primary adrenal insufficiency; due to an altered feedback relationship between cortisol and ACTH in this condition, persistent ACTH elevation should be expected at usual treatment doses, and suppression of ACTH can often indicate overtreatment.

Traditional replacement regimens have used *hydrocortisone* in doses of 20 to 30 mg/day; however, most current guidelines recommend lower doses of 15 to 20 mg/day based on estimates of normal daily rates of endogenous cortisol production. *Cortisone acetate*, which is inactive until converted to cortisol by 11β-HSD1, has been used in doses ranging from 25 to 37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. *Dexamethasone* and *prednisone* have also been used as chronic replacement; however, careful monitoring for iatrogenic development of cushingoid features is required due to their longer duration of action.

Although some patients with primary adrenal insufficiency can be maintained on *hydrocortisone* and liberal salt intake, most of these patients also require mineralocorticoid replacement; *fludrocortisone acetate* is used in doses of 0.05 to 0.2 mg/day. In primary adrenal insufficiency, mineralocorticoid dosing is based on resolution of electrolyte abnormalities and postural hypotension; reduction of salt craving is another valuable indicator of adequate mineralocorticoid replacement. Mineralocorticoid overtreatment may cause hypertension, hypokalemia, and edema. In secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because mineralocorticoid synthesis in the zona glomerulosa usually remains intact.

When initiating treatment in patients with adrenal insufficiency associated with panhypopituitarism, glucocorticoids need to be administered before initiating treatment with thyroid hormone. If used in isolation, thyroid hormone (and correction of hypothyroidism) will accelerate metabolism of any remaining endogenous cortisol present and thus may precipitate adrenal crisis.

Standard doses of glucocorticoids often must be adjusted upward in patients who are also taking drugs that increase their metabolic clearance (i.e., *phenytoin*, barbiturates, or *rifampin*) or who suffer the stress of intercurrent illness. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. The patient and family members should also be trained to administer parenteral *dexamethasone* (4 mg intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Glucocorticoid doses are also adjusted when patients with adrenal insufficiency undergo surgery. In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is *hydrocortisone* 100 mg parenterally every 8 h. Following surgery, the dose is halved each day until it is reduced to routine maintenance level .

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) encompasses a group of genetic disorders in which there is a deficiency in the activity of one of several enzymes required for the biosynthesis of glucocorticoids. The impaired production of cortisol and the consequent lack of negative-feedback inhibition lead to the increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. CAH includes a spectrum for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient.

In about 95% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (see Figure 50–3). Clinically, patients with 21-hydroxylase deficiency are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess, such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH frequently are born with virilized external genitalia that result from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero and often require reconstructive genital surgery. Some medical centers have successfully experimented with *dexamethasone* administration in utero with a goal of reducing female genital virilization; however, this approach is controversial because of concerns regarding abnormal behavioral development after prenatal exposure to glucocorticoids (Miller and Witchel, 2013). Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses. About 75% of patients with classic CAH have inadequate aldosterone production associated with salt wasting, failure to thrive, and potentially fatal hypovolemia and shock.

All patients with classic CAH require replacement therapy with *hydrocortisone* or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore physiological levels of steroid hormones and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of *hydrocortisone* is about 0.6 mg/kg daily in two or three divided doses. The mineralocorticoid used is *fludrocortisone acetate* (0.05–2.0 mg/day). Many experts also administer tablet salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone and androgens, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate ACTH suppression and excessive androgen secretion, whereas growth failure suggests glucocorticoid overtreatment.

Miscellaneous Endocrine Conditions

Prednisone rapidly reduces the neck pain associated with subacute thyroiditis in patients not responding to more conservative measures, and this treatment may be associated with shortened disease duration. High-dose glucocorticoids are also used in severe hyperthyroidism, or thyroid storm, due to their ability to downregulate the deiodinase involved in the conversion of T_4 to its active form T_3. *Prednisone* is the primary therapy for hypercalcemia related to vitamin D intoxication, as it reduces the renal 1α-hydroxylase necessary for converting 25-hydroxy vitamin D to its active 1,25-dihydroxy vitamin D form.

Diagnostic Applications of Dexamethasone

In addition to its therapeutic uses, *dexamethasone* is used as a diagnostic aid in patients suspected of having Cushing syndrome. To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increase cortisol biosynthesis, an overnight *dexamethasone* suppression test has been devised. Patients are given 1 mg of *dexamethasone* orally at 11 PM, and cortisol is measured at 8 AM the following morning. Suppression of cortisol to less than 1.8 μg/dL suggests strongly that the patient does not have Cushing syndrome. Drugs such as barbiturates that enhance *dexamethasone* metabolism or drugs (estrogens) or conditions (pregnancy) that increase the concentration of CBG can interfere with suppression and compromise the test.

A high-dose *dexamethasone* suppression test can be used as part of an evaluation to determine the etiology of biochemically documented Cushing syndrome. Following determination of baseline cortisol levels for 48 h, *dexamethasone* (2 mg every 6 h for 48 h, or 8 mg overnight) is administered orally. In many, but not all, patients with a pituitary source of ACTH excess (i.e., Cushing disease), cortisol will be suppressed. Conversely, in patients with most ectopic ACTH sources or with adrenocortical tumors, cortisol levels fail to be suppressed under these conditions. Since certain ectopic sources of ACTH, such as bronchial carcinoids are nevertheless suppressed by *dexamethasone*, the gold standard for establishing a pituitary source of ACTH is inferior petrosal sinus sampling after CRH administration.

Therapeutic Uses in Nonendocrine Diseases

There are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed next illustrate the principles governing glucocorticoid use in selected diseases. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. Approximate doses of a representative glucocorticoid (e.g., *prednisone*) are provided.

Rheumatic Diseases

Glucocorticoids are used widely in the treatment of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, granulomatosis with polyangiitis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, *prednisone* (1 mg/kg per day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Glucocorticoids are often used in conjunction with other immunosuppressive agents such as *cyclophosphamide* and *methotrexate*, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Intermediate-acting glucocorticoids, such as *prednisone* and *prednisolone*, are generally preferred over longer-acting steroids such as *dexamethasone*.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with their chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory drugs. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs (e.g., *methotrexate* or agents targeted at TNF) take effect. A typical starting dose is 5 to 10 mg of *prednisone* per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20–40 mg/day of *prednisone* or equivalent), with rapid taper thereafter. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5 to 20 mg of the very long-lasting *triamcinolone acetonide* or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., *prednisolone* rather than *prednisone*) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling

Charcot arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

Renal Diseases

Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids are the first-line treatment in both adults and children. Initial daily doses of *prednisone* are 1 to 2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6 to 8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2 to 3 weeks in 85% of patients, and more than 95% of patients enter remission within 3 months. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8 to 10 weeks (e.g., *prednisone* 120 mg every other day), followed by a 1- to 2-month period of tapering.

Allergic Diseases

The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with *epinephrine*. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioedema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (*methylprednisolone* 125 mg IV every 6 h or equivalent) are appropriate. For allergic rhinitis, many experts recommend intranasal steroids.

Pulmonary Diseases

The use of glucocorticoids in bronchial asthma and other pulmonary diseases is discussed in Chapter 44. Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. *Betamethasone* (12 mg IM every 24 h for two doses) or *dexamethasone* (6 mg IM every 12 h for four doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation. For women still at risk of preterm birth 7 or more days after receiving the initial glucocorticoid dose, a meta-analysis of 10 randomized clinical trials involving over 4730 women and 5700 infants showed that a second course of treatment reduced the risk of respiratory distress syndrome and serious neonatal morbidity without adverse effects in infants followed for 2 to 3 years after (McKinlay et al., 2012). Beyond 34 weeks of gestation, the lower risks of respiratory problems make the short-term value of antenatal glucocorticoids questionable given the potential for adverse long-term neuropsychiatric outcomes.

Infectious Diseases

Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. A recent and impactful example is the significant survival benefit of *dexamethasone* treatment in hospitalized COVID-19 patients requiring mechanical ventilation, which was established early during the pandemic (Horby et al., 2021). Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children 2 months of age or older, and in patients with HIV and *Pneumocystis carinii* pneumonia, glucocorticoids in combination with antimicrobial therapy can decrease the incidence of respiratory failure and mortality.

Ocular Diseases

Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival sac. For diseases of the posterior segment, intraocular injection or systemic administration is required. These uses of glucocorticoids are discussed in Chapter 74.

Skin Diseases

Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. A typical regimen for an eczematous eruption is 1% *hydrocortisone* ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatological disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/day of *prednisone*. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of *prednisone*. Chapter 75 presents the dermatologic uses of glucocorticoids.

Gastrointestinal Diseases

Patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn's disease) who fail to respond to more conservative management (i.e., rest, diet, and *sulfasalazine*) may benefit from glucocorticoids, particularly for acute exacerbations. For Crohn's disease, enteric-coated *budesonide* preparations are available that provide controlled ileal release while minimizing systemic exposure due to high first-pass metabolism (see Chapter 55).

Hepatic Diseases

Glucocorticoids are of benefit in autoimmune hepatitis both alone and in combination with immunosuppressants such as *azathioprine* or *6-mercaptopurine* as induction therapy. As many as 80% of patients show histological remission when treated with *prednisone* (40–60 mg daily initially, with tapering to a maintenance dose of 7.5–10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analyses did not support a beneficial role of corticosteroids. In the setting of severe hepatic disease, *prednisolone* should be used instead of *prednisone*, which requires hepatic conversion to be active.

Malignancies

Glucocorticoids are potent inducers of lymphocyte apoptosis, and this forms the basis for their use in the chemotherapy of many lymphoid malignancies, most commonly as a component of combination therapy (see Chapter 70–73). The therapeutic role in nonhematological malignancies is limited. Glucocorticoids are also widely used as adjuvants to mitigate side effects of chemotherapy or radiotherapy of many cancers. Glucocorticoids increase appetite, decrease weight loss, reduce fatigue, and are used to manage chemotherapy-induced nausea and vomiting. They also reduce hypersensitivity reactions and mitigate fluid retention associated with taxane chemotherapy (see Chapter 70). In the palliative setting, short-term glucocorticoids can provide moderate control for pain and radiotherapy pain flare for patients with bone metastases.

Cerebral Edema

Corticosteroids at very high doses (e.g., *dexamethasone* 4–16 mg every 6 h) are commonly used in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic.

Sarcoidosis

Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 20 to 40 mg/day of *prednisone*, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses may be as low as 5 mg/day of *prednisone*.

Thrombocytopenia

In thrombocytopenia, *prednisone* (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases and for initiation of treatment

of idiopathic thrombocytopenia, daily doses of *prednisone* (1–1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

Autoimmune Destruction of Erythrocytes

Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive Coombs test) are treated with *prednisone* (1 mg/kg per day). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

Organ Transplantation

Glucocorticoids remain key components of immunosuppressive regimens in organ transplantation and are the standard therapy for graft-versus-host disease. High doses of *prednisone* (50–100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (see Chapter 39). For some solid-organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely have become more common (Niederhaus et al., 2013).

Spinal Cord Injury

Large doses of *methylprednisolone sodium succinate* (30 mg/kg initially followed by an infusion of 5.4 mg/kg/h for 23 h) are a treatment option for patients with acute spinal cord injury. Although, multicenter controlled trials have demonstrated decreases in neurological defects in patients with acute spinal cord injury treated within 8 h of injury (Bracken, 2012), concerns regarding statistical analysis, reproducibility of data, and potential side effects of treatment have caused some experts to advocate against use of *methylprednisolone* in this setting (Evaniew and Dvorak, 2016).

Inhibitors of ACTH Secretion and the Biosynthesis and Actions of Adrenocortical Steroids

Hypercortisolism (Cushing syndrome), with its attendant morbidity and mortality, is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing disease) or by adrenocortical tumors or bilateral hyperplasia that overproduces cortisol. Less frequently, hypercortisolism may result from adrenocortical carcinomas or from ectopic ACTH- or CRH-producing tumors. Although surgery is the treatment of choice for any endogenous cause of Cushing syndrome, it is not always effective, and adjuvant therapy with pharmacological inhibitors becomes necessary. In these settings, inhibitors of ACTH secretion and of adrenal steroidogenesis are clinically useful. Inhibition of cortisol production by direct inhibition of steroidogenic enzymes leads to a compensatory increase in ACTH, which can partially override inhibition and often lead to accumulation of precursor steroids that can elicit undesirable responses. All of these agents pose the common risk of precipitating adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient's HPA axis must be carefully monitored (Hinojosa-Amaya et al., 2019). Most of the inhibitors discussed here are considered in detail in other chapters; mineralocorticoid receptor antagonists are not considered here but are discussed in Chapter 29.

Inhibitors of ACTH Secretion and Function

Pasireotide

Pasireotide is a somatostatin analogue that is an agonist at four of the five subtypes of somatostatin receptors, with especially high affinity for type 5. Through these interactions, *pasireotide* effectively inhibits growth hormone secretion and is used in the treatment of acromegaly (see Chapter 46). *Pasireotide* also inhibits ACTH secretion and reduces circulating levels of cortisol in patients with ACTH-producing pituitary tumors; the agent is FDA-approved for use in patients with Cushing disease who are not candidates for surgery or who have recurrent disease. At subcutaneous doses of 0.6 or 0.9 mg twice daily, urine cortisol concentrations normalized in 15% and 26% of patients, respectively. A long-acting preparation is now commonly used currently, in doses of 10 to 40 mg every 4 weeks. Treatment improves signs and symptoms of hypercortisolism, including hypertension, elevated low-density lipoprotein cholesterol, and elevated body mass index. Common adverse effects include hyperglycemia, gallstones, and transient GI discomfort (Colao et al., 2012).

Cabergoline

Cabergoline is a potent long-acting dopamine (D_2) receptor agonist used primarily to treat hyperprolactinemia (see Chapter 46). *Cabergoline* also inhibits ACTH secretion from corticotroph tumors, which are often D_2 receptor positive, and is occasionally used off-label for this purpose. In a nonrandomized retrospective study of 30 patients with Cushing disease treated with *cabergoline* monotherapy, 30% achieved normalization of urinary free cortisol for at least 1 year (mean 37 months; average dose 2.1 mg weekly) (Godbout et al., 2010).

Inhibitors of Steroidogenesis and Adrenolytic Agents

Ketoconazole

Ketoconazole is a CYP inhibitor and antifungal agent (see Chapter 61). At doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis because it inhibits multiple steroidogenic P450 enzymes, including CYP11A1, the common initial step (see Figure 50–3). At sufficiently high doses, it effectively blocks steroidogenesis in all primary steroidogenic tissues. *Ketoconazole* is an effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism. In most cases, a dosage regimen of 600 to 800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day (in two or three doses). Side effects include hepatic dysfunction with the possibility of severe hepatic injury. The potential of *ketoconazole* to alter drug transport and metabolism by inhibiting P-glycoprotein and CYP3A4 can lead to serious drug interactions (see Chapters 4 and 5). *Levoketoconazole* is the 2S,4R enantiomer of *ketoconazole* and responsible for most of its steroidogenesis inhibitory activity. It is currently in development for treatment of Cushing syndrome and has received orphan drug status in the U.S. and Europe. A recent clinical trial demonstrated successful control in 36% of enrolled patients at a median dose of 300 mg twice daily (Fleseriu et al., 2019).

Metyrapone

Metyrapone is a relatively selective inhibitor of CYP11B1 and thus inhibits the conversion of 11-deoxycortisol to cortisol, thereby reducing cortisol production and leading to elevation of its precursors (11-deoxycortisol, 11-deoxycorticosterone). Although biosynthesis of aldosterone is also impaired, the mineralocorticoid activity of 11-deoxycortisol and 11-deoxycorticosterone compensates for this and can lead to excessive mineralocorticoid effects, accounting for the hypertension and hypokalemia side effects of chronic *metyrapone* use. Off-label use in the treatment of endogenous hypercortisolism usually requires doses of 4 g/day. Because incomplete responses are common, it is often combined at lower doses (500–750 mg three to four times daily) with other agents that inhibit steroidogenesis. Side effects of chronic use, in addition to hypertension and hypokalemia, include hirsutism (due to upstream overproduction of adrenal androgens), nausea, headache, sedation, and rash.

The FDA-approved indication for *metyrapone* is for diagnostic assessment of HPA axis function, commonly in patients with suspected secondary adrenal insufficiency. *Metyrapone* (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 AM the next morning. A plasma cortisol less than 8 μg/dL validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level less than 7 μg/dL is highly suggestive of impaired HPA function.

Osilodrostat

Osilodrostat is a nonsteroidal, orally available, selective inhibitor of CYP11B1 and CYP11B2; it is FDA-approved for treatment of Cushing

disease in patients who are not surgical candidates or who have recurrent disease. Initial dosing is 2 mg twice daily, and it is titrated by 1- to 2-mg twice-daily increments every 2 weeks until satisfactory control is achieved. In a recent trial of patients with Cushing disease, initial control was achieved with an average dose of 5 mg twice daily. In the following discontinuation phase, 86% of those randomly assigned to continue on *osilodrostat* for 12 weeks stayed in control compared to 34% assigned to placebo. Adrenal insufficiency and adverse effects due to adrenal hormone precursors were common (Pivonello et al., 2020).

Etomidate

Etomidate, a substituted imidazole used primarily as an anesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses, primarily by inhibiting CYP11B1 activity. *Etomidate* has been used off-label to treat hypercortisolism when rapid control is required in the emergency setting ("Cushing crisis"). *Etomidate* is administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg/h to a maximum of 0.3 mg/kg/h (Biller et al., 2008).

Abiraterone Acetate

Abiraterone acetate, a CYP17A1 inhibitor approved for the treatment of prostate cancer (see Chapter 73), is under evaluation for treatment of endogenous Cushing syndrome and for reduction of adrenal androgen production in CAH (Auchus et al., 2014).

Mitotane

Mitotane is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. It also inhibits CYP11A1, thereby reducing steroid synthesis. Initial doses range from 2 to 6 g/day administered orally in three to four divided doses. The maximal dose can be as high as 16 g/day, if tolerated. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities. Primary adrenal insufficiency is an expected consequence, and glucocorticoid replacement is required, typically in higher than usual doses. See Chapter 70 for the structure of *mitotane* and additional details on its use.

Glucocorticoid Receptor Antagonists

Mifepristone

Mifepristone, a progesterone receptor antagonist used to terminate early pregnancy (see Chapter 48), is also a high-affinity GR antagonist. This latter activity reduces cortisol effects, including loss of negative feedback, which causes increases in serum levels of ACTH, cortisol, 11-deoxycortisol, and adrenal androgens. *Mifepristone* is approved for control of hyperglycemia in adults secondary to endogenous Cushing syndrome who have type 2 diabetes. The usual dose is 300 mg once daily. It is used off-label as treatment of intractable Cushing syndrome. Side effects include hypertension and hypokalemia due to action of deoxycortisol at the MR. Dose adjustments are made based on improvement in general symptoms such as fatigue and depression and reduction of cortisol-induced hyperglycemia. The expected paradoxical rise in cortisol level, if coupled with symptomatic response, can be an indication of drug activity.

GR Antagonists/Modulators in Development

Relacorilant is an orally available, high-affinity, selective antagonist for the glucocorticoid receptor currently undergoing clinical trials as a treatment for endogenous Cushing syndrome and adrenocortical carcinoma. Unlike *mifepristone*, it does not have appreciable affinity at the progesterone receptor and is thus expected to be devoid of antiprogesterone effects. *Miricorilant* is a high-affinity GR antagonist/modulator with significant MR antagonist activity. It is in development for nonalcoholic steatohepatitis and for antipsychotic-induced weight gain.

Mineralocorticoid Receptor Antagonists

MR antagonists have multiple therapeutic applications, and third-generation, highly selective, nonsteroidal agents are in advanced clinical development or approved in other countries. These drugs are covered in detail in Chapter 29.

Drug Facts for Your Personal Formulary: *Adrenal Related*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Replacement Therapy		
Hydrocortisone/cortisone	• Primary and secondary chronic adrenal insufficiency	• Hydrocortisone is the synthetic equivalent of cortisol. • Daily oral dose of hydrocortisone is 20–30 mg, preferably as divided doses. • Although nonphysiological glucocorticoids are sometimes used, hydrocortisone or cortisone is preferred for replacement therapy. • Tip: Two-thirds of dose in the morning, one-third of dose in the evening.
Hydrocortisone, other glucocorticoids	• Acute adrenal insufficiency • Critical illness-related cortisol insufficiency (CIRCI)	• CIRCI reflects inadequate cortisol production or may occur with abrupt cessation of administered glucocorticoids. • High-dose intravenous hydrocortisone (50–100 mg/6 h) or a constant infusion of 10 mg/h is needed. • An alternative is prednisone at 1 mg/kg per day.
Fludrocortisone (9α-fluorocortisol)	• Mineralocorticoid replacement	• Doses of 0.05–0.2 mg/day. • Lower dose is used initially and is titrated upward as required by blood pressure, plasma renin levels, and response to upright posture. • Fludrocortisone has a $t_{1/2}$ ≥24 h so divided doses are not necessary.
Anti-inflammatory Agents: Systemic		
Prednisolone, methylprednisolone Dexamethasone, budesonide Others	• Across the spectrum of inflammatory disease • Preterm (24–34 weeks) delivery	• Initial high-dose tapering to low dose in short-course therapy. • In early therapy: insomnia, weight gain, emotional lability. • With high-dose/long-term therapy: psychosis, increased susceptibility to infection, osteoporosis, osteonecrosis, myopathy, HPA axis suppression. • On cessation of therapy: acute hypocortisolism. • Tip: Constant vigilance.

Drug Facts for Your Personal Formulary: *Adrenal Related (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Anti-inflammatory Agents: Topical		
Betamethasone Hydrocortisone Beclomethasone Dexamethasone Triamcinolone acetonide	• Dermatitis, pemphigus, atopic dermatitis, vitiligo, psoriasis, etc.	• Fluorinated steroids have better skin penetration than hydrocortisone. • Effects are magnified by occlusive dressings. • Local adverse events: atrophy, striae, and exacerbation of skin infection. • Tip: Skin-lightening cosmetics include corticosteroids and may produce serious systemic adverse events.
Anti-inflammatory Agents: Ophthalmic		
Dexamethasone Triamcinolone acetonide Fluocinolone acetate (implant)	• Macular disease (degeneration, edema, retinal vein occlusion) • Postoperative inflammation • Corneal injury • Uveitis	• Commonly repeated at 3-month intervals. • Adverse effects: glaucoma, cataract formation. • Contraindications: glaucoma, eye infections.
Anti-inflammatory Agents: Inhaled		
Beclomethasone, budesonide, ciclesonide, flunisolide, fluticasone, mometasone, triamcinolone acetonide	• Asthma, chronic obstructive pulmonary disease	• Rapid metabolism postabsorption into blood is the key for lung selectivity and lower incidence of adverse events. • Chronic use in children may slow growth velocity without compromising final height. • Tip: Ciclesonide, a prodrug converted to active des-ciclesonide in the lung, has low oral bioavailability and less HPA suppression.
Anti-inflammatory Agents: Intranasal		
Mometasone furoate Fluticasone furoate Fluticasone propionate	• Allergic rhinitis, rhinosinusitis, rhinoconjunctivitis, nasal polyposis, postoperatively for sinus ostia stenosis surgery	• Potent localized activity, minimal systemic risk. • Tip: Avoid frequent use.
Anti-inflammatory Steroids: Intra-articular		
Hydrocortisone	• Relief of joint pain	• Local and systemic adverse events rare. • Success varies with difficulty (e.g., vertebral facet joints versus knees).
Chemotherapy		
Dexamethasone Prednisolone Methylprednisolone Prednisone	• Acute lymphatic leukemia • Chronic lymphatic leukemia • Thymoma • Non-Hodgkin lymphoma • Multiple myeloma, breast cancer	• Used in combination with a variety of chemotherapeutic agents. • Used for primary cytotoxic effects, plus relief of pain and nausea and appetite stimulation. • Tip: No place in acute or chronic myelogenous leukemia.
Diagnostics		
Dexamethasone	• Cushing disease	• ↓ ACTH secretion from pituitary corticotrophs but not from ectopic sources.
Metyrapone	Integrity of entire HPA axis	• Inhibits CYP11B1, thereby reducing cortisol and ↑ levels of precursor steroids. • Failure to adequately ↑ precursor levels indicates impaired HPA function.
Cosyntropin (synthetic ACTH)	• Ectopic ACTH secretion • Adrenal insufficiency • Lateralization of aldosterone overproduction	• Cosyntropin is a truncated synthetic form of ACTH used to test adrenal reserve. • Tip: Cosyntropin is commonly used as either a bolus before or a continuous infusion during adrenal venous sampling to distinguish between unilateral and bilateral aldosterone oversecretion in primary aldosteronism.
Stimulant of ACTH Secretion		
Corticorelin	• Peritumoral brain edema postsurgery (off-label use); diagnostic testing	• A synthetic CRH, preferred to high-dose dexamethasone in relieving peritumoral brain edema. • Used diagnostically to distinguish Cushing disease from ectopic ACTH syndrome.
Inhibitors of ACTH Secretion		
Pasireotide	• ACTH oversecretion (Cushing disease)	• Targets $SSTR_5$ (abundant on corticotrophs), ↓ ACTH secretion; used for recurrent or nonresectable ACTH-secreting adenomas.
Cabergoline	• ACTH oversecretion and hyperprolactinemia	• D_2 receptor agonist; ↓ ACTH secretion, ↓ prolactin secretion; useful but not FDA-approved for Cushing disease.
Inhibitors of Corticosteroid Production		
Ketoconazole	• Hypercortisolism (off-label use) • (Used at lower doses as antifungal agent; see Chapter 61)	• ↓ CYP17A1 (17α-hydroxylase) and CYP11A1 (cholesterol side chain cleavage), ↓ adrenal and gonadal steroidogenesis. • Adverse effects: hepatic toxicity; drug interactions due to inhibition of CYP3A4 and P-glycoprotein.

Drug Facts for Your Personal Formulary: *Adrenal Related (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Metyrapone	• Hypercortisolism; adjunctive therapy after pituitary irradiation	• Inhibits CYP11B1 (11-deoxy cortisol → cortisol). • ↓ cortisol; 4 g/day to maximally ↓ steroidogenesis. • Chronic use may cause hirsutism and hypertension.
Etomidate	• Rapid control of hypercorticolism (off-label use) • (Also a short-acting anesthetic; see Chapter 25)	• Inhibits CYP11B1 (11-deoxy cortisol → cortisol). • ↓ cortisol production at subanesthetic doses. • Administer as IV bolus, 0.03 mg/kg.
Mitotane	• Treating inoperable adrenocortical carcinoma (See also Chapter 70)	• Activated by adrenal cortical CYPs to an acyl chloride with cytolytic effects. • Inhibits CYP11A1 (cholesterol side chain cleavage), ↓ steroidogenesis.
Glucocorticoid Antagonist		
Mifepristone (RU486)	• Hypercortisolism • (Used at lower doses as antiprogesterone for termination of early pregnancy; see Chapter 48)	• GR antagonist, IC_{50} ~2.2 nM (IC_{50} for antiprogesterone effect, ~0.025 nM). • Used at 300–1200 mg/day to treat inoperable hypercortisolism that is resistant to other agents.

Chapter 51

Endocrine Pancreas and Pharmacotherapy of Diabetes Mellitus and Hypoglycemia

Alvin C. Powers and David D'Alessio

Diabetes mellitus is a heterogeneous spectrum of metabolic disorders, likely arising from disparate genetic and environmental factors, with a common outcome of impaired glucose homeostasis and hyperglycemia. The pathogenesis, for most persons, involves some combination of insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, and abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. A major source of the morbidity of diabetes is chronic end-organ damage that arises from prolonged hyperglycemia and includes retinopathy, neuropathy, nephropathy, and cardiovascular disease. These chronic complications can be mitigated in many patients by sustained control of the blood glucose and treatment of comorbidities such as hypertension and dyslipidemia (Nathan and DCCT/EDIC Research Group, 2013). A wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation are available (ADA, 2022c).

Physiology of Glucose Homeostasis

Regulation of Blood Glucose

The maintenance of glucose homeostasis is a highly developed systemic process involving the integration of several major organs (Figure 51–1). *Glucose tolerance* refers specifically to tests of this system using standardized oral or intravenous glucose challenges. The actions of insulin are of central importance for glucose homeostasis with webs of interorgan communication via other hormones, nerves, local factors, and substrates also playing vital roles. The pancreatic β cell is essential for normal glucose tolerance, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and regulating glucose output from the liver during fasting.

In the *fasting state* (Figure 51–1A), most of the fuel demands of the body are met by the oxidation of fatty acids. The brain does not effectively use fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are about 2 mg/kg/min in adult humans, largely to supply the CNS with an energy source. *Fasting glucose requirements are primarily provided by the liver.* Liver glycogen stores provide some of this glucose; conversion of lactate, alanine, and glycerol into glucose accounts for the remainder. The dominant regulation of hepatic *glycogenolysis* and *gluconeogenesis* is controlled by the pancreatic islet hormones insulin and *glucagon*. Insulin inhibits hepatic glucose production, and the decline of the circulating insulin concentration in the postabsorptive state (fasting) is permissive for higher rates of hepatic glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating hepatic gluconeogenesis and glycogenolysis. Insulin secretion is stimulated by *food ingestion*, nutrient absorption, and elevated blood glucose, and activation of the insulin receptor promotes glucose, lipid, and protein anabolism (Figure 51–1B). The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

Pancreatic *β cell* function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4–5.5 mM or 80–100 mg/dL). These other stimuli include nutrient substrates such as amino acids, *insulinotropic hormones* released from the GI tract and islet α cells, and autonomic neural pathways. Neural stimuli cause some increase of insulin secretion prior to food consumption and throughout the meal. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. *Glucose-dependent insulinotropic polypeptide (GIP)* and *glucagon-like peptide 1 (GLP-1)*, together termed *incretins,* are the essential gut hormones contributing to *glucose tolerance*. They are secreted in proportion to the ingested nutrient load and relay this information to the islet as part of a feed-forward mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of anticipatory, rapid insulin secretion is an

GLP-1: glucagon-like peptide 1
GLP-1RA: GLP-1 receptor agonist
GLUT: glucose transporter
G6P: glucose-6-phosphate
GPCR: G protein-coupled receptor
Hb: hemoglobin
HDL: high-density lipoprotein
HGP: hepatic glucose production
IAPP: islet amyloid polypeptide
IFG: impaired fasting glucose
IGT: impaired glucose tolerance
IRS: insulin receptor substrate
Kir: inward rectifying K^+ channel
LDL: low-density lipoprotein
MODY: maturity-onset diabetes of the young
mTOR: mammalian target of rapamycin
NPH: neutral protamine Hagedorn
PI3K: phosphatidylinositol-3-kinase
PPAR: peroxisome proliferator-activated receptor
SGLT2: sodium-glucose cotransporter 2
SST: somatostatin
SUR: sulfonylurea receptor

essential feature of normal glucose tolerance, and mimicking this pattern is one of the key challenges for successful insulin therapy in individuals with diabetes.

Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production (HGP) and stimulating the uptake and metabolism of glucose by liver, muscle, and adipose cells. Production of glucose is inhibited half-maximally by an insulin concentration of about 120 pmol/L, whereas glucose utilization is stimulated half-maximally at about 300 pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 min of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase; insulin also increases lipid storage by promoting lipoprotein-lipase synthesis and adipocyte glucose uptake. In muscle and other tissues, insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation. The extracellular matrix, e.g., that is between the intravascular space and skeletal muscle cells or adipocytes, is also important in insulin action and insulin resistance.

The limited glycogen stores in skeletal muscle are mobilized at the onset of physical activity, but most of the glucose support for exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from epinephrine and norepinephrine. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glycerol for hepatic gluconeogenesis.

Pancreatic Islet Physiology and Insulin Secretion

The pancreatic islets compose 1% to 2% of the pancreatic volume. The pancreatic islet is a vascularized, innervated miniorgan containing five endocrine cell types: *α cells* that secrete *glucagon, β cells* that secrete insulin, *δ cells* that secrete *somatostatin (SST)*, *PP* cells that secrete *pancreatic polypeptide*, and *ε cells* that secrete *ghrelin* (Walker et al., 2021).

Insulin is initially synthesized as a single polypeptide chain, *preproinsulin* (110 amino acids), which is processed first to *proinsulin* and then to *insulin* and *C-peptide* (Figure 51–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and the secretory granules of the β cell. The chemical properties of secretory granules are critical in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide, and their regulated intracellular transport carries insulin to the cell membrane for exocytosis. Equimolar quantities of insulin and C-peptide are co-secreted. Insulin has a $t_{1/2}$ of 5 to 6 min due to extensive hepatic clearance and renal filtration. C-peptide, in contrast, with no known physiological function or receptor, has a $t_{1/2}$ of about 30 min. Because of minimal hepatic clearance, measurements of peripheral C-peptide concentrations are useful in assessment of β cell secretion and to distinguish endogenous and exogenous hyperinsulinemia (e.g., in the evaluation of insulin-induced hypoglycemia). The β cell also synthesizes and secretes *islet amyloid polypeptide* (IAPP) or *amylin*, a 37–amino acid peptide. IAPP influences GI motility and the speed of glucose absorption. *Pramlintide* is an agent used in the treatment of diabetes that mimics the action of IAPP.

Insulin secretion is tightly regulated to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of circulating nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids, fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously, a response termed the *incretin effect* and attributed to the insulinotropic GI peptides GIP and GLP-1. Somatostatin release from islet δ cells acts on SST receptors on α and β cells to inhibit glucagon and insulin release through local, paracrine regulation. Recent studies have demonstrated that glucagon and GLP-1 produced in α cells also have local effects to promote insulin secretion. Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α_2 adrenergic receptors inhibits insulin secretion, whereas β_2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (e.g., hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α_2 adrenergic receptors.

The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via a facilitative glucose transporter, primarily glucose transporter type 1 (GLUT1) in human β cells (Figure 51–3) (Campbell and Newgard, 2021). On entry into the β cell, glucose is quickly phosphorylated by *glucokinase* (GK; also known as hexokinase IV); *this phosphorylation is the rate-limiting step in glucose metabolism in the β cell.* β Cell GK phosphorylates glucose most actively when blood glucose concentrations are 5 to 10 mM, accounting for high rates of intracellular glucose metabolism across the physiological range from fasting to prandial glycemia when insulin secretion is greatest. The *glucose-6-phosphate* (G6P) produced by GK activity enters the glycolytic pathway, producing changes in NADPH and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K^+ channel (K_{ATP} channel), leading to cell membrane depolarization. This heteromeric K_{ATP} channel consists of an inward rectifying K^+ channel (Kir6.2) and a closely associated protein known as the sulfonylurea receptor (SUR). Mutations in the K_{ATP} channel are responsible for specific types of neonatal diabetes and hyperinsulinemic hypoglycemia. Membrane depolarization following K_{ATP} closure leads to opening of a voltage-dependent Ca^{2+} channel and increased intracellular Ca^{2+}, resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by changes in

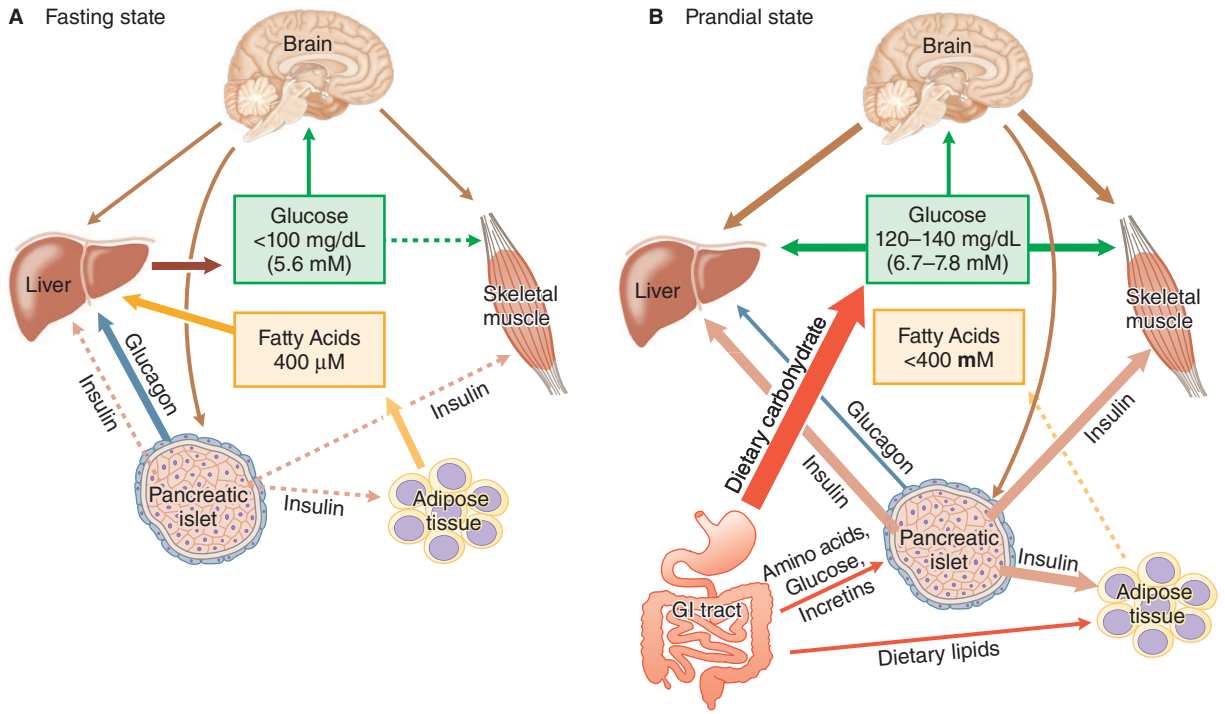

Figure 51–1 *Insulin, glucagon, and glucose homeostasis.* **A.** *Fasting State*—In healthy humans, plasma glucose is maintained in a range from 4.4 to 5 mM and fatty acids near 400 µM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. During overnight fasting, plasma insulin concentrations decrease, and plasma glucagon rises modestly, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased release of fatty acids into the circulation. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. **B.** *Prandial State*—During feeding, nutrient absorption causes an increase in plasma glucose and release of incretins from the gut and neural stimuli from the CNS. This combination of factors stimulates insulin secretion to rise in proportion to meal size. Protein-containing meals also cause a modest increase in glucagon secretion. Under the control of these changes in islet hormones, glucose is distributed primarily to the liver, skeletal muscle, and adipose tissue, which each take up glucose under the influence of insulin. Hepatic glucose production is diminished, and lipolysis inhibited, while total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The boldness of the *arrows* reflects relative intensity of action; a *dashed line* indicates little or no activity.

cAMP production and amino acid metabolism. G protein-coupled receptors (GPCRs) for glucagon, GIP, and GLP-1 and other regulatory peptides couple to G_s to stimulate adenylyl cyclase and insulin secretion; receptors for SST and α_2 adrenergic agonists couple to G_i to reduce cellular cAMP production and secretion.

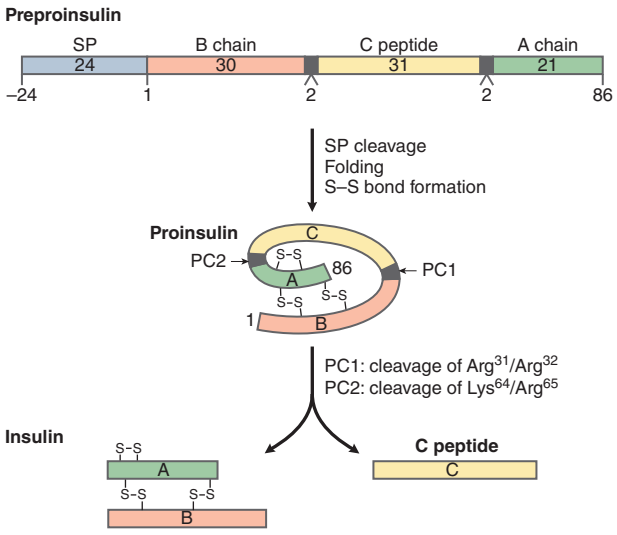

Figure 51–2 *Synthesis and processing of insulin.* The initial peptide, preproinsulin (110 amino acids) consists of a signal peptide (SP), B chain, C-peptide, and A chain. The SP is cleaved and S–S bonds form as the proinsulin folds. Two prohormone convertases, PC1 and PC2, cleave proinsulin into insulin, C-peptide, and two dipeptides. Insulin and C-peptide are stored in granules and co-secreted in equimolar quantities.

The pancreatic α cell secretes *glucagon*, most dramatically in response to hypoglycemia, but also after short periods of fasting or after protein-containing meals. Glucagon biosynthesis begins with *preproglucagon*, which is processed in a cell-specific fashion to several biologically active peptides, such as glucagon, GLP-1, and GLP-2 (see Figure 51–9). *In general, glucagon and insulin secretion are regulated in a reciprocal fashion by the blood glucose; that is, hyperglycemia stimulates insulin secretion and inhibits glucagon secretion. However, pharmacological administration of arginine and other amino acids stimulates both islet hormones, and SST inhibits the secretion of both insulin and glucagon.*

Insulin Action

The insulin receptor is expressed on virtually all mammalian cell types. Tissues that are critical for regulation of blood glucose are liver, skeletal muscle, fat (see Figure 51–1), specific regions of the brain, and the pancreatic islet. The actions of insulin are generally anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Insulin stimulates glycogenesis, lipogenesis, and protein synthesis; it also inhibits the catabolism of these compounds. On a cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin (e.g., activation of glucose and ion transport systems, phosphorylation or dephosphorylation of specific enzymes) occur within seconds or minutes; other effects (e.g., those promoting protein synthesis and regulating gene transcription and cell proliferation) manifest over minutes to hours to days. The effects of insulin on cell proliferation and differentiation occur over an even longer period of time.

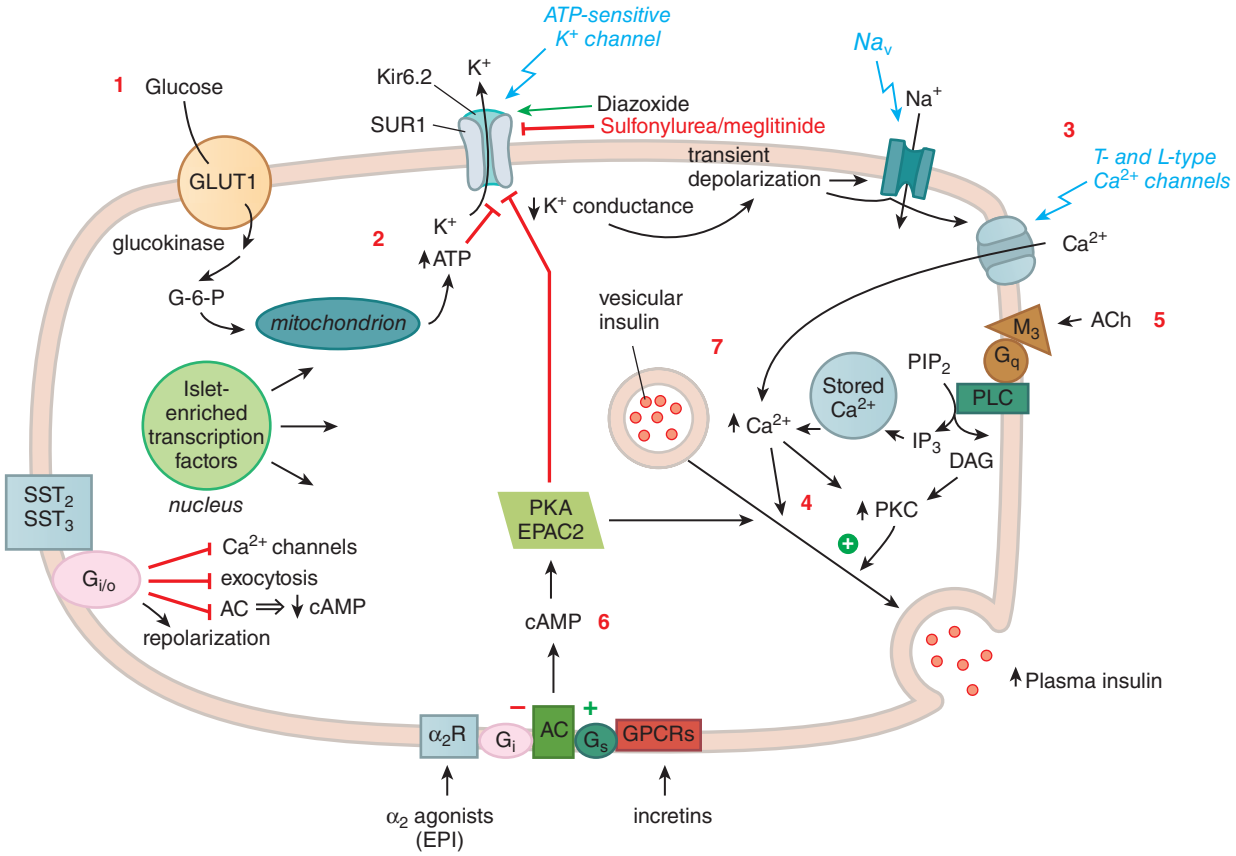

Figure 51–3 *Regulation of insulin secretion from a pancreatic β cell.* In the fasting state of basal glycemia, pancreatic β cells are hyperpolarized. With increases in glycemia, e.g., after meals, glucose transport into the β cells increases, primarily via GLUT1 in humans (1). Increased intracellular glucose leads to more glucose metabolism and elevated levels of ATP, which reduces K^+ conductance through the K_{ATP} channel (2); the decreased K^+ conductance causes local membrane depolarization and activation of Ca^{2+} and Na^+ channels (3), leading to a rise of intracellular calcium and stimulation of release of stored insulin (4), using the basic mechanisms described for exocytosis of neurotransmitters (see Chapter 10, Figures 10–4 to 10–6). ACh, acting via M_3 receptors, can activate the G_q-PLC-IP_3-Ca^{2+}-PKC pathway, potentiating insulin exocytosis (5); incretins, also acting via GPCRs, can activate the G_s-AC-cAMP-PKA/EPAC2 pathways, both of which enhance exocytosis (6). Elevated cAMP also leads to inhibition of the K_{ATP} channel, enhancing depolarization and furthering exocytosis (7). The depolarization/exocytosis period is limited by closure of voltage-sensitive ion channels, by export of Ca^{2+} and Na^+, and by sequestration of Ca^{2+} within the sarcoplasmic reticulum (SR) by the SERCA transporter. SST, acting via SST2 and SST3 that couple to $G_{i/o}$, can aid in restoring the hyperpolarized state of the cell, as can α_2 agonists. The K_{ATP} channel has SUR1 and Kir6.2 subunits; ATP binds to and inhibits Kir6.2; sulfonylureas and meglitinides bind to and inhibit SUR1; all three agents thereby promote insulin secretion. *Diazoxide* and ADP-Mg^{2+} (low ATP) bind to and activate SUR1, thereby inhibiting insulin secretion. Mitochondrial mutations and islet-enriched transcription factors can contribute to the development of diabetes. This schematic is a simplification; see Campbell and Newgard (2021) for greater detail. G, G protein, with subtype indicated by subscript; AC, adenylyl cyclase; EPAC, exchange protein activated by cAMP; GLUT, GLUT1 glucose transporter; GPCR, G protein-coupled receptor; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; SST2/3, somatostatin receptors.

The Insulin Receptor

Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the *insulin-like growth factor 1 receptor* (Haeusler et al., 2018; Saltiel, 2021). The insulin receptor is composed of linked α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of two extracellular α subunits and two membrane-spanning β subunits (Figure 51–4). The number of receptors varies from 40/cell on erythrocytes to 300,000/cell on adipocytes and hepatocytes.

The α subunits inhibit the inherent tyrosine kinase activity of the β subunits. Insulin binding to the α subunits releases this inhibition and allows transphosphorylation of one β subunit by the other, and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular mediators, including the *insulin receptor substrate* (IRS) and Src-homology-2-containing protein. These proteins interact with effectors that amplify and extend the signaling cascade.

Insulin action on glucose transport depends on the activation of *phosphatidylinositol-3-kinase* (PI3K). PI3K is activated by interaction with IRS proteins and generates phosphatidylinositol 3,4,5-trisphosphate, which regulates the localization and activity of mTOR. The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of GLUT4 to the plasma membrane through processes involving actin remodeling and other membrane trafficking systems.

GLUT4

GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue. In the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and in abundance to the plasma membrane (Saltiel, 2021), where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane. Following the facilitated diffusion into cells along a concentration gradient, glucose is phosphorylated to G6P by hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G6P can be isomerized to G1P and stored as glycogen (insulin enhances the activity of glycogen

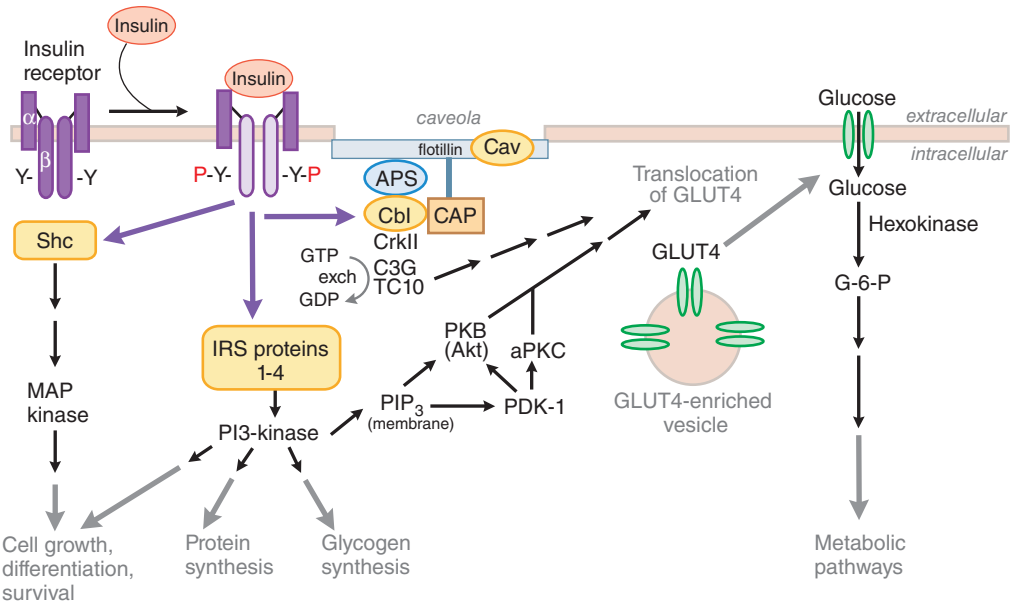

Figure 51–4 *Pathways of insulin signaling.* The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P indicates the phosphorylated tyrosine residue, Y) of the receptor's β subunits and a small number of specific substrates (yellow shapes): the IRS proteins and Src-homology-2-containing protein; within the membrane, a caveolar pool of insulin receptor phosphorylates Cav, APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In the target tissues such as skeletal muscle and adipocytes, a key event is the translocation of GLUT4 from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and noncaveolar pathways. In the noncaveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by phosphatidylinositol 3,4,5-trisphosphate) or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves a series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein TC10. The pathways are inactivated by specific phosphoprotein phosphatases (e.g., PTB1B). In addition to the actions shown, insulin stimulates the plasma membrane Na^+/K^+-ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K^+ in the cell. APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CAV, caveolin; CrkII, chicken tumor virus regulator of kinase II; GLUT4, glucose transporter 4; PDK, phosphoinositide-dependent kinase; Y-P, phosphorylated tyrosine residue.

synthase); G6P can also enter the glycolytic pathway (for ATP production) or the pentose phosphate pathway.

Pathophysiology and Diagnosis of Diabetes Mellitus

Glucose Homeostasis and the Diagnosis of Diabetes

Broad categories of glucose homeostasis are defined by the blood glucose in the fasting or fed state or the glucose following an oral glucose challenge. These include the following:

- Normal glucose homeostasis: fasting plasma glucose less than 5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG): 5.6–6.9 mmol/L (100–125 mg/dL)
- Impaired glucose tolerance (IGT): glucose level between 7.8 and 11.1 mmol/L (140 and 199 mg/dL) 120 min after ingestion of 75 g liquid glucose solution
- Hyperglycemia diagnostic for diabetes mellitus (Table 51–1)

The American Diabetes Association (ADA) and the World Health Organization (WHO) have adopted criteria for the diagnosis of diabetes based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of hemoglobin (Hb) type A_{1c} (A1c); exposure of proteins to elevated glucose produces nonenzymatic glycation of proteins, including Hb, so the level of A1c represents a measure of the average glucose concentration to which the Hb has been exposed (see Table 51–1). IFG and IGT portend a markedly increased risk of progressing to type 2 diabetes and are associated with increased risk of cardiovascular disease.

The four categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and gestational diabetes mellitus (Table 51–2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite diverse.

Screening for Diabetes and Categories of Increased Risk of Diabetes

Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing for

TABLE 51–1 ■ CRITERIA FOR THE DIAGNOSIS OF DIABETES

- Symptoms of diabetes plus random blood glucose concentration ≥11.1 mM (200 mg/dL)[a] or
- Fasting plasma glucose ≥7.0 mM (126 mg/dL)[b] or
- Two-hour plasma glucose ≥11.1 mM (200 mg/dL) during an oral glucose tolerance test[c] or
- HbA_{1c} ≥6.5%

Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

[a]*Random* is defined as without regard to time since the last meal.

[b]*Fasting* is defined as no caloric intake for at least 8 h.

[c]The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

Adapted from American Diabetes Association (2022a).

TABLE 51–2 ■ DIFFERENT FORMS OF DIABETES MELLITUS BY ETIOLOGY

I. **Type 1 diabetes β-cell destruction**, usually leading to absolute insulin deficiency
II. **Type 2 diabetes** (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect)
III. **Other specific types of diabetes**
  A. Monogenic disorders of β-cell function
    1. HNF-4α (MODY 1)
    2. Glucokinase (MODY 2)
    3. HNF-1α (MODY 3)
    4. Other forms of MODY: insulin promoter factor 1, HNF-1β, HNF-1α, NeuroD1, and other regulators of islet cells
    5. Permanent neonatal diabetes *KCNJ11* gene encoding Kir6.2 subunit of β cell K_{ATP} channel, insulin gene
    6. Mitochondrial DNA
  B. Genetic defects in insulin action, including type A insulin resistance, leprechaunism, Rabson-Mendenhall syndrome, lipodystrophy syndromes
  C. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy, mutations in carboxyl ester lipase
  D. Endocrinopathies—acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
  E. Drug or chemical induced—glucocorticoid, calcineurin and mTOR inhibitors, antipsychotics (atypical, others), protease inhibitors, β adrenergic agonists such as epinephrine, pyrinuron (a rodenticide no longer sold in the U.S.)
  F. Infections—congenital rubella, cytomegalovirus
  G. Uncommon forms of immune-mediated diabetes—"stiff-person" syndrome, anti-insulin receptor antibodies
  H. Other genetic syndromes sometimes associated with diabetes—Wolfram, Down, Klinefelter, Laurence-Moon-Biedl, Prader-Willi, and Turner syndromes; Friedreich ataxia; Huntington's disease; myotonic dystrophy; porphyria
IV. **Gestational diabetes mellitus**

MODY, maturity-onset diabetes of the young.
Adapted from American Diabetes Association (2017, 2022c).

non–glucose-related reasons. The ADA recommends widespread screening for type 2 diabetes of adults with the following features:

- Age more than 45 years
- Body mass index greater than 25 kg/m^2 (or >23 kg/m^2 in persons of Asian descent) with one of these additional risk factors: first-degree relative with diabetes, physical inactivity, hypertension, low HDL value, high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander), history of abnormal glucose testing (IFG, IGT, A1c of 5.7%–6.4%), cardiovascular disease, features of insulin resistance, or women with polycystic ovary syndrome
- Women who have previously had gestational diabetes mellitus

In screening for diabetes, fasting plasma glucose, A1c, and plasma glucose after an oral glucose tolerance test are equally valid, but the fasting glucose and A1c are used most commonly. Early diagnosis and treatment of type 2 diabetes should delay diabetes-related complications and reduce the burden of the disease. A number of interventions, including lifestyle modification and pharmacological agents, are effective. Screening for type 1 diabetes is not currently recommended outside a clinical trial.

Pathogenesis of Type 1 Diabetes

Type 1 diabetes accounts for 5% to 10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet, leading to total or near-total insulin deficiency (Powers, 2021). Type 1 diabetes can occur at any age, with up to 40% of individuals developing type 1 diabetes after the age of 30. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such as autoimmune adrenal insufficiency, Graves or Hashimoto disease, pernicious anemia, vitiligo, and celiac sprue. The concordance of type 1 diabetes in genetically identical twins is 60% to 70%, indicating a significant genetic component. The major genetic risk (40%–50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ. However, there likely is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1 diabetes (>75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

Genetically susceptible individuals are thought to have a normal β cell number or mass until β cell–directed autoimmunity develops and β cell loss begins. The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. The β cell destruction is likely cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as tumor necrosis factor-α, interferon-γ, and interleukin-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years, and when the majority of β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. The ADA and others now recognize three stages of type 1 diabetes: stage 1: autoimmunity as reflected by two autoantibodies with normoglycemia; stage 2: autoimmunity with dysglycemia; and stage 3: autoimmunity with hyperglycemia (usually symptomatic). Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are diagnosed as having latent-autoimmune diabetes of adults (Mishra et al., 2018).

Pathogenesis of Type 2 Diabetes

Type 2 diabetes is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and action (Gloyn and Drucker, 2018). Recent analyses of large databases of persons with type 2 diabetes have identified discrete clusters of patients with common features based on demographic and clinical factors (Ahlqvist et al., 2018). These clusters are reproducible in different patient cohorts and have clear associations with specific genetic loci and diabetic complications, supporting a model whereby several distinct pathogenic mechanisms lead to type 2 diabetes. Overweight or obesity is a common correlate of type 2 diabetes, occurring in approximately 80% of affected individuals. For the vast majority of individuals developing type 2 diabetes, there is no clear inciting incident; rather, the condition develops gradually over years, often with progression through an identifiable prediabetic stage.

In general, type 2 diabetes results when there is insufficient insulin action to maintain plasma glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 51–5). The etiology of type 2 diabetes has a strong genetic component. It is a heritable condition, and persons with a diabetic parent or sibling have a relative 4-fold increased risk of disease, increasing to 6-fold if both parents have type 2 diabetes. Although more than 400 genetic loci with clear associations to type 2 diabetes have been identified through genome-wide association studies, the contribution of each is relatively small (Cole and Florez, 2020).

Impaired β Cell Function

In type 2 diabetes, the sensitivity of the β cell to glucose is impaired, with associated loss of responsiveness to other stimuli, such as insulinotropic GI hormones and neural signaling (Kahn et al., 2021). This results in delayed or insufficient insulin secretion, allowing the blood glucose to

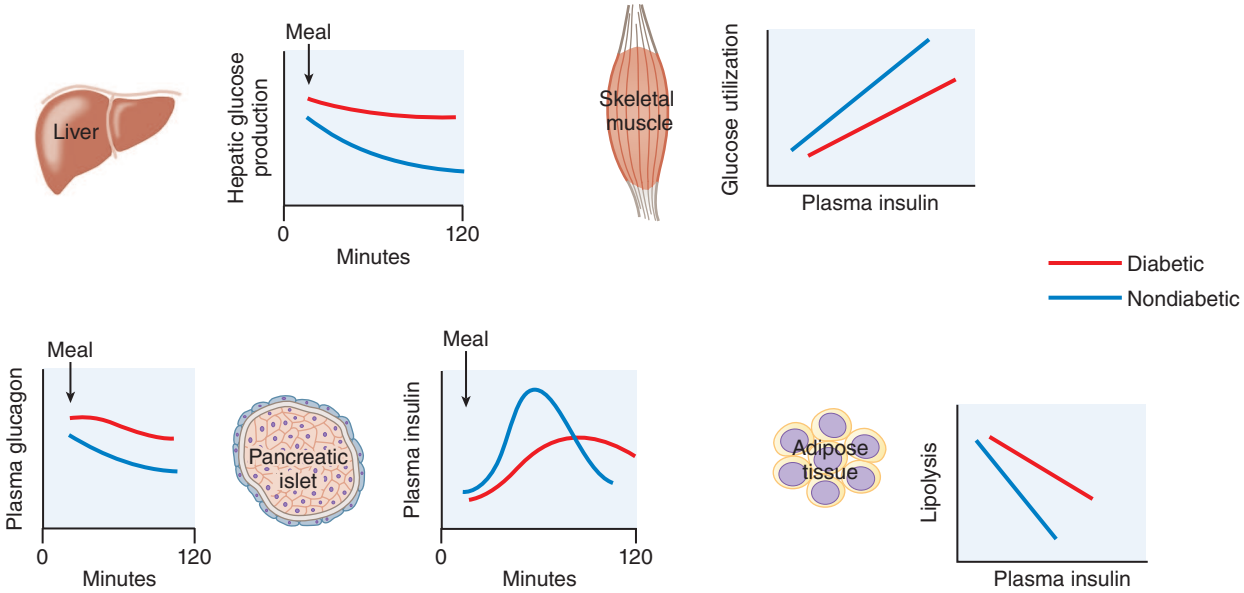

Figure 51–5 *Pathophysiology of type 2 diabetes mellitus.* Graphs show data from nondiabetic individuals (blue lines) and from individuals with diabetes (red lines), comparing postprandial insulin and glucagon secretion and hepatic glucose production, and comparing the sensitivities of muscle glucose use and adipocyte lipolysis to insulin.

rise dramatically after meals, and failure to restrain liver glucose release during fasting. The absolute mass of β cells may also be reduced in patients with type 2 diabetes, but studies are not definitive. Progressive reduction of functional β cell mass explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients sometimes have elevated levels of fasting insulin, a result of their higher fasting glucose level and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the type 2 diabetic islet. Whereas healthy subjects have only 2% to 4% of total circulating insulin as proinsulin, patients with type 2 diabetes can have 10% to 20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin. Many diabetic patients have elevated fasting and prandial glucagon secretion (Sandoval and D'Alessio, 2015).

Insulin Resistance

Insulin sensitivity is measured as the amount of glucose cleared from the blood in response to a fixed dose, or plasma concentration, of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as *insulin resistance.* There is considerable variability of insulin sensitivity among cells, tissues, and individuals, with insulin sensitivity being affected by many factors, including age, body weight, physical activity levels, illness, and medications. Persons with type 2 diabetes or glucose intolerance have reduced responses to insulin and can be distinguished from groups with normal glucose tolerance.

The major insulin-responsive tissues are skeletal muscle, adipose tissue, and liver. Insulin resistance in muscle and fat is generally marked by a decrease in transport of glucose from the circulation into these tissues. Insulin resistance in adipocytes also causes increased rates of lipolysis and release of fatty acids into the circulation, which can contribute to insulin resistance in other tissues, as well as hepatic steatosis and dyslipidemia. Hepatic insulin resistance generally refers to a blunted ability of insulin to suppress glucose production, but insulin-mediated glucose uptake into hepatocytes can also be impaired. The sensitivity of humans to the effects of insulin administration is inversely related to the amount of fat stored in the abdominal cavity; more visceral adiposity leads to more insulin resistance. Intracellular lipid or its by-products may have direct effects to impede insulin signaling. Enlarged collections of adipose tissue, visceral or other white, are often infiltrated with macrophages and can become sites of chronic inflammation. Adipocytokines, secreted from adipocytes and immune cells, including tumor necrosis factor-α, interleukin-6, resistin, and retinol-binding protein 4, can also cause systemic insulin resistance.

Sedentary persons are more insulin resistant than active ones, and physical training can improve insulin sensitivity. Physical activity can decrease the risk of developing diabetes and improve glycemic control in persons who have diabetes. Insulin resistance is more common in the elderly as insulin sensitivity decreases with age. At the cellular level, insulin resistance involves blunted steps in the cascade from the insulin receptor tyrosine kinase to translocation of GLUT4 transporters, but the molecular mechanisms are incompletely understood. While many different mutations have been identified in the insulin receptor, including those that affect insulin receptor number, ligand binding, receptor phosphorylation, and trafficking, it does not appear that mutations in specific components of the insulin signaling cascade are responsible for clinical insulin resistance in most individuals (Saltiel, 2021). Very rare mutations involving the insulin binding domains of the extracellular α-chain can cause very severe syndromes and sometimes are associated with lipodystrophy (Angelidi et al., 2021). Insulin resistance is a major risk factor for the development of type 2 diabetes.

Dysregulated Hepatic Glucose Metabolism

In type 2 diabetes, hepatic glucose output is excessive in the fasting state and inadequately suppressed after meals. Abnormal secretion of the islet hormones, insufficient insulin and excessive glucagon, likely accounts for a significant portion of dysregulated hepatic glucose metabolism in type 2 diabetes. Increased concentrations of glucagon, especially in conjunction with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogenolysis and abnormally high fasting glucose concentrations. The liver is resistant to insulin action in type 2 diabetes, and the capacity of insulin to suppress HGP and promote hepatic glucose uptake and glycogen synthesis after meals is reduced. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in the liver are relatively intact and may be accentuated by fasting hyperinsulinemia. This contributes to hepatic steatosis and further worsening of insulin resistance.

Pathogenesis of Other Forms of Diabetes

Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion (Hattersley and Patel, 2017). These fall in two broad categories: diabetes onset in the neonatal period (<12 months of age) and monogenic diabetes

in children or adults. Some forms of neonatal diabetes are caused by mutations in SUR or its accompanying inward rectifying K^+ channel or by mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, children, adolescents, and young adults may present with monogenic forms of diabetes known as MODY (maturity-onset diabetes of the young). Phenotypically, these individuals are often not obese or insulin resistant and may initially have only modest hyperglycemia. The most common causes are mutations in key islet-enriched hepatocyte nuclear transcription factors (HNF1A and HNF4A) or GK (see Table 51–2). Most individuals with MODY are treated similarly to those with type 2 diabetes, but patients with MODY3, the most common of the monogenic forms of diabetes, can be effectively treated with sulfonylureas.

Chronic diseases of the pancreas, such as pancreatitis or cystic fibrosis, impair insulin secretion, and endocrinopathies such as acromegaly and Cushing disease cause insulin resistance (see Table 51–2) and are secondary causes of diabetes. In addition, a variety of commonly used medications, such as glucocorticoids, atypical antipsychotics, *calcineurin* and mTOR inhibitors after organ transplantation, or protease inhibitors, can raise the blood glucose or lead to diabetes over time (see Table 51–2) (Fève, 2022).

Diabetes-Related Complications

Untreated diabetes can lead to severe metabolic disturbances that can be acutely life threatening, such as diabetic ketoacidosis and a hyperglycemic hyperosmolar state. These require hospitalization for insulin administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic end-organ effects of diabetes are commonly divided into microvascular and macrovascular complications. The microvascular complications are specific to people with diabetes and include retinopathy, nephropathy, and neuropathy. Macrovascular complications related to atherosclerosis, such as myocardial infarction and stroke, occur more frequently in individuals with diabetes but are not specific to diabetes like the microvascular complications. In the U.S., diabetes is the leading etiology of blindness in adults, the major reason for renal failure requiring dialysis or renal transplantation, and the most common cause of nontraumatic lower extremity amputations. The results of clinical trials indicate that microvascular complications can be prevented, delayed, or reduced by effective glucose lowering and macrovascular complications with use of specific diabetes medications.

Hyperglycemia duration and severity of hyperglycemia are major determinants of diabetes-related complications with the precise molecular mechanisms appearing to involve epigenetic changes from hyperglycemia, oxidative stress, dyslipidemia, advanced glycation end products, disordered sphingolipid metabolism (neuropathy), and increased growth factors such as VEGF-A in retinopathy (Jampol et al., 2020; Kato and Natarajan, 2019; Ruiz et al., 2019). The pathogenic processes may be different in each affected organ and influenced by genetic susceptibility.

Therapy of Diabetes

Goals of Therapy

The goals of therapy for diabetes are to alleviate the symptoms related to hyperglycemia (fatigue, polyuria, weight loss), to prevent or reduce the acute metabolic decompensation and chronic end-organ complications, and to allow the individual with diabetes to conduct the normal activities of life (e.g., exercise).

Glycemic control is assessed using both short-term (blood glucose self-monitoring; continuous glucose monitoring) and long-term (A1c, fructosamine) metrics. A1c reflects glycemic control over the prior 3 months, whereas measures of glycosylated serum proteins or albumin (fructosamine) reflect glycemic control over the preceding 2 weeks.

Continuous glucose monitoring (CGM) is a rapidly evolving technology that allows near real-time tracking of interstitial glucose as a reflection of blood glucose levels. Current CGM technology uses a sensor or electrode and detects a reaction between interstitial glucose and a glucose oxidase. It is being used very frequently in the management of type 1 diabetes and in some individuals with type 2 diabetes (Boughton and Hovorka, 2021). CGM provides glycemic data sets that translate into glycemic metrics such as the ambulatory glucose profile and time in a defined glycemic range (target range and above or below target range). The calculated glucose management indicator based on the mean glucose correlates with the A1c. Using capillary blood glucose measurements or CGM, patients can measure their glucose throughout their usual fasting and feeding periods and report these values to the diabetes management team and integrate with diet and exercise.

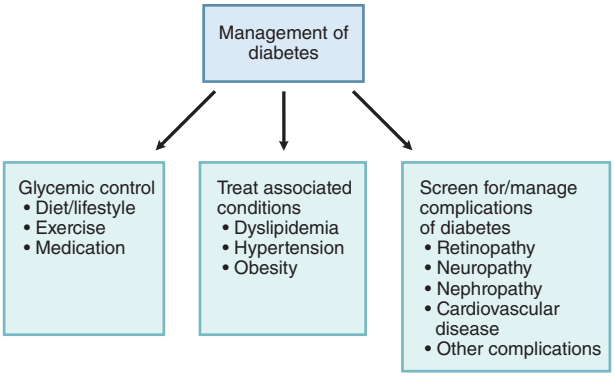

Figure 51–6 *Components of comprehensive diabetes care.*

The term *comprehensive diabetes care* describes optimal therapy for individuals with diabetes that is patient-centered and individualized and includes glucose management, treatment of abnormalities in blood pressure and lipids, and detection and management of diabetes-related complications (Figure 51–6). Table 51–3 shows the ADA-recommended treatment goals for comprehensive diabetes care for adults for glucose, blood pressure, and lipids (see Chapters 32 and 37). The treatment goals should be individualized to the patient and take into account factors such as risk of hypoglycemia, life expectancy, age, other medical conditions, duration of diabetes, and advanced macrovascular/microvascular complications of diabetes (see Table 51–3). Also, the patient's attitude toward diabetes, expectations, resources, and support systems should be considered.

Nonpharmacological Aspects of Diabetes Therapy

Patients with diabetes should be given education on glucose lowering through diet, exercise, and medications (ADA, 2022c). In type 1 diabetes, matching caloric intake and insulin dosing is critical for glucose control. In type 2 diabetes, lifestyle measures are directed at weight loss and reduction of blood pressure and atherosclerotic risk. There is now compelling evidence that metabolic surgery or marked caloric restriction can prevent or even reverse type 2 diabetes, with clinical trials of metabolic surgery showing greater efficacy than medical management (Douros et al., 2019).

Insulin Therapy

Insulin is the mainstay for treatment of virtually all patients with type 1 and many with type 2 diabetes (Hirsch et al., 2020). Although there are specific preparations of insulin that may be administered intramuscularly, intravenously, or nasally, long-term treatment relies predominantly on subcutaneous injection. Subcutaneous administration of insulin delivered into the peripheral circulation can lead to near-normal glycemia but differs from physiological secretion of insulin in two major ways:

- The absorption kinetics do not reproduce the rapid rise and decline of endogenous insulin in response to changes in blood glucose.
- Injected insulin is delivered into the peripheral circulation instead of being released into the portal circulation. Thus, the portal/peripheral insulin concentration is not physiological, and this may alter the influence of insulin on hepatic metabolism.

TABLE 51–3 ■ GOALS OF THERAPY FOR DIABETES IN NONPREGNANT ADULTS

INDEX	GOAL[a]
Glycemic control[b]	
A1c	<7.0%
Preprandial capillary blood glucose	4.4–7.2 mmol/L (80–130 mg/dL)
Peak postprandial capillary blood glucose	<10.0 mmol/L (<180 mg/dL)[c]
Time in range (as defined by CGM) 3.9–10.0 mmol/L (70–180 mg/dL)[d]	>70%
Blood pressure	<140/90[d]
Intensity of statin therapy for lipids (in addition to lifestyle therapy)[e]	
Age <40 years	
-No ASCVD risk factors	No statin
-ASCVD risk factors	Consider moderate dose
-ASCVD	High dose
Age 40–75 years	
-No ASCVD risk factors	Moderate dose
-ASCVD risk factors	High dose
-ASCVD	High dose
Age >75 years	
-No ASCVD risk factors	Consider moderate dose
-ASCVD risk factors	Moderate or high dose
-ASCVD	High dose

ASCVD, arteriosclerotic cardiovascular disease; CGM, continuous glucose monitoring.
[a]Goals should be individualized for each patient and may be different for certain patient populations (lower or higher). According to the ADA, "Goals should be individualized based on duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations."
[b]Achieving A1c value is an important goal, but a higher A1c value may be appropriate for older individuals or those with complex illnesses or moderate to severe cognitive impairment.
[c]At 1–2 h after beginning of a meal.
[d]Optimal from CGM assessment: <5% below 3.9 mmol/L (70 mg/dL) and <25% above 10.0 mmol/L (180 mg/dL).
[e]Lower blood pressure targets (<130/80 mmHg) may be appropriate for certain individuals with diabetes.
[e]For individuals with diabetes, very high risk for ASCVD, and LDL >70 mg/dL (1.3 mmol/L) or who cannot tolerate high-dose statins, see Chapter 37 for alternative approaches.
Adapted from American Diabetes Association (2022b, 2022c, 2022e).

Insulin Preparation and Chemistry

Human *insulin*, produced by recombinant DNA technology, is soluble in aqueous solution (Hirsch et al., 2020). Doses and concentrations of clinically used *insulin* preparations are expressed in international units. One international unit of *insulin* is defined as the bioequivalent of 34.7 μg of crystalline *insulin*; this is equivalent to the older working definition of a U.S. Pharmacopeia unit as the amount required to reduce the blood glucose concentration to 45 mg/dL (2.5 mM) in 2.2-kg rabbit fasted for 24 h. Most preparations of *insulin* are supplied in solution or suspension at a concentration of 100 units/mL, which is about 3.6 mg *insulin* per milliliter (0.6 mM) and termed U-100. *Insulin* also is available in more concentrated preparations (200 [*degludec* and *lispro insulins*], 300 [*glargine insulin*], or 500 [*regular* insulin] units/mL) for patients who are resistant to the hormone and require higher doses.

Insulin Formulations

Preparations of *insulin* are classified according to their duration of action into *short acting* and *long acting* (Table 51–4). Within the short-acting category, some distinguish the *very rapid-acting insulins* (*aspart*, *glulisine*, *lispro*) from regular *insulin*. Likewise, some distinguish formulations with a *longer duration of action* (*degludec, detemir, glargine*) from *NPH insulin*. Two approaches are used to modify the absorption and pharmacokinetic profile of *insulin*. The first approach is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human *insulin* so that it retains its ability to bind to the insulin receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular *insulin* (Figure 51–7). There is wide variability in the kinetics of *insulin* action among individuals and even with repeated doses in the same individual. The time to peak hypoglycemic effect and insulin levels can vary by 50%, due in part by large variations in the rate of subcutaneous absorption.

Short-Acting Regular Insulin. Native or regular *insulin* molecules associate as hexamers in aqueous solution at a neutral pH, and this aggregation slows absorption following subcutaneous injection. Regular *insulin* should be injected 30 to 45 min before a meal. Regular, unbuffered, *100-units/mL insulin* also may be given intravenously or intramuscularly. However, unbuffered, regular *insulin* (*500 units/mL*) is for subcutaneous injection only and should not be given by intravenous or intramuscular injection.

Short-Acting Insulin Analogues. The short-acting *insulin* analogues are absorbed more rapidly from subcutaneous sites than regular *insulin* (see Figures 51–7 and 51–8; see Table 51–4) (Hirsch et al., 2020). *Insulin* analogues should be injected 15 min or less before a meal. When used to treat glycemia at meals, the more rapid acting analogues have lower rates of hypoglycemia and modestly improved A1c levels compared to regular *insulin*.

Insulin lispro is identical to human insulin except at positions B28 and B29. Unlike regular *insulin*, *lispro* dissociates into monomers almost instantaneously following subcutaneous injection. This property results in more rapid absorption and shorter duration of action compared with regular *insulin*.

Insulin aspart is formed by the replacement of proline at B28 with aspartic acid, reducing self-association. Like *lispro*, *insulin aspart* dissociates rapidly into monomers following injection.

Insulin glulisine is formed when glutamic acid replaces lysine at B29 and lysine replaces asparagine at B3; these substitutions also result in a reduction in self-association and rapid dissociation into active monomers.

Long-Acting Insulins. *NPH insulin* (*insulin isophane*) is a suspension of native *insulin* complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other *insulin* solutions. *NPH insulin* dissolves more gradually when injected subcutaneously; thus, its duration of action is prolonged. *NPH insulin* is usually given either once a day (at bedtime) or twice a day in combination with short-acting *insulin*.

Insulin glargine is a long-acting analogue of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. *Insulin glargine* is a clear solution with a pH of 4.0, which stabilizes the *insulin* hexamer. When injected into the neutral pH of the subcutaneous space, aggregation occurs, resulting in prolonged, predictable absorption from the injection site. Owing to *insulin glargine*'s acidic pH, it cannot be mixed with short-acting *insulin* preparations that are formulated at a neutral pH. *Glargine* has a minimal peak absorption profile and provides more predictable 24-h insulin coverage than *NPH insulin* when injected once daily. Clinical trial data suggest that *glargine* has a lower risk of hypoglycemia, particularly overnight, compared to *NPH insulin*. *Glargine* may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. Most commonly, *glargine* formulation of 100 units/mL is used. It is also available in a formulation of 300 units/mL. *Glargine* biosimilar formulations are now available.

Insulin detemir is an *insulin* analogue modified by the addition of a saturated fatty acid to the ε amino group of Lys^{B29}, yielding a myristoylated *insulin*. When *insulin detemir* is injected subcutaneously, it binds to albumin via its fatty acid chain. In patients with type 1 diabetes, *insulin*

TABLE 51–4 ■ TIME-ACTION PROFILES OF INSULIN PREPARATIONS[a]

TYPE	PREPARATION	TIMES		
		ONSET (h)	PEAK (h)	EFFECTIVE DURATION (h)
Short acting				
	Aspart[b]	<0.25	0.5–1.5	3–5
	Glulisine			
	Lispro[c]			
	Regular	0.5–1.0	2–3	4–8
Long acting				
	Detemir	1–4	0[d]	12–24
	Glargine	2–4	0[d]	20–24
	Degludec	1–9	0[d]	42
	NPH	3–4	6–10	10–16
Inhaled insulin		<0.5	1–2	3
Insulin combinations				
	Mixture: short acting (25%–50%) and long acting (50%–76%)	<0.25–1.0	1.5[e]	Up to 10–16

[a]Insulin preparations available in the U.S.; see text for additional information about preparations.
[b]Aspart formulation with niacinamide (vitamin B_3) has more rapid onset of action.
[c]Lispro-aabc formulation has more rapid onset of action.
[d]Glargine, degludec, and detemir have little peak activity at steady state.
[e]Some mixtures will have dual peaks, one at 2–3 h and the second one several hours later.

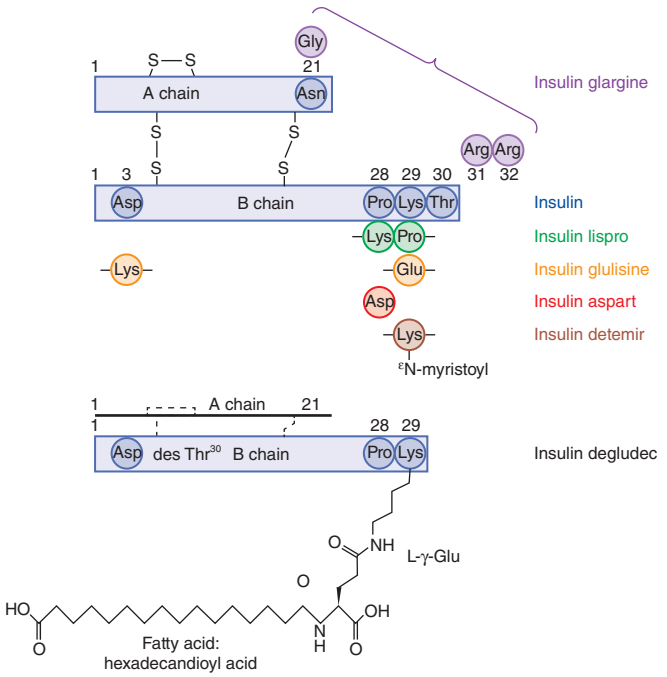

Figure 51–7 *Insulin analogues.* Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (*lispro*) or substituting Asp for Pro^{28B} (*aspart*) gives analogues with reduced tendencies for molecular self-association that are faster acting. Altering Asp^{3B} to Lys and Lys^{29B} to Glu produces an insulin (*glulisine*) with a more rapid onset and a shorter duration of action. Substituting Gly for Asn^{21A} and lengthening the B chain by adding Arg^{31} and Arg^{32} produces a derivative (*glargine*) with reduced solubility at pH 7.4 that is, consequently, absorbed more slowly and acts over a longer period of time. Deleting Thr^{30B} and adding a myristoyl group to the ε-amino group of Lys^{29B} (*detemir*) enhances reversible binding to albumin, thereby slowing transport across vascular endothelium to tissues and providing prolonged action. *Insulin degludec* is Lys^{29B} (Nε-hexadecandioyl-γ-Glu) des^{B30} human insulin. When *degludec* is injected subcutaneously, it forms multihexameric complexes that slow absorption; *degludec* also binds well to albumin; these two characteristics contribute to the prolonged effect of degludec (>24 h at steady state).

detemir, administered twice a day, has a smoother time-action profile and produces a reduced prevalence of hypoglycemia than *NPH insulin*. The absorption profiles of *glargine* and *detemir insulin* are similar, but *detemir* often requires twice-daily administration.

Insulin degludec is a modified *insulin* with one amino acid deleted (threonine at position B30) and is conjugated to hexadecanedioic acid via γ-L-glutamyl spacer at the amino acid lysine at position B29. *Degludec*, which is active at a physiological pH, forms multihexamers after injection subcutaneously. It is associated with less severe hypoglycemia than *glargine*.

Other Insulin Formulations. Stable combinations of short-acting and long-acting insulins provide convenience by reducing the number of daily injections.

Inhaled insulin is formulated for inhalation using a manufacturer-specific device (Heinemann and Parkin, 2018). This formulation should be used in combination with a long-acting *insulin* and has a more rapid onset and shorter duration than injected *insulin* analogues. It is not widely used. Adverse events include cough and throat irritation. It should not be used in individuals who smoke.

Insulin Delivery

Most *insulin* is injected subcutaneously. Pen devices containing prefilled *insulin* are popular. "Smart" pens record and report *insulin* injection and connect to CGM devices. Intravenous infusions of *insulin* are useful in patients with ketoacidosis or when requirements for *insulin* may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations. Long-acting *insulin* should not be given intravenously or intramuscularly or in an infusion device.

Continuous Subcutaneous Insulin Infusion. Short-acting insulins are the only form of the hormone used in subcutaneous *insulin* infusion devices. Several pumps are available for continuous subcutaneous *insulin* infusion (CSII) therapy; this technology is rapidly evolving with improvements in hardware and software (Boughton and Hovorka, 2021). *Insulin* infusion devices provide a constant basal infusion of *insulin* and have the option of different infusion rates during the day and night to help avoid the rise in blood glucose that occurs just prior to awakening from sleep (the dawn phenomenon) and bolus injections that are programmed according to the size and nature of a meal. *Insulin* infusion devices allow

one to deliver a more physiological profile of *insulin* replacement during exercise (where insulin production is decreased) and thus less hypoglycemia than traditional subcutaneous *insulin* injections provide. The integration of an *insulin* infusion device and CGM (open and closed loop systems) is rapidly evolving with algorithms and communication that alter the infusion rate for *insulin* delivery based on CGM data.

Factors That Affect Insulin Absorption

Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (*insulin* has a more rapid onset of action if delivered intramuscularly rather than subcutaneously). Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. The abdomen currently is the preferred site of injection in the morning because *insulin* is absorbed 20% to 30% faster from that site than from the arm. Rotation of *insulin* injection sites is recommended to avoid or limit subcutaneous scarring, lipohypertrophy, or lipoatrophy.

Insulin Dosing and Regimens

Several commonly used dosage regimens that include mixtures of *insulin* given in two or more daily injections are depicted in Figure 51–8. For most patients, *insulin*-replacement therapy includes long-acting *insulin* (basal) and a short-acting *insulin* to provide postprandial needs. In a mixed population of patients with type 1 diabetes, the dose of *insulin* is usually 0.4 to 0.7 units/kg body weight per day. Obese patients, those with type 2 diabetes, and pubertal adolescents may require more (about 1–2 units/kg per day) because of the accompanying *insulin* resistance. The basal dose is usually 40% to 50% of the total daily dose, with the remainder as prandial or premeal *insulin*. The *insulin* dose at mealtime should reflect the anticipated carbohydrate intake. A correction dose of short-acting *insulin* is added to the prandial *insulin* dose to allow correction of the blood glucose. *Administration of a single daily dose of long-acting insulin is not sufficient to achieve optimal glycemic control. More complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. In all patients, careful monitoring of therapeutic end points determines the insulin dose. This approach is facilitated by self-monitoring of glucose (capillary or CGM), measurements of A1c, and individualization of the patient's therapeutic regimen (see Tables 51–3 and 51–4).* In patients who have gastroparesis or loss of appetite, injection of a short-acting analogue postprandially, based on the amount of food actually consumed, may improve glycemic control.

Adverse Events

Hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. *Insulin* treatment of both type 1 and type 2 diabetes is associated with modest weight gain. Although uncommon, allergic reactions to recombinant human *insulin* may occur as a result of reaction to the small amounts of aggregated or denatured *insulin* in preparations, to minor contaminants, or because of sensitivity to a component added to *insulin* in its formulation (protamine, Zn^{2+}, etc.). Atrophy of subcutaneous fat at the site of *insulin* injection (lipoatrophy) was a rare side effect of older *insulin* preparations. Lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of *insulin*.

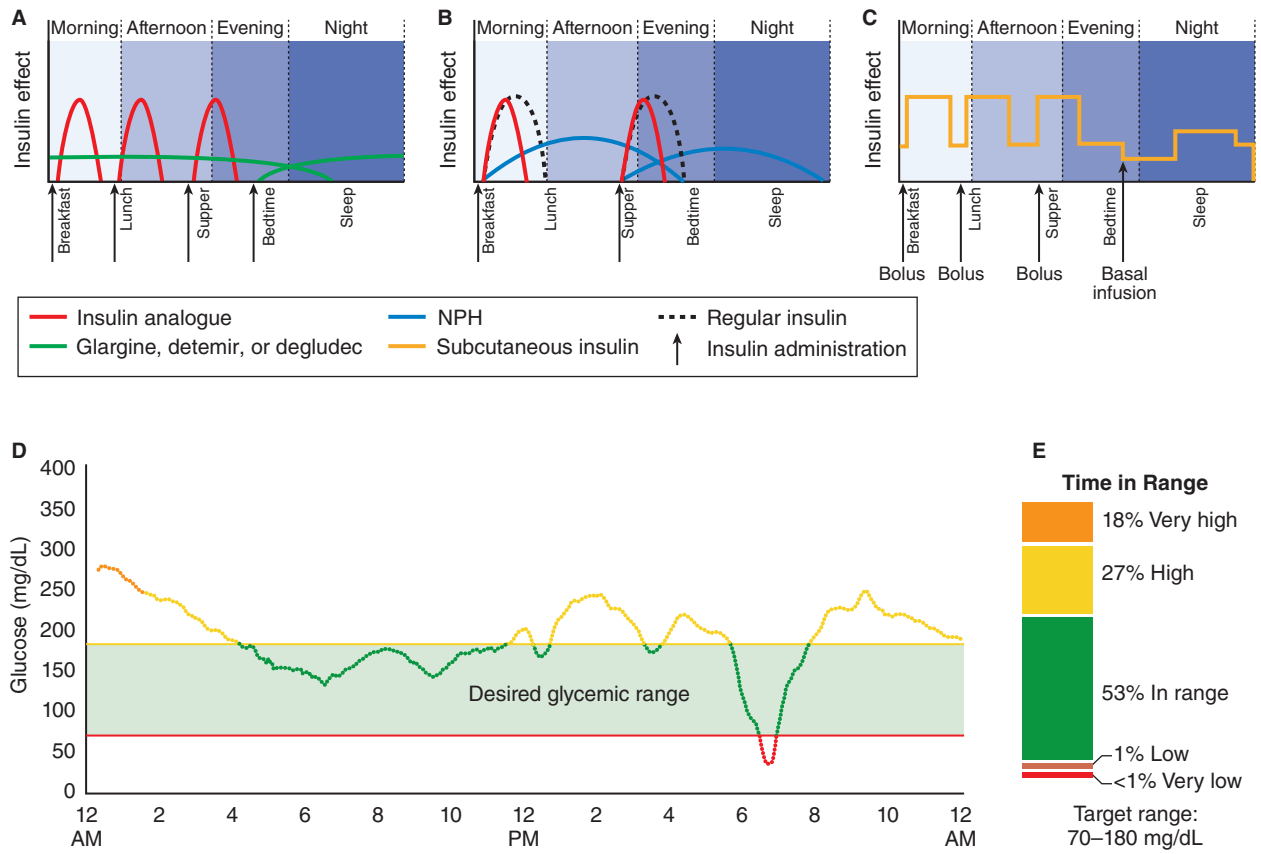

Figure 51–8 *Commonly used insulin regimens.* Panel **A** shows administration of a long-acting *insulin* like *glargine* (*detemir* or *degludec* could also be used; *detemir* may require twice-daily administration; *degludec* is used once daily; see text for details) to provide basal *insulin* and a premeal short-acting *insulin* analogue (see Table 51–4). Panel **B** shows a less-intensive *insulin* regimen with twice-daily injection of *NPH insulin* providing basal *insulin* and regular *insulin* or an *insulin* analogue providing mealtime *insulin* coverage. Only one type of short-acting *insulin* would be used. Panel **C** shows the insulin level attained following subcutaneous *insulin* (short-acting *insulin* analogue) by an *insulin* pump programmed to deliver different basal rates. At each meal, an *insulin* bolus is delivered. (Adapted from Kaufman FR, ed. *Medical Management of Type 1 Diabetes*, 6th ed. American Diabetes Association, Alexandria, VA, **2012**.) Panel **D** shows a daily glucose profile in an individuals with type 1 diabetes with the desired glycemic range shown in light green. The color of the glucose line corresponds to the glucose value category shown in Panel E. Panel E shows the time in range of glucose values over one month in an individual with type 1 diabetes.

Insulin Treatment of Ketoacidosis and Other Special Situations

Intravenous administration of *insulin* may be most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state (Umpierrez and Korytkowski, 2016). Subcutaneous *insulin* regimens are also effective. *Insulin* inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by about 10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the *insulin* not only to prevent hypoglycemia but also to allow clearance of all ketones. Patients with a nonketotic hyperglycemic hyperosmolar state may be more sensitive to *insulin* than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes, particularly K^+, is an integral part of the therapy because of the major K^+ deficit. A long-acting *insulin* should be administered subcutaneously before the *insulin* infusion is discontinued.

Treatment of Diabetes in Children or Adolescents

Diabetes is one of the most common chronic diseases of childhood in the U.S., with the rate gradually increasing over the past decade. An unfortunate corollary of the growing rates of obesity over the past three decades is an increase in the numbers of children and adolescents with non-autoimmune, or type 2, diabetes. Current estimates are that 15% to 20% of new cases of pediatric diabetes may be type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Current therapy for type 1 diabetes in children and adolescents is intensive, physiologically based *insulin* replacement using combinations of basal and prandial *insulin* replacement or CSII with a goal of near-normal glucose control while avoiding hypoglycemia (see Figure 51–8). The primary limiting factor of aggressive *insulin* therapy is hypoglycemia. In children and adolescents with type 1 diabetes, the recommended A1c goal is less than 7%, with a slightly higher goal (7.5%) in individuals who cannot recognize hypoglycemia or have hypoglycemia unawareness. *Insulin* infusion devices and CGM are being used with increasing frequency in the pediatric diabetic population and in older children and adolescents.

Because of the association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight and increasing physical activity are broadly recommended. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is *metformin*. *Metformin* is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). *Insulin* is the typical second line of therapy after *metformin*; basal *insulin* can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. The response to treatment is different in adolescents with type 2 diabetes, suggesting a different underlying pathophysiology. Weight gain is a more significant problem than hypoglycemia with *insulin* treatment in pediatric type 2 diabetes.

Management of Diabetes in Hospitalized Patients

Hyperglycemia is common in hospitalized patients and predisposes to worse outcomes and greater complications. The prevalence of elevated blood glucose levels during hospitalization is not well established but may exceed 30% of inpatients at tertiary care medical centers, with one-third of cases occurring in people without a prior diagnosis of diabetes. Rates of hyperglycemia are particularly high in persons with critical illness cared for in intensive care units where blood glucose levels correlate with severity of illness. Depending on the patient population, a significant number of patients with a first detection of hyperglycemia during hospitalization will have persistent hyperglycemia after recovery and meet diagnostic criteria for diabetes. Stress of illness has been associated with insulin resistance, often attributed to counterregulatory hormone secretion, cytokines, and other inflammatory mediators, although the role of specific mediators has not been proven. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally, fluid balance and tissue perfusion can affect the absorbance of subcutaneous *insulin* and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients should be adjusted for these variables.

Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, variable absorption from the gut, and side effects. In noncritically ill hospitalized patients, a basal plus bolus correction *insulin* regimen, adjusted for oral intake, is optimal. There is evidence from randomized trials that using only short-acting *insulin* in response to hyperglycemia (i.e., sliding-scale regimens) is less effective than scheduled *insulin* regimens. For the critically ill and those with variable blood pressure, edema, and diminished tissue perfusion, intravenous *insulin* is the treatment of choice. Intravenous administration of *insulin* also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. Although optimal blood glucose targets in hospitalized patients are incompletely defined, in general, levels of 140 to 180 m/dL (7.8–10.0 mM) in most hospitalized patients, with more stringent goals, such as 110 to 140 mg/dL (6.1–7.8 mmol/L), in some critically ill patients, are recommended.

Insulin Secretagogues and Glucose-Lowering Agents

A variety of *sulfonylureas, meglitinides, GLP-1 agonists, and inhibitors of dipeptidyl peptidase 4* (DPP-4) are used as secretagogues to stimulate insulin release (Table 51–5).

K_{ATP} Channel Modulators: Sulfonylureas

Sulfonylureas in current use includes *glyburide* (*glibenclamide*), *glipizide*, and *glimepiride* (Khunti et al., 2018). Some are available in an extended-release (*glipizide*) or a micronized (*glyburide*) formulation. *Glyburide* is generally not recommended because of increased risk of hypoglycemia and putative adverse effects during cardiac ischemia.

Mechanism of Action. Sulfonylureas stimulate insulin release by binding to a specific site on the β cell K_{ATP} channel complex (SUR) and inhibiting its activity. K_{ATP} channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (see Figure 51–3). The acute administration of sulfonylureas to patients with type 2 diabetes increases insulin release from the pancreas and shifts the insulin-glucose dose-response relationship to the left.

ADME. Sulfonylureas are effectively absorbed from the GI tract, but food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90%–99%) bound to protein, especially albumin. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg. Although their half-lives are short (3–5 h), their hypoglycemic effects are evident for 12 to 24 h, and they often can be administered once daily. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

Therapeutic Uses. Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Of properly selected patients, 50% to 80% respond to this class of agents. All members of the class appear to be equally efficacious. A significant number of patients who respond initially later cease to respond to the sulfonylurea and develop progressive hyperglycemia (so-called secondary failure). This may occur as a result of a change in drug metabolism but is more likely the result of progressive β cell failure. Some individuals with neonatal diabetes or MODY-3 respond to these agents with long-lasting therapeutic efficacy. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and significant hepatic or renal insufficiency.

Adverse Effects; Drug Interactions. Sulfonylureas may cause hypoglycemic reactions, including coma. Weight gain of 1 to 3 kg is a common side effect of improving glycemic control with sulfonylurea treatment.

TABLE 51–5 ■ PROPERTIES OF INSULIN SECRETAGOGUES

CLASS AND GENERIC NAME	DOSAGE[a] (mg)	DURATION OF ACTION (HOURS OR DOSING FREQUENCY)
Sulfonylureas[b]		
Glimepiride	1–8	24
Glipizide	5–40	12–18
Glipizide (extended release)	5–20	24
Glyburide[c]	1.25–20	12–24
Glyburide (micronized)[c]	0.75–12	12–24
Nonsulfonylureas (Meglitinides)[c]		
Nateglinide	180–360	2–4
Repaglinide	0.5–16	2–6
GLP-1 Agonists		
Dulaglutide	0.75–4.5	Weekly
Exenatide	0.005–0.010	Daily
Exenatide, extended release	2	Weekly
Liraglutide[d]	1.2–1.8	Daily
Lixisenatide	0.010–0.020	Daily
Semaglutide[d]	0.5–1.0	Weekly
Semaglutide, oral	7–14	Daily
Dipeptidyl Peptidase-4 Inhibitors		
Alogliptin	25	Daily
Linagliptin	5	Daily
Saxagliptin	2.5–5	Daily
Sitagliptin	25–100	12–16
Vildagliptin	50–100	Twice daily

[a]Dose should be lower in some patients.
[b]Glyburide no longer recommended because of hypoglycemia profile.
[c]Labeled for administration 3–4 times daily.
[d]Liraglutide 3.0 mg and semaglutide 2.4 mg are approved for weight loss independent of diabetes status.

Less frequent side effects include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by *disulfiram* or hyponatremia. Although there has been long-standing controversy over the cardiovascular safety of sulfonylureas, recent comparative clinical trials indicate that this class of drugs has no more risk of cardiovascular events than other commonly used glucose-lowering agents (Rosenstock et al., 2019; Vaccaro et al., 2017).

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). Some drugs (sulfonamides, *clofibrate*, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. Hypoglycemia may be more frequent in patients taking a sulfonylurea in combination with one or more of the following agents: androgens, anticoagulants, azole antifungals, *fenfluramine*, *gemfibrozil*, H_2 antagonists, magnesium salts, *methyldopa*, *probenecid*, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increasing hepatic metabolism, increasing renal excretion, or inhibiting insulin secretion (β blockers, Ca^{2+} channel blockers, *cholestyramine*, *diazoxide*, estrogens, hydantoins, *isoniazid*, *nicotinic acid*, phenothiazines, *rifampin*, sympathomimetics, thiazide diuretics, and urinary alkalinizers).

Dosage Forms Available. Treatment is initiated at the lower end of the dose range and titrated upward based on the patient's glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (*glimepiride*), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (see Table 51–5). Sulfonylureas such as *glipizide* or *glimepiride* appear safer than longer-acting sulfonylureas in elderly individuals with type 2 diabetes, but even the short-duration agents should be used with caution in elderly patients.

K_{ATP} Channel Modulators: Nonsulfonylureas

Repaglinide. *Repaglinide* is an oral insulin secretagogue that also stimulates insulin release by closing K_{ATP} channels in pancreatic β cells, although not by direct binding to the SUR (see Table 51–5) (Chen et al., 2015). The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 h with a $t_{1/2}$ of approximately 1 h. These features allow for a rapid on-off effect suitable for selected preprandial use. *Repaglinide* is metabolized primarily by the liver (CYP3A4) to inactive derivatives. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously.

The major side effect of *repaglinide* is hypoglycemia. *Repaglinide* also is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of *repaglinide* by displacing it from plasma protein-binding sites (β blockers, *chloramphenicol*, *warfarin*, monoamine oxidase inhibitors, nonsteroidal anti-inflammatory drugs, *probenecid*, salicylates, and *sulfonamide*) or altering its metabolism (*gemfibrozil*, *itraconazole*, *trimethoprim*, *cyclosporine*, *simvastatin*, *clarithromycin*).

Nateglinide. *Nateglinide* is an orally effective insulin secretagogue. *Nateglinide* also stimulates insulin secretion by blocking K_{ATP} channels in pancreatic β cells. *Nateglinide* promotes a more rapid but less-sustained secretion of insulin than other available oral antidiabetic agents. The drug's major therapeutic effect is reducing postprandial glycemic elevations in patients with type 2 diabetes.

Nateglinide is most effective when administered at a dose of 120 mg, three times daily, 1 to 10 min before a meal. It is metabolized primarily by hepatic CYPs (2C9, 70%; 3A4, 30%) and should be used cautiously in patients with hepatic insufficiency. About 15% of an administered dose is excreted by the kidney as unchanged drug. Some drugs reduce the glucose-lowering effect of *nateglinide* (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, nonsteroidal anti-inflammatory drugs, salicylates, monoamine oxidase inhibitors, and nonselective β blockers) may increase the risk of hypoglycemia with *nateglinide*. *Nateglinide* therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues, including *repaglinide*. As with sulfonylureas and *repaglinide*, secondary failure occurs.

Biguanides

Metformin is the only member of the biguanide class of oral hypoglycemic drugs available for use today. Previously available biguanides, *phenformin* and *buformin*, were removed from the market in the 1970s due to unacceptable rates of associated lactic acidosis.

Mechanism of Action. Several mechanisms have been proposed to explain the central pharmacological action of *metformin*, reduction of HGP primarily by limiting gluconeogenesis (LaMoia and Shulman, 2020). *Metformin* has specific actions on mitochondrial respiration that reduce intracellular ATP and increase AMP. Experimental evidence supports activation of AMP-dependent protein kinase by *metformin*, leading to stimulation of hepatic fatty acid oxidation, glucose uptake, and nonoxidative glucose metabolism and reduction of lipogenesis and

gluconeogenesis. *Metformin* also inhibits the mitochondrial glycerol phosphate dehydrogenase, thereby changing the redox state of the cell. Other evidence implicates other mechanisms, including blunting the effects of glucagon, inhibiting conversion of lactate and glycerol to glucose, and shifting the liver toward negative lipid balance. *Metformin* also appears to act in the gut.

Most of the pharmacological effects of *metformin* are mediated in the liver with minimal action on glucose metabolism or insulin sensitivity in skeletal muscle. *Metformin* has little effect on blood glucose in normoglycemic states, does not stimulate the release of insulin or other islet hormones, and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, *metformin* lowers blood glucose by reducing HGP. There is little information to support a direct effect of *metformin* on hepatic insulin signaling, but there are at least complementary effects of the drug to improve the dose-response relationship between insulin and hepatic glucose production.

ADME. Based on the pharmacokinetics of the common immediate-release form of *metformin*, it is recommended for twice-daily administration at doses of 0.5 to 1.0 g. The maximum dose is 2550 mg, but therapeutic benefit starts to plateau at 2000 mg. A sustained-release preparation is available for once-daily dosing starting at 500 mg daily, with titration up to 2000 mg as necessary. Fixed-dose combinations of *metformin* with *glipizide*, *glyburide*, *pioglitazone*, *linagliptin*, *saxagliptin*, *sitagliptin*, *alogliptin*, *canagliflozin*, *dapagliflozin*, and *empagliflozin* are available.

Metformin is absorbed primarily from the small intestine with a bioavailability of 70% to 80%. Peak concentrations after an oral dose occur at about 2 h; the drug's plasma $t_{1/2}$ is 4 to 5 h. *Metformin* does not bind to plasma proteins and is excreted unchanged in the urine. The transport of *metformin* into hepatocytes is mediated primarily by organic cation transporter type 1; renal uptake is mediated by organic cation transporter type 2. Export into the urine is by MATE1/2 (multidrug and toxin extrusion proteins).

Therapeutic Uses. *Metformin* is generally accepted as the first-line treatment of type 2 diabetes and is the most commonly used oral agent for this condition. *Metformin* is effective as monotherapy and in combination with other glucose-lowering medications. *Metformin* has been shown to be safe and effective to treat gestational diabetes, although it has not yet been given FDA approval for this indication.

Metformin has superior or equivalent efficacy of glucose lowering compared to other oral agents used to treat diabetes and reduces microvascular complications in patients with type 2 diabetes; more limited data support a beneficial effect to reduce macrovascular disease as well. *Metformin* does not typically cause weight gain and, in some cases, causes mild weight reduction. In persons with IGT, treatment with *metformin* delays the progression to diabetes. *Metformin* has been used as a treatment of infertility in women with polycystic ovarian syndrome. Although not formally approved for this purpose, *metformin* demonstrably improves ovulation and menstrual cyclicity and reduces circulating androgens and hirsutism.

Adverse Effects; Drug Interactions. The most common side effects (10%–25%) of *metformin* are GI: nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. *Metformin* has direct effects on GI function, including interference with the absorption of glucose and bile salts. Use of *metformin* is also associated with 20% to 30% lower blood levels of vitamin B_{12}, and these levels should be monitored. Most adverse GI effects of *metformin* abate over time with continued use and can be minimized by starting at a low dose and gradually titrating to a target dose over several weeks, as well as by having patients take the drug with meals. There is evidence suggesting that extended-release *metformin* has decreased GI side effects and can be substituted for immediate-release *metformin* in patients who are having difficulty tolerating the drug.

Because the previously available biguanides *phenformin* and *buformin* caused lactic acidosis, *metformin* has been carefully scrutinized for this side effect. Lactic acidosis associated with *metformin* has been rarely reported in patients with concurrent conditions that can cause poor tissue perfusion (e.g., sepsis, myocardial infarction, and congestive heart failure). However, recent analyses have raised doubts regarding whether the association of *metformin* with lactic acidosis is causal. Renal failure is a common comorbidity in patients with lactic acidosis associated with *metformin* use, and plasma *metformin* levels are inversely related to glomerular filtration rate (GFR) due to reduced clearance of drug from the circulation (e.g., levels rise above the usual therapeutic range when creatinine clearance drops below 40–50 mL/min). However, in recent studies of patients with severe renal failure, including some requiring dialysis, rates of lactic acidosis were not increased in those taking *metformin*. Current guidelines suggest that *metformin* may be used safely when the GFR is greater than 30 mL/min/1.73 m^2.

It is important to assess renal function before starting *metformin* and to monitor function at least annually. *Metformin* should be discontinued preemptively if renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to the hospital for severe illness. Metformin should not be used in patients with severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse. Cationic drugs that are eliminated by renal tubular secretion have the potential for interaction with *metformin* by competing for common renal tubular transport systems. Adjustment of *metformin* is recommended in patients who are taking cationic medications such as *cimetidine*, *furosemide*, and *nifedipine*.

Thiazolidinediones

Thiazolidinediones are ligands for the *peroxisome proliferator-activated receptor γ* (PPARγ) receptor, a nuclear hormone receptor that has two isoforms and is involved in the regulation of genes related to glucose and lipid metabolism. Two thiazolidinediones are currently available to treat patients with type 2 diabetes, *rosiglitazone* and *pioglitazone*; a third, *troglitazone*, was removed from the market in 2000 due to hepatotoxicity (Lebovitz, 2019).

Mechanism of Action; Pharmacological Effects. Thiazolidinediones activate PPARγ receptors, which are expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells; islet β cells; macrophages; and vascular endothelial cells. The endogenous ligands for PPARγ include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid, and the prostaglandin metabolite 15d-PGJ_2. Ligand binding to PPARγ causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes (see Chapter 3). The principal response to PPARγ activation is adipocyte differentiation. PPARγ activity also promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose sites to adipose tissue.

One consequence of the cellular responses to PPARγ activation is increased tissue sensitivity to insulin. *Pioglitazone* and *rosiglitazone* are insulin sensitizers and increase insulin-mediated glucose uptake by 30% to 50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPARγ agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce HGP and increase hepatic glucose uptake. It is not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these.

Thiazolidinediones also affect lipid metabolism. Treatment with *rosiglitazone* or *pioglitazone* reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triglyceride stores from nonadipose to adipose tissues and from visceral to subcutaneous fat depots. *Pioglitazone* reduces plasma triglycerides by 10% to 15% and raises HDL cholesterol levels. In contrast, *rosiglitazone* has minimal effects on plasma triglycerides, and the only consistent effect on circulating lipids is an increase of LDL cholesterol.

ADME. *Rosiglitazone* and *pioglitazone* are dosed once daily. The starting dose of *rosiglitazone* is 4 mg, and the maximum dose should not exceed

8 mg daily. The starting dose of *pioglitazone* is 15 to 30 mg, increased up to a maximum of 45 mg daily. Both agents are absorbed within 2 to 3 h, and bioavailability is unaffected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency but should not be used if there is active hepatic disease. *Rifampin* induces hepatic CYPs and causes a significant decrease in plasma concentrations of *rosiglitazone* and *pioglitazone*; *gemfibrozil* impedes metabolism of the thiazolidinediones and can increase plasma levels by about 2-fold; a dose reduction is suggested with this combination. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1 to 3 months.

Therapeutic Uses. Thiazolidinediones enhance insulin action on liver, adipose tissue, and skeletal muscle; confer improvements in glycemic control in persons with type 2 diabetes; and cause average reductions in A1c of 0.5% to 1.4%. A key feature of their pharmacology is that they reduce hyperglycemia, but do not cause hypoglycemia. Thiazolidinediones require the presence of endogenous insulin for pharmacological activity and are not used in type 1 diabetes. Both *pioglitazone* and *rosiglitazone* are effective as monotherapy and when added to *metformin*, sulfonylureas, or *insulin*. *Pioglitazone* is marketed in a fixed-dose combination with *alogliptin*.

Adverse Effects; Drug Interactions. The most common adverse effects of the thiazolidinediones are weight gain and edema. Thiazolidinediones cause an increase in body adiposity and an average weight gain of 2 to 4 kg over the first year of treatment. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount of weight gain compared with either drug alone. Macular edema has been reported in patients using either *rosiglitazone* or *pioglitazone*.

As with other side effects of thiazolidinediones, fluid retention is dose related. Use of thiazolidinediones is associated with a mild reduction of hematocrit, which may be an effect of fluid retention, although a primary effect on hematopoiesis has not been excluded.

Exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure of up to 2-fold. This has generally been attributed to the effect of the drugs to expand plasma volume in patients with type 2 diabetes who have an increased risk for heart failure. There does not appear to be an acute effect of *pioglitazone* or *rosiglitazone* to reduce myocardial contractility or ejection fraction. Thiazolidinediones can be used in diabetic patients without a history of heart failure or with compensated heart failure, but careful monitoring is important, especially when *insulin* is also used. Thiazolidinediones should not be used in patients with moderate-to-severe heart failure.

In the past, evidence suggested that *rosiglitazone* increased the risk of cardiovascular events (myocardial infarction, stroke). For this reason, the FDA restricted its use for several years, but this regulation has now been lifted as trial results suggested a neutral effect. Most evidence supports a mild beneficial effect of *pioglitazone* on overall cardiovascular events. In a trial of nondiabetic, insulin-resistant individuals who had a recent history of ischemic stroke or transient ischemic attack, *pioglitazone* reduced the risk of subsequent stroke or myocardial infarction and diabetes.

Treatment with thiazolidinediones has been associated with an increased risk of bone fracture in women, with some studies also showing effects in men. Therefore, the presence of osteoporosis and other risks for fracture should be considered before starting thiazolidinediones.

Pioglitazone and *rosiglitazone* are associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis. In clinical trials of patients with nonalcoholic steatohepatitis, *pioglitazone* reduced both hepatic lipid accumulation and inflammation (Gastaldelli and Cusi, 2019) and is the pharmacological agent with the strongest evidence for efficacy in this syndrome. Although *troglitazone* was removed from the market because of hepatotoxicity, case reports of acute liver injury with *pioglitazone* and *rosiglitazone* are rare. Nonetheless, thiazolidinediones should be withheld from patients with clinically apparent liver disease.

GLP-1–Based Agents

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The currently established incretins are GLP-1 and GIP, and both act through specific receptors on β cells to stimulate insulin secretion. The GLP-1 receptor has become an effective drug target, with numerous glucose-lowering drugs developed that work through this mechanism. The GLP-1 receptor is also expressed in the brain, and GLP-1 receptor agonists activate these to reduce food intake and possibly augment the glucose-lowering actions that occur through enhanced β cell function. Efforts to incorporate the GIP receptor into diabetes therapeutics are under development.

Both GLP-1 and glucagon are derived from preproglucagon, a 180–amino acid precursor with five separately processed domains (Figure 51–9). An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and GLP-2. Processing of the protein is sequential and occurs in a tissue-specific fashion. Pancreatic α cells cleave proglucagon primarily into glucagon and a large C-terminal peptide that includes both of the GLPs. Intestinal L cells and hindbrain neurons process proglucagon mostly into a large N-terminal peptide that includes glucagon and GLP-1 and GLP-2. GLP-2 affects the proliferation of epithelial cells lining the GI tract. *Teduglutide*, a GLP-2 analogue, is approved for treatment of short-bowel syndrome (see Chapter 54).

Given intravenously to diabetic subjects in supraphysiological amounts, GLP-1 stimulates insulin secretion, inhibits glucagon release, delays gastric emptying, reduces food intake, and normalizes fasting and postprandial insulin secretion. The insulinotropic effect of GLP-1 is glucose dependent in that insulin secretion at fasting glucose concentrations, even with high levels of circulating GLP-1, is minimal. Native GLP-1 is rapidly inactivated by the enzyme DPP-4, yielding a plasma $t_{1/2}$ of 1 to 2 min; thus, the endogenous peptide is not a useful therapeutic agent.

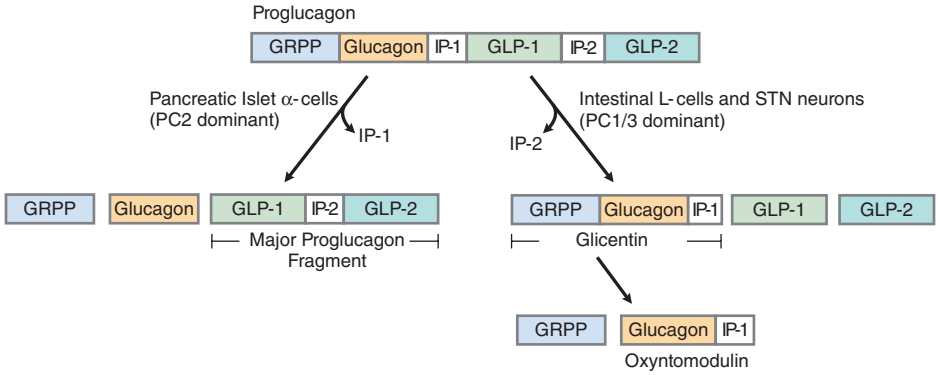

Figure 51–9 *Processing of proglucagon to glucagon, GLP-1, GLP-2, and glicentin-related pancreatic polypeptide (GRPP).* Proglucagon is synthesized in islet α cells, intestinal enteroendocrine cells (L cells), and a subset of neurons in the hindbrain. In α cells, prohormone processing is primarily by proconvertase 2, releasing glucagon, GRPP, and a major proglucagon fragment containing the two GLPs. In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving rise to glicentin, oxyntomodulin, GLP-1, and GLP-2. IP-1, intervening peptide-1; STN, solitary tract nucleus.

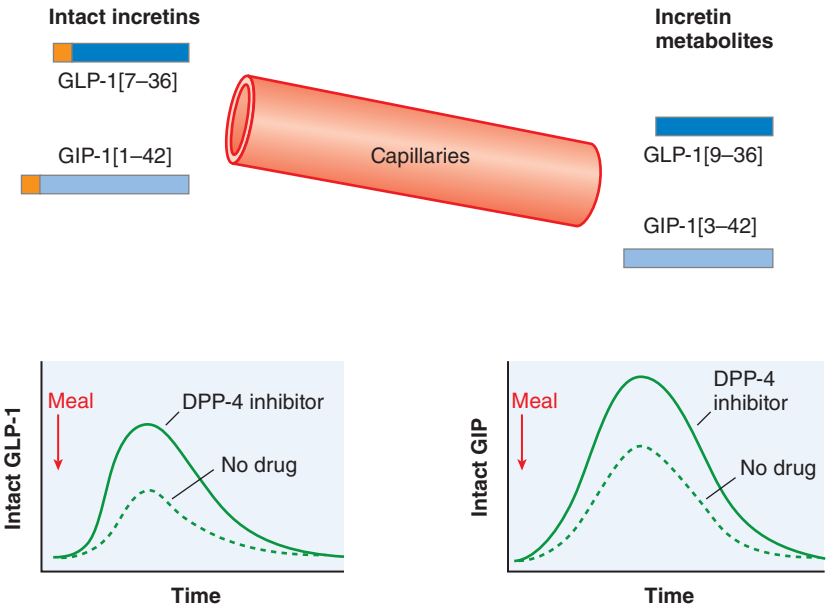

Figure 51–10 *Pharmacological effects of DDP-4 inhibition.* DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells, metabolizes the incretins, GLP-1, and GIP by removing the two N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1[9–36] and GIP[3–42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.

Two broad strategies have been taken to applying GLP-1 to therapeutics: the development of injectable, DPP-4-resistant peptide agonists of the GLP-1 receptor and the creation of small-molecule inhibitors of DPP-4 (Figure 51–10; see Table 51–5).

GLP-1 Receptor Agonists

Six *GLP-1 receptor agonists* (GLP-1RAs; *albiglutide, dulaglutide, exenatide, liraglutide*, *lixisenatide*, *semaglutide*) have been FDA-approved for treatment of diabetic patients, although *albiglutide* is no longer marketed in the U.S. (Table 51–5) (Nauck et al., 2022c).

Exenatide. Exendin-4 is a naturally occurring 39–amino acid reptilian peptide with 53% sequence homology to GLP-1. This peptide is a potent GLP-1RA that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and so has a longer circulating $t_{1/2}$ following injection than GLP-1. Synthetic exendin-4, *exenatide*, is approved for use as monotherapy and as adjunctive therapy for patients with type 2 diabetes not achieving glycemic targets with other drugs.

In clinical trials, *exenatide*, alone or in combination with *metformin*, *sulfonylurea*, or *thiazolidinedione*, was associated with improved glycemic control, as reflected in an approximately 1% decrease in A1c and weight loss that averaged 2.5 to 4 kg. Evidence from clinical trials indicated that *exenatide* can also be used in conjunction with basal *insulin*. An extended-release form of *exenatide* that is embedded in a biodegradable polymer to delay absorption into the circulation is administered by subcutaneous injection once a week with greater A1c lowering effectiveness than twice-daily *exenatide*.

Liraglutide. This is long-acting, DPP-4-resistant form of GLP-1 with a $Lys^{34}Arg$ substitution and addition of an α-glutamic acid spacer coupled to a C16 fatty acyl group at Lys^{26}. The fatty acid side chain delays absorption from the subcutaneous space and permits binding to albumin and other plasma proteins and accounts for a $t_{1/2}$ of approximately 13 h that permits once-daily administration; the fatty acid also seems to confer some protection from cleavage of the N-terminus by DPP-4. The pharmacodynamic profile of *liraglutide* mimics GLP-1 and *exenatide*. In clinical trials, *liraglutide* improved glycemic control and caused weight loss. *Liraglutide* can be added to oral agents or basal insulin. It is usually started at a subclinical dose and titrated over several weeks to treatment amounts to mitigate side effects (see Table 51–5). *Liraglutide* is available in a fixed-dose combination with *insulin degludec* that delivers a dose of 50 units of *insulin* with 1.8 mg, the top diabetes treatment dose, of *liraglutide*.

Dulaglutide. This is a fusion protein consisting of two molecules of a modified version of GLP-1 linked to the Fc portion of human immunoglobulin; the GLP-1 sequences are modified to protect against the action of DPP-4. *Dulaglutide* has a $t_{1/2}$ of approximately 5 days and is injected once weekly; like other GLP-1RAs, it is started at a low dose and escalated to treatment doses (see Table 51–5). Pharmacodynamics are comparable to other GLP-1RAs, and the drug can be used with other antidiabetic agents.

Lixisenatide. This is a modified form of exendin-4 with a C-terminal polylysine extension that has comparable pharmacodynamics to *exenatide*. *Lixisenatide* is rapidly absorbed to peak levels within 2 h and has a plasma $t_{1/2}$ of 2 h. *Lixisenatide* is available in fixed-dose combinations with *insulin glargine* that deliver doses of 15 to 60 units of *insulin* (in increments of 1 unit) with 5 to 20 μg of *liraglutide* (in increments of 0.33 μg).

Semaglutide. *Semaglutide* is a long-acting, DPP-4-resistant drug identical to *liraglutide* with the exception of an aminobutyric acid substitution at position 2, an α-glutamic acid–oligoethylene glycol linker at position 26, and coupling to a C-18 diacid (Knudsen and Lau, 2019). *Semaglutide* has a $t_{1/2}$ of 7 days that is due to tighter binding with albumin, and the injectable formulation is dosed once weekly. A separate formulation that includes the short-chain fatty acid sodium *N*-amino caprylate permits passage of sufficient *semaglutide* across the gastric mucosa to allow oral daily dosing.

While all of the GLP-1RAs have demonstrated efficacy as monotherapy, they are recommended as first-line agents. Although there are no systematic comparisons of all the drugs in this class, several clinical trials have directly compared two or three GLP-1RAs (Trujillo et al., 2021). While the differences in efficacy are modest relative to the overall effect of the drugs, *semaglutide* appears to be the most potent and *exenatide* for daily use and *lixisenatide* the weakest.

Weight Loss. All long-acting GLP-1RAs were reported to reduce body weight by 3 to 5 kg over 4 to 6 months in clinical trials of persons with type 2 diabetes. *Liraglutide* and *semaglutide* have been studied at higher doses (3.0 and 2.4 mg, respectively) in nondiabetic subjects with a body mass index greater than 30 and demonstrated to cause significant weight

loss. In these trials, *liraglutide* reduced body weight by 6 kg compared to a placebo-treated group and *semaglutide* by 13 kg compared to controls. Both drugs are now approved in the U.S. for this use.

Effects on Cardiovascular Risk. All of the approved GLP-1RAs currently available have been tested in placebo-controlled trials for safety in persons with established cardiovascular conditions or at high risk for cardiovascular disease (CVD). *Exenatide* and *lixisenatide* were both noninferior to placebo and are considered to confer no risk for CVD events. *Liraglutide* and *dulaglutide* both demonstrated superiority to placebo and significantly reduced risk of a composite endpoint including death from CVD, stroke, or myocardial infarction. Both oral and injectable *semaglutide* have demonstrated safety in diabetic persons with high risk for CVD; both drugs also conferred protection from events, although these were not prespecified endpoints in the studies, and trials that are testing superiority are ongoing. The findings from cardiovascular trials have led to current expert guidelines recommending a GLP-1RA for patients at high risk for CVD if access to these medications is available.

Mechanism of Action. All GLP-1RAs share a common mechanism, activation of the GLP-1 receptor, a member of glucagon receptor family of GPCRs (class B GPCRs). GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous systems, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several guanine nucleotide exchange factors. GLP-1 receptor activation also initiates signaling via PKC, PI3K, and β-arrestin and alters the activity of several ion channels (McLean et al., 2020). In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (see Figure 51–3). Activation of GLP-1 receptors in the CNS accounts for the effects of GLP-1RAs on food intake and gastric emptying and for side effects such as nausea.

ADME. *Exenatide* is given as a subcutaneous injection twice daily, typically before meals. It is rapidly absorbed, reaches peak concentrations in about 2 h, and has a plasma $t_{1/2}$ of 2 to 3 h. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. *Exenatide* is marketed as a pen that delivers 5 or 10 μg; dosing is typically started at the lower amount and increased as needed. There is a weekly preparation based on the embedding of *exenatide* in a polymeric microsphere that releases drug slowly after injection. Weekly *exenatide* is given as a suspension of 2 mg that is prepared from lyophilized material and diluent immediately prior to injection. Once in the circulation, the drug is metabolized similarly to short-acting *exenatide*; however, based on the extended rate of delivery, 5 to 6 weekly doses are required to reach therapeutic steady state. *Lixisenatide*, the other GLP-1RA based on exendin-4, has an elimination $t_{1/2}$ of approximately 3 h that involves a significant degree of renal clearance.

Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8 to 12 h; the elimination $t_{1/2}$ is 12 to 14 h. There is little renal or intestinal excretion of *liraglutide*; clearance is primarily through the metabolic pathways of large plasma proteins. *Liraglutide* is supplied in a pen injector that delivers 0.6, 1.2, 1.8, 2.4, or 3 mg of drug; the lowest dose is for treatment initiation, with elevation to the higher doses based on clinical response.

Dulaglutide and *semaglutide* have extended plasma $t_{1/2}$, are dosed weekly, and require 1 to 2 months to reach steady state. No effects of hepatic or renal impairment on clearance of these compounds has been demonstrated.

Adverse Effects; Drug Interactions. Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting; this is thought to be mediated through neural activation of specific CNS neurons that are activated following peripheral dosing of peptide. The doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Nonetheless, up to 30% to 50% of subjects report nausea at the initiation of therapy with any of the GLP-1RAs, although the GI side effects of these drugs wane over time. Activation of GLP-1 receptors in the CNS mediates the typical delay of gastric emptying, and GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics. In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare, but the combination of GLP-1 agonist with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of the reliance on renal clearance, *exenatide*, and probably *lixisenatide*, should not be given to persons with moderate-to-severe renal failure (creatinine clearance <30 mL/min). In clinical trials, patients treated with *liraglutide* and *semaglutide* had increased risk of gallbladder disease. Based on surveillance data, there is a possible association of GLP-1RA and pancreatitis, although this risk has not been observed in the analyses of clinical trials. Nonetheless, GLP-1RA should be used with caution in persons with a history of pancreatitis. The GLP-1 receptor is expressed by thyroid C cells. Although there is not an established clinical association with medullary carcinoma of the thyroid, GLP-1 agonists should not be given to these patients.

DPP-4 Inhibitors

Dipeptidyl peptidase 4 is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on vascular endothelial cells, on the surface of T lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position and seems to be especially critical for the inactivation of GLP-1 and GIP (Deacon and Lebovitz, 2016). DPP-4 inhibitors increase the area under the curve (AUC) of intact, bioactive GLP-1 and GIP after meal consumption (see Figure 51–10). A variety of small-molecule, orally available agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10% to 20% of total circulating GLP-1 immunoreactivity to nearly 100%. *Sitagliptin*, *saxagliptin, linagliptin*, and *alogliptin* are available in the U.S.; *vildagliptin* is available in the E.U.

Mechanism of Action; Pharmacological Effects. *Alogliptin, linagliptin*, and *sitagliptin* are competitive inhibitors of DPP-4; *vildagliptin* and *saxagliptin* bind the enzyme covalently. All five drugs can be given in doses that lower measurable activity of DPP-4 by more than 95% for 12 h. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety; chronic treatment with a DPP-4 inhibitor also does not affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduce A1c levels by an average of 0.4–0.8%. These compounds are also effective for chronic glucose control when added to *metformin*, thiazolidinediones, and sulfonylureas. The effects of DPP-4 inhibitors in combination regimens appear to be additive.

ADME. The recommended doses of the DPP4 inhibitors are *alogliptin*, 25 mg daily; *linagliptin*, 5 mg daily; *saxagliptin*, 5 mg daily; *sitagliptin*, 100 mg daily; and *vildagliptin*, 50 mg one or two times daily. DPP-4 inhibitors are absorbed effectively from the small intestine. *Alogliptin*, *saxagliptin*, *sitagliptin*, and *vildagliptin* circulate primarily in unbound form and are excreted largely unchanged in the urine; lower doses should be given to patients with reduced renal function. *Linagliptin* binds extensively to plasma proteins and is cleared primarily by the hepatobiliary system, with little renal clearance. Only *saxagliptin* is metabolized by hepatic microsomal enzymes, and its dose should be lowered to 2.5 mg daily when coadministered with strong CYP3A4 inhibitors (e.g., *ketoconazole, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ritonavir, saquinavir*, and *telithromycin*).

Adverse Effects. There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. Large cardiovascular safety studies have been completed for *alogliptin*, *saxagliptin*, and *sitagliptin*. There was no impact of these drugs on the incidence of cardiovascular events in diabetic patients, although patients treated with *saxagliptin* had an increase in hospitalization for heart failure. The FDA

has issued a warning that this class of drugs is rarely associated with severe joint pain. DPP-4 is expressed on lymphocytes and is also referred to as CD26.

α-Glucosidase Inhibitors

α-Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border (Hedrington and Davis, 2019). These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects. The drugs in this class are *acarbose*, *miglitol*, and *voglibose* (not available in the U.S.).

ADME. Dosing of *acarbose* and *miglitol* are similar. Both are provided as 25-, 50-, or 100-mg tablets that are taken before meals. Treatment should start with lower doses and be titrated as indicated by balancing postprandial glucose, A1c, and GI symptoms. *Acarbose* is minimally absorbed; the small amount of drug reaching the systemic circulation is cleared by the kidney. *Miglitol* absorption is saturable, with 50% to 100% of any dose entering the circulation. *Miglitol* is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance less than 30 mL/min.

Adverse Effects; Drug Interactions. The most prominent adverse effects are malabsorption, flatulence, diarrhea, and abdominal bloating. Mild-to-moderate elevations of hepatic transaminases are reported with *acarbose*, but symptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. Hypoglycemia has been described when α-glucosidase inhibitors are added to *insulin* or an insulin secretagogue. *Acarbose* can decrease the absorption of *digoxin*; *miglitol* can decrease the absorption of *propranolol* and *ranitidine*. The α-glucosidase inhibitors are contraindicated in patients with stage 4 renal disease.

Therapeutic Use. α-Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They can also be used in combination with other oral antidiabetic agents or *insulin*. In clinical studies, α-glucosidase inhibitors reduced A1c by 0.5% to 0.8%, fasting glucose by about 1 mM, and postprandial glucose by 2.0 to 2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids.

Na^+-Glucose Transporter 2 Inhibitors

The sodium-glucose cotransporter 2 (SGLT2) is a Na^+-glucose cotransporter located almost exclusively in the proximal portion of the renal tubule. SGLT2 is a high-affinity, low-capacity transporter that moves glucose against a concentration gradient from the tubular lumen using energy generated from Na^+ flux through the epithelial cells. Renal retention of glucose is nearly complete in nondiabetic persons, and SGLT2 accounts for 80% to 90% of this reclamation; the remainder is recovered by SGLT1 more distally in the tubule. Early studies in diabetic animals demonstrated that hyperglycemia could be nearly ameliorated by the naturally occurring compound *phlorizin*, an SGLT inhibitor. Based on this proof of principle, drugs that are specific inhibitors of SGLT2 have been developed to treat diabetes (Thomas and Cherney, 2018). These agents block glucose transport in the proximal tubule and lower blood glucose by promoting urinary loss.

Mechanism of Action; Pharmacological Effects. SGLT2 inhibitors reduce the rate of glucose reclamation in the proximal tubule and lower the renal threshold for glucose excretion from about 180 to 50 mg/dL (10 to 2.8 mM). In monotherapy, they reduce A1c by 0.7% to 1.0%, cause weight loss of 2 to 4 kg, and decrease blood pressure by 2 to 4 mmHg. There are currently four SGLT2 inhibitors available for clinical use—*canagliflozin, dapagliflozin, empagliflozin,* and *ertugliflozin*. These agents are indicated for use in combination with other oral agents and *insulin*; such use leads to an additional decrease of A1c of 0.5% to 0.8%. SGLT2 inhibitors are available in combination with *metformin* and DPP-4 inhibitors.

Effects on Cardiovascular Risk (See Also Chapter 33 for Details). All four of the currently available SGLT2 inhibitors have been tested in placebo-controlled trials to assess their impact on cardiovascular risk. *Empagliflozin* and *canagliflozin* decreased specified cardiovascular events in persons with type 2 diabetes and established CVD or at high risk for CVD. *Dapagliflozin* and *ertugliflozin* had effects on cardiac events that did not differ from placebo-treated patients; that is, they conferred no added risk. All the SGLT2 inhibitors decreased the risk of hospitalization for heart failure compared to placebo. *Dapagliflozin* had a significant effect on reducing hospitalization for heart failure and cardiovascular death in diabetic and nondiabetic subjects with established heart failure and reduced ejection fraction. *Canagliflozin* decreased admissions for heart failure in subjects with type 2 diabetes and diabetic nephropathy.

Effects on Diabetic Nephropathy. *Canagliflozin*, *dapagliflozin*, and *empagliflozin* each decreased the progression of renal disease compared to placebo in randomized trials of patients with reduced glomerular filtration and albuminuria. Based on the results of a series of clinical trials, current recommendations emphasize the use of SGLT2 inhibitors early in the management of individuals with diabetes and CVD, heart failure, or nephropathy.

ADME. Available SGLT2 inhibitors share favorable pharmacokinetic properties. They have good oral bioavailability (60%–80%) that is not affected by food and reach peak levels 1 to 2 h after ingestion. They are approximately 90% bound to circulating proteins with plasma $t_{1/2}$ of 12 h, making them suitable for once-daily dosing. The compounds are metabolized by glucuronidation, and the inactive metabolites are renally excreted; there is virtually no renal excretion of the parent drugs. All four drugs are available in tablets with two doses, *dapagliflozin* 5 and 10 mg, *canagliflozin* 100 and 300 mg, *empagliflozin* 10 and 25 mg, and *ertugliflozin* 5 and 15 mg; the higher-dose tablet is the maximum recommended amount of each drug.

Adverse Effects; Drug Interactions. The side effects of SGLT2 inhibitors are predictable from their mechanism of action. There is increase in lower urinary tract infections of approximately 2% and a 3% to 5% increase in genital mycotic infections. Urine glucose losses cause mild diuresis, which can lead to hypotension and associated symptoms in a small percentage of, usually older, patients. Importantly, because SGLT2 inhibitors ultimately depend on the rate of glucose filtration to be effective, potency decreases by 40% to 80% across the spectrum of stage 3 kidney disease (GFR 60–30 mL/min). SGLT2 inhibitors do not cause hypoglycemia alone but can potentiate the effects of drugs that do.

Early clinical trials with *canagliflozin* suggested that treated patients might have an increased risk of fractures. This finding has not been born out in subsequent studies of *canagliflozin* or reported for other SGLT2 inhibitors. Similarly, results from two trials suggested that use of *canagliflozin* doubled the risk for lower extremity amputation. While these results triggered a warning for the drug, this has been removed based on evidence from further clinical studies. Diabetic ketoacidosis (often with near-normal blood glucose) can occur in patients treated with SGLT2 inhibitors, especially during a concurrent illness. Patients starting SGLT2 inhibitors may have mild, transient worsening of renal function that resolves once the initial phase of diuresis has been compensated.

Other Glucose-Lowering Agents

Pramlintide. Islet amyloid polypeptide (amylin) is a 37–amino acid peptide produced in the pancreatic β cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, *pramlintide,* has been developed as a drug for the treatment of diabetes. *Pramlintide* likely acts through the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor reduces glucagon secretion, delays gastric emptying, and fosters a feeling of satiety.

ADME. *Pramlintide* is administered as a subcutaneous injection prior to meals. The drug is not extensively bound by plasma proteins and has a $t_{1/2}$ of 50 min. Metabolism and clearance are primarily renal. The doses in patients with type 1 diabetes start at 15 μg and are titrated upward to a maximum of 60 μg; in type 2 diabetes, the starting dose is 60 μg, and the maximum is 120 μg. Because of differences in the pH of the solutions, *pramlintide* should not be administered in the same syringe as insulin.

Adverse Effects; Drug Interactions. The most common adverse effects are nausea and hypoglycemia. Although *pramlintide* alone does not lower blood glucose, addition to insulin at mealtimes can cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial *insulin* doses be reduced 30% to 50% at the time of *pramlintide* initiation and then retitrated. Because of its effects on GI motility, *pramlintide* is contraindicated in patients with gastroparesis or other disorders of motility. *Pramlintide* is a pregnancy category C drug. *Pramlintide* can be used in persons with moderate renal disease (creatinine clearance >20 mL/min).

Therapeutic Uses. *Pramlintide* is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take *insulin* with meals.

Bile Acid–Binding Resins. The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is *colesevelam*.

Mechanism of Action. Bile acid metabolism is abnormal in patients with type 2 diabetes, and there have been intermittent reports that bile acid–binding resins lower plasma glucose in diabetic patients. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors.

ADME. *Colesevelam* is provided as a powder for oral solution and as 625-mg tablets; typical usage is 3 tablets twice daily before lunch and dinner or 6 tablets prior to the patient's largest meal. The drug is absorbed from the intestinal tract only in trace amounts, so its distribution is limited to the GI tract.

Adverse Effects; Drug Interactions. Common side effects of *colesevelam* are GI, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10% of treated patients. Like other bile acid–binding resins, *colesevelam* can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia and should be used cautiously in patients with plasma triglycerides greater than 200 mg/dL. *Colesevelam* can interfere with the absorption of commonly used agents (e.g., *phenytoin*, *warfarin*, *verapamil*, *glyburide*, L-*thyroxine*, and *ethinyl estradiol* and fat-soluble vitamins). *Colesevelam* is a pregnancy category B drug that has no contraindications in patients with renal or liver disease.

Therapeutic Uses. *Colesevelam* is approved for treatment of hypercholesterolemia and may be used for treatment of type 2 diabetes as an adjunct to diet and exercise. In clinical trials, *colesevelam* reduced A1c by 0.5% when added to *metformin*, sulfonylurea, or *insulin* treatment in type 2 diabetic patients.

Bromocriptine. A low-dose (0.8-mg) tablet formulation of *bromocriptine*, a dopamine receptor agonist, is approved for the treatment of type 2 diabetes. *Bromocriptine* is an established treatment of Parkinson's disease and hyperprolactinemia (see Chapters 15, 21, and 46). Effects of *bromocriptine* on blood glucose are modest and may reflect an action in the CNS. The dose range for *bromocriptine* is 1.6 to 4.8 mg, taken with food in the morning within 3 h of awakening. Side effects include nausea, fatigue, dizziness, orthostatic hypotension, vomiting, and headache.

Combined Pharmacological Approaches to Type 2 Diabetes

Managing the Progression of Type 2 Diabetes

For most patients, the pathological changes causing hyperglycemia in type 2 diabetes progress over time. Thus, most patients require stepwise intensification of therapy to maintain glycemic goals. Several academic societies and health organizations have issued guidelines, algorithms, or flowcharts for the treatment of type 2 diabetes. Figure 51–11 presents a simplified version; more details can be found in guidelines from the ADA, European Society for Study of Diabetes, American Association of

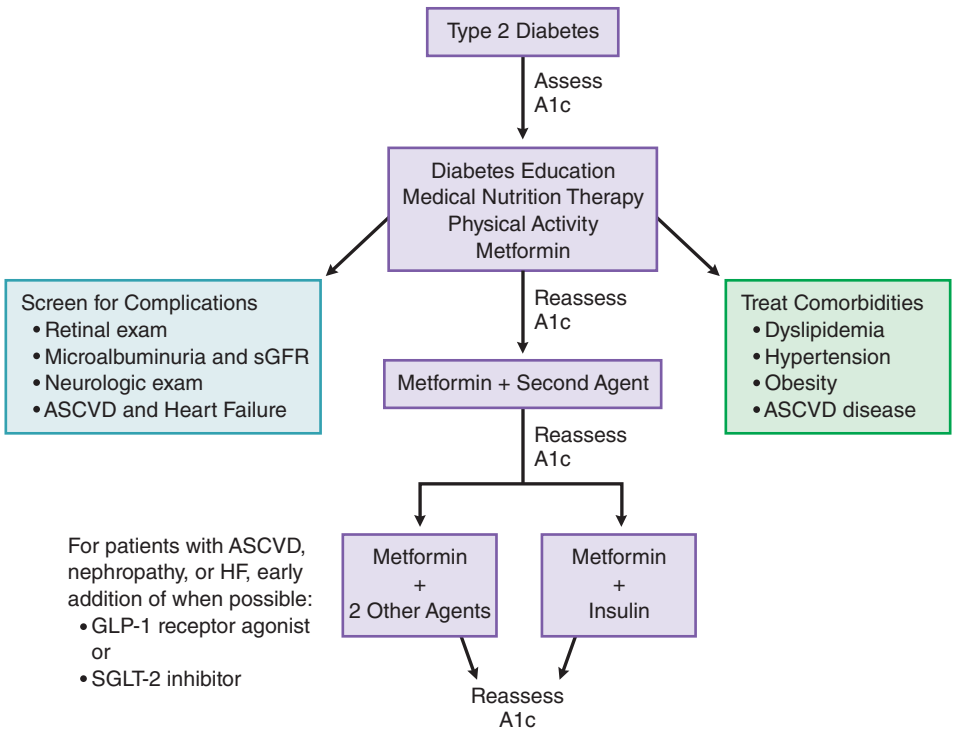

Figure 51–11 *Treatment algorithm for management of type 2 diabetes mellitus.* Patients diagnosed with type 2 diabetes, by fasting glucose, oral glucose tolerance testing, or A1c measurement, should have diabetes education that includes instruction on medical nutrition therapy and physical activity. *Metformin* remains the consensus first line of therapy and should be started at the time of diagnosis. Failure to reach the glycemic target, generally A1c of 7% or less within 2 to 3 months, should prompt the addition of a second agent (*insulin*, sulfonylurea, thiazolidinedione, DPP-IV inhibitor, GLP-1 agonist, or SGLT-2 inhibitor). Reinforce lifestyle interventions at every visit, and check A1c every 3 months. Treatment may escalate to *metformin* plus *insulin* or *metformin* plus two other agents from the list given. For individuals with established clinical atherosclerotic cardiovascular disease, a GLP-1 receptor agonist or SGLT-2 inhibitor should be added early in the course of treatment; for patients with heart failure or diabetic nephropathy, SGLT-2 inhibitors are favored as second agents (see text for details). ASCVD, atherosclerotic cardiovascular disease; eGFR, estimated glomerular filtration rate; HF, heart failure.

Clinical Endocrinology, and National Institute for Health and Care Excellence (United Kingdom) (ADA, 2022c). Table 51–6 summarizes available pharmacological agents for the treatment of diabetes. While there is no consensus as to preferred combinations or the order in which they are used, in general, selection involves consideration of comorbidities, side effect profile, cost, and A1c goal. Recent evidence suggests that individuals with type 2 diabetes who are at high risk for cardiovascular or renal disease benefit from SGLT2 inhibitors or GLP-1 agonists. The National Institutes of Health–funded Glycemia Reduction Approaches in Diabetes: A Comparative Effectiveness Study (GRADE) found that addition of *liraglutide* or basal *insulin* to metformin leads to slightly better glycemic control than *glimepiride* or *sitagliptin*. SLGT2 inhibitors were not tested in this study.

There is consensus that *metformin* and lifestyle changes should be the first interventions. After that, a number of pathways or combination of drugs can be used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target (ADA, 2022c; Davies et al., 2018). For example, the addition of a second oral agent may provide good therapeutic results. Combinations of fixed doses of most of the oral agents are now available; while most oral agents have additive effects, no specific combinations have been demonstrated to have particular efficacy that can be predicted for most patients. Another approach is to introduce basal long-acting *insulin* (at bedtime) in combination with an oral glucose-lowering agent. This combination allows the oral agent to provide postprandial glycemic control, while the basal *insulin* provides the foundation for normalizing fasting or basal glucose levels. Long-acting *insulin* can be combined with almost all of the oral antihyperglycemic agents in Table 51–6. The combination of therapies can be guided by an estimation of the β cell secretory *reserve* in the patient (i.e., a measurement of C-peptide level) and individualized patient glycemic goals. The progressive insulin deficiency in type 2 diabetes often makes it increasingly difficult to achieve the glycemic goal solely with oral antihyperglycemic agents; thus, *insulin* is often required.

Costs of Diabetes Drugs. Treatment of diabetes can be very expensive, especially because most patients use multiple agents, as well as drugs for associated conditions such as hypertension, dyslipidemia, and cardiovascular disease. Thus, cost has become a key issue in the management of diabetic patients since it has been documented to affect adherence to and choice of treatment plans (Table 51–7). Newer agents are costlier, while older drug classes like sulfonylureas and biguanides are inexpensive and available in generic formulations. In recent years, the price of all *insulin* formulations has increased steadily despite the addition of numerous new products to the market, including insulin biosimilars (Cefalu et al., 2018). The balance of cost-benefit ratio, especially of the new agents, remains a topic under debate but is important for clinical management. Shared decision making with patients, incorporating their circumstances and wishes, can be effective in diabetes treatment.

Emerging Therapies for Diabetes

A number of immunomodulatory approaches are being investigated to prevent or block the autoimmune process central to type 1 diabetes. Early in the disease course (stage 2 type 1 diabetes), suppression of the autoimmune process with anti-CD3 monoclonal antibodies that target T lymphocytes has been shown to delay the onset of type 1 diabetes. Recently, targeting the thioredoxin-interacting protein (TXNIP) with Ca^{2+} channel blockers has had a positive impact on recent-onset type 1 diabetes. The integration of an *insulin* infusion device and a glucose sensor is progressing rapidly so that the *insulin* infusion is being automated based on sensor results (closed loop).

Advances in protein chemistry have allowed the development of peptides that activate more than one receptor to improve glucose regulation. Most of these incorporate GLP-1 receptor agonism with the capacity to activate receptors for glucagon or the GIP receptor. Other new therapies being evaluated for type 2 diabetes include glucokinase activators, inhibitors of 11β-hydroxysteroid dehydrogenase-1, GPR40 agonists, and combined SLGT1 and SLGT2 inhibitors.

Metabolic or bariatric surgery is quite effective for obese individuals with type 2 diabetes. Whole pancreas and islet transplantation can normalize glucose control in type 1 diabetes.

Hypoglycemia

In the absence of prolonged fasting, healthy humans almost never have blood glucose levels below 3.5 mM. This is due to a highly adapted neuroendocrine counterregulatory system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The three most common clinical scenarios for hypoglycemia are as follows:

- Treatment of diabetes with *insulin* or oral agents that promote insulin secretion (sulfonylureas)
- Inappropriate production of endogenous insulin by a pancreatic islet tumor (insulinoma) or insulin-like growth factors by non-islet tumors such as hepatomas or sarcomas
- Use (purposeful or inadvertent) of a glucose-lowering agent in an individual without diabetes

Hypoglycemia in the first and third scenarios can occur in either the fasting or the fed state, whereas hypoglycemia secondary to neoplasms occurs primarily in the fasting or postabsorptive state.

Hypoglycemia is an adverse reaction to a number of oral therapies and is most pronounced and serious with *insulin* therapy. Hypoglycemia may result from an inappropriately large dose of *insulin*, from a mismatch between the time of peak delivery of *insulin* and food intake, or from superposition of additional factors that increase sensitivity to *insulin* (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). Hypoglycemia is the major risk that always must be weighed against benefits of pharmacological interventions to normalize glucose control. Hypoglycemia is especially problematic in the elderly and should be given strong consideration when individualizing glycemic goals.

The first physiological response to hypoglycemia is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of about 70 mg/dL (3.9 mM); thereafter, the counterregulatory hormones (glucagon, epinephrine, norepinephrine, growth hormone, and cortisol) are released. Symptoms of hypoglycemia typically become manifest at a plasma glucose level of 60 to 70 mg/dL (3.3–3.9 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms. Severe hypoglycemia can lead to seizure and coma.

In patients with type 1 and type 2 diabetes of longer duration, the glucagon secretory response to hypoglycemia becomes deficient. These individuals with diabetes thus become dependent on epinephrine for counter-regulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases; this phenomenon is central to hypoglycemia unawareness and autonomic neuropathy. With the ready availability of glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect, but affected patients often give a history of morning headaches, night sweats, or symptoms of hypothermia. Mild-to-moderate hypoglycemia may be treated simply by ingestion of oral glucose (15–20 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of *glucagon*.

Agents Used to Treat Hypoglycemia

Glucagon, a single-chain polypeptide of 29 amino acids interacts with the glucagon GPCR on the plasma membrane of target cells, most importantly the hepatocyte, activating the G_s-cAMP-PKA pathway with an acute rise in glucose production, primarily from glycogenolysis. *Glucagon* should be prescribed for individuals at risk for severe hypoglycemia,

TABLE 51–6 ■ COMPARISON OF AGENTS USED FOR TREATMENT OF DIABETES

TYPE AND AGENT	MECHANISM OF ACTION	HBA_{1c} REDUCTION (%)[a]	AGENT-SPECIFIC ADVANTAGES	AGENT-SPECIFIC DISADVANTAGES	CONTRAINDICATIONS AND PRECAUTIONS
Oral					
Biguanides[c]	↓ Hepatic glucose production, ↑ insulin sensitivity, influence gut function	1–2	Weight neutral, do not cause hypoglycemia, inexpensive	Diarrhea, nausea, vitamin B_{12} deficiency, lactic acidosis	GFR <30 mL/min, CHF, radiographic contrast studies, seriously ill patients, acidosis
Dipeptidyl peptidase 4 inhibitors[c]	Prolong endogenous GLP-1 action	0.4–0.8	Do not cause hypoglycemia		↓ Dose with renal disease
α-Glucosidase inhibitors[c]	↓ GI glucose absorption	0.5–0.8	↓ Postprandial glycemia	GI flatulence, elevated liver function tests	Renal/liver insufficiency
Insulin secretagogues—sulfonylureas[c]	↑ Insulin secretion	1–2	Inexpensive	Hypoglycemia, weight gain	Renal/liver insufficiency
Insulin secretagogues—nonsulfonylureas[c]	↑ Insulin secretion	1–2	Rapid onset of action, lower postprandial glucose	Hypoglycemia, precautions for elderly and renal impairment	Renal/liver insufficiency
SGLT2 inhibitors[c] (*the gliflozins*)	↑ Renal glucose excretion	0.5–0.8	Mild weight loss and BP reduction; do not cause hypoglycemia; CV and heart failure benefit	↑ Rate of lower urinary tract and genital mycotic infections; exacerbate tendency to hyperkalemia and DKA; see text for canagliflozin	Renal insufficiency
Thiazolidinediones[c] (*the glitazones*)	↓ Insulin resistance, ↑ glucose utilization	0.5–1.2	Lower insulin requirements	Peripheral edema, CHF, weight gain, fractures in females, macular edema	CHF, liver or renal insufficiency
Parenteral					
Insulin	↑ Glucose utilization, ↓ hepatic glucose production, and other anabolic actions	Not limited	Well-known safety/adverse effect profile from much clinical experience	Injection, weight gain, hypoglycemia	Hypoglycemia
GLP-1 receptor agonists[c,d]	↑ Insulin, ↓ glucagon, slow gastric emptying, satiety	0.5–1.5	Weight loss, do not cause hypoglycemia, ↓ CV events	Injection, nausea, pancreatitis	Renal disease, agents that also slow GI motility, pancreatic disease, medullary carcinoma of thyroid
Amylin agonists[b,c]	Slow gastric emptying, ↓ glucagon	0.25–0.5	Reduce postprandial glycemia; weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin	Agents that also slow GI motility
Other					
Medical nutrition therapy and physical activity[c]	↓ Insulin resistance, ↑ insulin secretion	1–3	Weight loss, improved CV health	Compliance difficult, long-term success low	
Inhaled insulin[c]	↑ Glucose utilization, ↓ hepatic glucose production, other anabolic actions	0.25–0.5	Rapid onset of action	Limited clinical experience	Pulmonary disease, smoking

BP, blood pressure; CHF, congestive heart failure; CV, cardiovascular; DKA, diabetic ketoacidosis.
[a]A1c reduction (absolute) depends partly on starting A1c value.
[b]Used in conjunction with insulin for treatment of type 1 diabetes.
[c]Used for treatment of type 2 diabetes.
[d]Semaglutide is available in an oral formulation.

TABLE 51–7 ■ RELATIVE COSTS OF THERAPEUTIC AGENTS FOR DIABETES

DRUG CLASS	AGENT	RELATIVE COST
α-Glucosidase inhibitors	Acarbose	+
	Miglitol	+++
Amylin analogue	Pramlintide	++++
Biguanides	Metformin, metformin ER	+
Dipeptidyl peptidase 4 inhibitors	Alogliptin, linagliptin, saxagliptin, sitagliptin, vildagliptin	++++
GLP-1 receptor agonists	Dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide	++++
Meglitinides	Nateglinide, repaglinide	++
SGLT2 inhibitors	Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin	++++
Sulfonylureas	Glimepiride, glipizide, glyburide	+
Thiazolidinediones	Pioglitazone	+
	Rosiglitazone	+++
Recombinant human insulin	Humulin regular, NPH and U-500, Novolin regular and NPH	+++
Basal insulin analogues	Degludec, detemir, glargine	++++
Prandial insulin analogues	Aspart, glulisine, lispro	++++
Inhaled insulin	Afrezza	+++

ER, extended release. Cost scale is based on average 2021 retail prices in the U.S. +, <$10/month; ++, <$100/month; +++, $100–$300/month; ++++, >$300/month.

and the patient's family or friends should be trained to inject this in an emergency. *Glucagon* is used to treat severe hypoglycemia when the diabetic patient cannot safely consume oral glucose and intravenous glucose is not available.

Until recently, lyophilized preparations of *glucagon*, produced by recombinant DNA technology, were the only available formulation for clinical use. Because native *glucagon* forms fibrils and is unstable in solution for more than a short period, these kits include a diluent for dissolving the peptide before treatment, a feature that delays and confounds use in emergencies. For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously, although in most circumstances, the intramuscular route is most applicable to emergency use. The onset of hyperglycemic action after *glucagon* is 5 to 10 min after injection and is maximal after 15 to 20 min. However, the effect is relatively short-lived and may be attenuated if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given oral glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects.

Recently, three new *glucagon* preparations have become available to treat hypoglycemia (Diana et al., 2021). A nasal formulation is available as single-use, 3-mg delivery devices, and while peak levels are lower and several minutes delayed compared to IM glucagon, in clinical trials, the efficacy in correcting hypoglycemia was comparable. Moreover, in tests of successful use in simulated emergency settings, nasal *glucagon* was superior. In addition, a liquid formulation of native *glucagon* is also in use. *Glucagon* dissolved in dimethyl sulfoxide is provided as an autoinjector or a prefilled syringe. The kinetics and clinical response are identical to older *glucagon* kits, but ease of use, time for successful administration, and proportion of rescued hypoglycemic events were better with the liquid stable *glucagon*. Finally, a *glucagon* analogue, *dasiglucagon* has 7 amino acid substitutions to the native sequence that improve solubility and allow a stable liquid formulation. Also available as a prefilled syringe or autoinjector, *dasiglucagon* has similar pharmacodynamics to native *glucagon*. All forms of *glucagon*, given in the recommended amounts to treat hypoglycemia, have GI side effects, with nausea occurring in 30% to 40% of patients and vomiting in 10% to 20%.

Other Pancreatic Islet–Related Hormones or Drugs

Diazoxide

Diazoxide (see Chapter 32) is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally. *Diazoxide* interacts with the K_{ATP} channel on the β cell membrane and either prevents its closing or prolongs the open time. This effect, opposite to that of the sulfonylureas (see Figure 51–3), inhibits insulin secretion.

The usual oral dose is 3 to 8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. *Diazoxide* circulates largely bound to plasma proteins and has a $t_{1/2}$ of about 48 h. *Diazoxide* has a number of adverse effects, including retention of Na^+ and fluid, hyperuricemia, hypertrichosis, thrombocytopenia, and leukopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism.

Somatostatin

Somatostatin is produced by δ cells of the pancreatic islet, by cells of the GI tract, and in the CNS. SST, which circulates primarily as 14– or a 28–amino acid forms, acts through a family of five GPCRs, $SSTR_{1–5}$. SST inhibits a wide variety of endocrine and exocrine secretions, including thyroid-stimulating hormone and growth hormone from the pituitary, and gastrin, motilin, VIP (vasoactive intestinal peptide), glicentin, insulin, glucagon, and pancreatic polypeptide from the GI tract/pancreatic islet. The physiological role of SST has not been defined precisely, but its short $t_{1/2}$ (3–6 min) prevents its use therapeutically. Longer-acting analogues such as *octreotide*, *lanreotide*, or *pasireotide* are useful for treatment of severe secretory diarrhea (see Chapter 54) and carcinoid tumors, glucagonomas, VIPomas, acromegaly, and Cushing disease (see Chapter 50). Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the SST analogues, as do GI symptoms.

Drug Facts for Your Personal Formulary: *Agents for Diabetes and Hypoglycemia*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Insulin Formulations		
Insulin—short acting (regular)	• Type 1 and type 2 diabetes • Control prandial rise in blood glucose • Acute correction of hyperglycemia • Intravenous infusion for DKA and hyperglycemia in hospitalized setting	• Injected SC, IM, or IV • Onset of action 30–45 min after subcutaneous injection • Duration of action of 4–6 h after subcutaneous injection • Major adverse event: hypoglycemia
Insulin analogues—short acting (lispro, aspart, glulisine)	• Type 1 and type 2 diabetes • Control prandial rise in blood glucose • Used in insulin pump for treatment of diabetes	• Genetically modified to accelerate insulin absorption profile • Injected SC or IM • Onset of action 5–15 min after SC injection • Duration of action of 3–5 h after SC injection • Major adverse event: hypoglycemia
Insulin—long acting (NPH)	• Provide basal insulin in type 1 and type 2 diabetes • Reduce fasting hyperglycemia in type 2 diabetes	• Formulated to prolong insulin absorption • Usually requires twice-daily subcutaneous injection to provide 24-h basal insulin coverage • Combined with short-acting insulin in basal/bolus regimen • Given at bedtime in type 2 diabetes to reduce hepatic glucose production • Duration of action of 8–12 h • Major adverse event: hypoglycemia
Insulin analogues—long acting (glargine, detemir, degludec)	• Provide basal insulin in type 1 and type 2 diabetes	• Genetically modified to prolong absorption • Once-a-day subcutaneous injection → 24-h basal insulin coverage • Combined with shorting-acting insulin in basal/bolus regimen • Duration of action of 18–42 h • Major adverse event: hypoglycemia
Oral Glucose-Lowering Agents		
Biguanides Metformin	• Therapy of type 2 diabetes • Usually initial agent in type 2 diabetes	• Reduce hepatic glucose production • Weight neutral • Do not cause hypoglycemia • Adverse events include diarrhea, nausea, lactic acidosis (black-box warning) • Use cautiously in renal insufficiency, hospitalized patients; temporarily discontinue therapy prior to potential renal insults (e.g., radiocontrast media) • Avoid use in patients with hepatic dysfunction • Can be combined with other agents • Inexpensive
α-Glucosidase inhibitors Acarbose, miglitol, voglibose	• Therapy of type 2 diabetes	• Reduce carbohydrate breakdown in GI tract • Adverse effects: GI flatulence, elevated liver function tests • Can be combined with other agents • Relatively modest glucose lowering
Dipeptidyl peptidase 4 inhibitors Sitagliptin, saxagliptin, linagliptin, alogliptin, vildagliptin	• Therapy of type 2 diabetes	• Prolong action of GLP-1; promotes insulin secretion • Can be combined with other agents • Relatively modest glucose lowering
Insulin secretagogues—sulfonylureas Second generation: glibenclamide, glipizide, and others	• Therapy of type 2 diabetes	• Stimulate insulin secretion • Major adverse event is hypoglycemia • Adjustments needed in renal/liver disease • Can be combined with other agents • Modest weight gain • Inexpensive
Insulin secretagogues—nonsulfonylureas Repaglinide, nateglinide	• Therapy of type 2 diabetes	• ↑ Insulin secretion; quicker onset and shorter duration than sulfonylureas • Major adverse event: hypoglycemia • Adjustments needed in renal/liver disease • Can be combined with other agents
SLGT2 inhibitors Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin	• Therapy of type 2 diabetes	• Prevent glucose reabsorption and promote renal glucose excretion • Mild weight loss and blood pressure reduction • Improve cardiovascular outcomes, reduce heart failure admissions, and improve heart failure outcomes • Slow diabetic nephropathy • Do not cause hypoglycemia • May ↑ rate of lower urinary tract and genital mycotic infections, hypotension, and DKA • Can be combined with other agents

Drug Facts for Your Personal Formulary: *Agents for Diabetes and Hypoglycemia (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Oral Glucose-Lowering Agents (cont.)		
Thiazolidinediones Rosiglitazone, pioglitazone	• Therapy of type 2 diabetes	• Increase insulin sensitivity • Adverse effects: peripheral edema, CHF, weight gain, fractures, macular edema • Use with caution in CHF, liver disease • Can be combined with other agents
Other Glucose-Lowering Agents		
GLP-1 agonists Dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide	• Therapy of type 2 diabetes	• ↑ Insulin secretion, ↓ gastric emptying, ↓ glucagon • Injected subcutaneously (one oral formulation available) • Often associated with weight loss • Improve cardiovascular outcomes • Adverse events include nausea • Do not use with agents that ↓ GI motility • Risk of hypoglycemia with insulin
Amylin analogue Pramlintide	• Adjunctive therapy with insulin in type 1 and type 2 diabetes	• Slows gastric emptying, decreases glucagon • Injected subcutaneously • ↓ Postprandial glycemia • Often associated with weight loss • Adverse events include nausea • Do not use with agents that ↓ GI motility • Risk of hypoglycemia with insulin
Drugs to Reverse Hypoglycemia		
Glucagon	• Emergency treatment of severe hypoglycemia	• Injected SC, IM, IV, or intranasal • Quickly raises blood glucose • Relaxes smooth muscles of the GI tract • Positive inotropism and chronotropism on heart
Other Pancreatic Islet-Related Hormones or Drugs		
Diazoxide	• Treatment of hypertensive crisis • Treatment of pathologic hyperinsulinemia	• Inhibits insulin secretion • Adverse events include nausea, vomiting, fluid retention, hyperuricemia, hypertrichosis, thrombocytopenia, and leukopenia
Somatostatin analogues Octreotide, lanreotide, pasireotide	• Treatment of carcinoid tumors, glucagonomas, VIPomas, acromegaly, and Cushing disease	• Injected intramuscularly • Inhibits hormone release • Adverse events include gallbladder abnormalities

Abbreviations: CHF, congestive heart failure; DKA, diabetic ketoacidosis.

Chapter 52

Agents Affecting Mineral Ion Homeostasis and Bone Turnover

Thomas D. Nolin and Peter A. Friedman

This chapter presents a primer on mineral ion homeostasis and the endocrinology of Ca^{2+} and phosphate metabolism, then some relevant pathophysiology, and finally pharmacotherapeutic options in treating disorders of mineral ion homeostasis.

PHYSIOLOGY OF MINERAL ION HOMEOSTASIS

Calcium

Elemental calcium is essential for many biological functions, ranging from muscle contraction and intracellular signaling (see Chapter 3) to blood coagulation (Chapter 36) supporting the formation and continuous remodeling of the skeleton.

Extracellular Ca^{2+} is in the millimolar range, whereas intracellular free Ca^{2+} is maintained at submicromolar levels. Different mechanisms evolved that regulate Ca^{2+} over this 10,000-fold concentration span. Changes in cytosolic Ca^{2+} (whether released from intracellular stores or entering via membrane Ca^{2+} channels) can modulate effector targets, often by interacting with the ubiquitous Ca^{2+}-binding protein *calmodulin*. The rapid association-dissociation kinetics of Ca^{2+} permit effective regulation of cytosolic Ca^{2+} over the range of 100 nM to 1 μM.

The body content of calcium in healthy adult men and women, respectively, is about 1300 and 1000 g, of which more than 99% is in bone and teeth. Ca^{2+} in extracellular fluids is stringently regulated within narrow limits. In adult humans, the normal serum Ca^{2+} concentration ranges from 8.5 to 10.4 mg/dL (4.25–5.2 mEq/L, 2.1–2.6 mM) and includes three distinct chemical forms: *ionized* (50%), *protein bound* (40%), and *complexed* (10%). Thus, whereas total plasma Ca^{2+} concentration is about 2.5 mM, the concentration of ionized Ca^{2+} in plasma is about 1.2 mM. The various pools of Ca^{2+} are illustrated schematically in Figure 52–1.

Albumin accounts for some 90% of the serum Ca^{2+} bound to plasma proteins; a change of plasma albumin concentration of 1.0 g/dL from the normal value of 4.0 g/dL can be expected to alter total Ca^{2+} concentration by about 0.8 mg/dL. The remaining 10% of the serum Ca^{2+} is complexed with small polyvalent anions, primarily phosphate and citrate. Only diffusible Ca^{2+} (i.e., ionized plus complexed) crosses cell membranes. The degree of complex formation depends on the ambient pH and the concentrations of ionized Ca^{2+} and complexing anions. Ionized Ca^{2+} is the physiologically relevant component, mediating calcium's biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia. Hormones that affect intestinal calcium absorption and renal calcium excretion tightly control the extracellular Ca^{2+} concentration; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

Calcium Stores

The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite; other ions, including Na^+, K^+, Mg^{2+}, and F^-, also are present in the crystal lattice. The steady-state content of Ca^{2+} in bone reflects the net effect of bone resorption and bone formation. Although the bulk of skeletal calcium is not readily available for meeting short-term needs, a rapidly exchangeable calcium pool at the endosteal surface can be both mobilized and serve to sequester acute increases of extracellular calcium.

Calcium Absorption and Excretion

In the U.S., about 75% of dietary Ca^{2+} is obtained from milk and dairy products. Guidelines for daily vitamin D and calcium supplementation (Institute of Medicine, 2011) are shown in Table 52–1. Figure 52–2 illustrates the components of whole-body daily Ca^{2+} turnover. Ca^{2+} enters the body only through the intestine. *Vitamin D–dependent Ca^{2+} transport* occurs in the proximal duodenum, whereas most Ca^{2+} uptake is mediated by *passive absorption* throughout the small intestine. When calcium intake is adequate or high, passive calcium absorption in the jejunum and ileum is the major absorptive process. Conversely, when intake is

Abbreviations

BMD: bone mineral density
CaSR: calcium-sensing receptor
CGRP: calcitonin gene–related peptide
CKD-MBD: chronic kidney disease–mineral bone disease
CTR: calcitonin receptor
CYP: cytochrome P450
DHT: dihydrotachysterol
ERK: extracellular signal–regulated kinase
FGF: fibroblast growth factor
FGF23: fibroblast growth factor 23
FGFR: FGF receptor
FGFR/KL: FGF receptor/klotho
FRS2α: FGFR substrate 2α
GPCR: G protein-coupled receptor
HRT: hormone replacement therapy
HVDDR: hereditary 1,25-dihydroxyvitamin D resistance
Ig: immunoglobulin
IL: interleukin
IP_3: inositol triphosphate
KL: klotho
MTC: medullary thyroid carcinoma
NF-κB: nuclear factor kappa B
$25\text{-}OHD_3$: 25-OH-cholecalciferol
OPG: osteoprotegerin
NPT2: sodium-dependent phosphate transport protein 2
PDDR: pseudovitamin D–deficiency rickets
P_i: inorganic phosphate
PKC: protein kinase C
PLC: phospholipase C
PTH: parathyroid hormone
PTHR: PTH receptor
PTHrP: PTH-related protein
RANK: receptor for activating NF-κB
RANKL: RANK ligand
RDA: recommended daily allowance
REMS: Risk Evaluation and Mitigation Strategy
SERM: selective estrogen receptor modulator
SGK1: serum and glucocorticoid–regulated kinase 1
TK: tyrosine kinase
TRPV6: transient receptor potential cation channel V6
VDDR-1: vitamin D–dependent rickets type I
VDR: vitamin D receptor
XLH: X-linked hypophosphatemia

low, vitamin D–dependent active calcium absorption is upregulated in the duodenum and accounts for the larger proportion of calcium that is absorbed.

This uptake, whether active or passive, is counterbalanced by an obligatory daily intestinal Ca^{2+} loss of about 150 mg/day that reflects the Ca^{2+} content of mucosal and biliary secretions and in sloughed intestinal cells. The efficiency of intestinal Ca^{2+} absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, chronic diarrhea, or malabsorption promote fecal loss of Ca^{2+}. Drugs such as glucocorticoids and phenytoin depress intestinal Ca^{2+} transport.

Urinary Ca^{2+} excretion is the difference between the amount filtered at the glomerulus and the quantity reabsorbed. About 9 g of calcium are filtered each day, of which more than 98% is reabsorbed by the tubules. The efficiency of reabsorption is highly regulated by PTH and is influenced

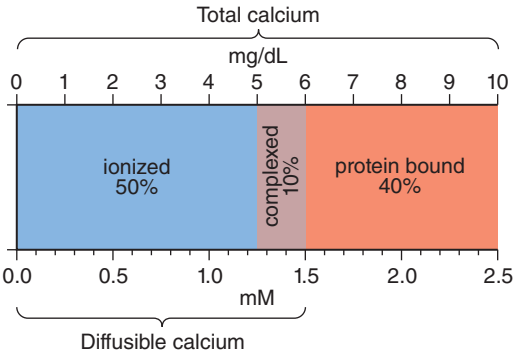

Figure 52–1 *Pools of calcium in serum.* Concentrations are expressed as milligrams per deciliter (top axis) and as millimoles per liter (bottom axis). The total serum calcium concentration is 10 mg/dL or 2.5 mM, divided into three pools: protein bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusable forms of calcium that can enter cells.

by filtered Na^+, the presence of nonreabsorbed anions, and diuretic agents (see Chapter 25). Sodium intake, and therefore Na^+ excretion, is directly related to urinary Ca^{2+} excretion. Diuretics that act on the ascending limb of the loop of Henle (e.g., *furosemide*) increase Ca^{2+} excretion. By contrast, thiazide diuretics uncouple the relationship between Na^+ and Ca^{2+} excretion, increasing sodium excretion but diminishing calcium excretion. Urinary Ca^{2+} excretion is a direct function of dietary protein intake, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.

Phosphate

Phosphate is present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone; about 15% is in soft tissue. In addition, phosphate is a dynamic constituent of intermediary and energy metabolism and acts as a key regulator of enzyme activity when

TABLE 52–1 ■ RECOMMENDED DAILY ALLOWANCE OF CALCIUM AND VITAMIN D

LIFE STAGE GROUP	CALCIUM (mg/day)[a]	VITAMIN D (IU/day)[a,b]
Infants 0–6 months	200[c]	400[d]
Infants 6–12 months	260[c]	400[d]
1–3 years old	700	600
4–8 years old	1000	600
9–13 years old	1300	600
14–18 years old	1300	600
19–30 years old	1000	600
31–50 years old	1000	600
51–70 years old	1000	600
51- to 70-year-old females	1200	600
>70 years old	1200	600
14–18 years old, pregnant/lactating	1300	600
19–50 years old, pregnant/lactating	1000	600

[a]Intake covering needs of ≥97.5% of population.
[b]Covers all forms of vitamin D. For details, see Institute of Medicine, 2011.
[c]For infants 0 to 6 months of age, adequate intake is 200 mg/day; it is 260 mg/day for infants 6 to 12 months of age. RDAs have not been established for infants.
[d]For infants 0 to 6 months of age, adequate intake is 400 IU/day; it is 400 IU/day for infants 6 to 12 months of age. RDAs have not been established for infants.

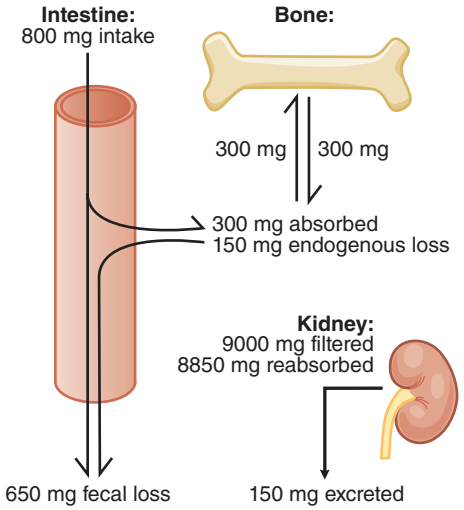

Figure 52–2 *Whole-body daily turnover of calcium.* In healthy adults, calcium intake is equal to calcium excretion, and no net gain or loss of skeletal calcium occurs. Daily dietary calcium intake averages 800 mg. Net intestinal absorption amounts to 150 mg and is balanced by an equivalent amount of calcium excretion by the kidneys. Fecal calcium excretion amounts to 650 mg. In the absence of a challenge to calcium homeostasis such as lactation, the kidneys are the primary site of calcium metabolism. (Adapted with permission from Yanagawa N, Lee DBN. Renal handling of calcium and phosphorus. In: Coe FL, Favus MJ, eds. *Disorders of Bone and Mineral Metabolism*. Raven Press, New York, **1992**, 3–40.)

transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues.

Biologically, phosphorus exists in both organic and inorganic (P_i) forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus is present as inorganic phosphate in the form of NaH_2PO_4 and Na_2HPO_4. At pH 7.4, the ratio of disodium to monosodium phosphate is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of P_i modifies tissue concentrations of Ca^{2+} and plays a major role in renal H^+ excretion. Within bone, phosphate is complexed with Ca^{2+} as hydroxyapatites and as calcium phosphate.

Absorption, Distribution, and Excretion

Phosphate is an abundant dietary component; even an inadequate diet rarely causes phosphate depletion. Phosphate is extensively absorbed from the GI tract primarily by passive movement (proportional to the concentration in the intestinal lumen), with a smaller fraction mediated by active vitamin D–dependent transport. The fact that most intestinal phosphate absorption is passive may explain why it continues in the presence of hyperphosphatemia, whereas renal phosphate transport is downregulated by elevated phosphate concentrations. The NPT2B Na-phosphate cotransporter mediates active GI phosphate transport, which proceeds through a classic feedback mechanism: Decreases of serum phosphate enhance the biogenesis of vitamin D, which in turn upregulates NPT2B expression.

In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. Small amounts of phosphate are secreted into the intestine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Renal phosphate excretion is the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is reabsorbed, predominantly by proximal tubules. Renal phosphate absorption is regulated by PTH and FGF23 and by other factors, primarily dietary phosphate. Additional hormonal regulators of intestinal phosphate absorption include gluco-corticoids, estradiol, and epidermal growth factor. Nonhormonal factors contributing to phosphate homeostasis include extracellular volume and acid-base status.

Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of effects on plasma P_i, Ca^{2+}, PTH, or FGF23 (Bourgeois et al., 2013). PTH and FGF23 increase urinary phosphate excretion by blocking phosphate reabsorption. Expansion of plasma volume increases urinary phosphate excretion.

Role of Phosphate in Urine Acidification

Phosphate is concentrated progressively as it traverses the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H^+ and Na^+ in the tubular urine converts Na_2HPO_4 to NaH_2PO_4, permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H^+ transport.

Pharmacological Actions of Phosphate

Phosphate salts are employed as mild laxatives (see Chapter 54) and to acidify the urine and treat hypophosphatemia.

Hormonal Regulation of Calcium and Phosphate Homeostasis

A number of hormones interact to control extracellular Ca^{2+} and phosphate balance. The most important are PTH, FGF23, and *1,25-dihydroxyvitamin D_3* (*calcitriol*), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 52–3).

Parathyroid Hormone

Parathyroid hormone is a polypeptide that helps to regulate plasma Ca^{2+} by affecting bone resorption/formation, renal Ca^{2+} excretion/reabsorption, and calcitriol synthesis (thus, GI Ca^{2+} absorption).

HISTORY

Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed *osteitis fibrosa cystica*, which Askanazy subsequently described in a patient with a parathyroid tumor in 1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassale and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively. MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca^{2+}. The relation of low plasma Ca^{2+} concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Ca^{2+} in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

Chemistry

Parathyroid hormone is a single polypeptide chain of 84 amino acids with a molecular mass of about 9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1 to 27 are required for optimal binding to the PTHR and hormone activity. Derivatives lacking the first and second residues bind to PTHRs but do not activate the cyclic AMP or IP_3-Ca^{2+} signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

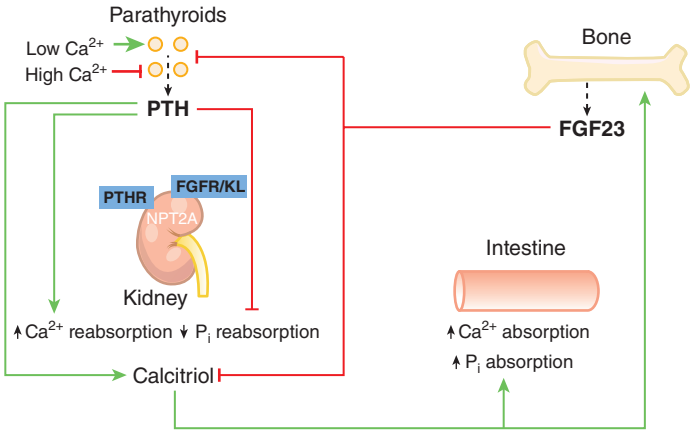

Figure 52–3 *Calcium homeostasis and its regulation by PTH, FGF23, and 1,25-dihydroxyvitamin D.* PTH, released from parathyroids (dotted line), has stimulatory effects on bone and kidney, increasing calcium mobilization and reabsorption, decreasing phosphate reabsorption, and stimulating 1α-hydroxylase activity in kidney mitochondria, leading to the production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol (Figure 52–6). FGF23, released from bone (dotted line), likewise dampens renal phosphate reabsorption and augments calcium recovery but decreases the production of 1,25-dihydroxyvitamin D by inhibiting 25(OH)1-α-hydroxylase (*CYP27B1*) and increasing metabolism by inducing 1,25(OH)$_2$vitamin D 24-hydroxylase (*CYP24A1*). FGF23 also suppresses PTH release by the parathyroid glands. Calcitriol, the biologically active metabolite of vitamin D, increases intestinal calcium and phosphate absorption and regulates FGF23 synthesis and release and calcium mobilization in bone.

Synthesis and Secretion

Parathyroid hormone is synthesized as a 115–amino acid peptide called *preproparathyroid hormone*, which is converted to *proparathyroid hormone* by cleavage of 25 amino-terminal residues in the endoplasmic reticulum. Proparathyroid hormone is converted in the Golgi complex to PTH by cleavage of six amino acids. PTH(1–84) resides within secretory granules until it is discharged into the circulation. PTH(1–84) has a $t_{1/2}$ in plasma of about 4 min; removal by the liver and kidney accounts for about 90% of its clearance. Proteolysis of PTH generates smaller fragments [e.g., a 33– to 36–amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH(7–84)]. PTH(7–84) and other amino-truncated PTH fragments are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms. PTH is commonly measured by a two-site immunoassay encompassing the PTH amino terminus and a downstream location. Such "whole" or "intact" PTH assays avoid fragments lacking residues 1 to 6 that circulate normally and accumulate in kidney failure (Smit et al., 2019; Suva and Friedman, 2020).

Physiological Functions and Mechanism of Action

The primary function of PTH is to maintain a constant concentration of Ca^{2+} and P_i in the extracellular fluid. The principal regulated processes are P_i excretion and Ca^{2+} absorption in kidney and mobilization of Ca^{2+} from bone (see Figure 52–3). Renal PTH activity on P_i and Ca^{2+} are spatially separated along the nephron. The actions of PTH on its target tissues are mediated by at least two GPCRs that can couple with G_s, G_q, and $G_{12/13}$ in cell type–specific manners (Garrido et al., 2009). The type I PTHR, which also binds PTH-related protein (PTHrP) mediates mineral ion homeostasis and the skeletal actions of PTH. A second PTHR expressed in arterial and cardiac endothelium, brain, pancreas, placenta, and elsewhere binds PTH but not PTHrP. A third putative PTHR, designated the cPTH receptor, interacts with carboxy-terminal PTH fragments that are truncated in the amino-terminal region, contain most of the carboxy terminus, and are inactive at the PTH_1 receptor; CPTH receptors are expressed on osteocytes (Scillitani et al., 2011).

Regulation of Secretion. *Plasma Ca^{2+} is the major factor regulating PTH secretion.* As the concentration of Ca^{2+} diminishes, PTH secretion increases; hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca^{2+} is high, PTH secretion decreases. Changes in plasma Ca^{2+} regulate PTH secretion by the plasma membrane–associated calcium-sensiing receptor on parathyroid cells. The CaSR is a GPCR that couples with G_q and G_i. Occupancy of the CaSR by Ca^{2+} stimulates the G_q-PLC-IP_3-Ca^{2+}, pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca^{2+} inhibits rather than stimulates secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca^{2+} inhibits renin secretion). Simultaneous activation of the CaSR-G_i pathway by Ca^{2+} reduces cyclic AMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CaSR by Ca^{2+} reduces signaling through G_i and G_q, thereby promoting PTH secretion. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and dopamine, also increase PTH secretion, but much less than does hypocalcemia. The active vitamin D metabolite 1,25-dihydroxyvitamin D (*calcitriol*) directly suppresses PTH gene expression. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

Effects on Bone. Parathyroid hormone exerts both catabolic and anabolic effects on bone. Chronically elevated PTH enhances bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast.

Effects on Kidney. In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, 1,25-dihydroxy vitamin D_3 (calcitriol; see Figure 52–3). As a result, filtered Ca^{2+} is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized 1,25-dihydroxy vitamin D_3 interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca^{2+} absorption, thereby contributing to the increase in plasma Ca^{2+}.

Calcitriol Synthesis. The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin D_3–1α-hydroxylase that catalyzes this step: P_i, PTH, and Ca^{2+} (see discussion later in this chapter). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P_i and a more direct effect of the hormone on the 1α-hydroxylase lead to increased circulating concentrations of calcitriol.

Integrated Regulation of Extracellular Ca^{2+} and Phosphate by PTH. Even modest reductions of serum Ca^{2+} stimulate PTH secretion. For minute-to-minute regulation of Ca^{2+}, adjustments in renal Ca^{2+}

handling suffice to maintain plasma calcium homeostasis. With prolonged hypocalcemia, the renal 1α-hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal Ca^{2+} absorption (see Figure 52–3), and delivery of Ca^{2+} from bone into the extracellular fluid is augmented. With prolonged and severe hypocalcemia, new bone-remodeling units are activated to restore circulating Ca^{2+} concentrations, albeit at the expense of skeletal integrity.

When plasma Ca^{2+} activity rises, PTH secretion is suppressed, and tubular Ca^{2+} reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal Ca^{2+} absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent response to positive or negative excursions of plasma Ca^{2+} concentrations.

Fibroblast Growth Factor 23

Fibroblast growth factor 23 is a member of the FGF19 family of endocrine FGFs. Osteocytes and other bone cells, including osteoblasts, and lining cells are the primary source of FGF23. FGF23 is secreted in response to dietary phosphorus load and to changes in serum phosphate and 1,25-dihydroxyvitamin D. *Its main function is the promotion of urinary phosphate excretion and the suppression of active vitamin D production by the kidney*. FGF23, unlike PTH, also suppresses intestinal phosphate absorption.

Synthesis and Secretion

Fibroblast growth factor 23 is synthesized as a 251–amino acid peptide. Cleavage of the amino-terminal signal sequence and glycosylation produce the active protein consisting of an amino-terminal core sequence and a shorter carboxy-terminal fragment (Figure 52–4). FGF23 is extensively O-glycosylated, which shields it from proteolysis and enhances secretion. FGF23 possesses a furin cleavage site, ^{176}RXXR^{179}. Hydrolysis produces FGF23 fragments that are biologically inactive or act as antagonists. Phosphorylation at Ser^{180} inhibits O-glycosylation, thereby making FGF23 more susceptible to protease degradation.

Regulated FGF23 proteolysis may contribute to maintaining serum phosphate levels by generating more of a carboxy-terminal cFGF23 peptide (cFGF23) relative to the amount of iFGF23 (intact FGF23). cFGF23 is now thought to inhibit FGF23 action by competitively blocking binding to FGFRs and klotho.

Unlike paracrine FGFs that require heparan sulfate for FGFR activation, FGF23 (and FGF19) binds heparan sulfate with very low affinity, and it is not necessary for signal transduction. FGF23 inhibits renal phosphate transport by activating FGFRs through a mechanism that entails the transmembrane form of α-klotho. *Klotho is as an essential coreceptor for FGFR activation and transduction of FGF23 signaling*. Cleaved klotho increases FGF23 formation, while FGF23 decreases expression of transmembrane klotho (Smith et al., 2012). FGFRs are receptor TKs consisting of an extracellular domain with immunoglobulin-like loops and an intracellular region that harbors TK domains (see Figure 52–4). The amino-terminal portion of FGF23 binds the FGFR, while the carboxy-terminal segment binds to klotho. This ternary complex (FGFR, klotho, and FGF23) then dimerizes, thereby enabling intracellular TK autophosphorylation of FGFR. Intracellular signaling is achieved primarily through ERKs and PLC.

Regulation of Secretion. Fibroblast growth factor 23 is released from bone into the circulation in response to elevations of serum phosphate, PTH, and 1,25 vitamin D. The sensing mechanism responding to these changes and its control over FGF23 secretion is unknown. Iron deficiency also influences FGF23 levels. FGF23 is normally released by both as iFGF23 and inactive cFGF23 fragments. In healthy individuals, low serum iron is associated with elevated cFGF23 levels, but not with iFGF23. The ratio of iFGF23:cFGF23 varies appreciably in disease states and in inherited disorders of FGF23 metabolism (Wolf and White, 2014).

Physiological Functions and Mechanism of Action

Effects on Kidney. Fibroblast growth factor 23 increases phosphate excretion and lowers vitamin D formation. The phosphaturic action of FGF23 is mediated by FGFR1c and to a lesser degree by FGFR4 (Gattineni et al., 2014). FGF23 and PTH reduce phosphate by mechanisms that involve endocytosis and downregulation of NPT2A and NPT2C, the principal Na-phosphate cotransporters that mediate phosphate retrieval from the tubular fluid. *Notably, although FGF23 and PTH exert parallel inhibitory actions on phosphate excretion, they have opposite effects on vitamin D metabolism. PTH stimulates the formation of the active form*

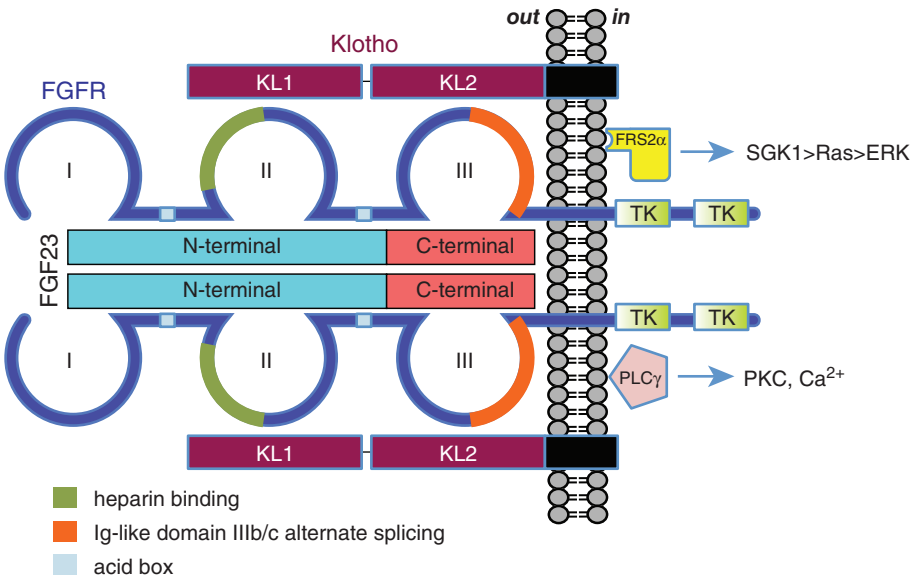

Figure 52–4 *FGF23-FGFR-Klotho complex.* FGF23 binding to the FGFR + klotho complex promotes dimerization of the ternary complex. FGFRs possess three Ig-like domains (I, II, III). Alternative splicing in domain III gives rise to FGFR1/2/3 isoforms. FGFR1c is believed to be the FGF23 receptor. FGF23 requires α-klotho to bind and activate FGFR1. FGF23 consists of a larger N-terminal region and shorter C-terminal segment. Intracellular proteolysis and inactivation of FGF23 occur at a site separating the two domains. Klotho is a transmembrane protein with two large extracellular KL1 and KL2 domains that can be cleaved by a disintegrin and metalloproteinase 10 and 17 (ADAM10/17). Full-length klotho and the shed extracellular domain of KL have distinct functions. Notably, full-length klotho is a coreceptor for FGFR1. Intracellular TK domains on FGFRs mediate downstream signaling, primarily through parallel pathways involving FRS2α, SGK1, ERK1/2 for FGF2 (Mandukhail et al., 2012), and PLCγ (which activates signaling by Ca^{2+}-activating PKC) (Ornitz and Itoh, 2015).

of vitamin D, whereas FGF23 reduces vitamin D levels by augmenting its metabolism to inactive forms.

Exogenous FGF23 administration reduces serum P_i and calcitriol synthesis. Although no clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy. The novel recombinant human IgG monoclonal antibody KRN23, which binds FGF23 and inhibits its activity, can increase P_i reabsorption and serum concentrations of P_i and calcitriol in patients with XLH (Carpenter et al., 2014; Imel et al., 2015).

Soluble klotho, a circulating cleavage product of membrane-associated klotho, when administered to mice, increased serum levels of FGF23 and reduced bone mineral content with a concomitant increase in fracture incidence (Smith et al., 2012). These findings suggest that a scavenging antibody directed to the soluble klotho fragment might provide an additional means to reduce FGF23 levels in patients with secondary hyperparathyroidism or chronic kidney disease-mineral bone disease (CKD-MBD).

Vitamin D

HISTORY

Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of chole- and ergo-calciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca and Kodicek (DeLuca, 1988).

Chemistry and Occurrence

Vitamin D is a hormone rather than a vitamin, and it plays an active role in Ca^{2+} homeostasis. The biological actions of vitamin D are mediated by the vitamin D receptor (VDR) a nuclear receptor. Vitamin D is the name applied to two related fat-soluble substances, vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol). Vitamin D_3 has a potency about 10-fold greater than that of vitamin D_2. This difference is likely attributable to the longer $t_{1/2}$ of vitamin D_3 and lower affinity of vitamin D_2 metabolites for the vitamin D–binding protein (Jones et al., 2014), dispelling the long-held notion that there is no practical difference between vitamin D_2 and vitamin D_3. The total concentration of serum 25-hydroxyvitamin D (D_2 + D_3) is now accepted as the clinical parameter for assessing vitamin D status and functional adequacy of vitamin D treatments.

The primary provitamin found in animal tissues is *7-dehydrocholesterol*, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to *cholecalciferol* (vitamin D_3). *Ergosterol*, present only in plants and fungi, is the provitamin for *ergocalciferol* (vitamin D_2). Vitamin D_2 is the active constituent of a number of commercial vitamin preparations and is in irradiated bread and irradiated milk.

Human Requirements and Units

Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates, insufficient cutaneous solar radiation, especially in winter, may necessitate dietary vitamin D supplementation (Faurschou et al., 2012). Serum levels of vitamin D vary widely, likely reflecting genetic background, diet, latitude, time spent out of doors, body size, developmental stage, and state of health, as well as plasma levels of *vitamin D–binding protein*, a specific α globulin. The actions of vitamin D may differ with the expression of components of the synthetic and action pathways of vitamin D. Other factors contributing to the rise of vitamin D deficiency may include diminished consumption of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of dairy products; an increased prevalence and duration of exclusive breastfeeding (human milk is a poor source of vitamin D); and increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation. The recommended amount of sunscreen and SPF advised by the World Health Organization may abolish endogenous vitamin D production (Faurschou et al., 2012). The U.S. Institute of Medicine suggests achieving a serum level for 25-OH vitamin D of 50 nmol/L (20 ng/mL). The most recent recommended daily intakes of vitamin D and calcium are shown in Table 52–1.

Metabolic Activation

Vitamin D requires modification to become biologically active. The primary active metabolite, 1α,25-dihydroxy vitamin D (*calcitriol*), is the product of successive hydroxylations (Figure 52–5).

25-Hydroxylation of Vitamin D. The initial hydroxylation occurs in the *liver* to generate 25-OH-cholecalciferol (25-OHD_3, or *calcifediol*) and 25-OHD_2 (ergocalciferol), respectively. 25-OHD_3 is the major circulating form of vitamin D_3; it has a biological $t_{1/2}$ of 19 days, and normal steady-state concentrations are 15 to 50 ng/mL, whereas 25-OHD_2 has a $t_{1/2}$ of 13 days.

1α-Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation occurs primarily in the *kidney*, where the enzyme 25-hydroxyvitamin D-1α-hydroxylase (*CYP27B1*) in the proximal tubules converts 25-OHD_3 to *calcitriol*. This process is highly regulated (see Figures 52–3 and 52–5). Dietary deficiency of vitamin D, calcium, or phosphate stimulates 1α-hydroxylation of 25-OHD_3, increasing the formation of biologically active 1,25$(OH)_2D_3$. In contrast, when Ca^{2+} concentrations are elevated, 25-OHD_3 is inactivated by 24-hydroxylation. Similar reactions occur with 25-OHD_2 (ergocalciferol). Calcitriol controls 1α-hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma $t_{1/2}$ of calcitriol is estimated at 3 to 5 days in humans.

24-Hydroxylation of Calcitriol. The 25(OH) vitamin D–24-hydroxylase enzyme *CYP24A1* catalyzes several steps of 1,25$(OH)_2D_3$ degradation. *CYP24A1* is upregulated by FGF23 and calcitriol and downregulated by PTH.

Physiological Functions and Mechanism of Action

Calcitriol augments absorption and retention of Ca^{2+} and phosphate and thereby helps to maintain normal concentrations of Ca^{2+} and phosphate in plasma. Calcitriol facilitates absorption of Ca^{2+} and phosphate in the small intestine, interacts with PTH to enhance their mobilization from bone, and decreases their renal excretion. The actions of calcitriol are mediated by the nuclear receptor VDR, a member of the steroid and thyroid hormone nuclear receptor superfamily. Calcitriol binds to cytosolic VDRs within target cells; the VDR-hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. Calcitriol also exerts rapid, nongenomic effects. These actions also involve the VDR but at an alternative site where calcitriol binds in a planar configuration.

Calcium is absorbed predominantly from the duodenum. In the absence of calcitriol, GI calcium absorption is inefficient and involves passive diffusion via a paracellular pathway. Ca^{2+} absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca^{2+} absorption (Kellett, 2011):

- Entry across mucosal membranes mediated by TRPV6 and $Ca_V1.3$ Ca^{2+} channels
- Diffusion through the enterocytes
- Active extrusion across serosal plasma membranes

Calcitriol upregulates the synthesis of FGF23, calbindin-D_{9K}, calbindin-D_{28K}, and the serosal plasma membrane Ca^{2+}-ATPase. Calbindin-D_{9K}

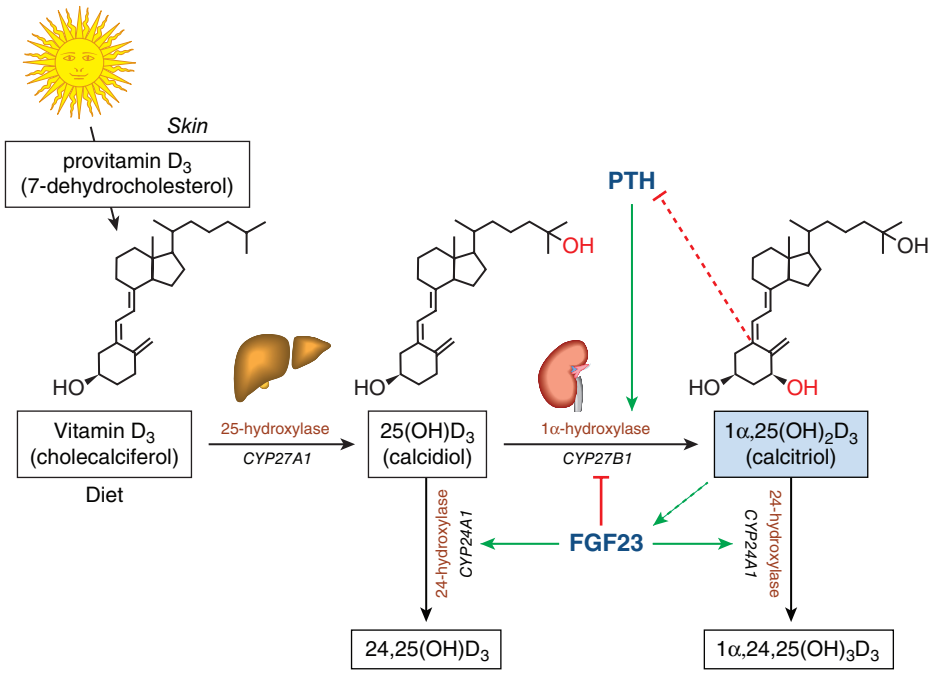

Figure 52–5 *Vitamin D metabolism.* Vitamin D (cholecalciferol) is formed in the skin by solar ultraviolet irradiation of 7-dehydrocholesterol or provided in the diet or by supplements. Sequential hydroxylation at position 25 (red) in the liver to $25(OH)D_3$ (calcidiol) and at position 1 (red) in the kidneys produces biologically active $1\alpha,25(OH)_2D_3$ (calcitriol). Metabolism of calcidiol and calcitriol by 24-hydroxylase reduces serum levels of $1\alpha,25(OH)_2D_3$. PTH promotes the formation of $1\alpha,25(OH)_2D_3$, while FGF23 reduces $1\alpha,25(OH)_2D_3$ levels by stimulating 24-hydroxylation by *CYP24A1* and inhibiting 1α-hydroxylase (*CYP27B1*). Elevated calcitriol levels decrease PTH synthesis by parathyroid glands and stimulate FGF23 release from osteocytes.

enhances the extrusion of Ca^{2+} by the Ca^{2+}-ATPase; the precise function of calbindin-D_{28K} is unsettled.

The primary role of calcitriol is to stimulate intestinal absorption of Ca^{2+}, which in turn indirectly promotes bone mineralization. Hence, PTH and calcitriol act independently to enhance bone resorption. Osteoblasts, the cells responsible for bone formation, express VDR, and calcitriol induces production of several osteoblast proteins, including osteocalcin, a vitamin K–dependent protein that contains γ-carboxyglutamic acid residues, and IL-1, a lymphokine that promotes bone resorption. Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. In a healthy scenario, osteoblast and osteoclast activities are coupled. Osteoporosis is a disease in which that coupling is disturbed; osteoblast responsiveness to calcitriol is profoundly impaired, osteoclast activity predominates, and bone resorption exceeds formation.

Other Effects of Calcitriol. Effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body. Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function. Calcitriol inhibits epidermal proliferation, promotes epidermal differentiation, and is used as a treatment of plaque psoriasis (see Chapter 75).

Calcitonin

Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH. The thyroid parafollicular C cells produce and secrete calcitonin. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of "calcium stress," such as growth, pregnancy, and lactation. Calcitonin acts through the CTR, a GPCR that links to G_s and G_q.

Regulation of Secretion

Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking cys1 and cys7. Serum $[Ca^{2+}]$ concentrations regulate the biosynthesis and secretion of calcitonin. Calcitonin secretion increases when serum Ca^{2+} is high and decreases when plasma Ca^{2+} is low. Thus,

HISTORY

Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca^{2+} concentrations. The physiological relevance of calcitonin has been challenged vigorously: Calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacological use in treating Paget disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid.

PTH secretion decreases and calcitonin release increases as serum calcium concentrations rise (Figure 52–6). The circulating concentrations of calcitonin are low, normally less than 15 and 10 pg/mL for males and females, respectively. The circulating $t_{1/2}$ of calcitonin is about 10 min. Abnormally elevated levels of calcitonin are characteristic of thyroid C cell hyperplasia and MTC. The calcitonin gene is localized on human chromosome 11p and contains six exons; differential splicing of the exons leads to tissue-specific production of calcitonin, katacalcin, and CGRP.

Bone Physiology

The skeleton is the primary structural support for the body and provides a protected environment for hematopoiesis. It contains both a large, mineralized matrix and a highly active cellular compartment.

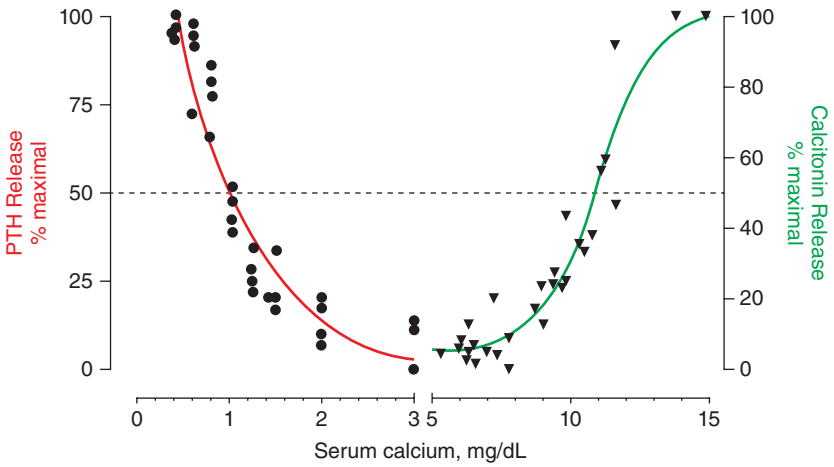

Figure 52–6 *Inverse relations between PTH and calcitonin release.* As serum calcium falls below its set point of about 1.2 mM, PTH secretion increases as a means to defend calcium homeostasis. Conversely, as calcium levels rise, PTH secretion is inhibited, while release of calcitonin increases. (Replotted from Imanishi et al., 2002; Torres et al., 1991.)

Bone Mass

Bone mineral density and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for about 60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium. Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. In women, loss of estrogen at menopause accelerates the rate of bone loss. *Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency of one is not compensated by excessive attention to another.*

Bone Remodeling

Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called *remodeling*, by which bone mass is adjusted throughout adult life. Remodeling is carried out by myriad independent "bone-remodeling units" throughout the skeleton. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated *osteoclasts* that resorb, or excavate, a cavity into the bone. Osteoclast production is regulated by osteoblast-derived cytokines (e.g., IL-1 and IL-6). One important mechanism is RANK and its natural ligand, RANKL (previously called *osteoclast differentiation factor*). On binding to RANK, RANKL induces osteoclast formation (Figure 52–7). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG) which acts as a decoy ligand that inhibits osteoclast production by competing effectively with RANKL for binding to RANK. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK.

The resorption phase is followed by invasion of preosteoblasts into the base of the resorption cavity. These cells become osteoblasts and elaborate new bone matrix constituents that help form *osteoid*. Once the newly formed osteoid reaches a thickness of about 20 μM, mineralization begins. A complete remodeling cycle normally requires about 6 months. Small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. *Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance.*

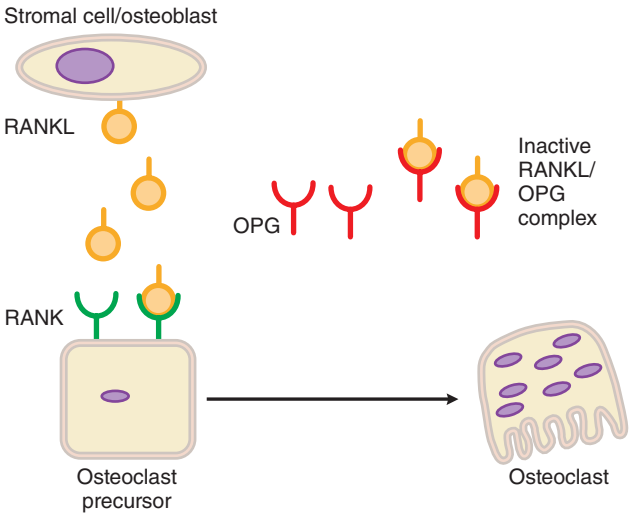

Figure 52–7 *Osteoclast formation.* Receptor for activating RANKL, acting on RANK, promotes osteoclast formation and subsequent resorption of bone matrix. OPG, a decoy receptor, binds to RANKL, reducing its interaction with RANK and thereby inhibiting osteoclast differentiation.

Disorders of Mineral Homeostasis and Bone

Abnormal Calcium Metabolism

Hypercalcemia

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption.

Hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTHrP is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue. PTHrP interacts with the PTHR in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in

humoral hypercalcemia of malignancy (Grill et al., 1998). In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to stimulation of 25(OH) vitamin D–1α-hydroxylase.

Vitamin D excess may cause hypercalcemia if sufficient 25-OHD is present to stimulate intestinal Ca^{2+} hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-OHD is diagnostic. Occasionally, patients with *hyperthyroidism* show mild hypercalcemia, presumably owing to increased bone turnover. *Immobilization* may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget disease or hyperthyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure. Serum assays for PTH, PTHrP, and 25-OH- and $1,25\text{-}(OH)_2D$ permit accurate diagnosis in the great majority of cases.

Hypocalcemia

Combined deprivation of Ca^{2+} and vitamin D, as observed with malabsorption states, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mild hypocalcemia (i.e., serum Ca^{2+} in the range of 8–8.5 mg/dL [2–2.1 mM]) is usually asymptomatic. Patients exhibit greater symptoms if the hypocalcemia develops acutely.

Symptoms of hypocalcemia include tetany and related phenomena, such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic *hypoparathyroidism*, ectodermal changes (e.g., consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts) occur. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present. Hypoparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. *Pseudohypoparathyroidism* is a family of various hypocalcemic and hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH; this resistance is due to mutations in $G_s\alpha$ (*GNAS1*), which normally mediates hormone-induced adenylyl cyclase activation (Bastepe, 2008). Multiple hormonal abnormalities have been associated with the *GNAS1* mutation, but none is as severe as the deficient response to PTH.

Disturbed Phosphate Metabolism

Dietary inadequacy rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (see Chapter 53). *Osteomalacia* is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action. *Hyperphosphatemia* occurs commonly in CKD. The increased phosphate level reduces the serum Ca^{2+} concentration, which in turn activates the parathyroid gland CaSR, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The CaSR agonists *cinacalcet* and *etelcalcetide* suppress PTH secretion and are approved as treatment of secondary hyperparathyroidism in adult patients with CKD receiving chronic dialysis therapy. Another CaSR agonist, *evocalcet*, is under investigation for treatment of secondary hyperparathyroidism in adult dialysis patients, and early clinical evidence suggests similar PTH lowering to *cinacalcet* (Fukagawa et al., 2018). In addition, *cinacalcet* is approved for treatment of hypercalcemia secondary to parathyroid cancer and for primary hyperparathyroidism in patients unable to be managed surgically. Potential new therapies targeting NPT2A with the small-molecule inhibitor PF-06869206 have been reported (Clerin et al., 2020).

The newly approved recombinant human monoclonal antibody to FGF23, *burosumab*, is extremely effective in correcting the hypophosphatemia associated with XLH, the most common form of hereditary rickets and osteomalacia. Monthly administration provides prolonged restoration of serum phosphate by reducing urinary phosphate excretion without adversely altering serum PTH or calcium levels. *Burosumab* is approved for treatment of XLH in children (Carpenter et al., 2018) and adults (Insogna et al., 2018) and for tumor-induced osteomalacia (Imanishi et al., 2021).

Disorders of Vitamin D

Hypervitaminosis D

The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism and from faddist use of excessive doses. The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of 50,000 units or more may result in poisoning. The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia.

Vitamin D Deficiency

Vitamin D deficiency results in inadequate absorption of Ca^{2+} and phosphate. The consequent decrease of plasma Ca^{2+} concentration stimulates PTH secretion, which acts to restore plasma Ca^{2+} at the expense of bone. FGF23 increases as well. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH and FGF23. In children, the result is failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as *rickets*. In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations less than 8 ng/mL are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia

The disorders of metabolic rickets and osteomalacia are characterized by abnormalities in calcitriol synthesis or response. Variants include the following:

- *Hypophosphatemic vitamin D–resistant rickets*: Usually, this is an X-linked disorder (XLH) of calcium and phosphate metabolism. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate.
- *Vitamin D–dependent rickets*, also called *VDDR-1* or *PDDR*: This is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol due to mutations in CYP1α (1α-hydroxylase).
- *HVDDR*, also called *vitamin D–dependent rickets type II*: This is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Multiple heterogeneous mutations of the VDR cause this variant.
- *CKD-MBD (renal rickets)*: Refers to the disordered bone morphology that attends CKD. The variant is characterized by abnormalities of bone turnover, mineralization, volume, linear growth, or strength, as well as underlying defects in mineral ion, PTH, or vitamin D metabolism.

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Many women (30%–50%) and men (15%–30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival.

Osteoporosis can be categorized as *primary* or *secondary*. *Primary osteoporosis* represents two different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. *Secondary osteoporosis* is due to systemic illness or chronic use of medications such as glucocorticoids or *phenytoin*. The most successful approaches to secondary osteoporosis are prompt resolution of the underlying cause and drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used in both conditions.

Paget Disease

Single or multiple sites of disordered bone remodeling characterize Paget disease. It affects up to 2% to 3% of the population more than 60 years of age. The primary pathological abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget disease.

Chronic Kidney Disease–Mineral Bone Disease

Bone disease is a frequent consequence of CKD and dialysis treatment. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa), vitamin D deficiency (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased serum phosphate and decreased calcium, leading to the loss of bone.

Pharmacological Treatment of Disorders of Mineral Ion Homeostasis and Bone Metabolism

Hypercalcemia

Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6–8 L/day). Agents that augment Ca^{2+} excretion, such as loop diuretics (see Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted.

Corticosteroids administered at high doses (e.g., 40–80 mg/day of *prednisone*) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (see Chapter 50). The response to steroid therapy is slow; from 1 to 2 weeks may be required before plasma Ca^{2+} concentration falls. *Calcitonin* may be useful in managing hypercalcemia. Reduction in Ca^{2+} can be rapid, although "escape" from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 h; if there is no response within 1 to 2 days, the dose may be increased to a maximum of 8 units/kg every 12 h. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 h. *Calcitonin* can lower serum calcium by 1 to 2 mg/dL.

Intravenous *bisphosphonates* (*pamidronate, zoledronate*) have proven very effective in the management of hypercalcemia (see further material for discussion of bisphosphonates). These agents potently inhibit osteoclastic bone resorption. *Pamidronate* is given as an intravenous infusion of 60 to 90 mg over 4 to 24 h. With *pamidronate*, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks. *Zoledronate* has largely superseded *pamidronate* because of its more rapid normalization of serum Ca^{2+} and longer duration of action.

Plicamycin (*mithramycin*; discontinued in the U.S.) is a cytotoxic antibiotic that also decreases plasma Ca^{2+} concentrations by inhibiting bone resorption. Reduction in plasma Ca^{2+} concentrations occurs within 24 to 48 h when a relatively low dose of this agent is given (15–25 μg/kg of body weight) to minimize the high systemic toxicity of the drug; indeed, its toxicity generally precludes its use.

Once the hypercalcemic crisis has resolved, or in patients with milder calcium elevations, long-term therapy is initiated. Parathyroidectomy remains the only definitive treatment of primary hyperparathyroidism. As described further in this chapter, a calcium mimetic that stimulates the CaSR is an effective therapeutic option for hyperparathyroidism. Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain Ca^{2+} levels within an acceptable range.

Hypocalcemia and Other Therapeutic Uses of Calcium

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Hypoparathyroidism is treated primarily with vitamin D and various calcium salts. *Calcium chloride* ($CaCl_2 \cdot 2H_2O$) contains 27% Ca^{2+}; it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and *must never be injected* into tissues. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The usual intravenous preparation is a 10% solution (equivalent to 1.36 mEq Ca^{2+}/mL). The rate of injection should be slow (not more than 1 mL/min) to prevent cardiac arrhythmias from a high concentration of Ca^{2+}. The injection may induce a moderate fall in blood pressure owing to vasodilation.

Calcium gluceptate injection (a 22% solution; 18 mg or 0.9 mEq of Ca^{2+}/mL; not available in the U.S.) is administered intravenously at a dose of 5 to 20 mL for the treatment of severe hypocalcemic tetany. *Calcium gluconate* injection (a 10% solution; 9.3 mg of Ca^{2+}/mL) given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia are typically treated by intravenous infusion of calcium gluconate at a dose of 10 to 15 mg of Ca^{2+}/kg of body weight over 4 to 6 h. Because the usual 10-mL vial of a 10% solution contains only 93 mg Ca^{2+}, many vials are needed. Treatment with intravenous Ca^{2+}, administered as calcium gluconate (10–30 mL of a 10% solution), also may be lifesaving in patients with extreme hyperkalemia (serum K^+ >7 mEq/L).

Additional FDA-approved uses of intravenous Ca^{2+} include treatment of black widow spider envenomation and management of magnesium toxicity. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium carbonate is relatively inexpensive and well tolerated, so it is prescribed most frequently. *Calcium carbonate* and *calcium acetate* are used to restrict phosphate absorption in patients with CKD and oxalate absorption in patients with inflammatory bowel disease. Recombinant full-length rhPTH(1–84) and a modified long-acting form of human PTH (LA-PTH) are novel therapies for managing chronic hypoparathyroidism that improve quality of life (Cusano et al., 2015).

Vitamin D

The physiology and corresponding mechanism of action of vitamin D were described previously in this chapter.

ADME

Vitamin D is absorbed from the small intestine. Bile is essential for adequate absorption of vitamin D and is also the primary route of vitamin D excretion. Patients who have intestinal bypass surgery or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption. Absorbed vitamin D circulates in the blood in association with vitamin D–binding protein. The vitamin disappears

from plasma with a $t_{1/2}$ of 20 to 30 h but is stored in fat depots for prolonged periods.

Therapeutic Uses for Vitamin D

The major therapeutic uses of vitamin D are:

- Prophylaxis and cure of nutritional rickets
- Treatment of metabolic rickets and osteomalacia, particularly in the setting of CKD
- Treatment of hypoparathyroidism
- Prevention and treatment of osteoporosis
- Dietary supplementation

Nutritional Rickets. Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The incidence of this condition in the U.S. is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breastfed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (see Table 52–1) (Wagner and Greer, 2008), usually administered with vitamin A, for which purpose a number of balanced vitamin A and D preparations are available. *Because the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.* Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca^{2+} and phosphate concentrations in about 10 days, with radiographic evidence of healing in about 3 weeks. However, a larger dose of 3000 to 4000 units daily often is prescribed for more rapid healing, particularly when severe thoracic rickets compromises respiration.

Treatment of Osteomalacia and CKD-MBD. Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with CKD are at risk for developing osteomalacia but also may develop a complex bone disease called CKD-MBD, formerly known as *renal osteodystrophy*. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In CKD-MBD, low BMD may be accompanied by high-turnover bone lesions, typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease.

The therapeutic approach to the patient with CKD-MBD depends on its skeletal manifestation. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended. Administration of calcium-containing phosphate binders along with calcitriol may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease. The increased calcium burden associated with calcium-based phosphate binders likely contributes to the increased incidence of vascular calcification in patients with CKD.

Non–calcium-containing phosphate binders are highly effective alternatives to traditional calcium-based agents. *Sevelamer hydrochloride* is a nonabsorbable polymer that acts as a nonselective anion exchanger. The drug is modestly water soluble, and only trace amounts are absorbed from the GI tract. *Sevelamer* not only effectively lowers serum phosphate concentration in hemodialysis patients but also binds bile acids and, to a lesser extent, low-density lipoprotein cholesterol and fat-soluble vitamins. Side effects of *sevelamer hydrochloride* include vomiting, nausea, diarrhea, dyspepsia, and metabolic acidosis.

Sevelamer carbonate is equivalent to *sevelamer hydrochloride* in terms of safety and tolerability, with a lower likelihood of inducing metabolic acidosis. *Lanthanum carbonate* is a poorly permeable trivalent cation that is highly effective in treating the hyperphosphatemia associated with CKD-MBD but is associated with GI side effects.

Two iron-based phosphate binders also are commercially available. *Sucroferric oxyhydroxide* is a polynuclear iron(III)–oxyhydroxide compound that binds phosphate by ligand exchange. The drug exhibits similar phosphate control efficacy as *sevelamer* with a lower daily pill burden. *Ferric citrate* also exhibits comparable phosphate control efficacy to *sevelamer* and to *calcium acetate*. In addition, *ferric citrate* delivers a significant amount of iron, resulting in increased erythropoietic parameters and the possibility of iron overload with chronic dosing. Diarrhea is a common side effect of both iron-based phosphate binders (Shah et al., 2015).

Niacin and *nicotinic acid* lower serum phosphate and have been proposed as alternatives to the use of *sevelamer*. Extended-release *niacin* does not improve cardiovascular outcomes and is associated with greater all-cause mortality. Although *nicotinic acid* reduces hyperphosphatemia, *sevelamer* exhibits greater efficacy in controlling hyperphosphatemia as well as the Ca·P product (Ahmadi et al., 2012; Kalil et al., 2015).

Hypoparathyroidism. Vitamin D and its analogues are the mainstay of the therapy of hypoparathyroidism. Dihydrotachysterol (DHT), a reduced form of vitamin D_2, has a faster onset, shorter duration of action, and greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent; however, it is no longer available in the U.S. Although most hypoparathyroid patients respond to any form of vitamin D, *calcitriol* may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

Prevention and Treatment of Osteoporosis. This is described separately further in the chapter.

Dietary Supplementation. See Table 52–1.

Adverse Effects of Vitamin D Therapy

The primary toxicity associated with *calcitriol* reflects its potent effect to increase intestinal absorption of Ca^{2+} and phosphate, along with the potential to mobilize osseous Ca^{2+} and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates *calcitriol* therapy and may limit its use at doses that effectively suppress PTH secretion. Noncalcemic vitamin D analogues provide alternative interventions, although they do not obviate the need to monitor serum Ca^{2+} and phosphorus concentrations. Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support; forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca^{2+} concentration falls to normal, and Ca^{2+} in soft tissue tends to be mobilized. Conspicuous improvement in kidney function occurs unless kidney damage has been severe.

Available Vitamin D Analogues

Cholecalciferol (vitamin D_3) and *calcitriol* (1,25-dihydroxycholecalciferol) are available for oral administration or injection. Several derivatives of vitamin D are also used therapeutically.

Doxercalciferol (1α-hydroxyvitamin D_2), a prodrug that first must be activated by hepatic 25-hydroxylation, is approved for use in treating secondary hyperparathyroidism. *DHT* is a reduced form of vitamin D_2. In the liver, DHT is converted to its active form, 25-OH dihydrotachysterol. DHT is effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum Ca^{2+} concentration after 2 weeks of daily administration. The hypercalcemic effects typically persist for 2 weeks but can last twice that long. DHT (not marketed in the U.S.) is available for oral administration in doses ranging from 0.2 to 1 mg/day (average 0.6 mg/day).

Ergocalciferol (calciferol) is vitamin D_2. It is available for oral administration. *Ergocalciferol* is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D–resistant rickets type II, typically in doses of 50,000 to 200,000 units/day in conjunction with calcium supplements. *1α-Hydroxycholecalciferol* (1-OHD_3, alfacalcidol) is a synthetic vitamin D_3 derivative that is already hydroxylated in the 1α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-$(OH)_2D_3$. It is equivalent to *calcitriol* in assays for stimulation of intestinal absorption of Ca^{2+} and bone mineralization; it does not require renal activation. It is available in the U.S. for experimental purposes.

Analogues of Calcitriol. Several vitamin D analogues suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriene (Calcipotriol). *Calcipotriol* is a synthetic derivative of *calcitriol* with a modified side chain. *Calcipotriol* is less than 1% as active as *calcitriol* in regulating Ca^{2+} metabolism. *Calcipotriol* has been studied extensively as a treatment of psoriasis and is available for topical use (see Chapter 75).

Paricalcitol. *Paricalcitol* (1,25-dihydroxy-19-norvitamin D_2) is a synthetic *calcitriol* derivative that lacks the exocyclic C19 and has a vitamin D_2 rather than vitamin D_3 side chain. It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Mazzaferro et al., 2014). *Paricalcitol* administered orally or intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with CKD.

Maxacalcitol. Known variously as 1,25-dihydroxy-22-oxavitamin D_3, OCT, and 22-oxacalcitriol, *maxacalcitol* differs from *calcitriol* only in the substitution of C-22 with an O atom. *Oxacalcitriol* has a low affinity for vitamin D–binding protein; thus, more of the drug circulates in the free (unbound) form and is metabolized more rapidly than *calcitriol*, with a consequent shorter $t_{1/2}$. *Oxacalcitriol* is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in CKD. *Oxacalcitriol* is not available in the U.S.

Calcitonin

Mechanism of Action

The CTR, a GPCR that couples to multiple G proteins, mediates *calcitonin*'s actions. The hypocalcemic and hypophosphatemic effects of *calcitonin* are caused predominantly by direct inhibition of osteoclastic bone resorption (Henriksen et al., 2010). The *calcitonin* peptide family also includes CGRP, the closely related peptide *adrenomedullin, intermedin*, and *amylin*. CGRP and adrenomedullin are potent endogenous vasodilators.

Diagnostic Use

Calcitonin is a sensitive and specific marker for the presence of MTC, a neuroendocrine malignancy originating in thyroid parafollicular C cells.

Therapeutic Use

Calcitonin lowers plasma Ca^{2+} and phosphate concentrations in patients with hypercalcemia. *Calcitonin* is administered through injection or nasal spray. Although *calcitonin* is effective for up to 6 h in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor downregulation (Henriksen et al., 2010). Use of *calcitonin* does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents. *Calcitonin* is effective in disorders of increased skeletal remodeling, such as Paget disease, and in some patients with osteoporosis. For Paget disease, *calcitonin* generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week. Side effects of *calcitonin* include nausea, hand swelling, urticaria, and, rarely, intestinal cramping. Hypersensitivity reactions, including anaphylaxis, have also been reported.

Bisphosphonates

Chemistry

Bisphosphonates are analogues of pyrophosphate that contain two phosphonate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate (Figure 52–8). These agents form a three-dimensional structure capable of chelating divalent cations such as Ca^{2+} and have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. *First-generation bisphosphonates* (*medronate*, *clodronate*, and *etidronate*) contain minimally modified side chains or possess a chlorophenol group (*tiludronate*) and are the least-potent agents. *Second-generation aminobisphosphonates* (e.g., *alendronate* and *pamidronate*) contain a nitrogen group in the side chain and are 10 to 100 times more potent than first-generation compounds. *Third-generation bisphosphonates* (e.g., *risedronate* and *zoledronate*) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents (Ebetino et al., 2011).

Mechanism of Action

Bisphosphonates directly inhibit bone resorption. They concentrate at sites of active remodeling, remain in the matrix until the bone is remodeled, and then are released in the acid environment of the resorption lacunae and induce apoptosis in osteoclasts. Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects (Cremers and Papapoulos, 2011). The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

ADME

All oral bisphosphonates are poorly absorbed from the intestine. They have remarkably limited bioavailability (<1% [*alendronate*, *risedronate*] to 6% [*etidronate*, *tiludronate*]), which is further reduced by food and medications containing divalent cations such as calcium supplements, antacids, and iron. Hence, these drugs should be administered with a full glass of water following an overnight fast and at least 30 min before breakfast. Bisphosphonates distribute extensively into bone, undergo negligible hepatic clearance, and are excreted unchanged by the kidneys. Renal excretion of bisphosphonates declines proportionally with kidney function, and they are not recommended for patients with a creatinine clearance of less than 30 mL/min (Cremers and Papapoulos, 2011; Ott, 2015).

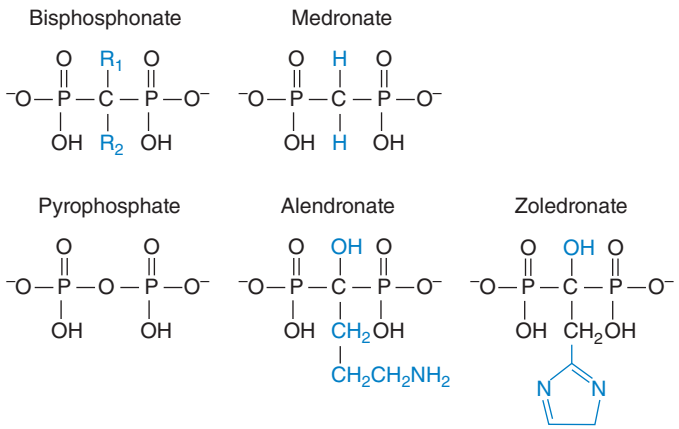

Figure 52–8 *Pyrophosphate and bisphosphonates.* The substituents (R_1 and R_2) on the central carbon of the bisphosphonate parent structure are shown in blue. Examples of a first-generation bisphosphonate (*medronate*), a second-generation aminobisphosphonate (*alendronate*), and a third-generation bisphosphonate (*zoledronate*) are shown.

Therapeutic Uses

Bisphosphonates are used extensively in conditions characterized by osteoclast-mediated bone resorption, including Paget disease, tumor-associated osteolysis, and hypercalcemia. In particular, much interest is focused on the role of bisphosphonates in the treatment of osteoporosis, including postmenopausal osteoporosis and steroid-induced osteoporosis. Bisphosphonate treatment is associated with increased BMD and protection against fracture. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation through their antiangiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggested that these agents delay or prevent development of metastases as a component of endocrine adjuvant therapy (Early Breast Cancer Trialists' Collaborative, 2015). Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Adverse Effects

Oral bisphosphonates can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Patients with active upper GI disease should not be given oral bisphosphonates. Initial parenteral infusion of *pamidronate* may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort, and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are short lived and generally do not recur with subsequent administration.

Zoledronate can cause severe hypocalcemia and has been associated with nephrotoxicity, deterioration of kidney function, and potential kidney disease. Infusion of *zoledronate*, 4 mg, should be performed over at least 15 min; patients should have standard laboratory and clinical parameters of kidney function assessed prior to treatment and periodically thereafter to monitor for deterioration in kidney function. Bisphosphonate use also is associated with osteonecrosis of the jaw (a rare event, with an incidence of ~2 in 100,000 patient-years in which the precise causal role of bisphosphonates has not been elucidated) as well as stress fractures in the lateral cortex of the femoral shaft (most commonly associated with *alendronate* and rarely with *zoledronate*) (Reid, 2015).

Available Bisphosphonates

Etidronate sodium is used for treatment of Paget disease and may be used parenterally to treat hypercalcemia (although largely supplanted for this use by *amidronate* and *zoledronate*). *Pamidronate* (available in the U.S. only for parenteral administration) is approved for management of hypercalcemia associated with malignancy and Paget disease and for prevention of bone loss in breast cancer and multiple myeloma; it also is effective in other skeletal disorders. For treatment of hypercalcemia, *pamidronate* may be given as an intravenous infusion of 60 to 90 mg over 2 to 24 h.

Several newer bisphosphonates have been approved for treatment of Paget disease. These include *tiludronate*, *alendronate*, and *risedronate*. *Tiludronate* standard dosing is 400 mg/day orally for 3 months. *Tiludronate* in recommended doses does not interfere with bone mineralization, unlike *etidronate*. *Zoledronate* is approved for treating Paget disease; administered as a single 5-mg infusion, *zoledronate* decreases bone turnover markers for 6 months with no loss of therapeutic effect. *Zoledronate* is widely used for prevention of osteoporosis in patients with prostate and breast cancer receiving hormonal therapy. It reduces both vertebral and nonvertebral fractures. A 4-mg formulation is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors. The potent bisphosphonate *ibandronate* is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly.

For patients in whom oral bisphosphonates cause severe esophageal [illegible] *intravenous zoledronate* and *ibandronate* offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, *ibandronate* (3 mg) is given intravenously every 3 months. *Zoledronate* is the first bisphosphonate to be approved for once-yearly intravenous treatment of osteoporosis (5 mg annually).

Parathyroid Hormone

Continuous administration of PTH or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, *intermittent* PTH administration promotes bone growth. Although hypoparathyroidism was the last classic endocrine-deficiency disease to have the missing hormone as an available treatment option, PTH analogues are now available to these patients.

Chemistry

As described previously, PTH is a single-polypeptide chain of 84 amino acids with a molecular mass of about 9500 Da. The classic biological activity of PTH is associated with the N-terminal portion of the peptide; residues 1 to 27 are required for optimal binding to the PTHR and hormone activity. Methionine residues at positions 8 and 18 may be oxidized, reducing PTH biological activity (Ursem et al., 2020). Such oxidized PTH is not detected by routine clinical analysis and may contribute to discrepancies between apparent circulating PTH levels and its action (Hocher et al., 2012; Zeng et al., 2020). Nonetheless, its contribution to skeletal turnover in chronic kidney disease is negligible (Ursem et al., 2021). Currently available PTH analogues include *teriparatide*, a synthetic human 34–amino acid amino-terminal PTH fragment [hPTH(1–34)], and a full-length replica of endogenous PTH, recombinant human PTH consisting of 84 amino acids [rhPTH(1–84)] (Kim and Keating, 2015). The PTHrP(1–34) analogue *abaloparatide* is FDA-approved for treating postmenopausal osteoporosis in women at high risk for fractures (Sleeman and Clements, 2019). Comprehensive skeletal evaluation of BMD in postmenopausal osteoporosis is required prior to initiating treatment. Consensus opinion recommends bisphosphonates in women without contraindications as the primary intervention for reducing hip, nonvertebral, and vertebral fractures (Black and Rosen, 2016). *Teriparatide* (see below) reduces the risk of nonvertebral and vertebral fractures. Preparations of human recombinant PTH (rhPTH) are not currently FDA- or EMA-approved.

Mechanism of Action

The physiological functions and mechanism of action of PTH were described previously in the chapter.

ADME

These agents are peptides and are administered by subcutaneous injection (see Drugs Available). Pharmacokinetics and systemic actions of *teriparatide* on mineral metabolism are the same as for PTH. Serum PTH concentrations peak at 30 min after the injection and are undetectable within 3 h, whereas the serum Ca^{2+} concentration peaks at 4 to 6 h after administration. *Teriparatide* bioavailability averages 95%. The drug's volume of distribution is approximately 0.1 L/kg. The elimination of *teriparatide* proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion. *Teriparatide* systemic clearance averages 62 L/h in women and 94 L/h in men. The elimination $t_{1/2}$ of serum *teriparatide* is about 1 h when administered subcutaneously versus 5 min when administered intravenously.

Abaloparatide is supplied in an injector pen with 30 daily doses. The peptide is rapidly absorbed (bioavailability = 36%), achieving peak concentrations approximately 30 min following subcutaneous injection. Elimination $t_{1/2}$ is approximately 1.7 h; clearance is, presumably, by proteolytic hydrolysis, with renal elimination of peptide fragments.

Therapeutic Uses

Teriparatide [hPTH(1–34)] and *abaloparatide* [PTHrP(1–34)] are the only anabolic agents currently available that increase new bone formation. They are approved for use in treating severe osteoporosis in patients at a high risk for fracture. In postmenopausal women with osteoporosis, *teriparatide* increases BMD and reduces the risk of vertebral and nonvertebral fractures. Candidates for treatment with *teriparatid* and

abaloparatide include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy. Men with primary or hypogonadal osteoporosis are also candidates for treatment with these agents.

Adverse Effects

Adverse effects include hypercalcemia (the incidence with *abaloparatide* is lower than observed with *teriparatide*; Miller et al., 2016), exacerbation of nephrolithiasis, and elevation of serum uric acid levels. Development of osteosarcoma has been a serious concern in patients treated with *teriparatide*; however, postmarketing surveillance suggests that there is no causal association between *teriparatide* use and osteosarcoma (Andrews et al., 2012). Nevertheless, *teriparatide* and *abaloparatide* carry black-box warnings, and use should be limited to no more than 2 years and avoided in patients who are at increased baseline risk for osteosarcoma (including those with Paget disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). Orthostatic hypotension may occur shortly after injection of *abaloparatide*.

Drugs Available

Teriparatide is administered by once-daily subcutaneous injection of 20 μg into the thigh or abdomen. *Abaloparatide* is administered at a starting dose of 80 μg by subcutaneous injection into the periumbilical region of the abdomen. The site of administration should be rotated, but the time at which the injection is made should be the same each day. Subcutaneous administration of *abaloparatide* reduced the risk of new vertebral and nonvertebral fractures over a period of 18 months (Miller et al., 2016). Shorter studies demonstrated increased lumbar spine and hip density that were greater than those achieved with *teriparatide* (Leder et al., 2015).

Long-acting formulations of PTH (LA-PTH) currently are in development (Maeda et al., 2013). Such formulations may offer an advantage over *teriparatide*, which is limited by its short (4- to 6-h) duration of effect on serum Ca^{2+} concentrations. Another agent that consists of the N-terminal biologically active region of PTH linked to a collagen-binding domain exhibited sustained increases in BMD by more than 10% for 1 year in rodents after single-dose administration (Ponnapakkam et al., 2012).

A novel class of drugs that inhibits the CaSR (*calcilytics*) stimulates the secretion of PTH and decrease renal excretion of Ca^{2+}. The calcilytic *ronacaleret*, investigated for potential treatment of postmenopausal osteoporosis, was less effective than *teriparatide*, and its development was subsequently halted (Fitzpatrick et al., 2012). The role of calcilytics in the treatment of diseases involving hypocalcemia or hypercalciuria continues to be explored (Nemeth and Shoback, 2013).

Calcium-Sensing Receptor Mimetics

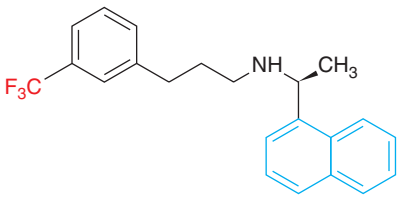
Calcimimetics are drugs that mimic the stimulatory effect of Ca^{2+} on the CaSR to inhibit PTH secretion by the parathyroid glands. *Cinacalcet* and *etelcalcetide*, the only approved drugs in the class currently, offer a pharmacotherapeutic alternative to surgery for the treatment of PTH hypersecretion diseases.

Chemistry

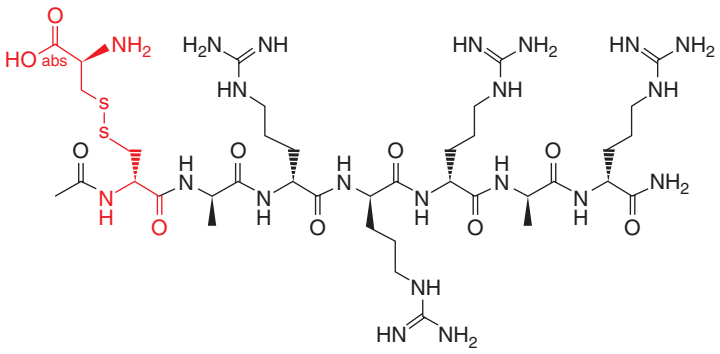
Cinacalcet is available as a hydrochloride and is formulated with one chiral center having an R-absolute configuration; the *R*-enantiomer is the more potent enantiomer and is primarily responsible for *cinacalcet*'s pharmacodynamic activity. *Etelcalcetide*, an octapeptide of D-amino acids, is available as a hydrochloride salt and is comparatively larger than *cinacalcet* (Figure 52–9).

Mechanism of Action

By enhancing the sensitivity of the CaSR to extracellular Ca^{2+}, calcimimetics lower the concentration of Ca^{2+} at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as aminoglycosides (e.g., *streptomycin*, *gentamicin*, and *neomycin*) and polybasic amino acids (e.g., *polylysine*) are full agonists and are referred to as *type I calcimimetics*. They are able to activate the CaSR directly with no other cofactors. On the other hand, *cinacalcet* and *etelcalcetide* are positive allosteric CaSR modulators that require the presence of Ca^{2+} or other full agonists to enhance the sensitivity of activation without altering the maximal response and are designated *type II calcimimetics* (Cianferotti et al., 2015; Filopanti et al., 2013).



Cinacalcet



Etelcalcetide

Figure 52–9 *Structures of cinacalcet and etelcalcetide.* *Cinacalcet* is depicted as the free base. The compound is a phenyl-propylamine derivative with a 3-trifluoromethyl group (red) and naphthalene moiety (blue). *Etelcalcetide* is a short eight-residue peptide formed from D-amino acids. The N-terminal D-Cys is linked to an L-Cys by a disulfide (S-S) bond and is capped with an acetyl group. Formation of a covalent disulfide bond between the D-cysteine in *etelcalcetide* and Cys^{482} of the CaSR allosterically activates the CaSR (Nemeth et al., 2018).

ADME

Cinacalcet exhibits first-order absorption, with peak serum concentrations achieved 2 to 6 h after oral administration. Maximal effects on serum PTH occur 2 to 4 h after administration. It has an extraordinarily large volume of distribution of 1000 L and is metabolized by multiple hepatic CYPs, including CYPs 3A4, 2D6, and 1A2. Metabolites are eliminated by biliary (15%) and renal excretion (85%). *Cinacalcet* has an elimination $t_{1/2}$ of 30 to 40 h.

Etelcalcetide exhibits linear pharmacokinetics after intravenous administration. Plasma concentrations reach steady state approximately 8 weeks after thrice-weekly dosing; its elimination $t_{1/2}$ is 3 to 5 days in hemodialysis patients (Wu et al., 2018). *Etelcalcetide* is neither a substrate nor an inhibitor of CYPs or drug transport proteins. The drug is cleared by renal excretion in patients with normal kidney function; hemodialysis is the predominant elimination pathway in patients receiving hemodialysis (Wu et al., 2018).

Therapeutic Uses

Cinacalcet and *etelcalcetide* are approved for the treatment of secondary hyperparathyroidism in adults with CKD on dialysis. In addition, *cinacalcet* is approved for hypercalcemia in adults with parathyroid carcinoma and for hypercalcemia in adult patients with primary hyperparathyroidism who are not candidates for surgical parathyroidectomy. Treatment with *cinacalcet* or *etelcalcetide* lowers serum PTH (Block et al., 2017a, 2017b; Martin et al., 2014; Nemeth and Shoback, 2013). In patients with secondary hyperparathyroidism on dialysis, treatment with *cinacalcet* significantly decreases bone turnover and improves bone histology (Behets et al., 2015). Moreover, by lowering serum FGF23 concentrations, *cinacalcet* treatment decreases the rate of cardiovascular death and major cardiovascular events (Moe et al., 2015).

Adverse Effects

The principal adverse event common to *cinacalcet* and *etelcalcetide* is hypocalcemia. Thus, the drugs should not be used if the initial serum [Ca^{2+}] is less than 8.4 mg/dL; serum Ca^{2+} and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy and after changing dosage. Seizure threshold is lowered by significant reductions in serum Ca^{2+}, so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is less than 100 pg/mL, and the drugs should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL. *Etelcalcetide* also may increase risk for upper gastrointestinal bleeding. Overall, however, the safety profile of *etelcalcetide* appears similar to *cinacalcet* (Block et al., 2019).

Drug Interactions

Drug interactions can be anticipated with drugs that interfere with Ca^{2+} homeostasis or that hinder *cinacalcet* absorption. Potentially interfering drugs include vitamin D analogues, phosphate binders, bisphosphonates, *calcitonin*, glucocorticoids, *gallium*, and *cisplatin*. Caution is recommended when *cinacalcet* is coadministered with strong inhibitors of CYP3A4 (e.g., *ketoconazole*, *erythromycin*, or *itraconazole*). Because *cinacalcet* is a strong inhibitor of CYP2D6, dose adjustment may be required for concomitant medications that are CYP2D6 substrates (e.g., many β adrenergic receptor blockers, *flecainide*, *vinblastine*, and most tricyclic antidepressants). Conversely, *etelcalcetide* is neither a substrate nor an inhibitor of CYPs or drug transport proteins and has no known risks for drug-drug interactions (Wu et al., 2018).

Drugs Available

Cinacalcet is available in 30-, 60-, and 90-mg tablets. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with CKD on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2 to 4 weeks to maintain the PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Etelcalcetide is available only as an injectable formulation and in single-dose 2.5-, 5-, and 10-mg vials. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with CKD on dialysis is 5 mg administered by intravenous bolus injection three times per week at the end of the dialysis treatment. The dose may be titrated upward in 2.5- or 5-mg increments, based on PTH and corrected serum calcium response, no more frequently than every 4 weeks up to a maximum recommended dosage of 15 mg three times per week.

The investigational CaSR agonist *evocalcet* exhibits similar PTH lowering and a better gastrointestinal side effect profile compared to *cinacalcet* in adult dialysis patients treated for secondary hyperparathyroidism (Fukagawa et al., 2018). The drug is currently not available for use in the U.S.

Fluoride

Fluoride is discussed because of its effects on dentition and bone and its toxic properties.

Mechanism of Action

Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts. However, the apparent effects of *fluoride* in osteoporosis are slight compared with those achieved with PTH or others. *Fluoride* can inhibit several enzyme systems and diminish tissue respiration and anaerobic glycolysis.

ADME

Fluoride is obtained from the ingestion of plants and water, with absorption taking place largely in the intestine. A second route of absorption is through the lungs, and inhalation of *fluoride* present in dusts and gases constitutes the major route of industrial exposure. *Fluoride* is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone. The kidneys are the major sites of *fluoride* excretion. Small amounts of *fluoride* also appear in sweat, milk, and intestinal secretions.

Therapeutic Use

Because it is concentrated in the bone, the radionuclide ^{18}F has been used in skeletal imaging. *Sodium fluoride* is a mainstay of therapy for the prevention of dental carries.

Fluoride and Dental Caries. Supplementation of water *fluoride* content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth. There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of *fluoride* solutions by dental personnel appears to be effective on newly erupted teeth and can reduce the incidence of caries by 30% to 40%. Dietary *fluoride* supplements should be considered for children less than 12 years of age whose drinking water contains less than 0.7 ppm *fluoride*. Adequate incorporation of *fluoride* into teeth hardens the outer layers of enamel and increases resistance to demineralization. The *fluoride* salts usually employed in dentifrices are *sodium fluoride* and *stannous fluoride*. *Sodium fluoride* also is available in a variety of preparations for oral and topical use.

Regulation of the *fluoride* concentration of community water supplies periodically encounters vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water.

Acute Poisoning

Acute *fluoride* poisoning usually results from accidental ingestion of *fluoride*-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of *fluoride* on the intestinal mucosa. Systemic symptoms

are varied and severe: increased irritability of the CNS consistent with the Ca^{2+}-binding effect of *fluoride* and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of *sodium fluoride* for humans is about 5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with limewater (0.15% calcium hydroxide solution) or other Ca^{2+} salts to precipitate the *fluoride*. *Calcium gluconate* is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

Chronic Poisoning

In humans, the major manifestations of chronic ingestion of excessive *fluoride* are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described more than 60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown– to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Mottling is one of the first visible signs of excess *fluoride* intake during childhood. Continuous use of water containing about 1 ppm of *fluoride* may result in very mild mottling in 10% of children; at 4 to 6 ppm, the incidence approaches 100%, with a marked increase in severity. Severe dental fluorosis formerly occurred in regions where local water supplies had a very high *fluoride* content (e.g., Pompeii, Italy, and Pike's Peak, CO). Current regulations in the U.S. require lowering the *fluoride* content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a *fluoride* content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time.

Integrated Approach to Prevention and Treatment of Osteoporosis

Osteoporosis is a major and growing public health problem in developed nations. Approximately 50% of women and 25% of men more than 50 years of age will experience an osteoporosis-related fracture. Important reductions in fracture risk can be achieved with attention to health (muscle-strengthening exercise; avoiding smoking and excessive alcohol use) and nutrition (i.e., increased dietary calcium or calcium or vitamin D supplements). Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Because bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a steady-state level, after which BMD reaches a new plateau (Figure 52–10).

Pharmacological treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. Antiresorptive drugs (such as the bisphosphonates, estrogen, the SERM *raloxifene*, and, to some extent, *calcitonin*) inhibit osteoclast-mediated bone loss, thereby reducing bone turnover. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of HRT have mandated a major reexamination of treatment options (see further and Chapter 48). In addition to antiresorptive agents, the FDA has approved the hPTH(1–34) fragment (*teriparatide*) and the hPTHrP(1–34) fragment (*abaloparatide*) for use in treating postmenopausal women with osteoporosis. *Teriparatide* is also approved for use in increasing bone mass in men with primary or hypogonadal osteoporosis.

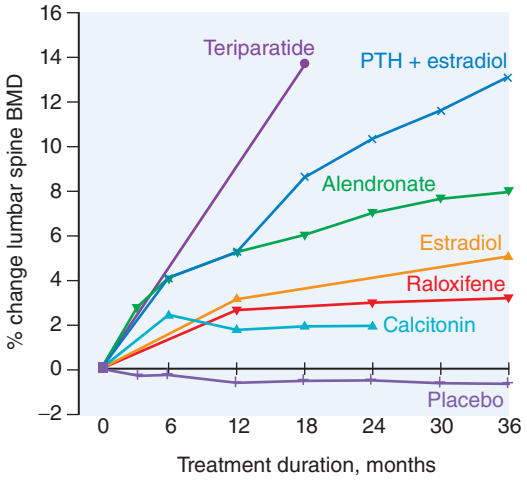


Figure 52–10 *Relative efficacy of different therapeutic interventions on BMD of the lumbar spine.* *Teriparatide* (40 μg) (Neer et al., 2001), PTH (25 μg) + *estradiol*, *alendronate* (10 mg), *estradiol* (0.625 mg/d), *raloxifene* (120 mg), and *calcitonin* (200 IU). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

Antiresorptive Agents

Bisphosphonates

Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates, *alendronate* and *risedronate*, have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization. *Alendronate*, *risedronate*, and *ibandronate* are used for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis.

Monoclonal Antibodies

Denosumab. RANK ligand (RANKL) binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. *Denosumab* is a human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG and thereby reducing the binding of RANKL to RANK. *Denosumab* blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously, 60 mg once every 6 months. Osteonecrosis of the jaw and fractures of the femoral shaft have been reported with *denosumab* use. It is contraindicated in the setting of preexisting hypocalcemia.

Burosumab. The recombinant human monoclonal anti-FGF23 antibody *burosumab* is effective in correcting the hypophosphatemia associated with XLH and osteomalacia. Monthly administration provides prolonged restoration of serum phosphate by reducing urinary phosphate excretion without adversely altering serum PTH or calcium levels. *Burosumab* is approved for treatment of XLH in children (Carpenter et al., 2018) and adults (Insogna et al., 2018) and for tumor-induced osteomalacia (Imanishi et al., 2021). It significantly improves biochemical markers of bone formation and resorption, as well as histomorphometric measures of osteomalacia in adults with XLH when administered

at 1 mg/kg every 4 weeks (Insogna et al., 2018, 2019). Nephrocalcinosis has been reported during *burosumab* treatment. The drug is contraindicated with oral phosphate and active vitamin D analogues, when serum phosphorus is within or above the normal limits, and in patients with severe kidney impairment or end-stage kidney disease.

Romosozumab. *Romosozumab* is a monoclonal antibody that binds sclerostin and relatively rapidly increases bone formation (McClung, 2018). In a clinical trial, initiation of *denosumab* maintained or increased bone mineral density following cessation of *romosozumab* (Cosman et al., 2016).

Selective Estradiol Receptor Modulators

Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. *Raloxifene* acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an antiestrogen on the breast (see Chapter 48). In postmenopausal women, *raloxifene* stabilizes and modestly increases BMD and reduces the risk of vertebral compression fracture (Komm and Mirkin, 2014). *Raloxifene* is approved for both the prevention and the treatment of osteoporosis. Adverse effects of *raloxifene* include worsening of vasomotor symptoms. The drug is also associated with an increased risk of deep vein thrombosis and pulmonary embolism, so it is contraindicated in adults with a history of venous thromboembolism.

Estrogen

Postmenopausal status or estrogen deficiency at any age significantly increases a patient's risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (see Chapter 48). However, the Women's Health Initiative studies indicated that HRT significantly increases risks of heart disease and breast cancer; consequently, HRT is now reserved only for the short-term relief of vasomotor symptoms associated with menopause.

Calcium

The rationale for using supplemental calcium to protect bone varies with time of life. For preteens and adolescents, adequate substrate calcium is required for bone accretion. Higher Ca^{2+} intake during the third decade of life is positively related to the final phase of bone acquisition. There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. In elderly subjects, supplemental calcium suppresses bone turnover and improves BMD. Patients may increase calcium by dietary means and may choose from many palatable, low-cost calcium preparations. The most frequently prescribed is carbonate, which should be taken with meals to facilitate dissolution and absorption. Traditional dosing of calcium is about 1000 mg/day, nearly the amount present in a quart of milk. Adults more than 50 years of age need 1200 mg of calcium daily. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of 2000 mg or more frequently are reported to be constipating.

Vitamin D and Its Analogues

Modest supplementation with vitamin D (400–800 IU/day) may improve intestinal Ca^{2+} absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. Supplemental vitamin D in combination with calcium reduces fracture incidence.

The use of *calcitriol* to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Higher doses of *calcitriol* appear to be more likely to improve BMD, but at the risk of developing hypercalciuria and hypercalcemia; therefore, close scrutiny of patients and dose are required. Restriction of dietary calcium may reduce toxicity during *calcitriol* therapy.

Calcitonin

Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis, most prominently in patients with high intrinsic rates of bone turnover. *Calcitonin* nasal spray (200 units/day) reduces the incidence of vertebral compression fractures by about 40% in osteoporotic women (Chesnut et al., 2000).

Thiazide Diuretics

Although not strictly antiresorptive, thiazides reduce urinary Ca^{2+} excretion and constrain bone loss in patients with hypercalciuria. *Hydrochlorothiazide*, 25 mg once or twice daily, may reduce urinary Ca^{2+} excretion substantially. Effective doses of thiazides for reducing urinary Ca^{2+} excretion generally are lower than those necessary for blood pressure control (see Chapters 29 and 32).

Anabolic Agents

Teriparatide, Abaloparatide, rhPTH

Teriparatide and *abaloparatide* increase new bone formation. *Teriparatide* and *abaloparatide* are approved by the FDA for treating osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. *Teriparatide* increases predominantly trabecular bone at the lumbar spine and femoral neck; it has less-significant effects at cortical sites. *Teriparatide* is approved at the 20-μg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects of *teriparatide* include injection-site pain, nausea, headaches, leg cramps, and dizziness. *Abaloparatide* is administered at a starting dose of 80 μg by subcutaneous injection into the periumbilical region of the abdomen. Subcutaneous administration of *abaloparatide* reduced the risk of new vertebral and nonvertebral fractures over 18 months. Differences in PTHR binding between *teriparatide* and *abaloparatide* permit the use of the higher dose of *abaloparatide* and may explain its greater bone formation with lower stimulation of bone resorption (Miller et al., 2016).

Preparations of rhPTH are not currently approved for use in the U.S. or E.U.

Combination Therapies

Osteoporosis

Because *teriparatide* stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of *alendronate* to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men. Sequential treatment with PTH(1–84) followed by *alendronate* increases vertebral BMD to a greater degree than *alendronate* or estrogen alone.

Paget Disease

Although most patients with Paget disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and *calcitonin* decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective.

Optimal therapy for Paget disease varies among patients. Bisphosphonates are the standard therapy. Intravenous *pamidronate* induces long-term remission following a single infusion. *Zoledronate* exhibits greater response rates and a longer median duration of complete response. Compared with *calcitonin*, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects.

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Vitamin D Analogues		
Ergocalciferol	• Vitamin D deficiency • Nutritional rickets • Vitamin D–resistant rickets • Familial hypophosphatemia • Hypoparathyroidism • Osteomalacia/osteoporosis	• Vitamin D_2 • May cause hypercalcemia
Cholecalciferol		• Vitamin D_3 • May cause hypercalcemia
Doxercalciferol	• Secondary hyperparathyroidism in patients with CKD	• 1-Hydroxylated ergocalciferol (1-OH-D_2) • "Activated" in the liver by 25-hydroxylation • May cause hypercalcemia, hypercalciuria, or hyperphosphatemia
Alfacalcidol	• Secondary hyperparathyroidism in patients with CKD	• 1-Hydroxylated cholecalciferol (1-OH-D_3) • "Activated" in the liver by 25-hydroxylation • May cause hypercalcemia, hypercalciuria, or hyperphosphatemia
Dihydrotachysterol	• Familial hypophosphatemia • Hypoparathyroidism • Osteoporosis • Secondary hyperparathyroidism in patients with CKD	• Reduced form of ergocalciferol • "Activated" in the liver by 25-hydroxylation • May cause hypercalcemia, hypercalciuria, or hyperphosphatemia • Not available in the U.S.
Calcifediol	• Hypocalcemia • Secondary hyperparathyroidism in patients with CKD	• 25-Hydroxylated form of cholecalciferol • "Activated" in the kidney by 1-hydroxylation • Not available in the U.S.
Calcitriol	• Hypocalcemia • Secondary hyperparathyroidism in patients with CKD • Hypoparathyroidism	• 1,25-Dihydroxylated form of cholecalciferol • Activated form of vitamin D • May cause hypercalcemia, hypercalciuria, or hyperphosphatemia
Paricalcitol	• Secondary hyperparathyroidism in patients with CKD	• 1,25-Dihydroxy-19-norvitamin D_2 • Minimal effects on serum calcium and phosphorus
Maxacalcitol	• Secondary hyperparathyroidism in patients with CKD	• 1,25-Dihydroxy-22-oxavitamin D_3 • Shorter $t_{1/2}$ than calcitriol • Potent suppressor of PTH gene expression • Not marketed in the U.S.
Calcipotriol	• Psoriasis	• Negligible effects on serum calcium • For topical application only
Phosphate-Binding Agents • Taken with meals to reduce the amount of dietary phosphate absorbed		
Calcium carbonate	• Treatment and prevention of CKD-MBD	• Inexpensive, well tolerated, commonly used • 40% elemental calcium
Calcium acetate	• Treatment and prevention of CKD-MBD	• Well tolerated, commonly used • 25% elemental calcium
Sevelamer hydrochloride	• Treatment and prevention of CKD-MBD	• Nonabsorbable polymer that acts as a nonselective anion exchanger • Risk of metabolic acidosis
Sevelamer carbonate	• Treatment and prevention of CKD-MBD	• Same polymeric structure as sevelamer hydrochloride, with chloride replaced by carbonate • Decreased risk of metabolic acidosis
Lanthanum carbonate	• Treatment and prevention of CKD-MBD	• Risk of gastrointestinal obstruction and ileus • Contraindicated in bowel obstruction
Sucroferric oxyhydroxide (oral formulation)	• Treatment and prevention of CKD-MBD	• Polynuclear iron(III)–oxyhydroxide compound that binds phosphate by ligand exchange • Negligible absorption of iron • Injectable formulation is used for iron replacement therapy
Ferric citrate	• Treatment and prevention of CKD-MBD	• Iron absorption may lead to increased systemic iron parameters and toxicity

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Bisphosphonates • Inhibit osteoclast-mediated bone resorption		
Etidronate	• Paget disease • Heterotopic ossification • Hypercalcemia	• Esophagitis, esophageal ulcers or erosions reported with oral administration • Contraindicated in those with abnormalities that delay esophageal emptying • Risk of nephrotoxicity • Osteonecrosis of the jaw reported
Clodronate	• Paget disease • Treatment and prevention of osteoporosis • Hypercalcemia of malignancy • Prevention of bone loss in breast cancer and multiple myeloma	• Risk of nephrotoxicity • Osteonecrosis of the jaw reported • Not available in the U.S.
Tiludronate	• Paget disease	• Esophagitis, esophageal ulcers or erosions reported with oral administration • Caution in creatinine clearance <35 mL/min • Osteonecrosis of the jaw reported
Pamidronate	• Paget disease • Hypercalcemia of malignancy • Prevention of bone loss in breast cancer and multiple myeloma	• 10–100 times more potent than etidronate • Risk of nephrotoxicity • Osteonecrosis of the jaw reported • Fractures of the femoral shaft reported • Available in the U.S. only for parenteral administration
Alendronate	• Paget disease • Treatment and prevention of osteoporosis	• 10–100 times more potent than etidronate • Esophagitis, esophageal ulcers or erosions reported with oral administration • Contraindicated in those with abnormalities that delay esophageal emptying • Osteonecrosis of jaw, fractures of femoral shaft reported
Ibandronate	• Treatment and prevention of osteoporosis	• Esophagitis, esophageal ulcers or erosions reported with oral administration • Contraindicated in those with abnormalities that delay esophageal emptying • Risk of nephrotoxicity • Osteonecrosis of jaw, fractures of the femoral shaft, anaphylaxis reported
Risedronate	• Paget disease • Treatment and prevention of osteoporosis	• Third-generation agent • 10,000 times more potent than etidronate • Esophagitis, esophageal ulcers or erosions reported with oral administration • Contraindicated in those with abnormalities that delay esophageal emptying • Osteonecrosis of jaw, fractures of the femoral shaft reported • Many dosing regimens (daily to 2 months)
Zoledronate	• Paget disease • Treatment and prevention of osteoporosis • Hypercalcemia of malignancy • Adjunctive treatment of bone metastases from solid tumors and osteolytic lesions of multiple myeloma	• Third-generation agent • 10,000 times more potent than etidronate • Contraindicated in hypocalcemia and creatinine clearance <35 mL/min • May cause severe hypocalcemia • Risk of nephrotoxicity • Osteonecrosis of jaw, fractures of femoral shaft, anaphylaxis reported • Annual dosing for postmenopausal use
Parathyroid Hormone Analogues		
Teriparatide *[hPTH(1–34)]* Abaloparatide *[hPTHrP(1–34)]*	• Treatment of osteoporosis	• Anabolic agents • Increase new bone formation • Use should be limited to ≤2 years • Should not be used in patients who are at increased baseline risk for osteosarcoma
rhPTH	• Adjunctive treatment of hypocalcemia in patients with hypoparathyroidism	Not currently approved for use in U.S. or E.U.
Long-acting PTH	• Treatment of hypoparathyroidism	• Increases serum calcium concentrations in rodents for almost 24 h • Investigational use only

Drug Facts for Your Personal Formulary: *Agents Affecting Mineral Ion Homeostasis and Bone Turnover (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Calcium-Sensing Receptor Mimetics		
Cinacalcet	• Secondary hyperparathyroidism in adults with CKD on dialysis • Hypercalcemia in adults with parathyroid carcinoma • Hypercalcemia in adults with primary hyperparathyroidism who are not candidates for surgical parathyroidectomy	• May cause severe hypocalcemia • Concomitant use of strong inhibitors of CYP3A4 should be avoided • Dose adjustment may be required for concomitant medications that are CYP2D6 substrates
Etelcalcetide	• Secondary hyperparathyroidism in adults with CKD on dialysis	• May cause severe hypocalcemia • May worsen heart failure • Upper GI bleeding reported
Evocalcet	• Secondary hyperparathyroidism in adults with CKD on dialysis	• May cause severe hypocalcemia • Not available in the U.S.
Miscellaneous Agents		
Calcitonin	• Paget disease • Hypercalcemia • Postmenopausal osteoporosis	• Direct inhibitor of osteoclastic bone resorption • Anaphylaxis/hypersensitivity reported
Denosumab	• Treatment and prevention of osteoporosis • Treatment to increase bone mass in adults at high risk for fracture receiving cancer therapy	• Human monoclonal antibody that binds with high affinity to RANKL • Contraindicated in setting of preexisting hypocalcemia • Osteonecrosis of the jaw reported • Fractures of the femoral shaft reported
Raloxifene	• Treatment and prevention of osteoporosis	• Selective estrogen receptor modulator • Contraindicated in adults with history of venous thromboembolism; increased risk of deep vein thrombosis and pulmonary embolism
Hydrochlorothiazide	• Osteoporosis • Hypercalciuria	• Reduce urinary calcium excretion • Constrain bone loss in patients with hypercalciuria
Burosumab	• Treatment of X-linked hypophosphatemia • Treatment of FGF23-related hypophosphatemia in tumor-induced osteomalacia	• Human monoclonal antibody that binds to and inhibits FGF23 activity • Contraindicated with oral phosphate and active vitamin D analogues • Contraindicated when serum phosphorus is within or above the normal limits • Contraindicated in patients with severe kidney impairment or end-stage kidney disease • Hyperphosphatemia and nephrocalcinosis reported
Fluoride		
Sodium fluoride	• Prophylaxis of dental caries	• Childhood consumption of fluoridated drinking water reduces incidence of caries in permanent teeth • Topical application can reduce the incidence of caries by 30%–40%

Chapter 53

Pharmacotherapy for Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease

Keith A. Sharkey and Wallace K. MacNaughton

The stomach has a number of critical functions in the processes of digestion: storage, digestion, and defense. The volume of the stomach is quite small at rest, but the gastric musculature can undergo receptive relaxation to accommodate a meal volume of 1 to 2 L. Food is broken down in the presence of acid by the grinding actions of the thick muscular coats of the stomach, and the contents then pass in a regulated manner into the duodenum. Gastric acid not only serves to facilitate digestion, but it also provides an effective antimicrobial milieu that facilitates defense against pathogens.

Gastric acid and pepsin in the stomach normally do not produce damage or symptoms of acid-peptic diseases because of intrinsic defense mechanisms. The stomach is protected by a number of factors, collectively referred to as "mucosal defense," many of which are stimulated by the local generation of prostaglandins (PGs) and nitric oxide (NO). If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases revolutionized approaches to prevention and therapy of these common disorders.

Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the tone of the lower esophageal sphincter, and stimulating esophageal motility (see Chapter 54).

Physiology of Gastric Secretion

Gastric acid secretion is a complex and continuous process: Neuronal (acetylcholine [ACh], gastrin-releasing peptide [GRP]); paracrine (histamine); and endocrine (gastrin) factors regulate the secretion of H^+ by parietal cells (acid-secreting cells) (Figure 53–1). Their specific receptors (M_3, BB_2, H_2, and CCK_2, respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. Some of these receptors are also present on ECL cells, where they regulate the release of histamine. The H_2 receptor is a G protein-coupled receptor (GPCR) that activates the G_s–adenylyl cyclase–cyclic AMP–PKA pathway (see Chapters 3 and 43). ACh and gastrin signal through GPCRs that couple to the G_q-PLC-IP_3-Ca^{2+} pathway in parietal cells; GRP uses the same signaling pathway to activate gastrin secretion from G cells. In parietal cells, the cyclic AMP and the Ca^{2+}-dependent pathways activate H^+,K^+-ATPase (the proton pump), which exchanges H^+ and K^+ across the parietal cell membrane. This pump generates the largest ion gradient known in vertebrates, with an intracellular pH of about 7.3 and an intracanalicular pH of about 0.8.

The important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagus, the hypothalamus, and the nucleus of the solitary tract. Efferent fibers originating in the dorsal motor nuclei descend to the stomach via the vagus nerve and synapse with ganglion cells of the enteric nervous system (ENS). ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M_3 receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the ENS via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the "cephalic" phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum (Engevik et al., 2020).

The ECL cells, the source of gastric histamine, are usually near parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H_2 receptors to stimulate gastric acid secretion.

Gastrin, produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS

Abbreviations

ACh: acetylcholine
cAMP: cyclic adenosine monophosphate (cyclic AMP)
CCK: cholecystokinin
CNS: central nervous system
CYP: cytochrome P450
DU: duodenal ulcer
ECL: enterochromaffin-like cell
ENS: enteric nervous system
GERD: gastroesophageal reflux disease
GI: gastrointestinal
GPCR: G protein-coupled receptor
GRP: gastrin-releasing peptide
GU: gastric ulcer
HIST: histamine
IP_3: inositol 1,4,5-trisphosphate
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
OTC: over the counter
PG: prostaglandin
PK: protein kinase
PLC: phospholipase C
PPI: proton pump inhibitor
SARS-CoV-2 (COVID-19): severe acute respiratory syndrome coronavirus 2 (coronavirus disease 2019)
SST: somatostatin

activation, local distention, and chemical components of the gastric contents. In addition to releasing ACh, some vagal fibers to the stomach also release GRP (a 27–amino acid peptide); GRP activates the BB_2 bombesin receptor on G cells, activating the G_q-PLC-IP_3-Ca^{2+} pathway and causing secretion of gastrin. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin, produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to less than 3 stimulates somatostatin release, which in turn suppresses gastrin release in a negative-feedback loop. Somatostatin-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of somatostatin's inhibitory effect may contribute to excess gastrin production.

Parietal Cell H^+,K^+-ATPase

H^+,K^+-ATPase is the enzyme responsible for secreting protons into the lumen of the gastric gland (Engevik et al., 2020). It is a heterodimeric protein composed of two subunits that are the products of two genes. The *ATP4A* gene encodes the α subunit that contains the catalytic sites of the enzyme and forms the membrane pore, and the *ATP4B* gene encodes the β subunit of the H^+,K^+-ATPase, which contains an N-terminal cytoplasmic domain, a transmembrane domain, and a highly glycosylated extracellular domain. Hydronium ions bind to three active sites present in the α subunit, and secretion involves a conformational change that allows the movement of protons. This movement is balanced by the transport of K^+. The stoichiometry of transport is pH dependent, varying between two H^+ and two K^+ per molecule of ATP to one of each under more acidic conditions. Inhibiting the H^+,K^+-ATPase (or proton pump) is the mainstay of modern pharmacotherapy for acid-related disorders.

Gastric Defenses Against Acid

The extremely high concentration of H^+ in the gastric lumen requires robust defense mechanisms to protect the esophagus, stomach, and proximal small intestine (Wallace, 2008). The primary esophageal defense is the gastroesophageal junction—the lower esophageal sphincter in association with the diaphragm and angle of His—which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow. One key defense is the secretion of a mucous layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by PGs E_2 and I_2, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit PG formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease. The proximal part of the duodenum is protected from gastric acid through the production of bicarbonate, primarily from mucosal Brunner's glands.

Figure 53–1 outlines the rationale and pharmacological basis for the therapy of acid-peptic disease. The PPIs are used most commonly, followed by the histamine H_2 receptor antagonists.

Proton Pump Inhibitors

The most potent suppressors of gastric acid secretion are inhibitors of the gastric H^+,K^+-ATPase or proton pump (Figure 53–2). These drugs diminish the daily production of acid (basal and stimulated) by 80% to 95% (Shin and Sachs, 2008).

Mechanism of Action and Pharmacology

Six PPIs are available for clinical use: *omeprazole* and its S-isomer, *esomeprazole*, *lansoprazole* and its R-enantiomer, *dexlansoprazole*, *rabeprazole*, and *pantoprazole*. All PPIs have equivalent efficacy at comparable doses.

Proton pump inhibitors are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (see Figure 53–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H^+,K^+-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-h) suppression of acid secretion, despite the much shorter plasma $t_{1/2}$ of about 0.5 to 3 h of the parent compounds. Because they block the final step in acid production, the PPIs effectively suppress stimulated acid production, regardless of the physiological stimulus, as well as basal acid production.

The amount of H^+,K^+-ATPase increases after fasting; therefore, PPIs should be given before the first meal of the day. In most individuals, once-daily dosing is sufficient to achieve an effective level of acid inhibition, and a second dose, which is occasionally necessary, can be administered before an evening meal. Rebound acid hypersecretion occurs following prolonged treatment with PPIs, and clinical studies suggest that rebound after ceasing treatment can provoke symptoms such as dyspepsia.

To prevent degradation of PPIs by acid in the gastric lumen and improve oral bioavailability, oral dosage forms are supplied in different formulations:

- Enteric-coated pellets within gelatin capsules (*rabeprazole*)
- Delayed-release tablets (*lansoprazole*, *pantoprazole, rabeprazole*)
- Delayed-release capsules (*dexlansoprazole*, *esomeprazole*, *omeprazole, lansoprazole*)
- Delayed-release oral suspension (*esomeprazole, omeprazole, pantoprazole*)

The delayed-release and enteric-coated preparations dissolve only at alkaline pH, which improves the oral bioavailability of these acid-labile drugs. Patients for whom the oral route of administration is not available can be treated parenterally with *esomeprazole sodium, omeprazole sodium*, or *pantoprazole*.

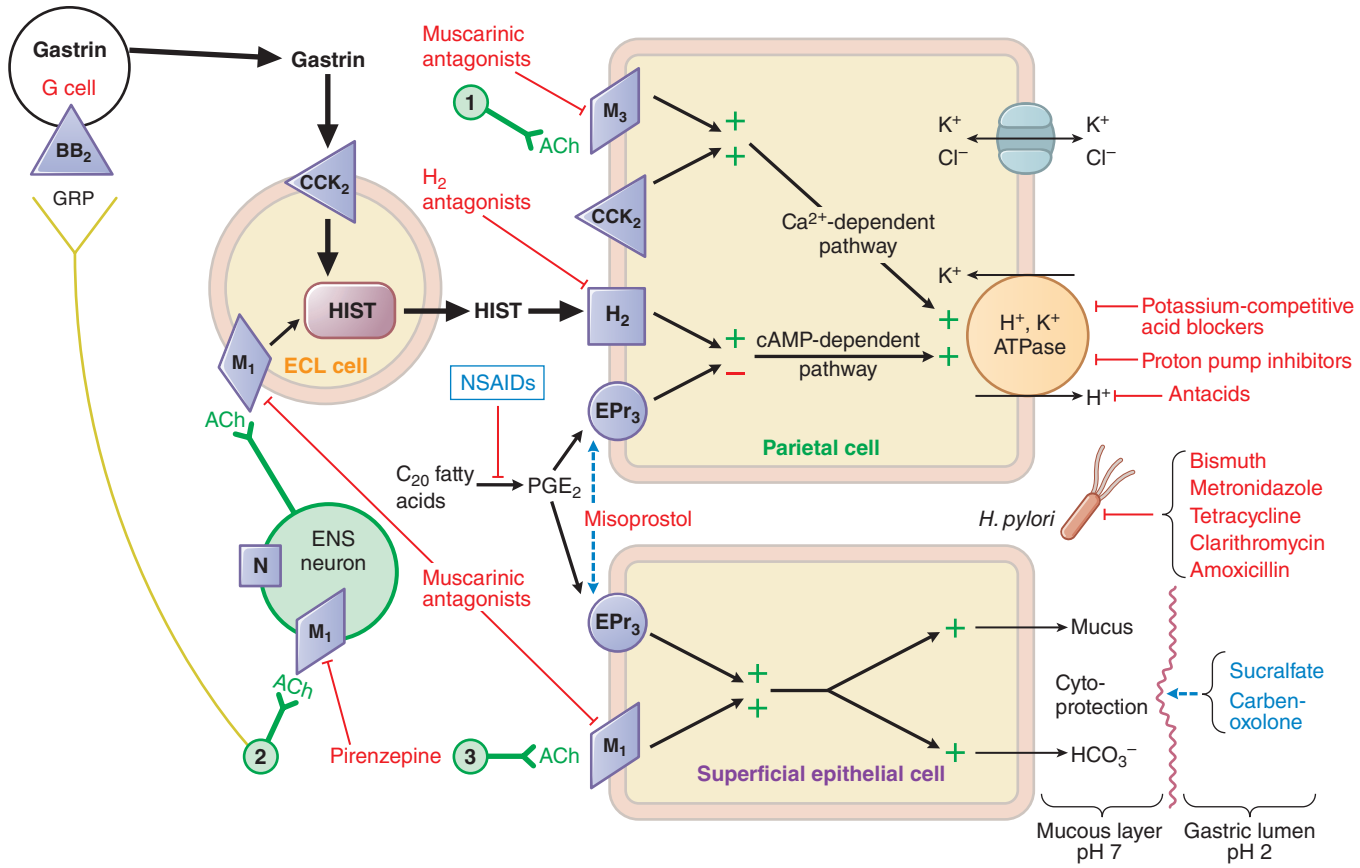

Figure 53–1 *Pharmacologist's view of gastric secretion and its regulation: the basis for therapy of acid-peptic disorders.* Shown are the interactions among neural input and a variety of enteroendocrine cells: an ECL cell that secretes histamine, a ganglion cell of the ENS, a G cell that secretes gastrin, a parietal cell that secretes acid, and a superficial epithelial cell that secretes mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (–). **1** and **3** indicate possible inputs from postganglionic cholinergic fibers; **2** shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include ACh and its muscarinic (M) and nicotinic (N) receptors; GRP and its receptor, the BB_2 bombesin receptor; gastrin and its receptor, the CCK_2; HIST and the H_2 receptor; and PGE_2 and the EP_3 receptor. A red line with a T bar indicates sites of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in red are drugs used to treat acid-peptic disorders. NSAIDs can induce ulcers via inhibition of cyclooxygenase. Not shown is a physiological pathway that reduces acid secretion: a D cell that secretes SST, which inhibits G-cell release of gastrin.

ADME

Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given about 30 min before meals. Concurrent administration of food may reduce somewhat the rate of absorption of PPIs, but this effect is not thought to be clinically significant. Once in the small bowel, PPIs are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Asians and Oceanians are more likely than Caucasians or Africans to have the CYP2C19 genotype that correlates with reduced metabolism of PPIs (25%–30% Asians, ~60% Oceanians vs. ~15% Caucasians or Africans), which may contribute to heightened efficacy or toxicity in this ethnic group (Lima et al., 2021). For chronic use of first-generation PPIs (*omeprazole, lansoprazole,* and *pantoprazole*) after efficacy has been achieved, reduction in the dose is recommended for those individuals with a CYP2C19 genotype that predicts reduced function (Lima et al., 2021).

Because not all pumps and all parietal cells are active simultaneously, maximal suppression of acid secretion requires several doses of the PPIs. For example, it may take 2 to 5 days of therapy with once-daily dosing to achieve the about 70% inhibition of proton pumps that is seen at steady state. More frequent initial dosing (e.g., twice daily) will reduce the time to achieve full inhibition but has not been shown to improve patient outcome. The resulting proton pump inhibition is irreversible; thus, acid secretion is suppressed for 24 to 48 h, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells. Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the PPIs. Hepatic disease substantially reduces the clearance of *esomeprazole* and *lansoprazole*. Thus, in patients with severe hepatic disease, dose reduction is recommended for *esomeprazole* and *lansoprazole*.

Therapeutic Uses and Adverse Effects

Prescription PPIs are primarily used to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, which is either complicated or unresponsive to treatment with H_2 receptor antagonists. They are also used in conjunction with antibiotics for the eradication of *H. pylori*. PPIs also are the mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. *Lansoprazole, pantoprazole*, and *esomeprazole* are approved for treatment and prevention of recurrence of NSAID-associated gastric ulcers in patients who continue NSAID use. It is not clear if PPIs affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. All PPIs are approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Over-the-counter *omeprazole, esomeprazole*, and *lansoprazole* are approved for the self-treatment of acid reflux. Therapeutic applications of the PPIs are discussed further in the section Therapeutic Strategies for Specific Acid-Peptic Disorders.

The PPIs generally cause remarkably few adverse effects and have a strong safety record (Malfertheiner et al., 2017a; Reimer, 2013). The most common side effects are headache, nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, interstitial

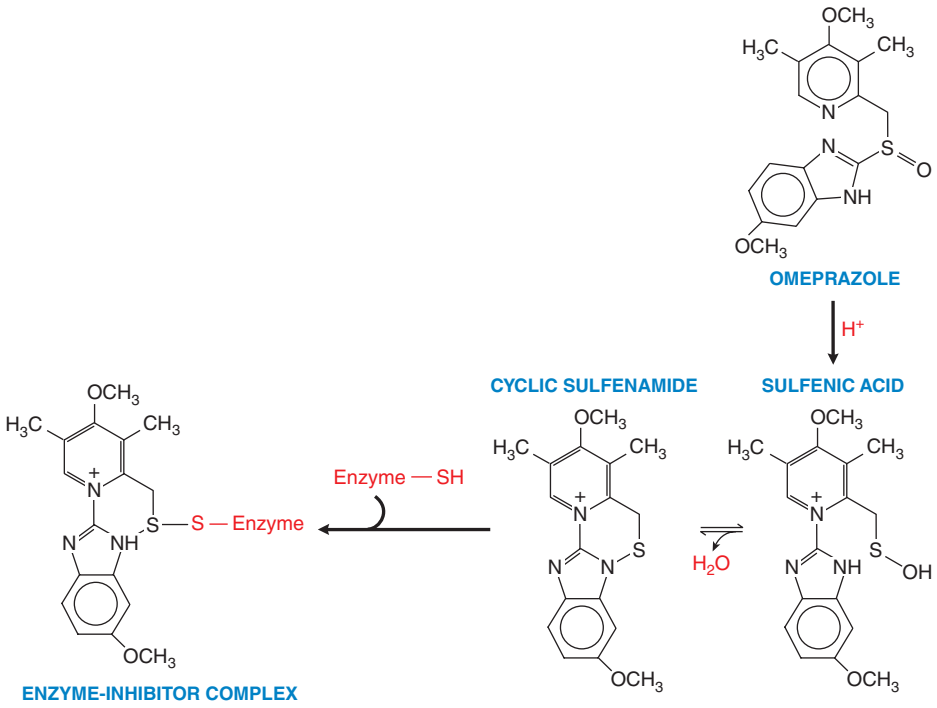

Figure 53–2 *Activation of a PPI from its prodrug form. Omeprazole* is converted to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. *Lansoprazole, rabeprazole*, and *pantoprazole* undergo analogous conversions.

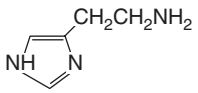
nephritis, pharyngitis, and skin rashes also have been reported. PPIs are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. PPIs have been observed to interact with *warfarin* (*esomeprazole, lansoprazole, omeprazole*, and *rabeprazole*); *diazepam* (*esomeprazole* and *omeprazole*); *atazanavir* or *nelfinavir* (*esomeprazole, dexlansoprazole, lansoprazole, omeprazole, pantoprazole*, and *rabeprazole*); and *cyclosporine* (*omeprazole* and *rabeprazole*). Among the PPIs, only *omeprazole* inhibits CYP2C19 (thereby decreasing the clearance of *disulfiram*, *phenytoin*, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of *imipramine*, several antipsychotic drugs, *tacrolimus*, and *theophylline*). There is some evidence that PPIs can inhibit conversion of *clopidogrel* (at the level of CYP2C19) to the active anticoagulating form, but this is controversial (Huang et al., 2012). *Pantoprazole* is less likely to result in this interaction; concurrent use of *clopidogrel* and PPIs (mainly *pantoprazole*) significantly reduces GI bleeding without increasing adverse cardiac events (see Chapter 36). Another drug interaction is between *methotrexate* and PPI therapy because PPIs can competitively inhibit *methotrexate* elimination and thereby increase *methotrexate* levels.

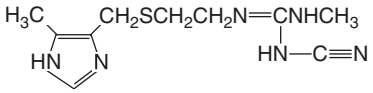
Chronic treatment with PPIs decreases the absorption of vitamin B_{12} (cobalamin), but the clinical relevance of this effect is not completely clear. Determination of serum vitamin B_{12} levels might be considered in long-term PPI users, especially those on high-dose PPIs and if they also have dietary restrictions that may limit vitamin B_{12} intake (see Chapter 45 for details of the importance of vitamin B_{12} to human health). Loss of gastric acidity also may affect the bioavailability of such drugs as *ketoconazole*, ampicillin esters, and iron salts. There is an association between PPI use and hypomagnesemia, with some guidelines recommending monitoring of magnesium levels in patients receiving long-term PPI therapy, particularly those also using diuretics or those with malabsorption disorders (Malfertheiner et al., 2017a; Nehra et al., 2018). Chronic use of PPIs has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infections (e.g., hospital-acquired pneumonia, community-acquired *Clostridium difficile*, spontaneous bacterial peritonitis in patients with ascites). Hypergastrinemia is more frequent and more severe with PPIs than with H_2 receptor antagonists and associated with this is ECL hyperplasia, fundic gland polyposis, and atrophic gastritis. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid on discontinuation of therapy and may promote the growth of GI tumors, although the risk appears very low (Malfertheiner et al., 2017a; Nehra et al., 2018). There have been associations made between long-term PPI use and increased risk of small intestinal bacterial overgrowth, chronic kidney disease, and dementia. These studies are not yet supported by well-controlled prospective trials, and the evidence for these significant adverse effects remains limited (Freedberg et al., 2017; Malfertheiner et al., 2017a; Nehra et al., 2018). Recently, a dose relationship between the use of PPIs and more severe infection and secondary infections in patients with the SARS-CoV-2 (COVID-19) virus has been described (Almario et al., 2021; Pranata et al., 2021). This finding highlights the importance of gastric acid for gastrointestinal defense and that PPI use should be limited to the lowest effective doses and only when indicated clinically.

H_2 Receptor Antagonists

The arrival of selective histamine H_2 receptor antagonists was a landmark in the treatment of acid-peptic disease. Before the availability of the H_2 receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H_2 receptor antagonists led to their availability without a prescription. Increasingly, however, PPIs are replacing the H_2 receptor antagonists in clinical practice.



HISTAMINE



CIMETIDINE

TABLE 53–1 ■ INTRAVENOUS DOSES OF H_2 RECEPTOR ANTAGONISTS

	CIMETIDINE	RANITIDINE	FAMOTIDINE
Intermittent bolus	300 mg every 6–8 h	50 mg every 6–8 h	20 mg every 12 h
Continuous infusion	37.5–100 mg/h	6.25–12.5 mg/h	1.7 mg/h

Mechanism of Action and Pharmacology

The H_2 receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H_2 receptors on the basolateral membrane of parietal cells (Black, 1993). Four different H_2 receptor antagonists, which differ mainly in their pharmacokinetics and propensity to cause drug interactions, were available in the U.S. until recently: *cimetidine*, *ranitidine*, *famotidine*, and *nizatidine*. However, due to contamination issues, some preparations of *ranitidine* and *nizatidine* have been withdrawn from use. These drugs are less potent than PPIs but still suppress 24-h gastric acid secretion by about 70%. Suppression of basal and nocturnal acid secretion is about 70%; because suppression of nocturnal acid secretion is important in the healing of duodenal ulcers, evening dosing of an H_2 receptor antagonist is adequate therapy in most cases. There is little evidence for the use of H_2 receptor antagonists for the treatment of bleeding ulcers, and they are no longer recommended for this purpose. All four H_2 receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of *cimetidine*, *ranitidine*, and *famotidine* also are available for use in critically ill patients (Table 53–1).

ADME

The H_2 receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations within 1 to 3 h. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4 to 5 h (*cimetidine*), 6 to 8 h (*ranitidine*), or 10 to 12 h (*famotidine*). The $t_{1/2}$ values of these agents after oral administration in adults range from 1 to 3 h; cimetidine clearance is faster in children, reducing its $t_{1/2}$ by about 30%. Only a small fraction of these drugs is protein bound. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce drug doses in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of these drugs. Hepatic metabolism accounts for a small fraction of clearance (from <10% to ~35%), but liver disease *per se* is generally not an indication for dose adjustment.

Therapeutic Uses and Adverse Effects

The major therapeutic indications for H_2 receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. For more information about the therapeutic applications of H_2 receptor antagonists, see Therapeutic Strategies for Specific Acid-Peptic Disorders.

The H_2 receptor antagonists generally are well tolerated, with a low incidence of adverse effects. Side effects are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less-common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Several reports have associated H_2 receptor antagonists with various blood disorders, including thrombocytopenia and vitamin B_{12} deficiency (Feldman and Burton, 1990; Lam et al., 2013). Gynecomastia and impotence have been reported to occur with cimetidine in a dose- and time-dependent fashion and resolve when the drug is discontinued (Jensen et al., 1983). H_2 receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H_2 receptor antagonists (see Antacids section). Drug interactions with H_2 receptor antagonists occur mainly with *cimetidine*, and its use has decreased markedly. *Cimetidine* inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6) and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. *Ranitidine* also interacts with hepatic CYPs, but with an affinity of only 10% of that of *cimetidine*. *Famotidine* and *nizatidine* are even safer in this regard. Slight increases in blood alcohol concentration may result from concomitant use of H_2 receptor antagonists and alcohol.

Tolerance and Rebound With Acid-Suppressing Medications

Tolerance to the acid-suppressing effects of H_2 receptor antagonists may develop within 3 days of starting treatment and may be resistant to increased doses of the medications (Sandevik et al., 1997). Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells.

Potassium-Competitive Acid Blockers

While PPIs were a significant advancement in the treatment of acid peptic diseases and GERD, there are many gastrointestinal conditions, such as nonerosive reflex disease and erosive esophagitis, where there remains significant unmet clinical need for more effective therapies. Potassium-competitive acid blockers have been developed over the last 30 years and have been found to rapidly suppress acid secretion. Currently, this drug class is available only in Asia. Clinical trials of one potassium-competitive acid blocker, *vonoprazan*, are currently being conducted in the U.S. and Europe.

Mechanism of Action and Pharmacology

There are currently three potassium-competitive acid blockers available for clinical use, the pyrimidine derivative *revaprazan*, the benzimidazole derivative *tegoprazan*, and the pyrrole derivative *vonoprazan* (Figure 53–3).

The potassium-competitive acid blockers are weak bases that bind competitively and reversibly to the potassium binding site of the H^+/K^+-ATPase following protonation (Engevik et al., 2020). The large size of these molecules prevents the access of K^+ cations to their binding site, thus blocking activation of the H^+/K^+-ATPase. They accumulate to a much higher concentration than PPIs in the canaliculi of the parietal cell. After oral administration, this class of drugs achieves a high plasma concentration that results in early onset of action. They are also able to bind to both the active and inactive forms of the H^+/K^+-ATPase, resulting in a faster and longer duration of acid suppression than is observed for PPIs. The potential advantage of the K^+-competitive agents is their immediate full effect from the first dose, their long half-life, and their long duration of effect, resulting in greater nocturnal acid suppression (Abdel-Aziz et al., 2020; Shibli et al., 2020). Of the three K^+-competitive acid blockers, *vonoprazan* has been studied to the greatest extent.

ADME

The K^+-competitive acid blockers are rapidly absorbed in the fed or fasted condition, reaching maximum serum concentrations in 0.5 to 2 h. These drugs dissociate only slowly from their target, which increases their duration of action and results in a maximal effect in 1 day (compared to 3–5 days for PPIs). Since K^+-competitive acid blockers do not require acid-catalyzed activation, they have similar efficacy of acid suppression irrespective of meals. The elimination of these agents is independent of CYP2C19 activity, making them less susceptible than PPIs to inter-individual variation. *Vonoprazan* is mainly metabolized in the liver via

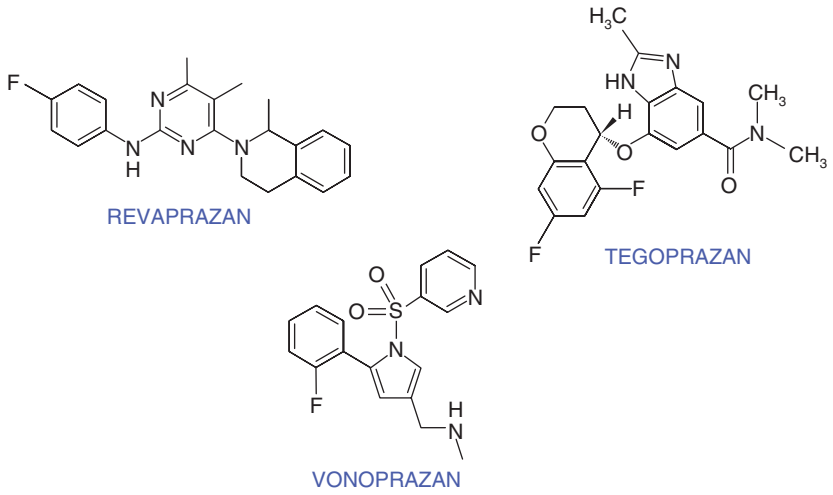


Figure 53–3 *The structures of potassium-competitive acid blockers.* *Revaprazan* is a pyrimidine derivative, *tegoprazan* is a benzimidazole derivative, and *vonoprazan* is a pyrrole derivative.

CYP3A4/5. The elimination $t_{1/2}$ values of these agents after oral administration in adults range from 2 to 9 h.

Therapeutic Uses and Adverse Effects

Revaprazan is approved in India and South Korea for the treatment of gastric ulcer, gastritis, and duodenal ulcer (200 mg daily); *tegoprazan* is approved in South Korea for erosive esophagitis and nonerosive reflux disease (50 mg daily). *Vonoprazan* fumarate is approved in Japan for the treatment of gastroduodenal ulcers, healing and prevention of erosive esophagitis, gastric protection in patients taking *aspirin* or NSAIDs, and eradication of *H. pylori* infection (10–20 mg daily).

Potassium-competitive acid blockers appear to be generally safe and well tolerated. In clinical trials of *vonoprazan*, the most frequent adverse effects were diarrhea, nasopharyngitis, dyspepsia, headache, and abdominal pain.

Agents That Enhance Mucosal Defense

Misoprostol

Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE_1) is a synthetic analogue of PGE_1 that is FDA-approved to prevent NSAID-induced mucosal injury.

Mechanism of Action and Pharmacology

Prostaglandin E_2 and prostacyclin (PGI_2) are the major PGs synthesized by the gastric mucosa. Contrary to their cyclic AMP–elevating effects on many cells via EPr_2 and EPr_4 receptors, these prostanoids bind to the EPr_3 receptor on parietal cells and stimulate the G_i pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE_2 also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Acid suppression appears to be the most important effect clinically (Wolfe and Sachs, 2000).

Because NSAIDs diminish PG formation by inhibiting cyclooxygenase, synthetic PG analogues offer a logical approach to counteract NSAID-induced damage.

ADME

Misoprostol is rapidly absorbed after oral administration and is rapidly and extensively deesterified to form misoprostol acid, the principal and active metabolite of the drug. A single dose inhibits acid production within 30 min; the therapeutic effect peaks at 60 to 90 min and lasts for up to 3 h. Food and antacids decrease the rate of *misoprostol* absorption. The free acid is excreted mainly in the urine, with an elimination $t_{1/2}$ of 20 to 40 min.

Therapeutic Uses and Adverse Effects

Misoprostol is rarely used because of its side effects (Rostom et al., 2009); see Chapters 41 and 48 concerning non-GI effects of *misoprostol*. The degree of inhibition of gastric acid secretion by *misoprostol* is directly related to dose; oral doses of 100 to 200 μg significantly inhibit basal acid secretion (up to 85%–95% inhibition) or food-stimulated acid secretion (up to 75%–85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg four times a day.

Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take *misoprostol*. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe cases may necessitate drug discontinuation. *Misoprostol* can cause clinical exacerbations of inflammatory bowel disease (see Chapter 55). *Misoprostol* is contraindicated for reducing the risk of NSAID-induced ulcers in women of childbearing potential unless the patient is at high risk of complications from gastric ulcers associated with use of the NSAID. It is also completely contraindicated during pregnancy because it can increase uterine contractility and abort a pregnancy (see Chapter 48).

Sucralfate

Mechanism of Action and Pharmacology

In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. *Sucralfate* consists of the octasulfate of sucrose to which $Al(OH)_3$ has been added. In an acid environment (pH <4), *sucralfate* undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 h after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, *sucralfate* may have other cytoprotective effects, including stimulation of local production of PGs and epidermal growth factor (Szabo, 2014). *Sucralfate* also binds bile salts; thus, some clinicians use *sucralfate* to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

Therapeutic Uses and Adverse Effects

Sucralfate is no longer used to treat peptic acid disease because PPIs are more effective. However, it is used for the initial treatment of GERD in pregnancy because it is poorly absorbed and for the treatment of mucositis secondary to cancer therapy (Lalla et al., 2014). Because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, *sucralfate* may offer an advantage over PPIs and H_2 receptor antagonists for the prophylaxis of stress ulcers. *Sucralfate* is also used in conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation

and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, *sucralfate* also has been used for radiation proctitis and solitary rectal ulcers. Because it is activated by acid, *sucralfate* should be taken on an empty stomach 1 h before meals. Use of antacids within 30 min of a dose of *sucralfate* should be avoided. The dose of *sucralfate* is 1 g three times daily for the treatment of GERD in pregnancy and 1 g four to six times daily for prophylaxis of stress ulcers for a maximum of 14 days. For the prevention of radiation-induced enteropathy in patients receiving radiation therapy to the pelvis, *sucralfate* is given as an oral dose of 500 mg twice daily. For the treatment of chronic radiation-induced proctitis, it can be given as an enema.

The most common side effect of *sucralfate* is constipation (~2%). *Sucralfate* should be avoided in patients with renal failure who are at risk for aluminum overload (Marks, 1991). Likewise, aluminum-containing antacids should not be combined with *sucralfate* in these patients. *Sucralfate* forms a viscous layer in the stomach that may inhibit absorption of other drugs, including *phenytoin, digoxin, cimetidine, ketoconazole*, and fluoroquinolone antibiotics. *Sucralfate* therefore should be taken at least 2 h after the administration of other drugs. The "sticky" nature of the viscous gel produced by *sucralfate* in the stomach also may be responsible for the development of bezoars in some patients.

Antacids

Mechanism of Action and Pharmacology

There are far more effective and persistent agents than antacids, but their price, accessibility, and rapid action make them popular with consumers as OTC medications, and they can be used for the acute treatment of acid reflux ("heartburn") and esophagitis (see discussion that follows). Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. $CaCO_3$ rapidly and effectively neutralizes gastric H^+, but the release of CO_2 from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration. Combinations of Mg^{2+} (rapidly reacting) and Al^{3+} (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate, a hydroxymagnesium aluminate complex, is converted rapidly in gastric acid to $Mg(OH)_2$ and $Al(OH)_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of Mg^{2+} and Al^{3+} theoretically counteract the adverse effects of each other on the bowel (Al^{3+} can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg^{2+} exerts the opposite effects), such balance is not always achieved in practice. *Simethicone,* a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with *aspirin*, that are marketed for "acid indigestion" are potentially unsafe in patients predisposed to gastroduodenal ulcers and should not be used.

Therapeutic Uses and Adverse Effects

Antacids are used for the relief of mild GERD symptoms that occur infrequently in adults, older children, and adolescents. They are given orally 1 and 3 h after meals and at bedtime. In general, antacids should be administered in suspension form because this formulation probably has greater neutralizing capacity than powder or tablet dosage forms. Antacids are cleared from the empty stomach in about 30 min. However, the presence of food is sufficient to elevate gastric pH to approximately 5 for about 1 h and to prolong the neutralizing effects of antacids for about 2 to 3 h.

Antacids vary in the extent to which they are absorbed and hence in their systemic effects. In general, most antacids can elevate urinary pH by about 1 pH unit. Antacids that contain Al^{3+}, Ca^{2+}, or Mg^{2+} are absorbed less completely than are those that contain $NaHCO_3$. With renal insufficiency, absorbed Al^{3+} can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca^{2+} is absorbed, causing transient hypercalcemia. The hypercalcemia from as little as 3 to 4 g of $CaCO_3$ per day can be problematic in patients with uremia. In the past, when large doses of $NaHCO_3$ and $CaCO_3$ were administered commonly with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca^{2+} (five to forty 500-mg tablets per day of calcium carbonate) taken with milk.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, *allopurinol*, and imidazole antifungals) by altering rates of dissolution and absorption, bioavailability, and renal elimination. Al^{3+} and Mg^{2+} antacids also are notable for their propensity to chelate other drugs present in the GI tract and thereby decrease their absorption. Most interactions can be avoided by taking antacids 2 h before or after ingestion of other drugs.

Other Acid Suppressants and Cytoprotectants

The M_1 muscarinic receptor antagonists *pirenzepine* and *telenzepine* (see Chapter 11) can reduce basal acid production by 40% to 50%. The ACh receptor on the parietal cell itself is of the M_3 subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M_1 receptors of intramural ganglia (see Figure 53–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (*pirenzepine*), they are rarely used today.

Rebamipide is used for ulcer therapy in India, parts of Asia, and Russia. It exerts cytoprotective effects by increasing PG generation in gastric mucosa and by scavenging reactive oxygen species. *Ecabet*, which appears to increase the formation of PGE_2 and PGI_2, also is used for ulcer therapy, mostly in Japan. *Carbenoxolone*, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Unfortunately, *carbenoxolone* inhibits the type I isozyme of 11β-hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 50). Bismuth compounds (see Chapter 54) are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects. In the colon, bismuth salts combine with hydrogen sulfide to form bismuth sulfide, which turns the stools black.

Therapeutic Strategies for Specific Acid-Peptic Disorders

Gastroesophageal Reflux Disease

Although most cases of acid reflux or gastroesophageal regurgitation follow a relatively benign course, these symptoms, often referred to as nonerosive reflux disease, can still be troubling (Boeckxstaens et al., 2014). More severe GERD is erosive esophagitis, characterized by endoscopically visible mucosal damage. This can lead to stricture formation and Barrett's metaplasia (replacement of squamous by intestinal columnar epithelium), which is associated with a small but significant risk of adenocarcinoma. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis (Altan et al., 2012). PPIs clearly are more effective than H_2 receptor antagonists in achieving these goals (Figure 53–4).

In general, the optimal dose for each patient is determined based on symptom control. Strictures associated with GERD also respond better to PPIs than to H_2 receptor antagonists. One of the complications of GERD, Barrett's esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia.

Regimens for the treatment of GERD with PPIs and histamine H_2 receptor antagonists are listed in Table 53–2. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H_2 receptor antagonists, twice-daily dosing usually is required. Antacids are insufficient and are recommended only for the patient with mild,

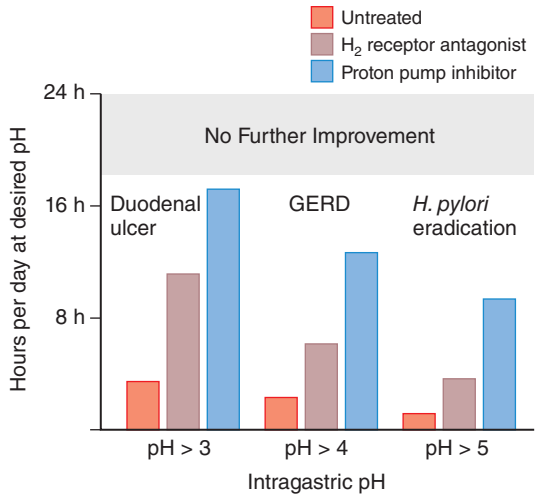

Figure 53–4 *Comparative success of therapy with PPIs and H_2 antagonists.* Data show the effects of a PPI (given once daily) and an H_2 receptor antagonist (given twice daily) in elevating gastric pH to the target ranges (i.e., pH 3 for duodenal ulcer, pH 4 for GERD, and pH 5 for antibiotic eradication of *H. pylori*).

infrequent episodes of acute acid reflux. In general, prokinetic agents (see Chapter 54) are not particularly useful for the treatment of refractory GERD, either alone or in combination with acid-suppressant medications. There is reasonable evidence that PPIs and, to a lesser extent, H_2 receptor antagonists are safe and effective for the treatment of GERD in children (Tighe et al., 2014).

Severe Symptoms and Nocturnal Acid Breakthrough

In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a PPI may be needed. However, it is difficult, if not impossible, to render patients achlorhydric, and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called *nocturnal acid breakthrough*, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion remains to be established. Patients with continuing symptoms on twice-daily PPIs are often treated by adding an H_2 receptor antagonist at night. Although this can further suppress acid production, the effect is short lived, probably due to the development of tolerance (Fackler et al., 2002).

Therapy for Extraintestinal Manifestations of GERD

Acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other

TABLE 53–2 ■ ANTISECRETORY DRUG REGIMENS FOR TREATMENT OF GERD

DRUG	ADULT DOSAGE	PEDIATRIC DOSAGE
H_2 receptor antagonists[a]		
Cimetidine	400 mg 4 times daily or 800 mg twice daily for 12 weeks	20–40 mg/kg/day divided every 6 h for 8–12 weeks
Famotidine	10–20 mg twice daily for up to 12 weeks	0.5 mg/kg/day at bedtime or divided every 12 h (infants <3 months)[b]
Nizatidine	150 mg twice daily	<12 years: 5–10 mg/kg/day[c] divided every 12 h >12 years: 150 mg twice daily
Ranitidine	150 mg twice daily	5–10 mg/kg/day divided, every 8–12 h
Proton pump inhibitors		
Esomeprazole magnesium Esomeprazole sodium Esomeprazole strontium	20–40 mg daily for 4–8 weeks 20–40 mg daily (IV)[e] 24.65 or 49.3 mg daily for 4–8 weeks	1–11 years: 10 mg/day, >12 years, 20 mg/day up to 8 weeks IV[d,e]: 0.5 mg/kg daily (infants >1 month); children: 10 mg daily (<55 kg); 20 mg daily (>55 kg)
Dexlansoprazole	30 mg daily for 4 weeks (nonerosive GERD); erosive GERD: 60 mg daily up to 6 months, then 30 mg daily up to 6 months (maintenance therapy)	60 mg/day for 8 weeks then 30 mg/g for 6 months (erosive esophagitis) 30 mg/day for 4 weeks (GERD)
Lansoprazole	15 mg (nonerosive GERD) or 30 mg (erosive GERD) daily up to 8 weeks	15–30 mg daily[d] for up to 12 weeks
Omeprazole	20 mg daily	5–20 mg daily[d]
Pantoprazole	40 mg daily (erosive GERD)	20–40 mg daily[d] for up to 8 weeks
Rabeprazole	20 mg daily (erosive GERD)	Children 1–11 years old: 5–10 mg daily up to 12 weeks >12 years: 20 mg daily up to 8 weeks
Potassium competitive acid blockers		
Revaprazan	200 mg daily	
Tegoprazan	50 mg daily	
Vonoprazan	10–20 mg daily	

[a]Not for erosive disease.
[b]For children and adolescents, individualize treatment duration and dose based on clinical response or pH determination (gastric or esophageal) and endoscopy. For infants, employ conservative measures (e.g., thickened feedings) and limit therapy to 8 weeks.
[c]Indicates off-label use.
[d]Varies by weight.
[e]Used when oral PPI cannot be given; short-term use only.

ear, nose, and throat conditions. PPIs (at higher doses) have been used with some success in certain patients with these disorders.

GERD and Pregnancy

Acid reflux is estimated to occur in 30% to 50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of safety data about use during pregnancy for the most commonly used drugs. The FDA has ceased to use a lettered risk classification system (A–D and X, progressing from no risk to high risk/do not use in pregnancy), preferring a more flexible and descriptive system customized for each drug. In the old system, most drugs used to treat GERD were considered safe for conservative use during pregnancy (old category B), except for *omeprazole* (old category C), which was to be used only when the benefits outweighed the risks. In the new system, physicians, pharmacists, and patients should consult the package insert for the most recent information on use in pregnancy. For cases of GERD during pregnancy and breastfeeding, literature reviews (Ali and Egan, 2007; Thélin and Richter, 2020) suggest a conservative progression of treatments, starting with antacids, alginates, or *sucralfate*, agents that are considered the first-line drugs in this setting. If symptoms persist, H_2 receptor antagonists can be used, with *cimetidine* having the most established track record in this setting, and with *nizatidine* to be avoided due to adverse data from animal studies. PPIs are reserved for women with intractable symptoms or complicated reflux disease; considering available data, *lansoprazole* and *pantoprazole* seem to be the safest choices.

Pediatric GERD

Reflux disease in infants and children is increasing at an alarming rate (Vandenplas, 2014). Children over 10 years can be diagnosed and treated similarly to adults, but infants and very young children require careful diagnosis to rule out cow's milk allergy or eosinophilic esophagitis. Many nonpharmacologic approaches can be used to alleviate some of the very troubling symptoms of this condition, which may not be due to acid reflux. If acid reduction is indicated, PPIs are more effective than H_2 receptor antagonists; however, the therapeutic efficacy of PPIs in newborns and infants is low, and there is an increased risk of adverse effects, including respiratory tract infections and gastroenteritis, which should be carefully considered. It is likely PPIs are overused in the treatment of pediatric GERD.

Peptic Ulcer Disease

Peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, PGs, NO, and other peptides and growth factors) and injurious factors (acid and pepsin) (Hunt et al., 2015; Wallace, 2008). On average, patients with *duodenal ulcers* produce more acid than do control subjects, particularly at night (basal secretion). Although patients with *gastric ulcers* have normal or even diminished acid production, ulcers rarely, if ever, occur in the complete absence of acid. Presumably, weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. *H. pylori* and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by D cells and, in time, cause decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production. Table 53–3 summarizes current recommendations for drug therapy of gastroduodenal ulcers.

The PPIs relieve symptoms of duodenal ulcers and promote healing more rapidly than do H_2 receptor antagonists, although both classes of drugs are effective in this setting (see Figure 53–4). A peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in most patients who do not receive prophylactic acid suppression. With the appreciation that *H. pylori* plays a major etiopathogenic role in most peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Intravenous *esomeprazole* (80 mg IV over 30 min, followed by 8 mg/h continuous infusion for a total of 72 h, then 40 mg orally or another single daily dose oral PPI, for an appropriate duration; off-label use) and *pantoprazole* (off-label use) are the preferred therapy in patients with acute bleeding ulcers (Laine and Jensen, 2012; Wong and Sung, 2013). The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

The NSAIDs also are frequently associated with peptic ulcers and bleeding. The effects of these drugs are mediated systemically; in the stomach, NSAIDs suppress mucosal PG synthesis (particularly PGE_2 and PGI_2) and thereby reduce mucus production and cytoprotection (see Figure 53–1). Thus, *minimizing NSAID use is an important adjunct to gastroduodenal ulcer therapy.*

TABLE 53–3 ■ REGIMENS FOR TREATING GASTRODUODENAL ULCERS IN ADULTS[a]

DRUG	ACTIVE ULCER	MAINTENANCE THERAPY
Proton pump inhibitors[b]		
Esomeprazole magnesium	NSAID risk reduction: 20 or 40 mg daily for up to 6 months	
Esomeprazole strontium	NSAID risk reduction: 24.65 or 49.3 mg daily for up to 6 months	
Lansoprazole	15 mg (DU) daily for 4 weeks 15 mg (NSAID risk reduction) daily for up to 12 weeks 30 mg (GU including NSAID associated) daily for up to 8 weeks	15 mg daily 30 mg daily[c]
Omeprazole	20 mg (DU and GU) daily for 4–8 weeks	20 mg daily[c]
Pantoprazole	20 mg (NSAID risk reduction) daily[c] 20 mg (GU) daily[c]	20 mg daily[c]
Rabeprazole	20 mg (DU for up to 4 weeks; GU[c]) daily	
Prostaglandin analogue		
Misoprostol	200 µg four times daily (NSAID-associated ulcer prevention)[d]	

[a]There is little evidence for the use of H_2 receptor antagonists for the treatment of bleeding ulcers.
[b]Deslansoprazole is not labeled for the treatment of active ulcers.
[c]Off-label use.
[d]Only misoprostol 800 µg/day has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction. (Rostom A, Moayyedi P, Hunt R. Canadian Association of Gastroenterology Consensus Group. Canadian consensus guidelines on long-term nonsteroidal anti-inflammatory drug therapy and the need for gastroprotective benefit versus risk. *J Clin Pharmacol Ther.* **2009**, 29:481–496.)

Treatment of *Helicobacter pylori* Infection

Helicobacter pylori, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suerbaum and Michetti, 2002). Because of the critical role of *H. pylori* in the pathogenesis of peptic ulcers, eradicating this infection is standard care in patients with gastric or duodenal ulcers (Malfertheiner et al., 2013). Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of *H. pylori* also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment. *H. pylori* eradication is also indicated for treatment of chronic atrophic gastritis and presence of intestinal metaplasia/dysplasia (with positive *H. pylori* biopsies).

Five important considerations influence the selection of an eradication regimen (Table 53–4) (Chey et al., 2017; Malfertheiner et al., 2017b):

- Single-antibiotic regimens are ineffective in eradicating *H. pylori* infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of *H. pylori* eradication.
- A PPI significantly enhances the effectiveness of *H. pylori* antibiotic regimens containing *amoxicillin* and *clarithromycin* (see Figure 53–4).
- A regimen of 10 to 14 days of treatment appears to be better than shorter treatment regimens.
- Poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is available and may improve patient compliance.
- The emergence of resistance to *clarithromycin* and *metronidazole* increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. In the presence of *in vitro* evidence of resistance to *metronidazole*, *amoxicillin* should be used instead. In areas with a high frequency of resistance to *clarithromycin* and *metronidazole*, a 14-day quadruple-drug regimen (three antibiotics combined with a PPI) generally is effective therapy.

TABLE 53–4 ■ THERAPY OF *HELICOBACTER PYLORI* INFECTION

Triple therapy × 10–14 days: PPI + clarithromycin 500 mg + amoxicillin 1 g twice a day (metronidazole 500 mg twice a day can be substituted for amoxicillin)
Quadruple therapy × 10–14 days: PPI + metronidazole 250 mg + bismuth subsalicylate 300 mg + tetracycline 500 mg four times daily
Or
Sequential therapy: PPI + amoxicillin 1 g twice a day for 5 days followed by PPI + clarithromycin 500 mg and tinidazole/metronidazole 500 mg twice a day for 5 days
Or
PPI + amoxicillin 1 g twice a day + levofloxacin 250 or 500 mg twice a day for 10 days
PPI *daily dosages*:
Omeprazole: 20 mg twice a day (triple therapy); 40 mg daily (dual therapy)
Lansoprazole: 30 mg twice a day (triple therapy); 30 mg three times daily for 14 days (dual therapy with amoxicillin)
Rabeprazole: 20 mg twice a day for 7 days
Pantoprazole: 40 mg twice a day[a]
Esomeprazole magnesium: 40 mg daily (triple therapy)
Esomeprazole strontium: 49.3 mg daily (triple therapy)

[a]Off-label use.
Data from Chey et al., 2017.

NSAID-Related Ulcers

Chronic NSAID users have a 2% to 4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if possible. Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≥8 weeks). PPIs are superior to H_2 receptor antagonists and misoprostol in promoting the healing of active ulcers and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Rostom et al., 2009). The FDA has approved fixed-dose combinations of NSAIDs with a PPI or H_2 antagonist; these combinations are intended to lower the risk of ulcers in patients who regularly use NSAIDs for arthritic pain.

Stress-Related Ulcers

Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care (Bardou et al., 2015). The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H_2 receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of PPIs are available, they are appropriate to consider. However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu. In this setting, *sucralfate* appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia.

Zollinger-Ellison Syndrome

Patients with Zollinger-Ellison syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I (Krampitz and Norton, 2013). This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. PPIs are the drugs of choice, usually given at about twice the routine dosage for peptic ulcers (*omeprazole* 60 mg daily, *esomeprazole* 80 mg daily, *lansoprazole* 60 mg daily, *rabeprazole* 60 mg daily, or *pantoprazole* 120 mg daily); some patients need two to three times these doses to control acid secretion. However, once control of acid secretion has been achieved, dose reduction is usually possible. PPIs are well tolerated and safe even at very high doses. If PPIs are unable to control gastric acid secretion, the long-acting somatostatin analogue *octreotide* (off-label indication) can be given to inhibit secretion of gastrin. This is not a first-line agent due to unpredictable response rates and the side effects of the treatment.

Functional Dyspepsia

The term *functional dyspepsia* refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration (Masuy et al., 2019). Functional dyspepsia can be subdivided into postprandial distress syndrome and epigastric pain syndrome, based on the presence of symptoms related to meals. It is defined as the presence of one or more of the following: postprandial fullness, early satiation, epigastric pain or burning, and no evidence of structural disease. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial.

The PPIs appear to be moderately effective in the treatment of patients with epigastric pain syndrome and are a first-line therapy (Masuy et al., 2019). In general, twice-daily PPIs are no better than once-daily PPIs. The dosing is as for GERD (Table 53–2). H_2 receptor antagonists are only marginally effective for the treatment of functional dyspepsia. Because central mechanisms may contribute to functional dyspepsia either through visceral hypersensitivity or other mechanisms, tricyclic antidepressants such as *amitriptyline* or *desipramine* (10–25 mg at night) (see Chapter 18) can be considered in patients with functional dyspepsia whose symptoms persist despite PPI therapy for 8 weeks. Prokinetic agents such as

metoclopramide (see Chapter 54) are a first-line therapy for the treatment of postprandial distress syndrome. The novel gastroprokinetic agent *acotiamide* has been applied to postprandial distress syndrome with symptom improvements noted in most trials (Masuy et al., 2019), and the $5HT_{1A}$ serotonin receptor agonist *buspirone* that relaxes the gastric fundus (see Chapter 15) improved gastric accommodation and GI symptoms in patients with functional dyspepsia. Antacids are not generally helpful for the treatment of functional dyspepsia.

Functional Esophageal Disorders

Functional esophageal disorders are disorders that cause esophageal symptoms and that are diagnosed based on negative results on standard esophageal tests, thereby excluding structural disorders, motility disorders like achalasia, and GERD (Amarasinghe and Sifrim, 2014). There are four of these common disorders: (1) functional heartburn, (2) functional chest pain, (3) functional dysphagia, and (4) globus. PPI therapy (off-label use) as outlined previously is routinely used for the initial treatment of functional heartburn, functional chest pain, and globus. As in functional dyspepsia, central mechanisms contribute to these disorders and similar approaches follow for the treatment of functional heartburn and functional chest pain if PPI therapy is ineffective, including the use of tricyclic antidepressants or selective serotonin reuptake inhibitors. For the treatment of globus, *gabapentin* or *pregabalin* is used.

***Acknowledgment**: We are grateful to Dr. José Geraldo Ferraz for his critical input to this chapter.*

Drug Facts for Your Personal Formulary: *Antisecretory Agents and Gastroprotectives*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Proton Pump Inhibitors		
Dexlansoprazole	• Gastroesophageal reflux disease • Erosive esophagitis	• Generally well tolerated • Possible interaction with clopidogrel (controversial) • Increased incidence of osteoporosis-related fractures of hip, wrist, or spine • Diarrhea • Interstitial nephritis • May cause cyanocobalamin (vitamin B_{12}) deficiency with daily long-term use (>3 years)
Esomeprazole Lansoprazole Omeprazole Pantoprazole	• Gastric ulcers • Duodenal ulcers • Erosive esophagitis • Gastroesophageal reflux disease • *Helicobacter pylori* eradication • Zollinger-Ellison syndrome	• OTC forms for acid reflux • Generally well tolerated • Possible interaction with clopidogrel (controversial) • Increased incidence of osteoporosis-associated fractures of hip, wrist, or spine • Diarrhea • Interstitial nephritis • May cause cyanocobalamin (vitamin B_{12}) deficiency with daily long-term use (>3 years) • Interactions with diagnostic investigations for neuroendocrine tumors
Rabeprazole	• Gastroesophageal reflux disease • *Helicobacter pylori* eradication • Zollinger-Ellison syndrome	• Generally well tolerated • Possible interaction with clopidogrel (controversial) • Increased incidence of osteoporosis-associated bone fractures of hip, wrist, or spine • Diarrhea • Interstitial nephritis
H_2 Receptor Antagonists		
Cimetidine Famotidine Nizatidine Ranitidine	• Gastric ulcer (to promote healing) • Duodenal ulcer (to promote healing) • Gastroesophageal reflux disease	• No longer recommend for treating active ulcers • Generally well tolerated • Beware of drug interactions with cimetidine
Potassium-Competitive Acid Blockers		
Revaprazan Tegoprazan Vonoprazan	• Gastric ulcer • Duodenal ulcer • Gastroesophageal reflux disease • *Helicobacter pylori* eradication (vonoprazan)	• Generally well tolerated • Only available in Asia
Mucosal Defensive Agents		
Misoprostol	• Ulcer prophylaxis	• Rarely used because of side effects (especially ↑ uterine contractility) • Not be used in women of childbearing potential or in pregnancy • Diarrhea; exacerbation of inflammatory bowel disease • Marketed in combination with diclofenac
Sucralfate	• Initial treatment of GERD in pregnancy	• Generally well tolerated • Constipation
Antacids	• Acid reflux • Esophagitis	• OTC; generally well tolerated; produce rapid but temporary effects • Na^+ and Al^{+3} loads: potential problems in cardiovascular and renal disease

Chapter 54 Gastrointestinal Motility and Water Flux, Emesis, and Biliary and Pancreatic Disease

Keith A. Sharkey and Wallace K. MacNaughton

Gastrointestinal Motility

The gastrointestinal (GI) tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium, the enteric nervous system (ENS), the autonomic nervous system (ANS), microbial mediators, innate and adaptive immune cells and their mediators, and local enteroendocrine and circulating hormones. Of these, the master regulator of physiological gut function is the ENS (Figure 54–1) (Fung and Vanden Berghe, 2020; Furness, 2012; Sharkey et al., 2018; Spencer and Hu, 2020).

The ENS is an extensive collection of nerves and glial cells that constitutes the third division of the ANS. It is the only part of the ANS that is truly capable of autonomous function if separated from the CNS. The ENS lies within the wall of the GI tract and is organized into two connected networks of neurons, nerve fibers, and glial cells: the *myenteric (Auerbach) plexus*, found between the circular and longitudinal muscle layers, and the *submucosal (Meissner) plexus*, located in the submucosa (Furness, 2012; Sharkey, 2015). The former is largely responsible for motor control, whereas the latter regulates secretion, ion and fluid transport, and blood flow. There is extensive two-way neuronal communication between the two plexuses to regulate these processes.

To prevent the unwanted translocation of toxins, antigens, commensal bacteria, and other potentially pathogenic components of the luminal contents, an elaborate "intestinal barrier" has developed. This consists of three components:

1. A physical barrier comprising the epithelial cells and the junctional proteins that maintain the integrity of this monolayer
2. An immune barrier, which comprises both innate and adaptive immune cells and specialized epithelial cells (microfold cells) that overlie Peyer's patches
3. A secretory barrier, which includes the secretion of antimicrobial peptides, secretory IgA, mucus, and water, driven by luminally directed ion transport

The secretory and immune components of the intestinal barrier are regulated by ENS and ANS neural mechanisms that integrate the control of these components of barrier function with digestive processes in the gut (Martin et al., 2018; Odenwald and Turner, 2017).

Generation and Regulation of GI Motor and Secretory Activity

The ENS is responsible for the largely autonomous nature of most GI motor and secretory activity. This activity is organized into relatively distinct "programs" that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation (Deloose et al., 2012). The fasting program of motor activity in the gut is called the MMC (migrating myoelectric complex when referring to electrical activity and migrating motor complex when referring to the accompanying contractions) and consists of a series of four phasic activities: I, quiescence; II, increasing frequencies of action potentials and smooth muscle contractions; III, peak contractile activity; and IV, declining activity toward a renewal of phase I. Phase II of the MMC is associated with the release of the peptide hormone motilin. Motilin agonists stimulate motility in the proximal gut. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6 to 10 min before proceeding caudally (toward the anus). One MMC cycle (i.e., all four phases) takes about 80 to 110 min. The MMC occurs in the fasting state, helping to sweep debris caudad in the gut and limiting the overgrowth of commensal luminal bacteria. The MMC is interrupted by

Abbreviations

ACh: acetylcholine
ANS: autonomic nervous system
CCK: cholecystokinin
CFTR: cystic fibrosis transmembrane conductance regulator
CTZ: chemoreceptor trigger zone
CYP: cytochrome P450
DOR: delta opioid receptor
ECG: electrocardiogram
ENaC: epithelial sodium channel
ENS: enteric nervous system
FDA: U.S. Food and Drug Administration
GC: guanyl cyclase
GERD: gastroesophageal reflux disease
GI: gastrointestinal
GLP: glucagon-like peptide
GPCR: G protein-coupled receptor
HIV: human immunodeficiency virus
5HT: serotonin, 5-hydroxytryptamine
IBS: irritable bowel syndrome
KOR: kappa opioid receptor
MOR: mu opioid receptor
NEP: neutral endopeptidase
NHE: Na^+-H^+ exchanger
NK: neurokinin
NO: nitric oxide
NTS: nucleus of the solitary tract
OTC: over-the-counter
PEG: polyethylene glycol
Pgp: P-glycoprotein (MDR1, ABCB1)
PK: protein kinase (e.g., PKA, PKC)
PONV: postoperative nausea and vomiting
QT: ECG interval (duration of ventricular depolarization and repolarization)
SLC: solute carrier transporter
SSRI: selective serotonin reuptake inhibitor
SST: somatostatin
TMEM: transmembrane protein
USP: U.S. Pharmacopeia
VIP: vasoactive intestinal peptide

the fed program in intermittently feeding animals such as humans. The fed program consists of high-frequency (12–15/min) contractions that either are propagated for short segments (propulsive) or are irregular and not propagated (mixing).

Peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudad. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems), which are of two broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is acetylcholine (ACh). The principal neurotransmitter of the inhibitory motor neurons is nitric oxide (NO), although important contributors may include ATP, vasoactive intestinal peptide (VIP), and pituitary adenylyl cyclase–activating peptide (PACAP). Enterochromaffin cells, the major population of enteroendocrine cells, scattered throughout the epithelium of the intestine, release serotonin (5HT) to initiate many gut reflexes by acting locally on enteric neurons (Mawe and Hoffman, 2013). Excessive release of 5HT in the gut wall (e.g., by chemotherapeutic agents) leads to vomiting by actions of 5HT on vagal nerve endings in the proximal small intestine. Compounds targeting the 5HT system are important modulators of motility, secretion, and emesis.

Other cell types are also important in the regulation of GI motility, including interstitial cells of Cajal and various other enteroendocrine cell populations. Interstitial cells of Cajal, which are distributed in networks within the gut wall, are responsible for setting the electrical rhythm and the pace of contractions in various regions of the gut (Huizinga and Chen, 2014). These cells also modulate excitatory and inhibitory neuronal communication to the smooth muscle. Enteroendocrine cell populations release locally acting hormones, such as ghrelin, cholecystokinin (CCK), motilin, and glucagon-like peptide-1 (GLP-1), all of which influence GI motility, before (e.g., ghrelin) or after meals (e.g., CCK and GLP-1) (Psichas et al., 2015).

Excitation-Contraction Coupling in GI Smooth Muscle

Control of tension in GI smooth muscle is dependent on the intracellular Ca^{2+} concentration (Sanders et al., 2012). There are basically two types of excitation-contraction coupling in these cells. *Ionotropic receptors* can mediate changes in membrane potential, which in turn activate voltage-gated Ca^{2+} channels to trigger an influx of Ca^{2+} (electromechanical coupling); *metabotropic receptors* activate various signal transduction pathways to release Ca^{2+} from intracellular stores (pharmacomechanical coupling). Inhibitory receptors act via PKA and PKG and lead to hyperpolarization, decreased cytosolic [Ca^{2+}], and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of the guanylyl cyclase–cyclic GMP pathway and cause the opening of several types of K^+ channels.

Functional and Motility Disorders of the Bowel

Gastrointestinal motility disorders are a heterogeneous group of conditions (Black et al., 2020; Faure et al., 2012). Common motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), GERD (gastroesophageal reflux disease, chronic reflux of gastric contents into the esophagus due to an increased frequency of transient lower esophageal sphincter relaxations, ineffective esophageal peristalsis, or gastric dysmotility), intestinal pseudoobstruction (myopathic and neuropathic forms of intestinal dysmotility), Hirschsprung disease, anorectal dysfunction, and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (e.g., diabetes mellitus or scleroderma). Motility disorders also traditionally include functional GI conditions, such as irritable bowel syndrome (IBS), functional dyspepsia, and noncardiac chest pain (Black et al., 2020). These disorders of brain-gut interaction are characterized by the presence of visceral hypersensitivity from the gut associated with GI motor abnormalities and other symptoms. For most of these disorders, treatment remains empirical and symptom based, reflecting limited understanding of the pathophysiology involved in most cases.

Prokinetic Agents and Other Stimulants of GI Motility

Prokinetic agents are medications that enhance coordinated GI motility and transit of material in the GI tract (Acosta and Camilleri, 2015; Bharucha and Lacy, 2020; Gudsoorkar and Quigley, 2020; Pittayanon et al., 2019; Tack and Camilleri, 2018). These agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility, or they mimic the effects of motilin. By contrast, activation of muscarinic receptors with the older cholinomimetic agents (see Chapter 11) or secondary to acetylcholinesterase inhibitors (see Chapter 12) enhances contractions in a relatively uncoordinated fashion that produces little or no net propulsive motor activity.

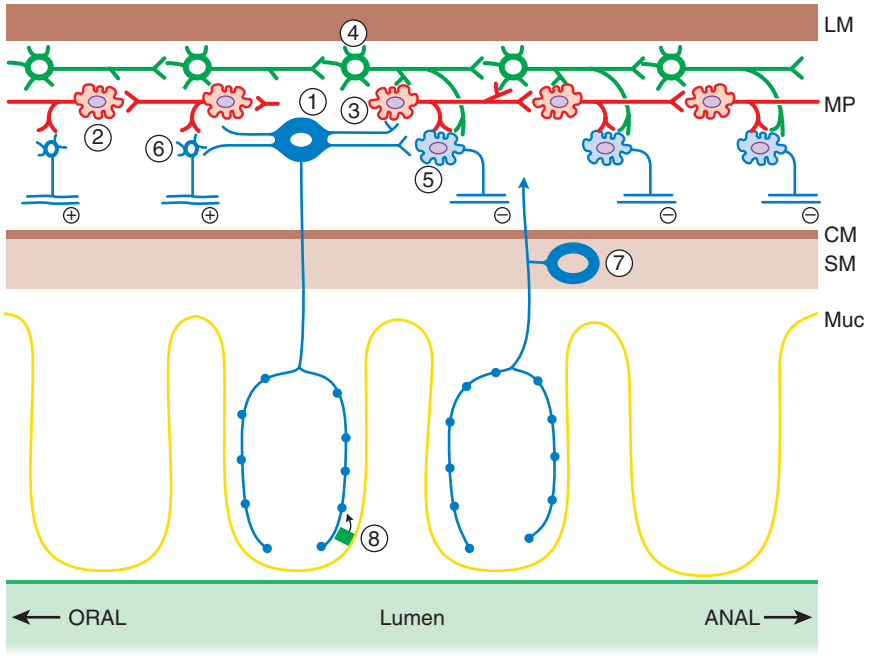

Figure 54–1 *The neuronal network that initiates and generates peristalsis* Mucosal stimulation leads to the release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neurons (1), which then communicate with ascending (2) and descending (3) interneurons in the local reflex pathways. The reflex results in contraction at the oral end via the excitatory motor neuron (6) and aboral relaxation via the inhibitory motor neuron (5). The migratory myoelectric complex (see text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). CM, circular muscle; LM, longitudinal muscle; MP, myenteric plexus; Muc, mucosa; SM, submucosa.

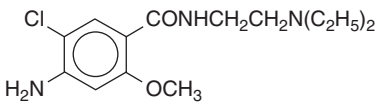
Dopamine Receptor Antagonists

Dopamine is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which result from suppression of ACh release from myenteric motor neurons, are mediated by D_2 dopaminergic receptors. Dopamine receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of dopamine receptors in the chemoreceptor trigger zone (CTZ) of the brainstem. Examples are *metoclopramide* and *domperidone* (Acosta and Camilleri, 2015; Reddymasu et al., 2007).

Metoclopramide



METOCLOPRAMIDE

Mechanism of Action and Pharmacology. *Metoclopramide* and other substituted benzamides are derivatives of *para*-aminobenzoic acid and are structurally related to *procainamide*. The mechanisms of action of *metoclopramide* are complex and involve $5HT_4$ receptor agonism, vagal and central $5HT_3$ antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to dopamine receptor antagonism. Administration of *metoclopramide* results in coordinated contractions that enhance transit. The effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. *Metoclopramide* has no clinically significant effects on large-bowel motility (Acosta and Camilleri, 2015).

ADME. *Metoclopramide* is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a $t_{1/2}$ of 4 to 6 h. Peak concentrations occur within 1 h after a single oral dose; the duration of action is 1 to 2 h.

Therapeutic Uses and Adverse Effects. *Metoclopramide* is a first-line therapy in patients with gastroparesis, who may experience improvements of gastric emptying. Because of adverse effects related to drug exposure, the recommended duration of use is less than 12 weeks. *Metoclopramide* injection is used as an adjunctive measure in medical or diagnostic procedures such as upper endoscopy or contrast radiography of the GI tract (single IV dose of 10 mg). Its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes, such as gastroparesis. *Metoclopramide* is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous, subcutaneous, or intramuscular administration. An intranasal formulation has also recently been developed and approved for diabetic gastroparesis (one spray is equivalent to a 10-mg oral dose). The initial regimen is 5 to 10 mg orally, 15 to 30 min before each meal and at bedtime, titrating up to the lowest effective dose. A dose of up to 40 mg/day given in divided doses can generally be tolerated. The onset of action is within 30 to 60 min. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10–15 min), subcutaneously, or intravenously (onset of action 1–3 min). *Metoclopramide* is used as an adjunctive agent for the prevention of *cisplatin*-induced delayed emesis and for emesis failing first-line treatments. For prevention of chemotherapy-induced emesis, *metoclopramide* can be given as an infusion of 1 to 2 mg/kg administered over at least 15 min, beginning 30 min before the chemotherapy is begun and repeated as needed every 2 h for two doses, then every 3 h for three doses. *Metoclopramide* is not recommended for the treatment of GERD or in children because of significant safety concerns (see discussion that follows) and limited efficacy.

The major side effects of *metoclopramide* include extrapyramidal effects. Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and reverse on discontinuation of *metoclopramide*. Tardive dyskinesia also can occur with chronic treatment and

may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. *Metoclopramide* also can cause anxiety, depression, and prolonged QT intervals. It may also cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release (seen infrequently in clinical practice). Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving *metoclopramide*.

Domperidone

Mechanism of Action and Pharmacology. In contrast to *metoclopramide*, *domperidone* predominantly antagonizes the D_2 receptor without major involvement of other receptors, but otherwise, its mechanism of action is similar (Reddymasu et al., 2007).

ADME. *Domperidone* is rapidly absorbed, yielding peak concentrations in 30 min. The drug undergoes metabolism via hepatic CYP3A4, N-dealkylation, and hydroxylation; it has a $t_{1/2}$ of 7 h. The metabolites are excreted in the feces (~two-thirds) and urine (~one-third).

Therapeutic Uses and Adverse Effects. *Domperidone* is available for use in the U.S. only through an expanded access to investigational drugs with the U.S. Food and Drug Administration (FDA), but it is readily available in many other countries. For the treatment of gastroparesis, *domperidone* has modest prokinetic activity in doses of 10 mg three times a day, which can be increased to 20 mg three times a day if needed. Although it does not readily cross the blood-brain barrier to cause extrapyramidal side effects, *domperidone* exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. *Domperidone* does not appear to have any significant effects on lower GI motility. Like *metoclopramide*, it has limited efficacy in children. There is an increased risk of serious ventricular arrhythmias, including sudden cardiac death, in association with *domperidone* use, especially in older persons (>60 years) and at doses above 30 mg/day. Like *metoclopramide*, it can also elevate prolactin levels, presenting as galactorrhea, gynecomastia, amenorrhea, or impotence.

Serotonin Receptor Agonists

Serotonin (5HT) plays an important role in the normal motor and secretory function of the gut (see Chapter 13) (Gershon and Tack, 2007; Mawe and Hoffman, 2013). Indeed, more than 90% of the total 5HT in the body exists in the GI tract. Enterochromaffin cells produce most of this 5HT and rapidly release it in response to chemical and mechanical stimulation (e.g., food boluses; chemotherapeutic agents such as *cisplatin*; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5HT triggers the peristaltic reflex (see Figure 54–1) by stimulating intrinsic sensory neurons in the myenteric plexus (via $5HT_{1p}$ and $5HT_4$ receptors), as well as extrinsic vagal and spinal sensory neurons (via $5HT_3$ receptors). In addition, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes, resulting in epithelial secretion.

The 5HT receptors occur on other neurons in the ENS, where they can be either stimulatory ($5HT_3$ and $5HT_4$) or inhibitory ($5HT_{1A}$). In addition, serotonin stimulates the release of other neurotransmitters. Thus, $5HT_1$ stimulation of the gastric fundus results in release of NO and reduction in smooth muscle tone. $5HT_4$ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both $5HT_3$ and $5HT_4$ receptors facilitate interneuronal signaling. Developmentally, 5HT acts as a neurotrophic factor for enteric neurons via the $5HT_{2B}$ and $5HT_4$ receptors. Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT) as 5HT reuptake by serotonergic neurons in the CNS. This reuptake also is blocked by SSRIs (see Figures 15–4 and 18–1), which explains the common side effect of diarrhea that accompanies the use of these agents (Gershon, 2013).

Because of the importance of 5HT on gut motor function, it became a major target for drug development. However, the availability of serotonergic prokinetic drugs has been restricted in recent years because of serious adverse cardiac events (Tack et al., 2012).

Cisapride

Mechanism of Action and Pharmacology. *Cisapride* is a $5HT_4$ agonist that stimulates adenylyl cyclase activity in neurons. It also has weak $5HT_3$ antagonistic properties and may directly stimulate smooth muscle. *Cisapride* was a commonly used prokinetic agent; however, it is no longer generally available and is rarely used because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the human ether-a-go-go related gene, the *HERG* K^+ channel (see Chapter 34).

ADME. *Cisapride* is metabolized by hepatic CYP3A4. It has an onset of action of 30 to 60 min and a $t_{1/2}$ of 6 to 12 h.

Therapeutic Uses and Adverse Effects. *Cisapride* is available only through an investigational, limited-access program for patients with GERD, gastroparesis, intestinal pseudoobstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an electrocardiogram (ECG). It has modest prokinetic activity in doses of 10 to 20 mg four times a day, given 30 min before meals. *Cisapride* is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities, or concomitant medications known to prolong the QT interval. Other side effects of *cisapride* include abdominal discomfort and diarrhea.

Prucalopride

Mechanism of Action and Pharmacology. *Prucalopride* is a specific $5HT_4$ receptor agonist (Figure 54–2) that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers.

ADME. *Prucalopride* has a time to peak action of 2 to 3 h and a $t_{1/2}$ of 24 h. It is primarily excreted in the urine as the unchanged drug.

Therapeutic Uses and Adverse Effects. Given once daily in doses of 1 to 4 mg orally, the drug improves bowel habits, significantly increases the number of spontaneous, complete bowel movements, reduces the severity of symptoms, and improves quality of life in patients with severe chronic constipation. *Prucalopride* is approved for use in adults with chronic constipation in whom laxatives fail to provide adequate relief. Cardiovascular risks do not seem to be elevated, but patients should be monitored

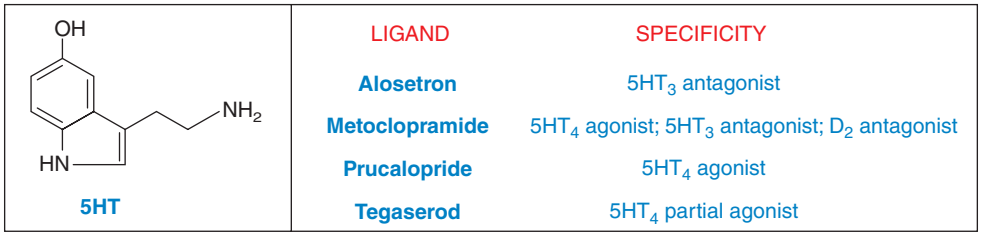


Figure 54–2 *Serotonergic agents modulating GI motility.*

(Diederen et al., 2015). The drug carries a warning for suicidal ideation, although no causal association has been established based on observations in clinical trials. Patients should be closely monitored and counseled to be aware of changes in mood or behavior. Headache, abdominal pain, nausea, and diarrhea are the most common adverse effects reported in clinical trials. *Prucalopride* is contraindicated in patients with intestinal perforation or obstruction, obstructive ileus, and inflammatory conditions of the GI tract such as Crohn's disease, ulcerative colitis, and toxic megacolon/megarectum.

Tegaserod

Mechanism of Action and Pharmacology. *Tegaserod* is an aminoguanidine indole that is structurally related to serotonin and is a partial $5HT_4$ agonist with negligible affinity for other receptor subtypes (see Figure 54–2). *Tegaserod* has multiple effects on the GI tract: It stimulates motility and accelerates transit in the esophagus, stomach, small bowel, and ascending colon; it also stimulates Cl^- secretion. The clinical efficacy of *tegaserod* has been proven only in female patients with constipation-predominant IBS. *Tegaserod* is indicated in women under the age of 65 who fail first-line therapies. *Tegaserod* is also an option for female patients with IBS with mixed bowel habits who fail other therapies.

ADME. *Tegaserod* has a time to peak action of about 1 h and a $t_{1/2}$ of 5 to 8 h. The drug is metabolized via hydrolysis and direct glucuronidation. It is primarily excreted in the feces as the unchanged drug, with the remainder excreted in the urine as metabolites.

Therapeutic Uses and Adverse Effects. Given in doses of 6 mg orally, twice a day and 30 min before meals, the drug improves bowel habits. It should be discontinued if adequate symptom control is not obtained in 4 to 6 weeks. *Tegaserod* carries a number of warnings and precautions. It is contraindicated in patients with a history of myocardial infarction, stroke, transient ischemic attacks or angina, ischemic colitis, severe renal impairment, moderate or severe hepatic impairment, bowel obstruction, or gallbladder disease. Like *prucalopride*, *tegaserod* carries a warning for suicidal ideation, based on observations in clinical trials. Patients should be closely monitored and counseled to be aware of changes in mood or behavior. Diarrhea is one of the most common adverse effects of *tegaserod*. Volume depletion, hypotension, and syncope associated with diarrhea have been reported. Other adverse effects reported in clinical trials include headache, abdominal pain, nausea, flatulence, dyspepsia, and dizziness.

Motilin and Macrolide Antibiotics

Mechanism of Action and Pharmacology

Motilin, a 22–amino acid peptide hormone secreted by enteroendocrine M cells and by some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the MMC and appear to be responsible for the amplification, if not the actual induction, of phase III activity. Motilin receptors are G protein-coupled receptors (GPCRs) found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by *erythromycin*, a property shared to varying extents by other macrolide antibiotics (e.g., *azithromycin*, *clarithromycin*, etc.; see Chapter 60). In addition to its motilin-like effects, which are most pronounced at higher doses (250–500 mg), *erythromycin* at lower doses (e.g., 40–80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation. *Erythromycin* has multiple effects on upper GI motility, increasing lower esophageal pressure and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

ADME

Erythromycin is metabolized by demethylation in the liver by CYP3A4. The time to peak action is about 0.5 to 2.5 h (ethylsuccinate formulation), and it has a $t_{1/2}$ of 2 h. It is primarily excreted in the feces.

Therapeutic Uses and Adverse Effects

Erythromycin is used as a prokinetic agent in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. *Erythromycin*-stimulated gastric contractions can be intense and result in "dumping" of relatively undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as bezoars or blood after a GI bleed prior to endoscopy. Rapid development of tolerance (~28 days) to the prokinetic effect of *erythromycin*, possibly by downregulation of the motilin receptor, and the agent's antibiotic effects (undesirable in this context) limit the use of *erythromycin* as a prokinetic agent. A standard dose of *erythromycin* for gastric stimulation is 1.5 to 3 mg/kg intravenous infusion every 6 h in a hospital setting or 125 mg orally every 12 h (Acosta and Camilleri, 2015). For small-bowel stimulation, a smaller dose (e.g., 3 mg/kg IV every 8 h) may be more useful; higher doses may retard the motility. Tachyphylaxis to *erythromycin* and potential side effects limit its use in the management of gastroparesis. Concerns about GI toxicity, ototoxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, QT prolongation, and sudden death, particularly when used in patients taking medications that inhibit CYP3A4, limit the use of *erythromycin* to acute situations or in circumstances where patients are resistant to other medications.

Other macrolides (e.g., *azithromycin* and *clarithromycin*) accelerate gastric emptying, but there are no clinical trials compared to other medications or placebo indicating any benefit. Moreover, their additional cost, potential for risk, and antibiotic resistance preclude consideration for their use in motility disorders.

Miscellaneous Agents for Stimulating Motility

The hormone CCK is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, and promotes satiety. The C-terminal octapeptide of CCK, *sincalide*, is useful for stimulating the gallbladder or pancreas and for accelerating barium transit through the small bowel for diagnostic testing of these organs. It is given by intravenous injection or infusion and has an onset of action of 5 to 15 min.

Currently, there are a number of agents under evaluation that stimulate motility whose mechanisms of action are based on well-established neurohumoral mechanisms (Tack and Camilleri, 2018). These include novel motilin receptor agonists and $5HT_4$ agonists (*velusetrag* and *naronapride*).

Agents That Suppress Motility

Smooth muscle relaxants such as organic nitrates, type 5 phosphodiesterase inhibitors, and Ca^{2+} channel antagonists produce temporary, if partial, relief of symptoms in motility disorders such as jackhammer esophagus, in which the lower esophageal sphincter fails to relax, resulting in severe difficulty in swallowing (Pandolfino and Gawron, 2015). Preparations of botulinum toxin (*onabotulinumtoxinA*), injected directly into the lower esophageal sphincter via an endoscope, in doses of 100 units given in four equal portions, inhibit ACh release from nerve endings and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance (Zhao and Pasricha, 2003). Other GI conditions in which botulinum toxin A has been used include gastroparesis, sphincter of Oddi dysfunction, and anal fissures, although currently there are no strong trial data to support its efficacy in these conditions.

Laxatives, Cathartics, and Therapy for Constipation

Overview of GI Water and Electrolyte Flux

Water normally accounts for 70% to 85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion of fluids and luminally directed secretion of water and electrolytes) and output

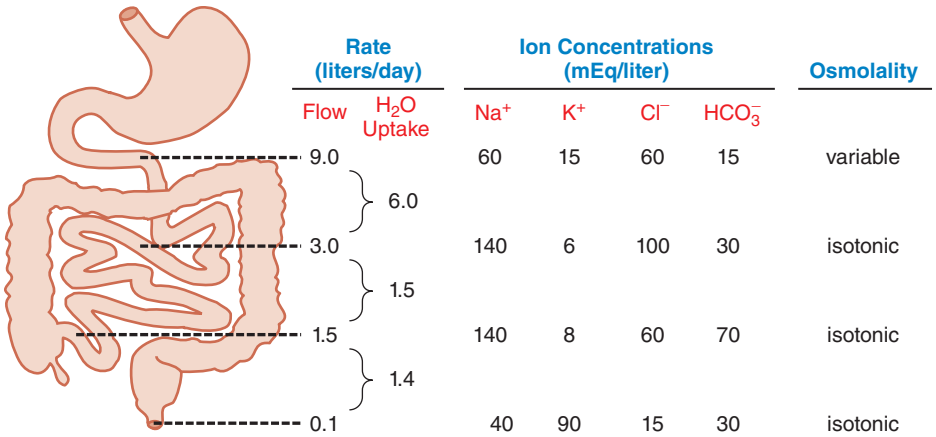

Figure 54–3 *Typical volume and composition of fluid that traverses the small and large intestines daily.* Of the 9 L of fluid typically presented to the small intestine each day, 2 L are from the diet and 7 L are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4 to 5 L/day.

(absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind sufficient fluid for proper expulsion of waste via the process of defecation.

Normally, about 8 to 9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 54–3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only about 1 to 1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving about 100 mL of fecal water daily. Under normal circumstances, these quantities are within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4–5 L). Neurohumoral mechanisms, pathogens, and drugs can alter secretion and absorption of fluid by the intestinal epithelium (Figure 54–4). Altered motility also contributes to this process. With decreased motility and excess fluid removal, feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

Constipation: General Principles of Pathophysiology and Treatment

Patients use the term *constipation* not only for decreased frequency but also for difficulty in initiation, passage of firm or small-volume feces, or a feeling of incomplete evacuation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, side effects of drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency. In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region.

Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions (Dinning et al., 2009). Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is usually based on physiologic principles.

Treatment of constipation includes both nonpharmacologic and pharmacologic approaches. Most guidelines recommend a diet rich in fiber (20–35 g daily), adequate fluid intake, and appropriate bowel habits and training as primary measures for subjects affected by constipation. Dietary and lifestyle factors, such as low intake of dietary fibers and physical inactivity, can predispose individuals to develop constipation (Bharucha and Lacy, 2020; Camilleri et al., 2017). Many drug classes cause constipation (Bharucha and Lacy, 2020). In order to correct this, stopping or reducing the doses of medications that cause constipation may be an option. Current evidence supports the use of osmotic or stimulant laxatives as first treatment strategies in patients with functional and chronic constipation (Bharucha and Lacy, 2020). Stimulant laxatives are frequently recommended in patients who do not respond to osmotic laxatives (Camilleri et al., 2017). When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period in order to achieve regular bowel evacuations and to avoid abuse. Treatment cycles may have to be repeated because of the chronic nature of the condition. In addition to perpetuating dependence on drugs, the laxative habit may give rise to chronic diarrhea leading to excessive loss of water and electrolytes and abdominal pain. Secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported.

Laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable. The terms *laxatives*, *cathartics*, *purgatives*, *aperients*, and *evacuants* often are used interchangeably. There is a distinction, however, between *laxation* (the evacuation of formed fecal material from the rectum) and *catharsis* (the evacuation of unformed, usually watery, fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are cathartics that act as laxatives at low doses.

Laxatives relieve constipation and promote evacuation of the bowel via:

- Enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms
- Decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport
- Altering motility by inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions

Laxatives can be classified based on their actions (Table 54–1) or by the pattern of effects produced by the usual clinical dosage (Table 54–2), with some overlap between classifications.

A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor (PAF; see Chapter 41) in the gut. PAF is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility (Izzo et al., 1998). NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce

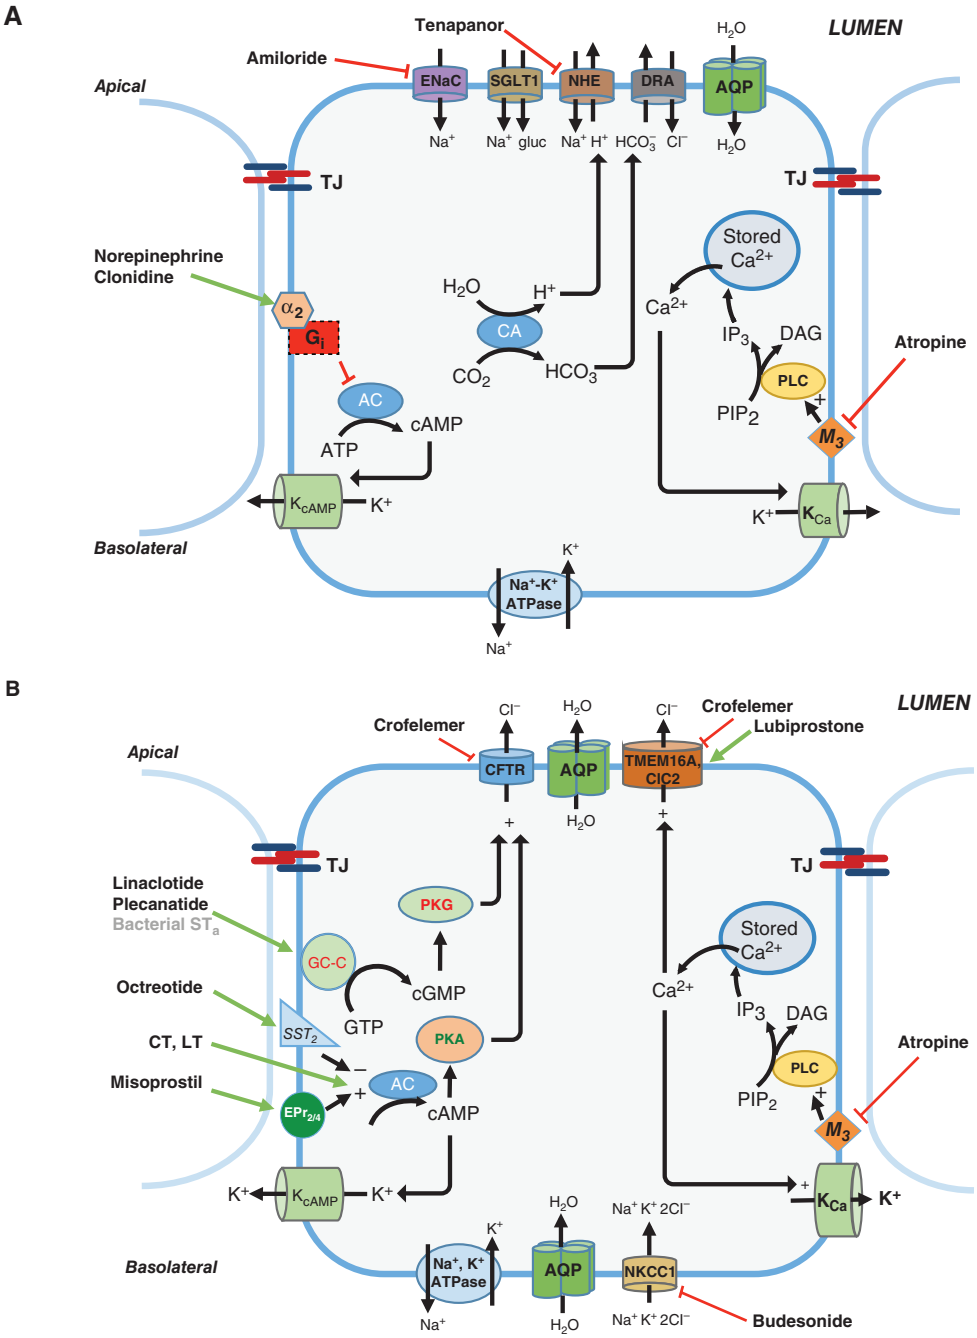

Figure 54–4 *Mechanism of action of drugs that alter intestinal epithelial absorption and secretion.* **A.** *Agents affecting intestinal epithelial absorption.* Absorption is driven by Na^+,K^+-ATPase in absorptive enterocytes, which creates the Na^+ gradient that facilitates Na^+ absorption through the epithelial sodium channel (ENaC) or through coupled transporters such as the Na^+-glucose cotransporter SGLT1 (SLC5A1) and members of the NHE family. ENaC is blocked by *amiloride* and similar compounds. Both NHE and the bicarbonate-Cl^- exchanger (SLC26A3, known as DRA, ***d**ownregulated in **a**denoma*), depend on the action of carbonic anhydrase (CA), which generates H^+ and HCO_3^- from water and CO_2 in the cytosol. *Tenapanor* inhibits NHE3, the most abundant isoform of NHE expressed in the intestine, reducing sodium absorption, which leads to fluid secretion into the lumen. Water enters the cell through apical aquaporin (AQP) water channels. As in secretion, regulation of K^+ channels by cyclic AMP and Ca^{2+} is essential. Thus, drugs that act on α_2 adrenergic receptors (e.g., *clonidine*) will reduce adenylyl cyclase activity and lower enterocyte cyclic AMP levels, thereby reducing absorption. **B.** *Agents affecting intestinal epithelial secretion.* Secretion is driven in secretory enterocytes by the Na^+ gradient established by the Na^+,K^+-ATPase. This Na^+ gradient drives the symporter NKCC1 (SLC12A2), which allows for the accumulation of Cl^- in the cell. Regulation of chloride channels in the apical (luminal) membrane drives Cl^- secretion. Vectorial movement of chloride drives the secretion of water through the paracellular route and through AQPs. Chloride secretion is rapidly regulated through phosphorylation of CFTR by the cyclic nucleotide–dependent protein kinases, PKA and PKG. Thus, drugs that stimulate adenylyl cyclase (i.e., *misoprostol*, acting through prostanoid EP_2 or EP_4 receptors) or guanylate cyclase C (GC-C: *linaclotide, plecanatide*) will stimulate Cl^- and water secretion. Several bacterial toxins cause water efflux and diarrhea by these mechanisms: cholera toxin (CT) and heat-labile *Escherichia coli* toxin (LT) stimulate cyclic AMP synthesis in the enterocyte by ADP-ribosylating $G\alpha_s$, blocking its GTPase activity and leading to constitutive activation of adenylyl cyclase; the heat-stable enterotoxins (e.g., ST_a) stimulate GC-C, the membrane-bound isoform of guanylyl cyclase. Drugs that inhibit adenylyl cyclase (e.g., *octreotide*, acting at SST_2 receptors) inhibit secretion. Calcium-dependent chloride channels (e.g., the Ca^{2+}-activated Cl^- channel TMEM16A (Lam et al., 2021); the ClC_2 chloride channel [Koster et al., 2020]) are regulated by increases in cytosolic Ca^{2+}, such as that induced by activation of muscarinic M_3 receptors that atropine blocks. Increases in cytosolic cyclic AMP and Ca^{2+} also regulate cyclic AMP–dependent and Ca^{2+}-dependent K^+ channels; his regulation is essential in maintaining the Na^+ gradient necessary to facilitate secretion. Apical chloride channels (CFTR, TMEM16A) can also be inhibited or activated by drugs such as *crofelemer* (inhibitor) or *lubiprostone* (activator). Drugs such as *bumetanide* inhibit NKCC1 function and thereby reduce secretion.

TABLE 54–1 ■ CLASSIFICATION OF LAXATIVES

1. Luminally active agents
Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.)
Osmotic agents (nonabsorbable inorganic salts or sugars)
Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)
2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility)
Diphenylmethanes (bisacodyl and sodium picosulfate)
Anthraquinones (senna and cascara)
Castor oil
3. Prokinetic agents (acting primarily on motility)
$5HT_4$ receptor agonists
Dopamine receptor antagonists
Motilides (erythromycin)
4. Prosecretory agents
ClC-2 chloride channel activator
Guanyl cyclase C activators
Sodium-hydrogen exchange 3 inhibitor

the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, magnesium sulfate, and bisacodyl (but not senna).

Dietary Fiber and Supplements

Bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is the part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects:

1. Production of short-chain fatty acids that are trophic for colonic epithelium
2. Increase in bacterial mass

Although fermentation of fiber generally decreases stool water, short-chain fatty acids may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 54–3). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

TABLE 54–2 ■ CLASSIFICATION AND COMPARISON OF REPRESENTATIVE LAXATIVES

LAXATIVE EFFECT AND LATENCY IN USUAL CLINICAL DOSAGE		
SOFTENING OF FECES, 1–3 DAYS	**SOFT OR SEMIFLUID STOOL, 6–8 h**	**WATERY EVACUATION, 1–3 h**
Bulk-forming laxatives	***Stimulant laxatives***	**Osmotic laxatives**[a]
Bran	Diphenylmethane derivatives	Magnesium sulfate
Psyllium preparations	Bisacodyl	Milk of magnesia
Methylcellulose		Magnesium citrate
Calcium polycarbophil		
Surfactant/osmotic laxatives	***Anthraquinone derivatives***	***Castor oil***
Docusates	Senna	
Poloxamers	Cascara sagrada	
Lactulose		

[a]Employed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.

TABLE 54–3 ■ PROPERTIES OF DIFFERENT DIETARY FIBERS

TYPE OF FIBER	WATER SOLUBILITY	% FERMENTED
Nonpolysaccharides		
Lignin	Poor	0
Cellulose	Poor	15
Noncellulose polysaccharides		
Hemicellulose	Good	56–87
Mucilages and gums	Good	85–95
Pectins	Good	90–95

In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereal grains, contains more than 40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight (a dose of 1–3 g up to three times a day). Fruits and vegetables contain more *pectins* and *hemicelluloses*, which are more readily fermentable and produce less effect on stool transit. *Psyllium husk*, derived from the seed of the plantago herb (*Plantago ovata*; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation. Psyllium husk contains a hydrophilic mucilloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass; the usual dose is 2.5 to 4 g (1–3 teaspoons full in 250 mL of fruit juice), titrated upward until the desired goal is reached. A variety of semisynthetic celluloses—such as methylcellulose (~2 g three times a day) and the hydrophilic resin calcium polycarbophil (1–2 g/day), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk. Malt soup extract, an extract of malt from barley grains that contains small amounts of polymeric carbohydrates, proteins, electrolytes, and vitamins, is another orally administered bulk-forming agent. The onset of action of these bulk-forming laxatives is generally between 12 and 72 h. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation) but usually decreases with time (Lacy et al., 2014).

Osmotically Active Agents

Polyethylene Glycol–Electrolyte Solutions. Long-chain PEGs (MW ~3350 Da; also known as macrogol) are poorly absorbed and retained in the lumen because of their high osmotic nature (Paré and Fedorak, 2014). Orally administered high-molecular-weight macrogols undergo no or minimal absorption. When used in high volume, aqueous solutions of PEGs with electrolytes produce an effective catharsis and have replaced oral sodium phosphates as the most widely used preparations for colonic cleansing prior to radiological, surgical, and endoscopic procedures.

Usually, 240 mL of this solution is taken every 10 min until 4 L is consumed or the rectal effluent is clear. To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the polyethylene glycol (PEG) molecules retains the added water, and the electrolyte concentration ensures little or no net ionic shifts. A powder form of PEG 3350 is now available as an over-the-counter (OTC) product for the treatment of occasional constipation and for the treatment of more chronic constipation; the PEG preparation is suitable because it has such a benign side effect profile. The usual dose is 8.5 to 34 g of powder per day in 8 oz of water, with an expected onset of action of 1 to 4 days. These laxatives may cause nausea, cramping, and bloating. In elderly patients or those with preexisting electrolyte abnormalities, it is important to monitor K^+ concentrations since PEG preparations can cause electrolyte imbalances.

Saline Laxatives. Laxatives containing magnesium cations or phosphate anions commonly are called *saline laxatives*: magnesium sulfate,

magnesium hydroxide, magnesium citrate, and sodium phosphate. Their cathartic action is believed to result from osmotic water retention, which then stimulates peristalsis. Other mechanisms may contribute, including the production of inflammatory mediators.

Magnesium-containing laxatives may stimulate the release of CCK, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. For every additional milliequivalent of Mg^{2+} in the intestinal lumen, fecal weight increases by about 7 g. The usual dose of Mg^{2+} salts contains 40 to 120 mEq of Mg^{2+} and produces 300 to 600 mL of stool within 0.5 to 6 h. The most common side effect is diarrhea, which is dose related. In patients with impaired renal function, hypermagnesemia may lead to renal failure.

Phosphate salts are better absorbed than Mg^{2+}-based agents and therefore need to be given in larger doses to induce catharsis. However, because of the risks of acute phosphate nephropathy, oral phosphates are not recommended for the treatment of constipation and should be completely avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and NSAIDs).

The Mg^{2+}-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities and in patients on diuretic therapy.

Nondigestible Sugars and Alcohols

Lactulose is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other nonabsorbable sugars such as *sorbitol* and *mannitol* are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and *vincristine*, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15 to 30 mL at night, with increases as needed up to 60 mL/day in divided doses. Effects may not be seen for 24 to 48 h after dosing begins. Abdominal discomfort or distention and flatulence are relatively common but usually subside with continued administration.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in "trapping" of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give enough lactulose (usually 20–30 g three to four times per day) to produce two to three soft stools a day with a pH of 5 to 5.5.

Stool-Wetting Agents and Emollients

Docusate. Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool and permitting easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. *Docusate sodium* (dioctyl sodium sulfosuccinate, 100 mg twice per day) and *docusate calcium* (dioctyl calcium sulfosuccinate, 240 mg/day) are well tolerated but have marginal efficacy in most cases of chronic constipation.

Mineral Oil. Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2 to 3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (e.g., vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur. Thus, "heavy" mineral oil should not be taken at bedtime, and "light" (topical) mineral oil should never be administered orally.

Stimulant (Irritant) Laxatives

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle and probably induce limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility (Lacy et al., 2014; Paré and Fedorak, 2014). This group includes *diphenylmethane derivatives*, *anthraquinones*, and *ricinoleic acid*.

Diphenylmethane Derivatives. ***Bisacodyl.*** *Bisacodyl* is marketed as enteric-coated and regular tablets and as a suppository for rectal administration. The usual oral daily dose of *bisacodyl* is 10 mg (to a maximum of 30 mg) for adults and 5 to 10 mg for children ages 6 to 12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, so the laxative effects after an oral dose usually are produced in 6 to 10 h. Suppositories (10 mg) work within 15 to 60 min. Due to the possibility of developing an atonic nonfunctioning colon, *bisacodyl* should not be used for more than 10 consecutive days. *Bisacodyl* is mainly excreted in the stool. Only 5% is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon; they can also cause colonic ischemia.

Sodium Picosulfate. *Sodium picosulfate* is a diphenylmethane derivative that is hydrolyzed by colonic bacteria to its active form and acts locally only in the colon. It is used as a preparation agent prior to endoscopic procedures. The most commonly reported adverse reactions are abdominal pain, bloating, and diarrhea. *Sodium picosulfate* should not be taken on a continuous daily basis as prolonged use may lead to fluid and electrolyte imbalances such as hypokalemia and to enteropathy. *Sodium picosulfate* is contraindicated in patients with reduced glomerular filtration rate, bowel perforation, and toxic megacolon. Caution should be exercised in patients with cardiac arrhythmias and those with renal impairment. *Phenolphthalein*, once among the most popular components of laxatives, has been withdrawn from the market in the U.S. because of potential carcinogenicity. *Oxyphenisatin* was withdrawn due to hepatotoxicity.

Anthraquinone Laxatives. These derivatives of plants such as aloe, cascara, and senna share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. For medicinal use, monoanthrones (oral mucosal irritants) are converted to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

Senna. Senna is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides sennoside A and B. From 15 to 30 mg are given as a single dose or a divided dose twice daily, resulting in an onset of action within 6 to 12 h. Chronic use of senna may lead to melanosis coli, and adverse effects include tolerance, nausea and vomiting, and abdominal cramping.

Cascara sagrada. Cascara sagrada is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. The synthetic monoanthrone *danthron* was withdrawn from the U.S. market because of concerns over possible carcinogenicity. The FDA has categorized aloe and cascara sagrada products sold for laxation as not generally recognized as safe and effective for OTC use because of a lack of scientific information about potential carcinogenicity. This judgment is medically prudent but may provoke wistfulness among Joyceans, who recall that cascara sagrada, the *sacred bark*, worked well for Leopold Bloom, in Dublin, on the morning of June 16, 1904:

> Midway, his last resistance yielding, he allowed his bowels to ease themselves quietly as he read, reading still patiently that slight constipation of yesterday quite gone. Hope it's not too big to bring on piles again. No, just right. So. Ah! Costive. One tabloid of cascara sagrada. Life might be so. (Joyce, 1922)

Castor Oil. A bane of childhood since the time of the ancient Egyptians, castor oil is derived from the bean of the castor plant, *Ricinus communis*. The castor bean is the source of an extremely toxic protein, ricin, as well

as the oil (chiefly of the triglyceride of ricinoleic acid). The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, *ricinoleic acid*, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1 to 3 h; however, the usual dose for a cathartic effect is 15 to 60 mL for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is not recommended now.

Enemas and Suppositories. Enemas are employed either by themselves or as adjuncts to bowel preparation regimens to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that are either osmotically active or irritants; however, their safety and efficacy have not been studied. Repeated enemas with hypotonic solutions can cause hyponatremia while repeated enemas with sodium phosphate–containing solution can cause hypocalcemia.

Glycerin. Glycerin is absorbed when given orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5 to 15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. *CEO-TWO* suppositories contain sodium bicarbonate and potassium bitartrate and make use of rectal distension to initiate laxation. When administered rectally, the suppository produces CO_2, which initiates a bowel movement in 5 to 30 min.

Prokinetic and Secretory Agents for Constipation

The term *prokinetic* is reserved for agents that enhance GI transit via interaction with specific receptors involved in the regulation of motility (Acosta and Camilleri, 2015; Gudsoorkar and Quigley, 2020; Tack and Camilleri, 2018).

The potent $5HT_4$ receptor agonist *prucalopride* (1–4 mg/day) may be useful for the treatment of chronic constipation. *Misoprostol*, a synthetic prostaglandin analogue, is primarily used for protection against gastric ulcers resulting from the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and for the medical termination of pregnancy (see Chapters 41, 48, and 53). Prostaglandins can stimulate colonic contractions, particularly in the descending colon, an effect that may explain the diarrhea that limits the usefulness of *misoprostol* as a gastroprotectant and *misoprostol*'s utility in patients with intractable constipation. Doses of 200 μg daily or every other day can be effective when used with PEG. *Misoprostol* should not be used in women who could become pregnant because it induces labor. It can also increase menstrual bleeding. *Colchicine*, a microtubule formation inhibitor used for gout (see Chapter 42), has also been shown to be effective in constipation (1 mg/day), but its toxicity limits widespread use.

Four recently introduced secretory agents, *lubiprostone*, *linaclotide*, *plecanatide*, and *tenapanor*, with novel mechanisms of action restricted to the gut lumen have demonstrated effectiveness in the treatment of chronic constipation in adults.

Lubiprostone. ***Mechanism of Action and Pharmacology.*** *Lubiprostone* is a prostanoid activator of ClC-2 Cl^- channels. The drug appears to bind to the EP_4 prostaglandin receptor for PGE_2, a GPCR that couples to G_s, activating adenylyl cyclase and leading to enhanced apical Cl^- conductance. The drug promotes the secretion of a chloride-rich fluid, thereby improving stool consistency and promoting increased frequency by reflexly activating motility (Wilson and Schey, 2015).

Therapeutic Uses and Adverse Effects. A dose of 8 μg twice daily was found to be effective in constipation-predominant IBS, although higher doses (24 μg twice daily) are given for chronic constipation and opioid-induced constipation (see discussion that follows). The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of *lubiprostone* include nausea (in up to 30% of patients), headache, diarrhea, allergic reactions, and dyspnea.

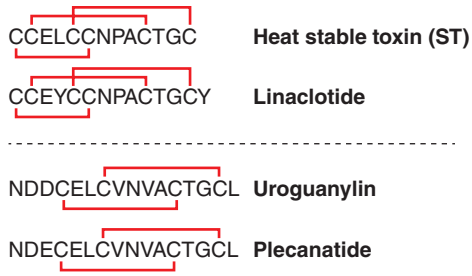

Figure 54–5 *Endogenous, bacterial, and pharmacological activators of intestinal guanylyl cyclase.* Amino acids are represented by the single letter amino acid code; the red connection lines represent intrachain disulfide bonds joining pairs of cysteines. In the intestinal tract, the naturally occurring ligands uroguanylin and bacterial heat stable toxin (ST) activate a membrane-spanning isoform of guanylyl cyclase, GC-C; these two peptides form the basis for two pharmacological activators of GC-C, *linaclotide* and *plecanatide*. *Plecanatide* is a synthetic analogue of uroguanylin; each has an aspartate in the N-terminal region that facilitates interaction with GC-C at acidic pH. *Linaclotide* is a synthetic analog of ST; both have rigid structure conferred by three pairs of disulfide bonds. The rigidity of ST and *linaclotide* renders their actions relatively pH independent (Data from Waldman and Camilleri, 2018).

Linaclotide. ***Mechanism of Action and Pharmacology.*** Another class of secretory agent is *linaclotide*, a 14–amino acid peptide agonist of the C isoform of membrane-spanning guanyl cyclase (GC-C). In the intestinal epithelium, GC-C is activated physiologically by guanylin and uroguanylin, pathologically by heat-stable bacterial toxins that cause diarrhea, and pharmacologically by *linaclotide*, which is a synthetic analog of a heat stable bacterial toxin (Figures 54-4 and 54–5). Activation of GC-C results in increased synthesis of cyclic GMP, resulting in enhanced chloride and bicarbonate secretion into the intestinal lumen, leading in turn to water secretion and enhanced motility. Some cellular cyclic GMP may be exported and reduce visceral pain by an action on primary afferent nerves innervating the GI tract (Yu and Rao, 2014).

Therapeutic Uses and Adverse Effects. This compound is approved in the treatment of constipation-predominant IBS and chronic constipation in adults at doses of 290 and 145 μg daily, respectively. Common side effects include diarrhea (which can be severe), gas, abdominal pain, and headaches. *Linaclotide* is contraindicated in children under 6 years old and is not recommended for older children.

Plecanatide. ***Mechanism of Action and Pharmacology.*** *Plecanatide* is a 16–amino acid synthetic analogue of uroguanylin and acts via the same basic mechanism, activation of GC-C, as does *linaclotide* (see Figure 54–5).

Therapeutic Uses and Adverse Effects. This agent is approved for the treatment of chronic idiopathic constipation in adults at a dose of 3 mg daily, with or without food. The most common adverse reaction is diarrhea (5%; severe in 0.6%). *Plecanatide* is contraindicated in children less than 6 years old and not advised in older children up to 18 years of age.

Tenapanor. ***Mechanism of Action and Pharmacology.*** *Tenapanor* is an inhibitor of isoform 3 of the Na^+-H^+ exchanger (NHE), the most abundantly expressed isoform of the NHE in the GI tract. Treatment with *tenapanor* reduces the absorption of Na^+ and enhances intestinal fluid volume and transit.

Therapeutic Uses and Adverse Effects. This agent is approved for the treatment of constipation-predominant IBS in adults at a dose of 50 mg orally twice daily. Diarrhea, abdominal distension, flatulence, and dizziness were the most frequent side effects. Severe diarrhea was reported in 2.5% of patients treated with *tenapanor*. It is contraindicated in children less than 6 years old and not advised in older children up to 18 years of age.

Opioid-Induced Constipation

Opioid analgesics can cause severe constipation. Laxatives are the first-line strategy for opioid-induced constipation, but they are frequently ineffective. *Lubiprostone*, described above, is one recent alternative. Another promising alternative strategy is the prevention of opioid-induced

constipation with peripherally acting MOR (mu opioid receptor) antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia and limiting the symptoms of opioid withdrawal (Crocket et al., 2019; Farmer et al., 2019; see also Chapter 23).

Methylnaltrexone

Mechanism of Action and Pharmacology. The peripherally restricted MOR antagonist *methylnaltrexone* is approved for the treatment of opioid-induced constipation. The efficacy of this compound has been shown in randomized placebo-controlled trials (Crocket et al., 2019; Farmer et al., 2019).

ADME. In patients who respond to the drug, its onset of action is 30 to 60 min. It is excreted largely unchanged in the urine and feces but does undergo some hepatic metabolism including sulfation. The time to peak plasma concentration is 30 min, and the $t_{1/2}$ is about 8 h.

Therapeutic Uses and Adverse Effects. *Methylnaltrexone* is given as a subcutaneous injection (12 mg/day) in adults with chronic noncancer pain after discontinuing other laxatives. In advanced illness (palliative care), dosing varies according to body weight (0.15 mg/kg), with dosing every other day to a maximum of daily injection if required. When administered repeatedly every other day for 2 weeks, bowel movements occurred in about 50% of patients, compared with 8% to 15% of patients receiving placebo. Abdominal pain, flatulence, and nausea frequently accompany this treatment. Serious diarrhea sometimes occurs that requires discontinuing therapy. Patients with known or suspected GI obstruction are at increased risk of perforation. Opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naldemedine

Mechanism of Action and Pharmacology. *Naldemedine* is a peripherally restricted opioid antagonist. It is a derivative of *naltrexone* made more polar and larger in mass with the addition of a side chain. It is also a substrate for the ATP-dependent efflux transporter P-glycoprotein (Pgp, MDR1, ABCB1; see Tables 4–1 and 4–4). These two properties limit its access to the CNS.

ADME. Following oral administration in the fasted state, *naldemedine* is rapidly absorbed, reaching peak concentrations in approximately 45 min. Food prolongs the time to peak (to ~2.5 h) but does not reduce the overall extent of absorption. *Naldemedine* is metabolized by hepatic CYP3A and is excreted in both the urine (57%) and feces (35%); its $t_{1/2}$ is 11 h.

Therapeutic Uses and Adverse Effects. *Naldemedine* is approved for the treatment of opioid-induced constipation in adult patients with chronic noncancer pain; dose is 0.2 mg/day orally. Common adverse reactions are abdominal pain, diarrhea, nausea, vomiting, and gastroenteritis. *Naldemedine* is contraindicated in patients with known or suspected obstruction of the GI tract. Opioid withdrawal may be precipitated with the use of this compound.

Naloxegol

Mechanism of Action and Pharmacology. *Naloxegol* comprises the MOR antagonist *naloxone* conjugated to a PEG polymer. This limits blood-brain barrier permeability because it is a substrate for the Pgp efflux transporter, so it behaves as a peripherally restricted MOR antagonist. It is approved for the treatment of opioid-induced constipation. Randomized placebo-controlled trials have demonstrated the efficacy of this compound (Crocket et al., 2019; Farmer et al., 2019).

ADME. The drug is given orally on an empty stomach and is rapidly absorbed. The time to peak plasma concentration is about 2 h with a secondary peak occurring 0.4 to 3 h after the first. *Naloxegol* is metabolized primarily by hepatic CYP3A, and metabolites are excreted in the feces (68%) and urine (16%). The plasma $t_{1/2}$ is variable (6–11 h).

Therapeutic Uses and Adverse Effects. *Naloxegol*, approved for opioid-induced constipation in adults, is given orally 12.5 or 25 mg once per day after discontinuing other laxatives. Diarrhea, abdominal pain, flatulence, nausea, and vomiting are the major adverse reactions. Precautions are the same as for *methylnaltrexone*: Patients with known or suspected GI obstruction are at increased risk of perforation, and opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naloxone and Oxycodone

Mechanism of Action and Pharmacology. This fixed-ratio (2:1 of *oxycodone:naloxone*) combination drug is given orally to relieve opioid-induced constipation when opioid pain relief is still required. The *naloxone* displaces *oxycodone* from the MOR in the GI tract without limiting the degree of central analgesia (Farmer et al., 2019). This combination drug carries with it the risks inherent with all opioids, including addiction and respiratory depression. Full details of this agent are given in Chapter 23.

Therapeutic Uses and Adverse Effects. *Naloxone-oxycodone* is approved in Canada and other countries for opioid-induced constipation in adults but currently not for this purpose in the U.S. This oral medication dosing is for pain control and is individualized. A single dose of 40 mg *oxycodone*/20 mg *naloxone* every 12 h should not be exceeded. Adverse GI reactions include nausea and vomiting, constipation, and diarrhea.

Other Agents for Opioid-Induced Constipation

In clinical trials, the MOR antagonist *alvimopan* (see separate discussion below) increased spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia. *Alvimopan* is approved for use in the U.S. for postoperative bowel recovery. However, due to significant cardiovascular adverse events, this drug is not FDA-approved for opioid-induced constipation, and further phase III trials are under way. In addition, the GC-C agonist *linaclotide* (see previous discussion) is in clinical trials for this condition.

Postoperative Ileus

Postoperative ileus refers to the intolerance to oral intake and nonmechanical obstruction of the bowel that occurs 3 to 5 days after abdominal and nonabdominal surgery. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving sympathetic nerves, enteric MOR, and the activation of local inflammatory mechanisms that reduce smooth muscle contractility (Bragg et al., 2015). The condition is exacerbated by opioids, which are the mainstay of postoperative analgesia. Prokinetic agents typically do not have much effect in this condition, but a new therapeutic agent, *alvimopan*, has been introduced to reduce GI recovery time after surgery.

Alvimopan

Mechanism of Action and Pharmacology. *Alvimopan* is an orally active, peripherally restricted MOR antagonist that is approved to accelerate the time to upper and lower GI recovery following partial large- or small-bowel resection surgery with primary anastomosis (Curran et al., 2008).

ADME. The drug is hydrolyzed by the gut flora to the active amide. The active metabolite is further metabolized by hepatic glucuronidases. The peak plasma concentration of the active metabolite occurs in about 36 h. The drug's $t_{1/2}$ is 10 to 18 h; the drug is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects. The drug is given 30 min to 5 h prior to surgery (12 mg) and then twice daily for up to a maximum of 7 days or until discharge, not to exceed 15 doses. Adverse effects include hypokalemia, dyspepsia, anemia, back pain, and urinary retention. Because of the risk of myocardial infarctions and neoplasia, this drug is available only through a restricted-access program in the U.S.

Antidiarrheal Agents

Diarrhea: General Principles and Approach to Treatment

Diarrhea (Greek and Latin: *dia*, "through," and *rheein*, "to flow or run") does not require any definition to people who suffer from "the too rapid evacuation of too fluid stools." Diarrhea is usually defined as excessive

fluid weight, with 200 g/day representing the upper limit of normal stool water weight for healthy adults in the Western world. Because stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes of diarrhea facilitates effective treatment (Thiagarajah et al., 2015). From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen), excessive secretion of electrolytes and water into the intestinal lumen, exudation of protein and fluid from the mucosa, and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a *benign*, self-limited illness requiring no treatment or evaluation. Acute diarrhea is frequently due to infection with bacteria, viruses, or protozoa. In more severe cases of diarrhea and in infants and small children, dehydration and electrolyte imbalances are the principal risk. *Oral rehydration therapy* therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Na^+ absorption links to glucose uptake by the enterocyte, which is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms (Menees et al., 2012). Nonspecific antidiarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms.

Empiric Antibiotic Therapy

The use of empiric antibiotic therapy for acute diarrhea (therapy given in the absence of diagnostic evaluation) must be carefully balanced with the risks. In patients with suspected or proven enterohemorrhagic *Escherichia coli*, antibiotics should be avoided because of the risk of hemolytic uremic syndrome. Similarly, in patients with suspected *Clostridium difficile*, other antibiotics should be discontinued if possible. Treatment of traveler's diarrhea, bacterial diarrhea, and those with more severe conditions is appropriate under some conditions, based on the severity of diarrhea and the duration of the symptoms (Steffen et al., 2015). The first-line therapy for acute (most commonly, traveler's) diarrhea in adults is oral *fluoroquinolone* antibiotics (see Chapter 57 for specific drug details): *ciprofloxacin* (500 mg twice daily for up to 3 days), *norfloxacin* (400 mg twice daily for up to 3 days), *ofloxacin* (200 mg twice daily for up to 3 days), or *levofloxacin* (500 mg daily for up to 3 days). *Azithromycin* (500 mg/day for 1–3 days or a maximum of 1000-mg single dose), *rifaximin* (200 mg three times per day for up to 3 days), and *rifamycin* (388 mg twice daily for 3 days) are alternative therapeutic agents. *Trimethoprim/sulfamethoxazole* is no longer recommended for prevention or treatment of traveler's diarrhea because of increasing resistance worldwide among likely pathogens. In children, the treatment of traveler's diarrhea remains controversial. *Azithromycin* (10 mg/kg to a maximum of 500-mg single dose) is the preferred treatment of children with traveler's diarrhea.

Bismuth Subsalicylate

Mechanism of Action and Pharmacology. Bismuth compounds are used to treat a variety of GI disorders, although their mechanism of action remains poorly understood (Menees et al., 2012). *Bismuth subsalicylate* is a popular OTC preparation that consists of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the *bismuth subsalicylate* reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid.

Bismuth is thought to have antisecretory, anti-inflammatory, and antimicrobial effects. Bismuth also relieves nausea and abdominal cramps. The clay in *bismuth subsalicylate* and generic formulations may have some additional benefits in diarrhea, but this is not clear. *Bismuth subsalicylate* is used for the prevention and treatment of traveler's diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis.

Therapeutic Uses and Adverse Effects. A recommended dose of the *bismuth subsalicylate* (30 mL of regular-strength liquid or two tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30 to 60 min, as needed, up to eight times a day. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract. Although 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same warning regarding Reye's syndrome as other salicylates and may also cause CNS side effects, hearing loss, and tinnitus.

Probiotics

The GI tract contains a vast and complex commensal microflora necessary for health, presented at length in Chapter 6. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea and possibly other disease conditions (see Chapter 55). Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal conditions, antibiotic-associated diarrhea, and infectious diarrhea (Menees et al., 2012). In clinical trials, preparations containing *Lactobacillus* GG and *Saccharomyces boulardii* have been found to be effective for these conditions.

Antimotility and Antisecretory Agents

Opioids. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either MORs or DORs on enteric nerves, epithelial cells, and muscle (see Chapter 23). These mechanisms include effects on intestinal motility (via MOR), intestinal secretion (via DOR, the delta opioid receptor), and absorption (via MOR and DOR). Commonly used antidiarrheals such as *diphenoxylate*, *difenoxin*, and *loperamide* act principally via peripheral MOR and are preferred over opioids that penetrate the CNS.

Loperamide. ***Mechanism of Action and Pharmacology.*** *Loperamide*, a compound with MOR activity, is an orally active antidiarrheal agent (Hanauer, 2008; Menees et al., 2012). The drug is 40 to 50 times more potent than *morphine* as an antidiarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. *Loperamide* also increases anal sphincter tone. In addition, *loperamide* has antisecretory activity against cholera toxin and some forms of *E. coli* toxin, presumably by acting on G_i-linked receptors to counter the stimulation of adenylyl cyclase activity by the toxins.

ADME. *Loperamide* is available OTC in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3 to 5 h. It has a $t_{1/2}$ of about 11 h and undergoes extensive hepatic metabolism.

Therapeutic Uses and Adverse Effects. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg/day. If there is clinical improvement and acute diarrhea does not occur within 48 h, *loperamide* should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2 to 5 years, 4 mg for ages 6 to 8 years, and 6 mg for ages 8 to 12 years. *Loperamide* is not recommended for use in children younger than 2 years. *Loperamide* is effective against traveler's diarrhea, used alone or in combination with antibiotics. It is used as adjunct treatment in many forms of chronic diarrheal disease (initially as for acute diarrhea, but with typical divided daily doses of 4–8 mg/day), with few adverse effects. *Loperamide* is more effective in

treating diarrhea than *diphenoxylate*. Overdosage, however, can result in constipation, CNS depression (especially in children), and paralytic ileus. In addition, the FDA has placed a black box warning on the drug, noting that exceeding the recommended dosage can result in cardiac events including torsades de pointes, cardiac arrest, and death. In patients with active inflammatory bowel disease involving the colon (see Chapter 55), *loperamide* should be used with great caution, if at all, to avoid development of toxic megacolon.

Diphenoxylate and Difenoxin. ***Mechanism of Action and Pharmacology.*** *Diphenoxylate* and its active metabolite *difenoxin* (diphenoxylic acid) are related structurally to *meperidine*. As antidiarrheal agents, *diphenoxylate* and *difenoxin* are somewhat more potent than *morphine* (Menees et al., 2012). Both drugs are listed as schedule V controlled substances by the Drug Enforcement Agency, and both are coformulated with *atropine* to discourage habituation.

ADME. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1 to 2 h. *Diphenoxylate* is rapidly deesterified to *difenoxin*, which is eliminated with a $t_{1/2}$ of about 12 h.

Therapeutic Uses and Adverse Effects. Both drugs are indicated for the treatment of diarrhea. The usual dosage for adults is two tablets initially (*diphenoxylate* or *difenoxin*), then one tablet every 3 to 4 h, not to exceed 20 mg/day (*diphenoxylate*) or 8 mg/day (*difenoxin*). Acute diarrhea usually improves in 48 h if the medication is effective. If chronic diarrhea does not improve within 10 days at the maximum daily dose, then these agents are not likely to be effective. *Diphenoxylate* is also sold as an oral solution (2.5 mg per 5 mL), which is recommended if used cautiously in children. For children, the initial dose is 0.3 to 0.4 mg/kg per day in four divided doses to a maximum of 10 mg/day. Once symptoms are controlled, dosing should be reduced; if no effect is seen in 48 h, the drug is unlikely to be effective. Both drugs can produce CNS effects when used in higher doses (40–60 mg/day) and thus have a potential for abuse or addiction. They are available in preparations containing small doses of *atropine* (considered subtherapeutic) to discourage abuse and deliberate overdosage: 25 μg of *atropine* sulfate per tablet with either 2.5 mg *diphenoxylate* hydrochloride or 1 mg of *difenoxin* hydrochloride. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the *atropine* (nausea, dry mouth, blurred vision, etc.) (see Chapter 11).

Other Opioids. Opioids used for diarrhea include *codeine* (in doses of 30 mg given three or four times daily) and opium-containing compounds. *Paregoric* (camphorated opium tincture) contains the equivalent of 2 mg of *morphine* per 5 mL (0.4 mg/mL); *deodorized tincture of opium*, which is 25 times stronger, contains the equivalent of 50 mg of *morphine* per 5 mL (10 mg/mL). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The antidiarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg *morphine*) four times daily; the adult dose of *paregoric* is 5 to 10 mL (equivalent to 2–4 mg *morphine*) one to four times daily. *Paregoric* is used in children at a dose of 0.25 to 0.5 mL/kg (equivalent to 0.1–0.2 mg *morphine*/kg) one to four times daily.

Enkephalins. Enkephalins are endogenous opioids that are important enteric neurotransmitters; they can inhibit intestinal secretion without affecting motility. *Racecadotril* is an example.

Racecadotril. ***Mechanism of Action and Pharmacology.*** *Racecadotril* (acetorphan), a prodrug, is rapidly converted in the body to thiorphan, a dipeptide inhibitor of enkephalinase (a neutral endopeptidase [NEP]; EC 3.4.24.11) that does not penetrate the CNS. By inhibiting peripheral enkephalin degradation, thiorphan potentiates the effects of endogenous enkephalins on the MOR in the GI tract to produce an antidiarrheal effect, acting predominantly as an antisecretory agent (Thiagarajah et al., 2015). In addition to enkephalins, substrates of NEP include neuropeptide Y, atrial and brain natriuretic peptides, substance P, and neurotensin, among others (Erdös and Skidgel, 1989). Thus, inhibition of enkephalinase activity could elevate the levels of these messengers as well, complicating interpretation of *racecadotril*'s effects on physiological systems.

Therapeutic Uses and Adverse Effects. *Racecadotril* is indicated for acute diarrhea. It is given orally as a 100-mg initial dose, which is repeated every 8 h as needed until diarrhea stops, for up to 7 days maximum. In children, it is given with oral rehydration solution according to body weight (1.5 mg/kg every 8 h), until symptoms improve or for a maximum of 7 days. This drug is available in many countries, but not the U.S., and is efficacious and safe in children with acute diarrhea. It produces less constipation than *loperamide* and has minimal other adverse effects (headache, itching).

α_2 Adrenergic Receptor Agonists

Mechanism of Action and Pharmacology. The α_2 adrenergic receptor agonists such as *clonidine* can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a role for use by diabetics with chronic diarrhea.

Therapeutic Uses and Adverse Effects. Oral *clonidine* (beginning at 0.6 mg three times daily) has been used in diabetic patients with chronic diarrhea; the use of a topical preparation may result in plasma levels of the drug that are steadier. *Clonidine* also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients (see Chapter 14 for details of the pharmacology of *clonidine*).

Octreotide and Somatostatin

Mechanism of Action and Pharmacology. *Octreotide* (see Chapter 46) is an octapeptide analogue of somatostatin (SST) that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. *Octreotide* inhibits secretion of 5HT and various GI peptides. Its greatest utility may be in the "dumping syndrome" seen in some patients after gastric surgery and pyloroplasty, in whom *octreotide* inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects. *Octreotide* is widely available. SST is available in some countries, but not the U.S.

ADME. *Octreotide* has a $t_{1/2}$ of 1 to 2 h and is administered either subcutaneously or intravenously as a bolus dose. The time to peak is 0.4 h after subcutaneous injection and 1 h after intramuscular injection. It is metabolized in the liver and excreted in the urine. SST has a plasma $t_{1/2}$ of 1 to 2 min.

Therapeutic Uses and Adverse Effects. Standard initial therapy with *octreotide* is 50 to 100 μg, given subcutaneously two or three times a day, with titration to a maximum dose of 500 μg three times daily, based on clinical and biochemical responses. A long-acting preparation of *octreotide* acetate enclosed in biodegradable microspheres is available for use in the treatment of diarrhea associated with carcinoid tumors and VIP-secreting tumors, as well as in the treatment of acromegaly (see Chapter 46). This preparation is injected intramuscularly once per month in a dose of 20 mg. Side effects of *octreotide* depend on the duration of therapy: Transient nausea, bloating, or pain at sites of injection may occur in the short term, with the potential for gallstone formation and hypo- or hyperglycemia occurring in the long term. However, there are also numerous other side effects, including cardiovascular, endocrine, and CNS.

Variceal Bleeding. SST and *octreotide* are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. *Octreotide* also may act through the ANS. For patients with variceal bleeding, therapy with *octreotide* usually is initiated while the patient is waiting for endoscopy (a 50-μg bolus dose followed by 50 μg hourly for 2–5 days) (Bhutta and Garcia-Tsao, 2015). Because of its short $t_{1/2}$ (1–2 min), SST can be given only by intravenous infusion (a 250-μg bolus dose followed by 250 μg hourly for 2–5 days). Higher doses (up to 500 μg/h) are more efficacious and can be used for patients who continue to bleed on the lower dose.

Intestinal Dysmotility. *Octreotide* has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, *octreotide* also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

Pancreatitis. Both SST and *octreotide* inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis (Li et al., 2011). The rationale for their use is to rest the pancreas so inflammation by the continuing production of proteolytic enzymes is not aggravated, to reduce intraductal pressures, and to ameliorate pain. However, clinical trials have demonstrated that neither agent is effective in the treatment of acute pancreatitis, although *octreotide* confers some benefit when given prophylactically to prevent postendoscopic retrograde cholangiopancreatography pancreatitis.

Telotristat Ethyl

Mechanism of Action and Pharmacology. This drug reduces diarrhea associated with carcinoid tumors by inhibiting tryptophan hydroxylase, the rate-limiting enzyme of 5HT biosynthesis. 5HT secretion stimulates fluid secretion and motility in the GI tract.

ADME. *Telotristat ethyl* is absorbed after oral administration and converted to the active agent *telotristat* by the action of carboxylesterases. Peak plasma levels of *telotristat* occur 1 to 3 h after ingestion. Clearance occurs with a $t_{1/2}$ of 5 h; elimination is via the feces.

Therapeutic Uses and Adverse Effects. *Telotristat* is given in combination with somatostatin analogue therapy for the treatment of diarrhea in carcinoid syndrome. A dose of 250 mg three times per day may be given to adult patients who are not adequately controlled by somatostatin analogue therapy alone. The main adverse effects are constipation, nausea, headache, increased gamma glutamyl transferase levels, depression, peripheral edema, flatulence, reduced appetite, and pyrexia.

Berberine

Berberine is a plant alkaloid that has complex pharmacological actions that include antimicrobial effects, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly to treat bacterial diarrhea and cholera but is also apparently effective against intestinal parasites (Menees et al., 2012). The antidiarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca^{2+} into cells. In addition, it inhibits intestinal secretion. *Berberine* is not FDA-approved for use in the U.S.

Bulk-Forming and Hydroscopic Agents

Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarbophil absorb water and increase stool bulk (calcium polycarbophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrhea in patients with IBS. Some of these agents also may bind bacterial toxins and bile salts.

Another bulk-forming agent is *dextranomer and hyaluronic acid. Dextranomer* microspheres are a network of dextran-sucrose beads with exposed hydroxy groups. When this complex is applied to an exudative wound surface, the exudate is drawn by capillary forces generated by the swelling of the beads. The sodium hyaluronate provides viscosity and facilitates injection of the *dextranomer*. This agent is licensed (as a device) for the treatment of fecal incontinence in adults. It is given as four 1-mL submucosal injections in the anal canal, which can be repeated after at least 4 weeks if the first treatment is inadequate. The major adverse effects include injection area pain and bleeding.

Bile Acid Sequestrants

Cholestyramine, *colestipol*, and *colesevelam* effectively bind bile acids and some bacterial toxins (Menees et al., 2012). *Cholestyramine* is useful in the treatment of bile salt–induced diarrhea, as in patients with resection of the distal ileum or after cholecystectomy. In these patients, excessive concentrations of bile salts reach the colon and stimulate water and electrolyte secretion. Patients with extensive ileal resection (usually >100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of *cholestyramine* aggravates the diarrhea. In patients having persistent diarrhea despite treatment, bile-acid malabsorption may be a contributing factor giving rise to bile salt–induced diarrhea. *Cholestyramine* and *colesevelam* can be given as an off-label use at a dose of 4 to 12 g of the dried resin per day. If successful, the dose may be titrated down to achieve the desired stool frequency. The use of these agents is limited by GI side effects, including bloating, flatulence, abdominal discomfort, and constipation, as well as malabsorption of fat-soluble vitamins and drug-drug interactions.

Crofelemer

Mechanism of Action and Pharmacology. *Crofelemer* is a purified oligomeric proanthocyanidin from "dragon's blood," the reddish latex-like sap of a South American euphorbia. This botanic extract is used for the treatment of diarrhea associated with antiretroviral therapy for HIV/AIDS (Crutchley et al., 2010). It is not approved for infectious or other diarrheas. This drug has minimal systemic absorption and works by inhibiting the cystic fibrosis transmembrane conductance regulator (CFTR, a cyclic AMP–stimulated Cl^- channel) and Ca^{2+}-activated chloride ion channels on the luminal aspect of the enterocyte, thereby reducing the water loss associated with chloride secretion into the lumen.

Therapeutic Uses and Adverse Effects. This drug is given orally (125 mg twice daily) to adults. Infectious diarrhea must be ruled out before treatment. The main adverse effects include upper respiratory tract infections, cough, flatulence, nausea, joint and back pain, and some other GI effects.

Irritable Bowel Syndrome

Irritable bowel syndrome affects up to 10% to 15% of the population in the U.S. and most other Western countries. Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. IBS appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders (Khan and Chang, 2010; Mayer et al., 2014). The disturbances in bowel function can be either constipation or diarrhea or both at different times. Considerable evidence suggests a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological, stimuli in this syndrome (Dekel et al., 2013; Mayer et al., 2014).

Many patients can be managed with fiber supplementation and dietary restrictions, notably by avoiding fermentable oligo-di-monosaccharides and polyols (FODMAPs), lactose, or gluten; however, many cannot. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific, using the agents discussed previously. An important role for serotonin in IBS has been suggested based on its involvement in sensitization of nociceptor neurons in inflammatory conditions and its role in the control of motility and secretion (Dekel et al., 2013). This has led to the development of specific receptor modulators for the treatment of IBS, such as the $5HT_3$ antagonist *alosetron* and the $5HT_4$ agonist *prucalopride* (see Figure 54–2).

An effective class of agents for IBS has been the tricyclic antidepressants (see Chapter 18), which can have neuromodulatory and analgesic properties independent of their antidepressant effect (Dekel et al., 2013). Tricyclic antidepressants have a proven track record in the management of chronic "functional" visceral pain in adults (off-label use). *Amitriptyline, nortriptyline, imipramine*, or *desipramine* can be used at lower doses than those used to treat depression. Starting doses of 10 to 25 mg *amitriptyline*, *nortriptyline,* or *imipramine* or 12.5 to 25 mg *desipramine* at bedtime should be given for 3 to 4 weeks because of their delayed onset of action; doses can be increased if tolerated and the patient is responsive to treatment. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns. SSRIs (see Chapters 15 and 18) have fewer side effects and have been advocated particularly for patients with functional constipation

because SSRIs can increase bowel movements and even cause diarrhea. However, they probably are not as effective as tricyclic antidepressants in the management of visceral pain. Antidepressant use in children is not strongly supported by clinical trials. α_2 Adrenergic agonists, such as *clonidine* (see Chapter 14), also can increase compliance and reduce distention-induced pain.

Alosetron

Mechanism of Action and Pharmacology

The $5HT_3$ receptor participates in sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. The clinical effect of $5HT_3$ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. *Alosetron*, a potent antagonist of the $5HT_3$ receptor, was initially withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. Nevertheless, the FDA has reapproved this drug under a limited distribution system for women with severe diarrhea-predominant IBS (Camilleri, 2013). The manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

ADME

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 h) is longer than expected from its $t_{1/2}$ of 1.5 h. It is metabolized by hepatic CYPs and is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects

The drug should be started at 1 mg/day divided into two doses for the first 4 weeks and, if tolerated, advanced to a maximum of 1 mg twice daily if necessary. If the response is inadequate after 4 weeks of 1 mg twice-daily dosing, treatment should be discontinued. The most serious adverse reactions are constipation and ischemic colitis, and therapy must be discontinued immediately in patients who develop those symptoms. Other adverse reactions include nausea and vomiting, GI discomfort and pain, diarrhea, flatulence, hemorrhoids, and others.

Additional $5HT_3$ antagonists currently available in the U.S. are approved for nausea and vomiting (see later in this chapter and Chapter 15).

Eluxadoline

Mechanism of Action and Pharmacology

Eluxadoline is a mixed MOR agonist, DOR antagonist, and KOR (kappa opioid receptor) agonist. It acts locally to reduce abdominal pain and diarrhea without producing constipation in patients with IBS. This opioid drug is FDA-approved for the treatment of diarrhea-predominant IBS in adults (Hornby, 2015).

ADME

Eluxadoline's time to peak C_p is 1.5 to 2 h; its $t_{1/2}$ is 3.7 to 6 h. The route of *eluxadoline*'s metabolism is not well established. The drug and its metabolic products are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS with a gallbladder, the therapeutic dose is 100 mg twice daily with food; the dose may be decreased to 75 mg twice daily in patients unable to tolerate the 100-mg dose. In patients without a gallbladder, *eluxadoline* is dosed at 75 mg twice daily to reduce the risk of sphincter of Oddi spasm and the potential complication of pancreatitis. Patients with known or suspected biliary duct obstruction, sphincter of Oddi disease or dysfunction, a history of pancreatitis, or structural diseases of the pancreas should not be given *eluxadoline*. There are also risks from constipation, and the drug should be discontinued if severe constipation occurs. There is some potential for addiction. The major adverse reactions to the drug are constipation, nausea, and abdominal pain.

Rifaximin

Mechanism of Action and Pharmacology

Antibiotics should not be used routinely in patients with IBS, but the FDA has approved the bacterial RNA polymerase inhibitor *rifaximin*, a poorly absorbed derivative of *rifamycin*, for diarrhea-predominant IBS (Saadi and McCallum, 2013).

ADME

Rifaximin is not suitable for treating systemic bacterial infections because of limited systemic exposure after oral administration. Most of an oral dose of *rifaximin* is recovered as unchanged drug in the feces. The half-life and AUC of the portion of the administered dose that enters the systemic circulation are increased in IBS patients ($t_{1/2}$ is 6 h), and the drug is cleared by the action of hepatic CYP3A; metabolites are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS, the therapeutic dose is 550 mg three times daily for 2 weeks. Patients may be re-treated with this regimen twice if symptoms recur. Adverse reactions include nausea, peripheral edema, dizziness, fatigue, the development of ascites, and elevation in serum alanine aminotransferase. If diarrhea worsens after treatment with *rifaximin*, then an evaluation for development of a severe infectious diarrhea or *C. difficile* enterocolitis should be performed.

Antispasmodics

Anticholinergic agents ("spasmolytics" or "antispasmodics") are used in patients with IBS but should not be used over the long term. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (see Chapter 11) and include the tertiary amines *dicyclomine* and *hyoscyamine* and the quaternary ammonium compounds *glycopyrrolate* and *methscopolamine* (off-label use). The advantage of the last two compounds is that they have a limited propensity to cross the blood-brain barrier and hence have a lower risk for neurological side effects such as light-headedness, drowsiness, or nervousness. These agents typically are given on either an as-needed basis or before meals to prevent the pain and fecal urgency that occur in some patients with IBS.

Dicyclomine is given in 20-mg doses orally every 6 h, increasing to 40 mg every 6 h unless limited by side effects. *Hyoscyamine* is available as sublingual tablets, orally disintegrating tablets, immediate-release oral capsules, tablets, elixir, and drops (all administered as 0.125–0.25 mg every 4 h as needed), as extended-release forms for oral use (0.25–0.375 mg every 12 h, or 0.375 mg every 8 h, as needed), and as an injection for intramuscular, intravenous, or subcutaneous use (0.25–0.5 mg every 4 h as needed). *Glycopyrrolate* is rarely used but is available as immediate-release tablets, as an oral solution, and as an injectable; the oral dose is 1 to 2 mg two or three times daily, not to exceed 6 mg/day. *Methscopolamine* is provided as 2.5- and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5 to 5 mg at bedtime.

Other Drugs

Cimetropium and *acotiamide* are muscarinic antagonists that are effective in patients with IBS but are not available in the U.S. *Acotiamide* appears to be a promising agent for the treatment of postprandial distress syndrome, one of two major forms of functional dyspepsia (Zala et al., 2015). *Otilonium bromide* is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca^{2+} channels and neurokinin NK_2 receptors; it is not available in the U.S. *Mebeverine hydrochloride*, a derivative of hydroxybenzamide, appears to have a direct effect on the smooth muscle cell, blocking K^+, Na^+, and Ca^{2+} channels. *Mebeverine* is used outside the U.S. as an antispasmodic agent. It is given orally, 100 to 135 mg three times daily or 200 mg twice daily, before meals.

Antinauseants and Antiemetics

Nausea and Vomiting

Emesis and the sensation of nausea that frequently accompanies it are generally viewed as components of a protective reflex that serve to rid the stomach and intestine of toxic substances (emesis) and prevent their further ingestion. Nausea serves as an unconditioned aversive stimulus for learning and memory (Horn, 2008; Hornby, 2015). Vomiting is a

complex process that appears to be coordinated by a central emesis center in the lateral reticular formation of the brainstem adjacent to both the CTZ in the area postrema on the floor of the fourth ventricle and the nucleus of the solitary tract (NTS). The lack of a blood-brain barrier at the CTZ permits monitoring of blood and cerebrospinal fluid constantly for toxic substances and relaying information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the NTS) and by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). The CTZ has high concentrations of receptors for serotonin ($5HT_3$), dopamine (D_2), ACh (muscarinic M_1), neurokinin (NK_1), cannabinoid (CB_1), and opioids. The NTS is rich in receptors for enkephalin, histamine, and ACh and expresses $5HT_3$ receptors. Myriad neurotransmitter agonists for these receptors are involved in nausea and vomiting (Figure 54–6). Antiemetics generally are classified according to the predominant receptor on which they are proposed to act (Table 54–4). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several antiemetic agents from different pharmacological classes may be used in combination (Table 54–5).

Nausea is distinct from emesis and is a frequent side effect of medications as well as a common feature of diseases that range from CNS disorders to GI disorders to infection. The brain centers involved in the sensation of nausea are located in higher brain regions than the emetic centers and include the insular, anterior cingulate, orbitofrontal, somatosensory, and prefrontal cortices. Most drugs used to treat emesis are relatively poor at preventing nausea (Andrews and Sanger, 2014).

$5HT_3$ Receptor Antagonists

Mechanism of Action and Pharmacology. The $5HT_3$ antagonists are the most effective drugs for the treatment of chemotherapy-induced and PONV (postoperative nausea and vomiting) in adults and children (Andrews and Sanger, 2014; Berger et al., 2017; Navari, 2013). However, they are less effective at suppressing acute nausea than they are at suppressing acute vomiting, and they are ineffective at reducing instances of delayed (24 h later) nausea and vomiting and anticipatory nausea and vomiting.

Ondansetron is the prototypical drug in this class. Other agents in this class include the first-generation antagonists *granisetron*, *dolasetron* (not available in the U.S. or Canada), and *tropisetron* (not available in the U.S.) and the second-generation antagonist *palonosetron*. *Palonosetron* has higher receptor affinity, a longer $t_{1/2}$, and demonstrated superiority over first-generation antagonists (Navari, 2014).

The $5HT_3$ receptors are present in several critical sites involved in emesis, including vagal afferents, the NTS (which receives signals from vagal afferents), and the area postrema itself (see Figure 54–6). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and stimulates vagal afferents (via $5HT_3$ receptors) to initiate the vomiting reflex. The highest concentrations of $5HT_3$ receptors in the CNS are found in the NTS and CTZ, and antagonists of $5HT_3$ receptors also may suppress nausea and vomiting by acting at these sites.

ADME. These agents are absorbed well from the GI tract and have a rapid onset of action. *Ondansetron* is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. The $t_{1/2}$ is 3 to 6 h. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. *Granisetron* also is metabolized predominantly by the liver by the CYP3A family and has a $t_{1/2}$ of 6 to 9 h, depending on the route of administration. *Dolasetron* is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver, while about one-third of it is excreted unchanged in the urine. The $t_{1/2}$ of the active metabolite hydrodolasetron is 6 to 8 h. *Palonosetron* is metabolized principally by CYP2D6; the metabolized and the unchanged forms are excreted in the urine in roughly equal proportions. The $t_{1/2}$ after intravenous injection is about 40 h in adults. The antiemetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level; these drugs require only once a day administration to be effective.

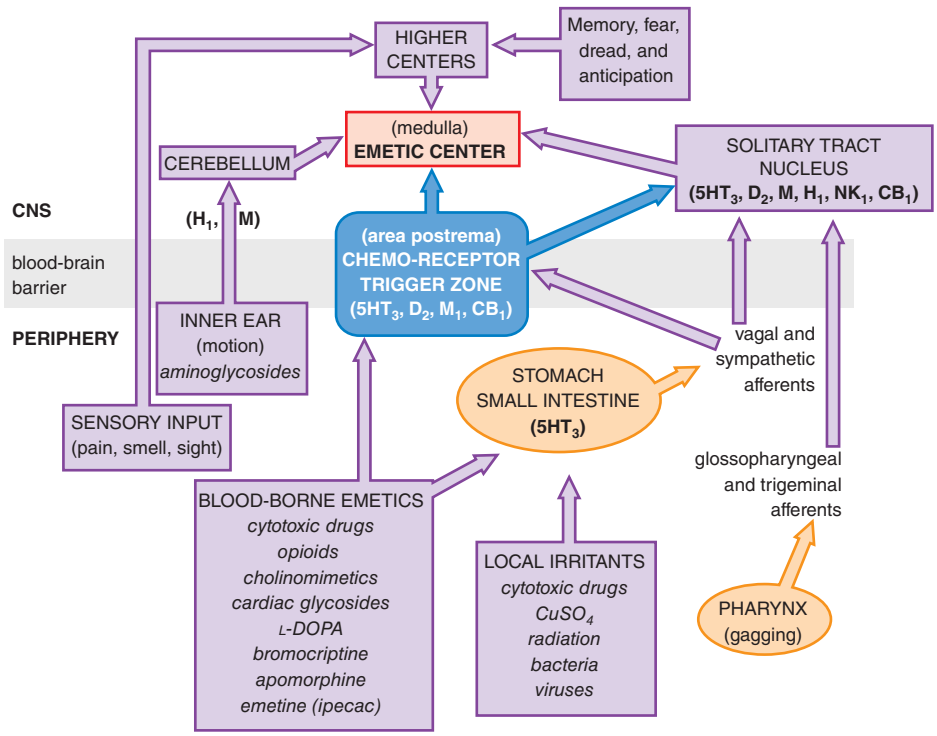

Figure 54–6 *Pharmacologist's view of emetic stimuli.* Many signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in *italics*. These pathways involve specific neurotransmitters and their receptors (**bold** type). Receptors are shown for dopamine (D_2), ACh (muscarinic, M), histamine (H_1), cannabinoids (CB_1), substance P (NK_1), and $5HT_3$. Some of these receptors also may mediate signaling in the emetic center.

TABLE 54–4 ■ GENERAL CLASSIFICATION OF ANTIEMETIC AGENTS

ANTIEMETIC CLASS	EXAMPLES	MOST EFFECTIVE AGAINST
$5HT_3$ receptor antagonists[a]	Ondansetron	Cytotoxic drug-induced emesis
Centrally acting dopamine receptor antagonists	Metoclopramide[b] Promethazine[c]	
Cannabinoid receptor agonists	Dronabinol, nabilone	
Neurokinin receptor antagonists	Aprepitant	Cytotoxic drug-induced emesis (delayed vomiting)
Histamine H_1 antagonists	Cyclizine	Vestibular emesis (motion sickness)
Muscarinic receptor antagonists	Hyoscine (scopolamine)	

[a]The most effective agents for chemotherapy-induced nausea and vomiting are the $5HT_3$ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy and reduce incidence of side effects. See Table 54–5.
[b]Also has some peripheral activity at $5HT_3$ receptors.
[c]Also has some antihistaminic and anticholinergic activity.

TABLE 54–5 ■ ANTIEMETIC AGENTS IN CANCER CHEMOTHERAPY[a]

Low risk of emesis: *Prechemotherapy* • Dexamethasone • Metoclopramide ± diphenhydramine • Prochlorperazine ± lorazepam	*Postchemotherapy (delayed emesis)* • None
Moderate risk of emesis: *Prechemotherapy* • $5HT_3$ antagonist + dexamethasone • Aprepitant + $5HT_3$ antagonist + dexamethasone • Fosaprepitant + $5HT_3$ antagonist + dexamethasone • Rolapitant + $5HT_3$ antagonist + dexamethasone • Netupitant/palonosetron + dexamethasone • Olanzapine + palonosetron + dexamethasone	*Postchemotherapy (delayed emesis)* • Dexamethasone *or* $5HT_3$ antagonist monotherapy (days 2 and 3) • Aprepitant ± dexamethasone (days 2 and 3) • ± Dexamethasone (days 2 and 3) • ± Dexamethasone (days 2 and 3) • ± Dexamethasone (days 2 and 3) • Olanzapine (days 2 and 3)
High risk of emesis: *Prechemotherapy* • Aprepitant + $5HT_3$ antagonist + dexamethasone • Fosaprepitant + $5HT_3$ antagonist + dexamethasone • Rolapitant + $5HT_3$ antagonist + dexamethasone • Netupitant/palonosetron + dexamethasone • Olanzapine + palonosetron + dexamethasone • Aprepitant *or* fosaprepitant + $5HT_3$ antagonist + dexamethasone + olanzapine	*Postchemotherapy (delayed emesis)* • Aprepitant (days 2 and 3) ± dexamethasone (days 2–4) • Dexamethasone (day 2), dexamethasone twice daily (days 3 and 4) • Dexamethasone (days 2–4) • Dexamethasone (days 2–4) • Olanzapine (days 2–4) • Aprepitant (days 2 and 3) if given on day 1 • + dexamethasone (days 2–4) + olanzapine (days 2–4)

[a]*Specific recommendations and doses are tailored to the patient and the chemotherapeutic regimen. For updated information, see the National Cancer Institute website (see Cancer Topics: Nausea and Vomiting).* Some patients profit from cannabinoids (dronabinol, nabilone) with or without a phenothiazine or dexamethasone.
NCCN Guidelines Insights: Antiemesis, Version 2. 2017 (Berger et al., 2017).

Therapeutic Uses and Adverse Effects. These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation. They also are effective against hyperemesis of pregnancy and PONV, but not against motion sickness. Unlike other agents in this class, *palonosetron* may be helpful in delayed emesis, perhaps reflecting its long $t_{1/2}$. These agents are available as tablets, oral solution, and intravenous preparations for injection. *Palonosetron*, in combination with the NK_1 receptor antagonist *netupitant* (see further discussion), is recently FDA approved for the treatment of acute and delayed nausea and vomiting. This combination is highly effective when combined with the corticosteroid *dexamethasone* (see further discussion). For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 54–6) infused over 15 min, beginning 30 min before chemotherapy, or in two or three divided doses, with the first usually given 30 min before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (*ondansetron* only) or orally. *Granisetron* is available as a transdermal formulation that is applied 24 to 48 h before chemotherapy and worn for up to 7 days (see Table 54–6). For the treatment of PONV, *ondansetron* is considered a gold standard (Gan et al., 2020). It is given as a 4-mg dose intravenously or 8-mg tablet orally. Other $5HT_3$ antagonists are also used for the treatment of PONV: *Dolasetron* is given as a 12.5-mg dose intravenously, *granisetron* 0.35 to 3 mg intravenously, and *palonosetron* 0.075 mg intravenously (Gan et al., 2020).

In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and light-headedness. ECG interval changes (QT prolongation) are a feature of the first-generation antagonists. The injectable form of *dolasetron* is contraindicated for prophylactic therapy for chemotherapy-induced nausea and vomiting; the oral form is associated with a lower risk of QT prolongation, but the risk is still present. *Palonosetron* does not appear to increase QT intervals (Gonullu et al., 2012). These drugs have also been associated with serotonin syndrome and should be used cautiously if patients are taking other medications, such as SSRIs, that could increase 5HT levels.

Dopamine Receptor Antagonists

Mechanism of Action and Pharmacology. The principal mechanism of action of dopamine receptor antagonists is D_2 receptor antagonism at the CTZ, reducing excitatory neurotransmitter release (Andrews and Sanger, 2014; Navari, 2013).

Phenothiazines. *Prochlorperazine* and, to a lesser extent, *chlorpromazine* (see Chapter 19) are among the most commonly used "general-purpose" antinauseants and antiemetics in adults and children. These drugs are not uniformly effective in cancer chemotherapy-induced emesis, but they possess antihistaminic and anticholinergic activities that are of value in other forms of nausea and vomiting, such as motion sickness and that of GI origin. These drugs are available as tablets, injectables, or suppositories. Typical dosing of *prochlorperazine* is 5 to 10 mg orally every 6 to 8 h, 5 to 10 mg intramuscularly, 2.5 to 10 mg intravenously every 3 to 4 h (maximum 40 mg/day), or 25 mg rectally every 12 h. The main adverse effects are extrapyramidal reactions, including dystonia, cardiac effects, and hypotension. These drugs are contraindicated due to increased mortality in elderly patients with dementia-related psychosis.

Benzamides. The prokinetic benzamide agents (see previous discussion) are moderately useful antiemetics but are no longer the drugs of

TABLE 54–6 ■ $5HT_3$ ANTAGONISTS IN CHEMOTHERAPY-INDUCED NAUSEA/EMESIS

DRUG	CHEMICAL NATURE	RECEPTOR INTERACTIONS	$t_{1/2}$	ADULT DOSE
Ondansetron	Carbazole derivative	$5HT_3$ antagonist, weak $5HT_4$ antagonist	3–4 h	16–24 mg (orally); 8–16 mg (IV)
Granisetron	Indazole	$5HT_3$ antagonist	5–9 h	2 mg (orally); 0.01 mg/kg (max 1 mg IV), 10 mg (subcutaneously); 3.1 mg/24 h transdermal patch
Dolasetron (not approved in the U.S.)	Indole moiety	$5HT_3$ antagonist	7–8 h	100 mg (orally)
Palonosetron	Isoquinoline	$5HT_3$ antagonist; highest affinity for $5HT_3$ receptor in class	37–48 h	0.25 mg (IV)

IV, intravenous.
NCCN Guidelines Insights: Antiemesis, Version 2.2017 (Berger et al., 2017).

choice for acute chemotherapy-induced nausea and vomiting due to their lack of efficacy and side effect profile. However, the antiemetic actions add to their value in the treatment of GI motor disturbances, and *metoclopramide* is a useful treatment of delayed emesis. *Amisulpride* is a benzamide derivative and an atypical antipsychotic (see Chapter 19). It was recently approved in the U.S. in adults for the prevention of PONV, either alone or in combination with an antiemetic of a different class, and to treat PONV in those who have received antiemetic prophylaxis with an agent of a different class or have not received prophylaxis. It is given as a single intravenous 5-mg dose to prevent PONV or as a single intravenous 10-mg dose to treat this condition. *Amisulpride* is contraindicated in patients with preexisting arrhythmias/cardiac conduction disorders, electrolyte abnormalities, congestive heart failure, or renal impairment and in patients taking other drugs (e.g., *ondansetron*) known to prolong the QT interval.

Butyrophenones. The butyrophenone *droperidol* is used for the treatment of PONV, and *haloperidol* is used as an adjunctive agent for nausea and vomiting in a palliative setting in cancer patients and for the acute treatment of cannabinoid hyperemesis syndrome (off-label). *Droperidol* is given as a single intravenous 0.625- to 1.25-mg dose at the end of surgery to prevent PONV. Its use has declined due to black box warnings (for much higher doses). However, the risks at the doses used to treat PONV appear low (Gan et al., 2020). *Haloperidol* is given as a single intravenous or intramuscular 5-mg dose for the treatment of cannabinoid hyperemesis syndrome and at 0.5 to 5 mg (by various routes of administration) for cancer patients. Potential adverse effects include QT prolongation, sedation, extrapyramidal symptoms, neuroleptic malignant syndrome, and hypotension. See Chapter 19 for further details of these drugs.

Olanzapine. *Olanzapine* is an atypical (second-generation) antipsychotic that is a dopamine (D_{1-4}) and $5HT_2$ receptor antagonist (see Chapters 15 and 19). It is an effective agent for the prevention of chemotherapy-associated delayed nausea or vomiting (off-label use; used in combination with a corticosteroid and $5HT_3$ antagonist) (Fonte et al., 2015). It is also gaining attention for the treatment of refractory non–chemotherapy-induced nausea and vomiting. It is given orally, 10 mg once daily for 3 to 5 days, beginning on day 1 of chemotherapy or 5 mg once daily for 2 days before chemotherapy, followed by 10 mg once daily (beginning on the day of chemotherapy) for 3 to 8 days. The adverse reactions are extensive and include many CNS, cardiovascular, and metabolic side effects that are described in Chapter 19.

Antihistamines

Histamine H_1 antagonists are primarily useful for motion sickness and PONV. They act on vestibular afferents and within the brainstem. *Cyclizine*, *meclizine, promethazine*, and *diphenhydramine* are examples of this class of agents. *Cyclizine* has additional anticholinergic effects that may be useful for patients with abdominal cancer. Sedation is always a common side effect of these drugs. For a detailed discussion of these drugs, see Chapter 43.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist for motion sickness is *scopolamine* (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (1.5 mg every 3 days). Its principal utility is in the prevention and treatment of motion sickness, with some activity in postoperative nausea and vomiting. In general, however, anticholinergic agents have no role in chemotherapy-induced nausea. The principal side effects are dry mouth, visual disturbances, and drowsiness.

Neurokinin Receptor Antagonists

Mechanism of Action and Pharmacology. The nausea and vomiting associated with emetogenic chemotherapy (see Chapters 69–73) has two components: an acute phase that universally is experienced (within 24 h after chemotherapy) and a delayed phase that affects only some patients (on days 2–5). $5HT_3$ receptor antagonists are not very effective against delayed emesis. However, antagonists of the NK_1 receptors, the receptors for the neuropeptide substance P, such as *aprepitant* (and its parenteral formulation *fosaprepitant*), have antiemetic effects in delayed nausea and improve the efficacy of standard antiemetic regimens in patients receiving multiple cycles of chemotherapy (Aapro et al., 2015). A new, highly selective NK_1 antagonist, *rolapitant*, with an exceptionally long plasma $t_{1/2}$ (180 h) is FDA-approved for the prevention of chemotherapy-induced delayed emesis.

Aprepitant. The NK_1 antagonist *aprepitant* is typically given with a $5HT_3$ antagonist and *dexamethasone*.

ADME. After absorption, *aprepitant* is bound extensively to plasma proteins (>95%); it is metabolized primarily by hepatic CYP3A4 and is excreted in the stools; its $t_{1/2}$ is 9 to 13 h. *Aprepitant* has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including *dexamethasone*, *methylprednisolone* (the dose of which may need to be reduced by 50%), and *warfarin*.

Therapeutic Uses and Adverse Effects. *Aprepitant* is contraindicated in patients receiving *cisapride, terfenadine, astemizole*, or *pimozide*, in whom life-threatening QT prolongation has been reported. *Aprepitant* is supplied in 40-, 80-, and 125-mg capsules and is administered for 3 days for highly or moderately emetogenic chemotherapy, along with a $5HT_3$ antagonist and *dexamethasone*. The injectable form, *fosaprepitant*, in a dose of 150 mg, may be substituted for the first dose of *aprepitant* at the start of the 3-day regimen. The recommended adult dosage of *aprepitant* for moderately and highly emetogenic chemotherapy is 125 mg administered 1 h before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen. *Aprepitant* and *fosaprepitant* are used for the treatment of PONV given orally (*aprepitant,* 40–125 mg) or intravenously (*fosaprepitant*, 150 mg) (Gan et al., 2020).

Rolapitant. *Rolapitant* is a potent NK_1 receptor antagonist that is administered with a $5HT_3$ antagonist and *dexamethasone* to help prevent delayed-phase chemotherapy-induced nausea and vomiting.

ADME. After a single oral dose of 180 mg, *rolapitant* is well absorbed with peak C_p at 4 h and $t_{1/2}$ at about 180 h. *Rolapitant* is metabolized primarily by CYP3A4 to form an active metabolite, M19 (C4-pyrrolidine-hydroxylated *rolapitant*). M19 has a $t_{1/2}$ of about 158 h. *Rolapitant* is eliminated mainly via the hepatic/biliary route.

Therapeutic Uses and Adverse Effects. A single 180-mg dose is administered orally 1 to 2 h prior to chemotherapy (together with $5HT_3$ antagonist and *dexamethasone*). The adverse effects include neutropenia, hiccups, decreased appetite, and dizziness. *Rolapitant* is a moderate inhibitor of CYP2D6 and of the Pgp and BCRP transporters. *Rolapitant* is contraindicated in patients receiving drugs that are CYP2D6 substrates, such as *thioridazine* or *pimozide*. A significant increase in plasma concentrations of *thioridazine* may result in QT prolongation and torsades de pointes.

Netupitant and Palonesetron Combination. A combination NK_1 receptor antagonist plus $5HT_3$ receptor antagonist (*netupitant* and *palonesetron*) has been approved (Abramovitz and Gaertner, 2016).

ADME. This combination is well absorbed; the drugs have a similar time to peak C_p (5 h) and very long half-lives (*netupitant*, ~80 h; *palonesetron*, ~48 h). They are excreted in the feces and urine. *Netupitant* is extensively metabolized by CYP3A4 (major) and CYP2C9 and CYP2D6 (minor) to active metabolites. *Palonesetron* is about 50% metabolized in the liver to inactive metabolites.

Therapeutic Uses and Adverse Effects. A single capsule is administered orally about 1 h prior to chemotherapy (together with *dexamethasone*, at doses varying according to the type of chemotherapy). The adverse effects are the same as for the $5HT_3$ antagonists (see previous discussion).

Cannabinoids

Cannabis has been widely used medicinally, including for the treatment of nausea and vomiting. It is an effective treatment, especially for nausea, though its use is limited because of its psychotropic side effects (Sharkey et al., 2014). See Chapter 26 for further details of the pharmacology of cannabis and cannabinoids. Two cannabinoids are used for the treatment of nausea and vomiting, *dronabinol* and *nabilone*.

Dronabinol. ***Mechanism of Action and Pharmacology.*** *Dronabinol* (Δ-9-tetrahydrocannabinol) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The mechanism of the antiemetic action of *dronabinol* is related to stimulation of the CB_1 subtype of cannabinoid receptors on neurons in and around the CTZ and brainstem emetic centers (see Figure 54–6) (Sharkey et al., 2014).

ADME. *Dronabinol* is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 to 4 h. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10%–20%). The principal active metabolite is 11-OH-delta-9-tetrahydrocannabinol. These metabolites are excreted primarily via the biliary-fecal route, with only 10% to 15% excreted in the urine. Both *dronabinol* and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of *dronabinol* can result in detectable levels of metabolites for several weeks.

Therapeutic Uses and Adverse Effects. *Dronabinol* is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. It also can stimulate appetite and has been used in patients with AIDS and anorexia. As an antiemetic agent, it is administered at an initial dose of 5 mg/m² given 1 to 3 h before chemotherapy and then every 2 to 4 h afterward for a total of four to six doses. If this is inadequate, incremental increases can be made up to a maximum of 15 mg/m² per dose. For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg/day.

Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilatation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like "highs" (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic) can occur, as can more disturbing effects such as paranoid reactions and abnormalities of thinking. After abrupt withdrawal of *dronabinol*, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, *dronabinol* can displace other plasma protein-bound drugs, the doses of which may have to be adjusted as a consequence. *Dronabinol* should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

Nabilone. ***Mechanism of Action and Pharmacology.*** *Nabilone* is a synthetic cannabinoid with a mode of action similar to that of *dronabinol*.

ADME. *Nabilone* is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 h. The $t_{1/2}$ is about 2 h for the parent compound and 35 h for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with only about 25% excreted in the urine.

Therapeutic Uses and Adverse Effects. *Nabilone* is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. A dose (1–2 mg) can be given the night before chemotherapy; usual dosing starts 1 to 3 h before treatment and then every 8 to 12 h during chemotherapy and for 2 days following its cessation. The adverse effects are largely the same as for *dronabinol*, with significant CNS actions in more than 10% of patients. Cardiovascular, GI, and other side effects are also common and, together with the CNS actions, limit the usefulness of this agent.

Glucocorticoids and Anti-inflammatory Agents

Glucocorticoids such as *dexamethasone* can be useful adjuncts (see Table 54–5) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of nonsteroidal anti-inflammatory drugs in the nausea and vomiting induced by systemic irradiation (Chu et al., 2014). *Dexamethasone* is given at doses between 4 and 10 mg for the treatment of PONV (Gan et al., 2020) and between 12 and 20 mg for the treatment of chemotherapy-induced nausea and vomiting (Berger et al., 2017). For a detailed discussion of these drugs, see Chapter 50.

Benzodiazepines

Benzodiazepines, such as *lorazepam* and *alprazolam*, by themselves are not very effective antiemetics, but their sedative, amnesic, and anxiolytic effects can be helpful in reducing the anticipatory component of nausea and vomiting in patients. For a detailed discussion of these drugs, see Chapter 22.

Phosphorated Carbohydrate Solutions

Aqueous OTC solutions of *glucose, fructose*, and *orthophosphoric* are available to relieve nausea. These solutions are given orally (15–30 mL, adults; 5–10 mL, children; repeated every 15 min until the symptoms alleviate; no more than five doses may be taken). Their mechanisms of action are unclear.

Doxylamine Succinate and Pyridoxine

Mechanism of Action and Pharmacology. Nausea commonly occurs in the early stages of pregnancy. This may or may not be accompanied by vomiting. The management of this condition depends on the severity of symptoms, which usually resolve by midpregnancy regardless of their severity. *Pyridoxine* (vitamin B_6) improves mild-to-moderate nausea, and its efficacy is improved when it is combined with the histamine H_1 antagonist *doxylamine* (Fantasia, 2014). Considering the caveats associated with the use of antinausea medications during early pregnancy, readers may wish to review the history of this drug combination; see the work of Slaughter et al. (2014).

ADME. *Doxylamine* is metabolized in the liver by N-dealkylation. It has a $t_{1/2}$ of 10 to 12 h and is excreted in the urine. *Pyridoxine* is well absorbed and has a $t_{1/2}$ of 2 to 3 weeks.

Therapeutic Uses and Adverse Effects. This drug-vitamin combination is given for the treatment of nausea and vomiting of pregnancy. Initially, two delayed-release tablets (a total of *doxylamine* 20 mg and *pyridoxine* 20 mg) are taken at bedtime. The dose may be increased to four tablets per day as needed for more severe nausea (one tablet in the morning, one tablet in the afternoon, two tablets at bedtime). The major side effects of this drug include drowsiness, dry mouth, light-headedness, and constipation.

Miscellaneous GI Disorders

Cystic Fibrosis, Chronic Pancreatitis, and Steatorrhea

Pancreatic Enzymes

Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). The goals of pharmacological therapy are prevention of malabsorption and palliation of pain (Trang et al., 2014). *Cystic fibrosis* is a genetic disorder that affects exocrine secretion. Exocrine pancreatic insufficiency occurs in most patients with more severe forms of cystic fibrosis. Pharmacological therapy is used to treat these patients (Somaraju and Solis-Moya, 2014).

Enzyme Formulations. Pancreatic enzymes (lipase, amylase, and proteases) are secreted together; hence, lipase can be used to titrate the doses of pancreatic enzyme supplements, which are typically prescribed based on the lipase content. Only *pancrelipase* is licensed for sale in the U.S. *Pancrelipase* products, of which there are six on the market, differ in their content of lipase, protease, and amylase and thus may not be interchangeable.

Replacement Therapy for Malabsorption. Fat malabsorption (*steatorrhea*) and protein maldigestion occur when the pancreas loses more than 90% of its ability to produce digestive enzymes. This occurs in chronic pancreatitis, following pancreatectomy, or in cystic fibrosis. The resultant diarrhea and malabsorption can be managed well if 90,000 USP (U.S. Pharmacopeia) units of pancreatic lipase are delivered to the duodenum during a 4-h period with and after meals. Alternatively, one can titrate the dosage to the fat content of the diet, with about 8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain 3000 to 40,000 USP units of lipase, 10,000 to 136,000 USP units of protease, and 15,000 to 218,000 USP units of amylase. In adults and children over 4 years, the initial dose of lipase is 500 USP units/kg per meal, increasing up to 2500 USP units/kg per meal. Children younger than 4 years have increased needs for lipase, and initial doses are higher. There are also special dosing regimens for breastfeeding infants. In all cases, lipase dosing should not exceed maximum recommendations and generally should not exceed 2500 USP units/kg per meal or 10,000 USP unit/kg per day.

Enzymes for Pain. Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative-feedback inhibition of the pancreas by the presence of duodenal proteases. The release of CCK, the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

Adverse Effects. Despite the fact that the enzymes are not absorbed and are excreted in feces, there are adverse effects, which include headache and abdominal pain; however, pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

Gallstones and Primary Biliary Cholangitis

Bile Acids

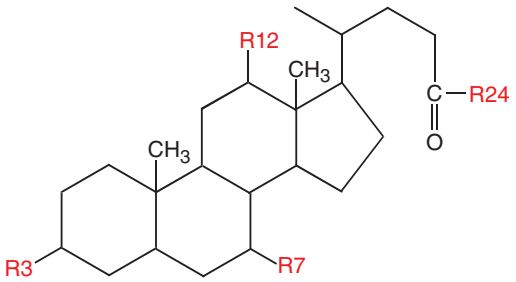
Bile acids and their conjugates are synthesized from cholesterol in the liver. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the emulsification and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine, returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called bile salts.

Traditional therapy for gallstones involves oral litholysis with *ursodeoxycholic acid* (*ursodiol*), but there is now evidence that inhibiting cholesterol synthesis (with statins) or intestinal cholesterol absorption (with *ezetimibe*) may have some beneficial effects to reduce gallstone formation (Portincasa et al., 2012). As for the treatment of gallstones, treatments for primary biliary cholangitis also involve the use of *ursodiol*. Recently, an alternative approach for the treatment for primary biliary cholangitis was developed based on agonism of the farnesoid X receptor by *obeticholic acid*. Activation of the farnesoid X receptor within hepatocytes results in potent suppression of bile acid synthesis (Gulamhusein and Hirschfield, 2020). New therapies are being developed for primary biliary cholangitis that include treatment with fibrates and peroxisome proliferator-activated receptor alpha (PPARα) agonists (Gulamhusein and Hirschfield, 2020).

Ursodeoxycholic Acid (Ursodiol). *Ursodeoxycholic acid* (*ursodiol*) (Figure 54–7) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid in the gut by intestinal bacteria.

Mechanism of Action and Pharmacology. *Ursodiol* is a naturally occurring hydrophilic bile acid. Litholytic bile acids such as *ursodiol*, when administered orally, alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. *Ursodiol* acts by replacing and/or displacing toxic concentrations of endogenous hydrophobic bile acids that tend to accumulate in cholestatic liver disease. *Ursodiol* may also have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

ADME. *Ursodiol* becomes a major biliary and plasma bile acid. Following oral administration, the majority of *ursodiol* is absorbed by



Bile Acid	R3	R7	R12	R24
Cholic acid	–OH	–OH	–OH	
Chenodeoxycholic acid	–OH	–OH	–H	glycine (75%)
Deoxycholic acid	–OH	–H	–OH	taurine (24%)
Lithocholic acid	$-SO_2^-$ / –OH	–H	–H	–OH (<1%)
Ursodeoxycholic acid	–OH	–OH	–H	

Figure 54–7 *Major bile acids in adults.*

passive diffusion. In the liver, *ursodiol* is conjugated with glycine or taurine, then secreted into bile. *Ursodiol* is primarily excreted in the feces.

Therapeutic Uses and Adverse Effects. *Ursodiol* is given for the prevention and treatment of gallstones and for the treatment of primary biliary cholangitis (Portincasa et al., 2012; Tabibian and Lindor, 2015). For gallstone treatment, it is given orally 8 to 10 mg/kg per day in divided doses, for gallstone prevention 300 mg twice daily, and for primary biliary cholangitis 13 to 15 mg/kg per day in two to four divided doses with food. Adverse effects at these doses are generally uncommon but include headache, GI disturbances, and nausea. At higher than recommended doses, there may be serious adverse effects of *ursodiol*.

Obeticholic Acid.

Obeticholic acid is a semisynthetic analogue of chenodeoxycholic acid.

Mechanism of Action and Pharmacology. *Obeticholic acid* is an agonist of the farnesoid X receptor, a nuclear receptor important for regulating bile acid and cholesterol metabolism. Farnesoid X receptors are expressed in the liver and intestine and are key regulators of bile acid synthesis, inflammation, and fibrosis. Activation of farnesoid X receptors regulates the *de novo* synthesis of bile acids from cholesterol, as well as increasing transport of bile acids out of the hepatocytes. Together these mechanisms reduce the size of the circulating bile acid pool while promoting secretion of bile, thereby reducing exposure to bile acids.

ADME. Patients are started at 5 mg daily for the first 3 months, which may be increased to 10 mg if tolerated, to a maximum dose of 10 mg daily. There is a dose adjustment for patients with advanced liver disease (5 mg weekly for the first 3 months, followed by 5 mg twice weekly to a maximum of 10 mg twice weekly). *Obeticholic acid* is conjugated with glycine or taurine in the liver and secreted into bile. The conjugates are absorbed in the small intestine, leading to enterohepatic recirculation. They can be deconjugated by enteric microbiota, leading to the conversion to *obeticholic acid* that can be reabsorbed or excreted in the feces.

Therapeutic Uses and Adverse Effects. *Obeticholic acid* is indicated for the treatment of primary biliary cholangitis in combination with *ursodiol* in adults with an inadequate response to *ursodiol* or as a monotherapy in adults unable to tolerate *ursodiol* (Gulamhusein and Hirschfield, 2020).

Obeticholic acid carries a black box warning: This drug can cause hepatic decompensation and liver failure in incorrectly dosed patients. Patients at an increased risk of hepatic decompensation must be monitored closely. The most common adverse reactions are pruritus, fatigue, abdominal pain and discomfort, rash, oropharyngeal pain, dizziness, constipation, arthralgia, thyroid function abnormality, and eczema.

Flatulence

"Gas" is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. OTC and herbal preparations are popular. *Simethicone*, a mixture of siloxane polymers stabilized with silicon dioxide, is an inert, nontoxic surfactant. Because of its capacity to collapse bubbles by forming a thin layer on their surface, it is an effective antifoaming agent, but whether this accomplishes a therapeutic effect in the GI tract is not clear. *Simethicone* is available in chewable tablets, liquid-filled capsules, suspensions, and orally disintegrating strips, either by itself or in combination with other OTC medications, including antacids and other digestants. The usual dosage in adults is 40 to 125 mg four times daily after meals; the pediatric dose is 20 to 50 mg four times daily after meals and at bedtime, depending on the age of the child. Activated charcoal may be used alone or in combination with *simethicone* but has not been shown conclusively to have much benefit. An α-galactosidase OTC preparation is available to reduce gas from baked beans.

Short-Bowel Syndrome

Short-bowel syndrome is a malabsorption disorder caused by removal of the small intestine or rarely because of a congenital bowel abnormality. Short-bowel syndrome requires total parenteral nutrition, and treatments are aimed at reducing the need for this, including supplemented specialized diets and implementing a therapy based on physiologic principles of the actions of gut hormones.

Teduglutide

Mechanism of Action and Pharmacology. The gut hormone GLP-2 is secreted by L cells of the ileum and colon and is the only intestinotrophic

TABLE 54–7 ■ ORAL ANTIBIOTIC TREATMENTS FOR SMALL INTESTINAL BACTERIAL OVERGROWTH

ANTIBIOTIC	SITE OF ACTION	ADULT DOSE	PEDIATRIC DOSE	NOTES
Amoxicillin-clavulanate	Systemic	875 mg twice daily	25–30 mg/kg (amoxicillin)/dose 2–3 times daily	10-day course
Ciprofloxacin	Systemic	500 mg twice daily		Not routinely recommended for children 10-day course
Doxycycline	Systemic	100 mg 1–2 times daily	≥8 years and >45 kg: adult dosing	Not routinely recommended for young children 10-day course
Metronidazole	Systemic	250 mg 3 times daily	10 mg/kg per dose twice daily	10-day course
Norfloxacin	Systemic	400 mg twice daily		Not recommended for children 10-day course
Rifaximin	Nonabsorbable	550 mg 3 times daily	Children and adolescents ≥12 years: adult dose Children 3–11 years: 200 mg 3 times daily	14-day course
Tetracycline	Systemic	250 mg 4 times daily	≥8 years and >45 kg: adult dose	Not routinely recommended for young children 10-day course
Trimethoprim-sulfamethoxazole	Systemic	160/800 mg twice daily	4–5 mg/kg of trimethoprim component per dose twice daily	10-day course

gut peptide. Among other actions, it enhances growth of the intestinal mucosa through the release of mediators, including insulin-like growth factor 1. *Teduglutide* is a 33–amino acid GLP-2 analogue recently approved for the treatment of short-bowel syndrome (Jeppesen, 2015).

ADME. The drug has a $t_{1/2}$ of 1 to 2 h and is excreted in the urine. It is catabolized by dipeptidyl peptidase 4 but more slowly than the native peptide because of the substituted amino acid structure.

Therapeutic Uses and Adverse Effects. *Teduglutide* is administered subcutaneously once daily (0.05 mg/kg) to help improve intestinal absorption of nutrients and thereby reduce the need for parenteral support. Common side effects include abdominal pain, nausea, headache, and flu-like symptoms. There is also the potential for *teduglutide* to cause cancer of the bowel; therefore, it is not recommended for patients with active malignancies.

Small Intestinal Bacterial Overgrowth

Small intestinal bacterial overgrowth (SIBO) is caused by excessive colonization of the small bowel with aerobic and anaerobic bacteria that are normally present in the colon. A patient generally presents with bloating, flatulence, abdominal discomfort, or diarrhea. The diagnosis may be made using a breath test or small-bowel aspirate, but frequently antibiotic therapy is typically begun on an empiric basis if the patient has a known underlying condition (e.g., scleroderma) and presents with typical symptoms. *Rifaximin* is well tolerated and has been demonstrated to be effective in the treatment of SIBO (Pimentel et al., 2020). In adults, it is given at a dose of 550 mg three times daily for 14 days. However, due to its costs, alternative antibiotics are also used (Table 54–7) (Pimentel et al., 2020).

Drug Facts for Your Personal Formulary: *Antisecretory Agents and Gastroprotectives*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Prokinetic Agents (agents acting through specific receptors to regulate GI motility)		
MOR antagonist Alvimopan	• Postoperative ileus	• Myocardial infarction • Hypokalemia • Dyspepsia
5HT$_4$ receptor agonists Cisapride Prucalopride Tegaserod	• Gastroesophageal reflux disease • Gastroparesis • Intestinal pseudoobstruction • Severe constipation • Neonatal feeding intolerance	• Serious cardiac risks • Risk of suicidal ideation • Headache • Diarrhea
D$_2$ receptor antagonist Domperidone Metoclopramide (also 5HT$_3$ receptor antagonist, 5HT$_4$ receptor agonist)	• Gastroparesis • Prevention of nausea and vomiting	• Serious cardiac risks, especially in older persons • Limited pediatric use • Tardive dyskinesia • Limited pediatric use • Short-term use only
Motilin receptors Erythromycin (stimulates motilin receptors on GI smooth muscle cells)	• Gastroparesis	• Short-term use only • Ototoxicity • Pseudomembranous colitis • Cardiac risks
CCK peptide analogue Sincalide (C-terminal octapeptide of CCK)	• Intravenous injection • Gallbladder contraction • Pancreatic secretion • Intestinal motility • Accelerates barium transit through small bowel for diagnostic testing	• Nausea, vomiting, diarrhea • Sweating • light-headedness • Headache • May cause serious allergic reactions
Laxatives		
Dietary Fiber		
Psyllium Methylcellulose	• Increase fecal bulk	• Bloating
Stool-Softening Agents		
Docusate	• Constipation	• Marginal efficacy
Mineral oil	• Constipation	• Side effects preclude regular use • Interferes with absorption of fat-soluble vitamins • Oil leakage
Osmotically Active Agents		
Polyethylene glycol–electrolyte solutions	• Colonic cleansing prior to examination • Constipation (powder form)	• Nausea • Cramping and bloating
Saline laxatives–Mg^{2+}	• Constipation	• Diarrhea • Renal insufficiency may predispose to Mg-accumulation

Drug Facts for Your Personal Formulary: *Antisecretory Agents and Gastroprotectives (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Nondigestible sugars and alcohols Lactulose Sorbitol	• Constipation caused by opioids • Idiopathic chronic constipation • Lactulose also used to treat hepatic encephalopathy	• Abdominal discomfort • Flatulence
Stimulant Laxatives		
Diphenylmethane derivatives Bisacodyl Sodium picosulfate	• Constipation • Bowel cleansing prior to colonoscopy, x-ray examination or surgery	• Diarrhea • Abdominal pain • Possible electrolyte imbalances and hypokalemia with prolonged use • Local irritation caused by suppositories
Anthraquinone laxatives Senna	• Constipation	• Plant derivatives • Melanosis coli • Nausea and vomiting • Cramping
Ricinoleic acid Castor oil	• Act on small intestine • Stimulate secretion • Increase intestinal transit	• Potential toxic effect from ricin • Not clinically recommended
Enemas and suppositories Glycerin	• Bowel distension • Glycerin for rectal use	• Discomfort
Prosecretory Agents		
Guanylate cyclase-C agonist Linaclotide Plecanatide	• Opioid-induced constipation	• Contraindicated in children up to 6 years • Diarrhea
Cl^- channel activator Lubiprostone	• Chronic idiopathic constipation • Opioid-induced constipation • IBS with constipation	• Nausea • Diarrhea
NHE3 inhibitor Tenapanor	• IBS with constipation	• Diarrhea • Abdominal distension • Flatulence
Drugs for Opioid-Induced Constipation		
MOR antagonists Methylnaltrexone Naloxegol Naldemedine	• Opioid-induced constipation	• Peripheral MOR antagonist • Diarrhea • Abdominal pain • Nausea and vomiting • Flatulence
Opioid receptor agonist/antagonist Oxycodone:naloxone (2:1 ratio)	• Opioid-induced constipation	• Respiratory depression • Addiction • Nausea and vomiting • Constipation • Diarrhea
Antidiarrheal Agents		
$5HT_3$ receptor antagonist Alosetron	• Diarrhea-predominant IBS in women	• Ischemic colitis • Constipation
Antibiotics—empiric therapy Fluoroquinolone Ciprofloxacin Levofloxacin Norfloxacin Ofloxacin *Alternative antibiotics* Azithromycin Rifaximin	• Acute diarrhea • Traveler's diarrhea • Azithromycin: preferred treatment for children with traveler's diarrhea • Rifaximin: preferred for diarrhea-predominant IBS	• Avoid if *Escherichia coli* suspected • Avoid if *Clostridium difficile* suspected • Controversial in children (azithromycin preferred) • Nausea • Peripheral edema • Dizziness
Bile acid sequestrants Cholestyramine Colesevelam Colestipol	• Bile salt–induced diarrhea	• Bloating • Flatulence • Abdominal discomfort • Constipation

Drug Facts for Your Personal Formulary: *Antisecretory Agents and Gastroprotectives (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Bismuth subsalicylate	• Acute diarrhea • Nausea and abdominal cramping	• Dark stools; darkened tongue
α_2 adrenergic receptor agonist Clonidine	• Diabetic diarrhea	• Hypotension, depression • Drowsiness, fatigue
Crofelemer (plant derived)	• HIV/AIDS diarrhea	• Infectious diarrhea must not be suspected • Inhibits CFTR and reduces Cl^- secretion
MOR/KOR agonist DOR antagonist Eluxadoline	• Diarrhea-predominant IBS	• Pancreatitis • Sphincter of Oddi spasm • Constipation
SST receptor agonist Octreotide	• Severe secretory diarrhea due to GI tumors • Postgastrectomy dumping syndrome	• Sinus bradycardia, chest pain • Headache, abdominal pain • Nausea, diarrhea
Enkephalinase inhibitor Racecadotril	• Acute diarrhea	• Proven safety in children
Tryptophan hydroxylase inhibitor Telotristat ethyl	• Severe diarrhea due to carcinoid tumors	• Adverse effects: constipation, nausea, headache, depression
Antispasmodic Agents (Anticholinergics)		
Dicyclomine Glycopyrrolate Hyoscyamine Methscopolamine	• Abdominal and urgency in IBS	• Contraindicated in colitis, reflux esophagitis, and bowel obstruction • Dizziness, dry mouth • Nausea, blurred vision
Antiemetic Agents		
Antihistamines Cyclizine Diphenhydramine Meclizine Promethazine	• Motion sickness • Nausea and vomiting	• Sedation • Dry mouth • Promethazine is contraindicated in children <2 years old
Doxylamine succinate and pyridoxine (H_1 receptor antagonist and vitamin B_6)	• Nausea and vomiting of pregnancy	• Drowsiness, light-headedness • Dry mouth • Constipation
NK_1 antagonists Aprepitant Fosaprepitant Rolapitant	• Chemotherapy-induced nausea and vomiting • Postoperative nausea and vomiting	• Given with dexamethasone and a $5HT_3$ antagonist • Contraindicated in patients on cisapride, pimozide, or thioridazine • Fatigue, constipation, hiccups
$5HT_3$ antagonists Dolasetron Granisetron Ondansetron Palonesetron	• Chemotherapy-induced nausea and vomiting • Radiation-induced nausea and vomiting • Postoperative nausea and vomiting	• ECG effects • Serotonin syndrome • Headache • Constipation • Fatigue, malaise
$NK_1/5HT_3$ antagonists Netupitant Palonesetron	• Chemotherapy-induced nausea and vomiting	• Serotonin syndrome • Headache • Constipation, fatigue
Cannabinoid receptor agonists Dronabinol Nabilone	• Chemotherapy-induced nausea and vomiting	• Psychoactive • Many CNS side effects
Dopamine receptor antagonists Olanzapine ($5HT_{2A}$ D_{1-4}, H_1, α_1 adrenergic, and M receptor antagonists) Phenothiazines (D_2, H_1, $5HT_{2A}$, M, and α_1 receptor antagonists) Chlorpromazine Prochlorperazine Benzamide Amisulpride Butyrophenone (D_{2-5}, $5HT_{2A}$, $5HT_{2B}$, $5HT_7$, H_1, α_{1A-1C} adrenergic antagonists) Droperidol Haloperidol	• Chemotherapy-induced nausea and vomiting • Refractory nausea and vomiting • Postoperative nausea and vomiting • Cannabinoid hyperemesis syndrome (haloperidol)	• Prolonged QT interval and torsades de pointes • Somnolence • Hypotension • Increased mortality in elderly patients with dementia-related psychosis • Extrapyramidal reactions

Drug Facts for Your Personal Formulary: *Antisecretory Agents and Gastroprotectives (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Muscarinic receptor antagonist Scopolamine	• Motion sickness • Nausea and vomiting	• Cardiovascular actions • Constipation, drowsiness, dry mouth, blurred vision; many other side effects (see Chapter 11)
Miscellaneous Agents		
Pancreatic enzymes	• Malabsorption (postpancreatectomy; cystic fibrosis) • Pancreatitis pain	• Headache • Abdominal pain
Simethicone	• Flatulence, bloating	
Teduglutide (GLP-2 receptor analogue)	• Short-bowel syndrome	• Colonic polyps/malignancy • Pancreatitis, abdominal pain and distention • Nausea, headache
Obeticholic acid (farnesoid X receptor agonist)	• Primary biliary cholangitis	• Can cause hepatic decompensation and liver failure • Pruritis
Antibiotics for the Treatment of Small Intestinal Bacterial Overgrowth		
Amoxicillin-clavulanate Ciprofloxacin Doxycycline Metronidazole Norfloxacin Rifaximin Tetracycline Trimethoprim-sulfamethoxazole	• Treatment of small intestinal bacterial overgrowth	• Nausea, vomiting, headache • GI disturbances • Abdominal pain

Chapter 55 Pharmacotherapy of Inflammatory Bowel Disease

Wallace K. MacNaughton and Keith A. Sharkey

Inflammatory Bowel Disease

Inflammatory bowel disease is a spectrum of remitting and relapsing, chronic, inflammatory intestinal conditions. IBD causes significant GI symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD conventionally is divided into two major subtypes: ulcerative colitis *and* Crohn's disease.

Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis). *Crohn's disease*, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn's disease is not necessarily confluent, frequently leaving "skip areas" of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or fistula formation. IBD is often associated with extraintestinal manifestations involving the joints, skin, or eyes (Ott and Scholmerich, 2013). IBD is also increasingly recognized to have comorbid psychological manifestations, notably anxiety and depression (Graff et al., 2009; Taft et al., 2017). Primary sclerosing cholangitis is a serious but infrequent extraintestinal manifestation of IBD, usually ulcerative colitis, in which inflammation and fibrostenosis occur in the intra- and extrahepatic biliary tree (Williamson and Chapman, 2014). Chronic, severe IBD is associated with an increased risk for the development of colorectal cancer (Beaugerie and Itzkowitz, 2015).

Pathogenesis of IBD

A summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 55–1. Both diseases are associated with an aberrant immune response to the commensal microbiota of the gut in genetically susceptible individuals. Evidence of dysbiosis of the microbiome in IBD supports this theory (Lee and Chang, 2020). Nevertheless, Crohn's disease and ulcerative colitis result from distinct pathogenic mechanisms at the level of mucosal immune activation (Xavier and Podolsky, 2007). Histologically, the transmural lesions in *Crohn's disease* exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in *ulcerative colitis* have lymphocytic and neutrophilic infiltrates.

Our understanding of the pathogenesis of both Crohn's disease and ulcerative colitis has increased dramatically in over the past two decades. The identification of disease susceptibility genes (McGovern et al., 2015) and the recognition of the role of the microbiome have led to an emerging area of therapeutic development that may yield new therapies (Cohen et al., 2019). However, current treatments focus on immune-based therapies because of the important role of cytokines in disease pathogenesis. Within the diseased bowel in *Crohn's disease*, the cytokine profile includes increased levels of IL-12, IL-23, IFN-γ, and TNF-α, findings characteristic of T_H1-mediated inflammatory processes. In contrast, the inflammatory response in *ulcerative colitis* resembles aspects of that mediated by the T_H2 pathway, including the involvement of IL-4 and IL-13. Understanding of the inflammatory processes has evolved with the description of regulatory T cells and proinflammatory T_H17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the proinflammatory cytokines IL-17, IL-21, IL-22, and IL-26. T_H17 cells seem to play a prominent role in intestinal inflammation, particularly in *Crohn's disease*.

Medical therapy for IBD is problematic. Because of the multifactorial nature of disease etiology, current therapy for IBD seeks to dampen the generalized inflammatory response. Regrettably, no agent can reliably accomplish this, and the response of an individual patient to a given drug may be limited and unpredictable. Recently, mucosal healing has become an important therapeutic aim, as opposed to simply the relief of symptoms. Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating the disease based on the presence and nature of extraintestinal manifestations. The major therapeutic options are considered in the following material.

Classifications of Drugs to Treat IBD

Mesalamine-Based Therapy

First-line therapy for mild-to-moderate ulcerative colitis generally involves 5-ASA (Bressler et al., 2015). 5-ASA–based treatments have largely been abandoned for the maintenance of remission in Crohn's disease (Sandborn et al., 2007) due to the fact that their anti-inflammatory effects are targeted topically to the mucosa, with limited effects on deeper inflammation, which has implications for long-term outcomes. The archetype for this class of medications is *sulfasalazine*, which consists of *5-ASA* linked to *sulfapyridine* by an *azo* bond (Figure 55–2).

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

Sulfasalazine is an oral prodrug that effectively delivers 5-ASA to the distal GI tract (Figure 55–3). The *azo* linkage in *sulfasalazine* prevents

Abbreviations

APC: antigen-presenting cell
5-ASA: 5-aminosalicylic acid, mesalamine
CNS: central nervous system
COX: cyclooxygenase
FDA: Food and Drug Administration
GI: gastrointestinal
GPCR: G protein-coupled receptor
HGPRT: hypoxanthine-guanine phosphoribosyl transferase
HPA: hypothalamic-pituitary-adrenal (axis)
5HT: 5-hydroxytryptamine (serotonin)
IBD: inflammatory bowel disease
IFN: interferon
IL: interleukin
JAK: Janus kinase
MAO: monoamine oxidase
6-MMP: 6-methyl-mercaptopurine
NE: norepinephrine
NF-κB: nuclear factor-κB
NSAID: nonsteroidal anti-inflammatory drug
PPAR-γ: peroxisome proliferator-activated receptor gamma
S1P: sphingosine-1-phosphate
STAT: signal transducer and activator of transcription
TB: tuberculosis
TGF: transforming growth factor
T_H: T helper (lymphocyte)
TNF: tumor necrosis factor
TPMT: thiopurine methyltransferase
TYK2: tyrosine kinase 2
XO: xanthine oxidase

absorption in the stomach and small intestine, and the individual components are not liberated until colonic bacterial *azoreductases* cleave the bond for local effect (Peppercorn and Goldman, 1972). 5-ASA is the therapeutic moiety, with little, if any, contribution by *sulfapyridine,* a *sulfonamide antibiotic*. Although 5-ASA is a salicylate and can inhibit cyclooxygenase (COX), its mode of action does not appear to involve this activity; indeed, traditional NSAIDs may exacerbate IBD and are strongly contraindicated. Many potential sites of action (effects on immune function and inflammation) have been demonstrated *in vitro* for *sulfasalazine* and *mesalamine* (Perrotta et al., 2015), including activation of the production of IL-1 and TNF-α, inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, activation of PPAR-γ, and inhibition of NF-κB, a transcription factor pivotal to production of inflammatory mediators. However, specific mechanisms of action underlying the efficacy of *sulfasalazine*/5-ASA in IBD have not been identified.

To preserve the therapeutic effect of 5-ASA without the adverse effects of *sulfapyridine*, several second-generation 5-ASA compounds have been developed. They are divided into two groups: *prodrugs* and *coated drugs*. Prodrugs contain the same azo bond as *sulfasalazine* but replace the linked *sulfapyridine* with either another 5-ASA (*olsalazine*) or an inert compound (*balsalazide*) (Jain et al., 2006). As is the case for *sulfasalazine*, colonic bacteria cleave *olsalazine* and *balsalazide* by azoreduction, producing two molecules of 5-ASA per molecule of *olsalazine* and equimolar quantities of 5-ASA (plus the carrier portion, 4-aminobenzoyl-b-alanine) from *balsalazide*. The alternative approaches employ *mesalamine* directly, using either a delayed-release formulation or a pH-sensitive coating. *Delayed-release mesalamine* releases drug throughout the GI tract, whereas *pH-sensitive mesalamine* is released in the small intestine and colon. These different distributions of drug delivery have potential therapeutic implications (Figure 55–4).

Oral *sulfasalazine* is effective in patients with mild or moderately active ulcerative colitis, with response rates of 60% to 80%. The usual initial dose is 500 to 1000 mg every 6 to 8 h and not more than a total of 4 g/day. The maintenance dose is 2000 mg/day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, *sulfasalazine* is of less-certain value, even though it is often added as an adjunct to systemic glucocorticoids. The drug plays a useful role in preventing relapses once remission has been achieved. Because they lack the dose-related side effects of *sulfapyridine*, the delayed and pH-dependent formulations can be used to deliver *mesalamine* with improved safety and tolerability. The doses of *mesalamine* used to treat active disease are 2.4 to 4.8 g/day for up to 8 weeks for induction, and current practice is to administer 5-ASA as a once-daily dose, which is as effective as a multiple daily dosing regimen (Feagan and Macdonald, 2012).

Topical preparations of *mesalamine* suspended in a wax matrix suppository or in a suspension enema are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical *hydrocortisone* in this setting, with response rates of 75% to 90%. *Mesalamine* enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 h; the suppository (500 and 1000 mg) should be used two to three times a day with the objective of retaining it for at least 3 h. Response to local therapy with *mesalamine* may occur within 7 to 14 days; however, the usual course of therapy is from 8 to 16 weeks for induction of remission. Once remission has occurred, lower doses can be considered for maintenance, although increasingly, the dose used for induction is continued for maintenance.

ADME

The pharmacokinetics of 5-ASA–based drugs are well described (Sandborn and Hanauer, 2003). About 20% to 30% of orally administered *sulfasalazine* (*mesalamine* prodrug) is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg *mesalamine* for every gram of the parent compound. Thereafter, the individual components of *sulfasalazine* follow different metabolic pathways. *Sulfapyridine* is absorbed rapidly from the colon and undergoes extensive hepatic metabolism, including acetylation and hydroxylation, and conjugation with glucuronic acid, prior to excretion in the urine. The acetylation phenotype of the patient determines plasma levels of *sulfapyridine* and the probability of side effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. Only 25% of *mesalamine* is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and liver and then excreted in the urine. Intraluminal concentrations of *mesalamine* therefore are very high (~1500 μg/mL).

The pH-sensitive coatings limit gastric and small intestinal absorption of *mesalamine*. The pharmacokinetics of delayed-release formulations differ somewhat. The ethylcellulose-coated microgranules are released in the upper GI tract as discrete prolonged-release units of *mesalamine*. Acetylated *mesalamine* can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, although some intact microgranules can later be detected in the colon. Because the delayed-release drug is released in the small bowel, a greater fraction of the 5-ASA in the delayed-release formulations is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects

Side effects of *sulfasalazine* occur in 10% to 45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue; these can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. *Sulfasalazine* reversibly decreases the number and motility of sperm but does not impair female fertility. *Sulfasalazine* inhibits intestinal folate absorption and therefore is usually administered with folate.

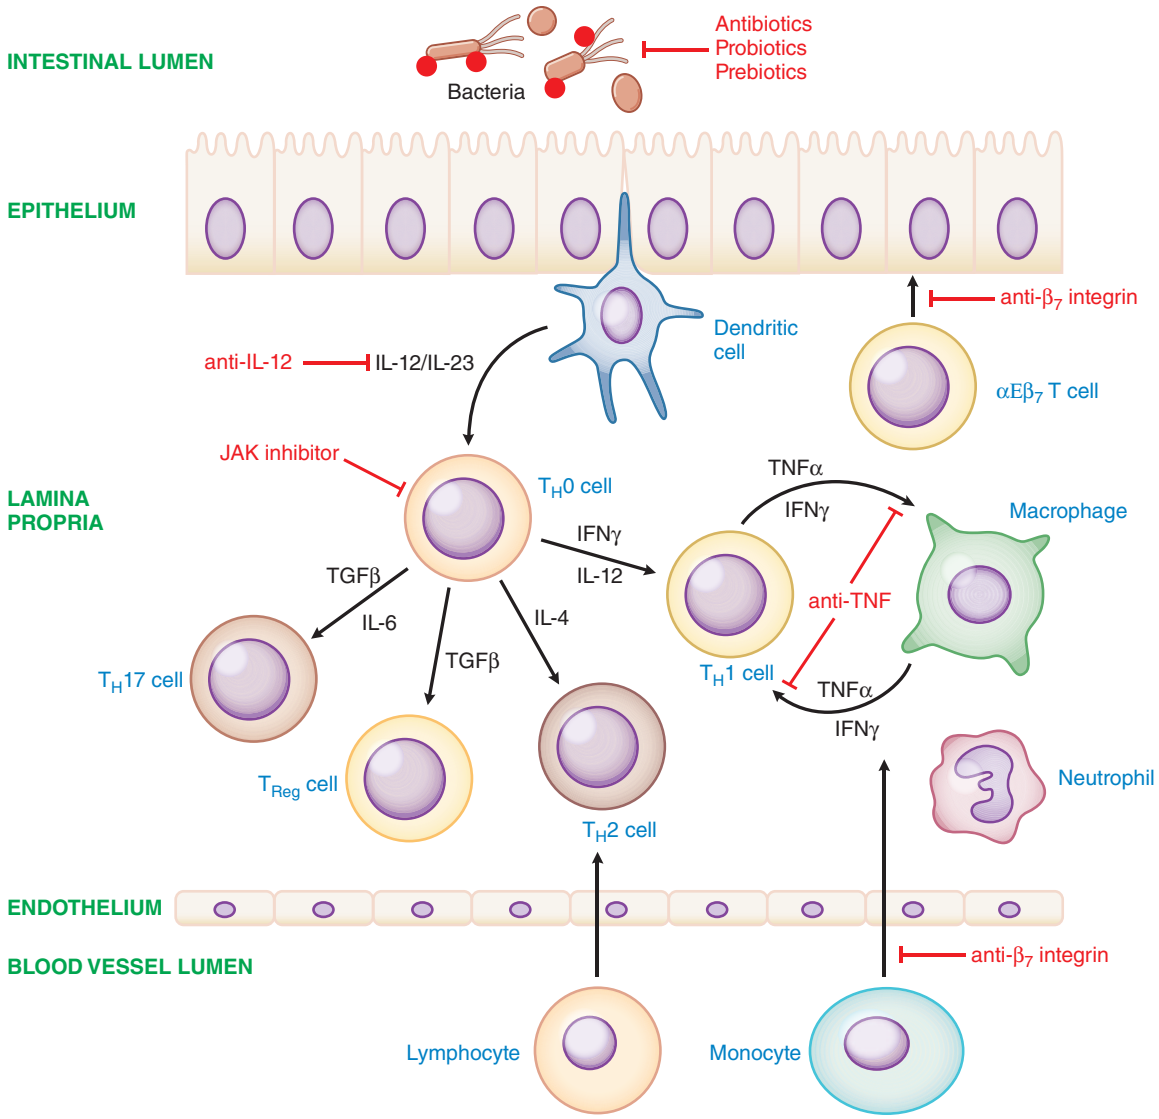

Figure 55–1 *Proposed pathogenesis of IBD and target sites for pharmacological intervention.* Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to APCs such as dendritic cells in the lamina propria. These cells then present the antigen(s) to $CD4^+$ lymphocytes and also secrete cytokines such as IL-12 and IL-23, thereby inducing the differentiation of T_H1 cells in Crohn's disease (or, under the control of IL-4, T_H2 cells in ulcerative colitis). The balance of proinflammatory and anti-inflammatory events is also governed by regulatory T_H17 and T_{Reg} cells, both of which serve to limit immune and inflammatory responses in the GI tract. T cells expressing αEβ7 integrin may interact with epithelial E-cadherin to alter epithelial barrier function. TGF-β and IL-6 are important cytokines that drive the expansion of the regulatory T-cell subsets. The T_H1 cells produce a characteristic array of cytokines, including IFN-γ and TNF-α, which in turn activate macrophages. Macrophages positively regulate T_H1 cells by secreting additional cytokines, including IFN-γ and TNF-α. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells, including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes, and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, *methotrexate*, and *cyclosporine*) affect multiple sites of inflammation. More site-specific interventions involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNF-α, IL-12/23, integrins, or members of the JAK signaling pathway.

Mesalamine formulations generally are well tolerated. Headache, dyspepsia, and skin rash are the most common side effects. Diarrhea appears to be particularly common with *olsalazine* (occurring in 10%–20% of patients). Nephrotoxicity, although rare, is a more serious concern. *Mesalamine* has been associated with interstitial nephritis; renal function should be monitored in all patients receiving these drugs. Pancreatitis, pericarditis, and pleuritis are less common adverse events that should be considered.

Both *sulfasalazine* and its metabolites cross the placenta but have not been shown to harm the fetus. The newer formulations also appear to be safe in pregnancy, but there have been some safety concerns about dibutyl phthalate, an inactive ingredient in the coating of some formulations, in the context of pregnancy.

Glucocorticoids

The glucocorticoids *prednisone, prednisolone, methylprednisolone, budesonide*, and *triamcinolone* are FDA-approved for the treatment of IBD. Numerous other corticosteroids are also used as short-term therapy in critical periods of ulcerative colitis and regional enteritis.

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

The effects of glucocorticoids on the inflammatory response are numerous, including downregulating expression of several cell adhesion molecules involved in inflammatory responses, reducing production of proinflammatory cytokines (e.g., TNF, IL-1, IL-8), and inhibiting transcription of genes for PLA2 and COX-2 (see Chapters 39, 50, 74, and 75).

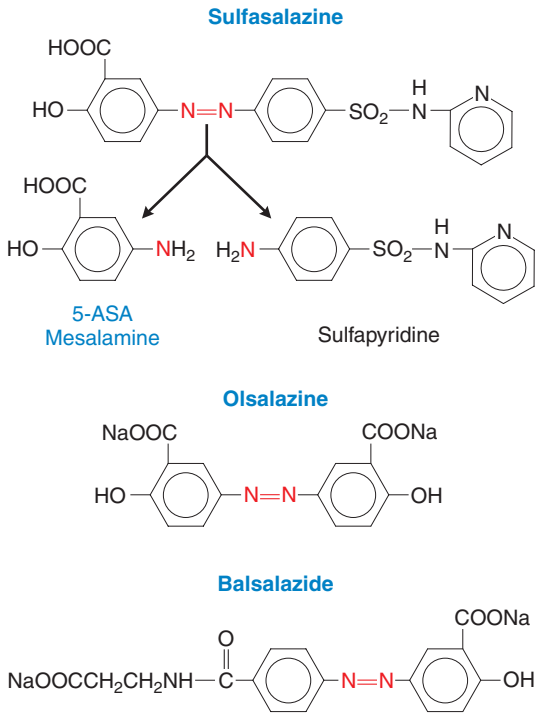

Figure 55–2 *Sulfasalazine and related agents.* The red N atoms indicate the diazo linkage that is cleaved to generate the active moiety, 5-ASA.

Glucocorticoids are indicated for moderate-to-severe IBD. Patients with IBD segregate into three general groups with respect to their response to glucocorticoids:

- *Glucocorticoid-responsive patients* improve clinically within 1 to 2 weeks and remain in remission as the steroids are tapered and then discontinued.
- *Glucocorticoid-dependent patients* respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered or discontinued.
- *Glucocorticoid-unresponsive* or *"steroid-resistant" patients* do not improve, despite prolonged high-dose steroids.

Glucocorticoids induce a reduction in the inflammatory response and symptomatic remission in most patients with Crohn's disease, with improvement generally occurring within 5 days of initiating treatment; however, some patients require treatment for several weeks before remission occurs. Glucocorticoids are sometimes used for prolonged periods to control symptoms in corticosteroid-dependent patients, as these patients will often experience a recurrence of their disease when

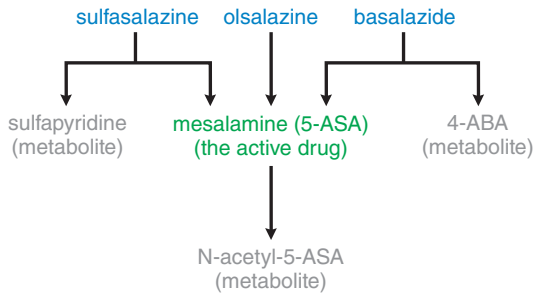

Figure 55–3 *Metabolic fates of the different oral formulations of 5-ASA.* Chemical structures are in Figure 55–2. 4-ABA, 4-aminobenzoyl-β-alanine.

the glucocorticoid is withdrawn. A proportion of patients with IBD are steroid resistant, and the failure to respond to steroids with sustained remission (i.e., a disease relapse) should prompt consideration of adjunctive and alternative therapies, including immunosuppressive agents and biological therapies (Manz et al., 2012). Glucocorticoids are not a safe or practical means to maintain remission in either ulcerative colitis or Crohn's disease due to the high rate of adverse events associated with their prolonged use. The most commonly used glucocorticoid in Crohn's disease is *prednisone,* given orally. For more severe cases, glucocorticoids such as *methylprednisolone* or *hydrocortisone* are given intravenously. Rectal preparations can be used in treating IBD in the lower colon and rectum.

Budesonide is a synthetic glucocorticoid. Compared to *prednisolone*, *budesonide* exhibits greater affinity (~15 times) for the glucocorticoid receptor. The agent is available in several delayed-release or enteric release formulations that are used for mild-to-moderate colonic or terminal ileal Crohn's disease or mild-to-moderate ulcerative colitis. *Budesonide*'s putative action is the delivery of therapeutic quantities of steroid to a specific portion of inflamed gut while minimizing systemic side effects owing to its local release and extensive first-pass hepatic metabolism to inactive derivatives such that systemic levels remain low. *Budesonide* is FDA approved for use in the short-term maintenance of remission (up to 3 months). Some older studies questioned the effectiveness of *budesonide* for this indication (Kuenzig et al., 2014). A multimatrix formulation of *budesonide* delays release until the local pH is greater than 7 (pH of distal ileum), thereby delivering the drug predominantly to the colon (Hoy, 2015; Maconi et al., 2020).

Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. *Betamethasone* and *budesonide* are available as retention enemas. Patients with distal disease usually respond within 3 to 7 days. Absorption, although less than with oral preparations, is still substantial (up to 50%–75%). *Hydrocortisone* also can be given once or twice daily as a 10% foam suspension that delivers 80 mg *hydrocortisone* per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining enemas.

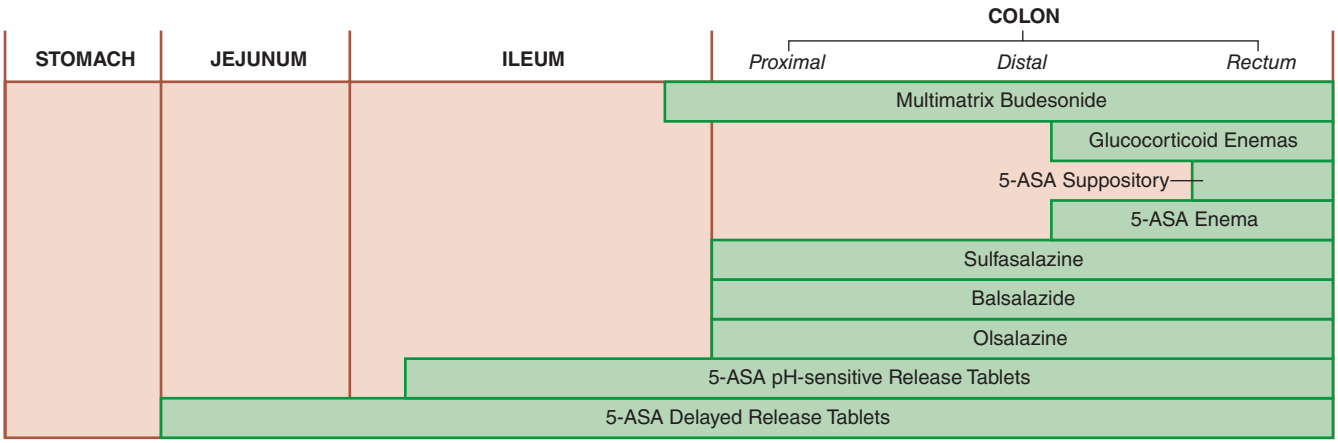

Figure 55–4 *Comparison of sites of release of multimatrix budesonide and various formulations of 5-ASA in the GI tract.*

ADME

Prednisone is the most commonly administered glucocorticoid and is used for the induction of remission of moderate-to-severe Crohn's disease (Benchimol et al., 2008). It is sometimes given as a first-line therapeutic to induce remission. *Prednisone* is most often administered orally but can be administered intravenously when patients present with severe, acute flares of disease. Initial doses in IBD are 40 to 60 mg of *prednisone* or equivalent per day; higher doses are generally no more effective. Most patients respond within 10 to 14 days, at which point the dose is reduced by 5 mg per week (tapered) over several weeks to months. *Prednisone* is absorbed at a rate of 50% to 90%; 65% to 90% of the absorbed drug is protein bound in the serum. It is metabolized to the active compound, *prednisolone*, in the liver. The $t_{1/2}$ for *prednisone* about 3.5 h, with metabolized drug excreted in the urine. Because of the complex nature of the mechanism of action of glucocorticoids, numerous drug interactions have been reported.

Budesonide for the treatment of IBD is administered orally at a dose of 9 mg/day for up to 8 weeks (Kane et al., 2002) followed by a 3-mg reduction every 4 to 6 weeks. There is usually no therapeutic benefit of continuing treatment beyond 3 months. The bioavailability of orally administered *budesonide* is limited (9%–21%) by its high first-pass metabolism by hepatic CYP3A4. The time to peak serum concentration is 7 to 19 h when given in capsule form. The $t_{1/2}$ is about 2 to 3.6 h but can be prolonged by agents that inhibit the activity of CYP3A4, such as the antifungal agent *ketoconazole* and the furanocoumarins in grapefruit juice. Excretion of metabolites is renal (60%) and fecal.

Triamcinolone, a widely used synthetic corticosteroid without significant mineralocorticoid activity, can provide temporary therapy for acute flare-ups of Crohn's disease and ulcerative colitis. *Triamcinolone* has high bioavailability (90%) when taken orally. The plasma $t_{1/2}$ is 3 to 5 h, but the receptor-bound drug within responsive cells prolongs the half-life of effectiveness to ~36 h. Chapters 74 and 75 cover the ophthalmic and dermatologic uses of *triamcinolone*.

Adverse Effects

The significant adverse events associated with conventional glucocorticoids such as *prednisone* limit their long-term use. These are numerous, but among the more common are skin and soft-tissue manifestations, including skin thinning and the development of Cushingoid features (weight redistribution and weight gain). Other side effects include cardiovascular events and psychiatric and cognitive effects. Conventional glucocorticoids can suppress the HPA axis, which can result in exogenous adrenal insufficiency when the drug is withdrawn abruptly. This effect necessitates the tapering of dose rather than quick withdrawal of the drug. The mechanisms underlying these and other adverse effects of conventional glucocorticoids are detailed in Chapter 46. *Budesonide* has a similar profile of adverse events, but with lower incidence due to its extensive first-pass hepatic metabolism.

Immunomodulatory Agents

Several drugs developed for cancer chemotherapy or as immunosuppressive agents in organ transplants are also used for treatment of IBD. Clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

Thiopurine Derivatives

The cytotoxic thiopurine derivatives *mercaptopurine* and *azathioprine* (see Chapters 39 and 70) are used off label to treat patients with severe IBD or those who are steroid resistant or steroid dependent (Coskun et al., 2016). Thiopurines are not used to treat mild-to-moderate disease (Solitano et al., 2020). These thiopurines impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: *Azathioprine* is converted to 6-mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides, the putative active moieties (Figure 55–5).

Therapeutic Uses. These drugs are generally used interchangeably with appropriate dose adjustments, typically *azathioprine* (1.5–2.5 mg/kg per day)

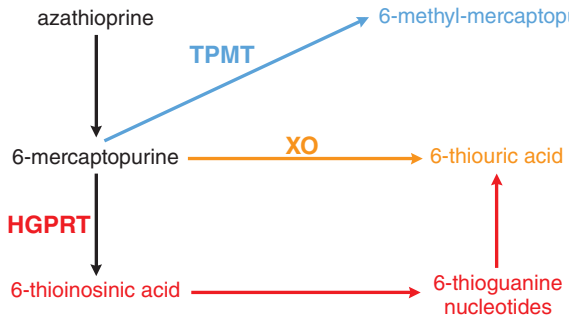

Figure 55–5 *Metabolism of azathioprine and 6-mercaptopurine.* The activities of these enzymes vary among humans because of genetic polymorphisms, explaining responses and side effects when *azathioprine* or *mercaptopurine* therapy is employed.

or *mercaptopurine* (1.5–2.0 mg/kg per day) in both Crohn's disease and ulcerative colitis as an adjunct to glucocorticoids and biologics (Nielsen et al., 2001). They help maintain remission in both diseases; they also may prevent or delay recurrence of Crohn's disease after surgical resection. Finally, they are used to treat fistulas in Crohn's disease. The clinical response to *azathioprine* or *mercaptopurine* may take weeks to months, such that other drugs with a more rapid onset of action (e.g., *mesalamine*, glucocorticoids, or biologics) are preferred in the acute setting.

In general, physicians who treat IBD believe that the long-term risks of *azathioprine-mercaptopurine* are lower than those of steroids. Thus, these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. In addition, patients who have not responded adequately to *mesalamine* but are not acutely ill may benefit by conversion from glucocorticoids to immunomodulatory drugs. Immunomodulators therefore may be viewed as steroid-sparing agents.

ADME. Favorable responses to *azathioprine-mercaptopurine* are seen in up to two-thirds of patients. *Mercaptopurine* has three metabolic fates (Figure 55–5):

- Conversion by XO to 6-thiouric acid
- Metabolism by TPMT to 6-MMP
- Conversion by HGPRT to 6-thioguanine nucleotides and other metabolites

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects.

The plasma $t_{1/2}$ of *mercaptopurine* is limited by its relatively rapid (i.e., within 1–2 h) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug's fate. Approximately 80% of the U.S. population has what is considered "normal" metabolism, whereas 1 in 300 individuals have minimal TPMT activity. In the latter setting, *mercaptopurine* metabolism is shifted away from 6-MMP and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, about 10% of the population are rapid metabolizers. In these individuals, *mercaptopurine* is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Pharmacogenetic typing can guide therapy (see Chapter 7).

Xanthine oxidase in the small intestine and liver converts *mercaptopurine* to thiouric acid, which has no therapeutic activity. Inhibition of XO by *allopurinol* diverts *mercaptopurine* to more active metabolites, such as 6-thioguanine, increasing both immunomodulatory and potential toxic effects. Thus, patients on *mercaptopurine* should be warned about potentially serious interactions with medications used to treat gout or

hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking *allopurinol*.

Adverse Effects. Adverse effects of *azathioprine-mercaptopurine* can be either *idiosyncratic* or *dose related*. Adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. One of the most serious idiosyncratic reactions is pancreatitis, which affects about 5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally; nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and blood counts should be monitored closely when therapy is initiated and at less-frequent intervals during maintenance therapy. Elevations in liver function tests also may be dose related. The serious adverse effect of cholestatic hepatitis is relatively rare. Thiopurines given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin lymphoma (4-fold increase).

Methotrexate

Methotrexate is a folic acid analogue that inhibits *dihydrofolate reductase*, thereby blocking DNA synthesis and causing cell death (Coskun et al., 2016). The anti-inflammatory effects of *methotrexate* may involve mechanisms in addition to inhibition of dihydrofolate reductase. These include inhibition of purine metabolism, inhibition of T-cell activation and production of cytokines and intercellular adhesion molecules, and inhibition of IL-1β receptor binding. For details of folate metabolism and the actions of *methotrexate*, see Chapters 45 and 70.

Therapeutic Uses. *Methotrexate* is reserved for patients whose IBD is either steroid resistant or steroid dependent. In Crohn's disease, it is used for maintenance of remission and as an adjunct to biologics to boost efficacy and reduce formation of antidrug antibodies (Patel et al., 2014). *Methotrexate* (15–25 mg/week) is generally administered subcutaneously. This choice of administration reflects the unpredictable intestinal absorption at higher doses of *methotrexate* and in the presence of intestinal disease. A dose of 12.5 to 25 mg weekly is often used for induction of the remission of the inflammatory response, with 15 to 25 mg given once weekly for maintenance of remission. *Methotrexate* is sometimes used in combination with anti–TNF-α antibody therapy (see discussion that follows).

ADME. *Methotrexate* is usually administered subcutaneously for induction and maintenance of remission of Crohn's disease. It can cause folate deficiency, so oral folic acid supplementation (1 mg/day) is often recommended. After administration, approximately 50% is bound to serum proteins. *Methotrexate* can cross the blood-brain barrier but is measured at much lower levels in cerebrospinal fluid than in serum. It has a $t_{1/2}$ of about 3 to 10 h at doses used for the treatment of Crohn's disease (see Appendix I). Approximately 90% of administered *methotrexate* is excreted unaltered in the urine, likely as a result of active tubular secretion.

Adverse Effects. Drugs that inhibit renal excretion of MTX may increase treatment-related toxicity. These include NSAIDs, *phenytoin*, *ciprofloxacin*, *penicillin*-type drugs, *probenecid*, *amiodarone*, and proton pump inhibitors. *Methotrexate*, at the doses used for the treatment of Crohn's disease, is generally well tolerated. When toxicity occurs, it manifests as nausea, loose stool, stomatitis, punctate cutaneous eruption, CNS symptoms (including headache, fatigue, and impaired ability to concentrate), alopecia, fever (drug related or due to infection), and hematologic abnormalities, particularly macrocytosis.

Cyclosporine

Cyclosporine is an inhibitor of calcineurin and a potent immunomodulator used most frequently after organ transplantation (see Chapter 39). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Therapeutic Uses. Between 50% and 80% of severely ill patients with IBD improve significantly (generally within 7 days) in response to intravenous *cyclosporine* (2–4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of *cyclosporine* levels is necessary to maintain a therapeutic level between 300 and 400 ng/mL of whole blood. Oral *cyclosporine* is less effective as maintenance therapy in Crohn's disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with formulations of *cyclosporine* that have increased oral bioavailability may be more effective. *Cyclosporine* can be used to treat fistulous complications of Crohn's disease. A significant rapid response to intravenous *cyclosporine* has been observed; however, frequent relapses accompany oral *cyclosporine* therapy, and other medical strategies are required to maintain fistula closure. Thus, calcineurin inhibitors generally are used to treat specific problems over the short term while providing a bridge to longer-term therapy.

ADME. *Cyclosporine* given orally is erratically and incompletely absorbed by the intestine. Following absorption, 90% to 98% is bound to serum lipoproteins. Depending on the formulation, the $t_{1/2}$ is biphasic, with the terminal phase being about 9 to 18 h.

Adverse Effects. The significant adverse effects associated with the use of *cyclosporine* limit its use to specific types of severe IBD. These side effects most often include increased susceptibility to infections, renal insufficiency, hypertension, seizures, and peripheral neuropathy. Significant drug interactions have been reported.

Other immunosuppressants that are being evaluated in IBD include the calcineurin inhibitor *tacrolimus* (FK506) (Rodríguez-Lago et al., 2020) and the inhibitors of inosine monophosphate dehydrogenase, *mycophenolate mofetil* and *mycophenolate* (Macaluso et al., 2017), to which lymphocytes are especially susceptible (see Chapter 39). *Tacrolimus* has been used for severe, acute, steroid-resistant IBD with good efficacy and safety profile (Hoffmann et al., 2019). Similarly, *mycophenolate mofetil* has been used for the induction and maintenance of remission in difficult-to-treat IBD or patients who are intolerant of thiopurines or who are steroid dependent (Smith and Cooper, 2014). Paradoxically, *mycophenolate mofetil* has been reported to cause colitis in patients who are taking the drug as a treatment to prevent transplant rejection (Calmet et al., 2015).

Biological Therapies for IBD

Anti–TNF-α Monoclonal Antibodies

The biological activity of tumor necrosis factor (TNF), a proinflammatory cytokine, comprises a host of issues in IBD, including release of additional proinflammatory cytokines from macrophages, upregulation of collagen production, and enhanced expression of adhesion molecules that localize leukocytes. Antibodies to TNF can reduce the proinflammatory effects of TNF. *Infliximab, adalimumab, certolizumab pegol*, and *golimumab* are monoclonal immunoglobulins that have been developed for the treatment of chronic inflammatory diseases. *Infliximab* is a chimeric antibody (25% mouse, 75% human), whereas *adalimumab* and *golimumab* are fully humanized antibodies. *Certolizumab pegol* is a humanized fragment antigen binding that is "pegylated" (i.e., bound to a polyethylene glycol polymer to increase serum half-life of the parent compound). These drugs bind to and neutralize both soluble and membrane-bound TNF-α, one of the principal cytokines mediating the T_H1 immune response characteristic of Crohn's disease (see Figure 55–1), thereby preventing its binding to p55 and p75 receptors. Chapters 38 and 39 present a more detailed and mechanistic view of antibody production and the use of antibodies to regulate immune function. *Infliximab, adalimumab,* and *golimumab* are approved for acute and chronic treatment of moderate-to-severe ulcerative colitis. *Infliximab, adalimumab*, and *certolizumab* are for treatment of moderate-to-severe Crohn's disease in patients who have responded poorly to conventional therapies.

Therapeutic Uses and ADME—Crohn's Disease. Monoclonal anti–TNF-α antibodies are used for moderate-to-severe Crohn's disease, including fistulizing disease that is resistant to other therapies (Peyrin-Biroulet et al., 2008). The antibody preparations are used for both the induction and the maintenance of remission in adults and children and are given parenterally. For induction therapy for Crohn's disease, these agents produce a clinical response in approximately 14 days, with improvement of symptoms in approximately 60% and remission in approximately 30%

of patients. Responsive patients may progress to maintenance therapy; see dosing schedules below.

Infliximab is given intravenously at an initial dose of 5 mg/kg, with subsequent doses of 5 mg/kg at weeks 2 and 6, followed by maintenance doses of 5 mg/kg every 8 weeks. The $t_{1/2}$ is about 8 to 10 days, although the clearance rate increases in patients who develop anti-infliximab antibodies. *Adalimumab* is given subcutaneously at an initial dose of 160 mg, with subsequent doses of 80 mg at week 2 and maintenance doses of 40 mg every second week starting on week 4. Bioavailability following a 40-mg dose is about 64%; the $t_{1/2}$ is about 2 weeks. *Certolizumab pegol* is given at an induction dose of 400 mg subcutaneously at weeks 0, 2, and 4, and then every 4 weeks for maintenance of response. Bioavailability when given subcutaneously is about 80%; the $t_{1/2}$ is about 2 weeks. For induction to treat moderate-to-severe ulcerative colitis, *golimumab* is administered subcutaneously, 200 mg at starting, 100 mg at 2 weeks, and then a maintenance dose of 100 mg every 4 weeks. *Golimumab* has a half-life of approximately 14 days. In treating severe ulcerative colitis, *golimumab* and *adalimumab* appear less efficacious than *infliximab*. The clearance of monoclonal anti–TNF-α antibodies is not well understood but is likely due to proteolytic degradation. The polyethylene glycol moiety of *certolizumab pegol* is cleared by urinary excretion.

Adverse Effects. The major serious adverse effect of anti-TNF agents is infection resulting from suppression of the inflammatory response. Concomitant administration of steroids enhances the likelihood of infection. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after *infliximab* infusion. Antibodies to *infliximab* can decrease its clinical efficacy (Lichtenstein, 2013). Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving *infliximab* efficacy but may increase the chance of infection. Because *adalimumab* and *certolizumab* are humanized antibodies, there is less chance for the development of an immune response against them. *Infliximab* therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or development of opportunistic infections with subsequent dissemination. The FDA recommends that candidates for *infliximab* therapy be tested for latent tuberculosis with purified protein derivative; patients testing positive should be treated prophylactically with therapy for latent tuberculosis. *Infliximab* is contraindicated in patients with severe congestive heart failure. There is concern about a possible increased incidence of non-Hodgkin lymphoma, but a causal role has not been established. Other adverse events including drug-induced lupus, multiple sclerosis–like syndrome, and nonmelanoma skin cancer have been reported.

Although *infliximab* was designed specifically to target TNF-α, it may have more complex actions. *Infliximab* binds membrane-bound TNF-α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, *infliximab* may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma $t_{1/2}$ of 8 to 10 days, may explain the prolonged clinical effects of *infliximab*. *Infliximab* (5 mg/kg infused IV at intervals of every 6–8 weeks) decreases the frequency of acute flares in approximately two-thirds of patients with moderate-to-severe Crohn's disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn's disease. Emerging evidence also supports its efficacy in maintaining remission and in preventing recurrence of fistulas. The combination of *infliximab* and *azathioprine* is more effective than *infliximab* alone in induction of remission and mucosal healing in steroid-resistant patients.

Other Monoclonal Antibodies for the Treatment of Crohn's Disease and Ulcerative Colitis

Antibodies have been derived that bind to subunits of the cell adhesion molecule integrin, thereby interfering with lymphocyte recruitment to areas of damage and inflammation. *Vedolizumab* is a humanized monoclonal antibody that binds to and inhibits the α_4-integrin subunit and therefore blocks binding of $\alpha_4\beta_1$ and $\alpha_4\beta_7$ on lymphocytes to *addressin* also known as mucosal vascular addressin cell adhesion molecule, MADCAM-1) on venular endothelial cells, thus preventing lymphocyte recruitment to the intestinal mucosa (Jovani and Danese, 2013). It is approved for use in the treatment of moderate-to-severe Crohn's disease and ulcerative colitis. *Vedolizumab* is generally given at a dose of 300 mg at 0, 2, and 6 weeks, with maintenance doses of 300 mg given every 8 weeks thereafter. The main side effects are headache, hypersensitivity reactions, arthralgia, nasopharyngitis, and fatigue. Anti–TNF-α drugs may enhance the adverse effects of *vedolizumab.*

Etrolizumab is another monoclonal antibody that binds the β_7 integrin subunit. It showed promise in phase III clinical trials for the treatment of moderate to severe Crohn's disease (Sandborn et al., 2020), whereas in trials with severe ulcerative colitis, *etrolizumab* had mixed results for induction of remission and no significant effect on maintenance of remission compared to control. Unlike *vedolizumab, etrolizumab* also blocks $\alpha E\beta_7$ heterodimers; thus, it has the potential to inhibit the interaction of $\alpha E\beta_7$-positive T cells with E-cadherin. Its effect is on the recruitment of T cells to both the vascular and epithelial compartments in the gut mucosa (Tang et al., 2018). Like many therapeutic monoclonal antibodies, *etrolizumab* has the potential to stimulate the production of antidrug antibodies, which have been observed in approximately 5% of patients.

Ustekinumab is a fully humanized monoclonal antibody that targets the p40 subunit common to the proinflammatory cytokines IL-12 and IL-23, thus preventing activation of IL-12β1 and IL-23 receptors on lymphocytes ($CD4^+$ T cells and natural killer cells) (Teng et al., 2015). Originally developed for the treatment of psoriasis, *ustekinumab* is also effective in the induction and maintenance of remission in Crohn's disease. Initial treatment is given intravenously at a dose of 260 to 520 mg depending on body weight, then 90 mg subcutaneously every 8 weeks thereafter for maintenance of remission. Time to peak C_p is 1 to 2 weeks. Side effects include upper respiratory tract infections, headache, arthralgia, infection, nausea, and nasopharyngitis. This agent has a variable and long elimination half-life (up to 120 days) and should be discontinued for 15 weeks prior to the administration of a live vaccine.

Therapeutic Uses and ADME—Ulcerative Colitis. Unlike Crohn's disease, ulcerative colitis can be cured with surgery (colectomy). Thus, the cost and potential adverse events associated with monoclonal antibody therapy need to be balanced with the effectiveness of the drug at preventing the need for colonic resection. Biologics are well established in their use in ulcerative colitis, particularly in those patients for whom primary therapy with glucocorticoids, 5-ASA, or immunomodulators has failed. *Infliximab, adalimumab,* and *golimumab* have become mainstays in the treatment of ulcerative colitis. *Vedolizumab* and *ustekinumab* are now indicated and approved for the treatment of moderate-to-severe ulcerative colitis. The administration, dosing, metabolism, and adverse events are similar for the use of these drugs in both ulcerative colitis and Crohn's disease.

Natalizumab is a chimeric (human-mouse) monoclonal antibody against $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins on leukocytes involved in inflammation. The drug effectively provides symptomatic relief from both multiple sclerosis and Crohn's disease and has been approved for induction and maintenance of remission in moderate-to-severe Crohn's disease. The drug must not be used in patients with immunodeficiency or in immunosuppressed patients due to possible increased risk of progressive multifocal leukoencephalopathy, an often lethal viral infection (human polyomavirus 2). As a result, *natalizumab* carries a boxed warning and is available only through TOUCH, a restricted distribution program.

Other Small-Molecule Drugs to Treat IBD

JAK Inhibitors

Janus kinases (JAKs) are signaling molecules that are activated following ligand binding and dimerization of many cytokine receptors. There are four members of the JAK family—JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2)—that act in various dimeric configurations. JAK1/JAK3 transduce signals from the receptors for a variety of interleukins that play roles in the activation of immune/inflammatory and autoimmune responses. IFN acts via JAK1 JAK2. By inhibiting JAK, *tofacitinib* inhibits immune/

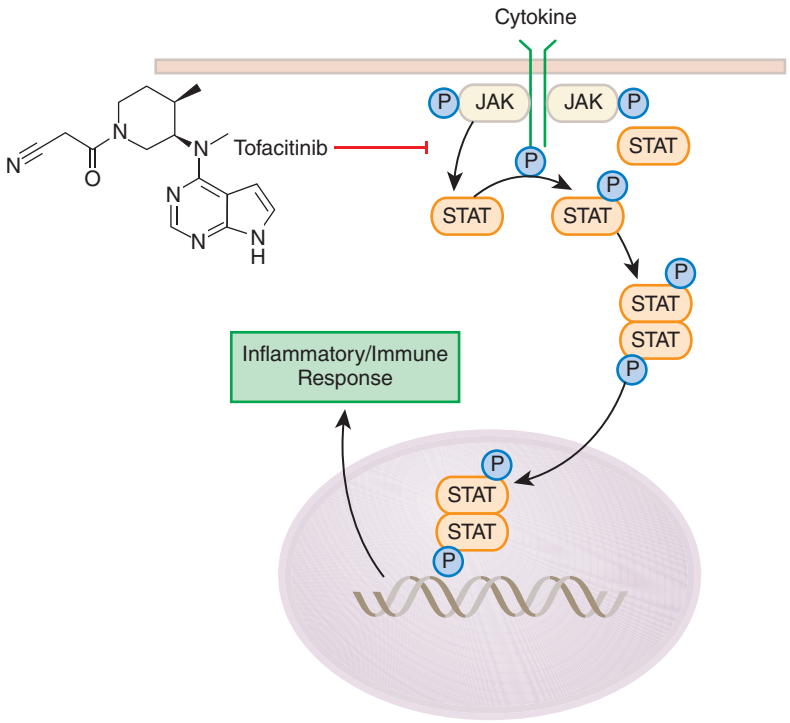

Figure 55–6 *Tofacitinib inhibits the JAK-STAT signaling pathway.* Binding of cytokines to their receptors triggers the phosphorylation of JAKs and receptor tyrosine kinases. The phosphorylation of JAKs leads to the phosphorylation and dimerization of STATs, which translocate to the nucleus to drive the expression of genes associated with numerous cellular processes including those associated with inflammation and immunity. *Tofacitinib* inhibits the activity of JAK and thereby prevents the phosphorylation of STAT and the resultant activation of inflammatory/immune responses. Unlike some biological therapies, *tofacitinib* does not elicit generation of neutralizing antibodies to itself.

inflammatory responses that are active in ulcerative colitis. Following activation, JAKs self-phosphorylate at tyrosine residues, and then phosphorylate members of the signal transducers and activators of transcription (STAT) family. Activated STAT proteins translocate to the nucleus where they stimulate the expression of genes related to the inflammatory response. The use of JAK inhibitors in IBD has recently been reviewed (Hernandez-Rocha and Vande Casteele, 2020).

Tofacitinib is a pyrrolopyrimidine that is pyrrolo[2,3-d]pyrimidine substituted at position 4 by an *N*-methyl,N-(1-cyanoacetyl-4-methylpiperidin-3-yl)amino moiety. Its citrated form is used therapeutically. *Tofacitinib* acts broadly, inhibiting JAK1, JAK2, JAK3, and TYK2, although its main effect is through inhibition of the JAK1/3 combination. Administration of *tofacitinib* also results in a decrease in circulating $CD16/56^{+}$ natural killer cells, which contributes to its immunosuppressive effects.

Several other so-called "jakinibs" have been developed to treat chronic inflammatory disease. For example, *ruxolitinib* is FDA-approved for the treatment of rheumatoid arthritis and psoriasis, but not for IBD at this point.

Therapeutic Uses and ADME. *Tofacitinib* is used to treat moderate-to-severe ulcerative colitis in patients who fail to respond to biological therapies. It is available in standard and extended-release formulations and is administered orally at a dose of 10 mg twice daily for 8 weeks. After this, it can be administered at a dose of 5 mg twice daily for the maintenance of remission of inflammation. The drug should be discontinued if a patient does not respond by 16 weeks. *Tofacitinib* is rapidly absorbed, with a time to peak plasma levels (T_{max}) of 0.5 to 1 h. Approximately 40% of the drug is bound to protein in the plasma, mostly albumin. It is active in the unmetabolized form, and the circulating drug is metabolized in the liver (˜70%), primarily via CYP3A4, and also in the kidneys (˜30%). Thus, *tofacitinib* is contraindicated in patients with hepatic insufficiency. Renal dysfunction or concomitant use of other substrates and inhibitors of CYP3A4 requires reduction of *tofacitinib* dosage (to 5 mg daily). The metabolized drug is excreted in the urine (80%) and the feces (14%).

Adverse Effects. The primary adverse effect of *tofacitinib* is immunosuppression, so patients can experience increased susceptibility to infection. The drug should not be taken with other immunosuppressants. Additional adverse effects include an increase in blood cholesterol, diarrhea, headaches, and stuffy or runny nose. Recently, *tofacitinib* has been associated with pulmonary embolism in a small number of patients. *Tofacitinib* is not recommended for use in children with *ulcerative colitis*, since its pharmacokinetics, safety, and effectiveness have not been established in the pediatric population. In September of 2021, the FDA modified the approved indications for *tofacitinib* and two JAK inhibitors, *baricitinib* and *upadacitinib,* that are used primarily in treating rheumatoid arthritis. Use of these agents is now limited to patients who have responded poorly to TNF antagonists. An updated boxed warning includes information about the risks of serious heart-related events, cancer, blood clots, and death (FDA, 2021). Two additional JAK inhibitors, *ruxolitinib* and *fedratinib*, are not indicated for the treatment of inflammatory conditions and are not included in the required modified labeling.

Sphingosine-1-Phosphate Receptor Agonists

Sphingosine-1-phosphate (S1P) is formed from ceramide through the action of ceramidase and the sphingosine kinase 1/2 enzymes. It is classed as a lysosphingolipid and signals through members of the S1P receptor family ($S1PR_{1\text{-}5}$) of GPCRs. Activation of S1PR triggers a number of signaling pathways to evoke numerous biological responses including lymphocyte trafficking, immune cell activation, and the synthesis of inflammatory mediators that contribute to gastrointestinal inflammatory disease (Sukocheva et al., 2020). The mechanism of action of S1PR agonists appears to relate to blocking the movement of lymphocytes from lymph nodes to sites of tissue injury (see Figure 39–3).

Therapeutic Use and ADME. *Ozanimod* is an $S1PR_1$ and $S1PR_5$ agonist (Scott et al., 2016) that is FDA-approved for the treatment of relapsing forms of multiple sclerosis (see Chapter 39). In clinical trials, *ozanimod* has shown significant benefit in cases of *ulcerative colitis* (Sandborn et al., 2016) and *Crohn's disease* (Feagan et al., 2020). *Ozanimod* is supplied as a

monohydrochloride and is given orally in pill form. The dosage is titrated from 0.23 mg in the first 4 days to 0.46 mg in days 5 to 7 and 0.92 mg/day thereafter. Peak plasma levels occur in 6 to 8 h. Extensive metabolism of the parent compound produces a series of active metabolites with similar specificity for $S1P_1R$ and $S1P_5R$; thus, although the plasma $t_{1/2}$ of the parent drug is approximately 21 h, the $t_{1/2}$ of the effect is approximately 11 days.

Adverse Effects. Adverse effects (incidence ≥4%) include upper respiratory infection, elevation of hepatic transaminases, bradyarrhythmia/atrioventricular conduction delays, orthostatic hypotension, urinary tract infection, back pain, and hypertension. An active metabolite of *ozanimod* inhibits MAO-B, providing the potential of serious hypertensive interactions between *ozanimod* and agents that increase sympathetic tone, NE, or 5HT (opioids, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, MAO inhibitors, tyramine, and foods containing tyramine). Since the S1P receptors have roles in embryonic development, and based on animal studies, the FDA recommends that females of childbearing age should use contraception during therapy and for 3 months thereafter.

Manipulating the Intestinal Microbiome to Treat IBD

Antibiotics and Probiotics

A balance normally exists in the GI tract among the mucosal epithelium, the normal gut flora, and the immune response (Biteen et al., 2016; Shreiner et al., 2015). Dysbiosis of the intestinal microbiome is now considered a key factor in the development of IBD (Dalal and Chang, 2014). Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used most prominently in Crohn's disease.

Antibiotics can be used as:

- Adjunctive treatment along with other medications for active IBD in severe cases where there is concern about coexisting sepsis
- Treatment for perforating or fistulizing complications of Crohn's disease
- Prophylaxis for recurrence in postoperative Crohn's disease

Metronidazole, *ciprofloxacin*, *amoxicillin-clavulanate,* and *piperacillin-tazobactam* are the antibiotics used most frequently. Crohn's disease–related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as *Clostridium difficile*, and postoperative complications.

More recently, *probiotics* have been used to treat specific clinical situations in IBD. Probiotics are mixtures of putatively beneficial lyophilized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis (Sokol, 2014). Jakubczyk and colleagues (2020) have suggested that species and strains of *Bifidobacterium* and *Lactobacillus* provide the best therapeutic effect. However, with conflicting reports in the literature, the utility of probiotics as a primary therapy for IBD remains unclear.

Fecal Transplant as Therapy in IBD

The recognition that the etiology of IBD involves dysbiosis of the intestinal microbiome has raised interest in methods to reestablish normal microflora in patients. Fecal transplant involves the instillation of a preparation of feces from a healthy donor into the colon, either by enema or during colonoscopy. This has proven to be an effective therapy for antibiotic-resistant *C. difficile* infection. Several clinical trials have assessed the efficacy of fecal transplant in Crohn's disease and ulcerative colitis, with varying results (Tan et al., 2020).

Supportive Therapy in IBD

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. Oral iron, folate, and vitamin B_{12} should be administered as indicated. *Loperamide* or *diphenoxylate* (see Chapter 54) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease in selected circumstances; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. *Cholestyramine* can be used to treat bile salt–induced diarrhea in patients who have undergone limited ileocolic resections. Anticholinergic agents (*dicyclomine hydrochloride*, etc.; Chapter 11) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected.

With the legalization of cannabis in many jurisdictions, the use of cannabis and various formulations of cannabinoid compounds has garnered increasing attention as a supportive therapy for IBD. As recently reviewed, data suggest that cannabis may improve symptoms of IBD. However, studies to date have not involved properly designed randomly controlled trials, and the mechanisms of action are unclear (Nasser et al., 2020). Chapter 26 provides an overview of the pharmacological actions of cannabinoids.

Pediatric IBD

Children and adolescents remain the population of IBD patients with the fastest growing incidence. On average, children present with more severe disease than do adults. In addition, while many children present with the classical symptoms of IBD, approximately 22% of children present with additional symptoms, such as growth failure, perianal disease, or other extraintestinal manifestations, as the primary symptom, thus complicating diagnosis.

The drugs used for treating pediatric IBD are the same as those used for the treatment of these diseases in adults. Exclusive enteral nutrition is an effective alternative to 5-ASA compounds, glucocorticoids, immunosuppressants, and biologics. Indeed, 8 to 12 weeks of liquid formula as the sole source of calories is as effective as glucocorticoids in relieving symptoms and has the advantage of supporting growth (Rosen et al., 2015). In terms of drug therapy, a child's immunization status should be considered before commencing immunosuppressive therapy (glucocorticoids, *azathioprine-methotrexate*, anti–TNF-α drugs). Children should be tested for latent tuberculosis, particularly prior to treatment with anti–TNF-α drugs. During treatment, children may receive inactivated vaccines, but live vaccines are not recommended.

Antibiotics have recently been shown to have some utility in treating mild-to-moderate pediatric Crohn's disease. In particular, *ciprofloxacin*, *metronidazole,* and *rifaximin* were demonstrably effective in small clinical trials (Serban, 2015). Their role in the treatment of ulcerative colitis has yet to be established.

Therapy of IBD During Pregnancy

Inflammatory bowel disease is a chronic disease that affects women in their reproductive years. In general, decreased disease activity increases fertility and improves pregnancy outcomes (Kim et al., 2021). At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease. The use of medical therapies to treat IBD during pregnancy and lactation has been reviewed (Laube et al., 2021), although studies that thoroughly investigated the use of medications to treat IBD in pregnancy are limited (Damas et al., 2015). *Mesalamine* and glucocorticoids are used frequently in pregnancy and generally are considered safe, whereas *methotrexate* is absolutely contraindicated in pregnant patients. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives. Anti–TNF-α drugs, particularly

infliximab and *adalimumab*, have been assessed for their safety for use during pregnancy and have been found to have low risk for adverse events (Laube et al., 2021). *Certolizumab pegol* is considered safe since it does not cross the placenta (Mariette et al., 2018). JAK inhibitors including *tofacitinib* are teratogenic in animal studies and have been associated with developmental abnormalities and pregnancy complications in some patients. Thus, JAK inhibitors should not be taken during pregnancy. Furthermore, since they are secreted in breast milk, they should not be taken by lactating mothers. While there have been data suggesting that the S1PR agonist *ozanimod* can cause developmental defects in experimental animals, there are limited data on the effects in pregnant patients. Thus, at present, *ozanimod* is contraindicated during pregnancy.

Drug Facts for Your Personal Formulary: *Drugs for the Treatment of Inflammatory Bowel Diseases*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Mesalamine-Based Drugs		
Mesalamine (5-ASA)	• Induction and maintenance of remission in mild-to-moderate ulcerative colitis • Used in combination with glucocorticoids for severe ulcerative colitis	• Effects are primarily topical with limited effects on deeper tissue inflammation • Following oral administration, jejunum is primary site of absorption, so utility in more distal disease is limited • Can be delivered as a suppository for rectal disease
Sulfasalazine	• Induction and maintenance of remission in mild-to-moderate ulcerative colitis • Used in combination with glucocorticoids for severe ulcerative colitis	• Prodrug, delivers 5-ASA to more distal GI regions following metabolism by colonic bacteria • Sulfapyridine is also released; may cause adverse effects in patients sensitive to sulfa drugs
Olsalazine	• Induction and maintenance of remission in mild-to-moderate ulcerative colitis • Used in combination with glucocorticoids for severe ulcerative colitis	• Prodrug with two azo-linked 5-ASA molecules • Eliminates the side effects associated with the sulfapyridine moiety of sulfasalazine
Balsalazide	• Induction and maintenance of remission in mild-to-moderate ulcerative colitis • Used in combination with glucocorticoids for severe ulcerative colitis	• Prodrug with a 5-ASA molecule linked to an inert, unabsorbable second moiety • Eliminates the side effects associated with the sulfapyridine moiety of sulfasalazine
Glucocorticoids: Minimize duration of use. Taper dose prior to stopping to minimize disease relapse and avoid adrenal insufficiency that follows rapid glucocorticoid withdrawal after prolonged therapy has suppressed the HPA axis.		
Prednisone	• Induction of remission in moderate-to-severe Crohn's disease and ulcerative colitis	• Hepatic metabolism to active moiety, prednisolone • Not used for maintenance therapy due to serious adverse effects
Methylprednisolone	• Induction of remission in moderate-to-severe Crohn's disease and ulcerative colitis	• Can be administered orally, intravenously, or intramuscularly to patients who respond poorly to oral prednisone • Preferred over hydrocortisone, which has higher incidence of Na^+ retention and K^+ wasting
Hydrocortisone	• Induction of remission in moderate-to-severe Crohn's disease and ulcerative colitis	• Administered intravenously to patients who respond poorly to oral prednisone
Budesonide	• Induction of remission in mild-to-moderate Crohn's disease and ulcerative colitis, particularly in distal disease • Not effective for long-term maintenance of clinical remission	• Prominent first-pass metabolism reduces side effects that can result from maintenance of higher systemic levels
Immunomodulatory Agents		
6-Mercaptopurine	• Used as an adjunct to glucocorticoids and biologics in the treatment of moderate-to-severe Crohn's disease and ulcerative colitis • Effective in maintenance of remission	• Slow-acting drug; maximum therapeutic benefit may take months to achieve • Other metabolites also have anti-inflammatory activity • Fourfold increased risk of lymphoma in patients with IBD treated with thiopurines
Azathioprine	• Used as an adjunct to glucocorticoids and biologics in the treatment of moderate-to-severe Crohn's disease and ulcerative colitis • Effective in maintenance of remission	• Prodrug metabolized nonenzymatically in blood to active form, 6-mercaptopurine • Other metabolites also have anti-inflammatory activity • Fourfold increased risk of lymphoma in patients with IBD treated with thiopurines
Methotrexate	• Maintenance of remission in Crohn's disease, particularly steroid-resistant or steroid-dependent disease • Often used in combination with biologic agents	• Folic acid analogue that has anti-inflammatory activity of unclear mechanism • Administered subcutaneously or orally • Cleared unaltered by the kidney, so inhibition of renal excretion mechanisms may lead to drug toxicity

Drug Facts for Your Personal Formulary: *Drugs for the Treatment of Inflammatory Bowel Diseases (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Immunomodulatory Agents (cont.)		
Cyclosporine	• Used to treat specific cases of severe Crohn's disease, including fistulizing disease • Not useful for maintenance of remission	• Erratic and incomplete absorption means blood levels must be monitored • Significant adverse events profile
Tacrolimus (FK506)	• Useful for the treatment of refractory Crohn's disease	• Immunomodulator with similar mechanism as cyclosporine but with better oral absorption
Biologics: Anti–TNFα Antibodies		
Exacerbation of bacterial, viral, and fungal infections can be serious with these agents, especially in presence of other immunosuppressants. Prior to receiving antibodies to TNF, patients should be tested for TB and, if positive, receive prophylactic TB therapy prior to administration of anti-TNF antibodies.		
Infliximab	• Induction or maintenance of remission in moderate-to-severe Crohn's disease or ulcerative colitis in patients who have not responded well to other therapies	• Partly humanized, chimeric anti–TNF-α monoclonal antibody • Usually administered by intravenous infusion • Patients may develop antibodies against the drug
Adalimumab	• Induction or maintenance of remission in moderate-to-severe Crohn's disease or ulcerative colitis in patients who have not responded well to other therapies	• Fully humanized anti–TNF-α monoclonal antibody; reduced incidence of antidrug antibodies • Administered subcutaneously • Useful for patients for whom infliximab has lost efficacy or has caused adverse reactions
Certolizumab pegol	• Induction or maintenance of remission in moderate-to-severe Crohn's disease in patients who have not responded well to other therapies	• Humanized anti–TNF-α monoclonal antibody bound to PEG to increase plasma $t_{1/2}$ • Administered subcutaneously • Useful for patients for whom infliximab has lost efficacy or caused adverse reactions • May be a better option in pregnant women due to less drug crossing placental barrier
Golimumab	• Approved for moderate to severe ulcerative colitis in adults not responsive or intolerant of traditional therapy	
Biologics: Other		
Vedolizumab	• Induction or maintenance of remission in moderate-to-severe Crohn's disease or ulcerative colitis in patients who have not responded to other therapies	• Humanized anti-$\alpha_4\beta_7$ monoclonal antibody • Given by intravenous infusion • May cause hypersensitivity reactions
Etrolizumab	• Induction or maintenance of remission in moderate-to-severe Crohn's disease or ulcerative colitis in patients who have not responded to other therapies	• Humanized monoclonal antibody that blocks $\alpha_4\beta_7$ and $\alpha E\beta_7$ • Given by intravenous infusion • Good safety profile with few serious adverse events in clinical trials
Ustekinumab	• Induction or maintenance of remission in moderate-to-severe Crohn's disease in patients who have not responded to other therapies	• Humanized monoclonal antibody against p40 subunit of IL-12 and IL-23 • Administered subcutaneously or IV • Long-term safety profile has not yet been established
Natalizumab	• Induction and maintenance of remission in moderate-to-severe Crohn's disease in adults with inadequate response to TNF-α antagonists or other traditional therapies; also used in treating multiple sclerosis	• Available only under TOUCH, a restricted distribution program • Boxed warning: progressive multifocal leukoencephalopathy • IV administration; do not use with other immunosuppressants • Discontinue after 12 weeks if no benefit of induction therapy
Other Small-Molecule Drugs		
Tofacitinib	• Treatment of moderate-to-severe ulcerative colitis in patients who have failed biological therapies and for whom TNF antagonists have failed to provide sufficient response	• Blocks members of the Janus kinase (JAK) family of signaling molecules, thereby inhibiting actions of TNF-α • Administered orally • An immunosuppressant that can increase susceptibility to infection • Boxed warning issued in September 2021; see text
Ozanimod	• Treatment of moderate-to-severe ulcerative colitis in patients who have failed biological therapies; also used for multiple sclerosis	• Sphingosine-1-phosphate (S1P) receptor modulator • Metabolites inhibit MAO-B ⇒ possible hypertensive interactions with drugs that elevate adrenergic tone, NE, and 5HT, and with dietary tyramine • Main adverse effects are increased upper respiratory tract infections and elevated hepatic transaminases • Women of childbearing age should use birth control during and for 3 months after using ozanimod

Drug Facts for Your Personal Formulary: *Drugs for the Treatment of Inflammatory Bowel Diseases (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Antibiotics		
Metronidazole	• Used as adjunctive therapy in mild-to-moderate Crohn's disease • Sometimes used in conjunction with ciprofloxacin • Used in pediatric IBD	• Modest therapeutic benefit in Crohn's disease • Little to no benefit in ulcerative colitis
Ciprofloxacin	• Used as adjunctive therapy in mild-to-moderate Crohn's disease • Sometimes used in conjunction with metronidazole • Used in pediatric IBD	• Modest therapeutic benefit in Crohn's disease; little/no benefit in ulcerative colitis • Boxed warning: tendinopathy, tendon rupture, peripheral neuropathy, CNS effects • Fluoroquinolones exhibit neuromuscular blocking activity; avoid using in patients with myasthenia gravis
Rifaximin	• Used as adjunctive therapy in mild-to-moderate Crohn's disease • Used in pediatric Crohn's disease	• Less experience with this drug compared to metronidazole or ciprofloxacin
Probiotics		
Various types and formulations	• Some utility in ulcerative colitis and pouchitis but few clinical trials	• Effects are transient; long-term colonic colonization rarely occurs • Watch for progress on fecal transplant therapy

Chapter 56 General Principles of Antimicrobial Therapy

Conan MacDougall

Antimicrobial Chemotherapy: Classes and Actions

This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action and mechanisms of resistance, and principles of drug selection. Chapters 57 through 68 present the pharmacological properties and uses of individual classes of antimicrobials.

Microorganisms of medical importance fall into four categories: *bacteria, viruses, fungi,* and *parasites.* The broad classification of *antibiotics*—a term we will use colloquially to encompass all manner of antimicrobial agents—follows this classification closely, so that we have antibacterial, antiviral, antifungal, and antiparasitic agents. However, there are many antibiotics that work against more than one category of microbes, especially those that target evolutionarily conserved pathways. Classification of an antibiotic can be performed along several dimensions, including the class and spectrum of microorganisms it kills, the biochemical pathway it interferes with, and the chemical structure of its pharmacophore.

Antimicrobial molecules should be viewed as ligands whose receptors are typically microbial proteins. The term *pharmacophore,* introduced by Ehrlich, defines that active chemical moiety of the drug that binds to the microbial receptor. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways inhibits the replication of or directly kills the microorganisms. The biochemical processes commonly inhibited include cell wall synthesis, cell membrane synthesis and function, ribosomal translation, nucleic acid metabolism, topoisomerase-mediated chromosomal conformational changes, viral proteases, viral integrases, viral envelope entry/fusion proteins, folate synthesis, and parasitic chemical detoxification processes. Recently, *antisense antibiotics* have been developed; these work by inhibiting gene expression in bacteria in a sequence-specific manner. Furthermore, *interferon*-based products work by inducing specific antiviral activities of the infected human cells.

Types and Goals of Antimicrobial Therapy

A useful way to organize the types and goals of antimicrobial therapy is to consider where antibiotics are initiated with respect to the disease progression timeline (Figure 56–1); therapy can be classified as *primary prophylaxis, preemptive, empirical, definitive,* or *suppressive/secondary prophylaxis.*

Primary Prophylaxis

Prophylaxis involves administering antibiotics to patients who are not yet infected or have not yet developed disease. The goal of *primary* prophylaxis is to prevent a first episode of infection in patients without evidence of infection. Primary prophylaxis can significantly reduce the likelihood of clinically significant infection but must be balanced against the risks of disruption of the microbiome, selection for antibiotic-resistant variants, toxicity, and cost. Thus, primary prophylaxis should be reserved for patients at significant risk, using antibiotics of the narrowest appropriate spectrum, for the shortest duration appropriate to provide adequate protection.

The most common use of antibiotics for primary prophylaxis is the administration of antibiotics in the perioperative period to prevent surgical site infections. Wound infection results when a critical number of bacteria are present in the wound at the time of closure, and chemoprophylaxis can be used to prevent wound infections after surgical procedures. Antibiotics directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection.

In some cases, primary prophylaxis may be initiated several days in advance of the surgical procedure, as with the use of intranasal *mupirocin* and topical *chlorhexidine gluconate* baths to reduce the burden of *Staphylococcus aureus* ahead of cardiac and orthopedic surgeries, among those found to be colonized with this organism on preprocedure screening (Schweizer et al., 2015). More commonly, for patients and procedures that carry significant risk of surgical site infection, antibiotics are administered in the perioperative period (Berrios-Torres et al., 2017).

Abbreviations

ABC: ATP binding cassette
AUC: area under the C_p-time curve
CCR5: chemokine receptor type 5
CD4: T-helper cells
CMV: cytomegalovirus
C_p: plasma concentration
C_{Pmax}: peak plasma concentration
CYP: cytochrome P450
DHFR: dihydrofolate reductase
DHPS: dihydropteroate synthase
E: effect
EC: effective concentration
ELF: epithelial lining fluid
E_{max}: maximal effect
HIV: human immunodeficiency virus
IC: inhibitory concentration
MALDI-TOF MS: matrix-assisted laser desorption/ionization time-of-flight mass spectrometry
MEC: minimum effective concentration
MIC: minimum inhibitory concentration
PAE: postantibiotic effect
PCR: polymerase chain reaction
PK/PD: pharmacokinetics-pharmacodynamics
PrEP: preexposure prophylaxis
***rpoB*:** RNA polymerase

The perioperative antimicrobial dose should be administered intravenously within 60 min prior to the surgical incision, so that local drug concentrations are above the *minimum inhibitory concentration* (MIC) of likely pathogens at the time of incision. The frequency of redosing during the procedure is based on the half-life of the drug to ensure adequate antibiotic concentrations above the MIC until closure of the surgical incision. This is especially important for those β-lactam antibiotics that have short half-lives; these should be redosed at intervals of two times the half-life.

For the majority of procedures, a single perioperative dose suffices to prevent infection, and administration of postoperative doses is associated with no significant increased benefit and increased risks of adverse effects and *Clostridioides difficile* superinfection (Branch-Elliman et al., 2019). The systemic antibiotic used is chosen based on the pathogen most likely to contaminate the incision, which in turn depends on the site where surgery is being performed. The most common pathogens infecting incision sites after clean surgery are staphylococci, specifically *S. aureus* and coagulase-negative staphylococci. In clean-contaminated surgery over the abdomen and pelvis, the same organisms remain important, but *Enterococcus* species and gram-negative rods are also common.

Primary prophylaxis may also be used in immunosuppressed patients such as those with HIV-AIDS or those status post solid organ transplantation on antirejection immunosuppressants. In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the typical patterns of pathogens that are major causes of morbidity during immunosuppression. A risk-benefit analysis determines choice and duration of prophylaxis. Prophylaxis of opportunistic infections in patients with HIV-related immunosuppression is typically started when the CD4 count falls below 200 cells/mm^3 and may be discontinued with sustained increases in the CD4 count above this threshold in response to antiretroviral therapy. In posttransplant patients, use of prophylaxis depends on the type of transplantation, time since the transplant procedure, and type and dose intensity of immunosuppressive therapy. Prophylaxis may be discontinued in patients based on benchmarks either of time since transplantation or reduction of immunosuppression. Examples of pathogens against which primary prophylaxis may be used include *Pneumocystis jirovecii, Toxoplasma gondii, Candida* species, *Aspergillus* species, cytomegalovirus (CMV), and other Herpesviridae. Doses used for primary prophylaxis are often lower than when the same drug is used for acute treatment.

An emerging area of primary prophylaxis is termed *preexposure prophylaxis* (PrEP) and is employed in patients at increased risk of contracting HIV infection (Mayer and Allan-Blitz, 2019). PrEP involves taking oral antiretroviral drugs on a regular basis (a once-monthly injectable regimen is also under study) to prevent establishment of HIV infection upon exposure, typically through sex or injection drug use. PrEP may be used among patients who are part of a known HIV-serodiscordant couple or to reduce risk of transmission when the status of sexual partners is not known. PrEP has been shown to significantly reduce the risk of new diagnoses of HIV, although regular monitoring for drug-related adverse effects is necessary.

Other examples of primary prophylaxis include antiretroviral postexposure prophylaxis following needlestick exposures, administration of *rifampin* to contacts of patients with meningococcal meningitis, use of anti-influenza antivirals in household contacts of influenza cases, and administration of macrolides to close contacts of cases of pertussis.

Preemptive Therapy

Preemptive therapy is used as a substitute for primary prophylaxis and as early targeted therapy in high-risk patients in whom a laboratory or other test indicates infection despite a lack of symptoms. The principle is that delivery of therapy prior to development of symptoms aborts impending disease, and such therapy is used for a short and well-defined duration. Preemptive therapy may be particularly useful when there are concerns for drug toxicity with long-term use as prophylaxis. This strategy's most prominent application is in prevention of CMV disease after hematopoietic stem cell transplants and solid-organ transplantation, where detection of low-level viremia via PCR is possible and current antiviral therapies (e.g., *valganciclovir*) carry significant risks of cumulative toxicity (Razonable et al., 2019).

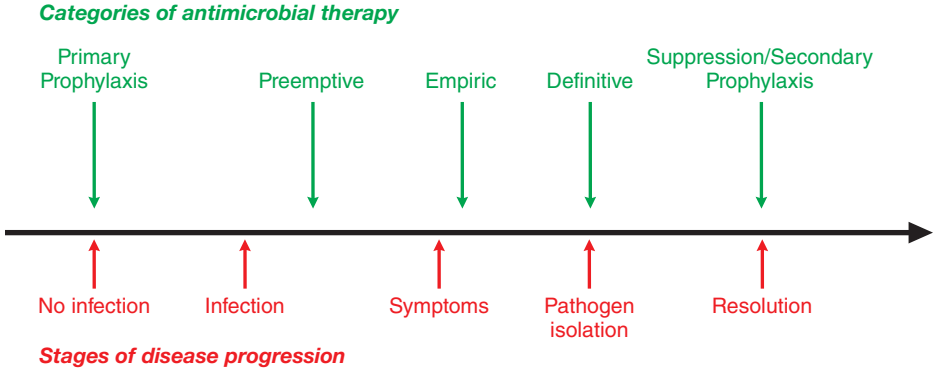

Figure 56–1 *Categories of antimicrobial therapy in relation to disease progression.*

Empiric Therapy

Empiric therapy is administered when an *infection is suspected but the specific causative organism and its susceptibility in that patient are not known*, with the antibiotics used based on the typical pathogens associated with the infectious syndrome(s). *Most use of antibiotics in clinical medicine is empiric use*. The rationale for this is 2-fold:

- Definitive identification and susceptibility of the causative microorganism(s) is typically delayed by at least 24 to 48 h from patient presentation (when microbiological results are able to be obtained), *and*
- For many infections, a delay in treatment until definitive identification of the infecting pathogen would be considered harmful to the patient.

For many subacute or chronic infections or acute infections of low severity, the risk in waiting a few days for definitive pathogen identification is low, and these patients can wait for more definitive microbiological evidence of infection without empirical treatment. If the risks of waiting are high, based on the nature of the infection, the patient's severity of illness, or the patient's immune status, then initiation of empiric antibiotic therapy should rely on the likely infectious syndrome, patient-specific risk factors (e.g., prior antibiotic use), and local epidemiology (e.g., prevalence of drug-resistant organisms). In some cases, it may be necessary to use a combination of antibiotics in order to achieve an adequate spectrum of activity for empiric coverage of the likely pathogens.

If the treating clinician wants to obtain samples for microbiological analysis to guide therapy, these samples are typically obtained during this period. It is optimal to obtain these samples before antimicrobials are administered, to improve the diagnostic yield; however, in some circumstances, it is not feasible to delay antimicrobial administration until diagnostic samples can be obtained.

Preliminary microbiology results may be available to allow tailoring of therapy before final microbiological data are available. The most valuable and time-tested method for early identification of bacteria is examination of the infected secretion or body fluid with Gram stain to identify the presence of gram-positive or gram-negative organisms. The predictive value of Gram staining varies by infection and specimen type but may be useful in reevaluating empirically selected regimens (e.g., if an empiric regimen has poor gram-positive coverage, the finding of gram-positive organisms in a sample may warrant expansion of the spectrum of activity). In malaria-endemic areas or in travelers returning from such an area, a simple thick-and-thin blood smear may mean the difference between a patient's survival on appropriate therapy or death while on the wrong therapy for a presumed bacterial infection. Rapid point-of-care diagnostic testing is increasingly available for a number of viral and bacterial infections. New technologies such as matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS), nucleic amplification techniques, microarray detection, and morphokinetic cellular analysis may not be rapid enough to allow deferral of empiric therapy but can shorten the empiric therapy phase by providing microbiological information more rapidly than traditional approaches (Bauer et al., 2014).

Notably, in many situations, patients will receive empiric therapy for the entire duration of their treatment because the actual organism causing the patient's infection is never determined. This may be due to the high cost or invasiveness of microbiological sampling, short duration of antibiotic therapy, high predictability of the causative pathogen based on symptom presentation, or failure of microbiological samples to detect the pathogen. In these situations, monitoring for symptomatic response will determine whether more aggressive approaches to determine the microbiological etiology are required.

Definitive Therapy

If a pathogen has been identified and susceptibility results are available, the optimal antibiotic regimen for that patient should be selected—the *definitive* therapy. This may or may not require adjustment of the empiric regimen if one was initiated. Selecting an optimal definitive regimen requires balancing the need for potent activity against the pathogen, risks of untoward effects (e.g., toxicities or drug interactions), costs, practicality (e.g., number of doses administered per day), and the desire to minimize the contribution to patient- and population-level antimicrobial resistance. The latter consideration suggests that narrower-spectrum antibiotics are preferred over broader-spectrum agents when the other factors are more or less equivalent. When the initial empiric regimen is broader in spectrum than the definitive regimen, this consideration is often known as *streamlining* or *de-escalation*.

For definitive therapy, combination antibiotic therapy is an exception, rather than a rule. Once a pathogen has been isolated, monotherapy is preferred unless compelling data exist in favor of combination therapy. Using multiple antibiotics where a single agent should suffice can lead to increased toxicity and unnecessary damage to the patient's protective fungal and bacterial flora. There are, however, special circumstances where evidence favors combination therapy:

- Preventing emergence of resistance to monotherapy (e.g., combination antiretroviral therapy for HIV, multidrug regimens for treatment of active *Mycobacterium tuberculosis* infection)
- Accelerating the rapidity or extent of microbial kill (e.g., combining penicillins and aminoglycosides for treatment of severe enterococcal infections, combining *amphotericin B* and *flucytosine* in patients with cryptococcal meningitis)
- Reducing toxicity—when sufficient efficacy of a single antibacterial agent can be achieved only at doses that are toxic to the patient and a second drug is coadministered to permit lowering the dose of the first drug (e.g., the use of reduced-dose combinations of *ganciclovir* and *foscarnet* in treatment of some resistant CMV infections) (Mylonakis et al., 2002)

In some cases, the antibiotic combination is already incorporated into standard pharmaceutical preparations. For example, the combination of a sulfonamide and an inhibitor of DHFR, such as *trimethoprim*, is synergistic owing to the inhibition of sequential steps in microbial folate synthesis; the combination formulation of *sulfamethoxazole* and *trimethoprim* is more commonly used than either agent separately. Similarly, many combination anti-HIV regimens are now completely coformulated, often in a single daily pill.

Posttreatment Suppressive Therapy and Secondary Prophylaxis

In some patients, the infection is controlled but not completely eradicated by the initial round of antimicrobial treatment and/or the immunological or anatomical defect that led to the original infection is still present. In such patients, antibiotics may be continued as *suppressive therapy,* differentiated from definitive therapy by use of a lower dose, different route of administration, or different antibiotic. Examples include treatment of cryptococcal meningitis or treatment of infections of implanted prosthetic materials (e.g., a prosthetic hip) that cannot be removed and against which definitive therapy is unlikely to eradicate the infection. Among immunocompromised hosts, suppressive therapy may eventually be discontinued if the patient's immune system reconstitutes (e.g., with a sustained elevation in an HIV-infected patient's CD4 count). Some patients in whom pathogen eradication may be achieved may still be candidates for ongoing antibiotic use in the form of secondary prophylaxis if they are at high risk for a new infection. Risks of toxicity from prolonged use of suppressive therapy and secondary prophylaxis can be significant, and assessment for potential discontinuation should be performed regularly.

The Pharmacokinetic Basis of Antimicrobial Therapy

Typically, a pathogen causes disease not in the whole body but in specific organs. Within an infected organ, only specific pathological compartments may be infected. Antibiotics are often administered orally or parenterally, far away from these sites of infection. Therefore, in choosing

an antimicrobial agent for therapy, a crucial consideration is whether the drug can penetrate to the site of infection. For example, the antibiotic *levofloxacin* achieves a ratio of peak concentrations in the skin tissue to plasma (C_{Pmax} ratio) of 1.4, a ratio of epithelial lining fluid (ELF) to plasma of 2.8, and a urine to plasma ratio of 67 (Chow et al., 2002; Conte et al., 2006; Wagenlehner et al., 2006). The two most important factors in predicting successful clinical and microbiological outcomes using *levofloxacin* are the site of infection and achieving a C_{Pmax} level of 12 times the MIC (C_{Pmax}/MIC ≥12). The failure rate of therapy is 0% in patients with urinary tract infections, 3% in patients with pulmonary infections, and 16% in patients with skin and soft-tissue infections (Preston et al., 1998). Clearly, the poorer the penetration into the anatomical compartment, the higher is the likelihood of failure.

The penetration of a drug into an anatomical compartment depends on the *physical barriers* that the molecule must traverse, the *chemical properties of the drug*, and the *presence of multidrug transporters*. Chapters 2 (pharmacokinetics) and 4 (membrane transporters) provide excellent discussions of these concepts. A unique consideration for drug penetration in treatment of infections is the presence of microorganism-produced *biofilms*. Examples of biofilms include endocardial vegetations on heart valves in endocarditis; biofilms formed by bacteria and fungi on prosthetic devices such as artificial heart valves, long-dwelling intravascular catheters, and artificial hips; and the biofilms formed within the lungs of patients suffering from cystic fibrosis. Bacterial and fungal biofilms are colonies of slowly growing cells enclosed within an exopolymer matrix. The exopolysaccharide is negatively charged and can bind positively charged antibiotics and restrict their access to the intended target. To be effective against infections in these compartments, antibiotics must penetrate the biofilm and endothelial barriers (Sun et al., 2013).

Impact of Susceptibility Testing on Success of Antimicrobial Agents

The microbiology laboratory plays a central role in the decision to choose a particular antibiotic agent over others. First, identification and isolation of the culprit organism take place when patient specimens are sent to the microbiology laboratory. Once the microbial species causing the disease has been identified, a more rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to identify what antibiotics the organism isolated from that sample is susceptible to, allowing for definitive therapy.

Millions of individuals across the globe become infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each may have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may undergo further evolution between the time of infection and the time of diagnosis. Therefore, one observes a distribution of concentrations of antimicrobial agents that can kill the pathogens. Often, this distribution is Gaussian, with a skew that depends on local susceptibility patterns.

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is modeled using the standard Hill-type curve for receptor and agonist (see Chapters 2 and 3), characterized by three parameters:

- IC_{50} (also termed EC_{50}), the inhibitory concentration that is 50% effective, a measure of the antimicrobial agent's potency
- E_{max}, a measure of the maximal effect
- H, the slope of the curve, or Hill factor

With changes in susceptibility, the sigmoid E_{max} curve shifts in one of two basic ways. The first is a shift to the right, an increase in IC_{50} (Figure 56–2A), meaning that much higher concentrations of antimicrobials than before are now needed to show specific effect. *Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect.* The change in IC_{50} may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now "resistant" to the particular antibiotic.

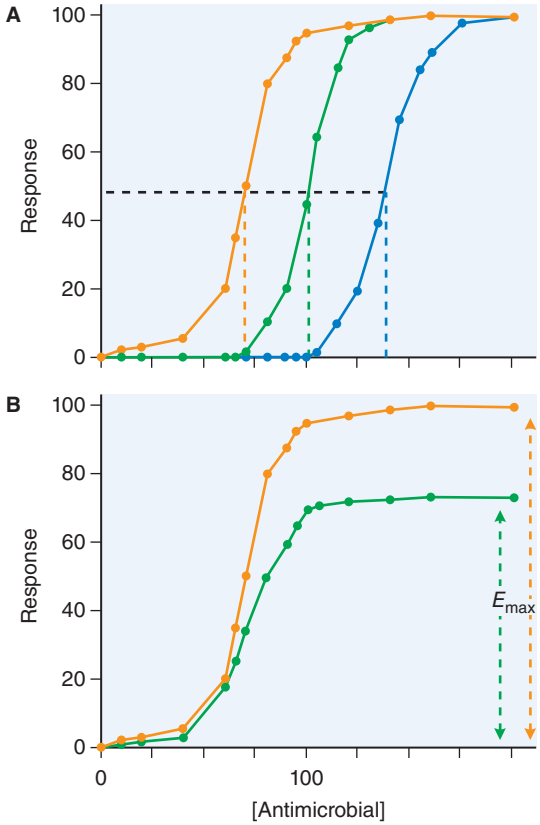

Figure 56–2 *Changes in sigmoid E_{max} model with increases in drug resistance.* An increase in resistance may show changes in IC_{50}: In **A**, the IC_{50} increases from 70 (orange line) to 100 (green line) to 140 (blue line). An increase in resistance may also show a decrease in E_{max}: In **B**, efficacy decreases from full response (orange line) to 70% (green line).

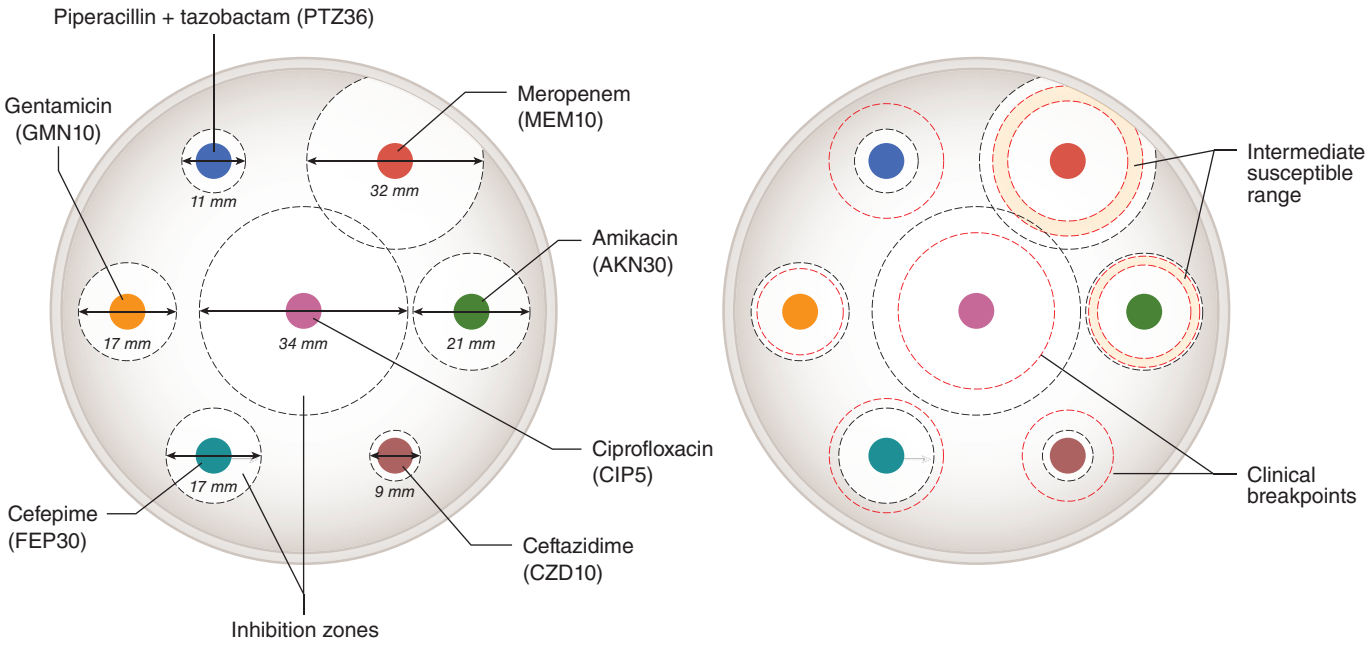
A second possible change in the curve is decrease in E_{max} (Figure 56–2B), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; that is, changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the microbe has developed an alternative pathway to overcome the biochemical inhibition. For example, *maraviroc* is an allosteric, noncompetitive antagonist that binds to the CCR5 receptor of a patient's CD4 cells to deny HIV entry into the cell. Viral resistance occurs by a mechanism that involves HIV adapting to use of the *maraviroc*-bound CCR5, which results in a decrease of E_{max} in phenotypic susceptibility assays (Hirsch et al., 2008).

Bacteria

For bacteria, *diffusion tests* use antimicrobial-impregnated disks placed on a solid growth medium upon which the bacterium of interest has been plated and allowed to incubate for 12 to 24 h (Figure 56–3A). The size of the zone of inhibition (area without bacterial growth) around each disk is given a categorical interpretation of susceptible, intermediate, or resistant. These interpretations are based on consensus *breakpoints* that have been established that relate the size of the zone of inhibition to the predicted clinical utility of the drug. In contrast, *dilution tests* employ antibiotics in serially diluted concentrations in a liquid broth medium that contains a culture of the test microorganism (Figure 56–3B).



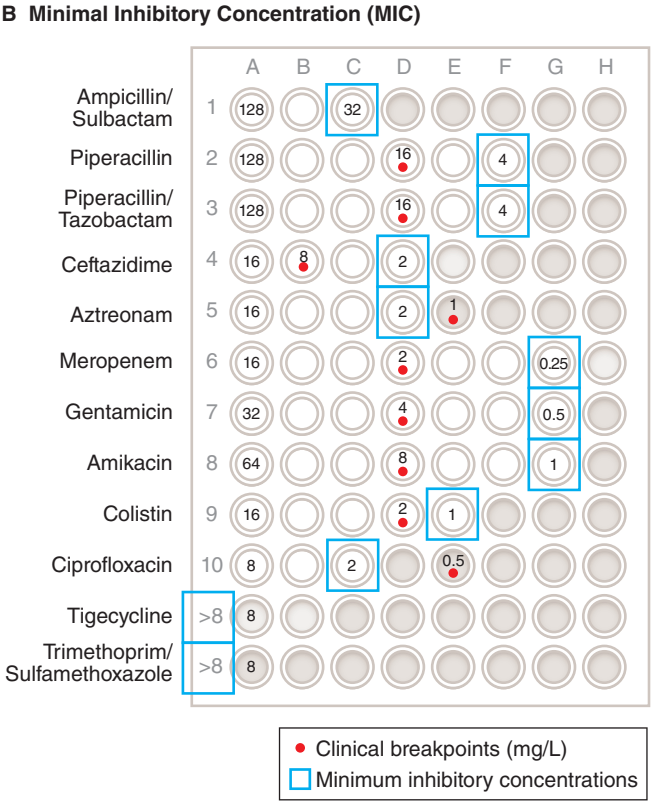


Figure 56–3 *Antibiotic susceptibility testing methods.* Once a bacterium is isolated from a clinical sample and grown in culture, it is incubated with antibiotics to determine if those drugs inhibit its growth. In **A**, *disk diffusion* testing is used. A solid agar plate is covered with a lawn of bacteria, and antibiotic-impregnated disks are placed on it. The area around the bacteria without visible growth is the zone of inhibition and used to determine susceptibility. In **B**, *dilution* testing is used. A sample of the bacterium is added to microtiter plates containing variable concentrations of antibiotics of interest. After incubation, the wells with the lowest concentration of an agent that has prevented visible growth are considered to represent the *minimum inhibitory concentration* (MIC) for the drug-organism pair. If the MIC is less than the clinical breakpoint, the isolate is considered to be susceptible to that antibiotic.

The lowest concentration of the agent that prevents visible growth after 18 to 24 h of incubation is the MIC, which is typically measured in doubling concentrations. In clinical laboratories, dilution tests are performed on commercial platforms that automate many of the steps in preparation, incubation, and interpretation. Interpretations are made by comparing the MIC obtained for each drug to the consensus breakpoints established for that drug-organism pair. When the MIC measured for an isolate is at or below the breakpoint for that drug-organism pair, the isolate is considered to be susceptible to that drug.

Recently, nucleic acid amplification–based reactions of specific bacterial genes have been used in the clinic for rapid diagnosis of drug resistance. The genes targeted are those encoding known drug resistance proteins or processes. For example, *rifampin* resistance in *M. tuberculosis* has been difficult to ascertain in a timely fashion: The bacteria take 2 to 3 weeks to grow in order to identify them as a cause of disease, and then a similar amount of time is needed to perform some version of the broth dilution tests. Small PCR reactors at points of care can purify and concentrate a patient's fluid sample, perform nucleic acid amplification of a target gene, identify mutations, and provide a result in less than 2 h. Similarly, PCR-based rapid identification of the *mecA* gene responsible for *methicillin* resistance in *S. aureus* in clinical or surveillance samples is frequently employed for infection control and clinical care in hospitals.

Fungi

For fungi that are yeasts (i.e., *Candida*), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ based on drug and the type of yeast, so there are cutoff points of 50% decrease in turbidity compared to controls at 24 h, 80% at 48 h, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles (e.g., *fluconazole*) have been extensively shown to correlate with clinical outcomes. Standardized tests for echinocandin antifungals and *amphotericin B*–based compounds are also available.

Susceptibility tests for molds have been developed, especially for *Aspergillus* species. Different terminology is required when evaluating echinocandins against molds because the fungal burden cannot be readily measured, given that hyphae will break up into unpredictable numbers of discrete fungi when under antifungal pressure. Furthermore, echinocandins often do not completely inhibit mold growth, but instead cause damage reflected by morphological changes in hyphae. Thus, the *minimum effective concentration* (MEC) for echinocandins is the lowest drug concentration at which short, stubby, and highly branched hyphae are observed on microscopic examination.

Viruses

In HIV phenotypic assays, the patient's HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks analogous gene sequences to produce a recombinant virus, which is coincubated with a drug of interest in a mammalian cell viability assay (Hanna and D'Aquila, 2001; Petropoulos et al., 2000). Growth is compared to a standardized wild-type control virus. Phenotypic assays are laborious and time-consuming, and genotypic testing is more commonly employed. These tests aim to detect the presence of mutations that are predicted to result in reduced phenotypic susceptibility. Where they are accessible, genotypic assays are a standard of care for HIV management and are also used to detect resistance-associated mutations in pathogens such as CMV.

Parasites

Susceptibility testing for parasites, especially those that cause malaria, has been performed in the laboratory. *Plasmodium* species in the patient's blood are cultured *ex vivo* in the presence of different dilutions of antimalarial drug. A sigmoid E_{max} curve for effect versus drug concentration is used to identify IC_{50} and E_{max}. These susceptibility tests are usually field tests at sentinel sites that are used to determine if there is drug resistance in a particular area. In general, susceptibility tests for parasitic infections are not standardized. These tests are primarily used in the research setting and not for individualization of therapy.

Basis for Selection of Dose and Dosing Schedule

Although susceptibility testing in the laboratory is central to decision making, it does not completely predict patient response. In susceptibility tests, the drug concentration is constant; by contrast, in patients, the drug concentration is dynamic and ever changing. Antibiotics are prescribed at a certain schedule (e.g., three times a day) so that there is a periodicity in the fluctuations of drug at the site of infection, and the microbe is exposed to a particular shape of the concentration-time curve. Harry Eagle performed studies on *penicillin* and discovered that the shape of the concentration-time profile was an important determinant of the efficacy of the antibiotic. This important observation was forgotten until William Craig and colleagues rediscovered it and performed systematic studies on several classes of antibiotics, initiating the era of antimicrobial PK/PD (Ambrose et al., 2007; Craig, 2007). These findings have now been extended to combination therapy and to microbes that require long treatment durations, such as *M. tuberculosis* and HIV.

As an example, consider an antibiotic with a serum $t_{1/2}$ of 3 h that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L; the antibiotic is administered with a dosing interval of 24 h (that is, a once-daily schedule). Figure 56–4A depicts the concentration-time curve of the antibiotic, with definitions of C_{Pmax}, AUC, and the fraction of the dosing interval for which the drug concentration remains above the MIC (T > MIC), as shown. The AUC is a measure of the total

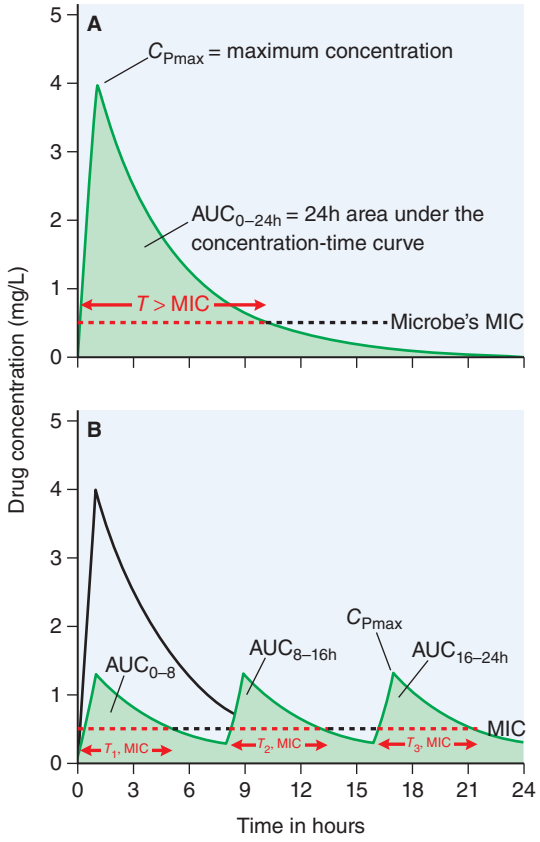

Figure 56–4 *Effect of different dose schedules on shape of the concentration-time curve.* The same total dose of a drug was administered as a single dose (panel **A**) and in three equal portions every 8 h (panel **B**). The total AUC for the fractionated dose in **B** is determined by adding $AUC_{0–8h}$, $AUC_{8–16h}$, and $AUC_{16–24h}$, which totals to the same $AUC_{0–24h}$ in **A**. The time that the drug concentration exceeds MIC in **B** is also determined by adding T_1 > MIC, T_2 > MIC, and T_3 > MIC, which results in a fraction greater than that for **A**.

concentration of drug and is calculated by taking an integral between two time points, 0 to 24 h ($AUC_{0–24}$) in this case.

Now, if one were to change the dosing schedule of the same antibiotic amount by splitting it into three equal doses administered at 0, 8, and 16 h, the shape of the concentration-time curve changes to that shown in Figure 56–4B. Because the same cumulative dose has been given for the dosing interval of 24 h, the $AUC_{0–24}$ will be similar whether it was given once a day or three times a day. For the same pathogen, therefore, the change in dose schedule does not change the $AUC_{0–24}$/MIC. However, the C_{Pmax} will decrease by a third when the total dose is split into thirds and administered more frequently (Figure 56–4B). Thus, when a dose is fractionated and administered more frequently, the C_{Pmax}/MIC ratio *decreases*. In contrast, the time that the drug concentration persists above MIC (T > MIC) will *increase* with the more frequent dosing schedule, despite the same cumulative dose being administered.

Some classes of antimicrobial agents exert greater antimicrobial effects when their concentration persists above the MIC for longer durations of the dosing interval. Indeed, increasing the drug concentration beyond four to six times the MIC does not increase microbial kill for such antibiotics. Two good examples are β-lactam antibacterials (e.g., *penicillin*) and the antifungal agent 5-fluorocytosine (Ambrose et al., 2007; Andes and van Ogtrop, 2000). There are usually biochemical explanations for this pattern; the clinical implication, however, is that a drug optimized by T > MIC should be dosed more frequently; given as a prolonged, instead of rapid, infusion; or have its $t_{1/2}$ prolonged by other drugs (as with the coadministration of *probenecid* with *penicillin*), so that drug concentrations persist above MIC (or EC_{95}) as long as possible. Thus, the effectiveness of *penicillin* is enhanced when it is given as a continuous infusion. Some antibiotics, such as *ceftriaxone* ($t_{1/2}$ = 8 h), have long half-lives, such that infrequent dosing still allows maintenance of an adequate T > MIC. HIV protease inhibitors are often "boosted" with *ritonavir* or *cobicistat*. This "boosting" inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above EC_{95}.

Conversely, the peak concentration is most predictive of efficacy for other antimicrobial agents. Persistence of concentration above the MIC has less relevance for these drugs—described as having "time-independent killing," meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class; aminoglycosides are highly effective when given once a day at sufficient dosage, despite their short half-lives. These C_{Pmax}/MIC–linked drugs can often be administered less frequently due to their long duration of PAE (post antibiotic effect), with effectiveness continuing long after antibiotic concentrations decline below the MIC.

Rifampin is such another such drug (Gumbo et al., 2007a). The entry of *rifampin* into *M. tuberculosis* increases with increased concentration in the bacillus microenvironment, likely because of a saturable transport process. Once inside the bacteria, the drug's macrocyclic ring binds the β subunit of DNA-dependent RNA polymerase (*rpoB*) to form a stable drug-enzyme complex within 10 min, a process not enhanced by longer incubation of drug and enzyme and only slowly reversed. The PAE of the *rifampin* is long and concentration dependent (Gumbo et al., 2007a).

There is a third group of *drugs for which it is the cumulative dose that matters most and for which the daily dosing schedule has no effect on efficacy*. Thus, it is the ratio of the total concentration (AUC) to MIC that is most predictive of effect and not the time that concentration persists above a certain threshold. Antibacterial agents such as *daptomycin* fall into this class (Louie et al., 2001). These agents also have a long PAE.

The shape of the concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure required for resistance suppression is much higher than that for optimal kill. Ideally, this higher exposure should be achieved by each dose for optimal effect, rather than the EC_{80}, as discussed previously. However, this is often precluded by drug toxicity at higher dosages. Second, although the relationship between kill and exposure is based on the inhibitory sigmoid E_{max} model, experimental work with preclinical models demonstrated that this model does not apply to resistance suppression (Gumbo et al., 2007b; Tam et al., 2007).

Mechanisms of Resistance to Antimicrobial Agents

Antibiotics were viewed as miracle cures when first introduced into clinical practice. However, as became evident soon after the discovery of *penicillin*, resistance eventually develops and dims the luster of the miracle. Today, every major class of antibiotic is associated with the emergence of significant resistance. When a microbial species is subjected to an existential threat, chemical or otherwise, that pressure will select for random mutations in the species' genome that permit survival. This evolution is greatly assisted by poor therapeutic practices by healthcare workers and the indiscriminant use of antibiotics in agriculture and animal husbandry.

Antimicrobial resistance can develop at any one or more of steps in the processes by which a drug reaches and combines with its target. Major mechanisms of antibiotic resistance include:

- Reduced concentration of the antibiotic at its target site
- Production of microbial enzymes that alter or destroy the antibiotic
- Alteration of antibiotic targets in ways that reduce antibiotic affinity

A host of less-common mechanisms have been discovered as well, including bypass of inhibited metabolic pathways, excision of antibiotic-target complexes, and overproduction of target enzymes. Organisms may also express resistance elements that interfere with the immune response; this can result in an effect similar to antibiotic resistance, as antibiotics typically work in concert with the immune system to clear infections (Sun et al., 2021). More than one mechanism may work in concert to confer resistance to an individual antibiotic.

Resistance Due to Reduced Concentration of Drug at Its Target Site

The outer membrane of gram-negative bacteria is a semipermeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called *porins*. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance.

Once an antibiotic crosses the cell membrane, its concentration may be reduced below the effective concentration through the action of *efflux pumps*, energy-dependent transporters that expel antibiotics to which the microbes would otherwise be susceptible. There are five major systems of efflux pumps that are relevant to antimicrobial agents:

- The multidrug and toxin extruder
- The major facilitator superfamily transporters
- The small multidrug resistance system
- The resistance nodulation division exporters
- ABC transporters

Resistance due to reduced concentrations of drug at the site of infection is a prominent mechanism of resistance for parasites, bacteria, and fungi, and can function selectively or broadly. For example, in *Pseudomonas aeruginosa*, resistance to the antipseudomonal carbapenem *imipenem* is significantly mediated through mutational loss of the OprD porin, the primary means by which *imipenem* crosses the outer membrane (Fernandez and Hancock, 2012). In contrast, *meropenem* is only minimally affected by isolated loss of OprD, but its activity is significantly reduced by upregulation of efflux pump activity, such as that of the MexA-MexB-OprM system. Upregulation of these efflux systems has less impact on *imipenem* but tends to raise MICs for a broader array of antibiotics including cephalosporins and aminoglycosides.

Resistance Due to Alteration or Destruction of Antibiotic

Drug inactivation is a common mechanism of drug resistance. The most prominent example is the enzymatic inactivation of β-lactam antibiotics through the function of β-lactamase enzymes (Bush, 2018). Over a thousand distinct β-lactamases have been identified, some of which can confer resistance to nearly all β-lactams. In some cases, β-lactamase-mediated resistance can be averted by coadministration of β-lactamase inhibitors (e.g., *clavulanate*, *avibactam*). Other examples of enzymatic inactivation leading to resistance include production of aminoglycoside-modifying enzymes and esterification of macrolides.

Resistance Due to Altered Target Structure

A common consequence of either single or multiple point mutations is a change in amino acid composition and conformation of an antimicrobial's target protein. This change can lead to reduced affinity of drug for its target or of a prodrug for the enzyme that activates the prodrug. Such alterations may be due to mutation of the natural target (e.g., fluoroquinolone resistance), enzyme-mediated target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., staphylococcal *methicillin* resistance caused by production of a low-affinity penicillin-binding protein) (Hooper, 2002; Lim and Strynadka, 2002; Nakajima, 1999). In HIV resistance, mutations associated with reduced affinity are encountered for protease inhibitors, integrase inhibitors, fusion inhibitors, and nonnucleoside reverse transcriptase inhibitors (Nijhuis et al., 2009). Similarly, benzimidazoles are used against myriad worms and protozoa and work by binding to the parasite's tubulin; point mutations in the β-tubulin gene lead to modification of the tubulin and drug resistance (Ouellette, 2001).

Heteroresistance and Viral Quasi-Species

Heteroresistance occurs when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing (Falagas et al., 2008; Rinder, 2001). A subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates (occurrence in 1 in 10^6 to 10^5 colonies). In bacteria, heteroresistance has been described especially for *vancomycin* in *S. aureus* and *Enterococcus faecium*; *colistin* in *Acinetobacter baumannii-calcoaceticus*; *rifampin*, *isoniazid*, and *streptomycin* in *M. tuberculosis*; and *penicillin* in *S. pneumoniae* (Falagas et al., 2008; Rinder, 2001). Increased therapeutic failures and mortality have been reported in patients with heteroresistant staphylococci and *M. tuberculosis* (Falagas et al., 2008; Hofmann-Thiel et al., 2009). For fungi, heteroresistance leading to clinical failure has been described for *fluconazole* in *Cryptococcus neoformans* and *Candida albicans* (Marr et al., 2001; Mondon et al., 1999).

Viral replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi-species that may contain drug-resistant subpopulations. This is often not termed heteroresistance, but the principle is the same: A virus may be considered susceptible to a drug because either phenotypic or genotypic tests reveal "lack" of resistance, even though there is a resistant subpopulation just below the limit of assay detection. These minority quasi-species that are resistant to antiretroviral agents have been associated with failure of antiretroviral therapy (Metzner et al., 2009).

EVOLUTIONARY BASIS OF RESISTANCE EMERGENCE

Development of Resistance via Mutation Selection

Genetic mechanisms by which antibiotic resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction. Mutations are random events that confer a survival advantage when drug is present. Mutation and antibiotic selection of resistant mutants are the molecular basis for resistance for many bacteria, viruses, and fungi. Mutations may occur in:

- A gene encoding the target protein, altering its structure so that it no longer binds the drug
- A gene encoding a protein involved in drug transport
- A gene encoding a protein important for drug activation or inactivation
- A regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme

In some instances, a single-step mutation results in a high degree of resistance. In *M. tuberculosis katG,* Ser315 mutations cause resistance to *isoniazid*; the M814V mutation in the reverse transcriptase gene of HIV-1 causes resistance to *lamivudine*; and *C. albicans fks1* Ser645 mutations cause resistance to echinocandins.

In other circumstances, however, it is the sequential acquisition of multiple mutations that leads to clinically significant resistance. For example, the combination of *pyrimethamine* (an inhibitor of DHFR) and *sulfadoxine* (an inhibitor of DHPS) blocks the folate biosynthetic pathway in *P. falciparum*. Clinically meaningful resistance occurs only when there is a single-point mutation in the *DHPS* gene accompanied by at least a double mutation in the *DHFR* gene.

Resistance by External Acquisition of Genetic Elements

As noted above, drug resistance may be acquired by mutation and selection, with passage of the trait *vertically* to daughter cells, provided the mutation is not lethal, does not appreciably alter virulence, and does not affect replication by the progeny. Drug resistance may also be acquired by *horizontal transfer* of resistance determinants from a donor cell, often of another bacterial species, by *transduction, transformation,* or *conjugation*. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes. The gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells, and the resistance gene can be eliminated when it no longer offers a selective advantage. Horizontal transfer of resistance genes is greatly facilitated by mobile genetic elements. Mobile genetic elements include plasmids and transducing phages. Other mobile elements—*transposable elements, integrons,* and *gene cassettes*—also participate. *Transposable elements* are of three general types: *insertion sequences, transposons,* and *transposable phages*.

Resistance Transfer in Action

A startling example of how the transfer mechanisms spread resistance is the recent description of the plasmid-mediated colistin resistance gene (*mcr-1*), which confers resistance to one of the last-resort antibiotics for multidrug-resistant gram-negative bacteria (Liu et al., 2016). *Colistin* is used in agriculture and animal husbandry. *Escherichia coli* strains carrying the *mcr-1* gene were found in pigs, then in pork, and then in patients. The plasmid carrying *mcr-1* was mobilized by conjugation to *E. coli* at a frequency of 10^{-1} to 10^{-3} cells per recipient and could be spread and maintained in other gram-negative rods of clinical significance. The resistant bacteria were initially identified in China, but within months, isolates were also identified in North America, South America, Europe, East Asia, and Africa and in other organisms, such as *Salmonella typhimurium*. The gene has now been demonstrated in gut microbiota of healthy individuals, suggesting integration in the human gut and the capacity to spread to organisms in the human microbiome.

Chapter 57

DNA Disruptors: Sulfonamides, Quinolones, and Nitroimidazoles

Conan MacDougall

Sulfonamides

HISTORICAL PERSPECTIVE

The sulfonamide drugs were the first effective chemotherapeutic agents used systemically for the prevention and cure of bacterial infections in humans. Investigations in 1932 at the I. G. Farbenindustrie in Germany resulted in the patenting of *prontosil* and several other azo dyes containing a sulfonamide group. Because synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal and other infections could be protected by *prontosil*. In 1933, Foerster reported giving *prontosil* to a 10-month-old infant with staphylococcal septicemia and achieving a dramatic cure. Favorable clinical results with *prontosil* and its active metabolite, *sulfanilamide*, in puerperal sepsis and meningococcal infections awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The development of the carbonic anhydrase inhibitor–type diuretics and the sulfonylurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of *prontosil*, Domagk was awarded the Nobel Prize in Medicine for 1938 (Lesch, 2007). The advent of *penicillin* and other antibiotics diminished the usefulness of the sulfonamides, but the introduction of the combination of *trimethoprim* (TMP) and *sulfamethoxazole* (SMX) in the 1970s increased the use of sulfonamides for the prophylaxis and treatment of infections.

Sulfonamides are derivatives of *para*-aminobenzenesulfonamide (*sulfanilamide*; Figure 57–1) and are congeners of *para*-aminobenzoic acid (PABA). Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in *sulfanilamide* itself. The sulfur must be linked directly to the benzene ring. The *para*-NH_2 group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted *in vivo* to a free amino group. Substitutions made in the amide NH_2 group (position N1) have variable effects on antibacterial activity of the molecule; substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds. The sulfone agent *dapsone* is discussed in Chapter 65.

Mechanism of Action

Sulfonamides are competitive inhibitors of *dihydropteroate synthase*, the bacterial enzyme responsible for the incorporation of PABA into *dihydropteroic acid*, the immediate precursor of *folic acid* (Figure 57–2). Sensitive microorganisms are those that must synthesize their own folic acid; those that can use preformed folate are not affected. Sulfonamides administered as single agents are typically *bacteriostatic*; cellular and humoral defense mechanisms of the host are essential for final eradication of the infection. Toxicity is selective for nonmammalian cells because mammalian cells require preformed folic acid, cannot synthesize it, and are thus insensitive to drugs acting by this mechanism (Grayson, 2010).

Synergists of Sulfonamides

Trimethoprim (TMP) exerts a synergistic effect with sulfonamides. It is a potent and selective competitive inhibitor of microbial *dihydrofolate reductase*, the enzyme that reduces *dihydrofolate* to *tetrahydrofolate*, which is required for one-carbon transfer reactions. Coadministration of a sulfonamide and TMP (e.g., trimethoprim-sulfamethoxazole [TMP-SMX]) introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate (see Figure 57–2); the combination is much more effective than either agent alone (Bushby and Hitchings, 1968). Similar complementary activity is seen with *pyrimethamine*, which is generally used in combination with agents such as *sulfadoxine*, *sulfadiazine*, or *dapsone*. The predominant systemic use of sulfonamides is now in such combinations.

Antimicrobial Activity

On their original introduction to therapeutic use, sulfonamides had a wide range of antimicrobial activity against both gram-positive and

SMX: sulfamethoxazole
UTI: urinary tract infection

gram-negative bacteria; a high percentage of isolates of *Streptococcus pyogenes*, *Streptococcus pneumoniae, Staphylococcus aureus*, and *Haemophilus influenzae* were susceptible to systemically achievable concentrations of sulfonamides. However, the increase in sulfonamide resistance is such that sulfonamide activity against these pathogens in serious infections cannot be assumed, and they play little part in empiric therapy (Grayson, 2010). Potent activity remains against most isolates of *Haemophilus ducreyi, Nocardia* spp., and *Klebsiella granulomatis*. Isolates of *Neisseria meningitidis* and *Shigella* are generally resistant, as are many strains of *Escherichia coli* isolated from patients with urinary tract infections (UTIs) (Olson et al., 2009). Sulfonamides and derivatives also possess important activity against parasites and fungi, and those applications are further discussed in Chapters 61, 65, and 66.

Bacterial Resistance

Bacterial resistance to sulfonamides can originate by random mutation and selection or by transfer of resistance by plasmids; it usually does not involve cross-resistance to other classes of antibiotics except to the extent that other resistance elements may be carried on mobile elements such as plasmids. Resistance to folate antagonists can result from (1) a lower affinity of dihydropteroate synthase for sulfonamides, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) increased production of an essential metabolite or drug antagonist (e.g., PABA) (Estrada et al., 2016). Plasmid-mediated resistance is due to plasmid-encoded, drug-resistant dihydropteroate synthetase.

ADME

Except for sulfonamides especially designed for their local effects in the bowel (see Chapter 55), this class of drugs is absorbed rapidly from the gastrointestinal (GI) tract. Typically, 70% to 100% of an oral dose is absorbed and can be found in the urine within 30 min of ingestion. Peak plasma levels are achieved in 2 to 6 h, depending on the drug. Peak plasma drug concentrations achievable *in vivo* are about 100 to 200 μg/mL. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. Sulfonamides are distributed throughout all tissues of the body. The sulfonamides readily enter pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50% to 80% of the simultaneously determined concentration in blood. Because the protein content of body fluids usually is low, the drug is present in the unbound active form. After systemic administration of adequate doses, *sulfadiazine* and *sulfisoxazole* attain concentrations in cerebrospinal fluid (CSF) that may be effective in meningitis. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis. Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues may cause both antibacterial and toxic effects.

Sulfonamides are metabolized in the liver. The major metabolite is the N4-acetylated sulfonamide. Acetylation results in products that have no antibacterial activity but retain the toxic potential of the parent substance. Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the $t_{1/2}$ depends on renal function. In acid urine, the older sulfonamides are insoluble, and crystalline deposits may form. Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

Sulfonamides for Systemic Use

Sulfisoxazole. *Sulfisoxazole* is a rapidly absorbed and excreted sulfonamide. It is bound extensively to plasma proteins. Following an oral dose of 2 to 4 g, peak concentrations in plasma of 110 to 250 μg/mL are found

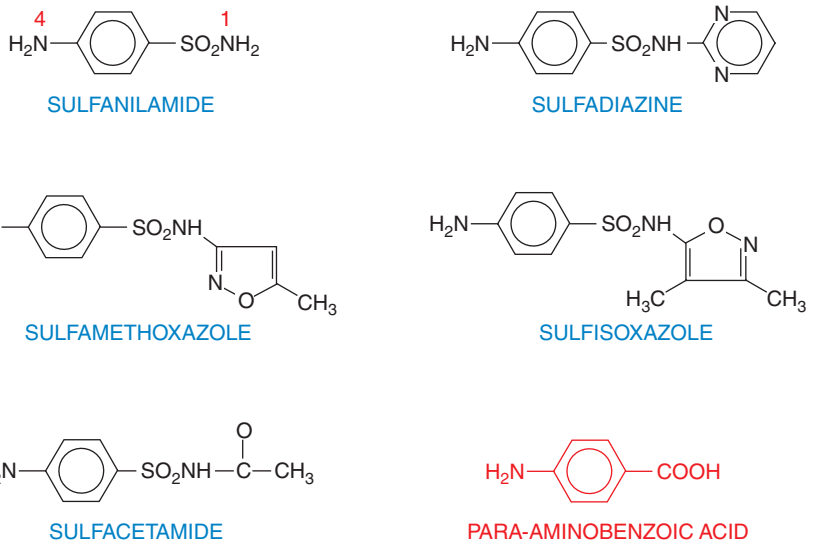

Figure 57–1 *Sulfanilamide and PABA.* Sulfonamides are derivatives of *sulfanilamide* and act by virtue of being congeners of PABA. The antimicrobial and dermatological anti-inflammatory agent *dapsone* (4,4′-diaminodiphenyl sulfone; see Chapters 65 and 75) also bears a resemblance to PABA and *sulfanilamide*.

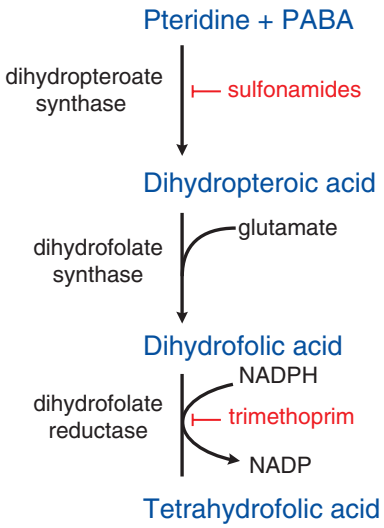

Figure 57–2 *Steps in folate metabolism blocked by sulfonamides and trimethoprim.* Coadministration of a sulfonamide and *trimethoprim* introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate; the combination is much more effective than either agent alone.

in 2 to 4 h. Approximately 30% of *sulfisoxazole* in the blood and about 30% in the urine is in the acetylated form. The kidney excretes about 95% of a single dose in 24 h. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. *Sulfisoxazole acetyl* is tasteless and hence preferred for oral use in children. *Sulfisoxazole acetyl* in combination with *erythromycin ethylsuccinate* is used in children with otitis media.

Sulfamethoxazole. *Sulfamethoxazole* is a close congener of *sulfisoxazole*, but its rates of enteric absorption and urinary excretion are slower ($t_{1/2}$ of 11 h). It is administered orally and employed for both systemic infections and UTIs. Precautions must be observed to avoid *sulfamethoxazole*-induced crystalluria because of the high percentage of the acetylated, relatively insoluble form of the drug in the urine. The clinical uses of *sulfamethoxazole* as a single agent are the same as those for *sulfisoxazole*. In the U.S., it is marketed only in fixed-dose combinations with TMP (discussed further in the following section Trimethoprim-Sulfamethoxazole).

Sulfadiazine. *Sulfadiazine* given orally is absorbed rapidly from the GI tract. Peak blood concentrations are reached within 3 to 6 h, with a $t_{1/2}$ of 10 h. About 55% of the drug is bound to plasma protein. Therapeutic concentrations are attained in CSF within 4 h of a single oral dose of 60 mg/kg. Both free and acetylated forms of *sulfadiazine* are readily excreted by the kidney; 15% to 40% of the excreted drug is in acetylated form. Alkalinization of the urine accelerates the renal clearance of both forms by diminishing their tubular reabsorption. Precaution must be taken to ensure fluid intake adequate to produce a daily urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

Sulfadoxine. This agent has a particularly long plasma $t_{1/2}$ of 7 to 9 days. Although no longer marketed in the U.S., its combination with *pyrimethamine* (500 mg *sulfadoxine* plus 25 mg *pyrimethamine*) is listed as a World Health Organization essential medicine and is used for the prophylaxis and treatment of malaria caused by *mefloquine*-resistant strains of *Plasmodium falciparum* (see Chapter 66). However, because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, and the emergence of resistant strains, the drug has limited usefulness for the treatment of malaria.

Sulfonamides for Topical Use

Sulfacetamide is the N1-acetyl-substituted derivative of *sulfanilamide*. Its aqueous solubility is about 90 times that of *sulfadiazine*. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to *sulfacetamide* are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. See Chapters 74 and 75 for ocular and dermatological uses. *Silver sulfadiazine* and *mafenide* are sulfonamides used topically, primarily in the prevention of infection in burn patients. These agents are covered in Chapter 75.

Therapeutic Uses

Use of sulfonamides as single agents for treatment of systemic infections has become uncommon. Because a significant percentage of UTIs are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice; TMP-SMX is preferred (although resistance to this agent is increasing as well). *Sulfisoxazole* may be used effectively for cystitis in areas where the prevalence of resistance is not high. The usual dosage is 2 to 4 g initially, followed by 1 to 2 g orally four times a day for 5 to 10 days. TMP-SMX is most commonly used for infections due to *Nocardia* spp., but *sulfisoxazole* and *sulfadiazine* are alternative agents, given in dosages of 6 to 8 g daily. For serious infections, addition of a second agent, such as *imipenem*, *amikacin*, or *linezolid*, is recommended. The combination of *pyrimethamine* and *sulfadiazine* is the treatment of choice for toxoplasmosis (see Chapter 67). *Pyrimethamine* is given as a loading dose of 2000 mg followed by 50 to 75 mg orally per day, with *sulfadiazine* 1 to 1.5 g orally every 6 h, plus folinic acid (*leucovorin*) 10 to 25 mg orally each day for at least 6 weeks (Panel on Opportunistic Infections, 2020). Patients should receive at least 2 L of fluid intake daily to prevent crystalluria.

Adverse Reactions

Hypersensitivity Reactions

Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatinal, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet syndrome, exfoliative dermatitis, and photosensitivity (Khan et al., 2019). Sulfonamide metabolites are hypothesized to be primarily responsible for dermatologic hypersensitivity reactions. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. Patients living with human immunodeficiency virus (HIV) infection manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. Patients who have allergic reactions are often advised to avoid other agents with sulfa moieties; however, only those with a sulfonamide (SO_2NH_2) moiety carry a risk of cross-allergenicity. Further, data suggest most patients who have a reaction to an antimicrobial sulfonamide can tolerate a non-antimicrobial agent with a sulfonamide moiety (e.g., *furosemide*), although avoidance may be preferred for severe reactions.

Disturbances of the Urinary Tract

Crystalluria has occurred in dehydrated patients with HIV who were receiving *sulfadiazine* for *Toxoplasma* encephalitis. Crystalluria can be prevented by maintaining daily urine volume of at least 1200 mL (in adults) or, if necessary, urine alkalinization because the solubility of *sulfadiazine* increases with elevations of pH.

Miscellaneous Reactions

Anorexia, nausea, and vomiting occur in 1% to 2% of persons receiving sulfonamides. Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in less than 0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3 to 5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow

atrophy and death. Aplastic anemia involving complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. Reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with acquired immunodeficiency syndrome [AIDS] or those receiving myelosuppressive chemotherapy). The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin, potentially causing an encephalopathy called *kernicterus*. Sulfonamides should not be given to pregnant women near term because these drugs cross the placenta and are secreted in milk.

Drug Interactions

Drug interactions of the sulfonamides are seen mainly with *warfarin*, the sulfonylurea hypoglycemic agents, and the hydantoin anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by inhibiting its metabolism or by displacing it from albumin. Frequent monitoring and dosage adjustment may be necessary when a sulfonamide is given concurrently.

Trimethoprim-Sulfamethoxazole

TMP inhibits bacterial dihydrofolate reductase (DHFR), an enzyme downstream from the one that sulfonamides inhibit in the same biosynthetic sequence (see Figure 57–2). The combination of TMP with *sulfamethoxazole* (SMX) was an important advance in the development of clinically effective and synergistic antimicrobial agents. In much of the world, the combination of TMP with SMX is known as *cotrimoxazole*. In addition to its combination with SMX, TMP is available in some countries as a single-entity preparation.

Mechanism of Action

The antimicrobial activity of the combination of TMP-SMX results from actions on sequential steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid (see Figure 57–2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate) in both bacteria and mammalian cells. However, TMP is a highly selective inhibitor of the DHFR of lower organisms relative to that of mammals: About 100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. The most effective ratio of SMX to TMP across the greatest number of microorganisms is 20:1. The combination is thus formulated to achieve an SMX concentration *in vivo* that is 20 times greater than that of TMP; SMX has pharmacokinetic properties such that the concentrations of the two drugs will thus be relatively constant in the body over a long period. Although each agent alone usually exerts bacteriostatic activity, when the organism is sensitive to both agents, bactericidal activity may be achieved.

Antimicrobial Activity

The antibacterial spectrum of TMP is similar to that of SMX, although TMP is 20 to 100 times more potent.

Spectrum of TMP-SMX in Combination

Although most *S. pneumoniae* are susceptible to TMP-SMX, there has been a disturbing increase in resistance (paralleling the rise in *penicillin* resistance), and its value as empiric therapy for many respiratory tract infections is questionable. The vast majority (>90%) of strains of *S. aureus* remain susceptible, even among *methicillin*-resistant isolates, although geographic variation exists. Activity against *Staphylococcus epidermidis* is more variable. *S. pyogenes* is usually sensitive when proper testing procedures (media with low thymidine content) are followed (Bowen et al., 2012). The *viridans* group of streptococci is typically susceptible, although susceptibility among *penicillin*-resistant strains is low (Diekema et al., 2001). Susceptibility in *E. coli* varies significantly by geographic region, although it has been declining in general, and in many places, TMP-SMX is no longer considered adequate empiric therapy. *Proteus mirabilis, Klebsiella* spp., *Enterobacter* spp., *Salmonella, Shigella, Pseudomonas pseudomallei, Serratia* spp., *Stenotrophomonas maltophila*, and *Alcaligenes* spp. are typically susceptible. Also usually susceptible are *Brucella abortus, Pasteurella haemolytica, Yersinia pseudotuberculosis, Yersinia enterocolitica*, and *Nocardia asteroides*. *Pseudomonas aeruginosa, Bacteroides fragilis*, and enterococci are clinically resistant.

Bacterial Resistance

Bacterial resistance to TMP-SMX has eroded the efficacy of this agent, especially among pneumococci and *E. coli*, although resistance to the combination is lower than it is to either of the agents alone. In addition to the resistance mechanisms to sulfonamides described above, resistance specific to TMP may develop. Resistance is typically due either to point mutations in genes encoding for DHFR or to the acquisition of a plasmid that codes for an altered DHFR (Estrada et al., 2016), both of which are associated with reduced binding of TMP.

ADME

The pharmacokinetic profiles of SMX and TMP are closely, but not perfectly, matched to achieve a near-constant ratio of 20:1 in their concentrations in blood and tissues over the course of their distribution and elimination. After a single oral dose of the combined preparation, TMP is absorbed more rapidly than SMX. Peak blood concentrations of TMP usually occur by 2 h in most patients, whereas peak concentrations of SMX occur by 4 h after a single oral dose. The half-lives of TMP and SMX are 11 and 10 h, respectively.

When 800 mg SMX is given with 160 mg TMP (one "double-strength" tablet; "single-strength" is 400 mg to 80 mg, maintaining the same ratio) twice daily, the peak concentrations of the drugs in plasma are about 40 and 2 μg/mL. Peak concentrations are similar (46 and 3.4 μg/mL) after intravenous infusion of 800 mg SMX and 160 mg TMP over a period of 1 h.

TMP is distributed and concentrated rapidly in tissues; about 40% is bound to plasma protein in the presence of SMX. The volume of distribution of TMP is almost nine times that of SMX. The drug readily enters CSF and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of SMX is bound to plasma protein. About 60% of administered TMP and from 25% to 50% of administered SMX are excreted in the urine in 24 h. Two-thirds of the sulfonamide is unconjugated. Metabolites of TMP also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

Therapeutic Uses

Urinary Tract Infections

Treatment of UTIs with TMP-SMX is highly effective for sensitive bacteria. Use for empiric therapy of UTIs is complicated by the increase in resistance among *E. coli*; guidelines recommend avoiding empiric use for UTIs when local resistance among *E. coli* exceeds 20% or if patients have recently received TMP-SMX (Gupta et al., 2011). Most treatment guidelines recommend 160/800 mg administered twice daily for 3 days for uncomplicated cystitis and for 10 to 14 days for complicated disease or pyelonephritis. TMP also is found in therapeutic concentrations in prostatic secretions, and TMP-SMX is a common treatment for acute or chronic bacterial prostatitis.

Bacterial Respiratory Tract Infections

TMP-SMX is effective for outpatients with mild acute exacerbations of chronic bronchitis. TMP-SMX should not be used to treat streptococcal pharyngitis because it does not eradicate the microorganism from the pharynx. It is effective for acute otitis media in children and acute maxillary sinusitis in adults that are caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

GI Infections

The combination is an alternative to a fluoroquinolone for treatment of shigellosis, but increasing resistance limits its use unless susceptibility

is confirmed. TMP and TMP-SMX are no longer recommended for prevention or treatment of traveler's diarrhea because of increasing resistance worldwide among likely pathogens.

Infection by Pneumocystis jirovecii

High-dose therapy (TMP 15–20 mg/kg per day plus SMX 75–100 mg/kg per day in three or four divided doses; typical maximum dose is 20 mg/kg per day of TMP) is effective for *Pneumocystis jirovecii* pneumonia (Panel on Opportunistic Infections, 2020). Adjunctive corticosteroids should be given at the onset of anti-*Pneumocystis* therapy in patients with a Po_2 less than 70 mmHg or an alveolar-arterial gradient less than 35 mmHg. Prophylaxis with TMP-SMX using a variety of dosing strategies (from daily to several times weekly) is effective in preventing pneumonia caused by this organism in patients with HIV as well as among patients with other immunocompromising conditions (e.g., neutropenia and solid-organ transplantation). Adverse reactions are less frequent with the lower prophylactic doses of TMP-SMX.

Methicillin-Resistant Staphylococcus aureus Infections

The increasing incidence of community-acquired infections due to *methicillin*-resistant *S. aureus* has provided a role for TMP-SMX as an adjunctive therapy to incision and drainage of complicated abscesses. However, it is less effective than standard therapy in the treatment of invasive *methicillin*-resistant *S. aureus* infections, including bacteremia (Paul et al., 2015).

Miscellaneous Infections

Nocardia infections have been treated successfully with the combination, but failures also have been reported. Although a combination of *doxycycline* and *streptomycin* or *gentamicin* is now considered the treatment of choice for brucellosis, TMP-SMX may be an effective substitute for the *doxycycline* combination. TMP-SMX also has been used successfully for infection by *Stenotrophomonas maltophilia* and infection by the intestinal parasites *Cyclospora* and *Isospora*. TMP-SMX is used as prophylaxis against infection due to *Toxoplasma gondii* in HIV-infected individuals and is an alternative for treatment of toxoplasmosis (see Chapter 67).

Adverse Effects

TMP-SMX extends the toxicity of the sulfonamides. Hematological reactions include various anemias, coagulation disorders, granulocytopenia, agranulocytosis, purpura, Henoch-Schönlein purpura, and sulfhemoglobinemia. TMP-SMX reportedly causes up to three times as many dermatological reactions as does *sulfisoxazole* (5.9% vs. 1.7%). Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. Permanent impairment of renal function may follow the use of TMP-SMX in patients with renal disease due to SMX crystalluria; liberal fluid intake should be encouraged to dilute the urine during therapy. An increase in serum creatinine without decrement in glomerular filtration rate may be observed with high-dose therapy due to TMP's inhibition of creatinine secretion. Hyperkalemia can also be observed, as TMP has a similar structure to potassium-sparing diuretics such as *triamterene*. Patients with HIV frequently have hypersensitivity reactions to TMP-SMX (rash, neutropenia, Stevens-Johnson syndrome, Sweet syndrome, and pulmonary infiltrates). Both rapid and slow desensitization protocols have been established for patients intolerant to medically necessary therapy (Khan et al., 2019).

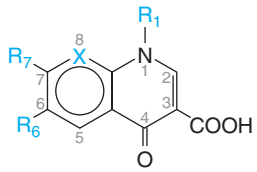
Drug Interactions

As with the sulfonamides alone, co-administration of TMP-SMX with *warfarin* can inhibit *warfarin* metabolism and lead to excessive anticoagulation with risks for bleeding. Caution is warranted with coadministration of agents that can increase potassium or suppress bone marrow when combined with high-dose TMP-SMX. Administration of TMP-SMX should be avoided in patients receiving high doses of *methotrexate* for treatment of malignancies, as TMP-SMX can increase *methotrexate* concentrations and lead to serious toxicity.

The Quinolones

The first quinolone, *nalidixic acid*, was isolated as a by-product of the synthesis of chloroquine and made available for the treatment of UTIs. The introduction of fluorinated 4-quinolones (fluoroquinolones), such as *norfloxacin*, *ciprofloxacin*, and *levofloxacin* (Table 57–1), represents a particularly important therapeutic advance. These agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases. However, due to potentially fatal side effects, many quinolones had to be withdrawn from the U.S. market: *lomefloxacin* and *sparfloxacin* (phototoxicity, QTc prolongation); *gatifloxacin* (systemic forms only: hypoglycemia); *temafloxacin* (immune hemolytic anemia); *trovafloxacin* (hepatotoxicity); *grepafloxacin* (cardiotoxicity); and *clinafloxacin* (phototoxicity). In all cases, the side effects were discovered during postmarketing surveillance (Sheehan and Chew, 2003). The FDA has issued new warnings for fluoroquinolones still being marketed, calling attention to their toxicities and recommending against their routine use in uncomplicated infections (Food and Drug Administration, 2018).

TABLE 57–1 ■ STRUCTURAL FORMULAS OF SELECTED QUINOLONES AND FLUOROQUINOLONES



CONGENER	R_1	R_6	R_7	X
Nalidixic acid	$-C_2H_5$	–H	$-CH_3$	–N–
Norfloxacin	$-C_2H_5$	–F		–CH–
Ciprofloxacin		–F		–CH–
Levofloxacin		–F		

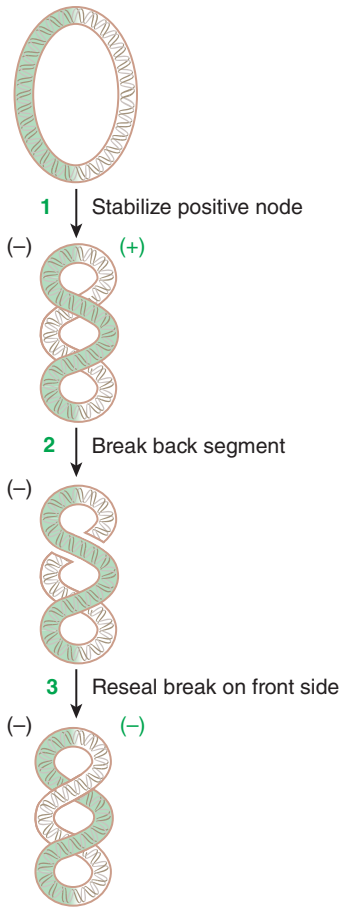


Figure 57–3 *Model of the formation of negative DNA supercoils by DNA gyrase.* DNA gyrase binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV.

Mechanism of Action

The quinolone antibiotics target bacterial *DNA gyrase* and *topoisomerase IV* (Mohammed et al., 2019). For many gram-positive bacteria, topoisomerase IV, which separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication, is the primary target. In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes. The gyrase introduces negative supercoils into the DNA to combat excessive positive supercoiling that can occur during DNA replication (Figure 57–3) (Cozzarelli, 1980). The quinolones, as a drug-metal complex, inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1–10 μg/mL).

Eukaryotic cells do not contain DNA gyrase. They do contain a mechanistically similar type II DNA topoisomerase, but quinolones inhibit it only at concentrations (100–1000 μg/mL) much higher than those needed to inhibit the bacterial enzymes.

Antimicrobial Activity

The fluoroquinolones were potent, bactericidal agents against most gram-negative pathogens when first introduced, including *Proteus, E. coli, Klebsiella,* and various species of *Salmonella, Shigella, Enterobacter,* and *Campylobacter*. As with TMP-SMX, resistance has continuously eroded the coverage that fluoroquinolones provide, especially among *E. coli* and *Proteus* spp., such that fluoroquinolones may not be reliable for empiric therapy due to the prevalence of these organisms in some regions (Olson et al., 2009). While once a standard therapy for *Neisseria gonorrhoeae* infections, resistance has increased to the point these agents are no longer recommended in most countries for empiric therapy of gonorrhea (Centers for Disease Control and Prevention, 2021). *Ciprofloxacin* and *levofloxacin* have sufficient activity against *Pseudomonas* spp. for use in systemic infections; a newly introduced agent, *delafloxacin*, also possesses *in vitro* activity, but to date, few patients with *Pseudomonas* infections have been treated with this agent. Fluoroquinolones have good *in vitro* activity against staphylococci, but they are less active against *methicillin*-resistant strains, and there is concern over development of resistance during therapy. Activity against streptococci is significantly greater with the newer agents, including *levofloxacin*, *gemifloxacin*, *moxifloxacin*, and *delafloxacin*. Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia, Mycoplasma, Legionella, Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*). *Ciprofloxacin*, *ofloxacin*, *levofloxacin*, and *moxifloxacin* have activity against *Mycobacterium fortuitum, Mycobacterium kansasii*, and *M. tuberculosis*. *Moxifloxacin* also has useful activity against intestinal anaerobes, such as *Bacteroides fragilis*.

Bacterial Resistance

Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV, leading to reduced binding affinity for the fluoroquinolones (Correia et al., 2017). Chromosomal mutations leading to upregulation of efflux pump–mediated active transport of the drug out of the bacteria or the reduction in expression of porin channels allowing quinolones to transit the outer membrane also contribute to resistance. Less commonly, plasmids can transfer genes that encode proteins capable of binding to and protecting the topoisomerases from quinolone effects or that directly modify the quinolone itself. Resistance emerging during the course of therapy can occur, especially in *E. coli*, *Pseudomonas*, and staphylococci.

ADME

Most quinolones are well absorbed after oral administration. Peak serum levels of the fluoroquinolones are obtained within 1 to 3 h of an oral dose. The volume of distribution of quinolones is high, with concentrations in urine, kidney, lung, and prostate tissue and stool, bile, and macrophages and neutrophils higher than serum levels. Food may delay the time to peak serum concentrations. Many fluoroquinolones have been detected in human breast milk; because of their excellent bioavailability, the potential exists for substantial exposure of nursing infants. Except for *moxifloxacin*, quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure.

Pharmacological Properties of Individual Quinolones

Norfloxacin

The gram-negative activity of *norfloxacin* (not available in the United States) is similar to, but somewhat less potent than, that of *ciprofloxacin*. However, the relatively low serum levels reached with *norfloxacin* limit its usefulness in the treatment of UTIs and gastrointestinal infections. The serum $t_{1/2}$ is 3 to 5 h for *norfloxacin*; approximately 25% of the drug is eliminated unchanged in the urine, with hepatic metabolism also occurring.

Ciprofloxacin

Ciprofloxacin's bioavailability is approximately 70%. Typical oral doses are 250 to 750 mg and intravenous doses are 200 to 400 mg twice daily (maximum dose 1.5 g/day orally). The elimination $t_{1/2}$ is about 5 h,

and the drug is typically dosed twice daily, with the exception of an extended-release formulation, which can be dosed once daily.

Ofloxacin/Levofloxacin

Ofloxacin has somewhat more potent gram-positive activity than *ciprofloxacin*; separation of the more active S- or levorotatory isomer yields *levofloxacin*, which has even better antistreptococcal activity. Bioavailability of both of these agents is excellent, such that intravenous and oral doses are the same; *levofloxacin* is dosed once daily (250–750 mg) as opposed to twice-daily dosing for *ofloxacin* (200–400 mg daily divided every 12 h).

Moxifloxacin

Moxifloxacin improves further on the gram-positive potency of *levofloxacin*, typically having minimal inhibitory concentrations one to two dilutions lower against *S. pneumoniae*. It also has expanded activity against anaerobic pathogens but is substantially less active than *ciprofloxacin* or *levofloxacin* against *P. aeruginosa*. *Moxifloxacin* is well absorbed, with equivalent intravenous and oral doses; the $t_{1/2}$ is about 12 h, allowing for daily dosing (usual dose 400 mg daily). *Moxifloxacin* undergoes hepatic sulfation and glucuronidation. Less than a quarter of systemic *moxifloxacin* is excreted unchanged via the kidneys, and because high concentrations are not achieved in the urine, it is not recommended for UTIs.

Gatifloxacin, Gemifloxacin

The agents *gatifloxacin* and *gemifloxacin* have a similar spectrum of activity to *moxifloxacin*, with enhanced potency against gram-positive organisms and poor activity versus *Pseudomonas*. They are less active than *moxifloxacin* against *B. fragilis*. Both have high bioavailability and renal elimination. *Gatifloxacin* is no longer available for systemic use in the U.S. due to toxicity concerns, but an ophthalmic preparation is licensed for the treatment of bacterial conjunctivitis.

Delafloxacin

Delafloxacin is a newly approved fluoroquinolone with potent activity against staphylococci; minimal inhibitory concentrations are at least 6-fold lower than *levofloxacin* for most isolates of *S. aureus*. Activity against gram-negatives, including *Pseudomonas*, is similar to that of *levofloxacin*. It is available for intravenous and oral administration and undergoes mixed renal and nonrenal elimination.

Therapeutic Uses

Urinary Tract Infections

The fluoroquinolones are a mainstay of treatment of upper and lower UTIs, being more efficacious than TMP-SMX or oral β-lactams. Because of their broad spectrum of activity and adverse effects, however, recent guidelines suggest reserving their use for complicated cystitis or pyelonephritis when possible (Gupta et al., 2011). *Moxifloxacin* does not accumulate in the urine and is not approved for treatment of UTIs. Typical treatment durations for quinolones are 3 days for uncomplicated cystitis and 5 to 7 days for uncomplicated pyelonephritis.

Prostatitis

Norfloxacin, *ciprofloxacin*, *ofloxacin*, and *levofloxacin* achieve good levels in prostatic secretions and are effective in the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4 to 6 weeks appear to be effective in patients not responding to TMP-SMX.

Sexually Transmitted Diseases

Fluoroquinolones lack activity for *Treponema pallidum* but have activity *in vitro* against *Chlamydia trachomatis* and *H. ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of *ofloxacin* or *levofloxacin* is an alternative to a 7-day treatment with *doxycycline* or a single dose of *azithromycin*; other available quinolones have not been reliably effective. Previously, a single oral dose of a fluoroquinolone such as *ciprofloxacin* had been effective treatment of sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to *ceftriaxone* being the first-line agent for this infection. A study of *delafloxacin* for single-dose therapy failed to meet its endpoint for efficacy. Chancroid (infection by *H. ducreyi*) can be treated with 3 days of *ciprofloxacin*.

GI and Abdominal Infections

Norfloxacin, *ciprofloxacin*, *ofloxacin*, and *levofloxacin* given for 1 to 3 days all have been effective in the treatment of patients with traveler's diarrhea, reducing the duration of loose stools by 1 to 3 days. *Ciprofloxacin* in a single daily dose has been used for prophylaxis of traveler's diarrhea, but resistance among *Campylobacter* and *Shigella* and increasing recognition of fluoroquinolone adverse effects have led to authorities discouraging this use. *Ciprofloxacin* and *ofloxacin* can cure most patients with enteric fever caused by *Salmonella typhi*, as well as bacteremic nontyphoidal infections in patients with HIV, and clear chronic fecal carriage. Quinolones should be avoided in the treatment of diarrhea due to Shiga toxin–producing *E. coli*. *Ciprofloxacin* and *levofloxacin*, when combined with *metronidazole*, or *moxifloxacin* alone, may be useful in the management of intra-abdominal infections if local susceptibilities allow.

Respiratory Tract Infections

Many newer fluoroquinolones, including *levofloxacin*, *moxifloxacin*, *gemifloxacin*, and *delafloxacin*, have excellent activity against *S. pneumoniae, H. influenzae,* and the atypical respiratory pathogens. Thus, these agents are frequently used in the management of community-acquired pneumonia. *Ciprofloxacin* and *levofloxacin* also play a role in the treatment of respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis and in combination with a β-lactam agent to provide broad gram-negative coverage for nosocomial pneumonia in patients at high risk for resistant isolates.

Bone, Joint, and Soft-Tissue Infections

The treatment of chronic osteomyelitis may require prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* or gram-negative rods. Failures are often associated with the development of resistance, particularly in *S. aureus*. Combination therapy with a fluoroquinolone and *rifampin* is an option for the management of early-onset prosthetic joint infections. *Levofloxacin*, *moxifloxacin*, and *delafloxacin* are approved for the treatment of skin and soft-tissue infections; although, they should generally be reserved for situations where their expanded spectrum of activity can be leveraged, such as diabetic foot infections.

Other Infections

Ciprofloxacin and *levofloxacin* are used for the prophylaxis of anthrax and are effective for the treatment of tularemia and plague due to *Yersinia pestis* (Hendricks et al., 2014). *Levofloxacin* and *moxifloxacin* may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and atypical mycobacterial infections as well as *Mycobacterium avium* complex infections in AIDS (see Chapter 65). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (Freifeld et al., 2011).

Adverse Effects

Gastrointestinal Adverse Effects

Common adverse reactions involve the GI tract, with 3% to 17% of patients reporting mild nausea, vomiting, and abdominal discomfort. Fluoroquinolones have emerged as a leading cause of *Clostridium difficile* colitis due to the spread of quinolone-resistant strains.

Neurologic Adverse Effects

Common side effects (1%–11%) involving the CNS include mild headaches, dizziness, insomnia, and anxiety. Rarely, hallucinations, delirium, and seizures have occurred, especially in patients who were also receiving *theophylline* or nonsteroidal anti-inflammatory drugs. Patients with

a history of epilepsy are at higher risk for fluoroquinolone-induced convulsions. Recently, the fluoroquinolones have been recognized as rare causes of peripheral neuropathy and possibly optic neuritis, which in some cases has been irreversible.

Musculoskeletal Adverse Effects

Arthralgias and joint pain are occasionally reported with fluoroquinolones. Tendon rupture or tendinitis (usually of the Achilles tendon) is a recognized serious adverse effect, especially in those more than 60 years old, in patients taking corticosteroids, and in solid-organ transplant recipients. Early animal studies suggested an increased risk of cartilage damage and malformation among young animals (Burkhardt et al., 1997). While arthralgias and joint pain during therapy are more common among children receiving quinolones relative to comparators during the course of therapy, studies have not noted long-term joint abnormalities or growth inhibition among children exposed to fluoroquinolones. The American Academy of Pediatrics suggests that fluoroquinolone use in children is appropriate when limited treatment options exist or when oral administration offers a significant risk/benefit advantage (Jackson and Schutze, 2016). Similarly, limited data suggest that fluoroquinolone use may be appropriate in pregnant women in the absence of alternative therapies.

Other Adverse Effects

Among the quinolones available in the U.S., *moxifloxacin* carries the highest risk for QT interval prolongation and torsades de pointes arrhythmias; *gemifloxacin*, *levofloxacin*, and *ofloxacin* appear to have lower risk; and *ciprofloxacin* has the lowest risk. However, the overall risk of torsades de pointes is small with the use of fluoroquinolones. *Gatifloxacin*'s propensity to cause both hypo- and hyperglycemia, especially in older adults, led to its removal for systemic use in the U.S. (Park-Wyllie et al., 2006). Other agents such as *levofloxacin* may rarely be associated with dysglycemias among at-risk patients. Rashes, including photosensitivity reactions, also can occur; patients with frequent sun exposure should be advised to protect themselves with clothing or sunscreen.

Drug Interactions

All quinolones form complexes with divalent and trivalent cations (e.g., calcium, iron, aluminum). When coadministered orally with quinolones, these cations can chelate the quinolone and reduce systemic bioavailability. Thus, a separation of at least 2 h between oral administration of quinolones and these cations is recommended. *Ciprofloxacin* inhibits the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur. Nonsteroidal anti-inflammatory drugs may augment displacement of γ-aminobutyric acid (GABA) from its receptors by the quinolones, enhancing neurological adverse effects (Halliwell et al., 1993). Due to risk for QT prolongation, quinolones should be used with caution in patients on class III (*amiodarone*) and class IA (*quinidine*, *procainamide*) antiarrhythmics.

Nitroimidazoles

Metronidazole and *tinidazole* are nitroimidazoles with activity against anaerobic bacteria and parasites. Here, we will discuss the antibacterial activity of *metronidazole*; an in-depth discussion of *metronidazole* and *tinidazole*, including their pharmacokinetics, adverse effects, and antiparasitic uses, will be reserved for Chapter 67; applications for treatment of *Helicobacter pylori* disease are discussed in Chapter 53 and for inflammatory bowel disease in Chapter 55.

Metronidazole

Antibacterial Activity and Resistance

Metronidazole is essentially a prodrug: The nitro group of *metronidazole* is reduced in anaerobic bacteria, some microaerophilc bacteria, and protozoans, producing the active form of the drug. The activation leads to formation of reactive compounds that interact with DNA, possibly disrupting its structure and inhibiting replication (Dingsang and Hunter, 2018). *Metronidazole* displays excellent activity against most anaerobic bacteria, including *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*, and *Eubacterium*. It is less active against *Gardnerella* and *Helicobacter,* and the gram-positive anaerobes *Actinomyces, Propionibacterium*, and *Lactobacillus* are typically resistant. Acquired resistance among normally susceptible organisms is uncommon, and resistance mechanisms are complex and incompletely described. In the case of *Bacteroides* spp., *metronidazole* resistance has been linked to a family of nitroimidazole (*nim*) resistance genes, which can be encoded chromosomally or episomally. These *nim* genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing.

Therapeutic Uses and Dosage

Metronidazole is a relatively inexpensive agent with efficacy against a broad spectrum of anaerobic bacteria. Typical doses are 250 to 500 mg twice or three times daily, via the intravenous or oral routes. The drug is frequently given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. *Metronidazole* is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (see Chapter 53). *Metronidazole* has been used as therapy for nonsevere *C. difficile* infection, although *vancomycin* or *fidaxomicin* are now preferred agents. For patients with fulminant, life-threatening *C. difficile* infection, intravenous *metronidazole* is administered in combination with oral *vancomycin*.

Drug Facts for Your Personal Formulary: *DNA Disruptors: Sulfonamides, Quinolones, and Nitroimidazoles*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Sulfonamides: Competitive inhibitors of bacterial dihydropteroate synthase, thereby disrupting folate synthesis **General: Bacteriostatic; limited efficacy as monotherapy, renal elimination, hypersensitivity reactions**		
Sulfadiazine (PO)	• Toxoplasmosis (with pyrimethamine)	• Good activity against *T. gondii* • Reasonable CSF penetration • Higher risk of crystalluria, requires hydration
Sulfadoxine (PO)	• Prophylaxis and treatment of malaria (with pyrimethamine)	• Some activity vs. *P. falciparum* • Long $t_{1/2}$
Sulfonamide and Dihydrofolate Reductase Inhibitor Combination: Sequential inhibition of folate synthesis, often bactericidal		
Trimethoprim-sulfamethoxazole (IV, PO)	• UTI • Upper respiratory tract infections • Shigellosis • *P. jirovecii* pneumonia • Skin/soft-tissue infections due to *S. aureus* • Infections due to *Nocardia*, *S. maltophila*, *Cyclospora*, *Isospora*	• Excellent activity vs. *S. aureus*, *S. epidermidis*, *S. pyogenes* • Good activity vs. *Proteus*, *E. coli*, *Klebsiella*, *Enterobacter*, *Serratia*, *Nocardia*, *Brucella* • Some activity vs. *S. pneumoniae* • Formulated in 5:1 (SMX:TMP) ratio, giving 20:1 serum levels • Well absorbed on oral administration • Good penetration into CSF • Metabolized and renally eliminated • Hypersensitivity reactions (i.e., rash) common • Dose-related bone marrow suppression, hyperkalemia
Quinolones: Bactericidal inhibitors of bacterial gyrase and topoisomerase, prevent DNA unwinding **General: Drug interactions with cations, neurological adverse effects, tendonitis/tendon rupture, photosensitivity, QT prolongation; typically avoided in children and pregnant women except for compelling indications**		
Norfloxacin (PO)	• UTI, prostatitis • Traveler's diarrhea	• Good activity vs. *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, *Salmonella*, *Shigella* • Some activity vs. *Pseudomonas* • Effective concentrations only achieved in GI and urinary tracts
Ciprofloxacin (IV, PO)	• UTI, prostatitis • Traveler's diarrhea • Intra-abdominal infections (with metronidazole) • *Pseudomonas* infections • Anthrax, tularemia	• Excellent activity vs. *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, *Salmonella*, *Shigella* • Good activity vs. *Pseudomonas* • Some activity vs. *S. aureus*, streptococci • Good bioavailability and tissue distribution • Renal and nonrenal elimination
Levofloxacin (IV, PO)	• Respiratory tract infections • UTI, prostatitis • *Chlamydia* • Traveler's diarrhea • Intra-abdominal infections (with metronidazole) • *Pseudomonas* infections	• Excellent activity vs. *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, *Salmonella*, *Shigella*, streptococci, *H. influenzae*, *Legionella*, *Chlamydia* • Good activity vs. *Pseudomonas*, *S. aureus* • Good bioavailability and tissue distribution • Renal elimination • S-isomer of ofloxacin
Moxifloxacin (IV, PO)	• Respiratory tract infections • Intra-abdominal infections • Mycobacterial infections	• Excellent activity vs. *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, streptococci, *H. influenzae*, *Legionella*, *Chlamydia* • Good activity vs. *S. aureus*, *B. fragilis* • Good bioavailability and tissue distribution • Renal and nonrenal elimination; not for UTI • QT prolongation
Nitroimidazoles: Bactericidal DNA-damaging agents; require activation by reductases present in anaerobes		
Metronidazole (IV, PO, topical)	• *C. difficile* colitis • Empiric coverage of anaerobic organisms, as in intra-abdominal and skin and soft-tissue infections • *H. pylori* gastritis (in combination with other agents) • Bacterial vaginosis	• Bacterial spectrum limited to anaerobic organisms, including *B. fragilis* and *Clostridium* • Excellent absorption • Wide distribution including CNS • Hepatic elimination • Inhibitor of CYP enzymes; drug interactions with warfarin • Peripheral neuropathy with prolonged use

Chapter 58

Cell Envelope Disruptors: β-Lactam, Glycopeptide, and Lipopeptide Antibacterials

Conan MacDougall

The bacterial cellular envelope typically consists of the inner membrane, the cell wall, and, in gram-negative organisms, the outer membrane. The cell envelope is a key target for antibacterial agents, including the β-lactam antibiotics, glycopeptides, and lipopeptides, as well as other minor classes (including bacitracin, discussed below, and polymyxins, discussed in Chapter 59). β-Lactam antibiotics—penicillins, cephalosporins, carbapenems, and monobactams—share a common structure (β-lactam ring) and mechanism of action (i.e., inhibition of the synthesis of the bacterial peptidoglycan cell wall). β-Lactams are the single most important antibacterial class given their broad and varied spectrum of activity, their potent antibacterial killing, and their generally favorable tolerability. Unfortunately, resistance to β-lactams has steadily increased, requiring development of new agents, which can evade (e.g., *ceftaroline*) or neutralize (e.g., β-lactamase inhibitors) these mechanisms. The glycopeptides, including *vancomycin*, and lipopeptides (*daptomycin*) provide important treatment alternatives for infections due to gram-positive organisms.

β-Lactams: Mechanisms of Action

The bacterial cell wall is comprised of heteropolymeric peptidoglycan that provides rigid mechanical stability. The β-lactam antibiotics inhibit the last step in peptidoglycan synthesis. In gram-positive microorganisms, the cell wall is 50 to 100 molecules thick; in gram-negative bacteria, it is only one or two molecules thick (Figure 58–1A). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (*N*-acetylglucosamine and *N*-acetylmuramic acid), that are cross-linked by peptide chains. Peptidoglycan precursor formation takes place in the cytoplasm. The synthesis of UDP–acetylmuramyl-pentapeptide is completed with the addition of a dipeptide, D-alanyl-D-alanine, which is formed by racemization and condensation of L-alanine. UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked with the release of the uridine nucleotides to form a long polymer. The cross-link is completed by a transpeptidation reaction that occurs outside the plasma membrane (Figure 58–1B).

The β-lactam antibiotics inhibit this last step in peptidoglycan synthesis (Figure 58–2) by acylating the transpeptidase via cleavage of the –CO–N– bond of the β-lactam ring. The transpeptidase targets for the actions of β-lactam antibiotics are collectively termed penicillin-binding proteins (PBPs). Notably, bacteria may produce multiple functionally related but distinct PBPs, and each PBPs can have varying affinities for individual β-lactams. The lethality of penicillins for bacteria appears to involve both lytic and nonlytic mechanisms (Bayles, 2000), and inhibition of some PBPs may be more consequential than others for bacterial killing.

β-Lactams: Mechanisms of Bacterial Resistance

Bacterial resistance to β-lactam antibiotics typically occurs through one of three mechanisms: alterations in the PBP target, reduction of concentration at the target site, and/or enzymatic degradation of the β-lactam itself. A sensitive strain may acquire resistance via mutations that decrease the affinity of PBPs for the antibiotic or by acquiring the ability to express new, low-affinity PBPs (e.g., via plasmid transfer). Altered PBPs with decreased affinity for β-lactam antibiotics can also be acquired by homologous recombination between PBP genes of different bacterial species (Zapun et al., 2008). Four of the five high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β-lactam antibiotics as a result of interspecies homologous recombination events. In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins. *Methicillin*-resistant *Staphylococcus aureus* (MRSA) is resistant via acquisition of an additional high-molecular-weight PBP (via a transposon) with a very low affinity for all β-lactam antibiotics; this mechanism is also responsible for *methicillin* resistance in the coagulase-negative staphylococci. In general,

Abbreviations

ESBL: extended-spectrum β-lactamase
GI: gastrointestinal
KPC: *Klebsiella pneumoniae* carbapenemase
MIC: minimum inhibitory concentration
MRSA: methicillin-resistant *Staphylococcus aureus*
MRSE: methicillin-resistant *Staphylococcus epidermidis*
PBP: penicillin-binding protein

resistance via alterations to the β-lactam target is more common among gram-positive versus gram-negative bacterial pathogens.

Bacterial resistance to β-lactam antibiotics also results from the inability of the agent to achieve sufficient concentrations at its site of action (Fernández and Hancock, 2012). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (see Figure 58–1A), and small β-lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs. In gram-negative bacteria, the inner membrane is internal to the outer membrane and capsule (see Figure 58–1A); the outer membrane functions as an impenetrable barrier for some antibiotics. Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that are formed by proteins called *porins*. The number and size of pores in the outer membrane vary among different gram-negative bacteria, thereby providing greater or lesser access for antibiotics to the site of action. Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (Figure 58–3) (Fernández and Hancock, 2012).

Bacteria also can inactivate β-lactam antibiotics enzymatically via the action of β-lactamases (see Figure 58–1A). Thousands of different β-lactamases have been variously characterized by according to their molecular class or functional characteristics (Bush and Jacoby, 2010). Their substrate specificities can be relatively narrow or can extend to almost all β-lactams. In general, gram-positive bacteria produce and secrete a large amount of β-lactamase, typically narrow-spectrum penicillinases. The sequence for staphylococcal penicillinase is encoded in a plasmid; this may be transferred by bacteriophage to other bacteria and their expression is inducible by substrate antibiotics. In gram-negative bacteria, β-lactamases are found in lower quantities, but their location in the periplasmic space between the inner and outer membranes (see Figure 58–1A) provides maximal protection of the microbe. β-Lactamases of gram-negative bacteria are encoded either chromosomally or via transferable elements such as plasmids; their expression may be constitutive or inducible. Of particular concern are carbapenemases: β-lactamases that are capable of hydrolyzing carbapenems, as well as penicillins and cephalosporins. Microorganisms expressing such β-lactamases (along with other resistance mechanisms) may be resistant to all or almost all antibacterials in clinical use (Queenan and Bush, 2007).

More than one of the aforementioned resistance mechanisms may be present in a pathogen, and they can work in concert to confer resistance. The local environment can also contribute to resistance to β-lactam antibiotics. Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart

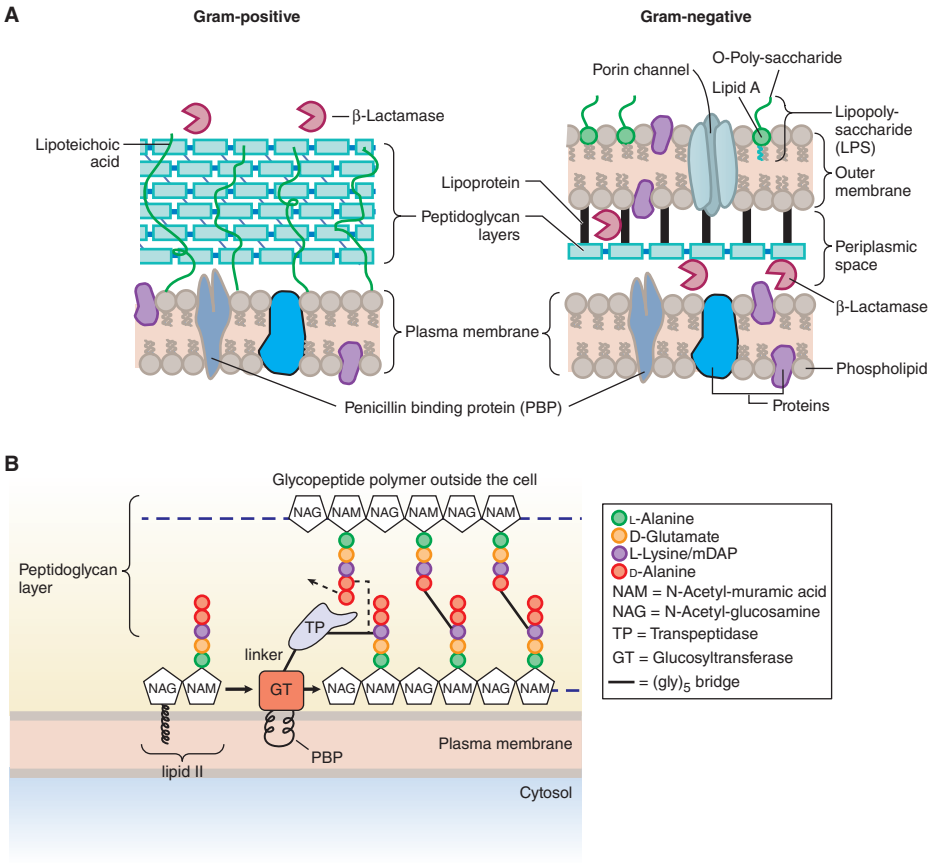

Figure 58–1 **A.** *Structure and composition of gram-positive and gram-negative cell envelope.* **B.** *Penicillin binding protein (PBP) activity and inhibition.* PBPs have two enzymatic activities that are crucial to synthesis of the peptidoglycan layers of bacterial cell walls: a transpeptidase that cross-links amino acid side chains, as shown for gram-positives, and a glycosyltransferase that links subunits of the glycopeptide polymer. The transpeptidase and glycosyltransferase domains are separated by a linker region. The glycosyltransferase is thought to be partially embedded in the membrane.

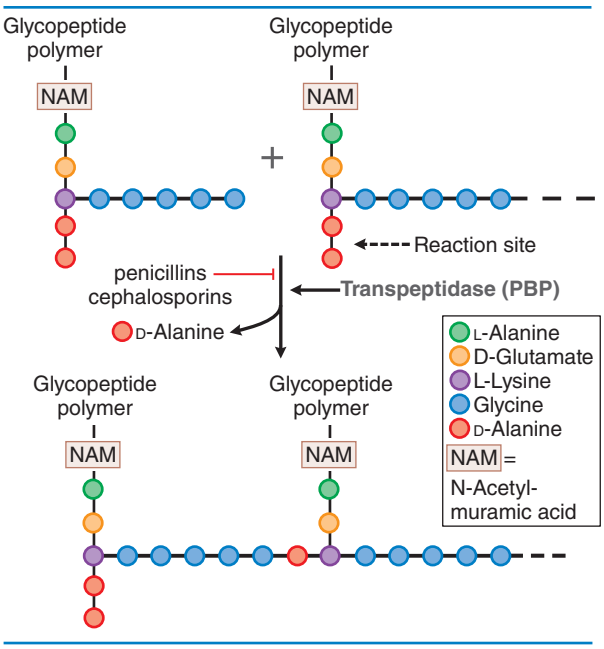

Figure 58–2 *Action of β-lactam antibiotics in S. aureus.* The bacterial cell wall consists of glycopeptide polymers (an NAM-NAG amino-hexose backbone) linked via bridges between amino acid side chains. In *S. aureus*, the bridge is $(Gly)_5$-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit.

valves) produce biofilms. Bacteria in biofilms secrete a protective extracellular matrix, which can consist of secreted exopolysaccharides, proteinaceous fibers, and DNA and, in part owing to decreased growth rates and drug penetrance, are much less sensitive to antibiotic therapy (Donlan, 2001). The β-lactam antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase. Similarly, bacteria that survive inside viable cells of the host generally are protected from the action of the β-lactam antibiotics, which limits the activity of these drugs against some important intracellular pathogens.

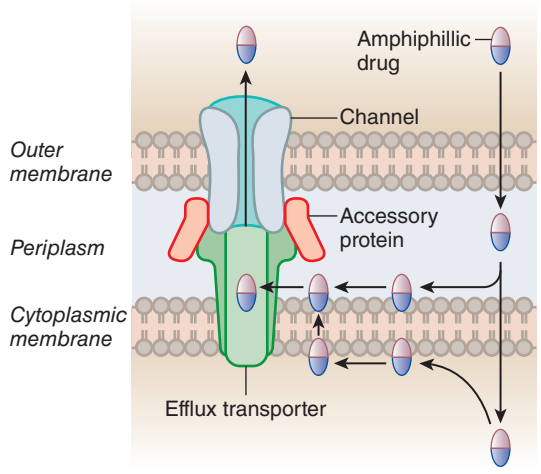

Figure 58–3 *Antibiotic efflux pumps of gram-negative bacteria.* Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of three proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. (Reprinted with permission from Oxford University Press. Nikaido H. Antibiotic resistance caused by gram-negative multidrug efflux pumps. *Clin Infect Dis*, **1998**, *27*(suppl 1): S32–S41. © 1998 by the Infectious Diseases Society of America. All rights reserved.)

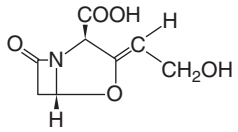
β-Lactamase Inhibitors

Because of the key role that β-lactamases play in conferring resistance to β-lactams, an increasing number of β-lactams are coformulated with molecules whose role is to "protect" the β-lactam from the β-lactamase. These β-lactamase inhibitors bind to β-lactamases and prevent the enzymes from hydrolyzing β-lactam agents in the vicinity. Older-generation β-lactamase inhibitors (e.g., *clavulanate*, *sulbactam*, and *tazobactam*) inactivate many plasmid-encoded β-lactamases but fail to provide protection at clinically achievable concentrations against the AmpC β-lactamases encoded chromosomally in some gram-negative bacilli (e.g., *Enterobacter*, *Citrobacter*, and *Pseudomonas*), as well as carbapenemases of the *Klebsiella pneumoniae* carbapenemase (KPC)- and metallo-β-lactamase type. *Avibactam*, *vaborbactam*, and *relebactam* are new β-lactamase inhibitors that are structurally dissimilar from the older generation, with a broader spectrum of inhibition.

Clavulanic acid has poor intrinsic antimicrobial activity but is an irreversible mechanism-based inhibitor that binds β-lactamases produced by a wide range of gram-positive and gram-negative microorganisms. *Clavulanic acid* is well absorbed by mouth and also can be given parenterally. It is combined with *amoxicillin* as an oral preparation and with *ticarcillin* as a parenteral preparation (*ticarcillin/clavulanate*, not available in the U.S.).



CLAVULANIC ACID

Sulbactam is a β-lactamase inhibitor similar in structure to *clavulanic acid*. It is available for intravenous or intramuscular use combined with *ampicillin* and with *cefoperazone* (not available in the U.S.). *Sulbactam* also possesses intrinsic activity against *Acinetobacter* spp. and has been used in high dosages to treat multidrug-resistant *Acinetobacter* infections.

Tazobactam is a β-lactamase inhibitor with good activity against many of the plasmid-mediated β-lactamases, including some of the extended-spectrum class. It is available as parenteral combination products with *piperacillin* and with *ceftolozane*.

Avibactam and ***relebactam*** are novel, structurally similar non–β-lactam β-lactamase inhibitors that provide clinically useful inhibition against both narrow- and extended-spectrum β-lactamase (ESBL)-type, chromosomal AmpC, and KPC-type β-lactamases (although not metallo-β-lactamases). *Avibactam* is coformulated with *ceftazidime*, while *relebactam* is coformulated with *imipenem/cilastatin*.

Vaborbactam is a novel, boronic acid–based non–β-lactam β-lactamase inhibitor that provides broad inhibition of β-lactamases similar to *avibactam* and *relebactam*. *Vaborbactam* is coformulated with *meropenem*.

The Penicillins

Despite the emergence of resistance, the penicillins remain the drugs of choice for a significant number of infectious diseases. Penicillins (Figure 58–4) consist of a thiazolidine ring (A) connected to a β-lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β-lactamases), improve affinity for PBPs, enhance the ability of the drug to traverse the outer membrane of gram-negative bacteria, and change the pharmacokinetic properties of the drug (Table 58–1).

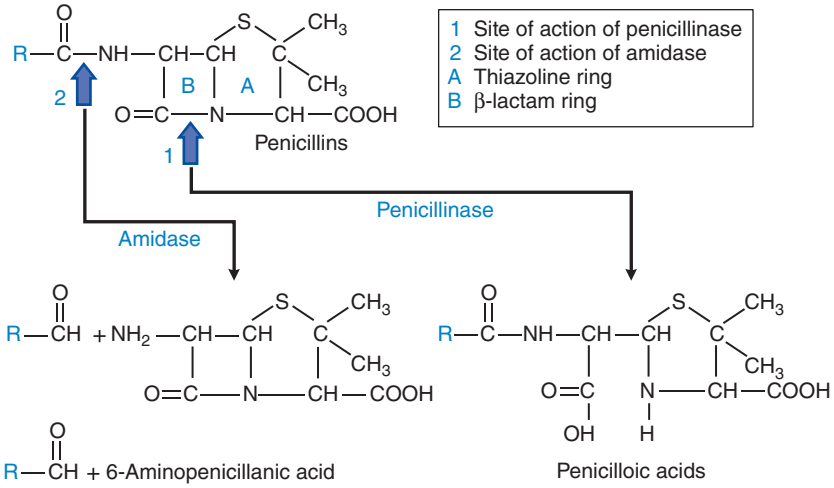


Figure 58–4 *Structure of penicillins and products of their enzymatic hydrolysis.*

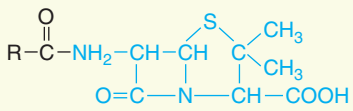
Classification of the Penicillins and Summary of Their Pharmacological Properties

Penicillins are classified according to their spectra of antimicrobial activity.

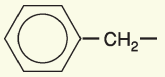
- ***Penicillin G*** and its close congener ***penicillin V*** are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinases. Thus, they are ineffective against most strains of *S. aureus*.
- **The penicillinase-resistant penicillins** *methicillin* (discontinued in the U.S.), *cloxacillin* and *flucloxacillin* (not currently marketed in the U.S.), *nafcillin, oxacillin*, and *dicloxacillin* have less-potent antimicrobial activity against microorganisms that are sensitive to *penicillin G*, but they are preferred agents for treatment of penicillinase-producing *S. aureus* and *Staphylococcus epidermidis* that are not *methicillin* resistant.
- *Ampicillin, amoxicillin,* and others such as *bacampicillin* and *pivampicillin* (not currently marketed in the U.S.) are the **aminopenicillins**, whose antimicrobial activity is similar to *penicillin G* but extends to include some gram-negative microorganisms (e.g., *Haemophilus influenzae*, *Escherichia coli*, and *Proteus mirabilis*) when those pathogens do not produce β-lactamases. These drugs are also available as coformulations with a β-lactamase inhibitor, such as *clavulanate* or *sulbactam*, which restores activity against some β-lactamase–producing organisms.
- Agents with extended antimicrobial activity against *Pseudomonas*, *Enterobacter*, and *Proteus* spp. include older agents largely out of use: *azlocillin, carbenicillin, mezlocillin, ticarcillin, ticarcillin/clavulanate,* and *carbenicillin indanyl sodium* (all discontinued in the U.S.). *Piperacillin* and the coformulation of *piperacillin/tazobactam* have antimicrobial activity against many isolates of *Pseudomonas*, *E. coli, Klebsiella*, and other gram-negative microorganisms. *Piperacillin* retains the activity of *ampicillin* against gram-positive cocci and *Listeria monocytogenes*.

TABLE 58–1 ■ CHEMICAL STRUCTURES OF SELECTED PENICILLINS

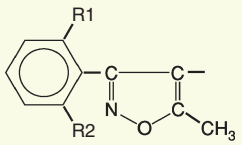


Penicillins are substituted 6-aminopenicillanic acid

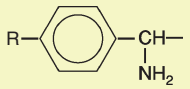
Addition of the substituents (R groups) shown below to the parent structure produces penicillins with altered susceptibility to inactivating enzymes (β-lactamases), antibacterial activity, and pharmacological properties.



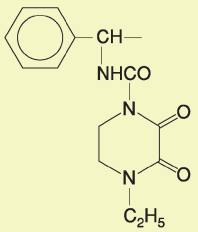
Penicillin G (Benzylpenicillin)



Oxacillin (R1=R2=H)/Cloxacillin (R1=Cl, R2=H) /Dicloxacillin (R1=R2=Cl)



Ampicillin (R=-H)/ Amoxicillin (R=-OH)



Piperacillin

General Common Properties

Following absorption of an oral dose, penicillins are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in CSF are variable but are less than 1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30 to 90 min. As a consequence, concentrations of these drugs in urine are high.

Penicillin G and Penicillin V

Antimicrobial Activity

The antimicrobial spectra of *penicillin G* (*benzylpenicillin*) and *penicillin V* (the phenoxymethyl derivative) are similar for aerobic gram-positive microorganisms. Most streptococci remain susceptible, but penicillin-resistant viridans streptococci and *S. pneumoniae* are becoming more common. Penicillin-resistant pneumococci are especially common in pediatric populations and may also be resistant to third-generation cephalosporins. Greater than 90% of strains of *S. aureus*, most strains of *S. epidermidis,* and many strains of gonococci are now resistant to

penicillin G. With rare exceptions, the meningococcus (*Neisseria meningitidis*) remains quite sensitive to *penicillin G*.

Most anaerobic gram-positive microorganisms, including *Clostridium* spp., are highly sensitive. Activity against gram-negative anaerobes is more variable, with the intestinal anaerobe *Bacteroides fragilis* displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. *Actinomyces israelii*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by clinically achievable concentrations of *penicillin G*. Spirochetes, including *Leptospira* spp. (leptospirosis), *Treponema pallidum* (syphilis), and *Borrelia burgdorferi* (Lyme disease), are typically penicillin susceptible. Penicillins are not effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

ADME

Oral Administration of Penicillin G and V. The virtue of *penicillin V* in comparison with *penicillin G* is that it is more stable in an acidic medium and therefore is better absorbed from the gastrointestinal (GI) tract, yielding plasma concentrations two to five times those provided by *penicillin G*. Thus, *penicillin V* is used for oral administration. Absorption is rapid, and maximal concentrations in blood are attained in 30 to 60 min. Ingestion of food may interfere with enteric absorption of all penicillins. Thus, oral penicillins should generally be administered at least 30 min before a meal or 2 h after.

Parenteral Administration of Penicillin G. After intramuscular injection, peak concentrations in plasma are reached within 15 to 30 min, declining rapidly thereafter ($t_{1/2}$ ~30 min). Repository preparations of *penicillin G* (*penicillin G benzathine*, *penicillin G procaine*) increase the duration of the effect. The repository compound favored for most indications is *penicillin G benzathine*, which releases *penicillin G* slowly from the injection site and produces relatively low but persistent concentrations in the blood. The average duration of demonstrable antimicrobial activity in the plasma is about 26 days for *benzathine penicillin G*. *Penicillin G procaine* has a prolonged $t_{1/2}$ compared to *penicillin G*, but shorter than that of *benzathine* formulations; it is typically dosed once daily. Neither depot formulation should be given intravenously as serious toxicity can result.

Distribution. *Penicillin G* is distributed extensively throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is about 0.35 L/kg. Approximately 60% of the *penicillin G* in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine. *Probenecid* markedly decreases the tubular secretion of the penicillins and also produces a significant decrease in the apparent volume of distribution of the penicillins (see Figure 42–2).

Penetration Into Cerebrospinal Fluid. *Penicillin* does not readily enter the CSF but penetrates more easily when the meninges are inflamed. The concentrations are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms if the minimum inhibitory concentration (MIC) of the organism is sufficiently low. *Penicillin* and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. *Probenecid* competitively inhibits this transport and thus elevates the concentration of *penicillin* in CSF. In uremia, other organic acids accumulate in the CSF and compete with *penicillin* for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.

Excretion. Approximately 60% to 90% of an intramuscular dose of *penicillin G* in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid. The $t_{1/2}$ for elimination of *penicillin G* is about 30 min in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. Clearance values are considerably lower in neonates and infants; as a result, *penicillin* persists in the blood several times longer in premature infants than in children and adults. The $t_{1/2}$ of the antibiotic in children less than 1 week of age is 3 h; by 14 days of age, it is 1.4 h. After renal function is fully established in young children, the rate of renal excretion of *penicillin G* is considerably more rapid than in adults. Anuria increases the $t_{1/2}$ of *penicillin G* from 0.5 to about 10 h. When renal function is impaired, 7% to 10% of the antibiotic may be inactivated each hour by the liver. The dose of the drug must be adjusted in patients with renal insufficiency or receiving dialysis. If hepatic insufficiency also is present, the $t_{1/2}$ will be prolonged even further.

HISTORY

The history of the brilliant research that led to the discovery and development of *penicillin* is well chronicled (Lax, 2004). In 1928, while studying *Staphylococcus* variants in the laboratory at St. Mary's Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus *Penicillium*, Fleming named the antibacterial substance *penicillin*.

A decade later, *penicillin* was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, a crude preparation was found to produce dramatic therapeutic effects when administered parenterally to mice with streptococcal infections. Sufficient *penicillin* was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous *penicillin* was only about 10% pure, and it required nearly 100 L of growth broth to obtain enough of the antibiotic to treat one patient for 24 h. Bedpans were used by the Oxford group for growing cultures of *Penicillium notatum*. Case 1 in the 1941 report from Oxford was that of a policeman, who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with *penicillin*, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to *penicillin* as a remarkable substance grown in bedpans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the U.S. There were 122 million units of *penicillin* made available during 1942, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, there were 200 patients who had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized a trial of the antibiotic in a military hospital. Soon thereafter, *penicillin* was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of *penicillin* marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable *penicillin* cost several dollars per 100,000 units; today, the same dose costs only a few cents.

Therapeutic Uses

Pneumococcal Infections. *Penicillin G* remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*, but resistance is an increasing concern. For parenteral therapy of sensitive isolates of pneumococci, *penicillin G* is favored. Because of concerns for β-lactam resistance, pneumococcal meningitis should be treated with a combination of *vancomycin* and a third-generation cephalosporin until it is established that the infecting pneumococcus is *penicillin* sensitive. *Dexamethasone* given prior to or at the same time as antibiotics is associated with an improved outcome in pneumococcal meningitis (de Gans et al., 2002). The recommended regimens for severe pneumococcal infections range from 12 to 24 million units of *penicillin G* per day by constant intravenous infusion or divided into boluses every 4 to 6 h for 7 to 14 days.

β-Hemolytic Streptococcal Infections. Streptococcal pharyngitis is a common respiratory manifestation of infection due to *Streptococcus pyogenes* (group A β-hemolytic *Streptococcus*). Penicillin-resistant isolates have yet to be observed. The preferred oral therapy is with *penicillin V*, 500 mg twice daily for 10 days. *Penicillin* therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with *penicillin* (Shulman et al., 2012). *S. pyogenes* is also a common cause of skin infections, ranging in severity from erysipelas and cellulitis to toxic shock and necrotizing fasciitis. The former two infections can be treated with oral *penicillin V*. The latter two are life-threatening infections associated with toxin production. Recommended treatment is with *penicillin* plus *clindamycin*, which may provide benefit by decreasing streptococcal toxin production (Stevens et al., 2014).

Infections Caused by Other Streptococci and Enterococci. The viridans group of streptococci is the most common cause of native valve infectious endocarditis. These are nongroupable α-hemolytic microorganisms that are increasingly resistant to *penicillin G*. In patients with endocarditis, it is important to determine quantitative microbial sensitivities to *penicillin G*, which guides drug selection, dosing, and use of combination therapy. Patients with highly penicillin-susceptible viridans group streptococcal native valve endocarditis can be treated successfully with daily doses of 12 to 20 million units of intravenous *penicillin G* for 4 weeks or for 2 weeks if given in combination with *gentamicin*. *Penicillin G* is a less-preferred alternative to *ampicillin* for the treatment of susceptible enterococcal infections.

Infections With Anaerobes. Pulmonary and periodontal infections usually respond well to *penicillin G*. Mild-to-moderate infections at these sites may be treated with oral medication (either *penicillin G* or *penicillin V* 250 mg four times daily). More severe infections should be treated with 12 to 24 million units of *penicillin G* IV. *Penicillin G* (12–24 million units per day given parenterally) plus *clindamycin* is recommended for clostridial gas gangrene. Adequate debridement of the infected areas is essential. Antibiotics probably have no effect on the outcome of tetanus due to *Clostridium tetani*. Debridement and administration of human tetanus immune globulin may be indicated.

Neisseria spp. Infections. *Penicillin G* is an alternative to third-generation cephalosporins for treatment of infections due to *N. meningitidis*. Patients should be treated with high doses of *penicillin* given IV. The occurrence of penicillin-resistant strains should be considered in patients who are slow to respond to treatment. *Penicillin G* does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure. Gonococci gradually have become more resistant to *penicillin G*, and penicillins are no longer the therapy of choice.

Syphilis. Therapy of syphilis with *penicillin G* is highly effective. Primary, secondary, and latent syphilis of less than 1 year in duration may be treated with one to three weekly intramuscular doses of 2.4 million units of *penicillin G benzathine*. Patients with neurosyphilis or cardiovascular syphilis typically receive intensive therapy with 18 to 24 million units of *penicillin G* daily for 10 to 14 days. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis.

Patients with secondary syphilis may develop the Jarisch-Herxheimer reaction, including chills, fever, headache, myalgias, and arthralgias occurring several hours after the first dose of *penicillin*. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Antipyretics give symptomatic relief, and therapy with *penicillin* should not be discontinued.

Actinomycosis. *Penicillin G* is the agent of choice for the treatment of all forms of actinomycosis (18–24 million units of *penicillin G* IV per day for 6 weeks). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

Listeria Infections. *Ampicillin* or *penicillin G*—with consideration for addition of *gentamicin* to both for immunosuppressed patients with meningitis—are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of *penicillin G* is 18 to 24 million units parenterally per day for at least 2 weeks. For endocarditis, the dose is the same, but the duration of treatment should be no less than 4 weeks.

Pasteurella multocida. *P. multocida* is a cause of wound infections after a cat or dog bite. It is susceptible to *penicillin G* and *ampicillin* and resistant to penicillinase-resistant penicillins and first-generation cephalosporins.

Prophylactic Uses of the Penicillins

Patients with anatomic or functional asplenia are at risk for infection with encapsulated bacteria including *S. pneumoniae* and *N. meningitidis*. In addition to vaccination, some asplenic patients receive antibacterial prophylaxis with *penicillin V*. The oral administration of 200,000 units of *penicillin G* or *penicillin V* every 12 h decreases the incidence of recurrences of rheumatic fever in susceptible individuals. The intramuscular injection of 1.2 million units of *penicillin G benzathine* once a month also yields excellent results. Prophylaxis must be continued throughout the year. Some suggest that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades, but the necessity of lifetime prophylaxis has not been established.

The Penicillinase-Resistant Penicillins

The penicillinase-resistant penicillins are resistant to hydrolysis by staphylococcal penicillinase. However, an increasing number of isolates of *S. aureus*, around half in most U.S. hospitals, and *S. epidermidis*, more than three-quarters, express a low-affinity PBP, giving them the MRSA or *methicillin*-resistant *S. epidermidis* (MRSE) phenotype. This term denotes resistance of these bacteria to all β-lactams, with the exception of *ceftaroline* and *ceftobiprole* (not available in the U.S.). Note that because *methicillin* was the first penicillinase-resistant penicillin in widespread use, the terms *MRSA* and *MRSE* are commonly used, despite the fact *methicillin* is currently rarely used. Alternative agents such as *vancomycin* or *daptomycin*, discussed below, may be used for infections due to organisms with this resistance mechanism.

The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin

Oxacillin, *cloxacillin* (not available in the U.S.), and *dicloxacillin* are semisynthetic isoxazolyl penicillin congeners that are markedly resistant to cleavage by penicillinase. *Nafcillin* is a similar congener of a slightly different structure. These drugs are not substitutes for *penicillin G* in the treatment of diseases amenable to it and are not active against enterococci, *Listeria*, or gram-negative organisms.

Pharmacological Properties. The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci. *Dicloxacillin* is the most active, and many strains of *S. aureus* are inhibited by concentrations of 0.05 to 0.8 μg/mL. *Nafcillin* is slightly more active than *oxacillin* against *penicillin G*–resistant *S. aureus* (most strains are inhibited by 0.06–2 μg/mL). Although it is the most active of the penicillinase-resistant penicillins against other microorganisms, it is not as potent as *penicillin G*.

Dicloxacillin and *cloxacillin* are available for oral administration; these agents are absorbed rapidly but incompletely (30%–80%) from the GI tract. Absorption increases when administered 1 h before or 2 h after meals. Peak concentrations in plasma are attained by 1 h. *Nafcillin* is only available for parenteral administration. All these congeners are bound to plasma albumin to a great extent (~90%–95%); none is removed from the circulation to a significant degree by hemodialysis. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis. The isoxazolyl penicillins are excreted by the kidney; there is also significant hepatic degradation and elimination in the bile. The $t_{1/2}$ for all are between 30 and 60 min. No dosing adjustments are needed for patients with renal failure. *Nafcillin* is a known inducer of the cytochrome P450 enzyme system, and caution should be used during coadministration with drugs metabolized via this pathway.

Therapeutic Indications

For mild to moderate skin and soft-tissue infections, the penicillinase-resistant penicillins can be administered orally (e.g., *dicloxacillin* 500 mg every 6 h) or parenterally (e.g., *nafcillin* 1–2 g every 6 h). For treatment of serious methicillin-susceptible *S. aureus* infections such as endocarditis, higher doses (e.g., *oxacillin* 2 g IV every 4 h) are employed.

The Aminopenicillins: Ampicillin and Amoxicillin

Aminopenicillins expand the spectrum of activity of *penicillin G* in a different direction from the penicillinase-resistant penicillins—they allow for useful activity against more gram-negative organisms. They are hydrolyzed by β-lactamases (from both gram-positive and gram-negative bacteria); thus, further expansion of their activity is enabled through coformulation with β-lactamase inhibitors (see the end of the chapter for further discussion of the chemistry and activity of β-lactamase inhibitors).

Antimicrobial Activity

Ampicillin and *amoxicillin* are generally bactericidal for susceptible gram-positive and gram-negative bacteria. The antimicrobial spectrum of *amoxicillin* is essentially identical to that of *ampicillin*, except that *amoxicillin* is less active and less effective than *ampicillin* for shigellosis. Gram-positive activity is broadly similar to that of the natural penicillins. Pneumococcal and viridans group streptococci isolates have varying levels of resistance to *ampicillin*, and penicillin-resistant strains should be considered *ampicillin/amoxicillin* resistant. Enterococci are about twice as sensitive to *ampicillin* as they are to *penicillin G*. That fraction of *H. influenzae* isolates that do not produce β-lactamases (between 60% and 80%) are typically *aminopenicillin* susceptible. From 30% to 60% of *E. coli*, a significant number of *P. mirabilis*, and all *Klebsiella* are resistant. Most strains of *Shigella*, *Pseudomonas*, *Serratia*, *Acinetobacter*, *B. fragilis*, and indole-positive *Proteus* also are resistant to this group of penicillins. Resistant strains of *Salmonella* are recovered with increasing frequency. Concurrent administration of a β-lactamase inhibitor such as *clavulanate* or *sulbactam* expands their spectrum of activity, particularly against *S. aureus*, *H. influenzae*, *E. coli*, *Klebsiella, Proteus*, and *B. fragilis*.

ADME

Ampicillin. An oral dose of 0.5 g of *ampicillin* produces peak concentrations in plasma of about 3 μg/mL at 2 h. Intake of food prior to ingestion of *ampicillin* diminishes absorption. Intramuscular injection of 0.5 to 1 g of sodium *ampicillin* yields peak plasma concentrations of about 7 to 10 μg/mL, respectively, at 1 h. Plasma levels decline with a $t_{1/2}$ of about 80 min. Severe renal impairment markedly prolongs the $t_{1/2}$. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes approximately 40% of the body store in about 7 h. Adjustment of the dose of *ampicillin* is required in the presence of renal dysfunction. *Ampicillin* appears in the bile, undergoes enterohepatic circulation, and is excreted in the feces.

Amoxicillin. *Amoxicillin* is a close chemical and pharmacological relative of *ampicillin*. *Amoxicillin* is stable in acid, designed for oral use, and absorbed more rapidly and completely from the GI tract than *ampicillin*. The absorption of *amoxicillin* appears to be partly saturable, with less fractional absorption at higher doses. Peak plasma concentrations of *amoxicillin* are 2 to 2.5 times greater than for *ampicillin* after oral administration of the same dose. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with *amoxicillin* is less than that following administration of *ampicillin*. The incidence of other adverse effects appears to be similar. Although the $t_{1/2}$ of *amoxicillin* is similar to that for *ampicillin*, effective concentrations of orally administered *amoxicillin* are detectable in the plasma for twice as long as with *ampicillin* because of the more complete absorption. For all these reasons, *amoxicillin* is generally preferred over *ampicillin* for oral administration. About 20% of *amoxicillin* is protein bound in plasma, a value similar to that for *ampicillin*. Most of a dose of the antibiotic is excreted in an active form in the urine, and dose adjustment is required in renal dysfunction. *Probenecid* delays excretion of the drug.

Ampicillin/Sulbactam and Amoxicillin/Clavulanate. The pharmacokinetic properties of the coformulated agents (*ampicillin/sulbactam* IV, *amoxicillin/clavulanate* by mouth) are broadly similar to those of the single-agent formulations.

Therapeutic Indications

Respiratory Infections. *Ampicillin* and *amoxicillin* are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*. The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, epiglottitis, and pneumonia caused by sensitive strains of these organisms. *Amoxicillin* is the most active of all the oral β-lactam antibiotics against both penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to *penicillin*, an increase in dose of oral *amoxicillin* (from 40 to 45 up to 80 to 90 mg/kg per day) for empirical treatment of acute otitis media in children is recommended. *Ampicillin*-resistant *H. influenzae* is a problem in many areas; use of *ampicillin/sulbactam* or *amoxicillin/clavulanate* can provide coverage for these organisms as well as for *Moraxella* (which universally produces a β-lactamase). *Amoxicillin* is also an option for empiric treatment of community-acquired pneumonia when patients are at low risk for drug-resistant pathogens or complications at a dose of 1 g every 8 h. *Amoxicillin* is an alternative treatment to *penicillin* for bacterial pharyngitis.

Urinary Tract Infections. Most uncomplicated urinary tract infections are caused by Enterobacterales, and *E. coli* is the most common species isolated from urinary tract infection patients. Aminopenicillins can be effective agents for urinary tract infections, but the high prevalence of resistance among *E. coli* and *Klebsiella* makes empiric use of these drugs for urinary tract infections challenging; using *amoxicillin/clavulanate* can provide broader coverage of these organisms. Cure rates generally with oral β-lactam agents for cystitis are lower than those with other drug classes such as fluoroquinolones or *trimethoprim-sulfamethoxazole*. Enterococcal urinary tract infections can be treated effectively with an aminopenicillin alone.

Enterococcal Bloodstream Infections and Endocarditis. *Ampicillin* at high doses (2 g IV every 4–6 h) is the drug of choice for treatment of serious enterococcal infections including endocarditis. The vast majority of isolates of *Enterococcus faecalis* are susceptible to aminopenicillins. Aminopenicillins as single agents may not provide bactericidal activity against enterococci; thus, for treatment of enterococcal endocarditis, synergistic combinations are recommended. Historically, this would be the combination of *ampicillin* plus *gentamicin*, but recent data suggest the combination of *ampicillin* and *ceftriaxone* provides similar therapeutic effect with less toxicity (Fernandez-Hidalgo et al., 2013). Addition of a β-lactamase inhibitor rarely adds to the activity an aminopenicillin alone against *Enterococcus*, as resistance in enterococci is almost exclusively mediated by PBP changes.

Meningitis. Acute bacterial meningitis in children is frequently due to *S. pneumoniae* or *N. meningitidis*. Because 20% to 30% of strains of *S. pneumoniae* now may be resistant to *ampicillin*, it is not indicated for empiric single-agent treatment of meningitis. *Ampicillin* has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. The combination of high-dose *ampicillin* and *vancomycin* plus a third-generation cephalosporin is a recommended regimen for empirical treatment of suspected bacterial meningitis in patients at risk for *L. monocytogenes*.

Antipseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

Antimicrobial Activity

This class contains a number of agents no longer in widespread use, including *carbenicillin*, *ticarcillin*, and *mezlocillin* (all discontinued in the U.S.). These agents are active against some isolates of *Pseudomonas aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners but are ineffective against most strains of *S. aureus*, *E. faecalis*, *Klebsiella*, and *L. monocytogenes*. The ureidopenicillin *piperacillin* is used most commonly as the combination product *piperacillin/tazobactam* and has broad activity against streptococci,

enterococci, and enteric gram-negative rods and good activity against *P. aeruginosa*.

ADME

Carbenicillin Indanyl Sodium. This indanyl ester of *carbenicillin* is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to *carbenicillin* by hydrolysis of the ester linkage. The active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, where available, the only use of this drug is for the management of urinary tract infections caused by *Proteus* spp. other than *P. mirabilis* and by *P. aeruginosa*.

Ticarcillin and Ticarcillin/Clavulanate. The semisynthetic penicillin *ticarcillin* is more active than *carbenicillin* versus *P. aeruginosa* but less active than *piperacillin*. The combination of *ticarcillin* and *clavulanate* has activity against other gram-negative aerobic and anaerobic organisms, such as *Stenotrophomonas maltophilia*, and has been used for intra-abdominal and urinary tract infections. In the U.S., the manufacture of *ticarcillin* alone and in combination with *clavulanate* has been discontinued.

Piperacillin and Piperacillin/Tazobactam. *Piperacillin* extends the spectrum of *ampicillin* to include most strains of *P. aeruginosa*, Enterobacterales (non–β-lactamase producing), many *Bacteroides* spp., and *E. faecalis*. Combined with a β-lactamase inhibitor (*piperacillin/tazobactam*), it has the broadest antibacterial spectrum of the penicillins, including activity against *methicillin*-susceptible *S. aureus*, *H. influenzae*, *B. fragilis*, and most *E. coli* and *Klebsiella*. The drug is only available for parenteral administration. High biliary concentrations are achieved. Distribution into the CNS by *piperacillin* is similar to that of other penicillins, but CSF concentrations of *tazobactam* may be inadequate to protect *piperacillin* against β-lactamase–producing organisms. The drug is eliminated renally and requires adjustment in renal dysfunction.

Therapeutic Uses

Piperacillin/tazobactam is an important agent for the treatment of patients with serious infections caused by gram-negative bacteria, including infections acquired in the hospital. This agent finds its greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to *ampicillin*; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. While organisms producing extended-spectrum β-lactamases may test as susceptible to *piperacillin/tazobactam*, a randomized trial found increased mortality among patients with infections due to ESBL-producing organisms compared to *meropenem* (Harris et al., 2018). Because of *piperacillin/tazobactam*'s good activity against *E. faecalis* and *B. fragilis*, this drug also has utility in mixed intra-abdominal infections. *Piperacillin/tazobactam* is dosed every 6 to 8 h in patients with normal renal function, at a dose of 4 g of *piperacillin* and 0.5 g of *tazobactam*. The infusion can be extended over 4 h to improve its antibacterial activity.

Adverse Reactions

Hypersensitivity Reactions. Hypersensitivity reactions are the most clinically important adverse effects noted with the penicillins, and these agents are among the most common causes of drug allergy.

Manifestations of hypersensitivity to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome, and anaphylaxis (Romano et al., 2003). Hypersensitivity reactions may occur with any dosage form of penicillin. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1 to 2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (known as the "major determinant"), which is formed when the β-lactam ring is opened. A large percentage of IgE-mediated reactions are to the major determinant, but a significant fraction are to other breakdown products. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to be formed, not the severity of the reaction that may result. Antipenicillin antibodies are detectable in virtually all patients who have received the drug as well as some who have never knowingly been exposed to it. Immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major determinant–specific skin-sensitizing antibodies.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004% to 0.04%. About 0.001% of patients treated with these agents die from anaphylaxis. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral or intradermal administration. The most dramatic reaction is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.

Skin rashes of all types may be caused by allergy to penicillin. The incidence of skin rashes appears to be highest following the use of *ampicillin*, at about 9%. Rashes follow the administration of *ampicillin* frequently in patients with infectious mononucleosis, but in such cases, patients can tolerate subsequent courses of *ampicillin* without experiencing a rash (Kerns et al., 1973). Serum sickness of variable intensity and severity, mediated by IgG antibodies, is rare; when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed until 1 or 2 weeks after the drug has been stopped and may persist for a week or longer. Vasculitis may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy, but hemolytic anemia is rare. Reversible neutropenia has been noted, occurring in up to 30% of patients treated with 8 to 12 g of *nafcillin* for more than 21 days. The bone marrow shows an arrest of maturation. Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. Penicillins rarely cause interstitial nephritis; *methicillin* (no longer marketed in the U.S.) has been implicated most frequently, but other antistaphylococcal penicillins as well as *piperacillin* appear to be among the most common culprits among β-lactams.

Evaluation of the patient's history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Although many patients are labeled as penicillin allergic, studies suggested that 90% or more of patients with a history of penicillin allergy will not manifest immediate hypersensitivity reactions on immunologic testing. Such testing can be performed in the clinical setting through commercially available penicillin skin-testing kits that contain the major antigenic determinant (benzylpenicilloyl polylysine); the negative predictive value of a penicillin skin test exceeds 95% for immediate-type hypersensitivity reactions (Shenoy et al., 2019). Occasionally, *desensitization* is recommended for truly penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. When full doses are reached, the penicillin should not be discontinued and then restarted during treatment of the infectious episode because immediate reactions may recur.

Other Adverse Reactions. The penicillins have minimal direct toxicity. Toxic effects include bone marrow depression, granulocytopenia, and hepatitis; the last effect is rare but is seen most commonly following the administration of *oxacillin* and *nafcillin*. The administration of *penicillin G* and *piperacillin*, and also of *carbenicillin* and *ticarcillin*, has been associated with impaired hemostasis due to defective platelet aggregation (Fass et al., 1987). Most common among the irritative responses to penicillins are pain and sterile inflammatory reactions at the sites of intramuscular

injections. In some individuals who receive penicillins intravenously, phlebitis or thrombophlebitis develops. Adverse responses to oral penicillin preparations may include nausea, vomiting, and mild-to-severe diarrhea.

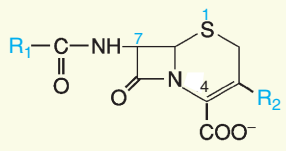
Intrathecal injection of *penicillin G* may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins or other β-lactams should be avoided. Similarly, high CSF concentrations of penicillins achieved through intravenous administration of excessive doses, including failure to adjust for reduced renal clearance, can lead to CNS dysfunction. Accidental intravenous instead of intramuscular injection of *penicillin G procaine* may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of toxic concentrations of *procaine*. Intravenous injection of *benzathine penicillin G* has been associated with cardiorespiratory arrest and death.

Penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. Normal microflora typically reestablish shortly after therapy is stopped; however, in some patients, superinfection results. Intestinal disease, ranging from mild diarrhea to life-threatening pseudomembranous colitis, due to *Clostridium difficile* superinfection has followed oral and, less commonly, parenteral administration of penicillins.

The Cephalosporins

Compounds containing 7-aminocephalosporanic acid are relatively stable in dilute acid and relatively resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme. Modifications at position seven of the β-lactam ring are associated with alteration in antibacterial activity; substitutions at position three of the dihydrothiazine ring alter the metabolism and pharmacokinetic properties of the drugs. The cephamycins are similar to the cephalosporins but have a methoxy group at position seven of the β-lactam ring of the 7-aminocephalosporanic acid nucleus (Table 58–2).

TABLE 58–2 ■ CHEMICAL STRUCTURES FOR SELECTED CEPHALOSPORINS



Cephem Nucleus

COMPOUND	R_1	R_2
First generation Cephalexin		$-CH_3$
Second generation Cefaclor		$-Cl$
Third generation Cefdinir		Antipseudomonal Ceftazidime		Anti-MRSA Ceftaroline		
HISTORY

Cephalosporium acremonium, the first source of the cephalosporins, was isolated in 1948 by Brotzu from the sea near a sewer outlet off the Sardinian coast (Grayson, 2010). Crude filtrates from cultures of this fungus were found to inhibit the *in vitro* growth of *S. aureus* and to cure staphylococcal infections and typhoid fever in humans. Culture fluids in which the Sardinian fungus was cultivated were found to contain three distinct antibiotics, which were named *cephalosporin P, N,* and *C*. With isolation of the active nucleus of cephalosporin C, 7-aminocephalosporanic acid, and with the addition of side chains, it became possible to produce semisynthetic compounds with antibacterial activity very much greater than that of the parent substance.

Mechanism of Action

Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin. PBP binding profiles differ somewhat from penicillins; for example, the lack of binding of cephalosporins to essential PBPs in *Enterococcus* spp. means this class as a whole lacks clinically useful activity against these organisms.

Mechanisms of Bacterial Resistance

As with the penicillins, resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the PBPs that are targets of the cephalosporins. Alterations in two PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three PBPs have inherently low affinity. With the exception of *ceftaroline* and *ceftobiprole*, cephalosporins lack activity against *methicillin*-resistant staphylococci due to their inability to bind to the low-affinity PBP expressed by these organisms.

The most prevalent mechanism of resistance to cephalosporins is inactivation by hydrolysis of the β-lactam ring. The cephalosporins have variable susceptibility to β-lactamases. *Cefoxitin*, *cefuroxime*, and the third-generation cephalosporins are more resistant to hydrolysis by the β-lactamases produced by gram-negative bacteria than first-generation cephalosporins. First- through third-generation cephalosporins, such as *ceftazidime* and *ceftriaxone*, are susceptible to hydrolysis by inducible, chromosomally encoded (*ampC*) β-lactamases present in gram-negative organisms such as *Citrobacter*, *Enterobacter*, and *Pseudomonas*. The inducible nature of these β-lactamases leads to a lower degree of susceptibility among wild-type isolates, whereas selection for mutants with high-level expression (stable derepression) can lead to clinical resistance. These class C enzymes are not substantially inactivated by classical β-lactamase inhibitors, such as *clavulanate* and *tazobactam*. *Cefepime*, *ceftolozane*, and *cefiderocol*, by virtue of their structures, may be less susceptible to hydrolysis by class C β-lactamases than are the third-generation agents. They are, however, susceptible to degradation by OXA- or KPC-type carbapenemases and metallo-β-lactamases. The β-lactamase inhibitor *avibactam* significantly inhibits the activity of AmpC-, OXA-, and KPC-type β-lactamases and enhances the activity of *ceftazidime* in the *ceftazidime/avibactam* coformulation.

Classification and General Pharmacology

Classification has traditionally been by unofficial *generations*, based on general features of antimicrobial activity (Table 58–3). Recent development of novel cephalosporins makes further use of this classification scheme problematic, as newer agents expand activity in different ways. In the absence of consensus on a new generations scheme to date, we will continue to employ this scheme for the first three generations and then differentiate agents after the third generation by their notable activity. None of the cephalosporins have reliable activity against the following bacteria: *Enterococcus*; *L. monocytogenes*; the atypical respiratory

TABLE 58–3 ■ CEPHALOSPORIN CLASSIFICATIONS ("GENERATIONS")

DRUG CLASS	USEFUL ANTIBACTERIAL SPECTRUM[a]
First Generation	
Cefazolin Cephalexin monohydrate Cefadroxil Cephradine*	Streptococci[b]; *S. aureus*[c]; some *Proteus, E. coli, Klebsiella*
Second Generation	
Cefuroxime Cefuroxime axetil Cefprozil	*E. coli*, *Klebsiella*, *Proteus*, *H. influenzae*, *Moraxella catarrhalis.* Not as active against gram-positive organisms as first-generation agents.
Cefoxitin Cefeotetan Cefmetazole*	Inferior activity against *S. aureus* compared to cefuroxime but with added activity against *Bacteroides fragilis* and other *Bacteroides* spp.
Third Generation	
Cefotaxime Ceftriaxone Cefdinir Cefditoren pivoxil Ceftibuten Cefpodoxime proxetil Ceftizoxime	*E. coli*, *Klebsiella*, *Proteus*, *H. influenzae*, *Moraxella catarrhalis, Citrobacter*[d], *Enterobacter*[d]; *Serratia*; *N. gonorrhoeae*; activity for *S. aureus*, *S. pneumoniae*, and *S. pyogenes* comparable to first-generation agents
Antipseudomonal Cephalosporins	
Ceftazidime	Gram-negative activity similar to third-generation with addition of activity against *Pseudomonas*[d]; poor activity vs gram-positive organisms
Ceftazidime/avibactam	Expands ceftazidime's activity against *Pseudomonas*[d] and multidrug-resistant Enterobacterales, but not against gram-positives
Ceftolozane/tazobactam	Similar to ceftazidime, with enhanced activity against *Pseudomonas*[d] and extended-spectrum beta-lactamase-producing Enterobacterales
Cefepime	Comparable to third generation but more resistant to some β-lactamases (especially those of *Pseudomonas*[d] and *Enterobacter*[d]); gram-positive activity similar to cefotaxime
Cefiderocol	Similar to ceftazidime with enhanced activity against *Pseudomonas*[d] and multidrug-resistant (including metallo-beta-lactamase-producing) Enterobacterales, and *Acinetobacter*
Anti-MRSA Cephalosporins	
Ceftaroline	Similar activity to third generation but uniquely adds activity against methicillin-resistant
Ceftobiprole*	*S. aureus*

[a]All cephalosporins lack clinically useful activity against enterococci, *Listeria monocytogenes*, and atypical respiratory pathogens *(Legionella, Mycoplasma, Chlamydophila* spp.). [b]Except for penicillin-resistant strains. [c]Except for methicillin-resistant strains. [d]Resistance to cephalosporins may develop during therapy through selection of isolates with de-repression of bacterial chromosomal β-lactamases, which destroy the cephalosporins. *Not marketed in the U.S.

pathogens (*Legionella pneumophila*, *Mycoplasma pneumoniae, Chlamydophila pneumoniae*); *C. difficile*; and *Campylobacter jejuni*.

Many cephalosporins, such as *cephalexin*, *cephradine*, *cefaclor*, *cefadroxil*, *loracarbef*, *cefprozil*, *cefpodoxime proxetil*, *ceftibuten*, *cefuroxime axetil*, *cefdinir*, and *cefditoren* (not all of these agents are available in the U.S.), are absorbed readily after oral administration; others can be administered intramuscularly or intravenously. Cephalosporins are excreted primarily by the kidney; thus, in general, the dosage should be reduced in patients with renal insufficiency. Exceptions are *cefpiramide* (no longer marketed in the U.S.) and *cefoperazone*, which are excreted predominantly in the bile; and *ceftriaxone*, which has mixed renal/nonrenal elimination. Just as for penicillins, *probenecid* slows renal tubular secretion of most cephalosporins. *Cefotaxime* is deacetylated to a metabolite with less antimicrobial activity than the parent compound that is excreted by the kidneys. The other cephalosporins do not undergo appreciable metabolism. Several cephalosporins, most notably *ceftriaxone*, *cefotaxime*, *ceftazidime*, and *cefepime*, penetrate across inflamed meninges in sufficient concentrations relative to typical MICs of the usual pathogens to be useful for the treatment of meningitis. Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor.

ADME and Agent-Specific Antibacterial Activity

First-Generation Cephalosporins

First-generation cephalosporins (e.g., *cefazolin*, *cephalexin*, and *cefadroxil*) have good activity against gram-positive bacteria and modest activity against gram-negative microorganisms. Most streptococci and *methicillin*-susceptible variants of *S. aureus* are susceptible; enterococci, MRSA, and *S. epidermidis* are resistant. Most oral cavity anaerobes are sensitive, but the *B. fragilis* group is resistant. These agents have modest activity against *Moraxella catarrhalis*, *E. coli*, and *K. pneumoniae*, sufficient for empiric use for mild but not severe infections. They lack activity against *H. influenzae*.

Cefazolin is relatively well tolerated after either intramuscular or intravenous administration; it is excreted by glomerular filtration and is about 85% bound to plasma proteins. *Cefazolin* is the only parenteral first-generation cephalosporin marketed in the U.S.

Cephalexin has the same antibacterial spectrum as the other first-generation cephalosporins. It is somewhat less active against penicillinase-producing staphylococci. Oral therapy with *cephalexin* (usually 0.5 g twice to four times daily) results in peak concentrations in plasma adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70% to 100% is excreted in the urine.

Cephradine (not available in the U.S.) and ***cefadroxil*** are oral agents similar in activity and pharmacokinetics to cephalexin.

Second-Generation Cephalosporins

The **second-generation cephalosporins** have somewhat increased activity against gram-negative microorganisms (including activity against *H. influenzae*) but less than the third-generation agents. A subset of second-generation agents (*cefoxitin* and *cefotetan*) also has modest activity against *B. fragilis*.

Cefoxitin and ***cefotetan*** are technically **cephamycins** and are resistant to some β-lactamases produced by gram-negative rods. Typical of second-generation cephalosporins, they have broader gram-negative activity, including most strains of *Haemophilus* spp., indole-positive *Proteus* spp., and *Klebsiella* spp. These antibiotics are less active than the first-generation cephalosporins against gram-positive bacteria but are more active against anaerobes, especially *B. fragilis*. ***Cefmetazole*** is a similar agent only marketed outside the U.S.

Cefuroxime has good activity against *H. influenzae* (including strains resistant to *ampicillin*), *N. meningitidis*, and *S. pneumoniae*. Activity against *E. coli* and *Klebsiella* is modest. Antistaphylococcal activity is inferior to first-generation cephalosporins. Unlike *cefoxitin*, *cefotetan*, and *cefmetazole*, *cefuroxime* lacks activity against *B. fragilis*. The drug can be given orally, intravenously, or intramuscularly every 8 to 12 h. Concentrations in CSF are about 10% of those in plasma, and the drug is effective but inferior to *ceftriaxone* for treatment of meningitis due to susceptible organisms.

Cefuroxime axetil is the 1-acetyloxyethyl ester of *cefuroxime*. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to *cefuroxime*; resulting concentrations in plasma are variable.

Cefprozil, ***cefaclor***, and ***loracarbef*** (the latter not available in the U.S.) are orally administered agents generally similar to *cefuroxime axetil*.

Third-Generation Cephalosporins

Third-generation cephalosporins generally are less active than first-generation agents against gram-positive cocci, although *ceftriaxone* and *cefotaxime* in particular have excellent antistreptococcal activity. These agents are much more active than prior generations against the Enterobacterales, although resistance is dramatically increasing due to β-lactamase–producing strains.

Cefotaxime is resistant to many narrow-spectrum β-lactamases and has good activity against most gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor, and the increasingly prevalent ESBLs and KPCs confer resistance to *cefotaxime*. *Cefotaxime* has a $t_{1/2}$ in plasma of about 1 h and should be administered every 4 to 8 h for serious infections. The drug is metabolized *in vivo* to desacetylcefotaxime, which is less active than is the parent compound. Concentrations achieved in the CSF are adequate for treatment of meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *N. meningitidis*.

Ceftriaxone has activity very similar to that of *cefotaxime* but a longer $t_{1/2}$ (~8 h), allowing for once-daily dosing for most indications. Administration of the drug twice daily has been effective for patients with meningitis. About half the drug can be recovered from the urine; the remainder is eliminated by biliary secretion. Single doses of intramuscular *ceftriaxone* have long been used in the management of urethral, cervical, rectal, or pharyngeal gonorrhea; increasing resistance has necessitated the use of higher doses (recently increased to 500 mg) (Centers for Disease Control and Prevention, 2021).

Ceftizoxime (not marketed in the U.S.) has a spectrum of activity *in vitro* that is similar to that of *cefotaxime*, except that it is less active against *S. pneumoniae* and more active against *B. fragilis*. The $t_{1/2}$ is 1.8 h, and the drug thus can be administered every 8 to 12 h for serious infections. *Ceftizoxime* is not metabolized; 90% is recovered in urine.

Cefpodoxime proxetil and ***cefditoren pivoxil*** (the latter not available in the U.S.) are orally administered prodrugs that are hydrolyzed by esterases during absorption to the active forms (*cefpodoxime* and *cefditoren*, respectively). These drugs provide similar, but less potent, activity as *cefotaxime* against *methicillin*-susceptible strains of *S. aureus* and *penicillin*-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, *M. catarrhalis,* and some enteric gram-negative rods. They are eliminated unchanged in the urine.

Cefixime is orally effective against urinary tract infections caused by *E. coli* and *P. mirabilis*; otitis media caused by *H. influenzae* and *S. pyogenes*; pharyngitis due to *S. pyogenes*; and uncomplicated gonorrhea (although intramuscular *ceftriaxone* is preferred for gonorrhea). It is available as an oral suspension. *Cefixime* has a plasma $t_{1/2}$ of 3 to 4 h and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/day for 5 to 7 days and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment.

Ceftibuten (not available in the U.S.) and ***cefdinir*** are orally administered cephalosporins similar in spectrum and pharmacokinetics to *cefixime*.

Antipseudomonal Cephalosporins

Antipseudomonal cephalosporins include *ceftazidime* (often classified as a third-generation cephalosporin), *ceftolozane/tazobactam*, *cefepime* (sometimes called a fourth-generation cephalosporin), *ceftazidime/avibactam*, and *cefiderocol*. *Ceftazidime* (with and without *avibactam*), *ceftolozane/tazobactam*, and *cefiderocol* have weaker gram-positive activity than third-generation agents, while *cefepime*'s activity is similar to that of *ceftriaxone*. The primary value of these agents is their expanded gram-negative activity, including activity against *P. aeruginosa* and, in the case of *ceftazidime/avibactam* and *cefiderocol*, extensively drug-resistant gram-negative pathogens such as carbapenemase-producing carbapenem-resistant Enterobacterales.

Ceftazidime is one-quarter to one-half as active against gram-positive microorganisms as is *cefotaxime*; activity against staphylococci is particularly poor. Its activity against the *Enterobacterales* is similar to *ceftriaxone*, but its major distinguishing feature is excellent activity against *Pseudomonas*. *Ceftazidime* has poor activity against *B. fragilis*. It only achieves therapeutic levels through parenteral administration, with a $t_{1/2}$ in plasma of about 1.5 h; the drug is renally eliminated and requires adjustment in renal dysfunction. The activity of *ceftazidime* against ESBL- and KPC-producing *Enterobacterales* and AmpC β-lactamase–overexpressing *Pseudomonas* is enhanced when it is combined with the β-lactamase inhibitor *avibactam* in ***ceftazidime/avibactam***.

Ceftolozane is a structural analogue of *ceftazidime* that has enhanced activity against *Pseudomonas*, including activity against strains resistant to *ceftazidime* through β-lactamase overexpression. It has similarly weak activity to *ceftazidime* against gram-positive organisms. It is commercially available as the coformulation ***ceftolozane/tazobactam***, which improves its activity against ESBL-producing *Enterobacterales*. Its pharmacokinetics are similar to *ceftazidime*, with a $t_{1/2}$ after intravenous administration of approximately 2.5 h and renal elimination.

Cefiderocol is a novel parenteral antipseudomonal cephalosporin. It has potent antipseudomonal activity and poor gram-positive activity similar to *ceftazidime* and *ceftolozane*. However, it is more stable against β-lactamase–mediated hydrolysis, including against broad-spectrum KPC-type and metallo-β-lactamases. In addition, it acts as a siderophore, binding to free extracellular iron and taking advantage of active transport mechanisms for iron that gram-negative bacteria employ. In this manner, it is able to achieve high concentrations in the periplasmic space. In combination, these attributes confer *in vitro* activity against most gram-negative aerobes, including those with multiple resistance

mechanisms such as efflux pumps, porin channel loss, and β-lactamase production. The pharmacokinetics of this agent are similar to *ceftazidime* and *ceftolozane*, although penetration into the CSF is currently not well characterized.

Cefepime and ***cefpirome*** (not available in the U.S.) are parenteral antipseudomonal cephalosporins sometimes also classified as "fourth-generation" agents. They provide similarly excellent activity to *ceftriaxone* against Enterobacterales and are relatively resistant to AmpC chromosomally encoded β-lactamases. Thus, they are active against many organisms such as *Enterobacter* and *Pseudomonas* that are resistant to other cephalosporins via overexpression of chromosomally encoded AmpC β-lactamases. However, other mechanisms (such as active efflux) in *Pseudomonas* may still confer *cefepime* resistance. *Cefepime* is susceptible to varying degrees to hydrolysis by ESBLs and to a significant extent to KPCs. *Cefepime* has higher activity than *ceftazidime* and comparable activity to *cefotaxime* for streptococci and methicillin-sensitive *S. aureus*. *Cefepime* is excreted renally; doses should be adjusted for renal failure. The serum $t_{1/2}$ is 2 h. *Cefepime* has excellent penetration into the CSF in animal models of meningitis.

Anti-MRSA cephalosporins have structural modifications allowing for binding to and inactivation of the altered PBPs expressed by MRSA, MRSE, and penicillin-resistant *S. pneumoniae*. *Ceftaroline* and *ceftobiprole* (not available in the U.S.) are the currently used agents in this class.

Ceftaroline fosamil is a cephalosporin with gram-negative activity comparable to *cefotaxime*. Its distinguishing feature is its enhanced gram-positive activity, especially its ability to bind to the low-affinity PBPs of MRSA and penicillin-resistant *S. pneumoniae*. Over 95% of MRSA and penicillin-resistant *S. pneumoniae* isolates are inhibited by *ceftaroline*. The parenteral preparation is a prodrug that is rapidly converted to active *ceftaroline* on intravenous administration. It is primarily eliminated by the kidneys with a $t_{1/2}$ of approximately 2 h. *Ceftaroline* has minimal protein binding (~20%) and appears to distribute well into most tissues, although penetration into the CSF has not yet been well characterized.

Ceftobiprole medocaril (not available in the U.S.) has similar activity to *ceftaroline* against gram-positive organisms. Its gram-negative spectrum includes activity similar to *ceftazidime* against *Pseudomonas* spp. and other gram-negative bacilli. As with *ceftaroline*, its intravenous formulation is a prodrug that is rapidly cleaved to the active moiety. Its pharmacokinetics are similar to those of *ceftaroline*.

Adverse Reactions

Hypersensitivity reactions to the cephalosporins are the side effects of greatest concern; they are similar in manifestation to those caused by the penicillins but generally less frequent than reactions to that class. Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia. Allergic cross-reactivity (i.e., the likelihood of a patient with a hypersensitivity reaction to penicillin having a reaction to a cephalosporin) appears to be primarily determined by reactions to β-lactam side chains, which may be similar between agents in different classes, rather than the β-lactam core ring structures. Thus, estimating the likelihood of cross-reactivity between a penicillin and cephalosporin depends on the agents involved (Chaudhry et al., 2019). Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of allergic reaction following the administration of a cephalosporin. However, patients who have a history of a severe, immediate reaction to a penicillin should be skin tested to confirm penicillin allergy before cephalosporin administration or initiated on cephalosporins via a test dose protocol, depending on the particular cephalosporin used.

A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin, but hemolysis is rare. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia. Cephalosporins, when used by themselves in recommended doses, rarely produce significant renal toxicity. Diarrhea can result from the administration of cephalosporins and may be more frequent with *cefoperazone*, perhaps because of its greater biliary excretion. The high binding affinity of *ceftriaxone* for serum albumin may displace bilirubin, potentially causing jaundice in neonates; for this reason, *cefotaxime* is the preferred agent in this patient population. *Ceftriaxone*'s high biliary concentrations combined with its affinity for calcium can lead to biliary pseudolithiasis. Cephalosporins containing a thiotetrazole group (*cefazolin*, *cefamandole* [not available in the U.S.], *cefotetan*, and *cefoperazone* [not available in the U.S.]) can prolong the prothrombin time, an effect that may be associated with clinically significant bleeding among patients receiving anticoagulation or with vitamin K deficiency. Encephalopathy and nonconvulsive status epilepticus have been reported with *cefepime*, especially when administered at high doses or among patients with renal dysfunction or preexisting brain injury.

Therapeutic Uses

The **first-generation cephalosporins** are excellent agents for skin and soft-tissue infections owing to their activity against *S. pyogenes* and *methicillin*-susceptible *S. aureus* (Stevens et al., 2014). A single 1- to 2-g dose of *cefazolin* just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Bratzler et al., 2013). Parenteral *cefazolin* (2 g IV every 8 h) is a drug of choice for serious infections, including endocarditis, due to *methicillin*-susceptible *S. aureus* (Baddour et al., 2015). Oral agents in this generation have utility for mild-to-moderate upper respiratory (e.g., pharyngitis) and urinary tract infections as well (e.g., *cephalexin* 250–500 mg orally every 6 h).

Second-generation cephalosporins generally have been replaced by third-generation agents. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are suboptimal (compared with oral *amoxicillin*) for treatment of penicillin-nonsusceptible *S. pneumoniae* pneumonia and otitis media. *Cefoxitin* and *cefotetan* play a useful role in perioperative prophylaxis for patients undergoing intra-abdominal and gynecological surgical procedures. They may also be used for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as peritonitis and pelvic inflammatory disease, although because of increasing resistance among *B. fragilis*, these agents are best used for mild-to-moderate infections.

The **third-generation cephalosporins** are drugs of choice for serious infections caused by *E. coli*, *Klebsiella*, *Proteus*, *Providencia*, *Serratia*, and *Haemophilus* spp. *Ceftriaxone* is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. *Cefotaxime* and *ceftriaxone* at higher doses (2 g every 12 h in adults) are used for the empiric treatment of meningitis in non-immunocompromised adults and children (in combination with *vancomycin* and *ampicillin* pending identification of the causative agent), owing to their excellent activity against *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria (Tunkel et al., 2004). Third-generation cephalosporins lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, pathogens that may cause community-acquired meningitis. The antimicrobial spectra of *cefotaxime* and *ceftriaxone* are excellent for the treatment of community-acquired pneumonia (with addition of a non–β-lactam agent with activity against atypical respiratory pathogens for empiric coverage).

The **antipseudomonal cephalosporins** are indicated for the empirical treatment of nosocomial infections where *Pseudomonas* and other resistant gram-negative bacilli are likely to be pathogens, including pneumonia, urinary tract infections, and intra-abdominal infections (in the latter instance, combined with an agent with activity against anaerobic organisms). *Ceftolozane/tazobactam* may have superior activity against some *ceftazidime*-resistant *Pseudomonas*, whereas *cefepime* has superior activity against nosocomial isolates of *Enterobacter*, *Citrobacter*, and *Serratia* spp. Activity of *ceftazidime*, *ceftolozane/tazobactam*, and *cefepime* is variable against ESBL-producing isolates and absent against KPC-expressing strains; *ceftazidime/avibactam* is more likely to be active against these highly resistant organisms. *Cefiderocol* is usually reserved for treatment of extensively drug-resistant gram-negative pathogens against which few or no alternative antibiotics are active.

The **anti-MRSA cephalosporins** are typically used for patients with documented or suspected severe infections due to staphylococci or streptococci. *Ceftaroline* is dosed at 600 mg every 12 h for treatment of community-acquired pneumonia or every 8 h if MRSA is suspected.

Other β-Lactam Antibiotics

Carbapenems

Carbapenems are β-lactams that contain a fused β-lactam ring and a five-member ring system that differs from the penicillins because it is unsaturated and contains a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than most other β-lactam antibiotics largely due to their greater resistance to β-lactamase–mediated hydrolysis.

Imipenem/Cilastatin and Imipenem/Cilastatin/Relebactam

Imipenem is formulated in combination with *cilastatin* (*imipenem/cilastatin*), a drug that inhibits the degradation of *imipenem* by a renal tubular dipeptidase and extends its $t_{1/2}$. Now, *imipenem* is available as a coformulation with the β-lactamase inhibitor *relebactam* (*imipenem/cilastatin/relebactam*), which extends its spectrum against organisms producing carbapenemases. For brevity, we will omit *cilastatin* when referring to these agents below.

Antimicrobial Activity. *Imipenem*, like other β-lactam antibiotics, binds to PBPs, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is highly resistant to hydrolysis by most β-lactamases. The *in vitro* activity of *imipenem* is excellent across a wide variety of aerobic and anaerobic microorganisms. Streptococci, including penicillin-resistant *S. pneumoniae*; *Enterococcus faecalis*; staphylococci (including penicillinase-producing strains but not MRSA); and *Listeria* (although *ampicillin* is more active) all are typically susceptible. Activity is excellent against the Enterobacterales with the exception of emerging carbapenemase-producing strains. Most strains of *Pseudomonas* and *Acinetobacter* are inhibited, but resistance to carbapenems among these organisms is increasing and can emerge during therapy. Anaerobes, including *B. fragilis*, are highly susceptible. *Imipenem* also displays activity against *Nocardia* spp. and some species of rapidly growing mycobacteria. Addition of *relebactam* restores the activity of *imipenem* against most carbapenemase-producing Enterobacterales but not metallo-β-lactamase producers; activity of the combination against *imipenem*-resistant *Pseudomonas* is variable.

ADME and Adverse Reactions. *Imipenem* is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal tubule. Both *imipenem* and *cilastatin* have a $t_{1/2}$ of about 1 h. When administered concurrently with *cilastatin*, about 70% of administered *imipenem* is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency. The $t_{1/2}$ of *relebactam* is also approximately 1 h, and it is excreted in the urine. Nausea and vomiting are the most common adverse reactions (1%–20%) across *imipenem* and *imipenem/relebactam*. Seizures have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Most patients who are allergic to other β-lactam antibiotics can safely receive carbapenems, although those with severe immediate-type reactions should consider an initial carbapenem challenge following a test dose protocol.

Therapeutic Uses. *Imipenem*, dosed at 500 to 1000 mg IV every 6 to 8 h in normal renal function, is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft-tissue, bone, and joint infections. Its primary role is for empirical treatment of serious infections in hospitalized patients who are at risk for resistant pathogens, such as those who have recently received other β-lactam antibiotics. When *imipenem* is used for treatment of severe *P. aeruginosa* infections, resistance may develop during therapy. *Imipenem/relebactam* is reserved for treatment of gram-negative pathogens resistant to all or almost all other alternative antibiotics.

Meropenem and Meropenem/Vaborbactam

Meropenem is a derivative of *thienamycin*. It does not require coadministration with *cilastatin* because it is not sensitive to renal dipeptidase. It may be coformulated with the β-lactamase inhibitor *vaborbactam*.

Antimicrobial Activity. The spectra of activity of *imipenem* and *meropenem* are broadly similar, with *meropenem* being somewhat less active against gram-positive organisms—particularly *Enterococcus*—and more active against gram-negative organisms. As with *imipenem*, carbapenemases that gram-negative organisms may produce can render *meropenem* ineffective; *vaborbactam* restores the susceptibility of *meropenem* against a large subset of these.

ADME and Adverse Reactions. *Meropenem* and *meropenem/vaborbactam* are available for intravenous administration and are renally cleared with half-lives on the order of 1 h. Although typically infused over 30 min, extending the infusion over 3 h can increase the time that *meropenem* concentrations spend above the organism's MIC and allow for treatment of low-level resistant pathogens. *Meropenem*'s toxicity is similar to that of *imipenem* except that it may be less likely to cause seizures; thus, it is preferred for treatment of meningitis when carbapenem therapy is required. Notably, *meropenem*, and other carbapenems to a lesser extent, significantly lowers serum concentrations of the antiepileptic agent *valproic acid* and should not be coadministered with this drug.

Therapeutic Uses. As with *imipenem*, *meropenem* is typically employed for hospital-onset infections of the respiratory, gastrointestinal, and urinary tracts when cephalosporin- or penicillin-resistant organisms are suspected (dosed at 1–2 g every 8 h in patients with normal renal function). *Meropenem/vaborbactam* is reserved for multidrug-resistant gram-negative pathogens (2 g of *meropenem* and 2 g of *vaborbactam* administered every 8 h in normal renal function).

Ertapenem

Ertapenem differs from *imipenem* and *meropenem* by having a longer $t_{1/2}$ that allows once-daily dosing and by lacking clinically useful activity against *Enterococcus*, *P. aeruginosa*, and *Acinetobacter* spp. Its activity against Enterobacterales, including ESBL-producing isolates, and anaerobes makes it useful in intra-abdominal or urinary tract infections. An advantage of this agent is its once-daily dose (at 1 g IV), which facilitates outpatient therapy.

Doripenem

Doripenem (not available in the U.S.) has a spectrum of activity that is similar to that of *meropenem*, with greater activity against some resistant isolates of *Pseudomonas*.

Monobactams

Monobactams are β-lactams that contain only a fused β-lactam ring, not a thiazolidine or dihydrothiazidine ring. Currently, *aztreonam* is the only member of this class in therapeutic use.

Aztreonam

Aztreonam is resistant to narrow-spectrum β-lactamases elaborated by most gram-negative bacteria as well as metallo-β-lactamases, but not most extended-spectrum or KPC-type β-lactamases. *Aztreonam* has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. Activity against Enterobacterales and *P. aeruginosa* is similar to that of *ceftazidime*. It is also highly active *in vitro* against *H. influenzae*. *Aztreonam* is administered intramuscularly, intravenously, or as an inhaled formulation. The $t_{1/2}$ for elimination of intravenously administered *aztreonam* is 1.7 h; most of the drug is recovered unaltered in the urine. The $t_{1/2}$ is prolonged to about 6 h in anephric patients. A notable feature is a lack of allergic cross-reactivity with other β-lactam antibiotics, with the possible

exception of *ceftazidime*, *ceftolozane*, and *cefiderocol* with which it shares similar or identical side chains. *Aztreonam* is therefore useful for treating gram-negative infections among patients with severe hypersensitivity reactions to other β-lactam classes. *Aztreonam* has a growing role in the treatment of metallo-β-lactamase–producing organisms, since it is generally stable to these enzymes; however, as co-production of *aztreonam*-hydrolyzing enzymes may occur, *aztreonam* is often coadministered with *ceftazidime/avibactam* in these cases (a specific *aztreonam/avibactam* combination agent is in development). The inhalation formulation is used to reduce the frequency of *Pseudomonas*-associated pulmonary exacerbations in patients with cystic fibrosis. *Aztreonam* generally is well tolerated, although hepatotoxicity, especially in infants and young children, can occur.

Other Cell Envelope Disruptors

Glycopeptides

Glycopeptides offer another mechanism by which the cell wall synthesis pathway in bacteria can be targeted. The class originator for glycopeptides is *vancomycin*, a tricyclic glycopeptide antibiotic produced by *Streptococcus orientalis*. *Teicoplanin* is a mixture of related glycopeptides available as an antibiotic in Europe. *Teicoplanin* is similar to *vancomycin* in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal). A new generation of glycopeptide congeners, the lipoglycopeptides, has been recently introduced into clinical practice. These agents include *telavancin*, *dalbavancin*, and *oritavancin*.

Antimicrobial Activity

Vancomycin possesses activity against the vast majority of gram-positive bacteria, including MRSA, penicillin-resistant streptococci, and *ampicillin*-resistant enterococci. Gram-positive organisms intrinsically resistant to *vancomycin* include *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Erysipelothrix*; *vancomycin* susceptibility across species of *Enterococcus* is variable. Essentially all species of gram-negative bacteria and mycobacteria are resistant to glycopeptides. The activity of *teicoplanin*, *telavancin*, *dalbavancin*, and *oritavancin* is generally similar to that of *vancomycin*; these agents are also active against some *vancomycin*-resistant enterococci (Goldstein et al., 2004).

Mechanism of Action

Glycopeptides inhibit the synthesis of the cell wall in sensitive bacteria by noncovalent, high-affinity binding to the D-alanyl-D-alanine terminus of cell wall precursor units. This directly blocks through steric hindrance both transglycosidase-mediated polymerization and the PBP-mediated cross-linking of cell wall units (similarly to β-lactams) (Figure 58–5). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria. The lipoglycopeptides are able to dimerize and anchor their lipid moieties into the bacterial membrane, allowing for increased binding to the D-Ala-D-Ala target site and improved potency. *Telavancin* and *oritavancin* possess a second mechanism of action: direct disruption of the bacterial membrane. This effect leads to more rapid bactericidal activity than that of *vancomycin*.

Resistance to Glycopeptides and Lipoglycopeptides

Glycopeptide-resistant strains of enterococci, primarily *E. faecium*, have emerged as major nosocomial pathogens in hospitals in the U.S. Determinants of *vancomycin* resistance are located on a transposon that is readily transferable among enterococci and, potentially, other gram-positive bacteria. These strains are typically resistant to multiple antibiotics, including *streptomycin*, *gentamicin*, and *ampicillin*.

Enterococcal resistance to glycopeptides is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl D-serine, both of which bind glycopeptides poorly (Zeng et al., 2016). Several enzymes within the *van* gene cluster are required for this target alteration to occur. The *vanA* genotype confers inducible resistance to *teicoplanin* and *vancomycin* in *E. faecium* and *E. faecalis*. Consistent with their dual mode of action, while MICs to *telavancin* and *oritavancin* may increase in isolates expressing *vanA*, they often remain in the susceptible range. In contrast, *vanA*-expressing isolates are frequently *dalbavancin* resistant. The *vanB* genotype, which tends to confer a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible

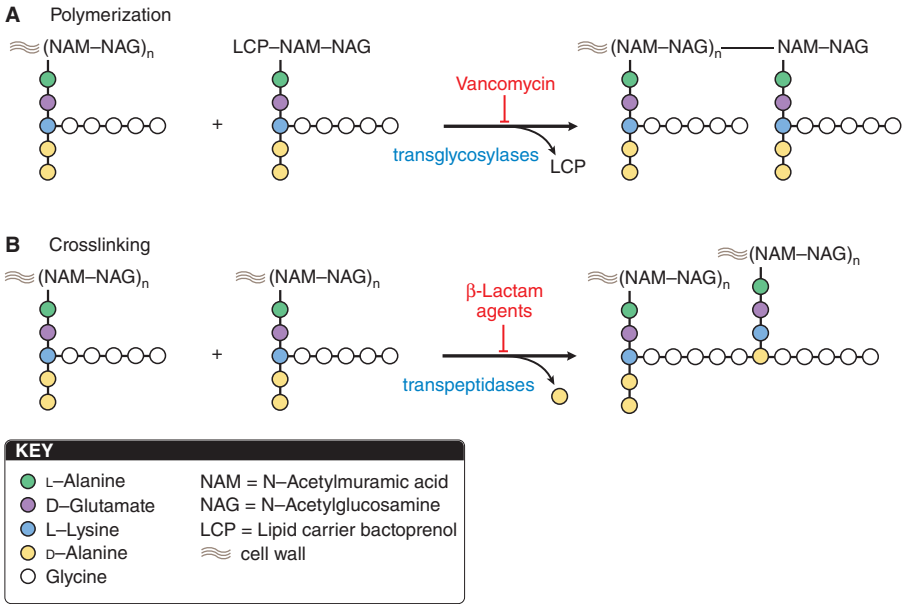

Figure 58–5 *Inhibition of bacterial cell wall synthesis in gram-positive bacteria: vancomycin and β-lactam agents.* *Vancomycin* and other glycopeptides inhibit the polymerization or transglycosylase reaction (**A**) by binding to the D-alanyl-D-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocking linkage to the glycopeptide polymer (indicated by the subscript n). These $(NAM–NAG)_n$ peptidoglycan polymers are located within the cell wall. VanA-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal D-lactate for D-alanine, reducing affinity for vancomycin by 1000-fold. β-Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (**B**) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the five glycines in this example) of one chain, displacing the terminal D-alanine of an adjacent chain. Glycopeptides may also act through this mechanism.

by *vancomycin* but not *teicoplanin*; consequently, many strains remain susceptible to *teicoplanin*. *Telavancin*, *dalbavancin*, and *oritavancin* are usually active as well. The *vanC* genotype that confers resistance only to *vancomycin* is the least important clinically and least characterized.

S. aureus and coagulase-negative staphylococci may express reduced or "intermediate" susceptibility to *vancomycin* (MIC 4–8 μg/mL) or, very rarely, high-level resistance (MIC ≥16 μg/mL) (Howden et al., 2010). Intermediate resistance is associated with a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10^5 to 1 in 10^6 colony-forming units) will grow in the presence of *vancomycin* concentrations greater than 4 μg/mL. Prior treatment courses and low *vancomycin* levels may predispose patients to infection and treatment failure with *vancomycin*-intermediate strains. These strains typically are resistant to *methicillin* and multiple other antibiotics; their emergence is a major concern because of *vancomycin*'s prominent role in the treatment of MRSA infection. High-level *vancomycin*-resistant *S. aureus* strains (MIC ≥32 μg/mL) harbor a conjugative plasmid into which the *vanA* transposon is integrated by an interspecies horizontal gene transfer from *E. faecalis* to an MRSA (Limbago et al., 2014). These isolates have been variably susceptible to *teicoplanin* and the lipoglycopeptides.

ADME

All glycopeptides are poorly absorbed after oral administration; the oral formulation of *vancomycin* is exclusively used in patients with *C. difficile* colitis. *Vancomycin* should be only administered intravenously, not intramuscularly, due to pain with intramuscular injection. Approximately 30% of *vancomycin* is bound to plasma protein. *Vancomycin* appears in various body fluids, including the CSF when the meninges are inflamed (7%–300%), bile, and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose of *vancomycin* is excreted by glomerular filtration; elimination $t_{1/2}$ is about 6 h in normal renal function. The drug accumulates if renal function is impaired, and dosage adjustments must be made. The drug can be cleared from plasma with hemodialysis.

Teicoplanin can be administered by intramuscular injection as well as intravenous administration. An IV dose of 1 g in adults produces plasma concentrations of 15 to 30 μg/mL 1 h after a 1- to 2-h infusion. *Teicoplanin* is highly bound by plasma proteins (90%–95%) and has an extremely long serum elimination $t_{1/2}$ (up to 100 h), allowing for once-daily dosing. Excretion is through glomerular filtration.

Telavancin achieves peak concentrations of approximately 90 μg/mL when administered at a dose of 10 mg/kg once daily. *Telavancin* is highly protein bound (>90%), with a $t_{1/2}$ of about 7 h. Studies of penetration into epithelial lining fluid and skin blister fluid demonstrated adequate tissue concentrations to provide effective therapy. *Telavancin* is eliminated primarily (70%–80%) by renal excretion, with a small component of metabolism. Dosage adjustment is required in renal dysfunction.

Dalbavancin and *oritavancin* have unique pharmacokinetic properties that allow for intermittent (weekly or less) dosing. Both are characterized by extremely long plasma $t_{1/2}$ (on the order of 10 days for terminal elimination) and are highly (>90%) protein bound. Penetration of *dalbavancin* into skin blister fluid and bone appears to be adequate, but penetration into CSF is very low. Between 33% and 50% of *dalbavancin* is eliminated unchanged in the urine, and dosage adjustment is recommended for renal dysfunction. *Oritavancin* has a large volume of distribution (~1 L/kg). Renal excretion is very slow, and dosage adjustment is not required in mild-to-moderate renal dysfunction.

Therapeutic Uses

Vancomycin should be infused at a rate of no more than 1 g/h to avoid infusion-related adverse reactions; recommended initial doses for adults are typically in the range of 30- to 45-mg/kg per day in two or three divided doses. Alteration of dosage is required for patients with impaired renal function. In functionally anephric patients and patients receiving dialysis with non–high-flux membranes, administration of 1 g (~15 mg/kg) every 5 to 7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required. For treatment of *C. difficile* colitis, *vancomycin* is available as capsules for oral administration or as a commercially prepared oral solution; alternatively, the intravenous formulation may be compounded into a solution for oral administration. The recommended oral dose of *vancomycin* is 125 mg four times daily, with escalation up to 500 mg four times daily in patients with life-threatening disease.

Monitoring recommendations and target drug exposures for *vancomycin* are evolving. Previously, recommendations called for monitoring serum trough concentrations, within 30 min prior to a dose, at steady state, typically before the fourth dose of a given dosage regimen. A trough serum concentration of at least 10 μg/mL is recommended; for patients with more serious infections, including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia, trough levels of 15 to 20 μg/mL are recommended. However, more recent data suggest the area under the curve as a more appropriate target for *vancomycin* exposures. Thus, new guidelines recommend targeting an area under the curve between 400 and 600 mg*h/L for serious MRSA infections (Rybak et al., 2020). Area under the curve can be estimated through sampling one or more levels during a dosing interval and applying standard population-based or Bayesian procedures.

Telavancin is administered intravenously at a dose of 10 mg/kg daily, with dosage adjustment required for patients with renal dysfunction. The approved dosage of intravenous *dalbavancin* for treatment of skin and soft-tissue infection is 1000 mg at the initiation of treatment, followed by a 500-mg dose 7 days later. *Dalbavancin* can be administered as a single 1500-mg IV dose for skin and soft-tissue infections. *Oritavancin* has been studied for skin and soft-tissue infections as a single 1200-mg IV dose. A variety of multiple-dose regimens for *dalbavancin* and *oritavancin* for treatment of complicated infections, such as osteomyelitis, are under investigation.

Skin/Soft-Tissue and Bone/Joint Infections. *Vancomycin* has long been a mainstay in the treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms, including MRSA, are the leading pathogens (Stevens et al., 2014). *Telavancin*, *dalbavancin*, and *oritavancin* offer alternatives for treatment of this condition, with *dalbavancin* and *oritavancin* offering the option for single or infrequent dosing.

Respiratory Tract Infections. *Vancomycin* is employed for the treatment of pneumonia when MRSA is suspected. Because *vancomycin* penetration into lung tissue is relatively low, aggressive dosing is generally recommended. *Telavancin* displayed similar efficacy to *vancomycin* in studies of nosocomial pneumonia due to gram-positive pathogens.

CNS Infections. *Vancomycin* is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant *S. pneumoniae* is common (Tunkel et al., 2004). Penetration of *vancomycin* across meninges is poor, especially with steroid coadministration; thus, aggressive dosing is typically warranted. *Vancomycin* is also used to treat nosocomial meningitis, often caused by staphylococci. Intraventricular *vancomycin* (at doses of 10–20 mg once daily) has been used in ventricular shunt infections.

Endocarditis and Vascular Catheter Infections. *Vancomycin* is standard therapy for staphylococcal endocarditis when the isolate is *methicillin* resistant or patients have a severe penicillin allergy (Baddour et al., 2015). However, β-lactams such as *nafcillin* or *cefazolin* are more effective than *vancomycin* for treatment of *methicillin*-susceptible *S. aureus* bloodstream infections; thus, patients should only receive *vancomycin* for *methicillin*-susceptible *S. aureus* infections if they have a documented, life-threatening allergy. *Vancomycin* is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for penicillin-resistant isolates. *Vancomycin* is used for the treatment of vascular catheter infections due to gram-positive organisms.

Other Infections. Orally administered *vancomycin* is a drug of choice for patients with *C. difficile*–associated diarrhea. *Vancomycin* is frequently employed as a component of empiric therapy for patients with fever and neutropenia. It is also used in surgical prophylaxis in patients with β-lactam allergies or if there is a high risk of MRSA infection.

Adverse Effects

Infusion-Related Reactions. Rapid intravenous infusion of *vancomycin* may cause erythematous or urticarial reactions, flushing, tachycardia, and rarely hypotension. The extreme flushing that can occur is not an allergic reaction but a direct effect of *vancomycin* on mast cells, causing them to release histamine. Typically, this reaction can be ameliorated by administering *vancomycin* more slowly, sometimes with premedication with histamine blockers. This reaction is generally not observed with *teicoplanin* but has been reported with lipoglycopeptides (i.e., *telavancin*).

Nephrotoxicity. Initial formulations of *vancomycin* contained impurities that were associated with a high incidence of nephrotoxicity. With the availability of impurity-free formulations, there was a question regarding whether *vancomycin* was intrinsically nephrotoxic. However, as the recommended dosage range for *vancomycin* dosages has increased, it seems clear there is indeed a degree of dose-related nephrotoxicity (Lodise et al., 2009). Coadministration with some penicillins might further increase the risk of nephrotoxicity. Results of clinical trials suggest *telavancin*'s nephrotoxicity may exceed that of *vancomycin*.

Other Toxic and Irritative Effects. True hypersensitivity reactions produced by glycopeptides are less common than the pseudoallergic infusion-related reactions and include macular skin rashes and anaphylaxis. Because of the long half-lives of *dalbavancin* and *oritavancin*, there is concern over prolonged effects if patients were to experience a severe hypersensitivity reaction, although, to date, few prolonged or delayed reactions have been described. *Telavancin* can cause QT interval prolongation and is contraindicated in pregnancy due to teratogenic effects observed in animal studies. Auditory impairment, sometimes permanent, has been described in association with *vancomycin* use; some investigators believe ototoxicity is associated with excessive concentrations of *vancomycin* in plasma (60–100 μg/mL or greater).

Drug Interactions. *Oritavancin* has a minor effect on CYP-mediated metabolism; it should be used with *warfarin* only with careful monitoring.

Lipopeptides

Daptomycin, the only member of its class, is a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus* with bactericidal activity against gram-positive bacteria, including *vancomycin*-resistant isolates.

Antimicrobial Activity

Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria. *Daptomycin* may be active against *vancomycin*-resistant strains, although MICs tend to be higher for these organisms than for their *vancomycin*-susceptible counterparts (Critchley et al., 2003). *Daptomycin* lacks clinically useful activity against gram-negative organisms.

Mechanism of Action

Daptomycin binds to the bacterial inner membrane, resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity.

Resistance to Lipopeptides

Daptomycin resistance has been reported to emerge while on therapy. Resistance occurs most commonly in treatment of high-inoculum infections, such as endocarditis, and among enterococci. The mechanisms of resistance to *daptomycin* have not been fully characterized but appear to be related to changes in cell surface charge that impede *daptomycin* binding (Stefani et al., 2015). Interestingly, coadministration of β-lactams with *daptomycin* (even when the pathogen is resistant to the β-lactam) can reverse this resistance; some early data suggest these combinations may be effective in treatment of severe staphylococcal and enterococcal infections (Bartash and Nori, 2017).

ADME

Daptomycin is poorly absorbed orally and should be administered intravenously. Direct toxicity to muscle precludes intramuscular injection. The serum $t_{1/2}$ is 8 to 9 h, permitting once-daily dosing. Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. Although the drug penetrates adequately into the lung, the drug is inactivated by pulmonary surfactant and thus is not useful in the treatment of pneumonia (Silverman et al., 2005). If the creatinine clearance is less than 30 mL/min, the dose is administered only every 48 h. For patients on hemodialysis, the dose should be given immediately after dialysis.

Therapeutic Uses

Daptomycin is indicated for treatment of complicated skin and soft-tissue infections and complicated bacteremia and right-sided endocarditis, where its efficacy is comparable to that of *vancomycin* or antistaphylococcal β-lactams (Fowler et al., 2006). FDA-approved doses are 4 to 6 mg/kg, but data suggest higher doses (8–12 mg/kg) are well tolerated and thus are recommended for invasive staphylococcal and enterococcal infections (Figueroa et al., 2009).

Adverse Effects

Musculoskeletal Toxicity. Elevations of creatine kinase may occur; this does not require discontinuation unless levels are greater than 10 times the upper limit of normal or findings suggest an otherwise-unexplained myopathy. Rhabdomyolysis has been reported to occur rarely. Eosinophilic pneumonia has been rarely described.

Drug Interactions. *Daptomycin* does not affect CYPs and has no important drug-drug interactions. Caution is recommended when *daptomycin* is coadministered with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively (Bland et al., 2014).

Bacitracins

Bacitracin is an antibiotic produced by the Tracy-I strain of *Bacillus subtilis*. The bacitracins are a group of polypeptide antibiotics. The commercial products have multiple components; the major constituent is *bacitracin A*. A unit of the antibiotic is equivalent to 26 μg of the U.S. Pharmacopeia standard.

Antimicrobial Activity, Mechanism of Action, and Resistance

Bacitracin inhibits the synthesis of the cell wall; a variety of gram-positive cocci and bacilli, *Neisseria*, *H. influenzae*, and *T. pallidum* are sensitive to the drug at 0.1 unit/mL or less. *Actinomyces* and *Fusobacterium* are inhibited by concentrations of 0.5 to 5 units/mL. *Enterobacteriaceae*, *Pseudomonas*, *Candida* spp., and *Nocardia* are resistant to the drug. Few data are available on *bacitracin* resistance.

ADME and Therapeutic Uses

Current use is largely restricted to topical application. *Bacitracin* is available in ophthalmic and dermatologic ointments and creams. A number of topical preparations of *bacitracin*, to which *neomycin* or *polymyxin B* or both (with or without *pramoxine* or *lidocaine*) have been added, are available. For open infections, such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. *Bacitracin* rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer, when caused by susceptible bacteria, respond well to the topical use of *bacitracin*. *Bacitracin* has been used with limited success for eradication of nasal carriage of staphylococci.

Adverse Effects

Nephrotoxicity results from the parenteral use of *bacitracin*.

Drug Facts for Your Personal Formulary: *Cell Envelope Disruptors: β-Lactam, Glycopeptide, and Lipopeptide Antibacterials*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Penicillins—Inhibitors of Bacterial Cell Wall Synthesis **General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis)**		
Penicillin G (IV), penicillin V (PO); IM depot formulations (benzathine, procaine)	• Penicillin-susceptible *Streptococcus pneumoniae* infections: pneumonia, meningitis • Streptococcal pharyngitis, endocarditis, skin and soft-tissue infection • *Neisseria meningitidis* infections • Syphilis	• Excellent activity vs. *Treponema pallidum*, β-hemolytic streptococci, *N. meningitidis,* gram-positive anaerobes • Good activity vs. *S. pneumoniae*, viridans streptococci • CSF penetration with inflammation
Penicillinase-resistant penicillins Oxacillin (IV), nafcillin (IV), dicloxacillin (PO)	• Skin and soft-tissue infections • Serious infections due to MSSA	• Excellent activity vs. MSSA • Good activity vs. streptococci • Nafcillin nonrenal elimination • CSF penetration with inflammation
Aminopenicillins and aminopenicillin/β-lactamase inhibitor combinations Amoxicillin (PO), ampicillin (PO/IV), amoxicillin/clavulanate (PO), ampicillin/sulbactam (IV)	• Respiratory tract infections (sinusitis, pharyngitis, otitis media, community-acquired pneumonia) • *Enterococcus faecalis* infections • *Listeria* infections • Intra-abdominal infections (amoxicillin/clavulanate, ampicillin/sulbactam)	• Ampicillin, amoxicillin: excellent activity vs. β-hemolytic streptococci, *E. faecalis*; good activity vs. *S. pneumoniae*, viridans streptococci, *Haemophilus influenzae;* some activity vs. *Proteus, Escherichia coli* • Ampicillin/sulbactam, amoxicillin/clavulanate: excellent activity vs. *H. influenzae, Bacteroides fragilis, Proteus*; good activity vs. *E. coli, Klebsiella*, MSSA • CSF penetration with inflammation • Rash more common than other penicillins; amoxicillin/clavulanate has more GI adverse effects than amoxicillin alone
Antipseudomonal penicillins Piperacillin/tazobactam (IV)	• Nosocomial infections: pneumonia, intra-abdominal infections, urinary tract infections	• Activity: ampicillin/sulbactam plus excellent activity vs. *E. coli*, *Klebsiella*; good activity vs. *Pseudomonas, Citrobacter, Enterobacter* • Poor CSF penetration of tazobactam component
Cephalosporins—Inhibitors of Bacterial Cell Wall Synthesis **General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis)**		
First-generation cephalosporins Cefazolin (IV), cephalexin (PO), cefadroxil (PO)	• Skin and soft-tissue infections • Serious infections due to MSSA • Perioperative surgical prophylaxis	• Excellent activity vs. MSSA, streptococci • Some activity vs. *Proteus, E. coli, Klebsiella* • Poor CSF penetration
Second-generation cephalosporins Cefuroxime (IV/PO), cefoxitin (IV), cefotetan (IV), cefaclor (PO), cefprozil (PO)	• Upper respiratory tract infections (sinusitis, otitis media) • Cefoxitin/cefotetan: gynecologic infections, perioperative surgical prophylaxis	• Good activity vs. MSSA, streptococci, *H. influenzae*, *Proteus*, *E. coli, Klebsiella* • Cefoxitin/cefotetan: some activity vs. *B. fragilis*
Third-generation cephalosporins Cefotaxime (IV), ceftriaxone (IV), cefpodoxime (PO), cefixime (PO), cefdinir (PO), cefditoren (PO), ceftibuten (PO)	• Community-acquired pneumonia, meningitis, urinary tract infections • Streptococcal endocarditis • Gonorrhea • Severe Lyme disease	• Excellent activity against streptococci, *H. influenzae*, *Proteus*, *E. coli, Klebsiella, Serratia, Neisseria* • Good activity vs. MSSA • Ceftriaxone renal and nonrenal elimination • Good CSF penetration • Ceftriaxone: neonatal kernicterus (use cefotaxime), biliary pseudolithiasis
Antipseudomonal cephalosporins Ceftazidime (IV), ceftolozane/tazobactam (IV), ceftazidime/avibactam (IV), cefepime (IV), cefiderocol (IV)	• Nosocomial infections: pneumonia, meningitis, urinary tract infections, intra-abdominal infections (with metronidazole)	• Excellent activity against *H. influenzae*, *Proteus*, *E. coli, Klebsiella, Serratia, Neisseria,* streptococci, MSSA[a] • Good activity vs. *Pseudomonas* (ceftazidime/avibactam, cefiderocol, ceftolozane/tazobactam >> ceftazidime, cefepime) • Some activity vs. *Enterobacter* (cefepime, ceftazidime/avibactam, cefiderocol >> ceftazidime, ceftolozane/tazobactam) • Ceftazidime/avibactam, cefiderocol active vs. ESBL- and KPC-producing Enterobacterales • Good CSF penetration • Cefepime: encephalopathy at high doses
Anti-MRSA cephalosporins Ceftaroline (IV)	• Community-acquired pneumonia • Skin and soft-tissue infections	• Excellent activity against streptococci, MSSA, MRSA[b] *H. influenzae*, *Proteus*, *E. coli, Klebsiella*, *Serratia*

Drug Facts for Your Personal Formulary: *Cell Envelope Disruptors: β-Lactam, Glycopeptide, and Lipopeptide Antibacterials* (*continued*)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Carbapenems—Inhibitors of Bacterial Cell Wall Synthesis **General: Bactericidal, renal elimination, hypersensitivity reactions (rash, anaphylaxis), seizure risk**		
Imipenem/cilastatin (IV), imipenem/cilastatin/relebactam (IV), meropenem (IV), meropenem/vaborbactam (IV)	• Nosocomial infections: pneumonia, intra-abdominal infections, urinary tract infections • Meningitis (meropenem)	• Excellent activity against streptococci, MSSA, *H. influenzae*, *Proteus*, *E. coli*, *Klebsiella*, *Serratia*, *Enterobacter*, *B. fragilis* • Good activity vs. *Pseudomonas Acinetobacter*, *Enterococcus faecalis*[c] • Good activity vs. carbapenemase-producing gram-negatives (imipenem/cilastatin/relebactam, meropenem/vaborbactam only) • Good CSF penetration • Imipenem coformulated with renal dihydropeptidase inhibitor cilastatin • Seizures at high doses in patients with prior seizure history (imipenem > meropenem)
Ertapenem (IV)	• Community-acquired infections and nosocomial infections without *Pseudomonas* risk	• Excellent activity against streptococci, MSSA, *H. influenzae*, *Proteus*, *E. coli*, *Klebsiella*, *Serratia*, *Enterobacter*, *B. fragilis* • Lacks activity against *Pseudomonas*, *Acinetobacter*, *Enterococcus* • Lower seizure risk than imipenem
Monobactam—Inhibitor of Bacterial Cell Wall Synthesis		
Aztreonam (IV, inhaled)	• Nosocomial infections: pneumonia, urinary tract infections	• Excellent activity against *H. influenzae*, *Proteus*, *E. coli*, *Klebsiella*, *Serratia* • Good activity vs. *Pseudomonas* • Lacks any gram-positive activity • Lacks cross-allergenicity with other β-lactams (except ceftazidime, ceftolozane, cefiderocol) • Good CSF penetration, renal elimination
Glycopeptides and Lipoglycopeptides—Inhibitors of Cell Wall Synthesis		
Vancomycin (IV, PO)	• Skin and soft-tissue infections • Bacteremia and endocarditis due to gram-positive bacteria • Pneumonia • Meningitis • *Clostridium difficile* colitis (oral formulation) • Surgical prophylaxis for procedures with high risk of MRSA	• Good activity vs. vast majority of gram-positive bacteria, *Staphylococcus* (including MRSA), streptococci, *E. faecalis* • Oral formulation not well absorbed and used only for treatment of *C. difficile* colitis • Modest CNS penetration in presence of inflammation • Renal elimination • Infusion-related reactions associated with rapid infusion • Nephrotoxicity with greater doses
Telavancin (IV)	• Skin and soft-tissue infections • Pneumonia	• Similar activity to vancomycin with activity against some vancomycin-resistant strains of *Enterococcus* • Renal elimination • Higher nephrotoxicity relative to vancomycin • QT prolongation • Avoid in pregnancy
Dalbavancin (IV)	• Skin and soft-tissue infections	• Similar activity to vancomycin • Highly protein bound • Extremely long $t_{1/2}$; once-weekly dosing for skin infections
Oritavancin (IV)	• Skin and soft-tissue infections	• Similar activity to telavancin • Highly protein bound • Extremely long $t_{1/2}$; single-dose therapy for skin infections
Lipopeptides—Disruptors of Bacterial Cell Membranes		
Daptomycin (IV)	• Skin and soft-tissue infections • Staphylococcal and streptococcal bacteremia • Vancomycin-resistant enterococcal infections	• Lipopeptide, similar spectrum of activity as vancomycin • Active against many vancomycin-resistant strains of *Enterococcus* • Highly protein bound; limited CNS penetration • Inactivated by pulmonary surfactant; not effective for pneumonia • Renal elimination • Rare myositis and rhabdomyolysis

MSSA, methicillin-sensitive *S. aureus*.
[a]Cefepime only.
[b]Only β-lactam with significant activity versus MRSA.
[c]Imipenem only.

Chapter 59

Miscellaneous Antibacterials: Aminoglycosides, Polymyxins, Urinary Antiseptics, Bacteriophages

Conan MacDougall and Robert T. Schooley

The small-molecule agents discussed in this chapter—aminoglycosides, polymyxins, and urinary antiseptics—primarily target gram-negative bacteria and have a limited set of clinical applications due to their toxicities and pharmacokinetic properties. Additionally, we discuss the (re-) emerging application of phages in infectious diseases therapeutics.

Aminoglycosides

ORIGINS

Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. *Streptomycin* was first isolated from a strain of *Streptomyces griseus*. *Gentamicin* and *netilmicin* are derived from species of the actinomycete *Micromonospora*. The difference in spelling (*-micin*) compared with the other aminoglycoside antibiotics (*-mycin*) reflects this difference in origin. *Tobramycin* is one of several components of an aminoglycoside complex known as "nebramycin" that is produced by *Streptomyces tenebrarius*. It is most similar in antimicrobial activity and toxicity to *gentamicin*. In contrast to the other aminoglycosides, *amikacin* (a derivative of kanamycin) and *netilmicin* and *plazomicin* (derivatives of sisomicin) are semisynthetic products.

Aminoglycosides (*gentamicin, tobramycin, amikacin, netilmicin, plazomicin, kanamycin, streptomycin, paromomycin,* and *neomycin*) are used primarily to treat infections caused by aerobic gram-negative bacteria. *Streptomycin* and *amikacin* are important agents for the treatment of mycobacterial infections, and *paromomycin* is used orally for intestinal amebiasis. Aminoglycosides are *bactericidal inhibitors* of protein synthesis. Most commonly, resistance is due to aminoglycoside-modifying enzymes or impaired accumulation of drug at the target site; these mechanisms may confer resistance to all aminoglycosides or only select agents. Resistance genes are frequently acquired via plasmids or transposons.

Aminoglycosides contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 59–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in CSF, and all are excreted relatively rapidly by the normal kidney. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve, although the relative propensities for toxicity vary somewhat among the agents.

Mechanism of Action

The aminoglycoside antibiotics are rapidly bactericidal against susceptible gram-negative organisms. Bacterial killing is concentration dependent: The higher the concentration, the greater is the rate of bacterial killing. The ratio of the peak concentration to the organism's *MIC* is thus a driver of aminoglycoside efficacy, although total drug exposure (AUC:MIC) is also an important predictor of antibacterial effect (Bland et al., 2018). The inhibitory activity of aminoglycosides persists after the serum concentration has fallen below the MIC, a phenomenon known as the *postantibiotic effect*. These properties help to explain the efficacy of high-dose, extended-interval dosing regimens.

Aminoglycosides diffuse through aqueous channels formed by *porin* proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on a transmembrane electrical gradient coupled to electron transport to drive permeation of these antibiotics. This energy-dependent phase is rate limiting and can be blocked or inhibited by divalent cations (e.g., Ca^{2+} and Mg^{2+}), hyperosmolarity, a reduction in pH, and anaerobic conditions. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess and in hyperosmolar acidic urine.

Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation (Figure 59–2). The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit. At least three

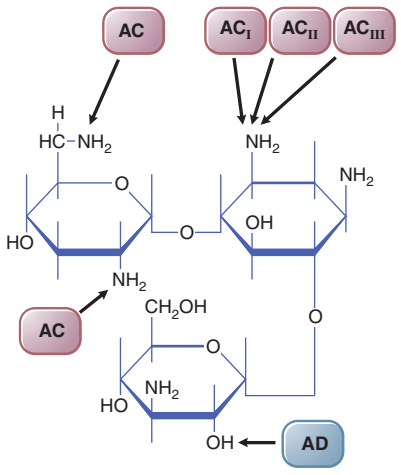
G6PD: glucose-6-phosphate dehydrogenase
GI: gastrointestinal
IM: intramuscular
IV: intravenous
MIC: minimal inhibitory concentration
mRNA: messenger RNA
PFU: plaque-forming units
PO: by mouth
UTI: urinary tract infection

of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, contribute to the *streptomycin*-binding site. *Aminoglycosides interfere with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes; the drugs also can cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains* (Davis, 1988). The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport (Busse et al., 1992).

Antimicrobial Activity

The antibacterial activity of *gentamicin, tobramycin, amikacin*, and *plazomicin* is directed primarily against aerobic gram-negative bacilli (Mingeot-Leclercq et al., 1999). *Kanamycin*, like *streptomycin*, has a more limited spectrum. The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (Table 59–1), although most Enterobacterales are susceptible. The superior activity of *tobramycin* against *Pseudomonas aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by



Tobramycin

Figure 59–1 *Aminoglycoside structure and sites of activity of plasmid-mediated enzymes capable of inactivating aminoglycosides. Tobramycin* is shown as a representative; structural characteristics protect some aminoglycosides from the actions of some of these enzymes, explaining differences in spectrum of activity. AC, acetylase; AD, adenylase.

this organism. Among other nonfermenting gram-negative rods such as *Acinetobacter*, *Stenotrophomonas*, and *Burkholderia,* aminoglycosides are uncommonly to rarely active. Gram-negative aerobic cocci such as *Neisseria*, *Moraxella*, and *Haemophilus* have varying susceptibilities. An increasing number of gram-negative bacilli encountered in health-care settings (especially *Klebsiella* and *Pseudomonas*) display extensive resistance to multiple classes of antibacterials; in these isolates, aminoglycosides may be the only class of commonly used agents with *in vitro* activity. *Amikacin* and *plazomicin* are typically the most active aminoglycosides against multidrug-resistant gram-negative bacilli.

Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as single agents to treat infections caused by gram-positive bacteria. However, in combination with a cell wall–active agent, such as a *penicillin* or *vancomycin*, an aminoglycoside may produce a synergistic bactericidal effect *in vitro*. This effect has been most commonly employed for treatment of infections due to staphylococci, enterococci, viridans group streptococci, and *Listeria*. *Gentamicin* (or in some cases *streptomycin*) is the drug of choice for use in combination therapies against gram-positive organisms, since other agents such as *tobramycin* and *amikacin* are minimally active. Clinically, the superiority of aminoglycoside combination regimens over cell wall agents alone is not proven except in relatively few infections (discussed later in the chapter).

Paromomycin (also known as *aminosidine*) is an aminoglycoside that is structurally related to *neomycin*. It has antibacterial activity similar to other aminoglycosides but has particularly notable antiparasitic activity. Parasites that are usually susceptible to *paromomycin* include *Leishmania* spp., *Entamoeba histolytica*, *Giardia lamblia*, and *Cryptosporidium parvum.*

Resistance to the Aminoglycosides

Bacteria may be resistant to aminoglycosides through

- inactivation of the drug by microbial enzymes;
- failure of the antibiotic to penetrate intracellularly; and
- low affinity of the drug for the bacterial ribosome.

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids. These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (see Figure 59–1). The ability of these enzymes to attack these groups in differing aminoglycosides explains some of the variability in antimicrobial activity across the class. *Amikacin* is a suitable substrate for only a few of these inactivating enzymes; thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to *amikacin*, particularly among gram-negative bacilli. *Plazomicin* likewise has structural modifications that make it a poor substrate for most aminoglycoside-modifying enzymes, expanding its activity against resistant gram-negatives, including among carbapenem-resistant isolates. A significant percentage of clinical isolates of *Enterococcus faecalis* and *Enterococcus faecium* are highly resistant to all aminoglycosides (Eliopoulos et al., 1984). Resistance to *gentamicin* in these organisms indicates cross-resistance to *tobramycin*, *amikacin*, *kanamycin*, and *netilmicin* because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures between *streptomycin* and other aminoglycosides, the most common enzyme seen in enterococci does not modify *streptomycin*, which is inactivated by another enzyme. Consequently, *gentamicin*-resistant strains of enterococci may be susceptible to *streptomycin*. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Transport of aminoglycosides across the cytoplasmic membrane is an active process that depends on oxidative metabolism. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

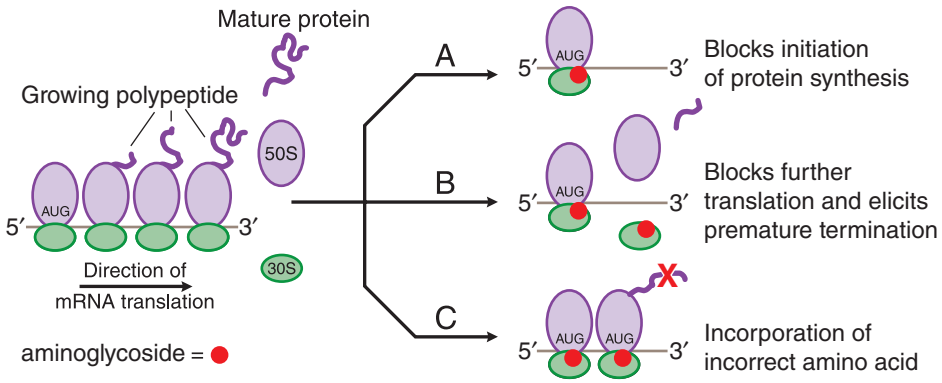


Figure 59–2 *Effects of aminoglycosides on protein synthesis.* **A.** Aminoglycoside (represented by red circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S-50S ribosomal complex at the start codon (AUG) of mRNA. As 30S-50S complexes downstream complete translation of mRNA and detach; the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to **B**, premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or **C**, incorporation of incorrect amino acids (indicated by the red X), resulting in the production of abnormal or nonfunctional proteins.

ADME

Absorption

The aminoglycosides are polar cations and therefore are poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. Nonetheless, long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of *gentamicin* from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Intoxication may occur when aminoglycosides are applied topically for long periods to large wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30 to 90 min. These concentrations range from 4 to 12 μg/mL following a 1.5- to 2-mg/kg dose of *gentamicin*, *tobramycin*, or *netilmicin*; from 20 to 35 μg/mL following a 7.5-mg/kg dose of *amikacin* or *kanamycin*; and from 100 to 150 μg/mL following a 15-mg/kg dose of *plazomicin*. There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic *P. aeruginosa* or mycobacterial pulmonary infections (Geller et al., 2002). *Amikacin* and *tobramycin* solutions for injection have been used, and commercially available preparations of these agents designed specifically for inhalation are now available. *Neomycin* is not used for parenteral administration; it is currently available in many brands of creams, ointments, and other products alone and in combination with *polymyxin*, *bacitracin*, other antibiotics, a variety of corticosteroids, and *lidocaine*. *Paromomycin* is available for parenteral use outside of the United States but is primarily used for its intraluminal activity as a poorly absorbed antiparasitic agent.

Distribution

Because of their polar nature, the aminoglycosides do not penetrate well into many tissues. Except for *streptomycin*, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients.

Concentrations of aminoglycosides in secretions and tissues are low (Panidis et al., 2005). High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contributes to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities. Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic (Kearney and

TABLE 59–1 ■ SUSCEPTIBILITIES AND TYPICAL MINIMAL CONCENTRATIONS THAT WILL INHIBIT 90% (MIC_{90}) OF CLINICAL ISOLATES FOR GRAM-NEGATIVE ORGANISMS

SPECIES	% SUSCEPTIBLE (MIC_{90} μg/mL)

Aweeka, 1999), and owing to their dose-related toxicity, dose increases to provide greater concentrations are not feasible. Treatment of meningitis with intravenous administration is generally suboptimal. Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels in the CNS, but the availability of extended-spectrum cephalosporins has generally made this unnecessary.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. *Streptomycin* and *tobramycin* can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; therefore, these agents should be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

Metabolism and Excretion

The aminoglycosides undergo minimal metabolism and are excreted almost entirely by glomerular filtration, achieving urine concentrations of 50 to 200 μg/mL. The half-lives of the aminoglycosides in plasma are 2 to 3 h in patients with normal renal function. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the $t_{1/2}$ of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the $t_{1/2}$ varies from 20 to 40 times that determined in normal individuals. *Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall exposure to aminoglycosides, it is critical to reduce the maintenance dose and/or extend the dosing interval of these drugs in patients with impaired renal function.*

Although excretion of aminoglycosides is similar in adults and children older than 6 months, half-lives of aminoglycosides may be prolonged significantly in the newborn: 8 to 11 h in the first week of life in newborns weighing less than 2 kg and about 5 h in those weighing more than 2 kg. Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates. Aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis (Young et al., 2013). Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue. Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis.

Aminoglycosides can be inactivated by various penicillins *in vitro* and thus should not be admixed in solution (Blair et al., 1982). Some reports indicate that this inactivation may occur *in vivo* in patients with end-stage renal failure, making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. *Amikacin* appears to be the aminoglycoside least affected by this interaction; penicillins with more nonrenal elimination (e.g., *piperacillin*) may be less prone to cause this interaction.

Dosing and Monitoring

High-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Administering higher doses at extended intervals (i.e., once daily) is likely to be at least equally efficacious and potentially less toxic than administration of divided doses. This dosing strategy takes advantage of the concentration-dependent activity of aminoglycosides to achieve maximal initial bacterial killing, and because of the post-antibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic oto- and nephrotoxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (compare the two dosage regimens shown in Figure 59–3). Typical doses for high-dose, extended-interval strategies are 5 to 7 mg/kg for *gentamicin* and *tobramycin*, 15 to 25 mg/kg for *amikacin*, and 15 mg/kg for *plazomicin*; among patients with normal renal function, these doses are administered every 24 h.

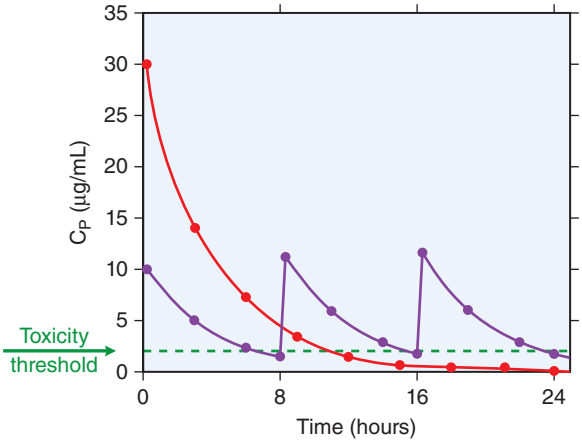

Figure 59–3 *Comparison of single-dose and divided-dose regimens for gentamicin.* In a hypothetical patient, a dose of *gentamicin* (5.1 mg/kg) is administered intravenously as a single bolus (red line) or in three portions, a third of the dose every 8 h (purple line), such that the total drug administered is the same in the two cases. The threshold for toxicity (green dashed line) is the plasma concentration of 2 μg/mL, the maximum recommended for prolonged exposure. The single-dose regimen produces a higher plasma concentration than the regimen given every 8 h; this higher peak provides efficacy that otherwise might be compromised due to prolonged subthreshold concentrations later in the dosing interval or that is provided by the lower peak levels achieved with the regimen every 8 h. The once-daily regimen also provides a 13-h period during which plasma concentrations are below the threshold for toxicity. The every-8-h regimen, by contrast, provides only three short (~1 h) periods in 24 h during which plasma concentrations are below the threshold for toxicity. The single high-dose, extended interval is generally preferred for aminoglycosides, with a few exceptions (during pregnancy, in neonates, etc.), as noted in the text.

Populations in which use of the high-dose/extended-interval dosing strategy is more controversial include pregnant patients, neonates, and pediatric patients and as combination therapy for endocarditis (Contopoulos-Ioannidis et al., 2004; Nestaas et al., 2005; Ward and Theiler, 2008). In these infections, multiple daily doses (with a lower total daily dose) are preferred by some clinicians since data documenting equivalent safety and efficacy of extended-interval dosing are more limited than in other adult populations. Extended-interval dosing is sometimes avoided in patients with significant renal dysfunction (i.e., creatinine clearance <25 mL/min), since every-36-h or every-48-h dosing schedules are often required. Typical doses for divided-dosing strategies are 1.7 to 2 mg/kg every 8 h for *gentamicin* and *tobramycin*. The dose range of *streptomycin* for most indications is 15 to 25 mg/kg daily or in divided doses twice daily. For long-term therapy of mycobacterial infections, three-times-weekly dosing of *amikacin* or *streptomycin* may be employed.

Concentrations of aminoglycosides achieved in plasma after a given dose vary widely among patients, and therapeutic drug monitoring is standard practice, especially among seriously ill patients (Abdul-Aziz et al., 2020). Traditionally, the peak concentration has been used to document that the dose produces therapeutic concentrations, while the trough concentration is used to avoid toxicity. For high-dose, extended-interval dosing regimens, fully characterizing the pharmacokinetics can be done through drawing peak and "midpoint" (6–18 h after the end of infusion) concentrations and calculating the predicted AUC (Bland et al., 2018). Alternatively, use of "random" concentrations obtained 6 to 18 h after infusion with comparison to a published nomogram is a less-intensive monitoring approach. For *plazomicin*, the manufacturer recommends obtaining trough concentrations, with dosage adjustment as necessary to maintain a trough below 3 μg/mL. For twice-daily and three-times-daily dosing strategies, steady-state trough concentrations should be less than 1 to 2 μg/mL for *gentamicin*, *netilmicin*, and *tobramycin* and less than

10 μg/mL for *amikacin* and *streptomycin*. Peak level goals vary by indication and infection severity but range from 4 to 8 μg/mL for *gentamicin*, *netilmicin*, and *tobramycin* and from 20 to 35 μg/mL for *amikacin* under twice-daily and three-times-daily strategies. When *gentamicin* is used at lower doses for synergistic effects with cell wall–acting agents to treat gram-positive infections, peak levels of 3 to 4 μg/mL and less than 1 μg/mL are recommended.

Therapeutic Uses

Several different types of infections can be treated successfully with aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less-toxic agent is contraindicated or less effective. When multiple aminoglycosides are appropriate for an indication, *gentamicin* is typically preferred because of long experience with its use and its lower cost.

Aminoglycosides may be used in combination with a cell wall–active agent (*β-lactam or glycopeptide*) for the therapy of serious proven or suspected bacterial infections. The three rationales for this approach are as follows:

- To expand the empiric spectrum of activity of the antimicrobial regimen
- To provide synergistic bacterial killing
- To prevent the emergence of resistance to the individual agents

Empiric combination therapy is used in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa*, *Enterobacter*, *Klebsiella*, and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire. The use of aminoglycosides to achieve synergistic bacterial killing and improve clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus* (Le and Bayer, 2003). Clinical data do not support the routine use of combination therapy for synergistic killing or suppression of emergent resistance of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections (Bliziotis et al., 2005). Aminoglycosides (primarily *streptomycin* and *amikacin*) may be a component of combination regimens for treatment of mycobacterial infections, usually due to the presence of multidrug resistance (see Chapter 65).

Urinary Tract Infections

Although the spectrum of activity and concentration in the urinary tract of aminoglycosides make them well suited for treatment of urinary tract infections, less-toxic alternatives are preferred for uncomplicated infections. However, as strains of *Escherichia coli* have acquired resistance to β-lactams, *trimethoprim-sulfamethoxazole*, and fluoroquinolones, use of aminoglycosides for urinary tract infections may increase. A single intramuscular dose of *gentamicin* (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. A 10- to 14-day course of *gentamicin* or *tobramycin* is an alternative for treatment of pyelonephritis if other agents cannot be used. *Plazomicin* is FDA-approved for treatment of complicated urinary tract infections including pyelonephritis when patients have limited or no treatment options, at a dose of 15 mg/kg daily.

Pneumonia

Aminoglycosides are ineffective for the treatment of pneumonia due to *Streptococcus pneumoniae*, which is a common cause of community-acquired pneumonia. In hospital-acquired pneumonia where aerobic multidrug-resistant gram-negative bacilli are frequently causative pathogens, an aminoglycoside in combination with a β-lactam antibiotic is recommended as standard empiric therapy to increase the likelihood that at least one agent is active against the infecting pathogen (Kalil et al., 2016). Once it is established that the β-lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside.

Meningitis

Availability of third-generation cephalosporins, especially *cefotaxime* and *ceftriaxone*, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β-lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*) and for *Listeria* meningitis (where a combination of *ampicillin* and *gentamicin* is recommended). If an aminoglycoside is necessary, direct instillation into the CNS is more likely to achieve therapeutic levels than intravenous administration. In adults, this can be achieved with 5 mg of a preservative-free formulation of *gentamicin* (or equivalent dose of another aminoglycoside) administered intrathecally or intraventricularly once daily.

Bacterial Endocarditis

"Synergistic" or low-dose *gentamicin* (3 mg/kg per day) in combination with a *penicillin* or *vancomycin* has been recommended in certain circumstances for treatment of bacterial endocarditis due to certain gram-positive organisms. *Penicillin* and *gentamicin* in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. For this indication, *gentamicin* may be given as a consolidated once-daily dose. In cases of enterococcal endocarditis, concomitant administration of *penicillin* (or *ampicillin*) and *gentamicin* (given as divided doses) for 4 to 6 weeks is recommended as standard therapy. However, safer alternatives, such as *ampicillin/ceftriaxone* combinations or use of the aminoglycoside for only the first 2 to 3 weeks, are gaining favor to limit the risk of toxicity due to prolonged aminoglycoside administration (Baddour et al., 2015). A 2-week regimen of *gentamicin* in combination with *nafcillin* is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis. For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits (Cosgrove et al., 2009).

Tularemia

Streptomycin (or *gentamicin*) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1 to 2 g (15–25 mg/kg) *streptomycin* per day (in divided doses) for 10 to 14 days.

Plague

A 10-day treatment course of *streptomycin* or *gentamicin* is recommended for severe forms of plague.

Mycobacterial Infections

Amikacin and *streptomycin* are second-line agents for the treatment of active tuberculosis as part of a combination regimen, usually employed if the patient's organism is resistant to standard therapy. *Amikacin* is also used as a component of combination regimens for nontuberculous mycobacteria (e.g., *M. avium, M. abscessus, M. chelonae*). See Chapter 65 for more about the use of these agents in treating tuberculosis and *M. avium* complex.

Parasitic Infections

Paromomycin's antiparasitic activity is leveraged to treat intestinal protozoal infections due to *E. histolytica*, *G. lamblia*, and *C. parvum*. It is available as oral capsules and indicated for treatment of intestinal amebiasis at a dose of 25 to 35 mg/kg per day in three divided doses. The drug also has activity against *Leishmania* spp., and is used parenterally for visceral leishmaniasis and topically for cutaneous leishmaniasis, although these formulations are not available in the United States (Ben Salah et al., 2013).

Cystic Fibrosis

Recurrent infections due to multidrug-resistant gram-negative bacilli, especially *Pseudomonas* species, are a hallmark of cystic fibrosis. Aminoglycosides are frequently used as therapy during acute exacerbations of cystic fibrosis, for which higher-than-standard doses (e.g., 10 mg/kg of *tobramycin*) are frequently employed due to the unusual pharmacokinetics observed in patients with cystic fibrosis. These agents may also be administered via inhalation between exacerbations to improve lung function and reduce exacerbation frequency.

Topical Applications

Neomycin is used widely for topical application in a variety of infections of the skin and mucous membranes. The oral administration of *neomycin* (usually in combination with *erythromycin* base) has been employed

primarily for "preparation" of the bowel for surgery. Orally administered *neomycin* is poorly absorbed from the GI tract—about 97% of an oral dose of *neomycin* is not absorbed and is eliminated unchanged in the feces. The portion that is absorbed is excreted by the kidney; a total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. *Neomycin* and *polymyxin B* have been used for irrigation of the bladder to prevent bacteriuria and bacteremia associated with indwelling catheters. For this purpose, 1 mL of a preparation containing 40 mg *neomycin* and 200,000 units *polymyxin B* per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The bladder is irrigated at the rate of 1 L every 24 h.

Neomycin is frequently employed as a topical agent for treatment of skin and mucous membrane infections, including as a component of over-the-counter therapies. Oral administration of aminoglycosides may be employed as "bowel prep" prior to surgical procedures or as "selective digestive decontamination" to reduce the risk of ventilator-associated pneumonia.

Adverse Effects

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity and neuromuscular blockade.

Ototoxicity

Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides (Guthrie, 2008). Aminoglycoside-induced ototoxicity may result in irreversible, bilateral, high-frequency hearing loss or vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Drugs such as *ethacrynic acid* and *furosemide* potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating *furosemide* are less convincing (Smith and Lietman, 1983).

Streptomycin and *gentamicin* produce predominantly vestibular effects, whereas *amikacin*, *kanamycin*, and *neomycin* primarily affect auditory function; *tobramycin* affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence could be as high as 25% (Brummett and Morrison, 1990). The incidence of vestibular toxicity is particularly high in patients receiving *streptomycin*; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage. Because the initial symptoms may be reversible, patients receiving high doses or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued.

A high-pitched tinnitus often is the first symptom of cochlear toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges are affected.

Among patients experiencing vestibular toxicity, moderately intense headache lasting 1 to 2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1 to 2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement ("mental past-pointing"), and difficulty in sitting or standing without visual cues. The acute stage ends suddenly and is followed by chronic labyrinthitis, in which the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for about 2 months. Recovery from this phase may require 12 to 18 months, and most patients have some permanent residual damage. Early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity

Approximately 8% to 26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells. The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border followed by mild proteinuria and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days. The nonoliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity of the collecting duct epithelium to vasopressin. Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate (Lietman and Smith, 1983). Toxicity correlates with the total amount of drug administered and with longer courses of therapy (de Jager and van Altena, 2002). High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by the area under the curve) than divided-dose approaches (see Figure 59–3). *Neomycin*, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. *Streptomycin* does not concentrate in the renal cortex and is the least nephrotoxic. Drugs such as *amphotericin B, vancomycin*, angiotensin-converting enzyme inhibitors, *cisplatin*, and *cyclosporine* may potentiate aminoglycoside-induced nephrotoxicity.

Neuromuscular Blockade

Acute neuromuscular blockade and apnea have been attributed to the aminoglycosides; patients with myasthenia gravis are particularly susceptible. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Neuromuscular blockade may be reversed by intravenous administration of a Ca^{2+} salt.

Other Adverse Effects

In general, the aminoglycosides have little allergenic potential. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity among drugs in this class. Aminoglycosides appear to be less commonly associated with superinfection due to *Clostridium difficile* than other classes of antibacterials. Individuals treated with 4 to 6 g/day of *neomycin* by mouth sometimes develop a sprue-like syndrome with diarrhea, steatorrhea, and azotorrhea; overgrowth of yeasts in the intestine also may occur. Orally administered *paromomycin* is associated with dose-related gastrointestinal toxicity, including nausea, abdominal pain, and diarrhea.

Polymyxins

The polymyxins are a group of closely related antibiotics elaborated by strains of *Bacillus polymyxa*. *Polymyxin B* is a mixture of polymyxins B_1 and B_2. *Colistin*, also known as *polymyxin E,* produced by *Bacillus colistinus,* is marketed either as *colistimethate* for intravenous administration or *colistin* base for topical use. These agents were initially developed more than 50 years ago but quickly fell out of favor for systemic use due to their toxicities. With the rise of resistant gram-negative organisms in the past decade, the use of polymyxins has increased.

Mechanism of Action

Polymyxins, simple basic peptides with molecular masses of approximately 1000 Da, are surface-active amphipathic agents that act as cationic

detergents. They interact strongly with phospholipids and disrupt the structure of cell membranes; sensitivity to *polymyxin B* appears related to the phospholipid content of the cell wall–membrane complex. *Polymyxin B* binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule.

Antimicrobial Activity

The antimicrobial activities of *polymyxin B* and *colistin* are similar and restricted to gram-negative bacteria, primarily aerobes. Most *Pseudomonas*, *Acinetobacter*, and Enterobacterales are susceptible, except for *Proteus* and *Serratia* spp. *Stenotrophomonas* and *Burkholderia* are usually resistant.

Resistance to Polymyxins

Although resistance among normally susceptible isolates to polymyxins is uncommon, emergence of resistance while on treatment has been documented and has become problematic among extensively drug-resistant *Acinetobacter* and *Klebsiella* (Rojas et al., 2017). Emergent resistance may occur over the course of a single treatment course.

ADME

Polymyxin B and *colistin* are not absorbed when given orally and are poorly absorbed from mucous membranes and surfaces of large burns. CMS (*colistimethate*) is the prodrug formulation for parenteral administration; it is hydrolyzed relatively slowly in the bloodstream to the active colistin sulfate moiety. There is significant interpatient variability in active colistin sulfate levels due to the competing effects of mostly renal elimination of the CMS parent drug, conversion of CMS to active *colistin*, and mostly nonrenal elimination of active *colistin*. CMS may be administered via inhalation for prevention and adjunctive treatment of lung infections. Intraventricular and intrathecal administration of CMS has been used for treatment of CNS infections. Patients with renal dysfunction require dose modification for CMS. *Polymyxin B* does not require conversion to its active moiety and primarily undergoes nonrenal clearance.

Therapeutic Uses

Because dosing of these agents varies by drug (*polymyxin B* or *colistin*), by the particular commercial preparation marketed in a specific country, and by the patient's degree of renal dysfunction, expert consultation is recommended (Tsuji et al., 2019).

Systemic Uses

Polymyxins are used systemically only for serious infections due to pathogens resistant to other effective therapies. Studies suggest polymyxins are less effective than newly introduced agents (e.g., *ceftazidime/avibactam*) for treatment of serious multidrug-resistant infections and should be reserved for infections due to pathogens resistant to these agents. Polymyxins have been used for treatment of a variety of infections when more effective and less toxic alternatives are not available, including bacteremia, pneumonia, bone/joint infections, burns, cellulitis, cystic fibrosis, endocarditis, gynecologic infections, meningitis, and ventriculitis. Polymyxins are often used in combination with other antimicrobials, including carbapenems, tetracyclines, and aminoglycosides. *Polymyxin B* is preferred for treatment of most systemic infections, while CMS is recommended for treatment of infections originating in the urinary tract (Tsuji et al., 2019). Inhaled *colistin* is used for prophylaxis against infection in some patients at risk for infection (e.g., lung transplant) and as an adjunct in the treatment of pneumonia.

Topical Uses

Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. *Colistin* is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to *polymyxin B*–sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *P. aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of *polymyxin B* often is curative.

Adverse Effects

The primary toxicity of polymyxins is dose-related nephrotoxicity via damage to renal tubular cells; the therapeutic window between effective and toxic exposures is narrow. Depending on the definitions of nephrotoxicity and patient populations, acute kidney injury may occur in up to 50% to 60% of patients. Although data are limited, nephrotoxicity may be modestly lower with *polymyxin B* relative to CMS (Zavascki and Nation, 2017). Patients who experience nephrotoxicity may require dose reduction or drug discontinuation.

Neurological reactions include muscle weakness, apnea, paresthesia, vertigo, and slurred speech. *Polymyxin B* applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitivity reactions are uncommon.

Antiseptic Agents for Urinary Tract Infections

Urinary tract antiseptics are concentrated in the lower urinary tract, where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections at the concentrations achievable with oral administration because effective concentrations are not achieved in plasma with safe doses; however, they can achieve concentrations adequate to treat and/or prevent UTIs.

Nitrofurantoin

Nitrofurantoin is a synthetic nitrofuran that is used for the prevention and treatment of UTIs.

Mechanism of Action and Antimicrobial Activity

Nitrofurantoin is activated by enzymatic reduction, with the formation of highly reactive intermediates that seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce *nitrofurantoin* more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. *Nitrofurantoin* is active against many strains of *E. coli* and enterococci. However, most *Proteus* and *Pseudomonas* spp. and many species of *Enterobacter* and *Klebsiella* are resistant. *Nitrofurantoin* is bacteriostatic for most susceptible microorganisms at concentrations of 32 μg/mL or less and is bactericidal at concentrations of 100 μg/mL or more. The antibacterial activity is higher in acidic urine.

Pharmacology, Toxicity, and Therapeutic Uses

Nitrofurantoin is absorbed rapidly and nearly completely from the GI tract. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly: The plasma $t_{1/2}$ is 0.3 to 1 h; about 40% is excreted unchanged into the urine. The average dose of *nitrofurantoin* yields a concentration in urine of about 200 μg/mL. This concentration is soluble at pH greater than 5, but the urine should not be alkalinized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance; thus, in patients with impaired glomerular function, the efficacy of the drug to treat UTIs may be decreased and the systemic toxicity increased (ten Doesschate et al., 2020).

The oral dosage of *nitrofurantoin* for adults is 50 to 100 mg four times a day with meals and at bedtime, and less for the macrocrystalline formulation (100 mg every 12 h for 7 days). A single 50- to 100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5 to 7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days; repeated courses should be separated by rest periods. Pregnant women and children younger than 1 month should not receive *nitrofurantoin*, and it should be used cautiously in patients with impaired renal function.

Nitrofurantoin is approved for the treatment of lower urinary tract infections and is recommended as first-line therapy for uncomplicated cystitis. It is not recommended for treatment of pyelonephritis or prostatitis.

Adverse Effects

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various other reactions occur occasionally, including chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency and in newborns exhibiting low levels of reduced glutathione in their red blood cells), cholestatic jaundice, and hepatocellular damage. Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. Interstitial pulmonary fibrosis can occur in patients (especially the elderly) taking the drug chronically. Headache, vertigo, drowsiness, muscular aches, and nystagmus occur occasionally but are readily reversible. Severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment. *Nitrofurantoin* colors the urine brown.

Fosfomycin

Fosfomycin is a phosphonic acid derivative that is used primarily for the prevention and treatment of UTIs in the U.S. where only an oral formulation is currently available. In other countries, the intravenous formulation is often used as an adjunctive agent for treatment of serious infections.

Mechanism of Action and Antimicrobial Activity

Fosfomycin inhibits MurA, an enolpyruvyl transferase that catalyzes the initial step in bacterial cell wall synthesis. This mechanism is unique among antibacterials; thus, cross-resistance to other agents is rarely seen. Optimal testing of *fosfomycin* activity requires supplementation of the media with glucose-6-phosphate. *Fosfomycin*'s usual spectrum of activity includes the uropathogens *E. coli*, *Proteus*, *Enterococcus*, and *Staphylococcus saprophyticus*. Activity against *Klebsiella*, *Enterobacter*, and *Serratia* spp. is variable; *Pseudomonas* and *Acinetobacter* are resistant. *Staphylococcus aureus* is frequently susceptible, although emergence of resistance during therapy has been reported.

Pharmacology, Toxicity, and Therapeutic Uses

Outside the U.S., *fosfomycin* is available as an intravenous formulation that can achieve adequate levels to treat some systemic infections, often as a combination with other antibacterials. In the U.S., *fosfomycin* is available only as a powder (*fosfomycin tromethamine*) that is dissolved in water and taken orally. Bioavailability of the oral formulation is approximately 40%, with a $t_{1/2}$ of 5 to 8 h. With oral administration of 3 g, systemic concentrations are low, but urinary concentrations are as high as 1000 to 4000 μg/mL. The FDA-approved dosing regimen is a single 3-g dose for uncomplicated UTI; some investigators have administered 3 g every other day for three doses for complicated UTI or 3 g every 10 days for UTI prophylaxis.

Adverse Effects

Overall, *fosfomycin* is well tolerated. Adverse effects are uncommon and usually consist of GI distress, vaginitis, headache, or dizziness.

Methenamine

Mechanism of Action and Antimicrobial Activity

Methenamine (hexamethylenamine) is a urinary tract antiseptic and prodrug that acts by generating formaldehyde via the following reaction:

$$N_4(CH_2)_6 + 6H_2O + 4H^+ \rightarrow 6HCHO + 4NH^+_4$$

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, requiring 3 h to reach 90% completion. Nearly all bacteria are sensitive to free formaldehyde at concentrations of about 20 μg/mL. Microorganisms do not develop resistance to formaldehyde. Urea-splitting microorganisms (e.g., *Proteus* spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde.

Pharmacology, Toxicology, and Therapeutic Uses

Methenamine is absorbed orally, but 10% to 30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, *methenamine* is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000 to 1500 mL, a daily dose of 2 g will yield a urine concentration of 18 to 60 μg/mL of formaldehyde; this is more than the MIC for most urinary tract pathogens. Low pH in and of itself is bacteriostatic, so acidification serves a double function; the acids commonly used are mandelic acid and hippuric acid. GI distress frequently is caused by doses more than 500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/day given for longer than 3 to 4 weeks. Renal insufficiency is not a contraindication to the use of *methenamine* alone, but the acids given concurrently may be detrimental; *methenamine mandelate* is contraindicated in renal insufficiency. *Methenamine* combines with sulfamethizole and perhaps other sulfonamides in the urine, resulting in mutual antagonism; therefore, these drugs should not be used in combination.

Methenamine is not a primary drug for the treatment of acute UTIs but is FDA-approved for chronic suppressive treatment of UTIs. The agent is most useful when the causative organism is *E. coli*, but it usually can suppress the common gram-negative offenders and often *S. aureus* and *Staphylococcus epidermidis* as well. *Enterobacter aerogenes* and *Proteus vulgaris* are usually resistant. A urinary pH less than 5 is typically necessary for *methenamine* to be active; some clinicians recommend monitoring of the urinary pH and even urinary acidification with ammonium chloride or ascorbic acid.

Bacteriophages

Bacteriophages (or phages), literally "eaters of bacteria," are viruses that infect bacteria. Phages were initially described just over a century ago when it was noted that agents from environmental sources that could pass through small-pore filters were capable of destroying specific subsets of bacteria (Twort, 1915). Subsequently, phages were shown to be viruses capable of infecting a specific range of bacteria. The host range of infectible bacteria may be narrow for an individual phage, but with an estimated 10^{31} distinct phages in the planet's biosphere, every bacterium has a wide collection of phages to which it is vulnerable (Wommack et al., 1999).

From the perspective of antimicrobial therapy, phages are best conceptualized as living antibiotics (Schooley and Strathdee, 2020). They were promoted as antimicrobials globally until the 1930s, at which time interest was lost in the West as optimism about the utility of traditional antibiotics grew. Phage therapy continued unabated throughout the 20th century in Russia and the former Soviet Republics where antibiotics were less available because of cost. Over the past 5 years, however, as it has become apparent that the traditional antibacterial pipeline is failing to adequately address the antimicrobial drug resistance crisis and as a number of well-studied (albeit anecdotal) successful uses of phages in the treatment of serious bacterial infections have been described, interest in phage therapeutics has reemerged in the U.S. and Western Europe (Aslam et al., 2020; Hatfull et al., 2021).

Phage Biology

Rational use and clinical development of phages requires a fundamental understanding of their biological properties. Phages are small structures, 50 to 200 nm, found in abundance in the biosphere. Most environmental phages are composed of a head that encapsidates a segment of double-stranded DNA encoding the phage's genetic program and a tail that provides binding specificity to the phage's bacterial prey. Phages cannot reproduce on their own; rather, they replicate within a bacterial host. Bacteriophages have two lifestyles: *lytic* and *temperate* (Figure 59–4). Lytic phage infection produces a single outcome, host lysis. Temperate phage

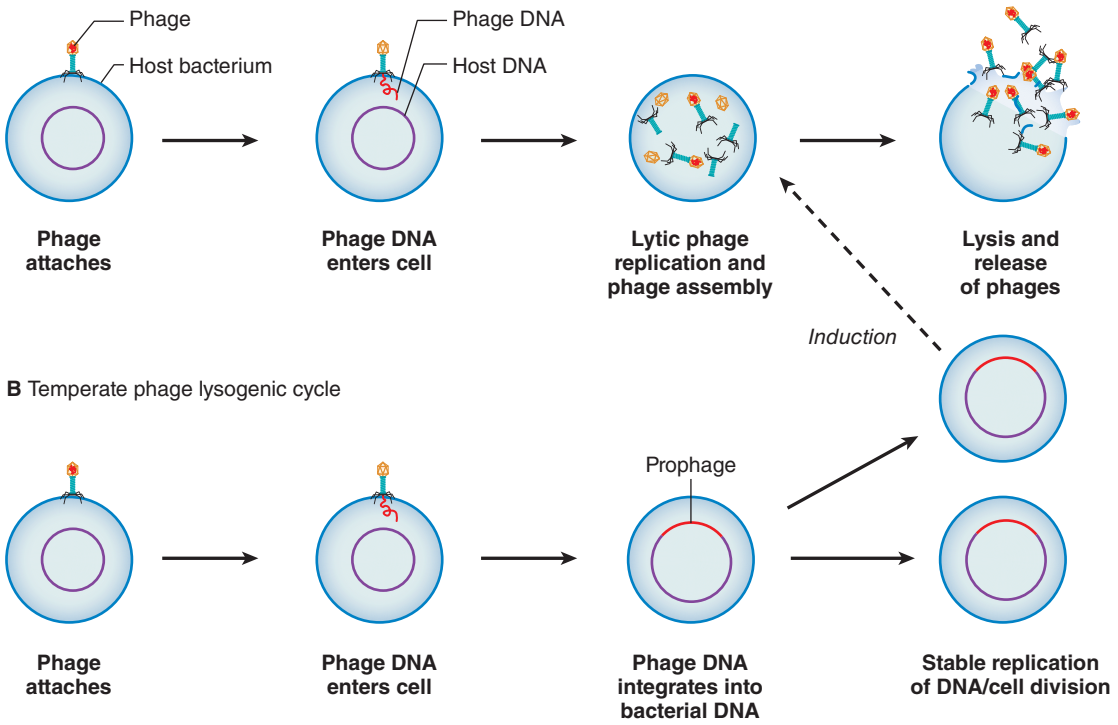

Figure 59–4 *Bacteriophage life cycles* **A.** *Lytic phage cycle.* Lytic phages infect bacteria via attachment, penetration, and injection of their DNA into the bacterial host, leading to inactivation of the host's genome and hijacking of the host replicative machinery for replication of the phage genome and the synthesis and assembly of new phage particles. The result is lysis of the host cell and release of a new crop of bacteriophage progeny. **B.** *Temperate phage lysogenic cycle.* Temperate phages attach and inject their DNA as described for lytic phages. However, rather than phage replication leading to lysis of the host cell, the temperate phage cycle involves incorporation of the phage DNA into the bacterial DNA and subsequent cell division with daughter cells containing the expanded complement of DNA. Environmental factors can induce these prophage cells to enter a lytic cycle, as indicated by the arrow marked "Induction."

infection produces a stable incorporation of the phage genome into the host's DNA, forming a prophage, with the lysogen reproduced as the host bacterium divides, possibly to be activated to a lytic phase by environmental factors.

Lytic Phages

Lytic phages infect their bacterial hosts, disrupting the host's DNA, taking over the host's synthetic machinery to make hundreds to thousands of progeny, producing lysins, and then lysing and destroying their hosts before moving on to repeat the cycle with other host bacteria. Since the timeline for this process may be on the order of 20 min, the expansion of a phage population and the collapse of the population's susceptible prey can occur on an explosive timeline. As this process proceeds, populations of phage-resistant bacteria emerge that are, in turn, chased by evolving phage populations that are capable of growth in these emerging phage-resistant populations.

Temperate Phages

In the temperate lifestyle, phages enter the host bacterium but do not hijack the host's replicative machinery for their own purposes; rather, the phage DNA encode genes for integrases that enable them to integrate their genetic code into the DNA of host bacteria and for additional genes (termed *repressors*) that repress the ability of incoming phages to attack the bacterial host. The DNA of temperate phages is replicated with that of their host and passed down to progeny bacteria. Periodically, either spontaneously or in response to environmental stimuli, these integrated phages are "induced." Under these conditions, phage proteins are synthesized and the phages enter a lytic life cycle. Temperate phages are poor candidates for therapeutics because they do not immediately lyse their hosts; furthermore, when they are induced, they may take bits and pieces of the host DNA with them and express them on to other bacteria that they infect. These genes can include genes encoding antibiotic resistance or enhance bacterial pathogenesis. Thus, it is generally accepted that temperate phages should not be administered with therapeutic intent. Recent advances in molecular biology have made it possible to genetically engineer phages to eliminate their lysogenic properties or to produce them synthetically with specifically designed host ranges and lytic capabilities.

Phage Selection and Production

Each lytic phage has a relatively narrow range (termed *host range*) of bacteria that are susceptible to attack; indeed, the host range of most phages is usually restricted to a single species. The host range of a given phage is determined by the presence or absence of receptors on the bacterial surface and on whether a given bacterium encodes enzymes (endonucleases) that can degrade the phage DNA after internalization. Some bacteria (e.g., *S. aureus*) are susceptible to populations of phages that can lyse a relatively large proportion of bacteria in the species. In these cases, a library of four to six phages might be able to lyse up to 85% of the bacteria that might be encountered clinically. Phages that attack other species (e.g., *Acinetobacter baumannii*) have a very narrow host range, and such a library would need to include 200 to 300 phages.

When a patient is deemed a candidate for phage therapy, it is first necessary to identify and to characterize phages to which the patient's pathogen is susceptible (Philipson et al., 2018). At present, this determination must be made empirically by pairing a patient's specific bacterium with a library of phages that have previously been identified as being active against bacteria of the same species and identifying those that specifically lyse the patient's isolate. If a laboratory is in possession of a collection of previously characterized phages with activity against the species of bacterium with which the patient is infected, such a screening process can be conducted in 24 to 48 h. Ideally, these phages have already been shown

to have an exclusively lytic lifestyle and to be free of genetic material that encodes bacterial resistance or factors that may enhance bacterial pathogenesis. If active phages are not identified in prescreened phage libraries, environmental searches can be undertaken (typically involving sewage, soil, or other sources in which the target bacterium exists in nature). Such a process may take weeks and is further complicated by the need to fully characterize any phages that emerge from the environmental search. When phages (at least one, and preferably more) are identified that have the needed bactericidal activity, they must be propagated in feeder bacteria to produce a sufficient number for a therapeutic course. Once produced, the phages must be purified to remove endotoxin and other impurities that may cause toxicity and then suspended in a buffer in which they are stable.

Pharmacology

Phages may be administered by intravenous, oral, topical, or inhaled routes. Historically, most phage therapy was administered by topical or oral routes because the technology required to fully separate highly purified phage populations from the remnants of the bacteria in which they were propagated had not been developed. With the development of efficient techniques (e.g., CsCl gradient centrifugation, organic extraction, affinity column separation), highly purified populations of phages can be obtained and safely administered parenterally. When phages have been properly prepared and sufficiently depleted of endotoxin and other impurities, clinically apparent toxicity is extremely rare.

Optimal frequency and dosing of phages is an area that remains under development. When administered intravenously, phages are cleared from the circulation by the reticuloendothelial system within 30 to 90 min. Unlike antibiotics, however, once phages arrive at the site of infection, phages can replicate in their bacterial hosts, depending on the multiplicity of infection and the size and contiguity of the bacterial population. Thus, rather than focusing on routes of clearance and systemic half-life, pharmacologic considerations center on the persistence and activity of these self-replicating antibiotics at the site of infection. From the practical perspective, well-purified phages should be administered at doses of 10^9 to 10^{10} plaque-forming units (PFU) per dose every several hours. Most published parenteral regimens have included one or more phages that are administered at approximately 10^9 PFU per dose every 8 to 12 h. Less has been done to delineate proper dosing of topical or orally administered phage preparations. Because of the uncertain stability and distribution associated with topical administration and the added complexity of predictable absorption from the GI tract, parenteral administration is preferred for most patients with significant systemic infections. Since phages (like antibiotics) select for resistant bacterial populations, it is generally preferable to administer them as "cocktails" consisting of several phages with activity against the pathogen at hand and that do not have overlapping resistance pathways. Principles regarding optimal valency are under development but will likely be dependent on the population size and the bacterial species under treatment.

Clinical Indications

Phages are not currently FDA-approved in the U.S. and must be administered as investigational agents in clinical trials or for individual patients under investigator-initiated Investigational New Drug applications. Indications for which phages may be considered include patients with serious or life-threatening bacterial or mycobacterial infections for whom antibiotic therapy has failed or is unlikely to be successful. This may include patients with multidrug-resistant bacterial infections. In addition, because of the capacity of phages to disrupt biofilms, patients with persistent infections on implanted devices for which removal and replacement are difficult or impossible are also candidates for therapy. Investigational efforts are under way to explore the ability of phages to influence the microbiome and/or to prophylactically reduce populations of specific bacteria.

Future Prospects

The full range of clinical applications for phage therapeutics is an area under active investigation. The delineation of their role in clinical medicine will require rigorous clinical and translational research that is designed on the principles under which traditional antibiotics are evaluated. Although the field is over a century old, the modern era of phage therapy began less than decade ago; a full understanding of their role in clinical medicine, as stand-alone agents or in combination with traditional antibiotics, is still in its infancy.

Drug Facts for Your Personal Formulary: *Aminoglycosides*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Aminoglycosides—Inhibitors of Bacterial Protein Synthesis		
General: Bactericidal, no GI absorption (<1%), oral administration used only for bowel decontamination or intestinal parasites, poor CSF penetration, renal elimination, nephrotoxicity, ototoxicity (cochlear and vestibular), neuromuscular blockade		
Gentamicin (IV)	• UTI • Peritonitis • Endocarditis in combination with a cell wall–active agent • Plague • Tularemia	• Good activity vs. Enterobacterales, *Pseudomonas* • Some activity vs. *Neisseria, Haemophilus, Moraxella* • Synergistic activity when combined with a cell wall agent against many organisms • Vestibular > cochlear toxicity • Toxicity primarily renal and reversible
Tobramycin (IV, inhalation)	• UTI • Lung infections, including cystic fibrosis exacerbations • Nosocomial sepsis of unknown origin	• Similar to gentamicin, with better activity against *Pseudomonas aeruginosa* • Cochlear ≈ vestibular toxicity
Amikacin (IV)	• UTI • Lung infections, including cystic fibrosis exacerbations • Nosocomial sepsis of unknown origin • Mycobacterial infections	• Similar to tobramycin, with activity against some gram-negative bacilli resistant to other aminoglycosides • Activity against a variety of mycobacteria • Cochlear > vestibular toxicity
Plazomicin (IV)	• UTI	• Similar to amikacin, with activity against some gram-negative bacilli resistant to other aminoglycosides

Drug Facts for Your Personal Formulary: *Aminoglycosides (continued)*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Aminoglycosides—Inhibitors of Bacterial Protein Synthesis		
General: Bactericidal, no GI absorption (<1%), oral administration used only for bowel decontamination or intestinal parasites, poor CSF penetration, renal elimination, nephrotoxicity, ototoxicity (cochlear and vestibular), neuromuscular blockade (cont.)		
Streptomycin (IV)	• Endocarditis in combination with a cell wall–active agent • Tuberculosis • Plague • Tularemia	• Similar to gentamicin, with activity against some gentamicin-resistant enterococci • Activity against *Mycobacterium tuberculosis* • Vestibular > cochlear toxicity • Vestibular toxicity is irreversible
Neomycin (PO, topical; urological irrigation)	• Minor skin infections • Bowel preparation prior to intra-abdominal surgery • Bladder irrigation	• Similar activity to gentamicin but only used topically, not systemically • Can cause skin rash
Paromomycin (PO, IM, topical)	• *Cryptosporidium* infection • Intestinal amebiasis • Leishmaniasis	• Diarrhea, nausea, vomiting • IM use for visceral leishmaniasis • Topical use for cutaneous leishmaniasis
Polymyxins—Bactericidal Cell Membrane–Disrupting Agents		
General: Substantial nephrotoxicity and neurotoxicity		
Colistin (polymyxin E) (IV, inhaled)	• Serious infections due to multidrug-resistant gram-negative organisms • Prevention of cystic fibrosis exacerbations (inhaled)	• Good activity vs. *Acinetobacter*, *E. coli*, *Klebsiella*, *Pseudomonas*, including multidrug-resistant strains • Prodrug; complex pharmacokinetics with renal and nonrenal elimination
Polymyxin B (IV, topical)	• Serious infections due to multidrug-resistant gram-negative organisms • Topical treatment/prevention of skin and soft-tissue infections	• Similar activity and toxicity as colistin • Nonrenally eliminated; does not achieve high urinary levels
Urinary Agents: Diverse mechanisms, effective concentrations reached only in urine with oral formulations		
Nitrofurantoin (PO)	• Cystitis treatment • Cystitis prophylaxis	• DNA damage through reactive intermediates • Excellent activity vs. *E. coli*, *Enterococcus* • Some activity vs. *Klebsiella*, *Enterobacter* • Rapid absorption and elimination • Colors urine brown • Acute pneumonitis and chronic interstitial pulmonary fibrosis
Fosfomycin (PO)	• Cystitis treatment	• Inhibits early cell wall synthesis • Excellent activity vs. *E. coli*, *Proteus*, *Enterococcus* • Some activity vs. *Klebsiella*, *Enterobacter* • Single-dose treatment of acute uncomplicated cystitis
Methenamine (PO)	• Chronic suppression of cystitis	• Forms formaldehyde in urine • Requires acidic urine for activity • Excellent activity against most uropathogens except for *Proteus* and *Enterobacter* • GI distress at high doses

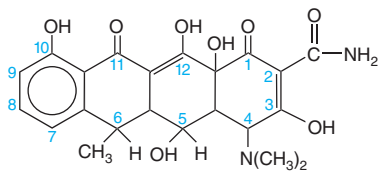
Chapter 60 Protein Synthesis Inhibitors

Conan MacDougall

The agents discussed in this chapter are *bacteriostatic protein synthesis inhibitors that target the ribosome,* including tetracyclines and their modern derivatives; macrolides; lincosamides; streptogramins (*quinupristin/dalfopristin*); oxazolidinones; and pleuromutilins.

Tetracyclines and Derivatives

The tetracyclines are a series of derivatives of a basic four-ring structure (shown for *doxycycline*). *Demeclocycline, tetracycline, minocycline,* and *doxycycline* are available in the U.S. for systemic use. In the last two decades, tetracycline derivatives engineered to overcome resistance mechanisms have been introduced. Glycylcyclines (*tigecycline*), fluorocyclines (*eravacycline*), and aminomethylcyclines (*omadacycline*) are tetracycline congeners with substituents that confer broad-spectrum activity including against tetracycline-resistant bacteria.



DOXYCYCLINE

Mechanism of Action

Tetracyclines and their derivatives inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 60–1). These drugs enter gram-negative bacteria by passive diffusion through channels formed by porins in the outer cell membrane and by active transport that pumps tetracyclines across the cytoplasmic membrane.

Antimicrobial Activity

Tetracyclines are typically bacteriostatic antibiotics with a spectrum of activity that encompasses a wide array of bacteria. Tetracyclines are intrinsically more active against gram-positive than gram-negative microorganisms, largely due to the ability of gram-negatives to efflux tetracyclines. Recent data from the U.S. on the activity of tetracyclines and other agents are displayed in Table 60–1. Activity against *Streptococcus pyogenes* and *penicillin*-susceptible *Streptococcus pneumoniae* is good, but resistance is common among group B streptococci and *penicillin*-resistant *S. pneumoniae.* Good activity is maintained against both *methicillin*-sensitive *Staphylococcus aureus* (MSSA) and *methicillin*-resistant *Staphylococcus aureus* (MRSA). Activity against enterococci improves with later-generation agents; *tigecycline* and

MSSA: methicillin-sensitive *Staphylococcus aureus*

eravacycline have good activity against multidrug-resistant enterococcal isolates. *Bacillus anthracis* is typically susceptible.

Activity of tetracyclines against *Haemophilus influenzae* has been largely retained since their introduction, but many Enterobacterales have acquired resistance to earlier-generation agents. Among almost 2000 isolates of *Escherichia coli*, only 59% were susceptible to *tetracycline*, with 84% susceptible to *minocycline* and 99% susceptible to *tigecycline* and *eravacycline* (Morrissey et al., 2020). Activity against *Klebsiella* spp. is typically more favorable, although even advanced-generation agents have poor activity versus *Proteus* spp. Among nonfermenting gram-negatives, *Pseudomonas aeruginosa* is intrinsically resistant, but *Burkholderia* spp., *Acinetobacter* spp., and *Stenotrophomonas maltophila* are often susceptible, with *minocycline*, *tigecycline*, and *eravacycline* having greater activity against these pathogens. Recent tetracycline derivatives are also typically more active against anaerobic gram-negatives such as *Bacteroides fragilis*. Most strains of *Brucella* also are susceptible to tetracyclines. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Vibrio cholerae*, and *Vibrio vulnificus* and inhibit the growth of *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. Tetracyclines are alternative agents for treatment of actinomycosis.

Tetracyclines are effective against many microorganisms that are intrinsically resistant to cell-wall-active antimicrobial agents, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*.

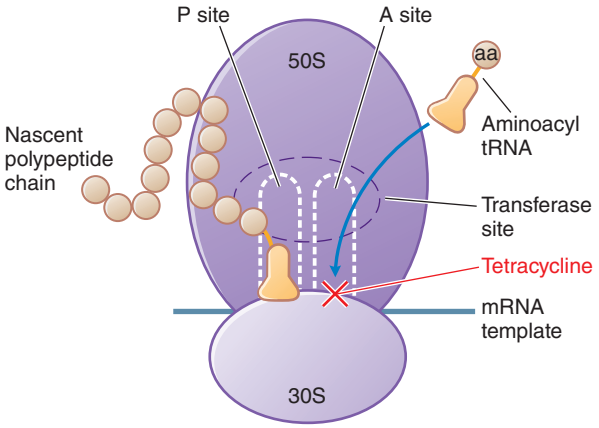

Figure 60–1 *Inhibition of bacterial protein synthesis by tetracyclines.* mRNA attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. Tetracyclines bind to the 30S subunit, block tRNA binding to the A site, and thereby inhibit protein synthesis.

Resistance to Tetracyclines and Derivatives

Resistance is frequently plasmid-mediated and often inducible. The three primary resistance mechanisms are as follows:

- Decreased accumulation of tetracyclines as a result of either decreased antibiotic influx or expression of an energy-dependent efflux pathway
- Production of a ribosomal protection protein that displaces tetracyclines from their targets
- Enzymatic inactivation of tetracyclines

Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative (Grossman, 2016). Tetracycline resistance due to a ribosomal protection mechanism (e.g., *tetM*) produces cross-resistance to *doxycycline* and *minocycline*. *Minocycline* and, to a

MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; NA, not applicable; NR, not reported; PCN-R, penicillin-resistant; PCN-S, penicillin-susceptible.
Entries are percentage of isolates inhibited at established or proposed susceptibility breakpoints. In parentheses are drug concentrations, in μg/mL, required to inhibit growth of 90% of isolates of that organism.
Sources: Data from: Gales AC, et al. *Diagn Microbiol Infect Dis*, **2008**, *60*:421–427; Critchley IA, et al. *Antimicrob Agents Chemother*, **2003**, *47*:1689–1693; Mendes RE, et al. *Antimicrob Agents Chemother,* **2015**, *59*:702–706; Jones RN, et al. *Diagn Microbiol Infect Dis,* **2013**, *75*:304–307; Mendes RE, et al. *Clin Infect Dis*, **2012**, *54*(S3):S203–S213; Morrissey I, et al. *Antimicrob Agents Chemother*, **2020**, *64*:e01715–01719; Pfaller MA, et al. *Antimicrob Agents Chemother*, **2018**, *62*:e02327; Sader HS, et al. *Antimicrob Agents Chemother*, **2012**, *56*:1619–1623.

lesser extent, *doxycycline* are more resistant to efflux and typically display lower minimum inhibitory concentrations against organisms expressing efflux pumps, although cross-resistance may still exist. Structural modifications to the glycylcyclines, fluorocyclines, and aminomethylcyclines reduce affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines. Less common emergent resistance mechanisms include enzymatic modification of the tetracyclines through "destructases" or mutation at the ribosomal target site.

ADME

Oral absorption of tetracyclines varies by the individual agent, ranging from approximately 33% for *omadacycline* to around 90% for *doxycycline* and *minocycline*. *Tigecycline* and *eravacycline* are available only for parenteral administration. Concurrent ingestion of divalent and trivalent cations (e.g., Ca^{2+}, Mg^{2+}, Al^{3+}, $Fe^{2+/3+}$, and Zn^{2+}) impairs absorption. Thus, dairy products, antacids, aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; bismuth subsalicylate; and dietary iron and zinc supplements can interfere with absorption of tetracyclines. After a single oral dose, the peak plasma concentration is attained in 2 to 4 h. These drugs have half-lives in the range of 6 to 12 h and frequently are administered two to four times daily. Food, including dairy products, does not interfere with absorption of *doxycycline* and *minocycline* but significantly impairs the absorption of *omadacycline*, which should be administered at least 4 h after and 2 h before a meal.

Tetracyclines distribute widely throughout the body, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow and in bone, dentine, and enamel of unerupted teeth. *Tigecycline* and *eravacycline* distribute rapidly and extensively into tissues, resulting in low serum levels that may be inadequate to treat bacteremias with an endovascular source. Inflammation of the meninges is not required for the passage of tetracyclines into the CSF. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relatively high concentrations are found in breast milk.

Tetracycline and *demeclocycline* are eliminated primarily by the kidney, although they also are concentrated in the liver, excreted in bile, and partially reabsorbed via enterohepatic recirculation. *Doxycycline* and *omadacycline* are largely excreted unchanged in both the bile and urine, *tigecycline* and *eravacycline* are mostly excreted unchanged along with a small amount of metabolites, and *minocycline* is extensively metabolized by the liver before excretion. Hence, no dose adjustment is needed in patients with renal dysfunction. Specific dosage adjustment recommendations in hepatic disease are available for *tigecycline* and *eravacycline*.

Therapeutic Uses

The early-generation tetracyclines remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. *Doxycycline*, the most frequently used tetracycline, is a drug of choice for many sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections and is also used for treatment of respiratory tract infections and for skin and soft-tissue infections caused by MRSA. *Minocycline* has utility for *doxycycline*-resistant strains of MRSA, *Acinetobacter* spp., and some nontuberculous mycobacteria. The glycylcyclines, fluorocyclines, and aminomethylcyclines have restored much of the antibacterial activity lost to the tetracyclines due to resistance and offer *in vitro* activity against a number of gram-positive and gram-negative organisms (De Rosa et al., 2015). However, some clinical data for these agents warrants caution. A pooled analysis of *tigecycline* clinical trials found a small but statistically significant increased risk of death with *tigecycline* versus comparators (Food and Drug Administration, 2016). While the activity of *eravacycline* and *omadacycline* is promising against multidrug-resistant gram-negatives commonly seen in urinary tract infections, both agents did not meet criteria for noninferiority in randomized trials for treatment of complicated urinary tract infections, possibly due to lack of accumulation in the urine.

The oral dose of *tetracycline* ranges from 1 to 2 g/day in adults. The typical oral or intravenous dose of *doxycycline* for adults is 100 mg every 12 h; for children more than 8 years of age, the dose is 4.4 mg/kg per day in two divided doses the first day, then 2.2 mg/kg given once or twice daily. The typical dose of *minocycline* for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 h; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 h. *Tigecycline* is administered intravenously to adults as a 100-mg loading dose, followed by 50 mg every 12 h. For patients with significant hepatic impairment, the loading dose should be followed by a reduced maintenance dose of 25 mg every 12 h. *Eravacycline*'s dose is 1 mg/kg intravenously every 12 h; in patients with severe hepatic impairment, the frequency is reduced to every 24 h. *Omadacycline* is administered with a loading dose (200 mg for 1 day intravenously or 450 mg for 2 days orally) followed by a maintenance dose of 100 mg intravenously or 300 mg orally. Dosages for *tigecycline*, *eravacycline*, or *omadacycline* in pediatrics have not been established.

Respiratory Tract Infections

Tetracyclines have good activity against *S. pneumoniae*, *H. influenzae,* and *Moraxella catarrhalis* and excellent activity against atypical pathogens such as *Mycoplasma* and *Chlamydophila pneumoniae*. *Doxycycline* is recommended as a single agent for treatment of uncomplicated community-acquired pneumonia in the outpatient setting or as an adjunctive agent with β-lactams for patients with complicated community -acquired pneumonia. *Doxycycline* is also used for treatment of acute exacerbations of chronic bronchitis and for sinusitis. *Tigecycline* and *omadacycline* are approved for the treatment of adults with community -acquired bacterial pneumonia.

Skin and Soft-Tissue Infections

Doxycycline and *minocycline* have good activity against staphylococci and may be useful in treatment of cutaneous infections especially if MRSA is suspected. *Tigecycline* and *omadacycline* are approved for the treatment of complicated skin and soft-tissue infections. Low doses of *tetracycline* have been used to treat acne (25 mg orally twice a day).

Intra-abdominal Infections

Resistance among Enterobacterales and gram-negative anaerobes limits the utility of older tetracyclines for intra-abdominal infections. However, *tigecycline* and *eravacycline* possess excellent activity against these pathogens as well as *Enterococcus* and have FDA indications for treatment of complicated intra-abdominal infections.

Sexually Transmitted Diseases

Doxycycline no longer is recommended for gonococcal infections because of the spread of resistance (Centers for Disease Control and Prevention, 2021). A 7-day treatment course of *doxycycline* is more effective than single-dose *azithromycin* in the treatment of uncomplicated genital infections due to *Chlamydia trachomatis. C. trachomatis* is often a coexistent pathogen in acute pelvic inflammatory disease, and *doxycycline* is a component of combination therapy regimens for this condition. Acute epididymitis is caused by infection with *C. trachomatis* or *Neisseria gonorrhoeae* in men less than 35 years of age. Effective regimens include a single injection of *ceftriaxone* (250 mg) plus *doxycycline* for 10 days. Sexual partners also should be treated. *Doxycycline* for 21 days is first-line therapy for treatment of lymphogranuloma venereum. Nonpregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen, such as *doxycycline* for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

Zoonoses

Tetracyclines can be lifesaving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Tetracyclines are also effective in treatment of ehrlichiosis and anaplasmosis. *Doxycycline* is the drug of choice for treatment of Rocky Mountain spotted fever,

ehrlichiosis, and anaplasmosis in adults and in children, including those less than 9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Woods, 2013). *Doxycycline* is a first-line treatment for adults with infections due to *Borrelia* spp., including *B. burgdorferi* (Lyme disease). Tetracyclines in combination with *rifampin* or *streptomycin* are effective for acute and chronic infections caused by *Brucella melitensis*, *Brucella suis*, and *Brucella abortus.* Although *streptomycin* is preferable, tetracyclines also are effective in tularemia. *Doxycycline* is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for bioterrorism exposures.

Other Infections

Actinomycosis, although most responsive to *penicillin G*, may also be successfully treated with a tetracycline. *Minocycline* is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira* spp.). The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *Mycobacterium marinum*. Tetracyclines in combination with *bismuth*, *metronidazole*, and a proton pump inhibitor are a first-line therapy for *H. pylori* infections (Chey et al., 2017; see also Table 53–4).

Adverse Effects

Gastrointestinal

All tetracyclines can produce GI irritation, most commonly after oral administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. *Omadacycline* specifically requires administration on an empty stomach, at least 4 h after and 2 h before food consumption. Tetracyclines have been associated with esophagitis and esophageal ulcers; patients should take oral formulations with a full glass of water while standing. *Tigecycline* administered intravenously has also been associated with nausea and vomiting that can be treatment-limiting.

Photosensitivity

Tetracyclines and derivatives may produce photosensitivity reactions in treated individuals exposed to sunlight. For ambulatory patients, reduction in sun exposure and use of sunscreen during therapy are recommended. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity (Vassileva et al., 1998).

Hepatic Toxicity

Hepatic toxicity has developed in patients with renal failure receiving 2 g or more of *tetracycline* per day parenterally, but this effect also may occur when large quantities are administered orally. Pregnant women are particularly susceptible.

Renal Toxicity

Tetracyclines may aggravate azotemia in patients with renal disease because of the catabolic effects of the drugs. *Doxycycline*, *minocycline*, and *tigecycline* have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving *demeclocycline*, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 29). Fanconi syndrome (characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria) has been observed in patients ingesting outdated *tetracycline*, presumably due to toxic effects of one or more breakdown products on the proximal renal tubules.

Effects on Bone

Children treated with tetracyclines may develop permanent brown discoloration of the teeth. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk is highest when a tetracycline is given to infants before the first dentition but may develop if the drug is given between the ages of 2 months and 5 years when these teeth are being calcified. Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children. Concern also exists over the potential for depressed bone growth due to deposition of tetracyclines in the skeleton during gestation and throughout childhood. Thus, tetracyclines are typically avoided in pregnant women and in children less than 8 years old unless there is a compelling indication (e.g., Rocky Mountain spotted fever).

Other Toxic and Irritative Effects

Thrombophlebitis may follow intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions. Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura. Tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Patients receiving *minocycline* may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24 to 48 h after drug cessation. Skin reactions rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after oral use.

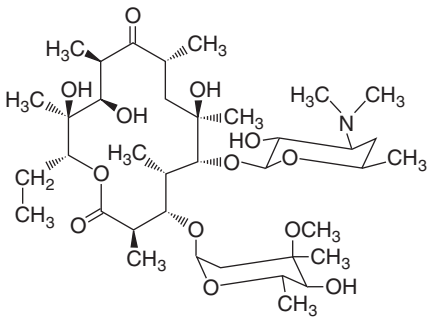
Drug Interactions

As mentioned, oral coadministration of tetracyclines and divalent and trivalent cations can lead to chelation of the tetracycline, with resultant poor absorption. There is some evidence for drug interactions between *doxycycline* and hepatic enzyme-inducing agents such as *phenytoin* and *rifampin*, but not for *minocycline* or *tigecycline*. *Eravacycline* is a substrate of CYP3A4 and its concentrations are reduced by inducers (e.g., *rifampin*) and increased by inhibitors (e.g., *itraconazole*) of CYP3A4.

Macrolides and Ketolides

Macrolide antibiotics are widely used agents for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia. Four macrolides are available for clinical use in the United States: *erythromycin*, *clarithromycin*, *azithromycin*, and *fidaxomicin*. *Erythromycin* is the original agent in the class, discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of *Streptomyces erythraeus*. *Azithromycin* and *clarithromycin* are semisynthetic derivatives of *erythromycin* that have largely replaced it in clinical use. *Fidaxomicin* is a non–systemically absorbed macrolide used only for the treatment of *Clostridium difficile* colitis. Ketolides (*telithromycin, cethromycin, solithromycin*) are semisynthetic derivatives of *erythromycin* with activity against some macrolide-resistant strains.

Macrolide antibiotics contain a multimembered lactone ring (14-membered rings for *erythromycin* and *clarithromycin* and a 15-membered ring for *azithromycin*) to which are attached one or more deoxy sugars. *Clarithromycin* differs from *erythromycin* only by methylation of the hydroxyl group at the 6 position, and *azithromycin* differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity.



ERYTHROMYCIN

Ketolides are structurally similar multimembered ring systems but with different substituents; a 3-keto group replaces the α-L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11–C12. These modifications render ketolides less susceptible to methylase-mediated (*erm*) and efflux-mediated (*mef* or *msr*) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains; however, concerns about the safety of *telithromycin* limited its use, and the manufacturer ceased marketing it in the U.S. (Brinker et al., 2009). The development of *cethromycin* and *solithromycin* has been stopped or stalled after unfavorable FDA reviews; whether their development will proceed is unclear.

Mechanism of Action

Macrolide and ketolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 60–2). *Erythromycin* does not inhibit peptide bond formation per se but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate about 100 times more *erythromycin* than do gram-negative bacteria.

Antimicrobial Activity

Erythromycin usually is bacteriostatic but may be bactericidal in high concentrations against susceptible organisms. *Erythromycin* has reasonably good activity against streptococci (see Table 60–1), but macrolide resistance among *S. pneumoniae* often coexists with *penicillin* resistance. Staphylococci are not reliably sensitive to *erythromycin*, and macrolide-resistant strains of *S. aureus* are potentially cross-resistant to *clindamycin* and *streptogramin B* (*quinupristin*). Gram-positive bacilli also are frequently sensitive to *erythromycin*, including *Clostridium perfringens*, *Corynebacterium diphtheriae*, and *Listeria monocytogenes*. *Erythromycin* is inactive against most aerobic enteric gram-negative bacilli. It has modest activity *in vitro* against *H. influenzae* and *Neisseria meningitidis* and good activity against most strains of *N. gonorrhoeae*. Useful antibacterial activity also is observed against *P. multocida*, *Borrelia* spp., and *Bordetella pertussis.* Macrolides are usually active against *C. jejuni*. *Erythromycin* is active against *M. pneumoniae* and *Legionella pneumophila*. Most strains of *C. trachomatis* are inhibited by *erythromycin*.

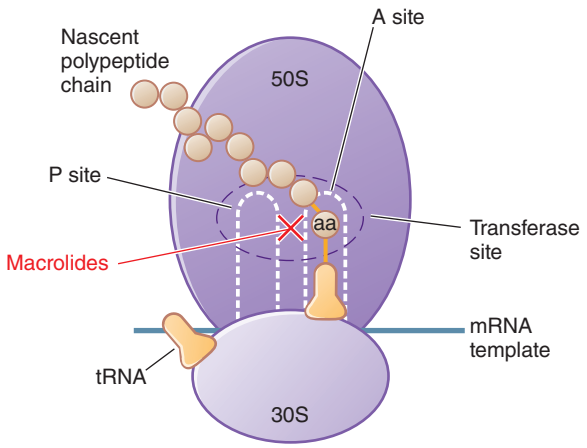


Figure 60–2 *Inhibition of bacterial protein synthesis by erythromycin, clarithromycin, and azithromycin.* Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. *Erythromycin* appears to inhibit the translocation step such that the nascent peptide chain temporarily residing at the A site fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 60–1 for additional nform: tio ı.

Azithromycin has similar activity as *erythromycin* against sensitive strains of streptococci and staphylococci, while *clarithromycin* is slightly more potent. *Clarithromycin* is somewhat less active than *erythromycin* against *H. influenzae*, whereas *azithromycin* is the most active macrolide against this organism. *Clarithromycin* and *azithromycin* have good activity against *M. catarrhalis*, *Chlamydia* spp., *L. pneumophila*, *B. burgdorferi*, *M. pneumoniae*, and *H. pylori*. *Azithromycin* and *clarithromycin* have enhanced activity against some nontuberculous mycobacteria, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium* spp.). *Clarithromycin* has good activity against *Mycobacterium leprae*. The spectrum of activity of the ketolides is similar to those of *clarithromycin* and *azithromycin*, but their capacity to withstand many macrolide resistance mechanisms increases their *in vitro* activity against macrolide-resistant *S. pneumoniae* and *S. aureus*.

Fidaxomicin is designed to have potent activity against *C. difficile* with minimal inhibition of other gastrointestinal flora. It does not have clinical utility for infections besides *C. difficile*.

Resistance to Macrolides and Ketolides

Resistance to macrolides usually results from one of four mechanisms (Nakajima, 1999):

- Drug efflux by an active pump mechanism
- Ribosomal protection by inducible or constitutive production of methylase enzymes, which modify the ribosomal target and decrease drug binding
- Macrolide hydrolysis by esterases produced by Enterobacterales
- Chromosomal mutations that alter a 50S ribosomal protein (in *Bacillus subtilis, Campylobacter* spp., mycobacteria, and gram-positive cocci)

ADME

Erythromycin base is incompletely absorbed from the upper small intestine. Because it is inactivated by gastric acid, it is administered as enteric-coated tablets or as capsules containing enteric-coated pellets that dissolve in the duodenum; food may delay absorption. Esters of *erythromycin* base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. Protein binding is about 70% to 80% for *erythromycin* base and even higher for the estolate. *Erythromycin* traverses the placenta, and drug concentrations in fetal plasma are about 5% to 20% of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum. *Erythromycin* is concentrated in the liver and excreted in the bile. The serum $t_{1/2}$ of *erythromycin* is about 1.6 h. Although the $t_{1/2}$ may be prolonged in patients with anuria, dosage reduction is not routinely recommended in patients in renal failure. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but hepatic first-pass metabolism reduces its bioavailability to 50% to 55%. Peak concentrations occur about 2 h after drug administration. *Clarithromycin* may be given with or without food, but the extended-release form should be administered with food to improve bioavailability. *Clarithromycin* and its active metabolite, 14-hydroxyclarithromycin, achieve high intracellular concentrations throughout the body, including the middle ear. *Clarithromycin* is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. The elimination $t_{1/2}$ are 3 to 7 h for *clarithromycin* and 5 to 9 h for 14-hydroxyclarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics and longer half-lives with higher dosages. The amount of *clarithromycin* excreted unchanged in the urine ranges from 20% to 40%, depending on the dose administered and the formulation (tablet vs. oral suspension). An additional 10% to 15% of a dose is excreted in the urine as 14-hydroxyclarithromycin. Dose adjustment is not recommended unless the creatinine clearance is less than 30 mL/min.

Azithromycin administered orally is absorbed rapidly (although incompletely: bio vaılability for the immediate-release form ılatı ɔn is

on the order of 30%–40%) and distributes widely throughout the body, except to the brain and CSF. *Azithromycin* also can be administered intravenously, producing plasma concentrations of 3 to 4 μg/mL after a 1-h infusion of 500 mg. *Azithromycin*'s unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. *Azithromycin* undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination $t_{1/2}$, 40 to 68 h, is prolonged because of extensive tissue sequestration and binding.

Fidaxomicin achieves high levels in the gut lumen and stool but is minimally absorbed, with peak plasma levels of *fidaxomicin* and its active metabolite in the nanogram per milliliter range; greater than 90% of the dose is recovered in stool as the parent drug or metabolite.

Therapeutic Uses

The usual oral dose of *erythromycin* (*erythromycin* base) for adults ranges from 1 to 2 g/day, in divided doses, usually given every 6 h. Food should not be taken concurrently, if possible, with *erythromycin* base or the stearate formulations, but this is not necessary with *erythromycin* estolate. The oral dose of *erythromycin* for children is 30 to 50 mg/kg per day, divided into four portions; this dose may be doubled for severe infections. Intravenous administration is generally reserved for the therapy of severe infections and is now used uncommonly; the usual dose is 0.5 to 1 g every 6 h.

Clarithromycin usually is given twice daily at a dose of 250 mg for adults with mild-to-moderate infections and 500 mg twice daily for more severe infections. The 500-mg extended-release formulation of *clarithromycin* is given as 2 tablets once daily.

Standard doses of *azithromycin* for treatment of infection are 250 to 500 mg orally or intravenously once daily. The extended-release *azithromycin* suspension should be given 1 h before or 2 h after meals when administered orally; there are no food requirements for the tablet or immediate-release suspension. Treatment or prophylaxis of nontuberculous mycobacterial infection can vary by indication and patient: 250 to 500 mg daily in combination with one or more other agents for treatment or 1200 mg once weekly for primary prevention of *Mycobacterium avium-intracellulare* (MAI).

Respiratory Tract Infections

Macrolides are suitable drugs for the treatment of a number of respiratory tract infections. *Azithromycin* and *clarithromycin* are suitable choices for treatment of community-acquired pneumonia among low-risk ambulatory patients in areas where resistance to macrolides among *S. pneumoniae* is low (e.g., <25%) (Metlay et al., 2019). For outpatient therapy of community-acquired pneumonia, pharyngitis, or sinusitis, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5. In hospitalized patients, a macrolide is commonly added to an antipneumococcal β-lactam for coverage of atypical respiratory pathogens. Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. In children, the recommended dose of *azithromycin* oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum 500 mg) and 5 mg/kg (maximum 250 mg/day) on days 2 through 5. A single 30-mg/kg dose is approved as an alternative for otitis media. *Azithromycin* and *clarithromycin* are generally preferred to *erythromycin* due to their broader spectrum and superior tolerability.

Skin and Soft-Tissue Infections

Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to *penicillin* (Stevens et al., 2014). *Erythromycin* has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either *penicillin*-sensitive or *penicillin*-resistant *S. aureus.* However, many strains of *S. aureus* are resistant to macrolides.

Sexually Transmitted Infections

A single 1-g dose of *azithromycin* can be used for treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis*, but is less effective than 7 days of doxycycline. (Centers for Disease Control and Prevention, 2021). This dose also is effective for chancroid. Chlamydial infections can be treated effectively with any of the macrolides. *Erythromycin* base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg per day in four divided doses for 14 days). *Azithromycin*, 1 g per week for 3 weeks, may be effective for lymphogranuloma venereum.

Diphtheria

Erythromycin for 7 days is very effective for acute infections or for eradicating the diphtheria carrier state. Other macrolides are not FDA-approved for this indication. Antibiotics do not alter the course of an acute infection with diphtheria or decrease the risk of complications. Antitoxin is indicated in the treatment of acute infection.

Pertussis

Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. *Clarithromycin* and *azithromycin* also are effective. If administered early in the course of whooping cough, *erythromycin* may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with *erythromycin* therapy because resistance has been reported.

Helicobacter pylori *Infection*

Clarithromycin 500 mg, in combination with *omeprazole* 20 mg (or *lansoprazole* 30 mg), and *amoxicillin* 1 g, each administered twice daily for 10 to 14 days, are effective for treatment of peptic ulcer disease caused by *H. pylori* (see Table 53–4).

Mycobacterial Infections

Clarithromycin or *azithromycin* is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by MAI in patients infected with human immunodeficiency virus (HIV) and for treatment of pulmonary disease in patients not infected with HIV (Masur et al., 2014). *Clarithromycin* (500 mg twice daily) plus *ethambutol* (15 mg/kg once daily) with or without *rifabutin* is an effective combination regimen. Either *clarithromycin* or *azithromycin* can be a component of combination therapy regimens for other nontuberculous mycobacterial infections such as those due to *Mycobacterium abscessus*. *Clarithromycin* also has been used with *minocycline* for the treatment of *M. leprae* in lepromatous leprosy.

Clostridium difficile Infection

Fidaxomicin administered as a dose of 200 mg orally twice daily is as effective as oral *vancomycin* for treatment of *C. difficile* colitis and is associated with a lower risk of relapse. Other macrolides are not effective in the treatment of *C. difficile* infection, and administration of these agents may predispose patients to *C. difficile* infection (although with a relatively lower risk than many other antimicrobial classes).

Adverse Effects

GI Toxicity

Oral or intravenous administration of *erythromycin* frequently is accompanied by moderate-to-severe epigastric distress. *Erythromycin* stimulates GI motility by acting on motilin receptors; indeed, *erythromycin* is used off-label as a prokinetic agent in the intensive care setting and in patients with diabetic gastroparesis. *Clarithromycin* and *azithromycin* may also cause GI distress, but typically to a lesser degree than *erythromycin*.

Cardiac Toxicity

Erythromycin, *clarithromycin*, *azithromycin*, and *telithromycin* have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. A large cohort study found a small but statistically significant increase in the risk of sudden cardiac death

with *azithromycin* compared to no antibiotic treatment or to *amoxicillin*. Risk factors for clinically significant cardiac toxicity include receipt of concomitant antiarrhythmic drugs or other agents that prolong QTc.

Hepatotoxicity

Cholestatic hepatitis is associated with long-term treatment with *erythromycin*. The illness starts after 10 to 20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Findings usually resolve within a few days after cessation of drug therapy. Hepatotoxicity has also been observed with *clarithromycin* and *azithromycin*, although at a lower rate than with *erythromycin* and *telithromycin*.

Other Toxic and Irritative Effects

Allergic reactions observed are fever, eosinophilia, and skin eruptions, which disappear shortly after therapy is stopped. Auditory impairment and tinnitus have been observed with macrolides, especially at higher doses.

Drug Interactions

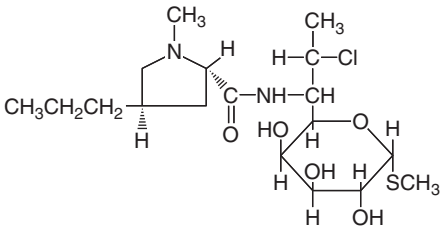
Erythromycin, *clarithromycin*, and *telithromycin* strongly inhibit CYP3A4 and cause significant drug interactions (Periti et al., 1992). *Erythromycin* and *clarithromycin* potentiate the effects of *carbamazepine*, corticosteroids, *cyclosporine*, *digoxin*, ergot alkaloids, *theophylline*, *triazolam*, *valproate*, and *warfarin*, probably by interfering with CYP-mediated metabolism of these drugs. Coadministration of *rifampin*, a potent inducer of CYP, may decrease serum concentrations of *clarithromycin* and *telithromycin*. CYP3A4 inhibitors (e.g., *itraconazole*) increase peak serum concentrations of *clarithromycin* and telithromycin. *Azithromycin* is much less likely to be involved in these drug interactions; however, caution is advised when the consequences of interaction are severe.

Lincosamides

The class originator *lincomycin* and its congener *clindamycin* are approved in the U.S. *Clindamycin* has largely replaced *lincomycin* in clinical practice and is principally used to treat gram-positive aerobic and anaerobic infections, as well as some parasitic infections.

Mechanism of Action

Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although *clindamycin*, *erythromycin*, and *chloramphenicol* are not structurally related, they act at sites in close proximity, and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others.



CLINDAMYCIN

Antimicrobial Activity

Clindamycin has good *in vitro* activity against *penicillin*-susceptible strains of pneumococci (but less against *penicillin*-resistant strains), *S. pyogenes*, and viridans streptococci (see Table 60–1). MSSAs usually are susceptible to *clindamycin*, but MRSA and coagulase-negative staphylococci are more likely to be resistant. *Clindamycin* is more active than macrolides against anaerobic bacteria, especially *B. fragilis*, but resistance to *clindamycin* in *Bacteroides* spp. increasingly is encountered. From 10% to 20% of clostridial species other than *C. perfringens* are resistant. Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant. *Clindamycin* plus *primaquine* and *clindamycin* plus *pyrimethamine* are second-line regimens for *Pneumocystis jirovecii* pneumonia and *T. gondii* encephalitis, respectively.

Resistance to Lincosamides

Macrolide resistance due to ribosomal methylation also may produce resistance to *clindamycin*. Because *clindamycin* does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. However, selection for a subpopulation of constitutive methylase producers may occur among staphylococci and streptococci with a macrolide-inducible phenotype (Lewis and Jorgensen, 2005). *Clindamycin* is not a substrate for macrolide efflux pumps; thus, strains that are resistant to macrolides by this mechanism are susceptible to *clindamycin*.

ADME

Clindamycin is nearly completely absorbed following oral administration. Peak concentrations of 2 to 3 μg/mL are attained within 1 h after the ingestion of 150 mg. Food in the stomach does not reduce absorption significantly. The $t_{1/2}$ of the antibiotic is about 3 h. *Clindamycin palmitate*, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly *in vivo*. The phosphate ester of *clindamycin*, which is given parenterally, also is rapidly hydrolyzed *in vivo* to the active parent compound.

Clindamycin is widely distributed in many fluids and tissues, including good concentrations in bone. CSF concentrations are limited, even when the meninges are inflamed, but concentrations sufficient to treat cerebral toxoplasmosis are achievable. The drug readily crosses the placental barrier. Ninety percent or more of *clindamycin* is bound to plasma proteins. *Clindamycin* accumulates in polymorphonuclear leukocytes and alveolar macrophages and in abscesses.

Clindamycin is inactivated by metabolism to *N*-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Dosage adjustments may be required in patients with severe hepatic failure. Only about 10% of the *clindamycin* administered is excreted unaltered in the urine, and small quantities are found in the feces.

Therapeutic Uses

The oral dose of *clindamycin* for adults is 150 to 300 mg every 6 h; for severe infections, it is 300 to 600 mg every 6 h. Children should receive 8 to 12 mg/kg per day of *clindamycin palmitate hydrochloride* in three or four divided doses or, for severe infections, 13 to 25 mg/kg per day. *Clindamycin phosphate* is available for intramuscular or intravenous use. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200 to 2700 mg/day, divided into three or four equal doses for adults. Children should receive 15 to 40 mg/kg per day in three or four divided doses.

Skin and Soft-Tissue Infections

Clindamycin is an alternative agent for the treatment of skin and soft-tissue infections, especially in patients with β-lactam allergies (Stevens et al., 2014). It is also useful for oral treatment of skin infections when MRSA and streptococci are potential pathogens. Because *clindamycin* inhibits toxin production, it is recommended as an adjunctive agent in necrotizing fasciitis or gas gangrene when toxin-producing bacteria (e.g., streptococci, staphylococci, clostridia) are suspected. Topical *clindamycin* is used for treatment of acne.

Respiratory Tract Infections

Clindamycin is effective for treatment of lung abscess and anaerobic lung and pleural space infections due to susceptible organisms (Levison et al., 1983). It has been used as an alternative agent for treatment of sinusitis, pharyngitis, and otitis media. *Clindamycin* in combination with *primaquine* is useful as an alternative agent for the treatment of *P. jirovecii* pneumonia in patients with HIV.

Other Infections

Owing to its good activity against staphylococci and excellent bone penetration, *clindamycin* is an alternative agent for treatment of osteomyelitis. *Clindamycin* in combination with *pyrimethamine* and *leucovorin* (folinic acid) is an effective alternative for acute treatment of encephalitis caused by *T. gondii* in patients with AIDS. *Clindamycin* plus *quinine* is an alternative regimen for nonsevere malaria. *Clindamycin* is also administered vaginally for bacterial vaginosis.

Adverse Effects

GI Effects

The reported incidence of diarrhea associated with the administration of *clindamycin* ranges from 2% to 20%. In most cases, this is mild to moderate in severity and resolves on drug discontinuation. However, *clindamycin* carries a relatively high risk of superinfection with *C. difficile*, with an odds ratio versus no antibiotic exposure of 16 in one meta-analysis, compared to 5.5 for cephalosporins and 5.5 for fluoroquinolones (Brown et al., 2013). This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. *Severe forms of* C. difficile *infection may be fatal.* The prescribing information for *clindamycin* in the U.S. includes a boxed warning about the risk of *C. difficile* infection. Discontinuation of the drug, combined with administration of oral *vancomycin* or *fidaxomicin*, is usually effective for treatment, but relapses occur. Agents that inhibit peristalsis (e.g., opioids) may prolong and worsen the condition.

Other Toxic and Irritative Effects

Skin rashes occur in about 10% of patients treated with *clindamycin* and may be more common in patients with HIV infection. Other uncommon reactions include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. *Clindamycin* may potentiate the effect of concomitant neuromuscular blocking agents.

Oxazolidinones

Oxazolidinones are a new class of synthetic protein synthesis inhibitors with activity primarily against gram-positive organisms, including multidrug-resistant pathogens. *Linezolid* is the class originator; a second agent, *tedizolid*, was FDA approved in 2014.

Mechanism of Action

Oxazolidinones inhibit protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. Because of their unique mechanism of action, these agents are active against strains that are resistant to multiple other agents, including *penicillin*-resistant strains of *S. pneumoniae*; *methicillin*-resistant, *vancomycin*-intermediate, and *vancomycin*-resistant strains of staphylococci; and *vancomycin*-resistant strains of enterococci.

Antimicrobial Activity

Linezolid is active against the vast majority of gram-positive organisms, including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as *Corynebacterium* spp., *Nocardia* spp., and *L. monocytogenes* (see Table 60–1). It has poor activity against most gram-negative aerobic bacteria. It is bacteriostatic against enterococci and staphylococci but may be bactericidal against streptococci. *Mycobacterium tuberculosis* is moderately susceptible, as are most rapidly growing mycobacteria, but MAI is frequently resistant. The available data to date suggest *tedizolid* has similar activity to *linezolid* (Rybak et al., 2014).

Resistance to Oxazolidinones

Resistance in enterococci and staphylococci is most commonly due to point mutations of the 23S rRNA. Because bacteria have multiple copies of 23S rRNA genes, significant resistance generally requires mutations in two or more copies. Recently, a transferable methyltransferase that confers resistance through ribosomal modification has been described. *Linezolid* resistance remains relatively low among normally susceptible organisms, although some sites report increasing frequency in enterococci, including cases of nosocomial transfer. Limited data suggest *tedizolid* may be active against some *linezolid*-resistant isolates, although reports of clinical use for *linezolid*-resistant isolates are lacking.

ADME

Linezolid is well absorbed after oral administration, with a bioavailability of 100%, and may be administered without regard to food. Dosing for oral and intravenous preparations is the same. The $t_{1/2}$ is about 4 to 6 h. *Linezolid* is 30% protein bound and distributes widely to well-perfused tissues, including favorable distribution into the central nervous system. *Linezolid* is nonenzymatically oxidized to aminoethoxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of a dose of *linezolid* appears in the urine, 30% as active compound and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. No dose adjustment in renal insufficiency is currently recommended by the manufacturer, although some studies have suggested accumulation in patients with renal dysfunction (Crass et al., 2019). *Linezolid* and its breakdown products are eliminated by dialysis; therefore, the drug should be administered after hemodialysis.

Tedizolid is administered orally and parenterally as a prodrug (*tedizolid phosphate*) that is rapidly and completely hydrolyzed to *tedizolid*. *Tedizolid* is well absorbed after oral administration (bioavailability >80%). *Tedizolid* displays greater protein binding (70%–90%) and a longer $t_{1/2}$ of about 12 h. There is minimal elimination of unchanged drug in the urine; the drug undergoes sulfation in the liver and is excreted primarily in the feces.

Therapeutic Uses

Linezolid is most commonly administered at a dose of 600 mg twice daily orally or intravenously. Lower doses and/or reduced frequency of dosing (e.g., 300 mg twice daily or 600 mg once daily) may be used for long-term therapy of mycobacterial infections. *Tedizolid* is given as a 200-mg IV or oral daily dose.

Skin and Soft-Tissue Infections

Linezolid and *tedizolid* are FDA-approved for treatment of skin and skin-structure infections caused by streptococci and *S. aureus* (MSSA and MRSA). A 6-day regimen of *tedizolid* provided similar outcomes to 10 days of *linezolid*.

Respiratory Tract Infections

Linezolid is approved for treatment of community-acquired pneumonia due to *S. pneumoniae* and nosocomial pneumonia due to *S. aureus*. A randomized clinical trial in patients with MRSA pneumonia demonstrated similar or better outcomes to *vancomycin* (Wunderink et al., 2012). Studies of *tedizolid* for pneumonia are under way.

Other Infections

Linezolid is commonly used for a variety of infections due to *vancomycin*-resistant *E. faecium*. *Linezolid* has been used in combination therapy for extensively drug-resistant tuberculosis, nontuberculous mycobacterial infections, and infections due to *Nocardia*.

Adverse Effects

Myelosuppression

Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving *linezolid*. Thrombocytopenia tends to be the most common effect, with an onset between 7 and 10 days. Effects are reversible on drug discontinuation. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function and in patients receiving courses of therapy lasting beyond 2 weeks. Treatment durations with *tedizolid* in clinical trials have been

limited; based on early clinical and *in vitro* data, *tedizolid* may have a lower propensity for causing myelosuppression.

Mitochondrial Toxicities

Patients receiving treatment with *linezolid* have developed peripheral neuropathy, optic neuritis, and lactic acidosis (Narita et al., 2007). These effects typically manifest after prolonged treatment durations (at least 6 weeks), although some cases of lactic acidosis have been described after only a few days of therapy. The underlying mechanism of these toxicities is believed to be inhibition of mitochondrial protein synthesis. In a study of patients receiving long-term *linezolid* for treatment of drug-resistant tuberculosis, 18% experienced optic neuritis and 64% experienced peripheral neuropathy during the first year of treatment, although only three patients discontinued *linezolid* due to adverse effects (Lee et al., 2012). *Linezolid* should generally not be used for long-term therapy if there are alternative agents. There are currently insufficient data to judge the risk of mitochondrial toxicities with *tedizolid*.

Drug Interactions

Linezolid is a weak nonspecific inhibitor of monoamine oxidase. Patients receiving concomitant therapy with an adrenergic or serotonergic agent (including selective serotonin reuptake inhibitors) or consuming more than 100 mg of tyramine a day may experience serotonin syndrome (e.g., palpitations, headache, hypertensive crisis). Coadministration of these agents is best avoided. However, in patients receiving selective serotonin reuptake inhibitors who acutely require *linezolid* therapy for short-term (10- to 14-day) treatment, coadministration with careful monitoring is reasonable. The relative potential for this interaction with *tedizolid* may be lower based on preclinical data. Neither *linezolid* nor *tedizolid* is a substrate or an inhibitor of CYPs.

Pleuromutilins

Pleuromutilins are derivatives of natural products of the *Pleurotus* spp. of fungi and were discovered in the 1950s. Two pleuromutilin agents are available for clinical use in humans, the topical agent *retapamulin* and the orally and intravenously administered agent *lefamulin*.

Mechanism of Action

Pleuromutilins are inhibitors of bacterial protein synthesis by targeting the 50S ribosomal subunit. The site of binding is near the A and P sites and results in inhibition of peptide bond formation (Paukner et al., 2017). There is some overlap with binding sites of oxazolidinones, lincosamides, phenicols, and streptogramins, although the mechanism of the pleuromutilins is unique and cross-resistance so far is uncommon. *Lefamulin*'s activity against gram-positive pathogens is typically bactericidal.

Antimicrobial Activity

The pleuromutilins as a class have potent activity against gram-positive pathogens, with the exception of enterococci. Minimum inhibitory concentrations are very low against staphylococci, including MRSA, and streptococci, including *penicillin*-resistant *S. pneumoniae*. They do not exhibit useful activity against enteric gram-negatives but have some activity against gram-negatives seen in community-acquired respiratory pathogens such as *H. influenzae* and *M. catarrhalis*. Activity against atypical respiratory pathogens such as *Chlamydophila*, *Mycoplasma*, and *Legionella* spp. is good. There is strong interest in use of *lefamulin* for treatment of sexually transmitted infections based on good *in vitro* data against *N. gonorrhoeae* and *C. trachomatis*.

Resistance to Pleuromutilins

Resistance to pleuromutilins among typically susceptible organisms is currently rare. Identified mechanisms of resistance are generally similar to those seen with other protein synthesis inhibitors, with point mutations leading to reduced drug binding to the ribosome appearing to be most common. Upregulated efflux and modification of the target through ribosomal protection proteins may also be seen described.

ADME

Retapamulin is available for topical use; absorption is generally low, although it may be increased in children or when applied to broken skin. Following intravenous administration, *lefamulin* achieves peak plasma concentrations of approximately 1.5 to 2 mg/L. The oral formulation has a relatively low bioavailability of approximately 25%, which is modestly reduced by food; however, at the higher oral doses recommended, peak plasma concentrations approximating those of IV administration can be achieved. The drug is highly protein bound (~95%), with a half-life of around 12 h, allowing for twice-daily dosing. Elimination is largely unchanged in the feces, with no need for dose adjustment in renal or hepatic dysfunction.

Therapeutic Uses

Retapamulin is indicated for the treatment of impetigo in adults and children, applied as a thin layer of a 1% cream twice daily. *Lefamulin* is indicated for the treatment of community-acquired bacterial pneumonia at a dose of 150 mg IV or 600 mg orally every 12 h and is under study for the treatment of skin and soft-tissue infections.

Adverse Effects

Lefamulin is generally well tolerated, with gastrointestinal adverse effects such as nausea and diarrhea being most common. Prolongation of the QT interval has been observed and may warrant monitoring in patients with risk factors for arrhythmia.

Drug Interactions

Retapamulin and *lefamulin* are substrates of CYP3A4. Concomitant use of *lefamulin* and strong inducers or inhibitors of these enzymes should be avoided or undertaken with caution.

Streptogramins

Streptogramins are semisynthetic derivatives of naturally occurring agents produced by *Streptomyces pristinaespiralis*. The only streptogramin in clinical use for humans is a fixed combination of *quinupristin* (a streptogramin B) with *dalfopristin* (a streptogramin A) in a 30:70 ratio. *Quinupristin* and *dalfopristin* are more soluble derivatives of the congeners pristinamycin IA and IIA and therefore are suitable for intravenous administration.

Mechanism of Action

Quinupristin and *dalfopristin* are protein synthesis inhibitors that bind the 50S ribosomal subunit. *Quinupristin* binds at the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. *Dalfopristin* binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of *quinupristin* at its target site. *Dalfopristin* directly interferes with polypeptide chain formation. The net result of the cooperative and synergistic binding of these two molecules to the ribosome is enhanced and often bactericidal activity.

Antimicrobial Activity

Quinupristin/dalfopristin is active against most gram-positive cocci and organisms responsible for atypical pneumonia (e.g., *M. pneumoniae*, *Legionella* spp., and *C. pneumoniae*) but is inactive against gram-negative organisms (see Table 60–1). The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against *Enterococcus faecium*.

Resistance to Streptogramins

Resistance to *quinupristin* is mediated by genes encoding a ribosomal methylase that prevents binding of drug to its target or genes encoding lactonases that inactivate type B streptogramins. Resistance to *dalfopristin* is mediated by genes that encode acetyltransferases that

inactivate type A streptogramins or staphylococcal genes that encode ATP-binding efflux proteins that pump type A streptogramins out of the cell. These resistance determinants are located on plasmids. Resistance to *quinupristin/dalfopristin* always is associated with a resistance gene for type A streptogramins. Methylase-encoding genes can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is preferred (e.g., endocarditis).

ADME

Quinupristin/dalfopristin is administered by intravenous infusion over at least 1 h. The $t_{1/2}$ is 0.85 h for *quinupristin* and 0.7 h for *dalfopristin*. The volume of distribution is 0.87 L/kg for *quinupristin* and 0.71 L/kg for *dalfopristin*. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. Hepatic insufficiency increases the plasma concentrations of active component and metabolites by 180% for *quinupristin* and 50% for *dalfopristin*.

Therapeutic Uses

Quinupristin/dalfopristin is approved in the U.S. for complicated skin and skin-structure infections caused by *methicillin*-susceptible strains of *S. aureus* or *S. pyogenes*. It is also used for treatment of infections caused by *vancomycin*-resistant strains of *E. faecium* (dose of 7.5 mg/kg every 8–12 h), and in Europe, it also is approved for treatment of nosocomial pneumonia and infections caused by MRSA. *Quinupristin/dalfopristin* should be reserved for treatment of serious infections caused by multidrug-resistant gram-positive organisms such as *vancomycin*-resistant *E. faecium*; it has largely been supplanted by newer agents with activity against resistant gram-positive organisms.

Adverse Effects

The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias, more likely to be problematic in patients with hepatic insufficiency, are managed by reducing the infusion frequency.

Drug Interactions

Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates with *quinupristin/dalfopristin* may result in significant toxicity. Caution and monitoring are recommended for drugs in which the toxic-therapeutic window is narrow or for drugs that prolong the QTc interval.

Phenicols

Chloramphenicol, an antibiotic produced by *Streptomyces venezuelae*, was introduced into clinical practice in 1948. *Chloramphenicol* can cause serious and fatal blood dyscrasias; consequently, the drug is now reserved for treatment of life-threatening infections (e.g., meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham et al., 2002). Other agents of similar structure (*thiamphenicol*, *florfenicol*) are used in veterinary medicine.

Mechanism of Action

Chloramphenicol inhibits protein synthesis in bacteria and, to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. *Chloramphenicol* acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and *clindamycin*). The drug prevents the binding of the amino acid–containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 60–3).

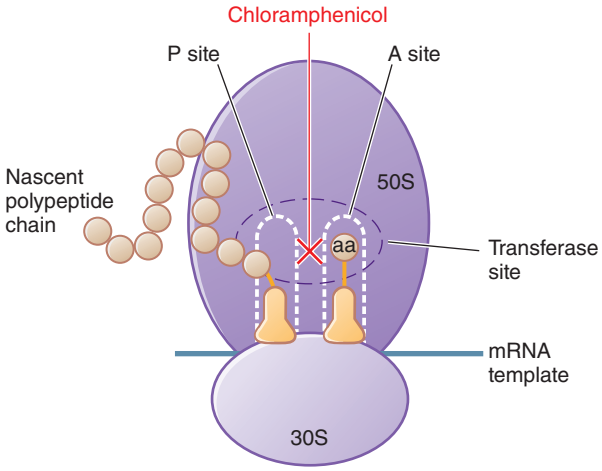


Figure 60–3 *Inhibition of bacterial protein synthesis by chloramphenicol. Chloramphenicol* binds to the 50S ribosomal subunit at the peptidyltransferase site, inhibiting transpeptidation. *Chloramphenicol* binds near the site of action of *clindamycin* and the macrolide antibiotics. These agents interfere with the binding of *chloramphenicol* and thus may interfere with each other's actions if given concurrently.

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S); erythropoietic cells are particularly sensitive.

Antimicrobial Activity

Chloramphenicol possesses a broad spectrum of antimicrobial activity. *Chloramphenicol* is bacteriostatic against most species, although it may be bactericidal against *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*. Strains of *S. aureus* tend to be less susceptible, but some isolates of highly resistant MRSA have been susceptible. *Chloramphenicol* is active against enterococci, including multidrug-resistant *E. faecium*. *Chloramphenicol* is active against *Mycoplasma*, *Chlamydia*, and *Rickettsia*. Enterobacterales are variably sensitive to *chloramphenicol*, but *P. aeruginosa* is resistant to even very high concentrations of *chloramphenicol*. Strains of *V. cholerae* have remained largely susceptible to *chloramphenicol*.

Resistance to Chloramphenicol

Resistance to *chloramphenicol* usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of *chloramphenicol* fail to bind to bacterial ribosomes.

ADME

Chloramphenicol has been available in oral, intravenous, and topical (e.g., ophthalmic) preparations. The oral and ophthalmic formulations are no longer available in the U.S., although they can be found in other parts of the world. *Chloramphenicol* administered in oral capsule form is absorbed rapidly from the GI tract. For parenteral use, *chloramphenicol succinate* is a prodrug that is hydrolyzed by esterases to *chloramphenicol in vivo*. *Chloramphenicol succinate* is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of *chloramphenicol succinate*. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active *chloramphenicol* (up to 4 h) and extending the period over which renal clearance of *chloramphenicol succinate* can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF. Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and *chloramphenicol* are excreted in the urine. Patients with impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. Variability in the metabolism and pharmacokinetics of *chloramphenicol* in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses

Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and less toxic are available, they should be used instead of *chloramphenicol*.

Bacterial Meningitis

Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β-lactams and in developing countries. The total daily dose for children should be 50 mg/kg of body weight, divided into four equal doses given intravenously every 6 h.

Rickettsial Diseases

The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in pregnant women, and in children less than 8 years of age who require prolonged or repeated courses of therapy, *chloramphenicol* is an alternative therapy. Rocky Mountain spotted fever; epidemic, murine, scrub, and recrudescent typhus; and Q fever respond well to *chloramphenicol*. For adults and children with these diseases, a dosage of 50 mg/kg per day divided into 6-h intervals is recommended. For severe or resistant infections, doses up to 100 mg/kg per day may be used for short intervals, but the dose must be reduced to 50 mg/kg per day as soon as possible. Therapy should be continued until the general condition has improved and the patient is afebrile for 24 to 48 h.

Adverse Effects

Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome *c* oxidase, ubiquinone–cytochrome *c* reductase, and the proton-translocating ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

Hematological Toxicity

Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Dose-related, reversible erythroid suppression probably reflects an inhibitory action of *chloramphenicol* on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Bone marrow suppression occurs regularly when plasma concentrations are 25 μg/mL or greater and is observed with the use of large doses of *chloramphenicol*, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop without prior dose-related marrow suppression.

Pancytopenia occurs more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. Although the incidence of the reaction is low, about 1 in 30,000 courses of therapy or more, the fatality rate is high when bone marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for about 70% of cases of blood dyscrasias due to *chloramphenicol*; hypoplastic anemia, paroxysmal nocturnal hemoglobinuria, and thrombocytopenia make up the remainder. The proposed mechanism involves conversion of the nitro group to a toxic intermediate by intestinal bacteria.

Effects on Neonates

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome* after exposure to *chloramphenicol*. This syndrome usually begins 2 to 9 days after treatment is started. Within the first 24 h, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. Over the next 24 h, neonates turn an ashen-gray color and become flaccid and hypothermic. A similar "gray syndrome" has been reported in adults who were accidentally overdosed with the drug. Death occurs in about 40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae. Two mechanisms apparently are responsible for *chloramphenicol* toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes *chloramphenicol*; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, *chloramphenicol* concentrations in plasma usually exceed 100 μg/mL and may be as low as 75 μg/mL.

Drug Interactions

Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system. Severe toxicity and death have occurred because of failure to recognize such effects. Concurrent administration of *phenobarbital* or *rifampin*, which potently induce CYPs, shortens the $t_{1/2}$ of the antibiotic and may result in subtherapeutic drug concentrations.

Mupirocin

Mupirocin is an antibiotic first isolated from *Pseudomonas fluorescens*. It is a mixture of several pseudomonic acids and is effective against gram-positive bacteria.

Mechanism of Action, Antimicrobial Activity, and Resistance

Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl tRNA synthase, leading to depletion of factors required for protein synthesis (Khoshnood et al., 2019). There is no cross-resistance with other classes of antibiotics. Resistance may occur through a variety of mechanisms and to various degrees. *Mupirocin* is for topical use only. The drug's activity ranges from bacteriostatic to bactericidal dependent on the dose. It is active primarily against gram-positive bacteria, including *S. pyogenes*, MSSA, and MRSA. Low-level resistance typically occurs through point mutations in the target synthetase enzyme. High-level resistance is mediated by a plasmid, which encodes a "bypass" Ile tRNA synthase that binds *mupirocin* poorly.

Therapeutic Uses

Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*. The nasal ointment is approved for eradication of *S. aureus* nasal carriage. The consensus is that patients who stand to benefit from *mupirocin* prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft-tissue infections.

Adverse Effects

Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes causes irritation that may take several days to resolve. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate-to-severe renal failure to avoid accumulation of polyethylene glycol.

Drug Facts for Your Personal Formulary: *Protein Synthesis Inhibitors*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Tetracyclines and Derivatives **General: Bacteriostatic; oral formulations interact with orally administered cations (calcium, iron, aluminum); avoid in pregnancy and children <8 years old due to permanent tooth discoloration; photosensitivity**		
Tetracycline (PO, topical)	• Inflammatory acne • *Helicobacter pylori* infections (in combination) • Topical first aid • Use for other indications has largely been replaced by doxycycline	• Good activity vs. rickettseae, *Chlamydia, Mycoplasma, Legionella, Ureaplasma, Borrelia, Francisella tularensis, Pasteurella multocida, Bacillus anthracis, Helicobacter pylori* • Some activity vs. *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Haemophilus influenzae* • Good CSF penetration • Renal excretion • Renal toxicity, hepatotoxicity at high doses
Doxycycline (IV, PO)	• Community-acquired pneumonia • Skin/soft-tissue infection • Urogenital chlamydia • Lymphogranuloma venereum • Syphilis (penicillin alternative) • Rocky Mountain spotted fever • Anthrax, tularemia • Lyme disease, leptospirosis • Periodontitis	• Similar to tetracycline, with improved activity vs. streptococci and staphylococci • Good CSF penetration • Dual renal/biliary elimination • Preferred tetracycline for most indications due to more favorable activity, tolerability, and frequency of administration
Minocycline (IV, PO, topical)	• Skin/soft-tissue infections • Mycobacterial infections • Nocardiosis • Acne	• Similar to doxycycline, with improved activity vs. staphylococci, *Acinetobacter*, and *Stenotrophomonas maltophilia* • Renal elimination • Vestibular toxicity
Tigecycline (IV) Eravacycline (IV) Omadacycline (IV, PO)	• Intra-abdominal infection • Skin and soft-tissue infection • Pneumonia • Tigecycline: increased risk of death in pooled analysis; reserve as alternative therapy	• Similar to minocycline, with improved activity vs. *Escherichia coli*, *Klebsiella*, enterococci, *Bacteroides fragilis* • Activity vs. nontuberculous mycobacteria • Wide distribution with low serum levels • Hepatic elimination
Macrolides and Ketolides **General: Bacteriostatic; widely distributed but with limited CSF penetration, gastrointestinal distress, QT prolongation, major (erythromycin, clarithromycin, telithromycin) to minor (azithromycin) inhibitor of drug-metabolizing CYPs**		
Erythromycin (IV, PO, topical)	• Erysipelas and cellulitis • Ophthalmia neonatorum • Diphtheria • Pertussis	• Good activity against *Mycoplasma, Chlamydia, Legionella, Campylobacter, Bordetella pertussis, Corynebacterium diphtheriae* • Some activity against *S. pneumoniae*, *S. pyogenes, H. influenzae* • Oral formulations have variable absorption • Stimulates motilin receptors; gastrointestinal prokinetic properties • Cholestatic hepatitis with long-term use
Clarithromycin (PO)	• Erysipelas and cellulitis • Community-acquired pneumonia • Acute exacerbations of chronic bronchitis • *Helicobacter pylori* gastritis (in combination with other agents) • *Mycobacterium avium* treatment and prophylaxis	• Similar to erythromycin, with improved activity vs. streptococci and staphylococci • Good activity vs. *Moraxella catarrhalis*, *H. pylori*, and nontuberculous mycobacteria • Active metabolite • Some drug accumulation in severe renal impairment • Tinnitus at high doses
Azithromycin (IV, PO, topical)	• Community-acquired pneumonia • Acute exacerbations of chronic bronchitis • Otitis media • Bacterial pharyngitis • Chlamydia • *Mycobacterium avium* treatment and prophylaxis	• Similar to clarithromycin, improved activity vs. *H. influenzae* • Extensive tissue distribution and concentration in tissues • Anti-inflammatory properties • Long $t_{1/2}$, ~48 h
Lincosamides **General: Bacteroiostatic**		
Clindamycin (IV, PO, topical)	• Skin and soft-tissue infection • Inflammatory acne • Lung abscess • Streptococcal pharyngitis • *Pneumocystis* pneumonia • Toxoplasma encephalitis • Nonsevere malaria • Bacterial vaginosis	• Good activity vs. *S. pneumoniae*, *S. pyogenes*, viridans streptococci, *Actinomyces*, *Nocardi*[a] • Some activity vs. *S. aureus*, *Bacteroides* spp., *Toxoplasma, Pneumocystis, Plasmodium* • Wide tissue distribution, especially into bone; modest CSF penetration • Metabolized in liver, excreted in urine and bile • Diarrhea, rarely *Clostridium difficile* colitis

Drug Facts for Your Personal Formulary: *Protein Synthesis Inhibitors (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Oxazolidinones		
General: Bacteriostatic; excellent oral absorption; wide distribution, including to CNS; myelosuppression; peripheral neuropathy with long-term use; risk of serotonin syndrome with concomitant antidepressant use		
Linezolid (IV, PO)	• Skin and soft-tissue infections • Pneumonia • Vancomycin-resistant enterococcal infections • Nocardiosis • Drug-resistant tuberculosis	• Good activity against streptococci, staphylococci, enterococci, *Nocardia, Listeria* • Some activity against mycobacteria • Nonenzymatic degradation with elimination in urine
Tedizolid (IV, PO)	• Skin and soft-tissue infections	• Similar activity to linezolid but lower risk of myelosuppression and drug interactions • Hepatic metabolism and fecal excretion • Longer $t_{1/2}$ than linezolid
Pleuromutilins		
General: Bactericidal		
Retapamulin (topical) Lefamulin (IV, PO)	• Skin and soft-tissue infections • Pneumonia	• Excellent activity against streptococci, staphylococci, *E. faecium*, *Mycoplasma, Legionella, Chlamydophila* • Good activity vs. *Haemophilus influenzae*, *Moraxella catarrhalis*, *Neisseria gonorrhoeae, Chlamydia trachomatis* • Hepatic metabolism and fecal excretion • CYP substrate; drug interaction potential • GI adverse effects, QT prolongation
Streptogramins		
General: Bacteriostatic to bactericidal depending on species and resistance		
Quinupristin/ dalfopristin (IV)	• Skin and soft-tissue infections • Vancomycin-resistant *Enterococcus faecium* infections	• Good activity against streptococci, staphylococci, *E. faecium*, *Mycoplasma, Legionella, Chlamydophila* • Hepatic metabolism with biliary excretion • Infusion site phlebitis • Arthralgias, myalgias • CYP inhibitor
Phenicols		
General: Bacteriostatic		
Chloramphenicol (IV, PO—not in the U.S.)	• Rickettsial infections • Bacterial meningitis • Because of risk of fatal toxicities, reserve as alternative therapy	• Good activity vs. *S. pneumoniae, H. influenzae, Neisseria meningitidis*, rickettsiae, *Vibrio, Enterococcus* • Variable serum levels due to clearance of prodrug before hydrolysis • Excellent CSF penetration • Hepatic clearance • Dose-dependent bone marrow suppression, idiosyncratic fatal aplastic anemia, fatal "gray baby syndrome" in neonates receiving high doses

Chapter 61

Antifungal Agents

P. David Rogers and Damian J. Krysan

Kingdom Fungi and Its Impact on Humans

There are 200,000 known species of fungi, and estimates of the total size of the kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, and smuts. About 400 fungal species cause disease in animals, and even fewer cause human disease. Nonetheless, fungal infections are associated with significant morbidity and mortality. The incidence of life-threatening fungal infections has increased in recent decades owing to an increase in immunocompromised patient populations, such as those receiving hematologic or solid-organ transplantation, cancer chemotherapy, and immunosuppressive medications, as well as those with human immunodeficiency virus–acquired immunodeficiency syndrome (HIV-AIDS). This has made antifungal agents increasingly important in the practice of modern medicine. With the currently available antifungal pharmacopeia, mortality rates for invasive fungal disease remain unacceptably high (Brown et al., 2012; Thornton, 2020).

Fungi are eukaryotes, making the discovery and development of drugs that target the pathogen without posing significant toxicity to the host a challenging undertaking. Differences in the biosynthesis of membrane sterols, the ability of fungi to deaminate cytosine, and the unique fungal cell wall that contains glucans and chitin have all been exploited to produce relatively safe and effective antifungal agents for the treatment of fungal infections (Roemer and Krysan, 2014). Since the advent of amphotericin B-deoxycholate in the late 1950s, research has sought safer and more effective alternatives for the treatment of systemic fungal infections. While amphotericin B remains the gold standard of systemic antifungal pharmacotherapy for a wide range of infections, alternative therapies have emerged for many clinically important fungal pathogens (Wiederhold, 2018).

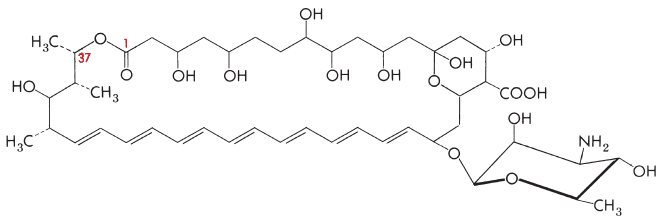
This chapter provides a comprehensive overview of currently available therapeutic options for the management of invasive, mucosal, and superficial fungal infections. With only a few exceptions, the antifungals in common clinical use act mainly at sites involving the cell wall and cell membrane (Figure 61–1). Table 61–1 summarizes common fungal infections and their pharmacotherapy. Recommended adult dosages are briefly discussed for each agent. Dosing recommendations for antifungal agents in children have been recently reviewed elsewhere (Downes et al., 2020).

Systemic Antifungal Agents: Drugs for Deeply Invasive Fungal Infections

Amphotericin B

Chemistry

Amphotericin B is an amphipathic or an photeric polyene macrolide molecule with the broadest spectrum of activity of any of the currently available antifungal drugs. Polyene macrolide compounds share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity when administered systemically, and a common mechanism of antifungal action. *Amphotericin B*, a heptaene macrolide, contains seven conjugated trans-double bonds and a 3-amino-3,6-dideoxymannose (mycosamine) connected to the macrolide ring through a glycosidic bond (Figure 61–2). The amphoteric properties of the drug, from which it derives its name, are due to the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH.



AMPHOTERICIN B

Mechanism of Action

The antifungal activity of *amphotericin B* depends principally on its ability to bind *ergosterol* in the membrane of sensitive fungi. *Amphotericin B* has long been thought to form pores or channels that increase the permeability of the membrane and allow leakage of cytosolic molecules and ions, leading to loss of membrane integrity. However, recent evidence suggests *amphotericin B* forms aggregates that sequester ergosterol from lipid bilayers much like a sponge, resulting in fungal cell death (Anderson et al., 2014) (see Figure 61–2).

Formulations

Four formulations of *amphotericin B* are commercially available: C-AMB (conventional *amphotericin B*), ABCD (*amphotericin B* colloidal dispersion), L-AMB, (liposomal *amphotericin B*), and ABLC (*amphotericin B* lipid complex). Table 61–2 summarizes the pharmacokinetic properties of the available *amphotericin B* preparations, which have recently been extensively reviewed (see Hamill, 2013).

C-AMB. *Amphotericin B* is insoluble in water but, when formulated with the bile salt deoxycholate, becomes suitable for intravenous infusion. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely less than 0.4 μm in diameter. As a result, filters in intravenous infusion lines that trap particles larger than 0.22 μm in diameter will remove significant amounts of drug. Furthermore, the addition of electrolytes to infusion solutions will cause the colloid to aggregate and complicate administration.

Abbreviations

ABCD: amphotericin B colloidal dispersion
ABLC: amphotericin B lipid complex
AIDS: acquired immunodeficiency syndrome
AUC: area under the C_p-time curve
C-AMB: conventional amphotericin B
CGD: chronic granulomatous disease
CDC: U.S. Centers for Diseases Control and Prevention
C_p: plasma concentration
CSF: cerebrospinal fluid
CYP: cytochrome P450
5FdUMP: 5-fluoro-2′-deoxyuridine-5′-monophosphate
5FU: 5-fluorouracil
5FUMP: 5-fluorouracil-ribose monophosphate
GI: gastrointestinal
HIV: human immundeficiency virus
L-AMB: liposomal amphotericin B
PJP: *Pneumocystis jirovecii* pneumonia
UPRTase: uracil phosphoribosyl transferase

ABCD. *Amphotericin B* colloidal dispersion contains roughly equimolar amounts of *amphotericin B* and cholesteryl sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when reconstituted in aqueous solution. ABCD provides much lower blood levels than C-AMB in humans, requiring administration of larger volumes to achieve equal blood levels. In a study of patients with neutropenic fever that compared daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common in patients who received ABCD as compared with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a study that compared ABCD (6 mg/kg) to C-AMB (1–1.5 mg/kg) in patients with invasive aspergillosis, ABCD was less nephrotoxic than C-AMB (15% vs. 49%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). ABCD is currently not commercially available in the U.S.

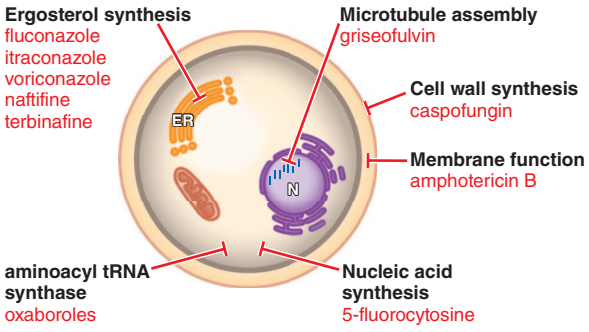


Figure 61–1 *Sites of action of antifungal agents.* Many antifungal agents act at sites involving cell wall and cell membrane function. *Amphotericin B* and other polyenes (e.g., *nystatin*) bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles (*itraconazole*, etc.) inhibit 14-α-sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of toxic 14-α-methylsterols. The allylamines (e.g., *naftifine* and *terbinafine*) inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins (e.g., *caspofungin*) inhibit the formation of glucans in the fungal cell wall. Metabolites of 5-fluorocytosine can disrupt fungal RNA and DNA synthesis. *Griseofulvin* inhibits microtubule assembly, thereby blocking fungal mitosis. Oxaboroles inhibit fungal aminoacyl tRNA synthase, thereby inhibiting fungal protein synthesis. ER, endoplasmic reticulum; N, nucleus, with microtubules.

L-AMB. Liposomal *amphotericin B* is a formulation in which *amphotericin B* is incorporated within a small, unilamellar liposomal vesicle formulation. The drug is supplied as a lyophilized powder and is reconstituted with sterile water for injection (Boswell et al., 1998). Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Boswell et al., 1998) (see Table 61–2).

ABLC. *Amphotericin B* lipid complex is a complex of *amphotericin B* with two phospholipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol) (Slain, 1999). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 h. Blood levels of *amphotericin B* are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis.

Comparisons

Compared to C-AMB, all three of the *amphotericin B* lipid formulations appear to reduce the risk of acute kidney injury (defined as a doubling of patient serum creatinine) during therapy by 58% (Barrett et al., 2003). In patients at high risk for nephrotoxicity, ABLC has been observed to be more nephrotoxic than L-AMB (Wingard et al., 2000). Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although L-AMB reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard et al., 2000), the difference depends on whether premedication is given and varies considerably among patients. Infusion-related reactions typically decrease with subsequent infusions. While less toxic, the lipid formulations are much more costly than C-AMB, making them unavailable in many countries and dictating prudent use in the U.S. and other resource-rich areas. Interestingly, C-AMB is tolerated by premature neonates much better than by older children and adults; as a result, it remains an important part of the antifungal formulary in the critical care nursery (Downes et al., 2020).

ADME

Gastrointestinal absorption of all *amphotericin B* formulations is negligible, and intravenous delivery is indicated for systemic use. In plasma, *amphotericin B* is more than 90% bound to proteins. Pharmacokinetic properties differ among the preparations (see Table 61–2). Azotemia, liver failure, and hemodialysis do not have a measurable impact on plasma concentrations. The concentration of *amphotericin B* (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor is approximately two-thirds that of trough concentrations in plasma. Regardless of formulation, very little *amphotericin B* penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid. Despite poor penetration into CSF, *amphotericin B ± flucytosine* is the treatment of choice for certain CNS fungal infections, such as cryptococcal meningitis and *Coccidioides* meningoencephalitis.

Antifungal Activity

Amphotericin B has useful clinical activity against a broad spectrum of pathogenic fungi, including *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides braziliensis*, *Aspergillus* spp., *Penicillium marneffei (Talaromyces marneffei)*, *Fusarium* spp., and Mucorales. *Amphotericin B* has limited activity against the protozoa *Leishmania* spp. and *Naegleria fowleri*. The drug has no antibacterial activity.

Fungal Resistance

Isolates of *Candida lusitaniae* are frequently resistant to *amphotericin B*. *Aspergillus terreus* and *Aspergillus nidulans* likewise appear to be less susceptible to *amphotericin B* than other *Aspergillus* spp. (Steinbach et al., 2004). Mutants selected *in vitro* for resistance to nystatin (a related polyene antifungal used topically) or *amphotericin B* replace ergosterol with certain precursor sterols. Mutations in ergosterol biosynthesis genes *ERG2*, *ERG3*, *ERG5*, *ERG6*, and *ERG11* reduce susceptibility to *amphotericin B*, likely the result of reduced ergosterol in the cell membrane of these

TABLE 61–1 ■ PHARMACOTHERAPY OF MYCOSES[a]

DEEP MYCOSES	DRUGS
Invasive aspergillosis	
Immunosuppressed	Voriconazole, isavuconazole, amphotericin B
Nonimmunosuppressed	Voriconazole, isavuconazole, amphotericin B, itraconazole
Blastomycosis	
Rapidly progressive or CNS	Amphotericin B
Indolent and non-CNS	Itraconazole
Candidiasis	
Deeply invasive	Amphotericin B, fluconazole, voriconazole, caspofungin, micafungin, anidulafungin
Coccidioidomycosis	
Rapidly progressing	Amphotericin B
Indolent	Itraconazole, fluconazole
Meningeal	Fluconazole, intrathecal amphotericin B
Cryptococcosis	
Non-AIDS and initial AIDS	Amphotericin B, flucytosine
Maintenance AIDS	Fluconazole
Histoplasmosis	
Chronic pulmonary	Itraconazole
Disseminated	
Rapidly progressing or CNS	Amphotericin B
Indolent non-CNS	Itraconazole
Maintenance AIDS	Itraconazole
Mucormycosis	Amphotericin B, isavuconazole
Pseudallescheriasis	Voriconazole, itraconazole
Sporotrichosis	
Cutaneous	Itraconazole
Extracutaneous	Amphotericin B, itraconazole
Prophylaxis in the immunocompromised host	Fluconazole Posaconazole Micafungin
Empirical therapy in the immunocompromised host (*category not recognized by FDA*)	Amphotericin B Caspofungin Fluconazole
Microsporidia Infection	Albendazole Fumagillin
Pneumocystis jirovecii pneumonia	Trimethoprim-sulfamethoxazole Pentamidine

SUPERFICIAL MYCOSES	DRUGS (*Administration mode*)
Candidiasis	
Vulvovaginal	*Topical*
	Butoconazole, clotrimazole, miconazole, nystatin, terconazole, tioconazole
	Oral
	Fluconazole
Oropharyngeal	*Topical*
	Clotrimazole, nystatin
	Oral (systemic)
	Fluconazole, itraconazole
	Posaconazole
Cutaneous	*Topical*
	Amphotericin B, clotrimazole, ciclopirox, econazole, ketoconazole, miconazole, nystatin
Ringworm	*Topical*
	Butenafine, ciclopirox, clotrimazole, econazole, haloprogin, luliconazole, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, sulconazole, terbinafine, tolnaftate, undecylenate
	Systemic
	Griseofulvin, itraconazole, terbinafine
Onychomycosis	*Systemic*
	Griseofulvin, itraconazole, terbinafine
	Topical
	Efinaconazole

[a]Not all formulations are available in all countries.

isolates (Geber et al., 1995; Hull et al., 2012; Martel et al., 2010). Resistance among clinical isolates of any fungal species is exceedingly rare, presumably because *amphotericin B* is fungicidal, and mutations that affect this critical membrane sterol are associated with significant fitness costs. *Candida auris* is an exception; nearly one-third of clinical isolates are considered resistant to *amphotericin B* based on tentative breakpoints proposed by the CDC (U.S. Centers for Diseases Control and Prevention) (CDC, 2020).

Therapeutic Uses

Intravenous administration of *amphotericin B* is the treatment of choice for invasive mucormycosis and in combination with *5-fluc tosine* is the gold standard for induction treatment of cryptococcal meningitis. *Amphotericin B* is also indicated for the treatment of severe or rapidly progressive histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis (talaromycosis). *Amphotericin B* is a salvage therapy for patients not responding to azole therapy for invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, or trichosporonosis. *Amphotericin B* (C-AMB or L-AMB) can also be given to selected patients with profound neutropenia with fever who do not respond to broad-spectrum antibacterial agents over 5 to 7 days. However, the more recently developed azoles and echinocandins are generally the drugs of choice for such patients because of their reduced toxicity.

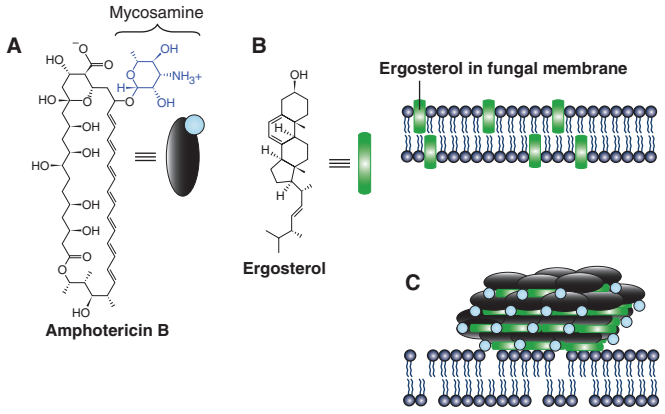

Figure 61–2 *Mechanism of action of amphotericin B.* The antifungal activity of *amphotericin B* depends on its capacity to bind ergosterol in the fungal cell membrane. **A.** *Amphotericin* is an amphipathic molecule with a mycosamine moiety (shown in blue) at one end of a 14-carbon hydrophobic chain. X-ray crystallography shows the molecule to be rigid and rod shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyenic portion. **B.** Ergosterol, here depicted as a green rod, decorates both bilayers of the fungal membrane. **C.** *Amphotericin B* appears to form aggregates that sequester and effectively extract ergosterol from lipid bilayers, much like a selective sponge, disrupting membrane structure and resulting in fungal cell death.

Typical adult doses for each *amphotericin B* formulation are summarized in Table 61–2. *Candida* esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB appears to be useful in patients with meningitis caused by *Coccidioides.* Small doses of C-AMB (from 0.01 to 1.5 mg, one to three times weekly) can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10 to 15 mg of *hydrocortisone*. However, the general use of intrathecal C-AMB administration cannot be recommended due to a lack of clinical data. Local injections of *amphotericin B* into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used to treat fungal endophthalmitis.

Adverse Effects

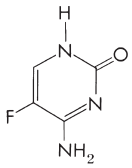
The major acute reactions to intravenous *amphotericin B* formulations are infusion-related fever and chills. These are due to the induction of a proinflammatory response in cells of the innate immune system signaling through the toll-like receptor 2 (TLR2) and CD14 (Rogers et al., 1998; Sau et al., 2003). Infusion-related reactions are most prominent with ABCD, whereas L-AMB administration appears to be less commonly associated with this adverse event. Tachypnea, respiratory stridor, or modest hypotension can also occur, but frank bronchospasm and anaphylaxis are rare. Patients with preexisting cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30 to 45 min; treatment with *meperidine* may shorten it. Pretreatment with oral *acetaminophen* or *ibuprofen* or use of intravenous *hydrocortisone sodium succinate* (hemisuccinate), 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions tend to abate with subsequent infusions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). The lipid formulations are significantly less nephrotoxic than C-AMB. Toxicity is dose dependent, usually transient, and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or *cyclosporine*. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3 to 4 g. Renal tubular acidosis and renal wasting of K^+ and Mg^{2+} also may be seen during and for several weeks after therapy. Supplemental K^+ is required in one-third of patients on prolonged therapy. Saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the Na^+ load.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely due to decreased production of erythropoietin and often responds to administration of recombinant erythropoietin. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Arachnoiditis has been observed as a complication of intrathecal administration of C-AMB.

Flucytosine

Flucytosine (5-fluorocytosine) is a fluorinated pyrimidine related to *fluorouracil* that has a limited role in the treatment of invasive fungal infections.



Flucytosine

Mechanism of Action

All susceptible fungi are capable of deaminating *flucytosine* to *5-fluorouracil* (5FU) (Figure 61–3), a potent antimetabolite that is used in cancer chemotherapy. *Fluorouracil* is metabolized first to 5-fluorouracil-ribose monophosphate (5FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase). 5FUMP is then either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2′-deoxyuridine-5′-monophosphate (5FdUMP), a potent inhibitor of *thymidylate synthase*, ultimately inhibiting DNA synthesis.

TABLE 61–2 ■ PHARMACOKINETIC DATA FOR AMPHOTERICIN B FORMULATIONS AFTER MULTIPLE ADMINISTRATIONS IN HUMANS

PRODUCT	DOSE (mg/kg)	C_{max} (μg/mL)	$AUC_{(1–24h)}$ (μg·hr/mL)	*V* (L/kg)	CL (mL/h/kg)
L-AMB	5	83 ± 35.2	555 ± 311	0.11 ± 0.08	11 ± 6
ABCD[a]	5	3.1	43	4.3	117
ABLC	5	1.7 ± 0.8	14 ± 7	131 ± 7.7	426 ± 188.5
C-AMB	0.6	1.1 ± 0.2	17.1 ± 5	5 ± 2.8	38 ± 15

[a]No longer marketed in the U.S.

For details, see the work of Boswell et al. (1998). From Boswell GW, et al. AmBisome (liposomal amphotericin B): a comparative review. *J Clin Pharmacol*, **1998**, *38*:583–592. © 1998 The American College of Clinical Pharmacology. Reprinted by permission of John Wiley and Sons.

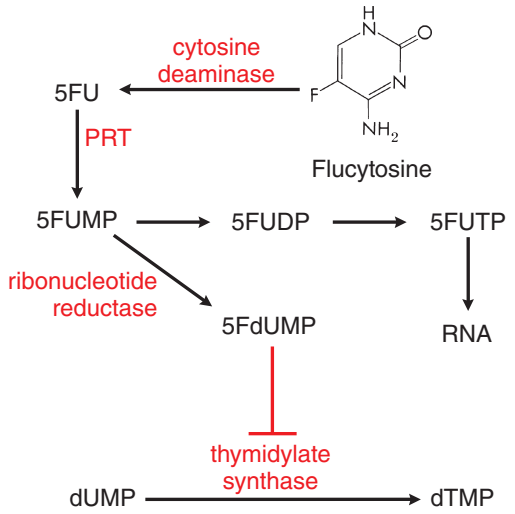


Figure 61–3 *Action of flucytosine in fungi. Flucytosine* is transported by cytosine permease into the fungal cell, where it is deaminated to 5FU. The 5FU is then converted to 5FUMP and then is either converted to 5FUTP (5-fluorouridine triphosphate) and incorporated into RNA or converted by ribonucleotide reductase to 5FdUMP, which is a potent inhibitor of thymidylate synthase. dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; PRT, phosphoribosyl pyrophosphate.

The selective action of *flucytosine* is due to the lack of *cytosine deaminase* in mammalian cells, which prevents metabolism to *fluorouracil*.

ADME

Flucytosine shows excellent bioavailability on oral administration and is absorbed rapidly from the gastrointestinal (GI) tract. It is widely distributed in the body, with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is about 70 to 80 µg/mL, achieved 1 to 2 h after a dose of 37.5 mg/kg. The *flucytosine* concentration in CSF is about 65% to 90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200 to 500 µg/mL. The $t_{1/2}$ of the drug is 3 to 6 h in normal individuals and may be as long as 200 h in patients with renal failure. The clearance of *flucytosine* is approximately equivalent to that of creatinine. In patients with decreased renal function, reduction of dosage is necessary; the plasma concentration (C_p) should be measured periodically. Peak concentrations should range between 50 and 100 µg/mL. *Flucytosine* is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis. The drug also is removed by peritoneal dialysis.

Antifungal Activity and Fungal Resistance

Flucytosine is currently used primarily as an adjunctive agent with *amphotericin B* in the induction phase of cryptococcal meningoencephalitis therapy. It has *in vitro* activity against a number of pathogens, but the emergence of resistance limits its usefulness as single-agent therapy.

Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when *flucytosine* is used alone for cryptococcosis and candidiasis. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (see Figure 61–3).

In *Candida albicans,* substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (*FURI*) causes a cysteine to become an arginine, modestly increasing *flucytosine* resistance (Dodgson et al., 2004). *Flucytosine* resistance is further increased if both *FURI* alleles n the c'ipl)id fungus are muta ɔd.

Therapeutic Uses

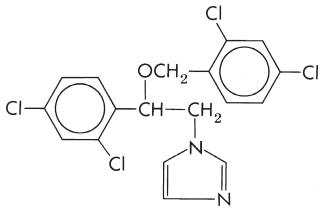
Flucytosine is given orally, 50 to 150 mg/kg per day, in four divided doses at 6-h intervals. Dosage must be adjusted for decreased renal function. *Flucytosine* is used almost exclusively in combination with *amphotericin B* for the treatment of cryptococcal meningitis, and this combination, as compared with *amphotericin B* alone, is associated with improved survival among patients with cryptococcal meningitis (Day et al., 2013). Based on this trial, the addition of *flucytosine* to *amphotericin B* is the current gold standard for the treatment of cryptococcal meningitis. Additional studies have also shown that a 2-week course of *fluconazole* plus *flucytosine* is as effective for cryptococcal meningitis induction therapy as 1 week of *amphotericin B* plus *flucytosine*. The *fluconazole*/*flucytosine* combination is an all-oral regimen and, therefore, much easier to administer in resource-limited regions with high burden of disease. The main limitation to broad implementation of this therapy in these regions is the expense and poor availability of *flucytosine* (Molloy et al., 2018).

Adverse Effects

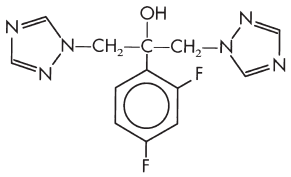
Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia. Patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects, including rash, nausea, vomiting, diarrhea, and severe enterocolitis, have been noted. In about 5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are concurrently receiving *amphotericin B*) and when plasma drug concentrations exceed 100 µg/mL. Toxicity may result from conversion of *flucytosine* to 5FU by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles

The azole antifungals include two broad classes, imidazoles and triazoles. Of the drugs now on the market in the U.S., *clotrimazole*, *miconazole*, *ketoconazole*, *econazole*, *butoconazole*, *oxiconazole*, *sertaconazole*, *sulconazole*, *tioconazole*, and *luliconazole* are *imidazoles*, and *efinaconazole*, *terconazole*, *itraconazole*, *fluconazole*, *voriconazole*, *posaconazole*, and *isavuconazole* are *triazoles*. The topical use of azole antifungals is described in the second section of this chapter.



MICONAZOLE



FLUCONAZOLE

Mechanism of Action

The major effect of imidazoles and triazoles on fungi is inhibition of 14-α-sterol demethylase, a cytochrome P450 (CYP) and the product of the gene *ERG11* (Figure 61–4). Imidazoles and triazoles thus impair the biosynthesis of ergosterol, resulting in depletion of membrane ergosterol and accumulation of the toxic product 14α-methyl-3,6-diol, leading to growth arrest (Kanafani and Perfect, 2008), possibly by disrupting the close packing of acyl chains of phospholipids and impairing the functions of membran -bound enzyme systems. Some azoles directl in(ease

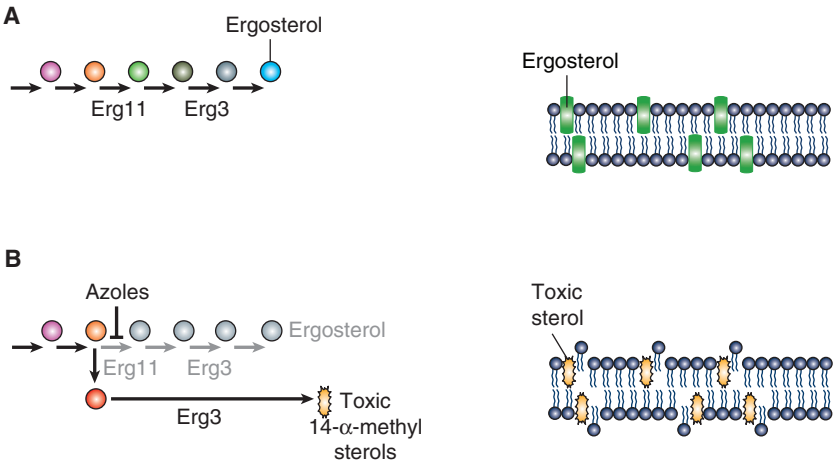


Figure 61–4 *Ergosterol biosynthesis and the mechanism of action of the azole antifungals.* **A.** Fungal ergosterol synthesis proceeds via a series of enzymic steps that include Erg11, a 14-α-sterol demethylase. The completed ergosterol is then inserted into both leaflets of the membrane bilayer. **B.** *Imidazole* and *triazole* antifungals inhibit the activity of 14-α-sterol demethylase, thereby reducing the biosynthesis of ergosterol and leading to the accumulation of 14-α-methylsterols. These methylsterols are toxic, disrupting the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, and thus inhibiting growth of the fungi.

permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Antifungal Activity

Azoles as a group have clinically useful activity against *C. albicans, Candida tropicalis, Candida parapsilosis, C. neoformans, Blastomyces dermatitidis, H. capsulatum, Coccidioides* spp., *Paracoccidioides brasiliensis,* and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *Candida glabrata* exhibits reduced susceptibility to the azoles, whereas *Candida krusei* and the agents of mucormycosis are more resistant. *Posaconazole* and *isavuconazole* have modestly improved spectrum of activity *in vitro* against the agents of mucormycosis.

Resistance

C. glabrata and *C. krusei* are considered intrinsically resistant to *fluconazole*, whereas 90% of *C. auris* isolates are resistant based on tentative breakpoints proposed by the CDC (CDC, 2020). In *C. albicans*, azole resistance can be due in part to accumulation of mutations in *ERG11*, the gene encoding the azole target, 14-α-sterol demethylase. Increased azole efflux by overexpression of ABC (ATP-binding cassette) and/or major facilitator superfamily transporters impart azole resistance in *C. albicans* and *C. glabrata*. Overexpression of these genes is due to activating mutations in genes encoding their transcriptional regulators. Mutation of the C5,6 sterol desaturase gene *ERG3* also can increase azole resistance in some species (Nishimoto et al., 2020). Such mutations prevent formation of the toxic product 14α-methyl-3,6-diol from 14α-methylfecosterol; the resulting accumulation of 14α-methylfecosterol produces functional membranes and overcomes the effect of azoles. Increased production of 14-α-sterol demethylase due to overexpression of *ERG11* occurs, owing to activating mutations in the gene encoding its transcriptional regulator Upc2.

Azole resistance has been increasingly described in isolates of *Aspergillus fumigatus* with mutations in the genes encoding enzymes of the sterol biosynthesis pathway including the azole target, increased azole export, and decreased ergosterol content. The most commonly characterized mechanism of resistance is due to the TR(34)/L98H mutation in the promoter region of *CYP51A,* which encodes the target of azoles in *A. fumigatus* (Berkow et al., 2018). Patients with cryptococcal meningitis who are treated with *fluconazole* monotherapy frequently relapse, and their isolates show decreased *fluconazole* susceptibility, which is linked to aneuploidy (Stone et al., 2019).

Interaction of Azole Antifungals With Other Drugs

The azoles interact with hepatic CYPs as substrates and inhibitors (Table 61–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some coadministered drugs (Table 61–4). Other coadministered drugs can decrease plasma concentrations of azole antifungal agents (Table 61–5). As a consequence of these and other interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 61–6).

Available Agents

Ketoconazole. *Ketoconazole*, administered orally, has been replaced by *itraconazole* except when the lower cost of *ketoconazole* outweighs the advantage of *itraconazole*. *Ketoconazole* is available for topical use, as described further in this chapter.

Itraconazole. *Itraconazole* is a triazole that lacks the corticosteroid suppression associated with *ketoconazole* while retaining most of

TABLE 61–3 ■ INTERACTIONS OF AZOLE ANTIFUNGAL AGENTS WITH HEPATIC CYPs

FLUCONAZOLE	VORICONAZOLE	ITRACONAZOLE	POSACONAZOLE	ISAVUCONAZOLE
CYP3A4, 5, 7 inhibitor (moderate)	CYP2C9 inhibitor and substrate	CYP3A4, 5, 7 inhibitor and substrate	CYP3A4 inhibitor (potent)	CYP3A4 inhibitor and substrate
CYP2C9 inhibitor (strong)	CYP3A4, 5,7 inhibitor			CYP2B6 inhibitor

TABLE 61–4 ■ DRUGS EXHIBITING ELEVATED C_p WHEN COADMINISTERED WITH AZOLE ANTIFUNGAL AGENTS

Alfentanil	Eplerenone	Losartan	Saquinavir
Alprazolam	Ergot alkaloids	Lovastatin	Sildenafil
Astemizole	Erlotinib	Methadone	Sirolimus
Buspirone	Eszopiclone	Methylprednisolone	Solifenacin
Busulfan	Felodipine	Midazolam	Sunitinib
Carbamazepine	Fexofenadine	Nevirapine	Tacrolimus
Cisapride	Gefitinib	Omeprazole	Triazolam
Cyclosporine	Glimepiride	Phenytoin	Vardenafil
Digoxin	Glipizide	Pimozide	Vinca alkaloids
Docetaxel	Halofantrine	Quinidine	Warfarin
Dofetilide	Haloperidol	Ramelteon	Zidovudine
Efavirenz	Imatinib	Ranolazine	Zolpidem
Eletriptan	Irinotecan	Risperidone	

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles.

ketoconazole's pharmacological properties and extending the antifungal spectrum. Importantly, *itraconazole* has activity against *Aspergillus* spp., whereas imidazoles do not. *Itraconazole* has been supplanted by other triazoles in the treatment of invasive mold infections but remains an important prophylactic agent in the prevention of mold infections in some patients (e.g., patients with chronic granulomatous disease [CGD]).

ADME. *Itraconazole* is available as a tablet, capsule, and a solution in hydroxypropyl-β-cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations more than 150% of those obtained with the capsule. The tablet formulation is approved only for onychomycosis. Super-bioavailable (SUBA)-*itraconazole*, a reformulation with enhanced GI absorption, has recently been approved by the FDA (U.S. Food and Drug Administration).

Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. *Itraconazole* is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. The native drug and metabolite are more than 99% bound to plasma proteins. Neither appears in urine or in CSF. The $t_{1/2}$ of *itraconazole* at steady state is about 30 to 40 h. Steady-state levels of *itraconazole* are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase *itraconazole* plasma concentrations, but azotemia and hemodialysis have no effect.

Therapeutic Uses. *Itraconazole* is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis, H. capsulatum, P. brasiliensis,* and *Coccidioides immitis.* The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with *amphotericin B*. Approximately half of the patients with distal subungual onychomycosis respond to *itraconazole* (Evans and Sigurgeirsson, 1999). Although not approved for these uses, *itraconazole* is a reasonable choice for the treatment of pseudallescheriasis, an infection that does not respond to *amphotericin B* therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis,

and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or penicilliosis have a decreased incidence of relapse if given prolonged *itraconazole* "maintenance" therapy. *Itraconazole* is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term *itraconazole* therapy has been used in non–HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez et al., 1999). *Itraconazole* solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the solution has more GI side effects than *fluconazole* tablets, *itraconazole* solution usually is reserved for patients not responding to *fluconazole*. Finally, *itraconazole* is also used as *Aspergillus* prophylaxis in patients with CGD.

Dosage. In treating deep mycoses, a loading dose of 200 mg of *itraconazole* is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. Divided doses may increase the AUC. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or, for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Once-daily *terbinafine* (250 mg), however, is superior to pulse therapy with *itraconazole*. For oropharyngeal candidiasis, *itraconazole* oral solution should be taken during fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with esophageal thrush unresponsive or refractory to treatment with *fluconazole* tablets are given 100 mg of the solution twice a day for 2 to 4 weeks. The typical dose for fungal prophylaxis in patients with CGD is 5 mg/kg per day. In pediatric patients, plasma levels are very erratic and therapeutic monitoring should be considered, particularly for patients being treated for systemic fungal infections (e.g., histoplasmosis and blastomycosis) (Downes et al., 2020).

Adverse Effects. *Itraconazole* carries an FDA boxed warning about possible serious adverse effects, including QT prolongation, heart failure, negative inotropic effects, and drug interactions. Serious hepatotoxicity has led, in rare cases, to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. In the absence of interacting drugs, *itraconazole* capsules and suspension are well tolerated at 200 mg daily. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. Of patients receiving 50 to 400 mg of the capsules per day, nausea and vomiting, hypertriglyceridemia, hypokalemia, increased serum aminotransferase, and rash occurred in 2% to 10%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving 600 mg or more daily and in those who recently have received prolonged *amphotericin B* therapy. Doses of 300 mg twice daily have led to other side

effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses greater than 400 mg/day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome. *Itraconazole* is contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy.

Drug Interactions. Tables 61–4, 61–5, and 61–6 list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with *quinidine*, *halofantrine* (an orphan drug used for malaria), *levomethadyl* (an orphan drug used for heroin addiction), *pimozide*, or *cisapride* (available only under an investigational limited access program in the U.S.). Other drugs may decrease *itraconazole* serum levels below therapeutic concentrations (Table 61–5).

Fluconazole.

Fluconazole is a fluorinated bis-triazole.

ADME. *Fluconazole* is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4 to 8 μg/mL after repetitive doses of 100 mg. Renal excretion accounts for more than 90% of elimination, and the elimination $t_{1/2}$ is 25 to 30 h. *Fluconazole* diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50% to 90% of the simultaneous values in plasma. The dosage interval should be increased from 24 to 48 h with a creatinine clearance of 21 to 40 mL/min and to 72 h at 10 to 20 mL/min. A dose of 100 to 200 mg should be given after hemodialysis. About 11% to 12% of drug in the plasma is protein bound.

Therapeutic Uses

- **Candidiasis.** *Fluconazole*, 100 to 200 mg daily for 7 to 14 days, is effective in oropharyngeal candidiasis. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A loading dose of 800 mg followed by 400 mg daily is useful in treating candidemia of nonimmunosuppressed patients (Pappas et al., 2007; Rex et al., 1994). Current treatment guidelines for candidemia indicate that *fluconazole* is an acceptable alternative to the first-line therapy of an echinocandin in select patients. *Fluconazole* is recommended as a step-down therapy provided the patient's isolate is susceptible to the azole and follow-up blood cultures are negative (Pappas et al., 2016).
- **Cryptococcosis.** *Fluconazole*, 400 mg daily, is used for the initial 8 weeks of the consolidation phase of the treatment of cryptococcal meningitis in patients with AIDS, after an induction course of at least 2 weeks of intravenous *amphotericin B*. If, after 8 weeks at 400 mg/day, the patient is no longer symptomatic, then the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment of cryptococcosis, responds to combination antiretroviral therapy, has a CD4 count maintained above 200/mm^3 for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance *fluconazole* as long as the CD4 response is maintained. *Fluconazole*, 400 mg daily, has been recommended as continuation therapy in patients without AIDS with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis (Perfect et al., 2010). Recent clinical trials indicate that *fluconazole* can be combined with *flucytosine* for induction therapy with efficacy similar to *amphotericin B* combined with *flucytosine* (Molloy et al., 2018).
- **Other Mycoses.** *Fluconazole* is the drug of choice for treatment of coccidioidal meningitis because of good penetration into the CSF and much lower morbidity compared to intrathecal *amphotericin B* (Galgiani et al., 2016). In other forms of coccidioidomycosis, *fluconazole* is comparable to *itraconazole*. Although *itraconazole* is the first-line therapy for blastomycosis, *fluconazole* is an alternative. *Fluconazole* has no useful activity against histoplasmosis or sporotrichosis, and is not effective in the prevention or treatment of aspergillosis. *Fluconazole* has no activity in mucormycosis.

Dosage. *Fluconazole* is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of *fluconazole* should be based on the infecting organism and the patient's response to therapy. Generally, recommended dosages are 50 to 400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 12 mg/kg once daily (maximum 600 mg/day) without a loading dose. In adult patients, doses of up to 1200 mg have been safely administered in clinical trials for the treatment of cryptococcal meningitis.

Adverse Effects. Side effects in patients receiving more than 7 days of drug, regardless of dose, include nausea, headache, skin rash, vomiting, abdominal pain, and diarrhea (all at 2%–4%). Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. *Fluconazole* has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Although a recent clinical study found no association between *fluconazole* receipt by mothers and most birth defects in their children, this study did find a statistically significant increase in tetralogy of Fallot in babies born to mothers who received *fluconazole* (Mølgaard-Nielsen et al., 2013). *Fluconazole* should be avoided during pregnancy.

Drug Interactions. *Fluconazole* is an inhibitor of CYP3A4 and CYP2C9. *Fluconazole*'s drug-drug interactions are shown in Tables 61–4, 61–5, and 61–6. Patients who receive more than 400 mg daily or azotemic patients who have elevated *fluconazole* blood levels may experience drug interactions not otherwise seen.

Voriconazole.

Voriconazole is a triazole with a structure similar to *fluconazole* but with increased activity *in vitro*, an expanded spectrum, and poor aqueous solubility.

ADME. *Voriconazole* is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce *voriconazole* bioavailability, oral drug should be given either 1 h before or 1 h after meals. Oral bioavailability is 96%; volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYPs 2C19 and 2C9; CYP3A4 plays a limited role. Plasma elimination $t_{1/2}$ is 6 h. *Voriconazole* exhibits nonlinear metabolism so that higher doses may cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure: About 20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Less than 2% of parent drug is recovered from urine; 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Patients with mild-to-moderate cirrhosis should receive the same loading dose of *voriconazole* but half the maintenance dose. The intravenous formulation of *voriconazole* contains sulfobutyl ether β-cyclodextrin (SBECD), which is excreted by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance less than 50 mL/min; in that setting, oral *voriconazole* is preferred. Therapeutic drug monitoring is frequently used, with *target* serum concentrations between 1 and 5 mg/L thought to maximize efficacy and minimize adverse events. Monitoring is particularly important for children, who have very unpredictable plasma levels of *voriconazole* (Downes et al., 2020).

Therapeutic Uses. *Voriconazole* shows superior efficacy to C-AMB in the therapy of invasive aspergillosis using rate of response as the primary end point (Herbrecht et al., 2002); survival also is superior with *voriconazole*. *Voriconazole* was compared to L-AMB for empirical therapy of neutropenic patients whose fever did not respond to more than 96 h of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that *voriconazole* might be more than 10% worse than L-AMB, the FDA did not approve *voriconazole* for this use

(Walsh et al., 2002); however, in a secondary analysis, there were fewer breakthrough infections with *voriconazole* (1.9%) than with L-AMB (5%).

Voriconazole is approved for use in esophageal candidiasis. In nonneutropenic patients with candidemia, *voriconazole* is comparable in efficacy and less toxic than initial C-AMB followed by *fluconazole* (Kullberg et al., 2005). *Voriconazole* is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *P. boydii* (*S. apiospermum*) and *Fusarium* infections. Positive responses in patients with cerebral fungal infections suggest that the drug penetrates infected brain.

Dosage. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 h for two doses, followed by 3 to 4 mg/kg every 12 h, administered no faster than 3 mg/kg/h. As the patient improves, oral administration is continued as 200 mg every 12 h. Patients failing to respond may be given 300 mg every 12 h.

Adverse Effects. *Voriconazole* is teratogenic in animals and generally contraindicated in pregnancy. Although *voriconazole* is generally well tolerated, occasional cases of hepatotoxicity have been reported, and liver function should be monitored. *Voriconazole* can prolong the QTc interval, a significant issue in patients with other risk factors for torsades de pointes. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time. Patients receiving their first intravenous infusion have had anaphylactoid reactions. Rash occurs in 6% of patients. The cyclodextrin component of intravenous formulations may be toxic to the kidney; thus, intravenous *voriconazole* should be used with caution in patients with renal failure (Neofytos et al., 2012).

Drug Interactions. *Voriconazole* is metabolized by, and inhibits, CYPs 2C19, 2C9, and 3A4 (in that order of decreasing potency). The major metabolite of *voriconazole*, the *voriconazole* N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease *voriconazole* plasma concentrations, respectively. *Voriconazole* and its major metabolite can increase the plasma concentrations of other drugs metabolized by these enzymes (see Tables 61–4, 61–5, and 61–6). Because the AUC of *sirolimus* increases 11-fold in the presence of *voriconazole*, coadministration is contraindicated. When starting *voriconazole* in a patient receiving 40 mg/day or more of *omeprazole*, the dose of *omeprazole* should be reduced by half.

Posaconazole.

Posaconazole is a synthetic structural analogue of *itraconazole* with the same broad antifungal spectrum but with up to 4-fold greater activity *in vitro* against yeasts and filamentous fungi, including some, but not all, of the agents that cause mucormycosis (Frampton and Scott, 2008). Activity against yeasts *in vitro* is similar to *voriconazole*. The mechanism of action is the same as other imidazoles, inhibition of sterol 14-α-demethylase.

ADME. *Posaconazole* is available as a delayed-release tablet, intravenous formulations, and a flavored suspension. The delayed-release tablet and intravenous formulations provide a more consistent bioavailability in the presence of concomitant disease states, medications, and dietary considerations that alter concentrations achievable with the oral suspension (Guarascio and Slain, 2015). The bioavailability of the oral suspension (*posaconazole*, 40 mg/mL) is significantly enhanced by the concomitant presence of food (Courtney et al., 2003; Krieter et al., 2004). The drug has a long $t_{1/2}$ (25–31 h), a large volume of distribution (331–1341 L), and extensive protein binding (>98%). Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7 to 10 days when dosed four times daily. Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase. Almost 80% of the drug is excreted in the stool, with 66% as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter et al., 2004). Hemodialysis does not remove drug from the circulation. Gastric acid improves absorption (Krishna et al., 2009); drugs that reduce gastric acid (e.g., *cimetidine* and *esomeprazole*) decrease *posaconazole* exposure by 32% to 50% (Frampton and Scott, 2008). Diarrhea reduces the average C_p by 37% (Smith et al., 2009).

Therapeutic Uses. *Posaconazole* is approved for treatment of oropharyngeal candidiasis, although *fluconazole* is the preferred drug because of safety and cost. *Posaconazole* is also approved for prophylaxis against candidiasis and aspergillosis in patients more than 13 years of age who have prolonged neutropenia or severe graft-versus-host disease (Ullmann et al., 2007). It is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are *itraconazole* and *voriconazole*. A recent comparison trial of *posaconazole* and *voriconazole* supports the use of *posaconazole* as a first-line treatment for invasive *Aspergillus* (Maertens et al., 2021). *Posaconazole* has increased activity against the molds that cause mucormycosis and is frequently used as an alternative to *amphotericin B* for intolerant patients (Cornely et al., 2019).

Dosage. For prophylaxis of invasive *Aspergillus* and *Candida* infections, the adult intravenous dose is 300 mg twice on day 1 and 300 mg daily thereafter. Duration of therapy is based on recovery from neutropenia or immunosuppression. The same dose is used for the delayed-release tablets. The dose for the oral suspension is 200 mg (5 mL) three times daily.

Adverse Effects. Common adverse effects include nausea, vomiting, diarrhea, abdominal pain, and headache (Smith et al., 2009). Although adverse effects occur in at least a third of patients, the rate of discontinuation due to adverse effects in long-term studies has been only 8%.

Drug Interactions. *Posaconazole* inhibits CYP3A4. Coadministration with *rifabutin* or *phenytoin* increases the plasma concentration of these drugs and decreases *posaconazole* exposure by 2-fold. *Posaconazole* increases the AUC of *cyclosporine*, *tacrolimus* (121%), *sirolimus* (790%), midazolam (83%), and other CYP3A4 substrates (Table 61–4) (Frampton and Scott, 2008; Krishna et al., 2009; Moton et al., 2009). *Posaconazole* can prolong the QTc interval and should not be coadministered with drugs that are CYP3A4 substrates that likewise prolong the QTc interval, such as *methadone*, *haloperidol*, *pimozide*, *quinidine*, *risperidone*, *sunitinib*, *tacrolimus*, and *halofantrine* (see Table 61–4).

Isavuconazole.

Isavuconazole is a triazole that is administered as the isavuconazonium prodrug.

ADME. *Isavuconazole* is available in both oral and cyclodextrin-free intravenous formulations. It is highly bioavailable (98%) and is more than 99% protein bound in serum. Administration of oral isavuconazonium with food reduces AUC by about 20%. The parent form, isavuconazonium sulfate, is rapidly hydrolyzed to the active form, *isavuconazole*, which has a long plasma half-life (~130 h). Overall bioavailability of the active form is 98%. *Isavuconazole* is eliminated by hepatic metabolism, predominantly by CYP3A4 and CYP3A5. Less than 1% of *isavuconazole* is excreted unchanged in urine. No renal dose adjustments are needed (Rybak et al., 2015).

Therapeutic Uses. *Isavuconazole* exhibits a broad spectrum of activity against most yeast species, including *Candida* spp., *Cryptococcus gattii* and *C. neoformans*, and molds such as *Aspergillus* spp. and most Mucorales species complex. The drug is approved for the treatment of invasive aspergillosis and invasive mucormycosis.

Dosage. *Isavuconazole* is dosed as 372 mg isavuconazonium sulfate (equivalent to 200 mg of *isavuconazole*) every 8 h for six doses followed by 372 mg isavuconazonium sulfate by mouth or intravenously once daily starting 12 to 24 h after the last loading dose.

Adverse Effects. *Isavuconazole* is generally well tolerated. GI disorders, pyrexia, hypokalemia, headache, constipation, and cough are the most frequently reported adverse effects.

Drug Interactions. *Isavuconazole* is both a substrate and an inhibitor of CYP3A4. Consequently, a 5-fold increase in *isavuconazole* AUC results when it is administered with strong CYP inhibitors such as *ketoconazole*. Substantial reductions in *isavuconazole* AUC also result from coadministration of *isavuconazole* with *rifampin*. *Midazolam* and *sirolimus* AUCs are increased by coadministration with *isavuconazole*. *Isavuconazole* causes a dose-related shortening of QTc and is contraindicated in patients with familial short QT syndrome.

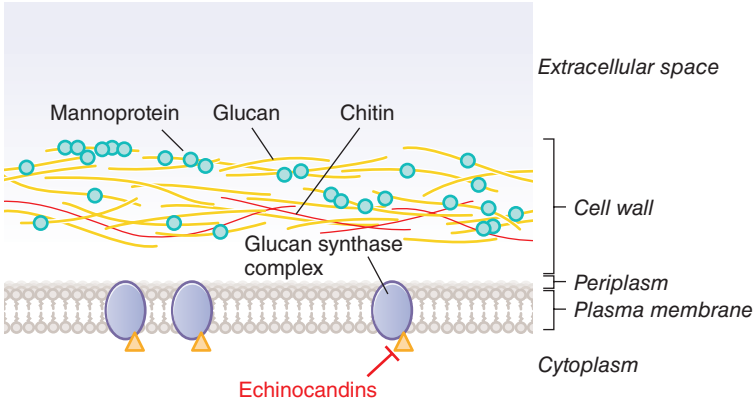

Figure 61–5 *The fungal cell wall and membrane and the action of echinocandins.* The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely β-1,3-glucan and chitin, which bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of β-1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. The Fks1p subunit of glucan synthase appears to be the target of echinocandins, and mutations in Fks1p cause resistance to echinocandins.

Echinocandins

Echinocandins are cyclic lipopeptides with a nucleus. Three echinocandins are approved for clinical use: *caspofungin*, *anidulafungin*, and *micafungin*. All act through the same mechanism but differ in pharmacological properties. Fungi that are susceptible to echinocandins include *Candida* and *Aspergillus* spp. (Bennett, 2006).

General Pharmacological Characteristics

Mechanism of Action. The echinocandins inhibit 1,3-β-D-glucan synthesis, which is an essential component of the fungal cell wall and is required for in cellular integrity (Figure 61–5).

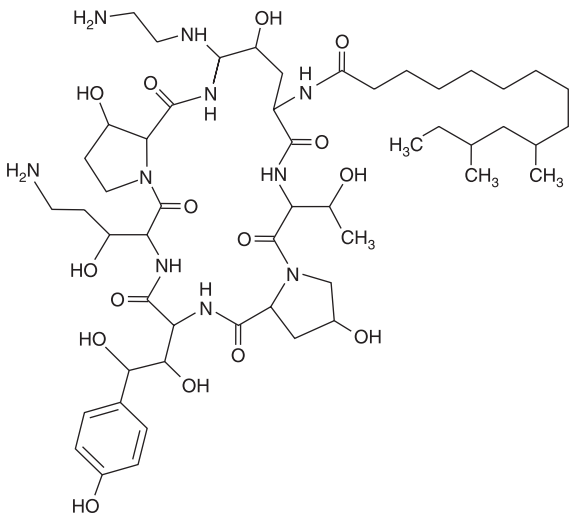
Antifungal Activity. Echinocandins exhibit fungicidal activity against *Candida* spp. In contrast, they are fungistatic against *Aspergillus* spp. and cause morphological changes to the filaments. Echinocandins do not appear to have clinically useful activity against dimorphic fungi such as *H. capsulatum* and do not have clinically useful activity against *C. neoformans*, *Trichosporon* spp., *Fusarium* spp., or agents of mucormycosis.

Resistance. Echinocandin resistance has emerged as a clinical problem and results from mutations leading to amino acid substitutions in the Fks subunits of glucan synthase (Perlin, 2015). Multidrug transporters do not appear to play a role in echinocandin resistance. Mutations conferring resistance occur in two conserved "hot spot" regions of *FKS1* in *C. albicans* and *C. auris*, and in *FKS1* and *FKS2* in *C. glabrata*. *Candida parapsilosis* complex and *Candida guilliermondii* display reduced *in vitro* echinocandin susceptibility as compared to other *Candida* spp. owing to inherently occurring polymorphisms in Fks hot spot regions. Species-specific clinical breakpoints for echinocandins have been recently described.

Echinocandins differ somewhat pharmacokinetically (Table 61–7), but all share extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight-to-modest effect of hepatic insufficiency on plasma drug concentrations (Kim et al., 2007; Wagner et al., 2006). Currently available echinocandins also lack oral bioavailability and are available only for intravenous administration. Generally speaking, adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. All three echinocandins are contraindicated in pregnancy.

Available Agents

Caspofungin. *Caspofungin acetate* is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of *Glarea lozoyensis* (Johnson and Perfect, 2003; Keating and Figgitt, 2003).



CASPOFUNGIN

TABLE 61–7 ■ PHARMACOKINETIC DATA FOR ECHINOCANDINS IN HUMANS

DRUG	DOSE (mg)	C_{max} (μg/mL)	AUC_{0-24h} (mg • h/L)	$t_{1/2}$ (h)	CL (mL/min/kg)	V_d (L)
Caspofungin	70	12	93.5	10	0.15	9.5
Micafungin	75	7.1	59.9	13	0.16	14
Anidulafungin	200	7.5	104.5	25.6	0.16	33.4

For details, see Wagner C, et al. (2006). From Wagner C, et al. The echinocandins: comparison of their pharmacokinetics, pharmacodynamics and clinical applications. *Pharmacology*, **2006**, 7 3:16 1–177. Copyright © 200 . R/ produced y permission of Karger ublishers, Basel, Switzerland

ADME. Catabolism is largely by hydrolysis and *N*-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increase the AUC by 55% and 76%, respectively.

Therapeutic Use. *Caspofungin* is approved for the treatment of invasive candidiasis. It is a first-line agent, along with other echinocandins, for the initial treatment of candidemia (Pappas et al., 2016). It is also approved as salvage therapy for patients with invasive aspergillosis who fail or are intolerant of approved drugs, such as *amphotericin B* formulations or *voriconazole*. *Caspofungin* is also approved for both esophageal and invasive candidiasis (Mora-Duarte et al., 2002; Villanueva et al., 2001) and for treatment of persistently febrile neutropenic patients with suspected fungal infections (Walsh et al., 2004).

Dosage. *Caspofungin* is administered intravenously once daily over 1 h. For candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving *rifampin* as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

Drug Interactions. *Caspofungin* increases *tacrolimus* levels by 16%, which should be managed by standard monitoring. *Cyclosporine* slightly increases *caspofungin* levels. *Rifampin* and other drugs activating CYP3A4 can cause a slight reduction in *caspofungin* levels.

Micafungin.

Micafungin is a water-soluble semisynthetic echinocandin derived from the fungus *Coleophoma empedri*.

ADME; Drug Interactions. *Micafungin* has linear pharmacokinetics over a large range of doses (1–3 mg/kg) and ages (premature infants to elderly). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol *O*-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Unlike *caspofungin*, reduction of the *micafungin* dose in moderate hepatic failure is not required. *Micafungin* shows age-dependent clearance in children, with rapid clearance in premature infants and intermediate clearance in children 2 to 8 years of age, compared to older children and adults (Downes et al., 2020).

In normal volunteers, *micafungin* appears to be a mild inhibitor of CYP3A4, increasing the AUC of *nifedipine* by 18% and *sirolimus* by 21%. *Micafungin* has no effect on *tacrolimus* clearance.

Therapeutic Uses. *Micafungin* is approved for the treatment of invasive candidiasis (Fritz et al., 2008) and esophageal candidiasis and for prophylaxis in hematopoietic stem cell transplant recipients.

Dosage. *Micafungin* is administered intravenously as a 100-mg daily dose over 1 h for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is required.

Anidulafungin.

Anidulafungin is a water-insoluble semisynthetic compound extracted from the fungus *A. nidulans*, from which the drug's name derives.

ADME; Drug Interactions. *Anidulafungin* is cleared from the body by slow chemical degradation (Vazquez and Sobel, 2006). No hepatic metabolism or renal excretion of active drug occurs; thus, no dose adjustment for hepatic or renal failure is needed. No clinically relevant drug-drug interactions have been observed with drugs likely to be coadministered with *anidulafungin*.

Therapeutic Use and Dosing. *Anidulafungin* is approved for the treatment of candidemia and other forms of *Candida* infections (Reboli et al., 2007), including intra-abdominal abscess, peritonitis, and esophageal candidiasis. For invasive candidiasis, *anidulafungin* is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily. *Anidulafungin* is not approved for use in children; the other two currently available echinocandins are approved and frequently used in premature infants.

Other Systemic Antifungal Agents

Griseofulvin

Griseofulvin is an orally administered, fungistatic antifungal agent originally isolated from the mold *Penicillium griseofulvum*. It is practically insoluble in water.

Mechanism of Action. *Griseofulvin* inhibits microtubule function and thereby disrupts assembly of the mitotic spindle, which disrupts fungal cell division.

ADME. Blood levels after oral administration of *griseofulvin* are quite variable. Some studies have shown improved absorption when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of *griseofulvin*, microsize and ultramicrosize powders are now used. *Griseofulvin* has a plasma $t_{1/2}$ of about 1 day; about 50% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is methylgriseofulvin. Barbiturates decrease *griseofulvin* absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. *Griseofulvin* is detectable in the stratum corneum of the skin within 4 to 8 h of oral administration. Sweat and transepidermal fluid loss play an important role in the transfer of the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

Antifungal Activity. *Griseofulvin* is fungistatic *in vitro* for various species of the dermatophytes *Microsporum, Epidermophyton,* and *Trichophyton.* The drug has no effect on other fungi or on bacteria. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to *griseofulvin in vitro*.

Therapeutic Uses. Mycotic disease of the skin, hair, and nails due to *Microsporum, Trichophyton,* or *Epidermophyton* responds to *griseofulvin* therapy. For tinea capitis in children, *griseofulvin* remains the drug of choice for efficacy, safety, and availability as an oral suspension. Efficacy is best for tinea capitis caused by *Microsporum canis, Microsporum audouinii, Trichophyton schoenleinii,* and *Trichophyton verrucosum. Griseofulvin* is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis, Trichophyton rubrum, T. verrucosum,* and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *Trichophyton mentagrophytes*) and beard (*Trichophyton* spp.). *Griseofulvin* also is highly effective in the treatment of tinea pedis, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum.* Topical therapy is sufficient for most cases of tinea pedis. *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses of *griseofulvin*. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6 to 9 months for fingernails, and at least a year for toenails. *Itraconazole* or *terbinafine* is much more effective for onychomycosis.

Adverse Effects. The incidence of serious reactions due to *griseofulvin* is very low: headache (15% of patients), GI and nervous system manifestations, and augmentation of the effects of alcohol. Hepatotoxicity has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme–like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes and severe angioedema develop rarely. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Drug Interactions. *Griseofulvin* induces hepatic CYPs and thereby increases the rate of metabolism of *warfarin*. Consequently, the dose of *warfarin* should be adjusted in some patients. The drug may also reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

Terbinafine

Terbinafine is a synthetic allylamine, structurally similar to the topical agent *naftifine* (see discussion that follows). It inhibits fungal squalene epoxidase and thereby reduces ergosterol biosynthesis.

ADME. *Terbinafine* is well absorbed, but bioavailability is about 40% due to first-pass metabolism in the liver. The drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ is about 12 h but extends to 200 to 400 h at steady state. *Terbinafine* is not recommended in patients with marked azotemia or hepatic failure. *Rifampin* decreases and *cimetidine* increases plasma *terbinafine* concentrations.

Therapeutic Uses. *Terbinafine*, given as one 250-mg tablet daily for adults, is somewhat more effective than *itraconazole* for nail onychomycosis. Duration of treatment varies with the site of infection but typically ranges between 6 and 12 weeks. The efficacy for the treatment of onychomycosis can be improved by the simultaneous use of *amorolfine* 5% nail lacquer (*amorolfine* is not approved for use in the U.S.). *Terbinafine* is also effective for the treatment of tinea capitis and has been used for the off-label treatment of ringworm elsewhere on the body.

Adverse Effects. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. Systemic *terbinafine* therapy for onychomycosis should be postponed until after pregnancy is complete.

Agents Active Against Microsporidia and *Pneumocystis*

Microsporidia are spore-forming unicellular eukaryotic organisms that were once thought to be parasites but are now classified as fungi (Field and Milner, 2015). They can cause several disease syndromes, including diarrhea in immunocompromised individuals.

Albendazole

Intestinal infections with most microsporidia are treated with *albendazole*, an inhibitor of α-tubulin polymerization (see Chemotherapy of Helminth Infections, Chapter 68) (Anane and Attouchi, 2010).

Fumagillin

Fumagillin is an acyclic polyene macrolide produced by the fungus *A. fumigatus*. *Fumagillin* and its synthetic analogue TNP-470 are toxic to microsporidia.

Immunocompromised individuals with intestinal microsporidiosis due to *Enterocytozoon bieneusi* (which does not respond as well to *albendazole*) can be treated successfully with *fumagillin* (Didier et al., 2005; Rex and Stevens, 2014; Szumowski and Troemel, 2015). For the treatment of intestinal microsporidiosis caused by *E. bieneusi*, *fumagillin* is used at a dose of 20 mg orally three times daily for 2 weeks (Medical-Letter, 2013; Molina et al., 2002; Rex and Stevens, 2014). *Fumagillin* is used topically to treat keratoconjunctivitis caused by *Encephalitozoon hellem* at a dose of 3 to 10 mg/mL in a balanced salt suspension. Adverse effects of *fumagillin* may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported (Anane and Attouchi, 2010). *Fumagillin* is not approved for use in humans in the U.S.

Pentamidine

Pneumocystis jirovecii is another fungus that, until recently, was classified as a protozoan parasite. It is the causative agent of PJP (*Pneumocystis jirovecii* pneumonia), formerly known as PCP (*Pneumocystis carinii* pneumonia). *Pentamidine* is one of several drugs or drug combinations used to treat or prevent PJP, which is a major cause of mortality in immunocompromised individuals, including patients with AIDS. Note, however, that *trimethoprim-sulfamethoxazole* is the drug of choice for the treatment and prevention of PJP (see Chapter 57).

Therapy for PJP. *Pentamidine* as therapy for PJP is reserved for two indications:

- As a 4 mg/kg single daily intravenous dose for 21 days to treat severe PJP in individuals who cannot tolerate *trimethoprim-sulfamethoxazole* and are not candidates for alternative agent
- As a "salvage" agent for individuals with PJP who fail to respond to *trimethoprim-sulfamethoxazole* (*pentamidine* may be less effective than the combination of *clindamycin* and *primaquine* or *atovaquone* for this indication) (Gilroy and Bennett, 2011; Rex and Stevens, 2014)

Prophylaxis. *Pentamidine* administered as an aerosol preparation is used to prevent PJP in at-risk individuals who cannot tolerate *trimethoprim-sulfamethoxazole*, such as patients with severe bone marrow suppression. For prophylaxis, *pentamidine isethionate* is given monthly as a 300-mg dose in a 5% to 10% nebulized solution over 30 to 45 min (Gilroy and Bennett, 2011). Aerosolized *pentamidine* has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens, and a risk for pneumothorax (Rex and Stevens, 2014). Recently, an intravenous dose of *pentamidine* every 28 days has been successfully used as PJP prophylaxis (Diri et al., 2016).

Adverse Effects. Reported adverse effects of inhaled *pentamidine* include bronchospasm (15%). For parenteral *pentamidine*, adverse effects (more likely with rapid injection) can include injection site irritation and pain, cardiac arrhythmias, severe hypotension, hypoglycemia, and acute pancreatitis. The FDA warns that administration of *pentamidine* should be limited to patients in whom *Pneumocystis* is identified and should proceed with careful monitoring for the development of adverse effects.

Topical Antifungal Agents

Topical agents are useful for the treatment of many superficial fungal infections, such as those confined to the stratum corneum, squamous mucosa, or cornea. Examples of infections that respond to topical therapy include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Preferred formulations for cutaneous application usually are creams or solutions. Ointments are inconvenient and can be too occlusive to the skin, particularly if the affected area is a macerated, fissured, or intertriginous lesion. Antifungal powders, whether applied by shake containers or aerosols, are useful only for lesions of the feet, groin, and similar intertriginous areas. With few exceptions, topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and should not be used for the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy.

Topical Imidazoles and Triazoles

The imidazoles and triazoles are closely related classes of drugs that are synthetic antifungal agents used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is rare among the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because *in vitro* fungal susceptibility testing does not correlate with clinical responses. The mechanism of action of the azole antifungals was discussed previously in this chapter.

Modes of Administration

Cutaneous Application. The preparations for cutaneous use are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3 to 6 weeks. Cutaneous formulations are not suitable for oral, vaginal, or ocular use.

Vaginal Application. Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1 to 7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—*clotrimazole* tablets (no longer marketed in the U.S.), *miconazole* suppositories, and *terconazole* cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended

for the higher dose of each. These preparations are administered for 3 to 7 days. Approximately 3% to 10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile irritation.

Oral Use. Use of the oral troche of *clotrimazole* is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

Individual Agents

Clotrimazole

Absorption of *clotrimazole* is less than 0.5% after application to the intact skin; from the vagina, it is 3% to 10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. In adults, an oral dose of 200 mg/day will give rise initially to plasma concentrations of 0.2 to 0.35 μg/mL, followed by a progressive decline.

In a small fraction of patients, *clotrimazole* on the skin may cause skin irritation, stinging sensations, erythema, edema, vesication, desquamation, pruritus, or urticaria. When applied to the vagina, about 1.6% of patients experience a mild burning sensation. In rare instances, lower abdominal cramps, a slight increase in urinary frequency, or skin rash may occur. Occasionally, a patient's sexual partner may experience penile or urethral irritation. Oral *clotrimazole* troches cause GI irritation in about 5% of patients.

Therapeutic Uses. *Clotrimazole* is available as a 1% cream, lotion, powder (no longer marketed in the U.S.), aerosol solution, and solution; 1% or 2% vaginal cream; vaginal tablets (no longer marketed in the U.S.) of 100, 200, or 500 mg; and 10-mg troches. On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days.

Topical *clotrimazole* cures dermatophyte infections in 60% to 100% of cases. The cure rates in cutaneous candidiasis are 80% to 100%. In vulvovaginal candidiasis, the cure rate is usually greater than 80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

Econazole

Econazole is the deschloro-derivative of *miconazole*. *Econazole* readily penetrates the stratum corneum and achieves effective concentrations at the level of the middermis. Approximately 3% of recipients experience local erythema, burning, stinging, or itching. *Econazole nitrate* is available as a water-miscible cream (1%) to be applied twice a day.

Efinaconazole

Efinaconazole is an azoleamine derivative with excellent *in vitro* activity against *T. rubrum* and *T. mentagrophytes*. It is available as a 10% topical solution for the treatment of onychomycosis.

Miconazole

Miconazole readily penetrates the stratum corneum of the skin and persists for more than 4 days after application. Adverse effects from topical application to the vagina include burning, itching, or irritation in about 7% of recipients, as well as infrequent pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. *Miconazole* is considered safe for use during pregnancy, although some experts advocate avoiding vaginal use during the first trimester.

Therapeutic Uses. *Miconazole nitrate* is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution. To avoid maceration, only the lotion should be applied to intertriginous areas. *Miconazole* is available as a 2% and 4% vaginal cream and as 100-, 200-, or 1200-mg vaginal suppositories to be applied high in the vagina at bedtime for 7 or 3 days or 1 day, respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate exceeds 90%. In the treatment of vulvovaginal candidiasis, the mycological cure rate at the end of 1 month is about 80% to 95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *C. glabrata* also respond to this drug.

Luliconazole

Luliconazole is available as a 1% cream and is effective for the topical treatment of interdigital tinea pedis, tinea cruris, and tinea corporis caused by susceptible organisms. It should be applied to the affected area once daily for 2 weeks.

Terconazole and Butoconazole

Terconazole is a ketal triazole. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for *clotrimazole* in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically comparable to *clotrimazole*. *Butoconazole nitrate* is available as a 2% vaginal cream; it is used at bedtime in nonpregnant females. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimesters).

Tioconazole

Tioconazole is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg of drug) is given at bedtime.

Oxiconazole, Sulconazole, and Sertaconazole

The imidazole derivatives *oxiconazole*, *sulconazole*, and *sertaconazole* are used for the topical treatment of infections caused by the common pathogenic dermatophytes. *Oxiconazole nitrate* is available as a 1% cream and lotion; *sulconazole nitrate* is supplied as a 1% solution or cream. *Sertaconazole* is a 2% cream marketed for tinea pedis.

Ketoconazole

The imidazole *ketoconazole* is available as a 0.5% cream, foam, gel, and shampoo for common skin dermatophyte infections, for tinea versicolor, and for seborrheic dermatitis.

Structurally Diverse Antifungal Agents

Ciclopirox Olamine

Ciclopirox olamine has broad-spectrum antifungal activity. It is fungicidal to *C. albicans, E. floccosum, M. canis, T. mentagrophytes,* and *T. rubrum*. It also inhibits the growth of *Malassezia furfur. Ciclopirox* appears to chelate trivalent metal cations and thereby inhibits metal-dependent enzymes required for degradation of peroxides within the fungal cell (Subissi et al., 2010). After application to the skin, it penetrates the epidermis to reach the dermis, but even under occlusion, less than 1.5% is absorbed into the systemic circulation. Furthermore, because the $t_{1/2}$ is 1.7 h, no systemic accumulation occurs. The drug penetrates hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81% to 94%. No topical toxicity has been noted.

Ciclopirox 0.77% gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. An 8% topical solution is an effective treatment of mild-to-moderate superficial white onychomycosis.

Haloprogin

Haloprogin is a halogenated phenolic ether. It is fungicidal to various species of *Epidermophyton, Pityrosporum, Microsporum, Trichophyton,*

and *Candida*. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and "sensitization" (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footgear is worn. *Haloprogin* is poorly absorbed through the skin; it is metabolized to trichlorophenol in the patient. However, systemic toxicity from topical application appears to be low. *Haloprogin* cream or solution is applied twice a day for 2 to 4 weeks. Its principal use is against tinea pedis, for which the cure rate is about 80%; it is thus approximately equal in efficacy to *tolnaftate*. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. *Haloprogin* is no longer available in the U.S.

Tolnaftate

Tolnaftate is a thiocarbamate that is effective in the treatment of most cutaneous mycoses caused by *T. rubrum, T. mentagrophytes, Trichophyton tonsurans, E. floccosum, M. canis, M. audouinii, Microsporum gypseum,* and *M. furfur,* but it is ineffective against *Candida*. In tinea pedis, the cure rate is about 80%, compared with about 95% for *miconazole*. *Tolnaftate* is available in a 1% concentration as a cream, gel, powder, aerosol powder, topical solution, or topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24 to 72 h. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7 to 21 days. Toxic or allergic reactions to *tolnaftate* have not been reported.

Naftifine

Naftifine is a synthetic allylamine that inhibits squalene-2,3-epoxidase, a key enzyme in the fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity *in vitro*. *Naftifine hydrochloride* is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation in 3% of treated patients and allergic contact dermatitis have been reported. *Naftifine* also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

Terbinafine

Like *naftifine*, *terbinafine* is an allylamine that targets ergosterol biosynthesis. *Terbinafine* 1% cream or spray, applied twice daily, is effective in tinea corporis, tinea cruris, and tinea pedis. *Terbinafine* is less active against *Candida* species and *Malassezia furfur,* but the cream also can be used in cutaneous candidiasis and tinea versicolor.

Butenafine

Butenafine hydrochloride is a benzylamine derivative with a mechanism of action similar to that of *terbinafine* and *naftifine*. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

Tavaborole

Tavaborole is an oxaborole antifungal indicated for the topical treatment of onchomycosis of the toenails. The drug inhibits fungal leucyl-tRNA synthetase, thereby inhibiting protein synthesis and ultimately causing fungal cell death.

Nystatin

Nystatin, a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to *amphotericin B* and acts through the same mechanism. The drug is not absorbed from the GI tract, skin, or vagina. *Nystatin* is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. The vaginal preparations are no longer marketed in the U.S. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions such as diaper rash and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of *nystatin* with corticosteroids also are available.

Allergic reactions to *nystatin* are uncommon. Although vaginal tablets of *nystatin* are well tolerated, imidazoles or triazoles are more effective agents than *nystatin* for vaginal candidiasis. *Nystatin* suspension is usually effective for oral candidiasis of the immunocompetent host and is widely used in neonates and infants for oral thrush. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

Undecylenic Acid

Undecylenic acid is 10-undecenoic acid, an 11-carbon unsaturated compound. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including those that cause ringworm. *Undecylenic acid* is available in a cream, powder, spray powder, soap, and liquid. *Zinc undecylenate* is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compounded *undecylenic acid* ointment contains both *undecylenic acid* (~5%) and *zinc undecylenate* (~20%). *Calcium undecylenate* is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compounded ointment, may be applied to the skin. These preparations are usually not irritating to tissue, and sensitization to them is uncommon. This agent retards fungal growth in tinea pedis, but the infection frequently persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical "cure" rate is about 50%, which is much lower than that obtained with the imidazoles, *haloprogin*, or *tolnaftate*. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer used for that purpose. *Undecylenic acid* preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

Benzoic and Salicylic Acids

An ointment containing *benzoic* and *salicylic acids* in a ratio of 2:1 (usually 6% and 3%) is known as Whitfield ointment. It combines the fungistatic action of benzoate with the keratolytic action of salicylate and is used mainly in the treatment of tinea pedis. Because *benzoic acid* is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed; thus, continuous medication is required for several weeks to months. The *salicylic acid* accelerates desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

Drug Facts for Your Personal Formulary: *Antifungal Agents*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Polyenes: Interact with ergosterol in the fungal cell membrane		
Amphotericin B deoxycholate (C-AMB)	• Invasive candidiasis and aspergillosis • Blastomycosis • Histoplasmosis • Coccidioidomycosis • Cryptococcosis • Mucormycosis • Sporotrichosis • Empirical therapy in the immunocompromised host	• Associated with significant nephrotoxicity, including azotemia, renal tubular acidosis, and hypochromic, normocytic anemia • Associated with acute reactions, including infusion-related fever and chills • C-AMB is better tolerated by premature neonates than by older children and adults
Amphotericin B colloidal dispersion (ABCD) (not available in the U.S.) Liposomal amphotericin B (L-AMB) Amphotericin B lipid complex (ABLC)		• All three amphotericin B lipid formulations are less nephrotoxic than C-AMB • Infusion-related reactions are highest with ABCD and lowest with L-AMB
Pyrimidines: Disrupt fungal RNA and DNA synthesis		
Flucytosine	• Cryptococcosis (with amphotericin B or fluconazole)	• Has broad activity but emergence of resistance limits usefulness as single-agent therapy • ↓ Dosage in patients with ↓ renal function • Toxicity more frequent in patients with AIDS or azotemia • May depress marrow → leukopenia & thrombocytopenia
Imidazoles and Triazoles: Inhibit ergosterol biosynthesis		
Ketoconazole	• Replaced by itraconazole for oral administration • Used topically for tinea versicolor, seborrheic dermatitis, common dermatophytes	• A reference substrate for and potent inhibitor of CYP3A4 • May cause redness in area of topical application • Topical preparations are available over the counter • Oral use can cause hepatotoxicity and adrenal insufficiency • In U.S., oral preparations available only with restrictions
Itraconazole	• Invasive aspergillosis • Blastomycosis • Coccidioidomycosis • Histoplasmosis • Pseudallescheriasis; Sporotrichosis • Ringworm; Onychomycosis	• Substrate for and potent inhibitor of CYP3A4 • Hepatotoxic • Contraindicated in pregnancy and in women considering becoming pregnant • Therapeutic monitoring useful, particularly in pediatric patients
Fluconazole	• Invasive candidiasis • Cryptococcosis • Oropharyngeal candidiasis • Coccidioidomycosis • Prophylaxis and empirical therapy in immunocompromised host	• Plasma concentrations are essentially the same whether the drug is given orally or intravenously • Concentrations in CSF = 50%–90% of C_p • Inhibitor of CYP3A4 and CYP2C9 • Contraindicated during pregnancy
Voriconazole	• Invasive aspergillosis • Invasive candidiasis • Pseudallescheriasis • Fusariosis	• Oral bioavailability is 96% • Monitor C_p; serum levels of 1–5 mg/L maximize efficacy and minimize toxicity • Metabolized by and inhibits CYPs (2C19 > 2C9 > 3A4) • Can prolong the QTc interval • Transient visual or auditory hallucinations are frequent after the first dose • Contraindicated in pregnancy
Posaconazole	• Oropharyngeal candidiasis • Mucormycosis • Prophylaxis in the immunocompromised host against aspergillosis and candidiasis	• Oral bioavailability enhanced by food • Drugs that ↓ gastric acid ↓ posaconazole exposure • Inhibits CYP3A4 • Can prolong the QTc interval • Adverse effects: headache and GI disorders
Isavuconazole (isavuconazonium prodrug)	• Invasive aspergillosis • Mucormycosis	• Oral bioavailability is 98% • Substrate of and inhibitor of CYP3A4 • Does not appear to prolong QTc

Drug Facts for Your Personal Formulary: *Antifungal Agents* (*continued*)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Echinocandins: Inhibit 1,3-β-D-glucan synthesis in the fungal cell wall		
Caspofungin	• Invasive candidiasis • Salvage for aspergillosis • Empirical therapy in the immunocompromised host	• ↓ Dose in moderate hepatic impairment
Micafungin	• Invasive candidiasis • Prophylaxis in the immunocompromised host	• Reduction of micafungin dose in moderate hepatic failure is not required
Anidulafungin	• Invasive candidiasis	• No dose adjustment is needed for hepatic or renal failure
Griseofulvin: Inhibits microtubule function, disrupts assembly of the mitotic spindle		
Griseofulvin	• Ringworm • Onychomycosis	• Absorption is reduced by barbiturates • Induces hepatic CYPs
Allylamines: Inhibit fungal squalene epoxidase and reduce ergosterol biosynthesis		
Terbinafine	• Ringworm • Onychomycosis	• Bioavailability is ~40% due to first-pass metabolism in the liver. • The drug accumulates in skin, nails, and fat • The initial $t_{1/2}$ is ~12 h but extends to 200–400 h at steady state
Agents Active Against Microsporidia and *Pneumocystis*		
Albendazole	• Microsporidia infection	• Anthelmintic • Inhibitor of α-tubulin polymerization
Fumagillin	• Microsporidia infection	• Used in immunocompromised individuals with intestinal microsporidiosis due to *E. bieneusi* unresponsive to albendazole • Not approved for human use in the U.S.
Trimethoprim-sulfamethoxazole	• *Pneumocystis jiroveci* pneumonia	• See Chapter 57
Pentamidine	• *Pneumocystis jiroveci* pneumonia	• Prophylaxis use to prevent PJP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole
Topical Antifungal Agents		
Imidazoles and triazoles Clotrimazole, miconazole, ketoconazole, etc.	• Dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis	• Available for cutaneous application as creams or solutions • Some are available as vaginal creams or suppositories or as oral troches
Tavaborole	• Toenail onychomycosis due to *T. rubrum* or *T. mentagrophytes*	• Apply daily for 48 weeks

Chapter 62

Antiviral Agents (Nonretroviral)

Edward P. Acosta

Most antivirals currently available in the U.S. have been developed and approved in the last 35 years. This flurry of activity was driven by successes in rational drug design and approval that began with the antiherpesvirus nucleoside analogue *acyclovir* (Elion, 1986), whose discovery and development resulted in the awarding of the 1988 Nobel Prize in Physiology/Medicine to Gertrude Elion and George Hitchings, an award they shared with James Black (see Chapter 43) "for their discoveries of important principles for drug treatment." Because viruses are obligatory intracellular microorganisms and rely on host biosynthetic machinery to reproduce, there were doubts about the possibility of developing antiviral drugs with selective toxicity, but those doubts have long been erased. Viruses are now obvious targets for effective antimicrobial chemotherapy, and it is certain that the number of available agents in this category will continue to increase. Indeed, the recent development of agents that target the viral protein NS5A has revolutionized treatment of infections of hepatitis B virus (HBV) and hepatitis C virus (HCV), and these agents are now allotted a chapter of their own, Chapter 63. Chapter 64 describes chemotherapy for retroviruses. This chapter covers antiviral agents for nonretroviral infections other than HBV and HCV.

Viral Replication and Drug Targets

Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a *capsid*. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit *virus-directed rather than host cell–directed* nucleic acid or protein synthesis (Table 62–1). Host cell molecules that are essential to viral replication also offer targets for intervention. Figure 62–1 gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses with the sites of antiviral drugs indicated.

DNA viruses include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes); adenoviruses (conjunctivitis, sore throat); hepadnaviruses (HBV); and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA (messenger RNA) by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. Poxviruses are an exception; they carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy either relies on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA. Most RNA viruses complete their replication in the host cell cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses include rubella virus (German measles); rhabdoviruses (rabies); picornaviruses (poliomyelitis, meningitis, colds, hepatitis A); arenaviruses (meningitis, Lassa fever); flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C, Zika virus); orthomyxoviruses (influenza); paramyxoviruses (measles, mumps); and coronaviruses (colds, severe acute respiratory syndrome [SARS]). Retroviruses are RNA viruses that include human immunodeficiency virus (HIV); chemotherapy for retroviruses is described in Chapter 64. Pharmacotherapy of viral hepatitis is covered separately in Chapter 63.

Table 62–2 summarizes currently approved drugs for nonretroviral infections, excluding those for viral hepatitis. Their pharmacological properties are presented in the material that follows, class by class, as listed in the table.

Antiherpesvirus Agents

Herpes simplex virus (HSV) type 1 typically causes diseases of the mouth, face, skin, esophagus, or brain. HSV-2 usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates. Agents used in treating HSV work by several mechanisms to inhibit viral DNA replication in the host cell (see Figure 62–1 and Table 62–1).

Acyclovir and Valacyclovir

Acyclovir is an acyclic guanine nucleoside analogue that lacks the 2′ and 3′ positions normally supplied by ribose. *Valacyclovir* is the L-valyl ester prodrug of *acyclovir*. *Acyclovir* is the prototype of a group of antiviral agents that are nucleoside congeners (Figure 62–2) that are phosphorylated intracellularly by a viral kinase and subsequently by host cell

Abbreviations

AIDS: acquired immune deficiency syndrome
AUC: area under curve of plasma drug concentration versus time
CDC: U.S. Centers for Disease Control and Prevention
Cl_{cr}: creatinine clearance
CMV: cytomegalovirus
CoV: coronavirus 2
CSF: cerebrospinal fluid
CYP: cytochrome P450 isozyme
EBV: Epstein-Barr virus
EIND: emergency investigational new drug
EVD: Ebola virus disease
FDA: U.S. Food and Drug Administration
G-CSF: granulocyte colony-stimulating factor
GI: gastrointestinal
HBV: hepatitis B virus
HCV: hepatitis C virus
HHV-6: human herpesvirus 6
HIV: human immunodeficiency virus
HSCT: hematopoietic stem cell transplantation
HSV: herpes simplex virus
IFN: interferon
mAb: monoclonal antibody
MERS: Middle East respiratory syndrome
mRNA: messenger RNA
NSAID: nonsteroidal anti-inflammatory drug
RdRp: RNA-dependent RNA polymerase
SARS: severe acute respiratory syndrome
TK: thymidine kinase
VZV: varicella zoster virus
WHO: World Health Organization

enzymes to become inhibitors of viral DNA synthesis. Related agents include *penciclovir* and *ganciclovir*.

Mechanisms of Action and Resistance

Acyclovir inhibits viral DNA synthesis via a mechanism outlined in Figure 62–3. Its selectivity of action depends on interaction with HSV TK (thymidine kinase) and DNA polymerase. The initial phosphorylation of *acyclovir* is facilitated by HSV TK and thus occurs only in cells infected with the virus. The affinity of *acyclovir* for HSV TK is about 200 times greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to *acyclovir* triphosphate, which competes for endogenous dGTP. The immunosuppressive agent *mycophenolate mofetil* (see Chapter 39) potentiates the antiherpes activity of *acyclovir* and related agents by depleting intracellular dGTP pools. *Acyclovir triphosphate* competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. *Acyclovir triphosphate* also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3′-hydroxyl group. By a mechanism termed *suicide inactivation*, the terminated DNA template containing *acyclovir* binds the viral DNA polymerase and leads to its irreversible inactivation.

Acyclovir resistance in HSV can result from impaired production of viral TK, altered TK substrate specificity (e.g., phosphorylation of thymidine but not *acyclovir*), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes. Resistant variants are present in native virus populations and in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral TK activity; viral DNA polymerase mutants are rare. Phenotypic resistance typically is defined by *in vitro* inhibitory concentrations of more than 2 to 3 μg/mL, which predict failure of therapy in immunocompromised patients. *Acyclovir* resistance in isolates of varicella zoster virus (VZV) is caused by mutations in VZV TK and less often by mutations in viral DNA polymerase.

TABLE 62–1 ■ STAGES OF VIRUS REPLICATION AND POSSIBLE TARGETS OF ACTION OF ANTIVIRAL AGENTS

STAGE OF REPLICATION	CLASSES OF SELECTIVE INHIBITORS
Cell entry Attachment Penetration	Soluble receptor decoys, antireceptor antibodies, fusion protein inhibitors
Uncoating Release of viral genome	Ion channel blockers, capsid stabilizers
Transcription[a] Transcription of viral mRNA Replication of viral genome	Inhibitors of viral DNA polymerase, RNA polymerase, reverse transcriptase, helicase, primase, or integrase
Translation of viral proteins Regulatory proteins (early) Structural proteins (late)	Interferons, antisense oligonucleotides, ribozymes, inhibitors of regulatory proteins
Posttranslational modifications Proteolytic cleavage Myristoylation, glycosylation	Protease inhibitors
Assembly of virion components	Interferons, inhibitors of the assembly of viral proteins
Release Budding, cell lysis	Neuraminidase inhibitors, antiviral antibodies, cytotoxic lymphocytes

[a]Depends on specific replication strategy of virus, but virus-specified enzyme required for part of process.

ADME

The oral bioavailability of *acyclovir* is about 10% to 30% and decreases with increasing dose (Wagstaff et al., 1994). Delivery of an oral dose can be enhanced by administration of the prodrug form, *valacyclovir*. *Valacyclovir* is an esterified version with higher bioavailability (55%–70%) than *acyclovir* (Steingrimsdottir et al., 2000); deesterification occurs rapidly and nearly completely following oral administration. Unlike *acyclovir*, *valacyclovir* is a substrate for intestinal and renal peptide transporters. *Acyclovir* distributes widely in body fluids, including vesicular fluid, aqueous humor, and CSF (cerebrospinal fluid). Compared with plasma, salivary concentrations are low, and concentrations in vaginal secretion vary widely. *Acyclovir* is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of *acyclovir* after topical administration is low. Renal excretion of unmetabolized *acyclovir* by glomerular filtration and tubular secretion is the principal route of elimination. The elimination $t_{1/2}$ of *acyclovir* is about 2.5 h (range 1.5–6 h) in adults with normal renal function. In neonates, the elimination $t_{1/2}$ of *acyclovir* is about 4 h and increases to 20 h in anuric patients.

Therapeutic Uses

Acyclovir's clinical use is limited to herpesviruses. *Acyclovir* is most active against HSV-1 (effective plasma drug concentration [C_p] range: 0.02–0.9 μg/mL), approximately half as active against HSV-2 (0.03–2.2 μg/mL), a tenth as potent against VZV (0.8–4.0 μg/mL) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) (generally >20 μg/mL) and human herpesvirus 6 (HHV-6). Uninfected mammalian cell growth generally is unaffected by high *acyclovir* concentrations (>50 μg/mL).

In immunocompetent persons, the clinical benefits of *acyclovir* and *valacyclovir* are greater in initial HSV infections than in recurrent ones.

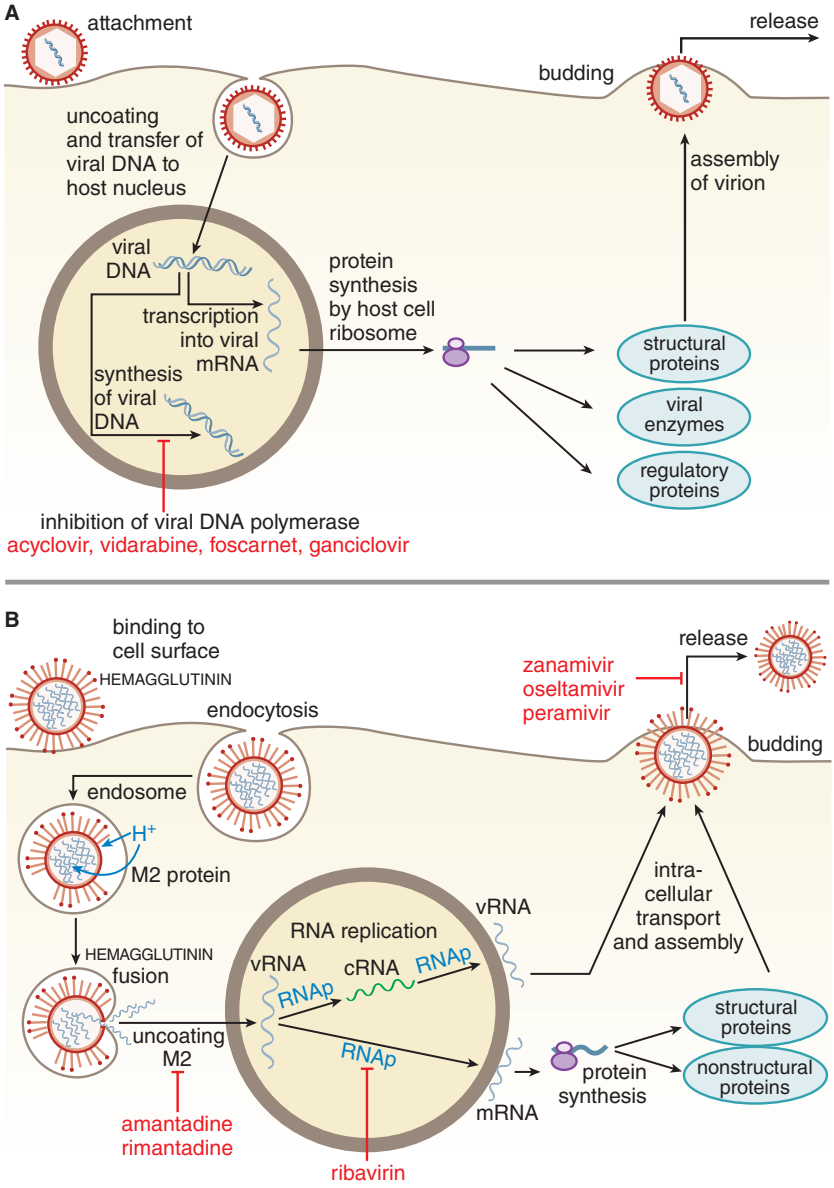

Figure 62–1 *Replicative cycles of DNA (**A**) and RNA (**B**) viruses.* The replicative cycles of herpesvirus (**A**) and influenza (**B**) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. The symbol ⊣ indicates a block to virus growth. **A.** *Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents.* Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as TKs, DNA polymerases, and so on. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. **B.** *Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents.* The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP (ribonuclear protein) segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNA polymerase (RNAp) complex. The neuraminidase inhibitors *zanamivir* and *oseltamivir* specifically inhibit release of progeny virus.

These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to *acyclovir*, higher doses must be used for treating VZV infections. Oral *valacyclovir* is as effective as oral *acyclovir* in HSV infections and more effective for treating herpes zoster. *Acyclovir* is ineffective therapeutically in established CMV infections, but *ganciclovir* is effective for CMV prophylaxis in immunocompromised patients. EBV-related oral hairy leukoplakia may improve with *acyclovir*. Oral *acyclovir* in conjunction with systemic corticosteroids appears beneficial in treating Bell's palsy; *valacyclovir* is ineffective in acute vestibular neuritis.

Herpes Simplex Virus Infections

In initial genital HSV infections, oral *acyclovir* (200 mg five times daily or 400 mg three times daily for 7–10 days) and *valacyclovir* (1000 mg twice daily for 7–10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous *acyclovir* (5 mg/kg every 8 h) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical *acyclovir* is much less effective than systemic administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. *Acyclovir* (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or *valacyclovir*

TABLE 62–2 ■ NOMENCLATURE OF ANTIVIRAL AGENTS

GENERIC NAME	OTHER NAMES	DOSAGE FORMS AVAILABLE
Antiherpesvirus agents		
Acyclovir	ACV, acycloguanosine	IV, O, T, ophth[a]
Cidofovir	HPMPC, CDV	IV
Famciclovir	FCV	O
Foscarnet	PFA, phosphonoformate	IV, O[b]
Fomivirsena[b]	ISIS 2922	Intravitreal
Ganciclovir	GCV, DHPG	IV, O, intravitreal, ophthalmic gel
Idoxuridine[b]	IDUR	Ophth
Penciclovir	PCV	T, IV[b]
Trifluridine	TFT, trifluorothymidine	Ophth
Valacyclovir		O
Valganciclovir		O
Anti-influenza agents		
Amantadine		O
Oseltamivir	GS4104	O
Peramivir	BCX 1812	IV
Rimantadine		O
Zanamivir	GC167	Inhalation
Other antiviral agents		
Ribavirin	(see Chapter 63)	O, inhalation, IV[b]
Telbivudine[b]	(see Chapter 63)	O
Tenofovir disoproxil fumarate	TDF (see Chapter 63)	O
Imiquimod		Topical

O, oral; ophth, ophthalmic; IV, intravenous; T, topical.
[a]Availability pending in the U.S.
[b]Not available in the U.S.

(500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1 to 2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral *acyclovir* (400 mg twice daily or 200 mg three times daily) or with *valacyclovir* (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by about 90%, and subclinical shedding is markedly reduced, although not eliminated. *Valacyclovir* suppression of genital herpes reduces the risk of transmitting infection to a susceptible partner by about 50% over an 8-month period (Corey et al., 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral *acyclovir* is effective in primary herpetic gingivostomatitis (600 mg/m^2 four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose *valacyclovir* (2 g twice over 1 day) shortens the duration of recurrent orolabial herpes by about 1 day (Elish et al., 2004). The U.S. Food and Drug Administration (FDA) has approved an *acyclovir/hydrocortisone* combination (Lipsovir) for early treatment of recurrent herpes cold sores. Topical *acyclovir* cream is modestly effective in recurrent labial (Spruance et al., 2002) and genital HSV infections. Preexposure *acyclovir* prophylaxis (400 mg twice daily for 1 week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. *Acyclovir* during the last month of pregnancy reduces the likelihood of viral shedding and the frequency of cesarean delivery in women with primary or recurrent genital herpes (Corey and Wald, 2009).

In immunocompromised patients with mucocutaneous HSV infection, intravenous *acyclovir* (250 mg/m^2 every 8 h for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral *acyclovir* (800 mg five times per day) and *valacyclovir* (1000 mg twice daily) for 5 to 10 days are also effective. Recurrences are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical *acyclovir* may provide some benefit. Intravenous *acyclovir* may be beneficial in viscerally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic *acyclovir* prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous *acyclovir* (250 mg/m^2 every 8–12 h) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral *acyclovir* (400 mg five times daily) is effective, and long-term oral *acyclovir* (200–400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer et al., 2000). In HSV encephalitis, *acyclovir* (10 mg/kg every 8 h for a minimum of 10 days) reduces mortality by more than 50% and improves overall neurological outcome compared with *vidarabine*. Higher doses (15–20 mg/kg every 8 h) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous *acyclovir* (20 mg/kg every 8 h for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections (Kimberlin et al., 2001). In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following *acyclovir* may occur. The value of continuing long-term suppression with *valacyclovir* after completing intravenous *acyclovir* is under study.

An ophthalmic formulation of *acyclovir* (availability pending in the U.S.) is at least as effective as topical *vidarabine* or *trifluridine* in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, *acyclovir*-resistant HSV isolates can cause extensive mucocutaneous disease and, rarely,

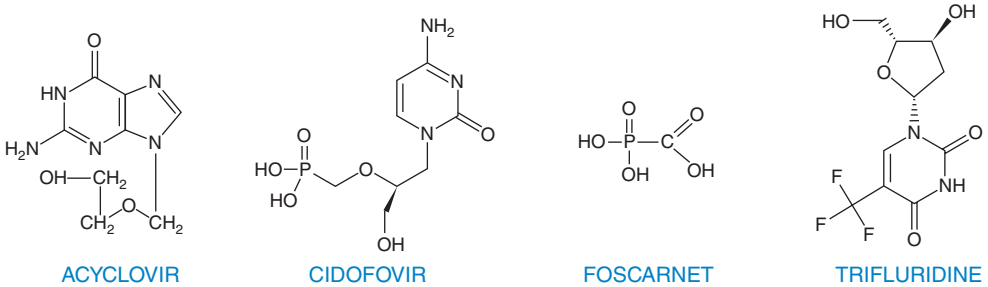

Figure 62–2 *Chemical structures of some antiherpes drugs.* Many antiherpes agents are nucleoside congeners that are phosphorylated sequentially by viral and host kinases to become triphosphate inhibitors of viral DNA synthesis (see Figure 62–3). *Foscarnet* is a pyrophosphate analogue that selectively blocks the pyrophosphate binding site on viral DNA polymerases, thereby inhibiting chain elongation.

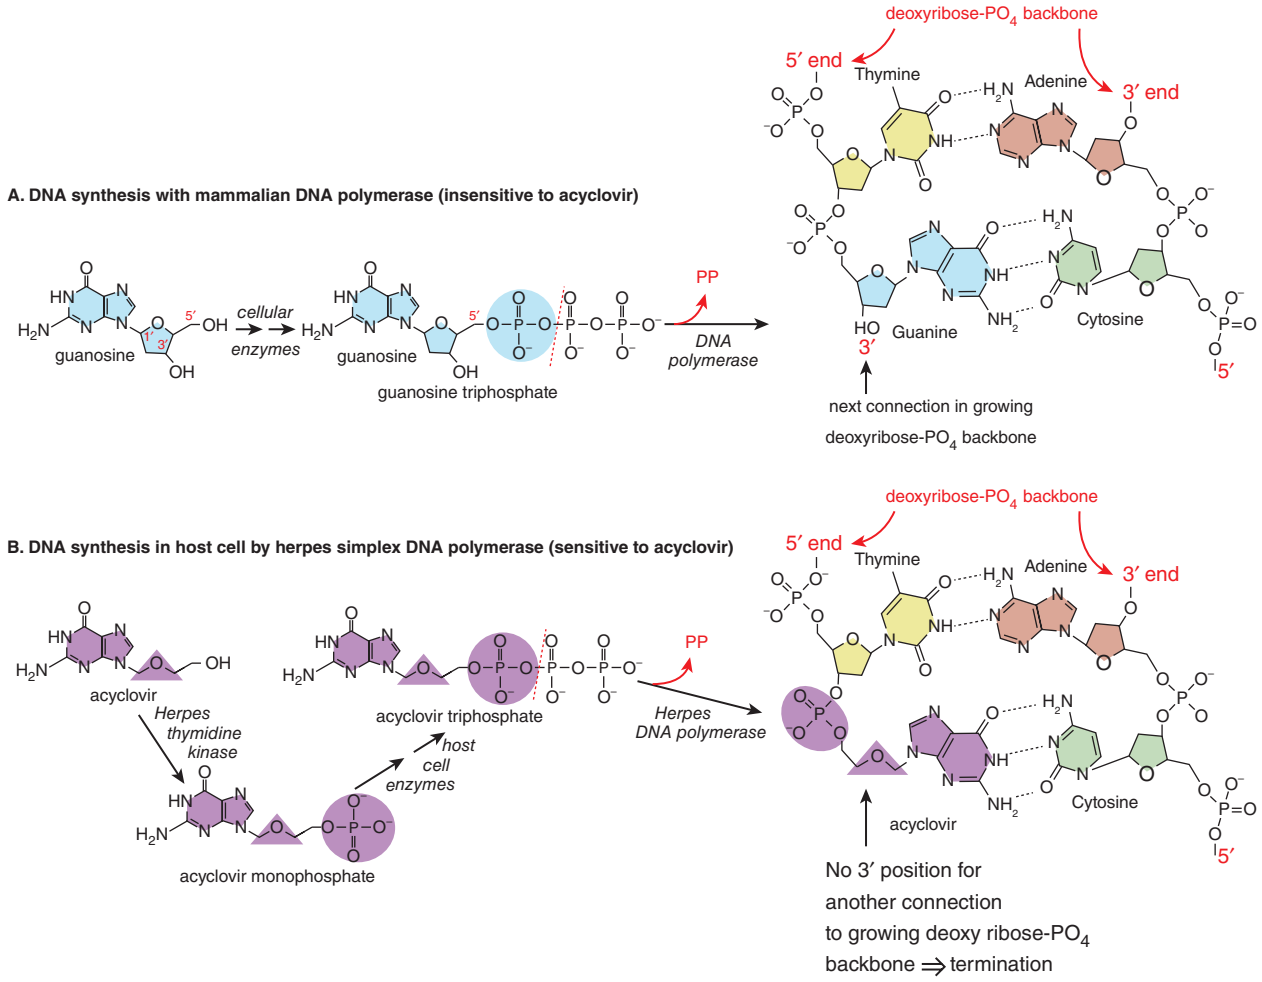

Figure 62–3 *Acyclovir inhibits DNA synthesis by HSV DNA polymerase.* After penetrating the membrane of a susceptible mammalian host cell, an HSV virion releases its capsid, which delivers viral DNA into the host cell, initiating viral DNA synthesis. *Acyclovir*, a guanine analogue, inhibits viral but not mammalian DNA polymerase. **A.** *DNA synthesis with mammalian DNA polymerase (insensitive to acyclovir).* In the presence of *acyclovir*, human DNA synthesis proceeds normally. Here, mammalian DNA polymerase removes pyrophosphate (PP) (----), from dGTP and uses dGTP to add a dGMP to the 3′ end of a growing nucleic acid polymer, the guanine base pairing with a cytosine and dGMP's 5′PO_4 bonding to the 3′OH group on the ribose of the preceding base, thymine. A 3′OH on the sugar of the added dGMP is available to form a 3′-5′ bond with the next nucleotide added. **B.** *DNA synthesis in host cell by HSV DNA polymerase (sensitive to acyclovir).* The guanine analogue *acyclovir* inhibits viral DNA polymerase by acting as a terminal substrate, but to do so, *acyclovir* must be phosphorylated to *acyclovir* triphosphate. The first phosphate group is added by the HSV TK, which has an affinity for *acyclovir* that is about 200 times that of the mammalian enzyme for *acyclovir*. Host cell enzymes add the second and third phosphates, producing *acyclovir triphosphate*, which concentrates 40- to 100-fold in HSV-infected cells over the concentrations in uninfected cells. Thus, *acyclovir triphosphate* competes well for endogenous dGTP. HSV DNA polymerase cleaves PP_i (----) from *acyclovir triphosphate* and adds *acyclovir monophosphate* to the 3′ end of the growing DNA strand. *Acyclovir* lacks a hydroxyl group in the 3′ position (indeed, it lacks that 3′ position), and further addition to the polymer by HSV DNA polymerase is not possible. Furthermore, a viral exonuclease activity associated with viral DNA polymerase cannot remove the *acyclovir* moiety. Compare the actions of *acyclovir* to those of *ganciclovir* and *penciclovir*, which have 3′OH groups, and to *foscarnet*, which binds avidly at the PP_i cleavage site of HSV DNA polymerase, preventing cleavage of PP_i from nucleoside triphosphates.

meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 4% to 7% of immunocompromised patients receiving *acyclovir* treatment. Recurrences after cessation of *acyclovir* usually are due to sensitive virus but may be due to *acyclovir*-resistant virus in patients with acquired immune deficiency syndrome (AIDS). In patients with progressive disease, intravenous *foscarnet* therapy is effective, and *vidarabine* is considered only when all other therapies have failed (Chilukuri and Rosen, 2003).

Untoward Effects

Acyclovir generally is well tolerated. Chronic *acyclovir* suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to *acyclovir* during pregnancy (Ratanajamit et al., 2003). Topical *acyclovir* in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions. Oral *acyclovir* has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. *Valacyclovir* also may be associated with headache, nausea, diarrhea, nephrotoxicity, and CNS (central nervous system) symptoms (confusion, hallucinations). Uncommon side effects include severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. *Acyclovir* has been associated with neutropenia in neonates. The principal dose-limiting toxicities of intravenous *acyclovir* are renal insufficiency and CNS side effects. Nephrotoxicity usually resolves with drug cessation and volume expansion. Hemodialysis may be useful in severe cases. Severe somnolence and lethargy may occur with combinations of *zidovudine* (see Chapter 64) and *acyclovir*. Concomitant *cyclosporine* and probably other nephrotoxic agents enhance the risk of nephrotoxicity. *Probenecid* decreases the *acyclovir* renal clearance and prolongs the elimination $t_{1/2}$.

Acyclovir may decrease the renal clearance of other drugs eliminated by active renal secretion, such as *methotrexate*.

Cidofovir

Cidofovir is a cytidine nucleotide analogue with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses.

Because *cidofovir* is a phosphonate that is phosphorylated by cellular but not viral enzymes, it inhibits *acyclovir*-resistant TK-deficient or TK-altered HSV or VZV strains, *ganciclovir*-resistant CMV strains with UL97 mutations (but not those with DNA polymerase mutations), and some *foscarnet*-resistant CMV strains. *Cidofovir* synergistically inhibits CMV replication in combination with *ganciclovir* or *foscarnet*.

Mechanisms of Action and Resistance

Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. *Cidofovir* is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to *cidofovir* develops in up to about 30% of patients with retinitis by 3 months of therapy. Highly *ganciclovir*-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to *cidofovir*, and prior *ganciclovir* therapy may select for *cidofovir* resistance. Some *foscarnet*-resistant CMV isolates show cross-resistance to *cidofovir*, and triple-drug-resistant variants with DNA polymerase mutations occur.

ADME

Cidofovir has very low oral bioavailability. Penetration into the CSF is low. Topical *cidofovir* gel may result in low plasma concentrations (<0.5 μg/mL) in patients with large mucocutaneous lesions. Plasma levels after intravenous dosing decline in a biphasic pattern with a terminal $t_{1/2}$ that averages 2.6 h. The active form, *cidofovir diphosphate*, has a prolonged intracellular $t_{1/2}$ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases (Hitchcock et al., 1996), thereby providing a modest measure of selective toxicity. A phosphocholine metabolite of the drug also has a long intracellular $t_{1/2}$ (~87 h) and may serve as an intracellular reservoir of drug. The prolonged intracellular $t_{1/2}$ of *cidofovir diphosphate* allows infrequent (weekly or biweekly) dosing regimens. *Cidofovir* is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine. *Probenecid* blocks tubular transport of *cidofovir* and reduces renal clearance and associated nephrotoxicity. Elimination relates linearly to creatinine clearance; the $t_{1/2}$ increases to 32.5 h in patients on chronic ambulatory peritoneal dialysis. Hemodialysis removes more than 50% of the administered dose.

Therapeutic Uses

Intravenous *cidofovir* is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous *cidofovir* has been used for treating *acyclovir*-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients, and extensive molluscum contagiosum in HIV patients. Reduced doses without *probenecid* may be beneficial in BK virus nephropathy in patients with a renal transplant. Topical *cidofovir* gel eliminates virus shedding and lesions in some HIV-infected patients with *acyclovir*-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralesional *cidofovir* induces remissions in adults and children with respiratory papillomatosis.

Untoward Effects

Nephrotoxicity is the principal dose-limiting side effect of intravenous *cidofovir*. Concomitant oral *probenecid* and saline prehydration reduce the risk of renal toxicity; however, *probenecid* alters renal clearance of many agents (see Figure 42–2), albeit not of *cidofovir*. For example, *probenecid* alters *zidovudine* pharmacokinetics such that *zidovudine* doses should be reduced when *probenecid* is present (as should the doses of other drugs whose renal secretion *probenecid* inhibits, e.g., β-lactam antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs], *acyclovir*, *lorazepam*, *furosemide*, *methotrexate*, *theophylline*, and *rifampin*).

On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10% to 15% show an elevated serum creatinine concentration, and 15% to 20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly, and low intraocular pressure occurs infrequently with intravenous *cidofovir*. Administration with food and pretreatment with antiemetics, antihistamines, or *acetaminophen* may improve tolerance. Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse before initiation of *cidofovir* treatment is recommended after prior exposure to aminoglycosides, intravenous *pentamidine*, *amphotericin B*, *foscarnet*, NSAID, or contrast dye. *Cidofovir* and oral *ganciclovir* are poorly tolerated in combination at full doses.

Topical application of *cidofovir* is associated with dose-related application site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. *Cidofovir* is considered a potential human carcinogen. It may cause infertility and no adequate human data have established whether this drug poses a pregnancy risk (former pregnancy category C).

Famciclovir and Penciclovir

Famciclovir is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. *Penciclovir* is an acyclic guanine nucleoside analogue. *Penciclovir* is similar to *acyclovir* in its spectrum of activity and potency against HSV and VZV. It also is inhibitory for HBV.

Mechanisms of Action and Resistance

Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, *penciclovir* is phosphorylated initially by viral TK. *Penciclovir triphosphate* is a competitive inhibitor of viral DNA polymerase (see Figure 62–3). Although *penciclovir triphosphate* is approximately one-hundredth as potent as *acyclovir triphosphate* in inhibiting viral DNA polymerase, it is present in infected cells at much higher concentrations and for more prolonged periods. The prolonged intracellular $t_{1/2}$ of *penciclovir triphosphate*, 7 to 20 h, is associated with prolonged antiviral effects. Because *penciclovir* has a 3′-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation. Resistance during clinical use is low. TK-deficient, *acyclovir*-resistant herpesviruses are cross-resistant to *penciclovir*.

ADME

Oral *penciclovir* has low (<5%) bioavailability. In contrast, *famciclovir* is well absorbed orally (bioavailability ~75%) and is converted rapidly to *penciclovir* by deacetylation of the side chain and oxidation of the purine ring during and following absorption. Food slows absorption but does not reduce overall bioavailability. The plasma elimination $t_{1/2}$ of *penciclovir* averages about 2 h, and more than 90% is excreted unchanged in the urine. Following oral *famciclovir* administration, nonrenal clearance accounts for about 10% of each dose, primarily through fecal excretion, but *penciclovir* (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma $t_{1/2}$ averages 9.9 h in renal insufficiency (creatinine clearance [Cl_{cr}] <30 mL/min); hemodialysis efficiently removes *penciclovir*.

Therapeutic Uses

Oral *famciclovir*, topical *penciclovir*, and intravenous *penciclovir* are approved for managing HSV and VZV infections.

Oral *famciclovir* (250 mg three times a day for 7–10 days) is as effective as *acyclovir* in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated *famciclovir* treatment (125 or 250 mg twice daily for 5 days) reduces healing time and symptoms by about 1 day. *Famciclovir* (250 mg twice daily for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice daily) reduce HSV recurrences in HIV-infected persons. Intravenous *penciclovir* (5 mg/kg every 8 or 12 h for 7 days) (not available in the U.S.) is comparable

to intravenous *acyclovir* for treating mucocutaneous HSV infections in immunocompromised hosts. In immunocompetent persons with recurrent orolabial HSV, topical 1% *penciclovir* cream (applied every 2 h while awake for 4 days) shortens healing time and symptoms by about 1 day (Raborn et al., 2002).

In immunocompetent adults with herpes zoster of 3 days' duration or less, *famciclovir* (500 mg three times a day for 10 days) is at least as effective as *acyclovir* (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those 50 years or older. *Famciclovir* is comparable to *valacyclovir* in treating zoster and reducing associated pain in older adults (Tyring et al., 2000). *Famciclovir* (500 mg three times a day for 7–10 days) also is comparable to high-dose oral *acyclovir* in treating zoster in immunocompromised patients and in those with ophthalmic zoster (Tyring et al., 2001).

Famciclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than *lamivudine* (Lai et al., 2002). *Famciclovir* is also ineffective in treating *lamivudine*-resistant HBV infections owing to emergence of multiply resistant variants.

Untoward Effects

Oral *famciclovir* is associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical *penciclovir* (~1%) rarely is associated with local reactions. The short-term tolerance of *famciclovir* is comparable with that of *acyclovir*. *Penciclovir* is mutagenic at high concentrations. Long-term administration (1 year) does not affect spermatogenesis in men. Safety during pregnancy has not been established.

Ganciclovir and Valganciclovir

Ganciclovir is an acyclic guanine nucleoside analogue that is similar in structure to *acyclovir*. *Valganciclovir* is the L-valyl ester prodrug of *ganciclovir*. *Ganciclovir* has inhibitory activity against all herpesviruses and is especially active against CMV.

Mechanisms of Action and Resistance

Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral TK during HSV infection and by a viral phosphotransferase encoded by the *UL97* gene during CMV infection. *Ganciclovir diphosphate* and *ganciclovir triphosphate* are formed by host enzymes. At least 10-fold higher concentrations of *ganciclovir triphosphate* are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of dGTP incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (see Figures 62–1A and 62–3).

Cytomegalovirus can become resistant to *ganciclovir* by either of two mechanisms: reduced intracellular *ganciclovir* phosphorylation owing to mutations in the viral phosphotransferase or mutations in viral DNA polymerase. Highly resistant variants with both mutations are cross-resistant to *cidofovir* and variably to *foscarnet*. *Ganciclovir* also is much less active against *acyclovir*-resistant TK-deficient HSV strains.

ADME

The oral bioavailability of *ganciclovir* is low, only 6% to 9% following ingestion with food. On the other hand, oral doses of the prodrug *valganciclovir* are well absorbed and hydrolyzed rapidly to *ganciclovir*; thus, *valganciclovir* provides greater bioavailability of the *ganciclovir* moiety, about 60%. Food further increases the bioavailability of *valganciclovir* by about 25%. Following intravenous administration of *ganciclovir*, vitreous fluid levels are similar to or higher than those in plasma and decline with a $t_{1/2}$ of 23 to 26 h. Intraocular sustained-release *ganciclovir* implants provide vitreous levels of about 4.1 μg/mL. The plasma elimination $t_{1/2}$ is about 2 to 4 h. Intracellular *ganciclovir triphosphate* concentrations are 10-fold higher than those of *acyclovir* triphosphate and decline much more slowly, with an intracellular elimination $t_{1/2}$ longer than 24 h. These differences may account in part for *ganciclovir*'s greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections. Over 90% of *ganciclovir* is eliminated unchanged by renal excretion. Plasma $t_{1/2}$ increases in patients with severe renal insufficiency.

Therapeutic Uses

In CMV retinitis, initial induction treatment (5 mg/kg IV every 12 h for 10–21 days) is associated with improvement or stabilization in about 85% of patients (Faulds and Heel, 1990). Reduced viral excretion is usually evident by 1 week, and funduscopic improvement is seen by 2 weeks. Because of the high risk of relapse, patients with AIDS with retinitis require suppressive therapy with high doses of *ganciclovir* (5 mg/kg per day). Oral *ganciclovir* (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treatment but has been replaced in practice by oral *valganciclovir*. Oral *valganciclovir* (900 mg twice daily for 21 days of initial treatment) is comparable to intravenous dosing for initial control and sustained suppression (900 mg daily) of CMV retinitis (Schreiber et al., 2009). Intravitreal *ganciclovir* injections have been used in some patients, and an intraocular sustained-release *ganciclovir* implant is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 h for 14–21 days) may benefit other CMV syndromes in patients with AIDS or recipients of solid-organ transplants (Kotton et al., 2010). *Ganciclovir* has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Schreiber et al., 2009).

A *ganciclovir* ophthalmic gel formulation is effective in treating HSV keratitis (Colin et al., 1997). Oral *ganciclovir* also reduces HBV DNA levels and aminotransferase levels in chronic HBV infection (Hadziyannis et al., 1999), but the drug is not approved for this indication.

Untoward Effects

Myelosuppression is the principal dose-limiting toxicity of *ganciclovir*. Neutropenia occurs in about 15% to 40% of patients and is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Recombinant granulocyte colony-stimulating factor (G-CSF; *filgrastim*, *lenograstim*) may be useful in treating *ganciclovir*-induced neutropenia (see Chapter 45). Thrombocytopenia occurs in 5% to 20% of patients. *Zidovudine* and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair *ganciclovir* excretion. *Probenecid* and possibly *acyclovir* reduce renal clearance of *ganciclovir*. Oral *ganciclovir* increases the absorption and peak plasma concentrations of *didanosine* by approximately 2-fold and that of *zidovudine* by about 20%. CNS side effects (5%–15%) range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients must interrupt or prematurely stop intravenous *ganciclovir* therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described. Risk of *ganciclovir*'s use during pregnancy has not been ruled out.

Letermovir

Letermovir is the first newly licensed antiviral agent with CMV activity in over 20 years. It is indicated for prophylaxis of CMV infection and disease in adult CMV-seropositive recipients of an allogeneic hematopoietic stem cell transplantation (HSCT). The drug is also being evaluated in pediatric HSCT patients. Given *letermovir*'s efficacy and safety profile, the drug is being evaluated for treatment of neonatal symptomatic congenital CMV infection in combination with *ganciclovir*.

Mechanisms of Action and Resistance

Letermovir is a novel inhibitor of the CMV viral enzyme DNA terminase (UL56/UL89), which plays an important role in the cleavage of newly synthesized CMV DNA into individual viral genomes. These genomes are subsequently inserted into CMV procapsids to generate infectious CMV virions (Goldner et al., 2011). *Letermovir* has demonstrated potent, selective, and reversible inhibition of CMV activity in preclinical studies *in vitro* and efficacy against the virus *in vivo* (Goldner et al., 2011; Lischka et al., 2010). The median EC_{50} of *letermovir* against a collection of clinical

CMV isolates in cell culture was 2.1 nM (range, 0.7–6.1 nM; FDA, 2017). In a phase II trial, seven *letermovir*-treated participants experienced virological failure (Lischka et al., 2016). All but one of the resistance mutations were found to represent natural polymorphisms that did not affect susceptibility to *letermovir*. One subject from the 60-mg daily dose group exhibited the UL56 genotype, V236M, conferring *in vitro* resistance to *letermovir*. In a phase III trial, the protein subunit pUL56 substitutions V236M, E237G, C325W, and R369T were detected in three subjects, which significantly shifted the susceptibility (Douglas et al., 2020).

Cross-resistance is not likely with drugs outside of this class. *Letermovir* is fully active against viral populations with substitutions conferring resistance to CMV DNA polymerase inhibitors (*cidofovir*, *foscarnet*, and *ganciclovir*). These agents are expected to be fully active against *letermovir*-resistant viral populations.

ADME

Letermovir pharmacokinetics are nonlinear and time dependent and exhibit greater than dose-proportional changes in exposure. There is considerable variability in absorption after oral administration. The net effect of *letermovir* on CYP3A is moderate inhibition, and concentrations of CYP2C8 substrates are predicted to be increased by *letermovir* (Wang et al., 2019). *In vitro*, *letermovir* inhibits efflux transporters P-glycoprotein, multidrug resistance-associated protein 2 (MRP2), bile salt export pump (BSEP), breast cancer resistance protein (BCRP), hepatic uptake transporter OATP1B1/3, and organic anion transporter 3 (OAT3). Thus, one may expect drug-drug interactions involving those transporters.

Therapeutic Uses

Letermovir is dosed at 480 mg once daily orally or as an intravenous infusion over 1 h through 100 days after transplant. It is available as 240- and 480-mg oral tablets and a 20-mg/mL solution for infusion. The 240-mg dose is for patients receiving concomitant *cyclosporine*, which doubles *letermovir* exposure (assessed as AUC [area under curve of plasma drug concentration vs. time]) likely due to *cyclosporine*'s inhibition of liver uptake transporters OATP1B1/3. In a phase III trial in CMV-seropositive recipients of allogeneic HSCT, *letermovir* was superior to placebo in preventing clinically significant CMV infection through week 24 after transplantation (Marty et al., 2017). Among 495 patients with undetectable CMV DNA at baseline, 37.5% had clinically significant CMV infection or reached a primary endpoint by week 24 after transplantation compared to 60.6% of placebo recipients ($P < 0.001$).

Untoward Effects

Vomiting was reported in 18.5% of patients (vs. 13.5% for placebo). Edema was reported in 14.5% (vs. 9.4% for placebo), and atrial fibrillation or flutter was reported in 4.6% (vs. 1.0% for placebo). The rates of myelotoxic and nephrotoxic events were similar in the *letermovir* and placebo groups. All-cause mortality at 24 and 48 weeks after transplantation was 10.2% versus 15.9% ($P = 0.03$) and 20.9% versus 25.5% among *letermovir* versus placebo recipients, respectively. The frequency and severity of adverse events were similar in the two groups overall.

Foscarnet

Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analogue that is inhibitory for all herpesviruses and HIV.

Mechanisms of Action and Resistance

Foscarnet inhibits viral nucleic acid synthesis by interacting directly at HSV DNA polymerase or HIV reverse transcriptase (see Figures 62–1A and 62–3). *Foscarnet* reversibly blocks the pyrophosphate binding site of the viral DNA polymerase, inhibiting cleavage of pyrophosphate from deoxynucleotide triphosphates and thereby inhibiting chain elongation (deoxynucleotide triphosphate + $DNA_n \rightarrow$ diphosphate + DNA_{n+1}). *Foscarnet* has about 100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase α. Herpesviruses resistant to *foscarnet* have point mutations in the viral DNA polymerase.

ADME

Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration; in addition, the drug's oral bioavailability is low. Vitreous levels approximate those in plasma; CSF levels average 66% of those in plasma at steady state. Over 80% of *foscarnet* is excreted unchanged in the urine. Dose adjustments are necessary for small decreases in renal function. Plasma elimination has initial bimodal half-lives totaling 4 to 8 h and a prolonged terminal elimination $t_{1/2}$ of 3 to 4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10% to 20% of a given dose. *Foscarnet* is cleared efficiently by hemodialysis (~50% of a dose).

Therapeutic Uses

Intravenous *foscarnet* is effective for treatment of CMV retinitis, including *ganciclovir*-resistant infections, other types of CMV infection, and *acyclovir*-resistant HSV and VZV infections.

In CMV retinitis in patients with AIDS, *foscarnet* (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90–120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. In CMV retinitis in patients with AIDS, *foscarnet* (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90–120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, *foscarnet* (60 mg/kg every 12 h for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous *ganciclovir* and causes less neutropenia (Reusser et al., 2002). When used for CMV infections, *foscarnet* may reduce the risk of Kaposi sarcoma in HIV-infected patients. Intravitreal injections of *foscarnet* also have been used. In *acyclovir*-resistant mucocutaneous HSV infections, lower doses of *foscarnet* (40 mg/kg every 8 h for ≥7 days) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. *Foscarnet* also appears to be effective in *acyclovir*-resistant VZV infections. Topical *foscarnet* cream is ineffective in treating recurrent genital HSV in immunocompetent persons but appears to be useful in chronic *acyclovir*-resistant infections in immunocompromised patients.

Untoward Effects

Major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are generally reversible after cessation. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Saline loading may reduce the risk of nephrotoxicity. *Foscarnet* is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca^{2+} and phosphate, hypomagnesemia, and hypokalemia. Concomitant intravenous *pentamidine* administration increases the risk of symptomatic hypocalcemia. CNS side effects include headache (25%), tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical *foscarnet* may cause local irritation and ulceration, and oral *foscarnet* may cause gastrointestinal (GI) disturbance. Preclinical studies indicate that high *foscarnet* concentrations are mutagenic. Safety in pregnancy or childhood is uncertain.

Fomivirsen

Fomivirsen, a 21-base phosphorothioate oligonucleotide, provides antisense therapy. The drug is complementary to the mRNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. *Fomivirsen* is active against CMV strains resistant to *ganciclovir*, *foscarnet*, and *cidofovir*. *Fomivirsen* is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous ($t_{1/2}$ ~55 h) through distribution to the retina and probable exonuclease digestion. In HIV-infected

patients with refractory, sight-threatening CMV retinitis, *fomivirsen* injections (330 µg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression. Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15% to 20% of patients. Recent *cidofovir* use may increase the risk of inflammatory reactions. *This drug is no longer available in the U.S.*

Docosanol

Docosanol is a long-chain saturated alcohol that is approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. *Docosanol* inhibits the *in vitro* replication of many lipid-enveloped viruses, including HSV. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 h of prodromal symptoms or lesion onset reduces healing time by about 1 day and is well tolerated. Treatment initiation at papular or later stages provides no benefit.

Idoxuridine

Idoxuridine is an iodinated thymidine analogue that inhibits the *in vitro* replication of various DNA viruses, including herpesviruses and poxviruses. *Idoxuridine* lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. In the U.S., *idoxuridine* is approved only for topical (ophthalmic) treatment of HSV keratitis. *Idoxuridine* formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. Adverse reactions include pain, pruritus, inflammation, and edema of the eye or lids; allergic reactions are rare.

Trifluridine

Trifluridine is a fluorinated pyrimidine nucleoside that has *in vitro* inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses. *Trifluridine* inhibits replication of herpesviruses, including *acyclovir*-resistant strains, and also inhibits cellular DNA synthesis at relatively low concentrations. *Trifluridine monophosphate* irreversibly inhibits thymidylate synthase, and *trifluridine triphosphate* is a competitive inhibitor of thymidine triphosphate incorporation into DNA; *trifluridine* is incorporated into viral and cellular DNA. *Trifluridine*-resistant HSV has been described.

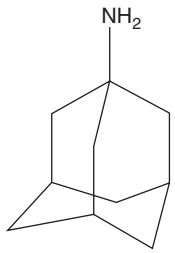
Trifluridine currently is used for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical *trifluridine* is more active than *idoxuridine* and comparable to *vidarabine* in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions and irritation are uncommon. Topical *trifluridine* also appears to be effective in some patients with *acyclovir*-resistant HSV cutaneous infections.

Anti-influenza Agents

Recently, there has been concern about the possibility of new influenza pandemics stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1 that is thought to be of swine origin. Six drugs are currently approved for the treatment and prevention of influenza virus infection: the adamantane antivirals *amantadine* and *rimantadine*; *oseltamivir*; *zanamivir*; *peramivir*; and *baloxavir marboxil*. Resistance to these drugs has arisen as a consequence of their overuse, including in veterinary applications. Development of resistance and the spread of resistant viruses are major challenges in the chemotherapy and chemoprophylaxis of influenza and are likely to drive future recommendations for use of these drugs in global populations. The U.S. Centers for Disease Control and Prevention (CDC) annually issues recommendations for influenza vaccinations and comments on effective medications (CDC, 2021).

Amantadine and Rimantadine

Amantadine and its derivative *rimantadine* are uniquely configured tricyclic amines. *Rimantadine* has $H_3C-CH(NH_2)-$ in place of the $-NH_2$ group.



AMANTADINE

Mechanisms of Action and Resistance

Amantadine and *rimantadine* inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly, probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH–induced conformational changes in hemagglutinin during its intracellular transport later in replication. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain; resistant isolates typically appear in the treated patient within 2 to 3 days of starting therapy.

ADME

Table 62–3 summarizes important pharmacokinetics properties of these antiviral agents. The two adamantanes differ in several respects. *Amantadine* is excreted largely unmetabolized in the urine ($t_{1/2}$ of elimination is ~12–18 h in young adults, increasing up to twice that in the elderly and even more in those with renal impairment). By contrast, elimination of *rimantadine* depends on hepatic function; the drug is subject to phase 1 and phase 2 reactions prior to renal excretion of metabolites (elimination $t_{1/2}$ ~24–36 h; 60%–90% is excreted in the urine as metabolites). Elderly patients require only one-half the weight-adjusted dose of *amantadine* needed for young adults. *Amantadine* is excreted in breast milk. *Rimantadine* concentrations in nasal mucus average 50% higher than those in plasma.

Therapeutic Uses

Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. *Amantadine* and *rimantadine* are active only against susceptible influenza A viruses (not influenza B); *rimantadine* is 4- to 10-fold more active than *amantadine*. Virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs.

Seasonal prophylaxis with either *amantadine* or *rimantadine* (a total of 200 mg/day in one or two divided doses in young adults) is about 70% to 90% protective against influenza A illness. These agents are efficacious in preventing nosocomial influenza and in curtailing nosocomial outbreaks during pandemic influenza. Doses of 100 mg/day are better tolerated and still appear to be protective against influenzal illness. Seasonal prophylaxis is an alternative in high-risk patients, if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4–8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

TABLE 62–3 ■ PHARMACOLOGICAL CHARACTERISTICS OF ANTIVIRALS FOR INFLUENZA

[f]Types of influenza.

The adamantanes are effective against influenza A H1N1 if treatment is initiated within 2 days of the onset of symptoms (Schmidt, 2004). In uncomplicated influenza A illness of adults, early *amantadine* or *rimantadine* treatment (200 mg/day for 5 days) reduces the duration of fever and systemic complaints by 1 to 2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding. The usual regimen in children (≥1 year of age) is 5 mg/kg per day, up to 150 mg, administered once or twice daily. Resistant variants have been recovered from about 30% of treated children or outpatient adults by the fifth day of therapy.

Untoward Effects

The most common side effects related to *amantadine* and *rimantadine* are minor dose-related CNS and GI effects: nervousness, light-headedness, difficulty concentrating, insomnia, loss of appetite, and nausea. CNS side effects (5%–33%) occur in patients treated with *amantadine* at doses of 200 mg/day but are significantly less frequent with *rimantadine*. The neurotoxic effects of *amantadine* appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in elderly patients. At comparable doses of 100 mg/day, *rimantadine* is significantly better tolerated in nursing home residents than *amantadine*. High *amantadine* plasma concentrations (1.0–5.0 µg/mL) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with *amantadine* and possibly with *rimantadine*. No adequate human data have established whether the adamantanes pose a pregnancy risk (former pregnancy category C).

Oseltamivir

Oseltamivir carboxylate is a transition-state analogue of sialic acid that is a potent selective inhibitor of the neuraminidases of influenza A and B virus. *Oseltamivir phosphate* is an ethyl ester prodrug that lacks antiviral activity. *Oseltamivir carboxylate* has an antiviral spectrum and potency similar to that of *zanamivir*: It inhibits *amantadine*- and *rimantadine*-resistant influenza A viruses and some *zanamivir*-resistant variants.

Mechanisms of Action and Resistance

Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions. This enzymatic action is essential for release of virus from infected cells. Interaction of *oseltamivir carboxylate* with the neuraminidase causes a conformational change within the enzyme's active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract. Influenza variants selected *in vitro* for resistance to *oseltamivir carboxylate* contain hemagglutinin or neuraminidase mutations. Seasonal influenza A (H1N1) has become virtually 100% resistant to *oseltamivir* worldwide (Moscona, 2009; Schirmer and Holodniy, 2009). Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to *oseltamivir*.

ADME

Table 62–3 summarizes a number of pharmacokinetic properties of *oseltamivir carboxylate*. Oral *oseltamivir phosphate* is absorbed rapidly and cleaved by esterases in the GI tract and liver to the active carboxylate. Food does not decrease bioavailability but reduces the risk of GI intolerance. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. *Probenecid* doubles the plasma $t_{1/2}$ of the carboxylate, which indicates tubular secretion by the anionic pathway. Children younger than 2 years exhibit age-related changes in *oseltamivir carboxylate* clearance and total drug exposure (Kimberlin et al., 2009).

Therapeutic Uses

Oral *oseltamivir* is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1 to 12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by about 1 to 2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40% to 50%. Treatment reduces by about 50% the risk of subsequent hospitalization in adults (Kaiser et al., 2003). When used for prophylaxis during the typical influenza season, *oseltamivir* (75 mg once daily) is effective (~70%–90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use protects against influenza in household contacts (Schirmer and Holodniy, 2009).

Untoward Effects

Oral *oseltamivir* is associated with nausea, abdominal discomfort, and, less often, emesis. GI complaints typically resolve in 1 to 2 days despite continued dosing and are preventable by administration with food. An increased frequency of headache was reported in one prophylaxis study in elderly adults. Neither the phosphate nor the carboxylate form interacts with cytochrome P450 isozymes (CYPs) *in vitro*. *Oseltamivir* does not appear to impair fertility, but safety in pregnancy is uncertain.

Zanamivir

Zanamivir is a sialic acid analogue that potently and specifically inhibits the neuraminidases of influenza A and B viruses. *Zanamivir* inhibits *in vitro* replication of influenza A and B viruses, including *amantadine*- and *rimantadine*-resistant strains and several *oseltamivir*-resistant variants.

Mechanisms of Action and Resistance

Zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract. *In vitro* selection of viruses resistant to *zanamivir* is associated with mutations in the viral hemagglutinin or neuraminidase. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of *zanamivir*, but the altered enzymes show reduced activity or stability. *Zanamivir*-resistant variants usually have decreased infectivity in animals.

ADME

See Table 62–3 for pharmacokinetic properties of *zanamivir*. Oral bioavailability of *zanamivir* is less than 5%, and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath actuated and requires a cooperative patient. Following inhalation of the dry powder, about 15% is deposited in the lower respiratory tract and about 80% in the oropharynx. Overall bioavailability is 4% to 17%.

Depending on the strain, *zanamivir* competitively inhibits influenza neuraminidase activity at concentrations of about 0.2 to 3 ng/mL but affects neuraminidases from other pathogens and mammalian sources only at 106-fold higher concentrations. *Zanamivir* inhibits *in vitro* replication of influenza A and B viruses, including *amantadine*- and *rimantadine*-resistant strains and several *oseltamivir*-resistant variants. It is active after topical administration in animal influenza models.

Therapeutic Uses

Inhaled *zanamivir* is effective for the prevention and treatment of influenza A and B virus infections. Early *zanamivir* treatment (10 mg [two inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children 5 years or older shortens the time to illness resolution by 1 to 3 days and in adults reduces by 40% the risk of lower respiratory tract complications that require use of antibiotics. Once-daily inhaled *zanamivir* is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission. Intravenous *zanamivir* ($t_{1/2}$ ~1.7 h) is available in the U.S. as an emergency investigational new drug (EIND) and in the E.U. on a compassionate use basis for life-threatening, resistant influenza.

Untoward Effects

Orally inhaled *zanamivir* generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. *Zanamivir* is not generally recommended for treatment of patients with underlying airway disease because of the risk of serious adverse events. Preclinical studies of *zanamivir* revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy risk not ruled out). No clinically significant drug interactions have been recognized to date. *Zanamivir* does not diminish the immune response to injected influenza vaccine.

Peramivir

Peramivir is an FDA-approved inhibitor of influenza virus neuraminidase indicated for the treatment of acute uncomplicated influenza in patients 18 years and older who have been symptomatic for no more than 2 days. While *peramivir* was in clinical development, the FDA authorized its emergency use for treatment of pandemic 2009 A/H1N1 in certain adult and pediatric patients.

Mechanisms of Action and Resistance

Peramivir has a mechanism of action similar to that of other neuraminidase inhibitors. Neuraminidase resistance can occur as the result of point mutations in either the neuraminidase or hemagglutinin genes or both. Structurally, *peramivir* differs somewhat from others in the class via a substitution resulting in multiple binding site interactions, which confers some activity against cross-resistant viruses. Antiviral resistance is currently low to the three available neuraminidase inhibitors among circulating influenza viruses. This will likely change with each influenza season. In general, cross-resistance across these agents exists, with the degree of cross-resistance depending on the viral strain and which point mutations occur.

ADME

Peramivir is not significantly metabolized in humans. It is not a substrate for CYPs and is neither a substrate nor an inhibitor of P-glycoprotein. The elimination half-life following intravenous administration of 600 mg as a single dose is approximately 20 h. Clearance is largely (90%) via renal excretion of the unchanged compound. Negligible accumulation is observed after repeated dosing. Following a 600-mg dose infused over 30 min, the end-of-infusion C_{max} was 46.8 μg/mL, and the $AUC_{0-\infty}$ was 102.7 μg*h/mL. Dosing should be adjusted in patients with altered Cl_{cr}. A single 200-mg dose should be administered for those with an estimated Cl_{cr} (Cockcroft-Gault) between 30 and 49 mL/min, and 100 mg should be administered for a Cl_{cr} of 10 to 29 mL/min. No clinically significant drug interactions have been recognized to date. Table 62–3 summarizes pharmacokinetic data for *peramivir*.

Therapeutic Uses

Peramivir is administered as a single 600-mg dose, administered via intravenous infusion over 15 to 30 min. A phase II clinical trial demonstrated that intravenous *peramivir* (300 or 600 mg as a single-dose infusion) reduced the time to alleviation of symptoms, from 82 h (placebo) to 59 h (treatment with 600 mg *peramivir*) (Kohno et al., 2010). A phase III trial demonstrated that *peramivir* (300 or 600 mg) was comparable in extent of symptom relief to oral *oseltamivir* (75 mg twice a day for 5 days) in patients with seasonal influenza A or B and with comparable rates of adverse events (Kohno et al., 2011). At present, *peramivir*'s primary use may be limited to patients with acute, uncomplicated influenza who cannot absorb or cannot take oral agents. Further studies are needed regarding the use of *peramivir* in severely ill hospitalized patients and in the pediatric population.

Untoward Effects

The most common adverse event (>2%) is diarrhea. Hypersensitivity reactions (e.g., Stevens-Johnson syndrome and erythema multiforme) have occurred, and treated patients with influenza may be at increased risk for neuropsychiatric events such as hallucinations, delirium, and abnormal behavior. Frequency and severity of adverse effects (*peramivir* 300 or 600 mg) are comparable to those with *oseltamivir* (75 mg twice daily for 5 days) (Kohno et al., 2011). Patients receiving 600 mg *peramivir* or *oseltamivir* had decreased neutrophil counts (10.4% vs. 9.3%), diarrhea (8.2% vs. 7.4%), and vomiting (1.6% vs. 4.1%), respectively.

Baloxavir Marboxil

Baloxavir marboxil is indicated for the treatment of acute uncomplicated influenza in patients 12 years of age and older who have been symptomatic for up to 2 days and for those at high risk of developing influenza-related complications. It is also approved for postexposure prophylaxis of influenza in patients 12 years of age or older following contact with an individual who has influenza. It is active against both type A and type B influenza.

Mechanisms of Action and Resistance

Baloxavir marboxil is an orally administered prodrug. Following absorption, the drug undergoes near complete hydrolysis to form active baloxavir acid. *Baloxavir* is a selective inhibitor of influenza cap-dependent endonuclease that blocks influenza proliferation by inhibiting the initiation of mRNA synthesis (Heo, 2018). *Baloxavir* has activity against *oseltamivir*-resistant viruses, and with its unique mechanism of action,

it may act synergistically with other agents, particularly for uncomplicated infection. The emergence of polymerase acidic protein variants with I38T/M/F substitutions conferring reduced susceptibility to *baloxavir* occurred in 9.7% of *baloxavir* recipients in a phase III trial, typically at day 5 or later, but in none of 95 randomly selected placebo recipients (Hayden et al., 2018).

ADME

Baloxavir marboxil is rapidly and completely metabolized to baloxavir acid by hydrolysis in the intestine, blood, and liver mainly by arylacetamide deacetylase (AADAC). Baloxavir acid is primarily metabolized by UGT1A3 with a minor contribution from CYP3A4 and is primarily eliminated by biliary excretion (Ng, 2019). t_{max} occurs around 4 h after dose, and the drug undergoes a multiphasic decay with a terminal $t_{1/2}$ of approximately 80 h (Koshimichi et al., 2018). Coadministration of *baloxavir* with dairy products, calcium-fortified beverages, polyvalent cation-containing laxatives, antacids, or oral supplements (e.g., calcium, iron, magnesium, selenium, zinc) should be avoided since chelation with these polyvalent cations may decrease plasma exposure and curtail efficacy. The drug can be administered with or without food, but food decreases the C_{max} and AUC by 48% and 36%, respectively. Table 62–3 summarizes pharmacokinetic data for *baloxavir*.

Therapeutic Uses

Baloxavir marboxil is administered as a single oral dose: 40 mg for individuals weighing 40 to less than 80 kg and 80 mg for individuals weighing 80 kg or more (FDA, 2019a). A preservative-free (40 mg/20 mL) oral suspension formulation is also available; the *baloxavir* dose is the same for treatment and prophylaxis. The primary phase III trial was a double-blind, placebo- and *oseltamivir*-controlled, randomized trial that enrolled patients aged 12 to 64 years with influenza-like illness from the U.S. and Japan (Hayden et al., 2018). The median time to alleviation of symptoms was similar in the *baloxavir* (53.5 h) and *oseltamivir* (53.8 h) groups, relative to placebo (80.2 h). *Baloxavir* was associated with greater reductions in viral load at day 1 versus placebo or *oseltamivir*. Overall, the clinical benefits of *baloxavir* resemble those of *oseltamivir*.

Untoward Effects

Adverse events were reported in 20.7%, 24.6%, and 24.8% of *baloxavir*, placebo, and *oseltamivir* recipients, respectively. The primary *baloxavir* adverse event was diarrhea.

Interferon

Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (see Chapters 38 and 39). Three major classes of human IFNs with significant antiviral activity are α, β, and γ. Clinically used recombinant α-IFNs are nonglycosylated proteins of about 19,500 Da, with the pegylated forms predominating in the U.S. market. The mechanism of action, ADME, untoward effects, and therapeutic uses of IFNs are covered in Chapter 63. Recombinant, natural, and pegylated IFNs currently are approved in the U.S. for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, IFNs have been granted orphan drug status for a variety of rare disease states, including idiopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

Papillomavirus

In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36% to 62% of patients, but other treatments are preferred. Relapse occurs in 20% to 30% of patients. Verruca vulgaris may respond to intralesional IFN-α. Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients. Chapter 40 presents information on the recommended schedule of immunizations against human papilloma virus (HPV).

Other Viruses

Interferons have been shown to have virological and clinical effects in various herpesvirus infections, including genital HSV infections, localized herpes zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and *trifluridine* combinations appear active in *acyclovir*-resistant mucocutaneous HSV infections. In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of *zidovudine* and IFN is associated with only transient benefit and excessive hematological toxicity. IFN-α (3 million units thrice weekly) is effective for treatment of HIV-related thrombocytopenia that is resistant to *zidovudine* therapy.

Interferon has broad-spectrum antiviral activity against respiratory viruses other than adenovirus. However, prophylactic intranasal IFN-α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds.

Anti–Zaire Ebolavirus Agents

The family *Filoviridae* consists of three genera, *Ebolavirus*, *Marburgvirus*, and *Cuevavirus*. *Ebolavirus* is further subdivided into five species, each of which is represented by a unique virus: *Taï Forest ebolavirus*, *Reston ebolavirus*, *Sudan ebolavirus*, *Bundibugyo ebolavirus*, and *Zaire ebolavirus* (Baseler et al., 2017). Each species is named after the location in which it was first identified. Ebola virus was discovered in 1976, but it is believed to be an ancient virus that split from other viruses thousands of years ago. Current evidence suggests few differences in human pathology or pathogenesis among the ebolaviruses with the exception of members of the species *Reston ebolavirus*, which appear to be nonpathogenic for humans. Ebola (named after the Ebola River in Zaire) viruses cause a severe and often deadly illness known as Ebola virus disease (EVD), previously referred to as Ebola hemorrhagic fever. Fatality rates during EVD outbreaks average 50% but range from 25% to 90%. Viral particles contain one molecule of single-stranded negative-sense RNA enveloped in a lipid membrane. Ebola virus is spread through direct contact with blood or other bodily fluids, such as semen, feces, or vomit of infected persons (or animals), including close contact with deceased EVD victims, which are highly infectious. Infection can also be spread through needles, syringes, clothing, and bedding that have been contaminated with the virus.

Two monoclonal antibody (mAb) therapies are FDA-approved for *Zaire ebolavirus*. Both treatments were evaluated in a randomized controlled trial during the 2018–2020 Ebola outbreak in the Democratic Republic of the Congo (formerly Zaire). Overall survival was much higher for patients receiving either of the two treatments, but neither antibody has been evaluated for efficacy against species other than *Zaire ebolavirus*. A *Zaire ebolavirus* vaccine was FDA-approved in 2019 (FDA, 2019b).

Inmazeb (Atoltivimab, Maftivimab, and Odesivimab) and Ebanga (Ansuvimab)

Inmazeb and Ebanga (*ansuvimab*) are mAbs for the treatment of *Zaire ebolavirus*. Inmazeb is a cocktail of three recombinant human IgG1monoclonal antibodies, *atoltivimab, maftivimab,* and *odesivimab*. *Ansuvimab* is a single mAb. All four of the mAbs target the cell surface *Zaire ebolavirus* glycoprotein, which mediates virus attachment and membrane fusion with host cell membranes. The glycoprotein is expressed on the surface of a host cell infected with *Zaire ebolavirus*, making the cell a target for antibodies that mediate killing of these cells by antibody-dependent cellular cytotoxicity or other effector functions. The three mAbs in Inmazeb can bind the glycoprotein simultaneously (FDA, 2020a). *Ansuvimab* is a recombinant human IgG1κ monoclonal antibody that also targets the *Zaire ebolavirus* glycoprotein (FDA, 2020b).

Both agents were evaluated in the PALM trial, which was part of the emergency response to the ongoing EVD outbreak in the Democratic Republic of the Congo that started in August 2018 (Mulangu et al., 2019). Briefly, all patients received standard care and were randomly assigned in a 1:1:1:1 ratio to intravenous administration of the triple mAb ZMapp (triple mAb control), the antiviral agent *remdesivir*, the single mAb *ansuvimab*, or the triple IgG1 mAb cocktail (*atoltivimab, maftivimab,* and *odesivimab*). The primary endpoint was death at day 28. A total of 673 patients were included in the primary analyses. The case fatality rates at day 28 for ZMapp and *remdesivir* were 50% and 53%, respectively. The case fatality rate at day 28 was significantly reduced to 34% for patients receiving *ansuvimab* and to 35% for those receiving the three-mAb cocktail. However, in patients with a high viral load, these results were 70% and 64%, respectively, compared with 85% for the control and *remdesivir* groups, indicating essentially no activity. The dose for both agents is the same (50 mg/kg as a single dose by intravenous infusion), and their elimination half-lives are consistent with IgG antibodies (~24 days). A total of 29 serious adverse events were determined by investigators to be potentially related to study drugs, but these were difficult to extricate given the underlying EVD.

Novel 2019 Coronavirus

A SARS coronavirus 2 (SARS-CoV-2) viral outbreak, which rapidly became a worldwide pandemic, began in late 2019 in Wuhan, China. In February 2020, the World Health Organization (WHO) named the disease that SARS-CoV-2 causes COVID-19 (CO, corona; VI, virus; and D, disease). SARS-CoV-2 belongs to the β-coronavirus family, which also contains SARS-CoV and Middle East respiratory syndrome CoV (MERS-CoV). The first case in the U.S. was reported in January 2020. Older adults and people with severe underlying medical conditions (e.g., heart or lung disease, diabetes, obesity) were at higher risk for developing more serious complications from the infection. Early common symptoms included fever or chills, dry cough, shortness of breath, fatigue, body aches, loss of smell and/or taste, and headache, among many others. In May of 2020, the FDA granted emergency use authorization for *remdesivir* and full approval in October that same year. *Remdesivir* is currently the only FDA-approved small-molecule therapy for SARS-CoV-2. Vaccines (mRNA-type and traditional protein-based vaccines) became available during the 12 to 15 months following the start of the pandemic. Refer to Chapter 40 for information on these vaccines.

Remdesivir

Remdesivir was initially developed in response to the ongoing threat of RNA-based viruses that represented a potential for global pandemics, including viruses such as Ebola, MERS, and SARS. In early *in vitro* studies, *remdesivir* showed activity against Ebola and a broader range of viruses (Madelain et al., 2018; Warren et al., 2015). As such, *remdesivir* was included in a randomized controlled trial of Ebola virus therapeutics but was found to be inferior to the antibody-based therapeutics with respect to mortality. It was subsequently used in the first U.S. case of SARS-CoV-2, and no adverse events were reported (Holshue et al., 2020). Following multiple clinical trials, *remdesivir* was FDA-approved for COVID-19 treatment.

Mechanisms of Action and Resistance

Remdesivir, a nucleotide analogue, acts by inhibiting RNA-dependent RNA polymerase (RdRp). It is a phosphoramidate prodrug that is anabolized in cells to the active moiety, *remdesivir triphosphate*. Biochemical studies showed that the RdRp can use *remdesivir triphosphate* as a substrate, leading to the incorporation of *remdesivir monophosphate* into the growing RNA (Siegel et al., 2017). Following *remdesivir monophosphate* incorporation, the RdRp extends RNA by only three more nucleotides, after which chain elongation terminates, ending RNA synthesis (Gordon et al., 2020). Clinical resistance data are not available, but two substitutions in the viral RdRp at residues F476L and V553L together conferred a 5.6-fold reduction in susceptibility in cell culture resistance profiling (FDA, 2020c). *Remdesivir* has shown *in vitro* inhibitory activity against SARS-CoV-2 (Wang M et al., 2020).

ADME

Nonclinical metabolism studies indicate *remdesivir* is 80% metabolized in the liver by carboxylesterase 1 and 10% from cathepsin A and CYP3A each. Human mass balance data show that *remdesivir* is extensively metabolized and primarily eliminated in urine as the nucleoside metabolite GS-441524. *In vitro*, *remdesivir* is a substrate for CYP3A4 and for OATP1B1 and P-glycoprotein transporters. *In vitro*, it is an inhibitor of CYP3A4, OATP1B1, OATP1B3, and MATE1. Following multiple doses, the mean C_{max} and AUC_{tau} were 2229 ng/mL and 1585 ngxhr/mL, respectively; the C_{trough} was not quantifiable at 24 h post dose as the terminal $t_{1/2}$ is approximately 1 h (FDA, 2020c).

Therapeutic Uses

Remdesivir is indicated for adults and pediatric patients (12 years of age and older and weighing at least 40 kg) for the treatment of COVID-19 requiring hospitalization. The drug is infused over 30 to 120 min. Recommended dosage is a single loading dose of 200 mg on day 1 followed by 100-mg once-daily maintenance doses from day 2 onward. For patients not requiring mechanical ventilation, the recommended duration of treatment is 5 days; for patients not responding to initial treatment, 5 additional days are recommended.

Multiple phase III clinical trials have assessed the safety and efficacy of *remdesivir*. The primary study leading to its indication was from the ACTT-1 study group, which was a double-blind, randomized, placebo-controlled trial of intravenous *remdesivir* in adults hospitalized with COVID-19 and with evidence of lower respiratory tract infection (Beigel et al., 2020). The primary outcome was the time to recovery at 29 days. Patients who received *remdesivir* had a shorter time to recovery versus placebo recipients (10 days vs. 15 days, respectively; $P < 0.001$). Overall, day 15 mortality was 6.7% versus 11.9% and day 29 mortality was 11.4% versus 15.2% for *remdesivir* versus placebo, respectively. Prior to this study, a randomized, double-blind, placebo-controlled, multicenter trial at 10 hospitals in China evaluated *remdesivir* in adults with severe COVID-19 (Wang Y et al., 2020). The primary endpoint was time to clinical improvement up to day 28. Time to clinical improvement was similar in the *remdesivir* (median, 21 days) and placebo (median, 23 days) groups. A large trial conducted by the WHO compared *remdesivir*, *hydroxychloroquine*, *lopinavir* (without *interferon*), *interferon*, and *interferon* plus *lopinavir* against no trial therapy. The specified primary objective was in-hospital mortality at day 28. In the *remdesivir* arm, the mortality rate was 12.5%, versus 12.7% in the control arm ($P = 0.5$). The other drug regimens also did not demonstrate a mortality benefit. Another trial demonstrated that in patients with severe COVID-19 not requiring mechanical ventilation, there were no clinically significant differences between a 5-day versus a 10-day course of *remdesivir* therapy (Goldman et al., 2020). Collectively, these data suggest that *remdesivir* has marginal clinical benefit in patients with moderate to severe COVID-19 and that its definitive place in therapy has yet to be established.

Untoward Effects

Across all clinical trials to date, *remdesivir* has demonstrated a good safety profile, particularly given the patient populations within which it has been evaluated. From the ACTT-1 trial, serious adverse events were reported in 24.6% of patients receiving *remdesivir* versus 31.6% of patients receiving placebo. The most common nonserious adverse events occurring in at least 5% of all patients included decreased glomerular filtration rate, hemoglobin, and lymphocyte count; respiratory failure; pyrexia; hyperglycemia; and increased glucose. The incidence of these events was similar across both the placebo and *remdesivir*-treated groups.

Drug Facts for Your Personal Formulary: *Antiviral Agents for Herpes Virus and Influenza*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
ANTIHERPES AGENTS		
Guanine nucleoside analogues		
Acyclovir Valacyclovir (Val, an ester prodrug form of acyclovir)	• Clinical use limited to herpes viruses • Efficacy against: HSV-1 > HSV-2 > VZV > EBV > CMV = HHV-6	• Acyclovir has low bioavailability (~20%); Val has bioavailability of ~70% • Concentrates in breast milk • Clearance via renal excretion of acyclovir, requires good kidney function; $t_{1/2}$ prolonged in neonates and anuric patients • Safely used long term (10 years)
Cidofovir	• Active against human herpes, papilloma, polyoma, pox, adenoviruses	• Low oral bioavailability • Plasma $t_{1/2}$ ~2.6 h, but active diphosphate metabolite has long $t_{1/2}$ in cells, as does a phosphocholine metabolite ($t_{1/2}$ = 86 h) • Major risk: nephrotoxicity, reduced by oral probenecid and saline prehydration (beware interactions of probenecid and other medicines)
Famciclovir (Fam), a prodrug form, rapidly converted to penciclovir (Pen)	• Penciclovir similar to acyclovir against HSV and VZV; also inhibits HBV	• Oral bioavailabilities: Pen, <5%; Fam, ~75% • Food reduces rate but not extent of Pen absorption • Safety in pregnancy not established
Valganciclovir (Val), a prodrug valyl ester of ganciclovir (Gan)	• Gan has inhibitory activity against all herpesviruses, especially CMV	• Gan less active against acyclovir-resistant TK-deficient HSV strains • Active triphosphate form has long cellular $t_{1/2}$ • IV administration gives good levels in vitreous with long dwell time ($t_{1/2}$ ~25 h) • Major adverse effects: myelosuppression, neutropenia • Risk in pregnancy not ruled out
Pyrophosphate analogue		
Foscarnet	• Active against all herpesviruses and HIV	• Poorly soluble in water; requires large volumes of diluent • Adverse effects: nephrotoxicity, hypocalcemia • Safety in pregnancy and childhood uncertain
Other agents		
Fomivirsen (antisense oligonucleotide)	• Inhibits CMV replication	• No longer available in the U.S.
Docosanol (long-chain alcohol)	• 10% topical cream for labial herpes	• Treatment initiation at papular or later stages provides no benefit • Available over the counter
Idoxuridine (iodinated thymidine analogue)	• Ophthalmic HSV keratitis (in the U.S.)	• Adverse effects: pain, pruritus, inflammation, edema of eye/eyelid • Not available in the U.S.
Trifluridine (trifluoropyrimidine nucleoside)	• Ocular herpes; first-degree keratoconjunctivitis, recurrent epithelial keratitis from HSV1/2; for ophthalmic use	• More active than idoxuridine in HSV ocular infections • Triphosphate form incorporated into host and viral DNA, so not used systemically
ANTI-INFLUENZA AGENTS		
Inhibitors of viral M2 protein function		
Amantadine (Ama) Rimantadine (Rima)	• Active only against susceptible influenza A viruses (not B) • Seasonal prophylaxis against influenza A (70%–90% protective)	• Rima 4- to 10-fold more active than Ama • Resistant isolates appear after 2–3 days of therapy • Virtually all H3N2 strains of influenza are resistant to these drugs • Vaccination is more cost-effective
Inhibitors of viral neuraminidase (see pharmacokinetic data in Table 62–3)		
Oseltamivir	• Treatment and prevention of influenza A and B	• Probenecid doubles plasma $t_{1/2}$
Zanamivir	• Treatment and prevention of influenza A and B	• Inhalable formulation • IV formulation available as EIND • No clinically significant drug interactions
Peramivir	• Treatment of acute uncomplicated flu in patients ≥18 years and symptomatic ≤2 days	• Supplied as IV infusion; for patients who cannot use oral agents • Comparable in efficacy and adverse effects to oseltamivir • No clinically significant drug interactions reported

Drug Facts for Your Personal Formulary: *Antiviral Agents for Herpes Virus and Influenza (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Inhibitor of Viral Cap-Dependent Endonuclease (blocks initiation of mRNA synthesis)		
Baloxavir marboxil	• Treatment of acute uncomplicated flu in patients ≥12 years and at risk of complications • As a postexposure preventative against developing influenza	• Do not administer with products or foods containing high amounts of calcium, iron, magnesium, aluminium, zinc, or selenium (dairy products, antacids, laxatives, etc.). These products will reduce absorption.
CYTOKINES		
Interferon (recombinant α-IFNs; natural and pegylated IFNs)	Treatment of condyloma acuminatum, chronic HCV and HBV infection, Kaposi sarcoma (in patients with HIV, other malignancies, multiple sclerosis)	See Chapter 63
AGENTS FOR CORONA VIRUS AND EBOLA VIRUS		
Remdesivir		• See text of this chapter
Vaccines against Ebola virus		• See text of this chapter
Vaccines against SARS-CoV-19		• See Chapter 40

HEPATITIS C VIRUS

- HCV Overview
- Genetic Heterogeneity of HCV
- HCV Genome and Life Cycle
- HCV Drug Targets and Treatment Approach
- Clinical Implications of HCV Resistance
- Hepatic Impairment: Implications for HCV Treatment
- Pharmacotherapy of HCV Infection
- Investigational Agents and the Future for Treatment of HCV

Hepatitis viruses cause inflammation and necrosis of the liver. Hepatitis A and E, which are transmitted via the fecal-oral route, are typically self-limiting, although a small percentage (1%–2%) of those infected will develop fulminant hepatic failure. Hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D viruses, however, are transmitted parenterally. Hepatitis B and C may or may not cause symptoms of acute infection, but both may progress to chronic infection. Individuals with chronic hepatitis B or C infection are at risk for cirrhosis, liver failure, and hepatocellular carcinoma. There are two notable differences between HBV and HCV. *First*, HBV is a vaccine-preventable illness, whereas there is no vaccine available to prevent HCV. *Second*, HCV can be cured with effective treatment, whereas the current treatments for HBV are not completely curative. The hepatitis D virus is defective and requires the presence of the HBV to propagate. Individuals coinfected with hepatitis B and D are at greater risk for cirrhosis and hepatocellular carcinoma compared with individuals with only hepatitis B infection, but fortunately, only about 5% of individuals with HBV are coinfected with hepatitis D.

There are no antiviral therapies available for the treatment of hepatitis A and E viruses. Limited options are available to treat hepatitis D, including *pegylated interferon α* (pegIFN-α), which is successful in only 20% to 35% of patients (Durantel and Zoulim, 2016) and *bulevirtide*, an agent recently approved in Europe (Kang and Syed, 2020). Multiple drugs are available for the treatment of hepatitis B and C. Available therapies for HBV include pegIFN-α and nucleoside and nucleotide analogues. Several investigational agents are in various stages of clinical development for the treatment of HBV (Soriano et al., 2020). Hepatitis C is treated with combinations of drugs that inhibit the RNA-dependent RNA polymerase (RdRp, NS5B), the NS5A replication complex, and the NS3 protease. Therapeutic strategies for these two chronic viral infections, hepatitis B and C, are very different and are described separately in this chapter.

Several agents employed against hepatitis viruses, including pegIFN-α, *ribavirin*, and the nucleoside/nucleotide analogues *lamivudine*, *emtricitabine*, and *tenofovir*, are also used to treat other conditions, described in Chapters 64 (Antiretroviral Agents and Treatment of HIV Infection), 74 (Ocular Pharmacology), and 75 (Dermatological Pharmacology).

Assessing the stage and severity of liver disease is an important aspect of treating individuals with chronic viral hepatitis. Individuals with cirrhosis require additional monitoring for potential complications (e.g., varices and hepatocellular carcinoma), and the approach to treatment differs in cirrhotics and decompensated cirrhotics compared to individuals without significant liver fibrosis. Cirrhosis can be diagnosed with histological, radiographic, or laboratory tests. However, decompensated cirrhosis (also known as end-stage liver disease) is a clinical diagnosis based on the presence of variceal hemorrhage, ascites, jaundice, or hepatic encephalopathy. Decompensated cirrhosis carries a high risk of mortality (median survival 2 years), and these individuals should be evaluated for liver transplantation.

The urgency for liver transplantation in individuals with decompensated cirrhosis is determined using the Model for End-Stage Liver Disease (MELD) score. A MELD score is calculated based on a patient's bilirubin, international normalized ratio (INR), and serum creatinine. Individuals with higher MELD scores have a higher risk for mortality and a more urgent need for transplantation. Cirrhosis may also be categorized based on the Child Pugh score. The Child-Pugh score accounts for bilirubin, albumin, and INR values and the presence/absence of ascites and encephalopathy. Higher scores are associated with more advanced disease: mild hepatic impairment (Child-Pugh category A; score of 5–6), moderate hepatic impairment (Child-Pugh category B; score of 7–9), and severe hepatic impairment (Child-Pugh category C; score of 10–15). Individuals with Child-Pugh B and C scores have decompensated cirrhosis. Familiarity with MELD and Child-Pugh scoring and the diagnoses of compensated versus decompensated cirrhosis is helpful for understanding the pharmacological basis of hepatitis B and C treatment.

Hepatitis B Virus

HBV Overview

Worldwide, an estimated 2 billion people have been infected with HBV and approximately 240 million have chronic disease (World Health Organization [WHO], 2015). Areas with the highest HBV endemicity are sub-Saharan Africa and countries in the WHO Western-Pacific region (e.g., China) (Schweitzer et al., 2015). In these regions, HBV is most likely acquired perinatally. Those infected at birth have a 90% risk of progressing to chronic disease; otherwise, the risk of chronic HBV disease in adults is 5% (Tong and Revill, 2016). The lifetime risk of developing cirrhosis, liver failure, or hepatocellular carcinoma in individuals with HBV is 15% to 40% (Lin et al., 2016). There are about 686,000 HBV-related deaths annually, which makes HBV the leading cause of liver-related deaths worldwide (WHO, 2020a).

Genetic Heterogeneity of HBV

There are 10 described HBV genotypes (A–J) and at least 35 subtypes with distinct geographical distributions (Tong and Revill, 2016). Genotype A is most frequent in North America and Africa, genotypes B and

Abbreviations

2–5(A): 2′-5′-oligoadenylate
ALT: alanine aminotransferase
AUC: area under the plasma concentration-time curve
BCRP: breast cancer resistance protein
cccDNA: covalently closed circular DNA
C_{max}, C_{Pmax}: maximal blood or plasma concentration
C_p: plasma concentration
Cl_{cr}: creatinine clearance
CYP: cytochrome P450
DAA: direct-acting antiviral
dATP: deoxyadenosine triphosphate
DCV/SOF: daclatasvir/sofosbuvir
EBR: elbasvir
eGFR: estimated glomerular filtration rate
ER: endoplasmic reticulum
ESRD: end-stage renal disease
GLE: glecaprevir
GZR: grazoprevir
HBcAg: hepatitis B core antigen
HBeAg: hepatitis B e antigen
HBsAg: hepatitis B surface antigen
HBV: hepatitis B virus
HCV: hepatitis C virus
HSPGs: heparin sulfate proteoglycans
IFN: interferon
INR: international normalized ratio
LDV/SOF: ledipasvir/sofosbuvir
MELD: Model for End-Stage Liver Disease
MHC: major histocompatibility complex
MRP: multidrug resistance protein
MU: million units
NTCP: Na^+/taurocholate cotransporter
ORF: open reading frame
PEG: polyethylene glycol
pegIFN: pegylated interferon
PIB: pibrentasvir
P-gp: P-glycoprotein
PPI: proton pump inhibitor
RAS: resistance-associated substitution
RdRp: RNA-dependent RNA polymerase
SOF/VEL: sofosbuvir and velpatasvir
SR-B1: scavenger receptor B1
SVR: sustained virologic response
TAF: tenofovir alafenamide fumarate
TDF: tenofovir disoproxil fumarate
VEL: velpatasvir
VOX: voxilaprevir
WHO: World Health Organization

C are dominant throughout East Asia and are primarily transmitted via the perinatal route, and genotype D is most common in southern Europe and India. Genotype E is largely restricted to sub-Saharan Africa, while genotypes F and H cocirculate in indigenous peoples of South America. Genotypes I and J have been described in only three individuals and one individual, respectively.

Genotypes have relevance for the clinical manifestation of infection and the response to antiviral therapy. Clinically relevant features of HBV genotypes include the rate and durability of hepatitis B e antigen (HBeAg) (loss or seroconversion; A and D > B and C), the risk of developing aggressive HBeAg(−) chronic hepatitis B (C and D > A), spontaneous HBeAg loss (B > C), cirrhosis (C), hepatocellular carcinoma (C in Asians, F in Alaska Natives), and response to antivirals (A and B > C and D).

HBV Genome and Life Cycle

Hepatitis B virus is a small, enveloped, relaxed circular DNA virus with a complete minus strand and an incomplete plus strand, approximately 3200 kb in length (Tsukuda and Watashi, 2020). The viral nucleocapsid contains the hepatitis B core antigen (HBcAg), viral polymerase, and the viral DNA surrounded by an outer lipoprotein envelope containing the HBV surface antigen (HBsAg). HBV is compact and contains four overlapping open reading frames (ORFs). ORF C encodes the HBcAg and HBeAg, ORF P encodes the polymerase and terminal protein, ORF S/pre-S encodes HBsAg, and ORF X encodes the regulatory X protein.

Figure 63–1 depicts the HBV life cycle (Brahmania et al., 2016; Lin et al., 2016; Tong and Revill, 2016; Tsukuda and Watashi, 2020). The HBV life cycle is not fully defined, but current understanding is nicely reviewed by Tsukuda and Watashi (2020). Briefly, HBV initially attaches to heparin sulfate proteoglycans (HSPGs) on the hepatocyte surface and then to cell surface receptors like sodium taurocholate cotransporting peptide (NTCP/SLC10A1) with greater specificity and affinity. This triggers endocytosis of the nucleocapsid into the hepatocyte, where it is then transported to the nucleus and enters through the nuclear pore complex. The partial double strand is then repaired to form covalently closed circular DNA (cccDNA). The cccDNA is not eliminated by available treatments; thus, a complete cure is not currently possible. cccDNA complexes with host proteins to form a minichromosome that becomes a template for the transcription of the various virally derived RNAs. These RNAs are transported to the cytoplasm, and some of the smaller RNAs are then made into various viral proteins, including the envelope protein. These proteins can actually be released without any genetic material (known as subviral particles). Filamentous and spherical HBsAg particles are produced in 3 to 4 log excess over virions (complete virus particles). These subvirus particles are thought to contribute to immune tolerance and T-cell exhaustion by increasing the amount of antigen that is circulating. The larger pregenomic RNA is used to form the HBcAg protein, which is also encapsidated. In the capsid, HBV is reverse transcribed back to viral DNA. The nucleocapsids are then either returned to and recycled in the nucleus to make more cccDNA or they assemble with envelope protein for cellular release.

Some patients develop mutations in the HBV genome that prevent HBeAg formation despite active HBV replication; this condition is known as HBeAg(−) disease.

HBV Drug Targets and Treatment Approach

Hepatitis B virus is a dynamic condition. Individuals with chronic infection can pass through several phases of disease throughout their lifetimes. At present, treatment is typically reserved for individuals with high levels of circulating HBV DNA and alanine aminotransferase elevations, those with cirrhosis, or for prevention of reactivation of disease in those receiving immunosuppressive therapies (e.g., chemotherapy) (Terrault et al., 2018). When treatment is necessary, the approach to HBV therapy in children and adults is similar, but most children have normal alanine aminotransferase levels and do not require treatment.

Current HBV therapies cannot achieve a complete cure, and only a small proportion (~10%) of patients achieve a functional cure. A functional cure is defined as undetectable HBV DNA with seroconversion from HBsAg to the anti-HBs. This is analogous to a resolved acute infection, but cccDNA persists, which can lead to reactivation of the disease. Existing treatment options include pegIFN-α, which has nonspecific antiviral and immunomodulatory effects, or the nucleoside/-tide analogues (Figure 63–2) *adefovir*, *entecavir*, *lamivudine*, *telbivudine*, and *tenofovir*, which inhibit the HBV polymerase. IFN treatment is finite (48–52 weeks), whereas individuals may require lifelong treatment with nucleoside/-tide analogues. *Entecavir* and *tenofovir* (*tenofovir disoproxil fumarate* [TDF] or *tenofovir alafenamide fumarate* [TAF]) are the preferred nucleoside/-tide therapies due to their potency, good tolerability,

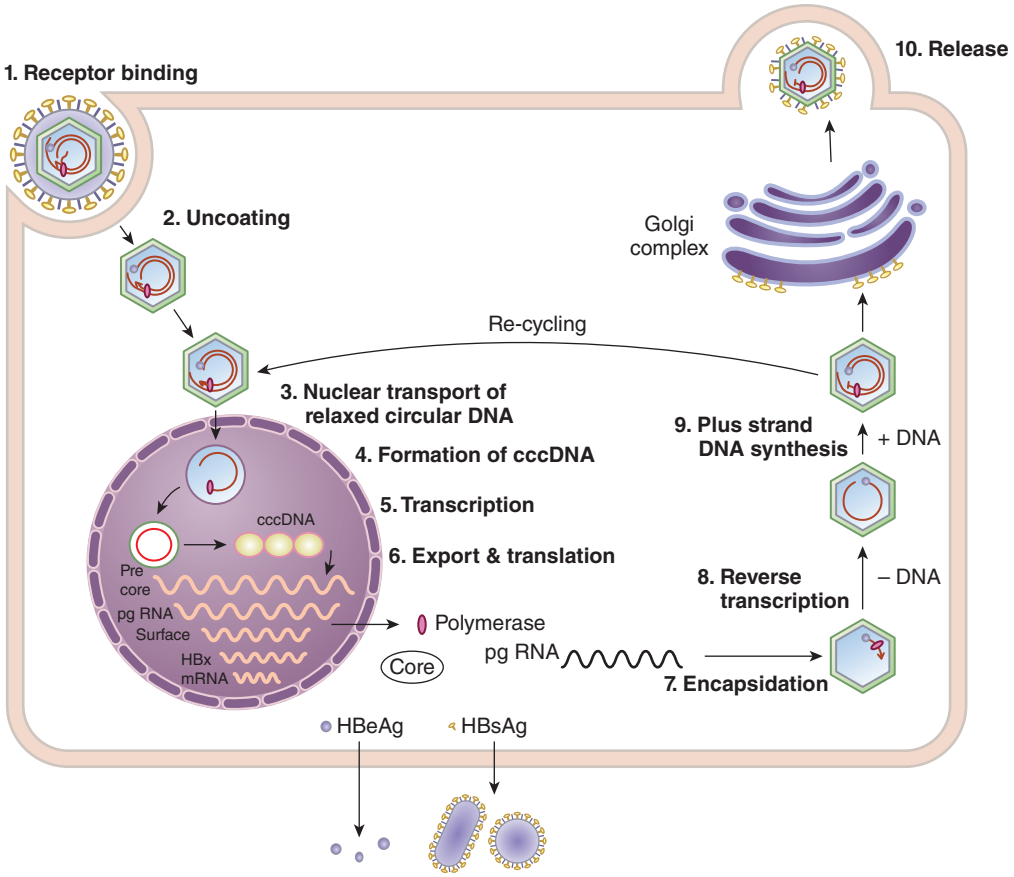

Figure 63–1 *Hepatitis B life cycle.* Not all steps in the hepatitis B viral life cycle have been completely elucidated. The figure represents our current understanding. For further details, consult the following references: Brahmania et al., 2016; Liang et al., 2015; Tong and Revill, 2016; and Tsukuda and Watashi, 2020.

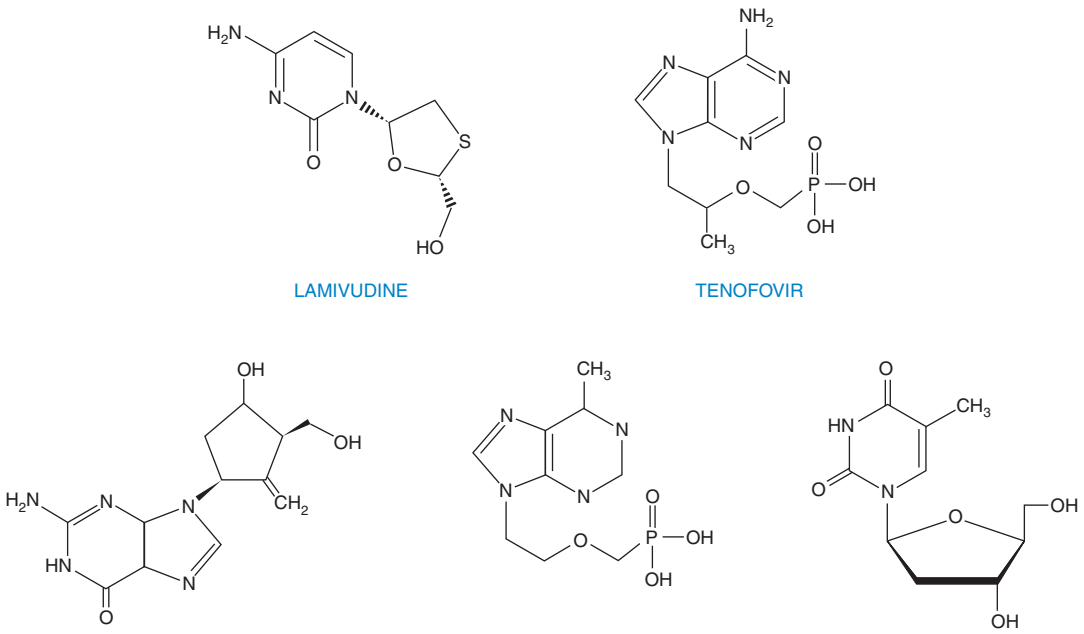

Figure 63–2 *Chemical structures of nucleos(t)ide analogues used to treat hepatitis B.*

and low potential for the development of resistance (Martin et al., 2015). Considerations in selecting between the preferred therapies for HBV include the severity of liver disease, patient willingness, prior treatment, side effects, HBV genotype/serotype, comorbidities, and cost.

Because a functional cure occurs in only a small number of patients with current agents and a complete cure is not possible, treatment goals with either pegIFN-α or nucleoside/-tide analogues are to suppress HBV DNA replication and promote seroconversion from HBeAg to anti-HBe, which in turn will slow the progression of liver disease; reduce the risk for complications, including hepatocellular carcinoma; and prolong survival (Liang et al., 2015).

Clinical Implications of HBV Resistance

Hepatitis B virus replicates at a high rate. The viral polymerase also lacks proofreading capability. These conditions result in the generation of a large number of viral mutations. Mutations that confer a replication advantage are preferentially selected under pressure from antiviral therapy. Mutations in the reverse transcriptase/polymerase domain confer resistance to nucleoside analogues.

Lamivudine has the lowest genetic barrier to the development of resistance. After 4 years of treatment with *lamivudine*, 71% of patients have developed the M204V/I mutation, which renders this drug ineffective. Twenty-two percent of individuals treated with *telbivudine* develop this mutation after 2 years of therapy. With *adefovir*, about 29% of patients have developed an N236T mutation after 5 years of treatment. Resistance is uncommon with TDF and was not observed through 4 years with TAF. The rate of resistance with *entecavir* is 1% or less after 5 years in treatment-naïve individuals, whereas in those with preexisting M204V/I mutation, the prevalence of resistance is much higher, 51% after 5 years (Bhattacharya and Thio, 2010; Ghany and Doo, 2009).

The emergence of resistance has important clinical consequences. Resistance leads to therapeutic failure and a rapid resurgence of viral replication. This resurgence in HBV replication may predispose patients to hepatic decompensation. For this reason, monotherapy with *lamivudine*, *adefovir*, or *telbivudine* is not recommended for the treatment of hepatitis B (Terrault et al., 2018). Individuals taking these drugs require frequent monitoring of HBV DNA and counseling on the importance of excellent adherence to the daily therapy.

Hepatic Impairment: Implications for HBV Treatment

Prolonged suppression of HBV DNA production prevents disease progression in individuals with cirrhosis and aids reversal of liver damage. Although pegIFN-α can be used in individuals with compensated cirrhosis, it is contraindicated in those with decompensated cirrhosis. Nucleoside/-tide analogue therapy is the treatment of choice for decompensated disease (Martin et al., 2015). In general, nucleoside/-tide analogue treatment improves liver function and increases the 5-year survival rate in individuals with decompensated cirrhosis from 14% to 35% to 55% to 86% (Honda et al., 2015). It may also prevent the need for liver transplantation.

The nucleoside/-tide analogues of choice for the treatment of decompensated cirrhosis are *entecavir* and *tenofovir*. Both agents require adjustments for renal impairment. TDF has been associated with nephrotoxicity, and *entecavir* has been associated with lactic acidosis in this population, so careful monitoring is imperative. Also, a combination of nucleoside/-tide analogues may be needed to improve efficacy in those with preexisting viral resistance. All nucleoside/-tide analogues carry a black-box warning for the risk of lactic acidosis, a risk that may be greater in individuals with advanced liver disease.

Pharmacotherapy of HBV Infection

Practice guidelines are available from several authorities on the treatment of HBV (Martin et al., 2015; Terrault et al., 2018; WHO, 2015). A description of current HBV therapies follows, and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided at the end of the chapter.

Interferons

Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative effects (see Chapters 38 and 39). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human IFNs with significant antiviral activity currently are recognized: α (>18 individual species), β, and γ. Clinically used recombinant α-IFNs are nonglycosylated proteins of about 19,500 Da. Attachment of IFN proteins to large inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing. PegIFN-α is a first-line agent for the treatment of HBV.

Mechanisms of Action and Resistance. IFN-α may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin-1, interleukin-2, and tumor necrosis factor). IFN-α exhibits antiviral and antiproliferative actions; stimulates the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and upregulates expression of class I major histocompatibility complex (MHC) antigens and other surface markers. In addition, IFNs downregulate production of a number of cellular proteins, which may be an equally important mediator of the pharmacological benefit of IFNs (Teijaro, 2016).

Following binding to specific cellular receptors, IFNs activate the Jak-STAT signal transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration.

Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2–5(A) synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2–5(A) synthetase produces adenylate oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eukaryotic initiation factor 2 (eIF-2). IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs among virus families.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects or by modifying the immune response to infection. For example, IFN-induced expression of MHC antigens may contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

Host genetics may predict IFN responsiveness. Single-nucleotide polymorphisms (rs12979860 and rs12980275) on or near the *IL-28B* gene on chromosome 19 have been associated with decreased responsiveness to IFN therapy with hepatitis C treatment (Sonneveld et al., 2012). Data are conflicting on whether *IL-28B* genetics are associated with response to IFN in individuals with HBV (Martin et al., 2015). This gene encodes IFN-λ-3. INF-λ enhances and sustains effects of INF-α on viral replication.

ADME. Oral administration of IFN-α does not result in detectable IFN levels in serum or increases in 2–5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN's biological activity). After intramuscular or subcutaneous injection of IFN-α, absorption exceeds 80%. Pegylated IFN-α is dosed subcutaneously once per week. The dose of pegIFN-α2a is 180 μg and should be reduced for patients with Cl_{Cr} less than 30 mL/min. Plasma levels are dose related, peaking at 4 to 8 h and returning to baseline by 18 to 36 h. Levels of 2–5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 h and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 h and decreases slowly

to baseline by 6 days after injection. After systemic administration, low levels of IFN are detected in respiratory secretions, cerebrospinal fluid, eye, and brain.

Two pegIFNs are available commercially: pegIFN-α2a and pegIFN-α2b. PegIFN-α2b has a straight-chain 12,000-Da type of PEG that increases the plasma $t_{1/2}$ from 2–3 to 30–54 h. PegIFN-α2a consists of an ester derivative of a branched-chain 40,000-Da PEG bonded to IFN-α2A and has a plasma $t_{1/2}$ of about 80 to 90 h. For pegIFN-α2a, peak serum concentrations occur up to 120 h after dosing and remain detectable throughout the weekly dosing interval; steady-state levels occur 5 to 8 weeks after initiation of weekly dosing. For pegIFN-α2A, dose-related maximum plasma concentrations occur at 15 to 44 h after dosing and decline by 96 to 168 h. Increasing PEG size is associated with longer $t_{1/2}$ and less renal clearance. About 30% of pegIFN-α2b is cleared by the kidneys; the remainder is cleared by both the liver and cellular degradation of IFN-receptor complexes. PegIFN-α2a is cleared by the liver and kidney. Patients with end-stage renal disease (ESRD) require dose reductions of both pegIFN products.

Therapeutic Uses. Nonpegylated forms of IFN may be used in certain clinical scenarios, but in the U.S., use of pegIFN-α predominates. PegIFN-α2a is FDA-approved for the treatment of hepatitis B and C. Its use in hepatitis C has been completely replaced by all oral direct-acting antiviral (DAA) agents (see further discussion). However, it remains a preferred agent for the treatment of HBV. IFNs are contraindicated in patients with advanced liver disease because they can precipitate clinical deterioration and increase the risk of bacterial infections.

Unlike nucleoside/-tide analogues, which may require lifelong administration for the treatment of hepatitis B, IFN (or pegIFN) treatment is finite. Plasma HBV DNA and polymerase activity decline promptly with α-IFN (pegIFN-α) in most patients, but complete disappearance is sustained in only about one-third of patients. The advantage of α-IFN (pegIFN-α) compared with nucleoside/-tide analogues, besides the finite treatment duration, is the higher rate of HBeAg loss (~32%–36%) and HBsAg loss (~4%–11%) (Terrault et al., 2018). However, not all patients respond to α-IFN, and there are significant toxicities associated with this therapy.

Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. In addition, individuals with genotypes A and B are more likely to respond to α-IFN than genotypes C or D. Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes.

Untoward Effects. Injection of recombinant IFN doses of 1 to 2 MU (million units) or more usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 h. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with antipyretics.

The principal dose-limiting toxicities of systemic IFN are depression, myelosuppression with granulocytopenia and thrombocytopenia; neurotoxicity manifested by somnolence, confusion, behavioral disturbance, and rarely, seizures; debilitating neurasthenia; autoimmune disorders, including thyroiditis and hypothyroidism; and uncommonly, cardiovascular effects with hypotension and tachycardia. Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal et al., 1998). The development of serum-neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as *zidovudine* and *ribavirin* and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy.

Pegylated IFNs are generally better tolerated than standard IFNs, although the frequencies of fever, nausea, injection site inflammation, and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-coinfected persons.

Pediatric and Geriatric Uses. Interferon-α2b is approved for children 1 year or older. The dose is 6 million IU/m² thrice weekly. PegIFN-α2a is not approved for children with HBV but is approved for treatment of children 5 years or older with HCV. Thus, the guidelines of the American Association for the Study of Liver Diseases state that providers may consider using this drug in children with HBV (Terrault et al., 2018). The dose of pegIFN-α2a in children with chronic HCV is 180 μg/1.73 m² × body surface area once weekly. PegIFN-α2a contains benzyl alcohol, which has been associated with neurological toxicities in infants and neonates.

Elderly patients may experience more toxicities from IFN treatment, and dose adjustments are necessary in renal impairment.

Entecavir

Entecavir is a guanosine analogue. *Entecavir* inhibited HBV DNA synthesis (50% reduction, EC_{50}) at a concentration of 0.004 μM in human HepG2 cells transfected with wild-type HBV. The median EC_{50} value for *entecavir* against *lamivudine*-resistant HBV was 0.026 μM (range 0.010–0.059 μM).

Mechanisms of Action and Resistance. *Entecavir* requires intracellular phosphorylation. *Entecavir triphosphate* competes with endogenous deoxyguanosine triphosphate and inhibits all three activities of the HBV polymerase (reverse transcriptase):

- Base priming
- Reverse transcription of the negative strand from the pregenomic messenger RNA
- Synthesis of the positive strand of HBV DNA

Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases α, β, and δ and mitochondrial DNA polymerase γ.

Susceptibility to *entecavir* is reduced with *lamivudine* and *telbivudine* resistance. In cell-based assays, 8- to 30-fold reductions in *entecavir* susceptibility were observed for *lamivudine*-resistant strains. In patients with preexisting *lamivudine* resistance, *entecavir* resistance emerged in 7% and 43% after 1 and 4 years, respectively.

Entecavir monotherapy in HIV/HBV-coinfected patients, including antiretroviral therapy–naïve patients, has significant anti-HIV activity and can result in the development of the M184V variant (Sasadeusz et al., 2008). Thus, *entecavir* should only be used in combination with fully suppressive antiretroviral therapy in individuals with HIV/HBV coinfection.

ADME. The recommended dose for nucleoside treatment–naïve adults without decompensated cirrhosis is 0.5 mg once daily. For adults with *lamivudine* or *telbivudine* resistance or for those with decompensated cirrhosis, the dose is 1 mg once daily. The dose must be reduced for individuals with Cl_{Cr} less than 50 mL/min. Time to peak C_p occurs in 0.5 to 1.5 h. Steady state is reached after 6 to 10 days of once-daily dosing. The tablet and oral solution can be used interchangeably. Administration with food decreases C_{max} by 44% to 46% and AUC by 18% to 20%; thus, *entecavir* should be administered on an empty stomach.

Entecavir is extensively distributed in tissues and binds slightly (13%) to serum proteins. It is primarily eliminated unchanged in the kidney, probably by both glomerular filtration and net tubular secretion. *Entecavir* exhibits biphasic elimination, with a terminal $t_{1/2}$ of 128 to 149 h. Dose reductions are needed for patients with Cl_{Cr} less than 50 mL/min, typically by extension of the dosing interval.

Therapeutic Uses. *Entecavir* is FDA-approved for the treatment of chronic HBV infection in adults and children 2 years or older with evidence of active viral replication and evidence of either persistent elevations in serum aminotransferases or histologically active disease. *Entecavir* is considered a first-line agent for HBV because of its potency, durability, and low genetic barrier to the development of resistance (Terrault et al.,

2018). In HBeAg-positive individuals, 61% are virologically suppressed, 22% to 25% have HBeAg loss, 68% to 81% normalize alanine aminotransferase (ALT), and 4% to 5% have HBsAg loss after 2 to 3 years of continuous entecavir treatment. In HBeAg-negative individuals, 90% to 91% are virologically suppressed and 78% to 88% normalize ALT after 2 to 3 years of *entecavir* treatment, but fewer than 1% have HBsAg loss at 1 year. *Entecavir* use reduces the risk of hepatocellular carcinoma relative to untreated historical controls. Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA of 10^8 or greater, the combination of *entecavir* and TDF was superior to *entecavir* alone (Lok et al., 2012). Nucleoside/-tide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virological breakthrough on *entecavir* or TDF. The safety of *entecavir* in pregnancy is unknown.

Untoward Effects. Severe acute exacerbations of HBV have been reported in patients who have discontinued anti-HBV therapy, including *entecavir*. Hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV coinfection, especially if HIV is not being treated. Lactic acidosis and severe hepatomegaly with steatosis may occur in patients with decompensated cirrhosis receiving *entecavir*. More common adverse reactions include headache, fatigue, dizziness, and nausea (Sasadeusz et al., 2008).

Pediatric and Geriatric Uses. *Entecavir* oral solution is approved in children older than 2 years, and dosing is weight based up to 30 kg. *Entecavir* exposures following a single 1-mg dose were 29% higher in elderly versus young HBV-seronegative volunteers. This difference is likely explained by declines in renal function with age.

Tenofovir

Tenofovir, an acyclic nucleoside phosphonate, is available in two different prodrug formulations, TDF and TAF. TAF is described separately in a following discussion. With TDF, esterases cleave the diester, yielding *tenofovir* in plasma, which enters cells and is subsequently phosphorylated by cellular kinases to *tenofovir diphosphate* (see Figure 64–4). The drug has activity against both HIV-1 and HBV. In cell cultures *in vitro*, the EC_{50} for *tenofovir* against HBV ranges from 0.14 to 1.5 μM.

Mechanisms of Action and Resistance. Chapter 64 describes the mechanism of action of *tenofovir*. The genetic barrier to resistance for TDF is high, but a few reports have identified potential variants (Mokaya et al., 2020).

ADME. The TDF dose is 300 mg once daily; the dose is reduced in patients with renal impairment. The bioavailability of *tenofovir* is approximately 25%. *Tenofovir* exposures are increased 40% with a high-fat meal. Binding to plasma proteins is negligible (<8%). *Tenofovir* is not metabolized by CYP enzymes. The $t_{1/2}$ of *tenofovir* in plasma is 17 h, and the $t_{1/2}$ of the active form of the drug, *tenofovir diphosphate*, is 6 days and 17 days in peripheral blood and red blood cells, respectively. *Tenofovir* pharmacokinetics are not altered in hepatic impairment, but plasma exposures rise as Cl_{Cr} drops, becoming 2.8- and 7.3-fold higher in those with Cl_{Cr} of 30 to 49 mL/min and 12 to 29 mL/min compared to those with Cl_{Cr} greater than 80 mL/min. Doses should be reduced in those with Cl_{Cr} below 50 mL/min. Roughly 10% of the dose is removed by a 4-h hemodialysis session.

Therapeutic Uses. TDF is approved for the treatment of HBV infection in individuals 2 years or older. Due to its safety, efficacy, and resistance profile, TDF is a preferred agent for the treatment of HBV. In HBeAg-positive individuals, 76% are virologically suppressed, 21% have conversion from HBeAg to anti-HBe, 68% normalize ALT, and 8% have HBsAg loss after 3 years of continuous TDF treatment. In HBeAg-negative individuals, 93% are virologically suppressed and 76% normalize ALT after 2 to 3 years of treatment, but none have HBsAg loss at 1 year (Terrault et al., 2018).

Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA 10^8 or greater, the combination of *entecavir* and TDF was superior to *entecavir* alone (Lok et al., 2012). Nucleoside/-tide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virological breakthrough on *entecavir* or TDF. TDF has a pregnancy category of B, although a study found that infants born to HIV-infected women receiving TDF had 12% lower bone mineral density compared to infants born to women receiving other antiretroviral agents. HIV-infected individuals are generally treated with *tenofovir* and *emtricitabine*. *Emtricitabine* is a cytidine analogue with activity against HIV and HBV. Refer to Chapter 64 for additional information about *emtricitabine*.

Untoward Effects and Drug Interactions. *Tenofovir* has a low potential for interactions but is not devoid of interactions. *Tenofovir* is a substrate for several membrane transporters, including OAT1 and MRP4, and TDF is a substrate for P-glycoprotein (P-gp) and breast cancer resistance protein (BCRP), and thus, *tenofovir* may be affected by drugs that inhibit or induce these transporters. Some HCV therapies (e.g., *sofosbuvir*, *ledipasvir*, and *velpatasvir*) increase *tenofovir* exposures; patients receiving such combinations require more frequent renal monitoring.

Pediatric and Geriatric Uses. Primary considerations in treating the elderly with TDF are the bone and renal toxicities; a thorough study of TDF in the geriatric population has not been published. TDF has been studied in children and is approved for those 2 years or older. The dose of TDF in children is 8 mg/kg, with a maximum of 300 mg daily.

Adefovir

Adefovir dipivoxil is a diester prodrug of *adefovir*, an acyclic phosphonate nucleotide analogue of adenosine monophosphate. Inhibitory concentrations of *adefovir* against HBV range from 0.2 to 1.2 μM in cell culture.

Mechanisms of Action and Resistance. *Adefovir dipivoxil* is deesterified to *adefovir*. *Adefovir* is converted by cellular enzymes to the diphosphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to deoxyadenosine triphosphate (dATP) and also serves as a chain terminator of viral DNA synthesis.

Resistance to *adefovir* emerges in about 29% of patients after 5 years of treatment. The development of viral resistance may increase the risk of hepatic decompensation. Thus, *adefovir*, *lamivudine*, and *telbivudine* are not recommended for the treatment of HBV.

ADME. The *adefovir dipivoxil* dose is 10 mg once daily but must be reduced for those with renal impairment. The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine, liver, and blood to *adefovir*, providing a bioavailability of about 30% to 60%. Food does not affect bioavailability. *Adefovir* is scantily protein bound (<5%) and has a volume of distribution of about 0.4 L/kg.

The drug is eliminated unchanged by the kidney through a combination of glomerular filtration and tubular secretion. After oral administration of *adefovir* dipivoxil, about 30% to 45% of the dose is recovered within 24 h; the serum $t_{1/2}$ of elimination is 5 to 7.5 h. The intracellular $t_{1/2}$ of the active diphosphate form *in vitro* ranges from 5 to 18 h, although typically the half-lives are much longer *in vivo*. Dose reductions are recommended for Cl_{Cr} values below 50 mL/min. *Adefovir* is removed by hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unknown.

Therapeutic Uses. *Adefovir dipivoxil* is approved for treatment of chronic HBV infections in individuals 12 years and older. However, *adefovir dipivoxil* is not a preferred agent for the treatment of HBV because it is associated with the development of viral resistance and nephrotoxicity.

Untoward Effects and Drug Interactions. *Adefovir dipivoxil* causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria, which usually are reversible months after discontinuation. Other adverse effects include headache, abdominal discomfort, diarrhea, and asthenia. Adverse events lead to premature discontinuation in about 2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dL is approximately 2% but is higher in those with

preexisting renal insufficiency. Acute, sometimes severe, exacerbations of hepatitis can occur in patients stopping *adefovir* or other anti-HBV therapies. Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease *adefovir* clearance. *Ibuprofen* increases *adefovir* exposure modestly. An increased risk of lactic acidosis and steatosis may exist when *adefovir* is used in conjunction with other nucleoside analogues or antiretroviral agents. *Adefovir* is transported efficiently by renal tubular OAT1.

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. The diphosphate's inhibitory effects on renal adenylyl cyclase may contribute to nephrotoxicity (Shoshani et al., 1999). *Adefovir dipivoxil* is not associated with reproductive toxicity, although high intravenous doses of *adefovir* cause maternal and embryotoxicity with fetal malformations in rats (pregnancy category C).

Pediatric and Geriatric Uses. *Adefovir* should be avoided in elderly patients due to the risk for nephrotoxicity. This drug is approved in children 12 years or older at the same dose as that used in adults.

Lamivudine

Lamivudine, the (−)-enantiomer of 2′,3′-dideoxy-3′-thiacytidine, is a nucleoside analogue that inhibits HIV reverse transcriptase and HBV DNA polymerase. Details of its *mechanism of action, ADME, and drug interaction potential* are described in Chapter 64. *Lamivudine* inhibits HBV replication *in vitro* by 50% at concentrations of 4 to 7 ng/mL.

Mechanisms of Action and Resistance. Cellular enzymes convert *lamivudine* to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination.

After 5 years of treatment, approximately 71% of patients develop resistance to *lamivudine*. Point mutations in the *YMDD* motif of HBV DNA polymerase result in a 40- to 104-fold reduction in the *in vitro* susceptibility (Ono et al., 2001). *Lamivudine* resistance confers cross-resistance to related agents, such as *emtricitabine*. *Lamivudine*-resistant HBV retains susceptibility to *tenofovir* and partially to *adefovir* and *entecavir*. *Lamivudine* resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients.

Therapeutic Uses. *Lamivudine* is approved for the treatment of chronic HBV hepatitis in adults and children 2 years or older. However, *lamivudine* is not a preferred agent for the treatment of HBV because it is associated with a high rate of viral resistance.

The *lamivudine* dose is 100 mg once daily. In adults, doses of 100 mg/day for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in 41% or more of patients, and reductions in hepatic inflammation in more than 50% of patients. Seroconversion with antibody to HBeAg occurs in fewer than 20% of recipients at 1 year. In children 2 to 17 years of age, *lamivudine* (3 mg/kg per day to a maximum of 100 mg/day for 1 year) is associated with normalization of aminotransferase levels in about one-half and seroconversion to anti-HBe in about one-fifth of cases (Jonas et al., 2002). If resistant variants do not emerge, prolonged therapy is associated with sustained suppression of HBV DNA, continued histological improvement, and an increased proportion of patients experiencing a loss of HBeAg and undetectable HBV DNA. Prolonged therapy is associated with an approximate halving of the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis (Liaw et al., 2004). However, the frequency of *lamivudine*-resistant variants increases progressively with continued drug administration. Consider dose reduction for patients with renal impairment.

Untoward Effects. At the doses used for chronic HBV infection, *lamivudine* generally is well tolerated. Aminotransferase rises after therapy occur in *lamivudine* recipients, and flares in posttreatment aminotransferase elevations (>500 IU/mL) occur in about 15% of patients after cessation.

Pediatric and Geriatric Uses. The dose of *lamivudine* for use in children 2 to 17 years old is 3 mg/kg per day to a maximum of 100 mg/day. *Lamivudine* is not associated with increased toxicities in the elderly.

Telbivudine

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV DNA polymerase. In a cell culture model, the EC_{50} for inhibition of viral DNA synthesis by *telbivudine* was 0.2 μM. The U.S. manufacturer has ceased producing *telbivudine*.

Mechanisms of Action and Resistance. *Telbivudine* is phosphorylated by cellular kinases to the active triphosphate form, telbivudine 5′-triphosphate, which inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5′-triphosphate. Incorporation of telbivudine 5′-triphosphate into viral DNA causes chain termination.

Resistance to *telbivudine* emerges in about 22% of patients after 2 years of treatment. The development of viral resistance may increase the risk for hepatic decompensation. Thus, this drug, along with *lamivudine* and *adefovir*, is not recommended for the treatment of HBV.

ADME. The standard *telbivudine* dose is 600 mg once daily. The bioavailability of *telbivudine* is 68% (Zhou et al., 2006), and the drug is widely distributed into tissues. Food does not affect the pharmacokinetics of *telbivudine*. The drug is eliminated unchanged in the urine. *Telbivudine* concentrations decline biexponentially with an elimination $t_{1/2}$ of 40 to 49 h. Patients with moderate-to-severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

Therapeutic Uses. *Telbivudine* is indicated for the treatment of chronic HBV in adult patients (≥16 years) with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or aspartate aminotransferase [AST]) or histologically active disease. Although *telbivudine* has superior efficacy compared with *lamivudine* and *adefovir*, its use is associated with the development of resistance. Thus, *telbivudine* is not a preferred agent for the treatment of HBV.

Untoward Effects and Drug Interactions. *Telbivudine* is generally well tolerated and safe. The most common adverse events resulting in *telbivudine* discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3 to 4, are more common in *telbivudine*-treated than in *lamivudine*-treated patients after 2 years of therapy. The risk of peripheral neuropathy is increased when *telbivudine* is used with IFN-α, so this combination should be avoided.

Pediatric and Geriatric Uses. *Telbivudine* is not approved for children younger than 16 years. The primary consideration in treating geriatric patients with *telbivudine* is renal function.

Tenofovir Alafenamide

A different prodrug of *tenofovir*, TAF, is a phosphonate ester of *tenofovir* (Ray et al., 2016).

Mechanisms of Action and Resistance. The active ingredient of TAF is *tenofovir*, an inhibitor of HBV reverse transcriptase and HIV-1 reverse transcriptase. TAF is relatively more stable in the plasma than TDF; it is taken up into cells (e.g., hepatocytes), where it is deesterified, concentrated, and phosphorylated to *tenofovir diphosphate*. *Tenofovir diphosphate* is a competitive inhibitor of reverse transcriptase, competing with the physiological substrate dATP; when incorporated into DNA, the drug results in chain termination. No resistance to TAF has been observed after 96 weeks of treatment (Cathcart et al., 2018).

ADME. The dose of TAF for hepatitis B is 25 mg once daily. Plasma concentrations of *tenofovir* when administered as TAF are 90% less than when administered as TDF. The renal adverse effects of *tenofovir* are mediated through uptake by OAT1 in the kidney. TAF is not a substrate for OAT1, so less *tenofovir* is delivered to the kidneys, and there is less renal toxicity with this agent. However, TAF is preferentially taken up by several cell types, including peripheral blood mononuclear cells, and cellular concentrations of the active form, *tenofovir diphosphate*, are actually higher than those achieved with TDF.

Therapeutic Uses. TAF is used at a daily dose of 25 mg to treat HBV. Two studies have found TAF noninferior to TDF in terms of suppressed HBV DNA after 48 weeks of treatment with smaller declines in bone mineral density and estimated glomerular filtration rate (eGFR).

Untoward Effects and Drug Interactions. TAF has similar efficacy to TDF with fewer adverse effects on bone mineral density and kidney function (Cl_{Cr}, eGFR, proteinuria). Common side effects of *tenofovir* include nausea, rash, diarrhea, depression, and weakness. HBV "flare up" can result from sudden discontinuation of the drug.

Investigational Agents and the Future for Treatment of HBV

Several studies are investigating whether the nucleoside/-tide analogues can be safely discontinued in persons who are noncirrhotic and have converted from HBeAg positive to negative in order to stimulate HBsAg loss (Hadziyannis and Hadziyannis, 2020). Preliminary data suggest this approach may lead to HBsAg loss in a small percentage (~5%) of patients within 48 weeks of discontinuing nucleoside reverse transcriptase inhibitors (Hall et al., 2020).

Current therapies provide a functional cure (i.e., a cure that mimics naturally acquired immunity off therapy) in only a minority of patients, and none provides a complete cure because cccDNA persists in cells. Thus, new agents are needed to treat HBV. Multiple antiviral and immune modulators are in various stages of clinical development for HBV. Antiviral targets include entry inhibitors, cccDNA disruptors, translation inhibitors, capsid assembly inhibitors, polymerase inhibitors, and secretion inhibitors. Antivirals in more advanced stages of clinical development include *bulevirtide*, JNJ-6379, ABI-H0731, ARO-HBV, and REP-2139 (Soriano et al., 2020). *Bulevirtide*, an entry inhibitor, irreversibly binds to NTCP. It is given as a daily subcutaneous injection and recently received regulatory approval in Europe for treatment of hepatitis D. It is moving into phase III development for treatment of HBV. Capsid inhibitors, such as JNJ-6379 and ABI-H0731, destabilize HBcAg assembly, leading to aberrant capsids or capsids devoid of genetic material. ARO-HBV contains two RNA interference compounds that silence mRNA produced by cccDNA or viral DNA integrated into host. REP-2139 reduces HBsAg subparticle release, preventing these particles from exhausting adaptive immune responses. Immunomodulators in development include checkpoint inhibitors and toll-like receptor or RIG-1 agonists, among others (Soriano et al., 2020). It is likely that combinations of these compounds with or without IFN and/or the nucleoside/-tide analogues will be required for optimal efficacy.

Hepatitis C Virus

HCV Overview

Approximately 71 million people have chronic HCV infection. Africa and Central and East Asia have the highest prevalence of HCV. The majority of individuals infected with HCV, about 70%, will develop chronic infection, which may progress to cirrhosis (WHO, 2020b). Approximately 6% of cirrhotic individuals will develop symptoms of decompensated liver disease (e.g., ascites, hepatic encephalopathy, or variceal bleeding) each year, and 4% will develop hepatocellular carcinoma. These long-term complications carry a high risk of mortality and generally occur more than 20 years after infection (Freeman et al., 2001). There are approximately 400,000 HCV-related deaths annually.

Genetic Heterogeneity of HCV

Hepatitis C virus exhibits remarkable within- and between-subject genetic heterogeneity, which is a major obstacle to the development of a universal preventive vaccine. At least six HCV genotypes have been identified. HCV strains belonging to different genotypes differ at 30% to 35% of nucleotide sites. Among genotypes, transmissibility does not seem to differ, whereas the rate of disease progression and response to treatment with current therapies does differ. Globally, genotype 1 is most prevalent (Messina et al., 2015), followed by genotype 3. Genotypes 2, 4, and 6 together account for 25% of those living with HCV. Within the U.S., 75% of HCV isolates are genotype 1a or 1b, and the remainder are primarily genotype 2 or 3 (Zein et al., 1996).

HCV Genome and Life Cycle

The HCV genome consists of a positive-sense, single-stranded RNA, about 9600 nucleotides long, which encodes three structural proteins (core, E1, and E2); the ion channel protein p7; and six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) (Tang and Grise, 2009). HCV replicates entirely within the cytoplasm (Figure 63–3); it does not establish latency, and it is curable. Cure of HCV is synonymous with achieving a sustained virologic response (SVR). SVR is defined as having no measurable HCV RNA in the blood 12 weeks following treatment cessation. Achieving SVR decreases the progression of liver disease and reduces liver-related and all-cause mortality.

The HCV life cycle is shown in Figure 63–3. Not all steps in the hepatitis C viral life cycle have been completely elucidated. HCV binds two host receptors on the hepatocyte surface, low density lipoprotein (LDLr) and HSPGs. This initiates binding of E2 with CD81 and scavenger receptor B1 (SR-B1). The N-terminal hypervariable region of E2 interacts with SR-B1 (Kalemera et al., 2019). Proteins in the tertiary structure of E2 bind the large extracellular loop of CD81. These interactions create a tight junction between hepatocytes. Within the tight junction, HCV interacts with claudin-1 (CLDN1) and folds up with the hepatocyte membrane. This clathrin-covered endosome disperses inside the cell and fuses with host membranes, which permits uncoating of the capsid shell and release of the HCV RNA into the cytosol. HCV polyprotein translation begins when the ribosomal subunits bind the HCV RNA in the endoplasmic reticulum (ER). The polyprotein is co- and posttranslationally cleaved by both host and viral proteases to produce the 10 proteins described above. HCV proteins and host factors rearrange the host cell membranes to form the membranous web. In this web, the NS5B RdRp catalyzes the synthesis of a negative-sense RNA intermediate (template) that is used to create copies of positive-sense progeny HCV RNA. These newly made HCV RNAs are either used for RNA translation and replication or incorporated into nucleocapsid particles. Following RNA replication, HCV RNA is shuttled to the lipid droplet where core protein accumulates, oligomerizes, and engages the NS3 and NS5A proteins (Roder et al., 2019). Core oligomers bound to viral RNA bud into the ER lumen, acquiring an ER-derived lipid bilayer envelope that contains E1 and E2. After budding into the ER lumen, the virion moves through the very-low-density lipoprotein (VLDL) secretory pathway, acquiring apolipoproteins and other lipids en route. The lipoviroparticle fuses with the hepatocyte membrane and is subsequently released into extracellular compartment.

HCV Drug Targets and Treatment Approach

For many years, HCV was treated with a prolonged regimen of subcutaneously administered IFN-α (or pegIFN-α) with or without the purine nucleoside analogue *ribavirin*. SVR rates with this therapy were low, and tolerability was poor. Now, several antivirals that directly target various steps in the HCV life cycle (so-called DAAs) are the mainstay of HCV treatment. DAAs are administered orally, have few side effects, are typically taken for a period of 8 or 12 weeks, and achieve SVR rates of approximately 95% in most patient populations. Use of pegIFN-α for the treatment of HCV has been replaced by DAAs, although *ribavirin* is still used in combination with DAAs to improve SVR rates in certain clinical scenarios.

Detailed knowledge of the HCV life cycle and the structures of HCV proteins has permitted development of targeted inhibitors of HCV replication and revolutionized pharmacotherapy of HCV infection. Available DAAs target three major sites in the HCV life cycle: the NS3 protease, the NS5B polymerase, and NS5A (see Figure 63–3) (Ciesek and Manns,

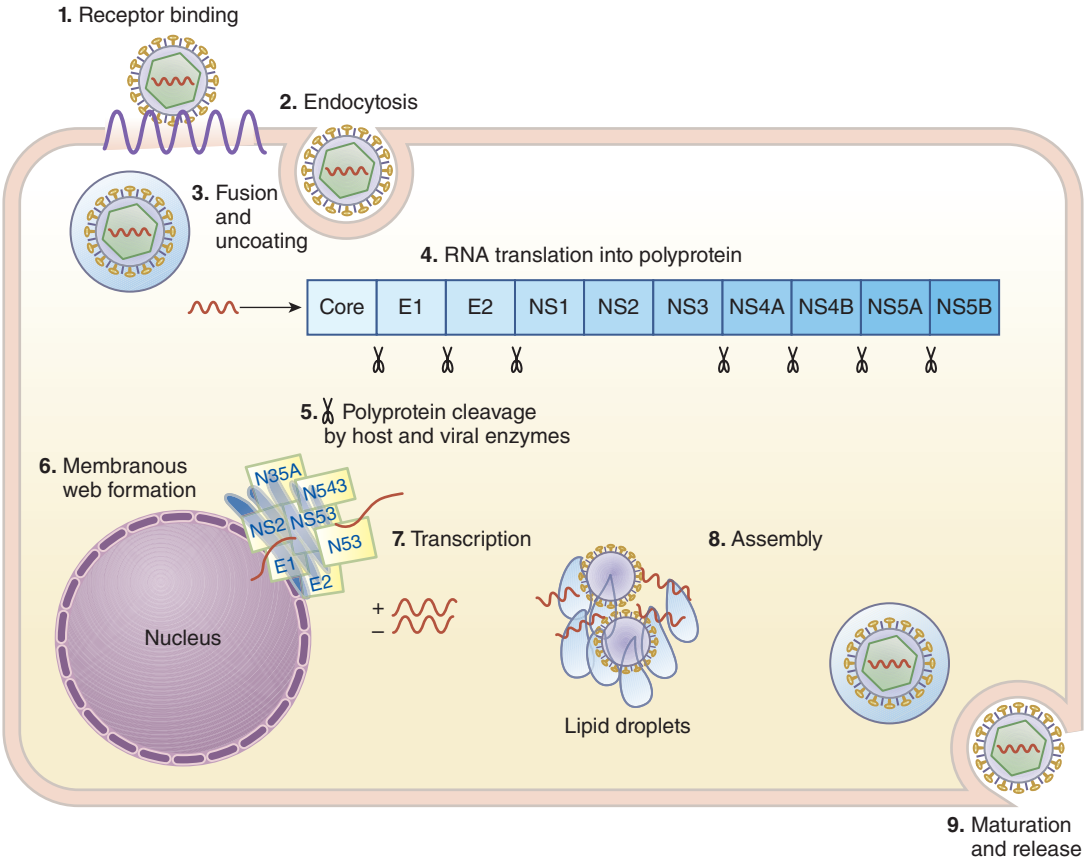

Figure 63–3 *Hepatitis C life cycle.* Not all steps in the hepatitis C viral life cycle have been completely elucidated. This figure represents our current understanding. For further details, consult the following references: Ciesek and Manns, 2011; Dubuisson and Cosset, 2014; and Holmes and Thompson, 2015.

2011; Dubuisson and Cosset, 2014; Holmes and Thompson, 2015). Inhibition of the NS3 protease prevents the cleavage of the viral polyprotein and formation of the replication complex. The NS5B enzyme is essential for HCV replication as it catalyzes the synthesis of the complementary minus-strand RNA and subsequent genomic plus-strand RNA. There are two types of NS5B RdRp inhibitors: nucleotide and nonnucleoside inhibitors. The nucleotide inhibitors are active site inhibitors, whereas the nonnucleoside inhibitors are allosteric inhibitors. Another target, NS5A, encodes a protein that appears essential to the replication machinery of HCV and critical in the assembly of new infectious viral particles (Gish and Meanwell, 2011). However, the specific functions of this protein have not been established.

Clinical Implications of HCV Resistance

On average, almost a trillion HCV particles are produced in an infected individual each day (Neumann et al., 1998). The HCV NS5B polymerase enzyme lacks a proofreading function and has relatively poor fidelity (Brown, 2009); therefore, there is a continuous generation of a large variety of spontaneous viral mutations. Thus, even untreated persons have HCV genomes that harbor preexisting resistance-associated substitutions (RASs). These naturally occurring RASs may affect the chances of achieving a cure with DAA treatment.

The likelihood that a DAA will select for and allow outgrowth of viral populations carrying RASs during treatment depends on several factors, including the DAA's genetic barrier to resistance (the number and type of base-pair mutations needed to result in amino acid substitutions that confer resistance), the level of drug exposure(s), and the viral fitness (replicative capacity) of the RAS. Nucleotide NS5B polymerase inhibitors have a high genetic barrier to resistance; three or more RASs are required for full resistance. In contrast, the nonnucleoside NS5B polymerase inhibitors, NS3 protease inhibitors, and NS5A inhibitors generally have a low genetic barrier to the development of resistance; that is, only one or two amino acid substitutions result in lack of drug efficacy. For drugs in these classes, there is swift emergence of RASs during monotherapy. Thus, as with HIV treatment, HCV treatment requires a combination of agents to optimize viral suppression and protect against the development of resistance. Data are emerging on the impact of treatment-emergent NS5A RASs on the likelihood of achieving SVR with current therapies. NS5A RASs have been shown to persist for several years after treatment cessation, and some NS5A inhibitors suffer from broad cross-resistance at key positions (Q30R, L31M/V, Y93H/N).

Hepatic Impairment: Implications for HCV Treatment

The vast majority of HCV-infected individuals have at least a 90% chance of achieving SVR with current therapies. There are some groups, however, such as those with decompensated cirrhosis, who have lower rates of SVR. Treating those with decompensated cirrhosis and achieving SVR have been shown to improve MELD scores and reverse fibrosis, but significant morbidity may persist (Bittermann and Reddy, 2021; Verna et al., 2020).

Studies indicated the optimal time to treat HCV is early in the course of illness. The risk of developing decompensated cirrhosis or hepatocellular carcinoma, requiring a liver transplant, or dying from HCV-related complications is significantly lower in those treated with minimal fibrosis compared to those treated once bridging fibrosis or cirrhosis has developed. Treating all patients early in the course of disease is challenging, however, because many patients with HCV are unaware of their disease.

Pharmacotherapy of HCV Infection

A description of current DAA therapies follows, and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided in

the Drug Facts table at the end of this chapter. Up-to-date information on testing, managing, and treating HCV can be found in guidelines from the American Association for the Study of Liver Diseases and Infectious Diseases Society of America (http://www.hcvguidelines.org). An important aspect of treating HCV is identification and management of drug-drug interactions with DAAs. The University of Liverpool offers a free, comprehensive, and reliable web-based drug interactions resource (available at http://www.hep-druginteractions.org).

Sofosbuvir

Sofosbuvir is a prodrug based on a uridine analogue. In cells, *sofosbuvir* is metabolized to an active form (known as GS-461203) that competes with uridine triphosphate for incorporation into HCV RNA by NS5B polymerase.

Mechanisms of Action and Resistance. *Sofosbuvir* is a prodrug, a 5′ monophosphorylated uridine analogue on which the charges of the phosphate group are masked by groups that are readily removed in the body. The active drug, generated in the host mammalian cell, inhibits HCV RNA polymerase. Figure 63–4 shows the cellular pharmacology of *sofosbuvir*.

Sofosbuvir provides a high barrier to the development of resistance, but the S282T RAV has been reported in patients who relapsed to *sofosbuvir*-based treatment. L159F, V321A, and C316N/H/F have also been observed (Lontok et al., 2015).

ADME. The dose of *sofosbuvir* is 400 mg taken once daily. The absolute bioavailability of *sofosbuvir* is estimated to be at least 80% based on recovery of *sofosbuvir* and its primary metabolite, GS-331007, following administration of a radiolabeled dose. A high-fat meal increases *sofosbuvir*'s AUC by 67% to 91%, but, based on the drug's high therapeutic index, the increased exposure is not thought to increase the likelihood of toxicities (Kirby et al., 2015). *Sofosbuvir* exhibits time-independent, near-linear pharmacokinetics across a range of doses. *Sofosbuvir* is 63% protein bound, whereas protein binding of the deesterified GS-331007 is minimal.

The primary metabolic route of *sofosbuvir* is hydrolysis to GS-331007. GS-331007 lacks antiviral activity and cannot be rephosphorylated. The majority of a *sofosbuvir* dose is converted to GS-331007 and eliminated in the urine via a combination of tubular secretion and glomerular filtration. *Sofosbuvir* AUC is increased 2.3-fold and 2.5-fold in patients with

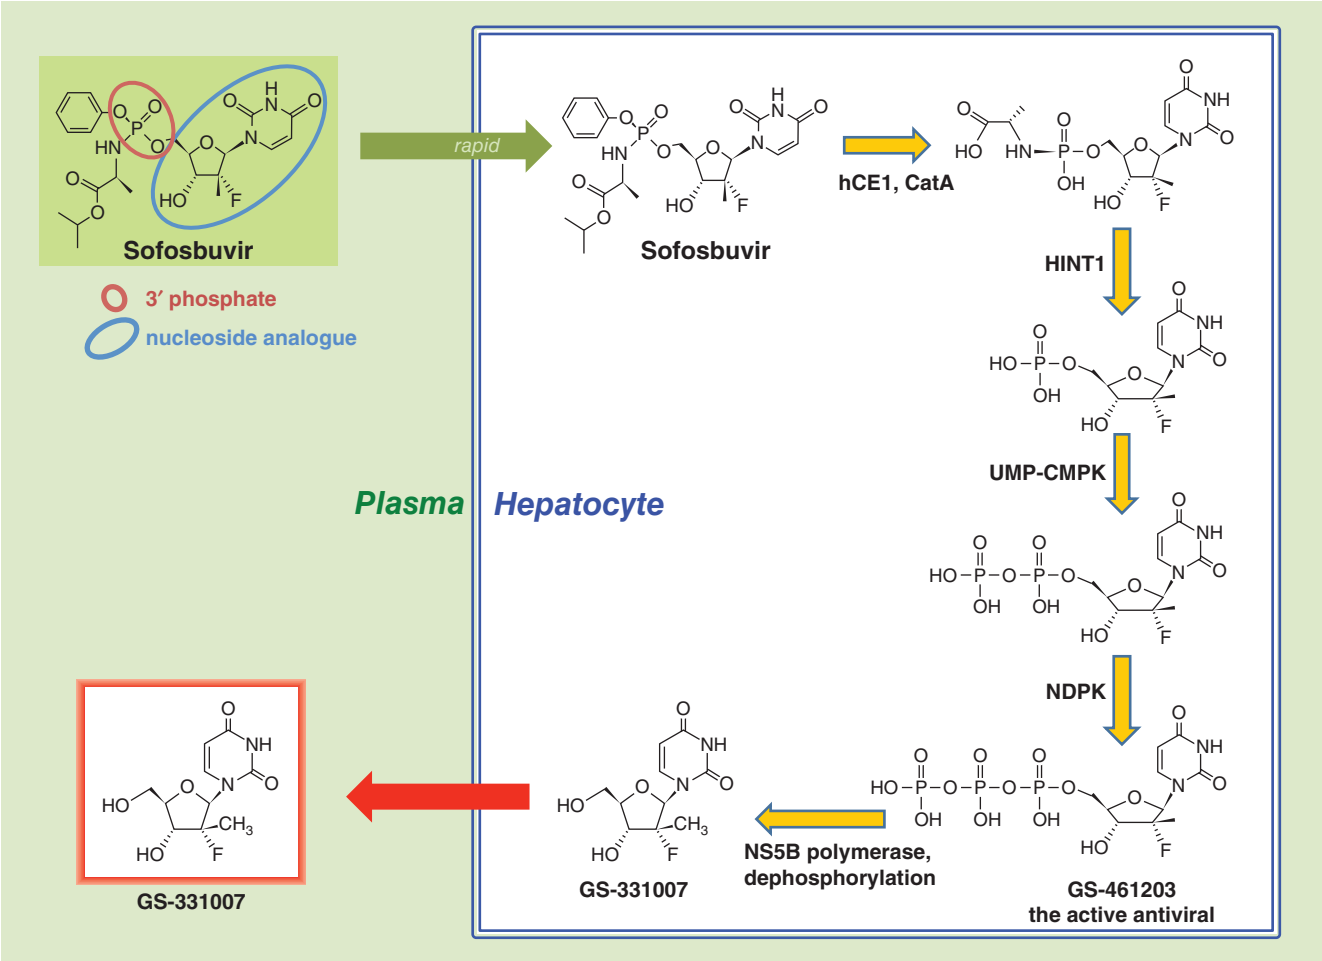

Figure 63–4 *Cellular pharmacology of sofosbuvir.* Some nucleoside analogues act as antiviral agents in infected cells, but first they must cross the plasma membrane and then be phosphorylated, starting at the 5′ position, a slow reaction catalyzed by nucleoside kinase. Use of a monophosphorylated nucleoside avoids the slow nucleoside kinase reaction, but the charge on the phosphate groups would greatly slow passage of the molecule across the plasma membrane. *Sofosbuvir* circumvents these issues by having a phosphate (red ellipse) at the 5′ position of the nucleoside analogue (blue ellipse) but masking the two negative charges of the phosphate group with adducts that esterases/amidases can readily remove. *Sofosbuvir* crosses the plasma membrane rapidly. The carboxyl ester moiety is hydrolyzed by CatA or hCE1. Histidine triad nucleotide-binding protein 1 (HINT1) catalyzes the phosphoramidate cleavage, yielding the monophosphate form, retained in the cell by ion trapping. Subsequent phosphorylation occurs via the pyrimidine nucleotide biosynthetic pathway. The triphosphate (GS-461203) is the active form responsible for the antiviral activity of *sofosbuvir*. GS-461203 acts as a defective deoxynucleotide triphosphate (dNTP) substrate and inhibits HBV RNA polymerase (NS5B); it may also act as a chain terminator. Dephosphorylation of GS-461203 yields a uridine analogue metabolite, GS-331007, that cannot be readily rephosphorylated, lacks antiviral activity, and exits the cell. Most (90%) of the drug-related material measured in plasma is GS-331007. CatA, cathepsin A; hCE1, human carboxylesterase 1; NDPK, nucleoside diphosphate kinase; UMP-CMPK, uridine/cytidine monophosphate kinase.

moderate and severe hepatic impairment (i.e., Child-Pugh B and C), respectively, but GS-331007 AUC is unchanged. No dose adjustment is needed for this population; available data suggest *sofosbuvir* is safe and effective in individuals with decompensated cirrhosis when combined with appropriate DAAs (Charlton et al., 2015; Manns et al., 2016).

In contrast, *sofosbuvir* and GS-331007 pharmacokinetics are affected by renal impairment. *Sofosbuvir* and GS-331007 AUC increased about 60% in those with eGFR of 50 to 80 mL/min/1.73 m^2, 107% in those with eGFR of 30 to 50 mL/min/1.73 m^2, and 171% in those with an eGFR less than 30 mL/min/1.73 m^2. Despite these increased exposures, there are no renal restrictions on the use of *sofosbuvir*-based therapies to treat HCV since emerging data indicate the drug's safety and efficacy in this population. *Sofosbuvir*'s AUC is 60% higher in HCV-infected persons, and the AUC of GS-331007 is 39% lower compared with HCV-seronegative volunteers. The mechanism for this is unclear. The median terminal half-lives of *sofosbuvir* and GS-331007 are 0.4 and 27 h, respectively.

Therapeutic Uses. The NS5B polymerase region is well conserved across genotypes. Thus, *sofosbuvir* is active against all HCV genotypes. In individuals with genotype 1 HCV, 7 days of *sofosbuvir* monotherapy reduces HCV RNA by 4.65 logs (Lawitz et al., 2013). *Sofosbuvir* is used in combination with the NS5A inhibitors *daclatasvir*, *ledipasvir*, or *velpatasvir*. It is also used with *velpatasvir* and the NS3 protease inhibitor, *voxilaprevir*, as a salvage regimen for those who previously failed NS5A-based HCV treatment. The efficacy and tolerability of *sofosbuvir* in these combination therapies are described in subsequent sections.

Untoward Effects and Drug Interactions. There are no hallmark toxicities associated with *sofosbuvir* use. Side effects observed when *sofosbuvir* is administered as part of combination DAA treatment are described in the material that follows with the concomitant antiviral.

Sofosbuvir is not a cytochrome P450 (CYP) substrate, inhibitor, or inducer and therefore has a low potential for CYP-mediated drug interactions. However, *sofosbuvir* is a substrate for the efflux transporters P-gp and BCRP and should not be used with potent inducers of these transporters (e.g., *rifampin*, St. John's wort, *phenytoin*, *carbamazepine*). *Sofosbuvir* is also an inhibitor of carboxylesterase-2 (CES-2), an enzyme involved in the hydrolysis of many drugs, including TDF (Shen and Yan, 2017). *Sofosbuvir*-containing DAA treatments have been associated with bradycardia, the requirement for pacemaker insertion, and fatal cardiac arrest in patients taking *amiodarone*. The mechanism(s) for this is unclear, but the interaction appears to be more pharmacodynamic rather than pharmacokinetic in nature (Regan et al., 2016). If the combination cannot be avoided, cardiac monitoring in an inpatient setting is advised for the first 48 h of *sofosbuvir*-based treatment, with daily heart rate monitoring for an additional 2 weeks.

Pediatric and Geriatric Uses. *Sofosbuvir/ledipasvir* and *sofosbuvir/velpatasvir* are approved in children as described in the *ledipasvir* and *velpatasvir* sections that follow. In licensing trials, the response rates of adults under 65 years and over 65 years of age were similar.

Ribavirin

Ribavirin, a purine nucleoside analogue with a modified base and D-ribose sugar, inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses *in vitro*.

Mechanisms of Action and Resistance. Host cell enzymes phosphorylate *ribavirin* to mono-, di-, and triphosphate derivatives. The exact mechanism(s) of action of *ribavirin* or its phosphorylated derivatives *in vivo* is unknown, but several immunomodulatory and antiviral effects have been observed *in vitro*, including:

1. Inhibiting the HCV RdRp
2. Depleting guanosine triphosphate (and thus nucleic acid synthesis in general) through inhibition of inosine 5′-monophosphate dehydrogenase
3. Enhancing viral mutagenesis
4. Converting the T-helper cell phenotype from 2 to 1
5. Inducing IFN-stimulated genes
6. Modulating natural killer cell response

Ribavirin may select for HCV resistance mutations *in vitro*, but this has not been observed *in vivo*.

ADME. *Ribavirin* dosing is typically weight based. Individuals weighing less than 75 kg receive 1000 mg daily in two divided doses. Individuals weighing at least 75 kg receive 1200 mg daily in two divided doses. Dose reductions are necessary for those with renal impairment, and individuals with renal impairment or decompensated cirrhosis may have difficulty tolerating 1000 or 1200 mg of *ribavirin*. Decompensated cirrhotics are often initiated on a lower dose of 600 mg daily and increased as tolerated.

Ribavirin oral bioavailability averages 50%. Food increases plasma levels substantially. *Ribavirin* is a substrate for equilibrative and concentrative nucleoside uptake transporters (ENT1 [SLC29A1], CNT2 [SLC28A2], and CNT3 [SLC28A3]) and thus is widely distributed throughout the body. The half-lives of the mono-, di-, and triphosphate derivatives in red blood cells and peripheral blood mononuclear cells mirror the plasma $t_{1/2}$ of parent *ribavirin* (7–10 days) (Wu et al., 2015). Hepatic metabolism (deribosylation and hydrolysis to a triazole carboxamide) and renal excretion of *ribavirin* and its metabolites are the principal routes of elimination. The dose of *ribavirin* should be reduced in patients with renal impairment. Even with a reduced dose, patients with renal impairment have difficulty tolerating *ribavirin*.

Therapeutic Uses. *Ribavirin* can be administered orally, intravenously, and by inhalation. The aerosolized form of *ribavirin* is used in the treatment of a variety of respiratory viruses, including respiratory syncytial virus. Intravenous *ribavirin* has been used to treat hemorrhagic fever and severe influenza. Oral *ribavirin* is used in combination with DAAs for the treatment of chronic HCV infection in certain scenarios (e.g., with *sofosbuvir* and *ledipasvir* or *velpatasvir* in the setting of decompensated cirrhosis, with *grazoprevir/elbasvir* in individuals with genotype 1a HCV and preexisting NS5A RASs). The efficacy of *ribavirin* in combinations with these DAAs is described in subsequent sections.

Untoward Effects and Drug Interactions. Aerosolized *ribavirin* may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of valves and tubing with *ribavirin*. Healthcare workers should use techniques to reduce environmental exposure; pregnant women should not directly care for patients receiving *ribavirin* aerosol due to the possibility of fetal harm from exposure to the aerosol. Bolus intravenous infusion may cause rigors. Systemic *ribavirin* causes dose-related reversible hemolytic anemia, with associated increases in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. The *ribavirin* dose is often reduced when hemoglobin decreases to less than 10 g/dL or declines by more than 3 g/dL and discontinued if hemoglobin becomes less than 8.5 g/dL.

Anemia occurs in 5% to 11% of patients receiving *ribavirin* in combination with DAAs (clinical trials of mostly noncirrhotic subjects); 18% to 40% of patients post–liver transplant or with decompensated cirrhosis receiving *ribavirin* with DAAs experienced anemia, with many receiving *ribavirin* doses lower than the typical 1000 to 1200 mg daily. Two polymorphisms in the gene encoding inosine triphosphatase protect against *ribavirin*-induced hemolytic anemia; the frequency of the protective alleles in the general population is about 10%.

Other *ribavirin* toxicities include fatigue, cough, rash, and pruritus. Preclinical studies indicated that *ribavirin* is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. *Ribavirin* is present in higher amounts in sperm than plasma. Thus, *ribavirin* is contraindicated in men and women who are attempting conception and for up to 6 months following cessation of treatment. *Ribavirin* has minimal drug interactions but should not be used with the HIV nucleoside analogue *didanosine*.

Pediatric and Geriatric Uses. *Ribavirin* is indicated for the treatment of HCV in children 5 years and older. Doses range from 400 to 1200 mg daily depending on body weight, administered in two divided doses.

Specific pharmacokinetic evaluations for *ribavirin* in the elderly have not been performed. The primary consideration in treating older individuals with *ribavirin* is renal function. The dose of *ribavirin* should be reduced in those with an eGFR less than or equal to 50 mL/min/1.73 m^2.

Ledipasvir

Ledipasvir, an NS5A inhibitor, is available only as part of a fixed-dose combination tablet with the NS5B nucleotide polymerase inhibitor, *sofosbuvir* (LDV/SOF).

Mechanisms of Action and Resistance. *Ledipasvir* is an inhibitor of NS5A. Baseline NS5A RASs were detected in 16% of the 2144 participants in the phase II and III studies of LDV/SOF (Sarrazin et al., 2016). For treatment-naïve patients, slightly lower rates of SVR are observed among persons with HCV genotype 1a *with* versus *without* baseline NS5A RASs (92% vs. 98%, respectively). Treatment-experienced patients with baseline NS5As RASs achieve lower SVR rates compared with treatment-experienced patients with no baseline RASs. NS5A RASs are detected in the majority of patients who fail to respond to LDV/SOF treatment. These NS5A RASs persist for at least 2 years and may affect the success of future HCV treatments.

ADME. *Ledipasvir*, 90 mg, is available as part of a fixed-dose combination tablet with *sofosbuvir* (German et al., 2016). This tablet is administered once daily without regard to meals. LDV/SOF should not be used in individuals with an eGFR less than 30 mL/min/1.73 m^2.

Ledipasvir absorption is pH dependent. Concomitant use of antacids, H_2 receptor antagonists, and proton pump inhibitors (PPIs) is problematic. The bioavailability of *ledipasvir* in humans is unknown (30%–50% in rats, monkeys, and dogs). *Ledipasvir* concentrations are similar when given fasted versus a high-fat (1000 kcal) meal. *Ledipasvir* is greater than 99.8% bound to human plasma proteins. *Ledipasvir* is primarily eliminated unchanged in the feces. Approximately 30% is metabolized via uncertain pathways. *Ledipasvir* pharmacokinetics are not significantly altered by hepatic or renal impairment. The $t_{1/2}$ of *ledipasvir* is 47 h. *Ledipasvir* AUC and $C_{P_{max}}$ are 24% and 32% lower in HCV-infected subjects, respectively, compared with HCV-seronegative volunteers.

Therapeutic Uses. LDV/SOF is FDA-approved for individuals with HCV (genotype 1, 4, 5, and 6 disease) and those with decompensated cirrhosis. *In vitro*, *ledipasvir* has limited activity against genotype 3; its activity against genotype 2 is reduced by the highly present L31M RAV; thus, LDV/SOF is not recommended for this genotype.

The SVR rates with 12 weeks of LDV/SOF therapy were 96% and 99% in clinical trials of HCV treatment-naïve patients and 95% in treatment-experienced patients without cirrhosis. Treatment-experienced individuals with cirrhosis should be treated for either 24 weeks with LDV/SOF or 12 weeks with LDV/SOF plus *ribavirin* to improve the likelihood of achieving a cure. LDV/SOF for 12 weeks achieved an SVR rate of 95% in two studies with a small number of individuals with genotype 4 disease. SVR was 93% in 44 patients with genotype 5 and 96% in 25 patients with genotype 6 receiving 12 weeks of LDV/SOF.

Treatment of individuals with HIV/HCV coinfection for 12 weeks yielded similarly high SVRs. However, SVR rates with 8 weeks of LDV/SOF in persons with HIV were slightly lower; thus, this group should be treated for 12 weeks. In treating patients with decompensated cirrhosis, *ribavirin* is added to LDV/SOF treatment to increase SVR rates, usually at a *ribavirin* dose of 600 mg daily due to poor tolerability of *ribavirin* in this patient population.

Untoward Effects and Drug Interactions. Among patients receiving 12 weeks of LDV/SOF in phase III clinical trials, 13% to 14% reported fatigue and headache. The addition of *ribavirin* to LDV/SOF in cirrhotic patients increased the number and frequency of adverse effects.

Ledipasvir relies on an acidic environment for optimal absorption; thus, gastric acid modifiers should be used with caution. In one large cohort, use of PPIs was found to be an independent predictor of relapse to LDV/SOF treatment (Terrault et al., 2016). If gastric acid modifiers must be used, temporal separation is necessary with antacids (by 4 h); H_2 blocker and PPI doses should not exceed the equivalent of 40 mg *famotidine* twice daily and 20 mg *omeprazole* once daily. The *omeprazole* must be administered simultaneously with LDV/SOF in the fasted state. Like *sofosbuvir*, *ledipasvir* is a substrate for P-gp and BCRP and thus cannot be used with potent inducers of these transporters. The CYP3A inducer *efavirenz* reduces ledipasvir concentrations by 30%, and the pharmacokinetic enhancer *cobicistat* increases *ledipasvir* concentrations by 2-fold; given the rather high therapeutic index of *ledipasvir*, these changes are not expected to have clinical relevance. *Ledipasvir* inhibits P-gp and BCRP and may increase the concentrations of *rosuvastatin* via inhibition of BCRP; thus, this combination is not recommended. LDV/SOF increases the exposure to *tenofovir*, which may increase the risk of renal toxicity in HIV-infected individuals taking TDF with a boosting agent such as *ritonavir* or *cobicistat*. Use of TAF instead of TDF is an option for patients taking an antiretroviral regimen, which includes *ritonavir* and *cobicistat*.

Pediatric and Geriatric Uses. LDV/SOF is approved in children 3 years and older with HCV genotypes 1, 4, 5, or 6. LDV/SOF dosing in children is weight based and administered as tablets or oral pellets. The SVR rate was 98% in 100 adolescents 12 to 17 years receiving the FDA-approved adult dose of LDV/SOF with good tolerability. Two trials of children 3 to 11 years showed similar SVR rates to adults. Age is not associated with *ledipasvir* exposures in population pharmacokinetic analyses over the range of 18 to 80 years. No differences in safety or efficacy have been observed between individuals 65 years and older and younger patients.

Daclatasvir

Daclatasvir is an NS5A inhibitor.

Mechanism of Action and Resistance. *Daclatasvir* binds to the N-terminus of NS5A and inhibits both viral RNA replication and virion assembly. The Y93H RAV is detected in most patients who fail *daclatasvir/sofosbuvir* (DCV/SOF) treatment. This variant has been shown to persist for several years after treatment cessation.

ADME. *Daclatasvir* is available as 30-mg and 60-mg tablets. The standard dose of *daclatasvir* is 60 mg, but the dose should be reduced to 30 mg with strong CYP3A inhibitors and increased to 90 mg with moderate CYP3A inducers (Table 63–1). The absolute bioavailability of *daclatasvir* is 67%. A high-fat, high-calorie meal reduces *daclatasvir* exposure by 23%, but a low-fat meal has no effect. The drug is approved for administration without regard to meals. *Daclatasvir* is highly protein bound (99%).

Daclatasvir is metabolized by CYP3A and is therefore susceptible to the effects of potent inhibitors and inducers of this enzyme, but the drug itself does not appear to inhibit or induce any CYPs. *Daclatasvir* is a substrate for P-gp. *Daclatasvir* inhibits P-gp, BCRP, and OATP1B1/3 and thus may increase exposures of drugs that are substrates for these transporters. Total exposure to *daclatasvir* is about 37% lower in patients with Child-Pugh B and C decompensated cirrhosis, but unbound concentrations are unchanged, and no dose adjustment is needed in such patients. *Daclatasvir* AUC increases in those with ESRD; with an eGFR of 15 to 29 mL/min/1.73 m^2, AUC is roughly doubled. Given the high therapeutic index of *daclatasvir*, this change is unlikely to have clinical relevance. The half-life of *daclatasvir* is 12 to 15 h. *Daclatasvir* pharmacokinetics are similar in HCV-seropositive and -seronegative individuals.

Therapeutic Uses. *Daclatasvir* is FDA-approved for use in combination with *sofosbuvir* in those with genotype 1 and 3 disease, in individuals with HIV coinfection regardless of HCV genotype, and in persons with advanced liver disease (Keating, 2016). It is rarely used in the U.S., however, because there are coformulated and cheaper alternatives. In Japan, *daclatasvir* is also approved in combination with the HCV NS3/4A protease inhibitor asunaprevir; this combination is not available in the U.S.

The SVR rates are 86% to 90% in treatment-naïve and treatment-experienced individuals receiving 12 weeks of DCV/SOF. Lower SVR rates occur in those with cirrhosis (63%). Thus, cirrhotic patients with genotype 3 disease may benefit from the addition of *ribavirin*. In HIV-coinfected individuals with HCV genotypes 1 to 4, 96% achieved SVR with 12 weeks of *daclatasvir* and *sofosbuvir* administration. In a group

TABLE 63–1 ■ DACLATASVIR (DCV) DOSING WITH INDUCERS AND INHIBITORS OF CYP3A4

STRONG CYP3A INHIBITORS	MODERATE CYP3A INHIBITORS	STRONG CYP3A INDUCERS	MODERATE CYP3A INDUCERS
Decrease DCV Dose to 30 mg	**Standard DCV Dose, 60 mg**	**DCV Contraindicated**	**Increase DCV Dose to 90 mg**
Ritonavir-boosted atazanavir	Ritonavir-boosted darunavir	Rifamycins	Bosentan
Clarithromycin	Ritonavir-boosted lopinavir	St. John's wort	Dexamethasone
Itraconazole	Ciprofloxacin	Antiepileptics	Efavirenz
Ketoconazole	Diltiazem		Etravirine
Nefazodone	Erythromycin		Modafinil
Nelfinavir	Fluconazole		Nafcillin
Posaconazole	Fosamprenavir		Rifapentine
Telithromycin	Verapamil		
Voriconazole			

of individuals primarily (75%) infected with HCV genotype 1 with advanced liver disease and with Child-Pugh A (n = 12), B (n = 32), and C (n = 16) cirrhosis, 92%, 94%, and 56%, respectively, achieved SVR with 12 weeks of DCV/SOF plus *ribavirin* treatment.

Untoward Effects and Drug Interactions. *Daclatasvir* is well tolerated. The most commonly reported adverse events in genotype 3 patients receiving DCV/SOF were headache and fatigue (14% each). HIV-coinfected patients reported fatigue (17%), nausea (13%), and headache (11%). When combined with *ribavirin* in patients with advanced cirrhosis, the most common adverse effects were anemia (20%), fatigue (18%), nausea (17%), and headache (15%).

Daclatasvir is primarily a victim rather than a perpetrator in drug-drug interactions (Garimella et al., 2016). *Daclatasvir* cannot be used with potent CYP3A inducers but may be used with moderate inducers, if the *daclatasvir* dose is increased from 60 to 90 mg. The *daclatasvir* dose must be reduced from 60 to 30 mg with potent CYP3A inhibitors. Table 63–1 lists some comedications necessitating a *daclatasvir* dose modification.

Pediatric and Geriatric Uses. *Daclatasvir* exposures in adolescents receiving the adult dose (60 mg daily) are similar to historical data in adults. *Daclatasvir* has not been studied in children younger than 12 years and has not been evaluated in the elderly. Age was not significantly associated with *daclatasvir* pharmacokinetics in population modeling over the range of 18 to 79 years; no unique safety concerns were evident in those over 65 years of age, and SVR rates were comparable in older and younger subjects in trials.

Velpatasvir

Velpatasvir (VEL) is an NS5A inhibitor available as part of a fixed-dose combination product with *sofosbuvir* (SOF/VEL).

Mechanism of Action and Resistance. Baseline RASs do not appear to influence the likelihood of achieving SVR with SOF/VEL except in cirrhotic patients with genotype 3 disease where the SVR rate was 73% compared with 93% in those without baseline RASs (Foster et al., 2015).

ADME. SOF/VEL is a fixed-dose combination tablet containing 400 mg of *sofosbuvir* and 100 mg of VEL taken once daily. As with *ledipasvir*, VEL absorption is pH dependent, and gastric acid modifiers require special dosing considerations with this agent; food has little effect on VEL's absorption. VEL is greater than 99.5% protein bound. VEL is predominantly excreted in feces as parent and metabolite; less than 1% of a dose appears in urine. VEL AUC changes only modestly (−17% to +14%) with moderate and severe hepatic impairment. In patients with severe renal impairment (eGFR <30 mL/min/1.73 m^2), the AUC of VEL increases by 50%. The VEL $t_{1/2}$ is 15 h. VEL AUC and C_{max} are reduced by approximately 40% in HCV-infected individuals compared with healthy volunteers.

Therapeutic Uses. SOF/VEL is active against all HCV genotypes (1–6). SVR rates were 99% in patients with genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3 patients with 12 weeks of SOF/VEL in trials. Patients with genotype 3 and cirrhosis should undergo resistance testing prior to initiating SOF/VEL. Cirrhotic genotype 3 patients with the Y93H RAS have diminished SVR with 12 weeks of SOF/VEL and should receive an alternative treatment. In decompensated patients, 83% achieved SVR with SOF/VEL for 12 weeks, 94% achieved SVR with SOF/VEL plus *ribavirin*, and 86% achieved SVR with 24 weeks of SOF/VEL.

Untoward Effects and Drug Interactions. The most common adverse reactions with SOF/VEL are headache (22%), fatigue (15%), nausea (9%), asthenia (5%), and insomnia (5%). When *ribavirin* is given with SOF/VEL to patients with decompensated cirrhosis, adverse events are more frequent: fatigue (32%), anemia (26%), nausea (15%), headache (11%), insomnia (11%), and diarrhea (10%).

Velpatasvir has a pharmacological profile similar to that of *ledipasvir* but is subject to more CYP3A-mediated interactions. As with *ledipasvir*, antacids should be separated by 4 h, and H_2 blocker doses should not exceed the equivalent of 40 mg of *famotidine* twice daily, and PPI doses should not exceed the equivalent of 20 mg of *omeprazole* daily. The timing of the PPI in relation to SOF/VEL differs from LDV/SOF and is important to adhere to. SOF/VEL should be taken with food 4 h prior to a PPI dose. VEL is a substrate for CYPs 3A4, 2C8, and 2B6 but has not been shown to inhibit any CYPs. VEL is a substrate for and weak inhibitor of P-gp and a weak inhibitor of BCRP and OATP1B1/1B3. In terms of its potential to act as a perpetrator of drug interactions, VEL causes the following changes to transporter probe substrates (Mogalian et al., 2016): The AUC of *pravastatin* (an OATP1B1 substrate) increases by 35% and the AUC of *rosuvastatin* (an OATP1B1 and BCRP substrate) increases by approximately 170% when coadministered with VEL in healthy volunteers. Similarly, the AUC of *digoxin* (a P-gp substrate) increases by 34%. Single-dose *rifampin*, an OATP1B1 inhibitor, increases the AUC of VEL by 47%; however, multiple doses of rifampin, which induces CYP metabolism and transporter expression, reduces the AUC of VEL by about 82%. Single-dose *cyclosporine* (a mixed OATP/P-gp/MRP2 inhibitor) doubles the VEL AUC. *Ketoconazole* (CYP3A inhibitor) increases the VEL AUC by 70%. *Efavirenz* reduces the VEL AUC by 50%. *Efavirenz*, *rifampin*, and other potent inducers should be avoided.

Pediatric and Geriatric Uses. SOF/VEL is approved in children with any HCV genotype aged 6 years or older and weighing 17 kg or more. Children weighing 30 kg or more receive the adult dose, and those weighing 17 kg to less than 30 kg receive SOF/VEL 200 mg/50 mg once daily. Twelve percent of participants in phase III trials (156 subjects) were age 65 or older; no differences in efficacy or safety were observed in this group compared with those younger than 65 years.

Voxilaprevir

Voxilaprevir (VOX) is an NS3 protease inhibitor available as part of a fixed dose combination product with SOF/VEL (SOF/VEL/VOX).

Mechanism of Action and Resistance. SOF/VEL/VOX is used for second-line treatment of patients who have previously failed a DAA regimen. The presence of NS3, NS5A, or NS5B RASs prior to treatment does not influence the likelihood of achieving SVR.

ADME. The fixed-dose tablet contains 400 mg of *sofosbuvir*, 100 mg of VEL, and 100 mg of VOX. The absolute bioavailability of VOX in humans is unknown, but it is 83% in rats and 27% in dogs. VOX exposures are increased 112% with a light-fat meal, 185% with a moderate-fat meal, and 435% with a high-fat meal relative to fasting. The $t_{1/2}$ of VOX is 33 h. VOX is primarily eliminated through biliary excretion; 94% is excreted in the feces (40% as parent drug). VOX is more than 99% protein bound. VOX exposures are 71% higher in persons with eGFR less than 30 mL/min/1.73 m^2, but this is unlikely to have clinical relevance unless combined with other risk factors for increased VOX exposures. However, VOX exposures are increased 299% with moderate and 500% with severe hepatic impairment. Higher VOX exposures may increase the potential for hepatotoxicity or liver failure, and this treatment should therefore not be used in patients with decompensated cirrhosis. This is a class effect for HCV NS3 protease inhibitors. VOX exposures are 260% higher in persons with HCV versus those without HCV.

Therapeutic Uses. SOF/VEL/VOX for 12 weeks is used in patients with genotypes 1 to 6 who have previously failed DAA treatment. Among those who previously failed an NS5A-containing regimen, SVR was 96% after 12 weeks of SOF/VEL/VOX (Bourliere et al., 2017). Patients with genotype 3 and cirrhosis have lower SVR rates and require the addition of *ribavirin* to SOF/VEL/VOX to maximize SVR.

Untoward Effects and Drug Interactions. The most common adverse reactions with SOF/VEL/VOX are headache (21%), fatigue (17%), diarrhea (13%), and nausea (13%).

The same drug interactions with *sofosbuvir* and VEL apply to SOF/VEL/VOX. Since it is administered with VEL, careful adherence to dosing limitations for the gastric acid modifiers is necessary, but there are no temporal separation requirements with PPIs as there are with LDV/SOF or SOF/VEL. VOX is a substrate for P-gp, BCRP, OATP1B1/3, CYP1A2, CYP2C8, and CYP3A4. Potent OATP1B1 inhibitors (e.g., *cyclosporine*) should not be used with VOX. VOX is an inhibitor of P-gp, BCRP, and OATP1B1/3. VOX increases exposures of BCRP substrates and should be avoided with *methotrexate*, *mitoxantrone*, *imatinib*, *irinotecan*, *lapatinib*, *rosuvastatin*, *sulfasalazine*, and *topotecan*. VOX does not cause significant increases in ethinyl estradiol exposures, but a few cases of liver enzyme elevations have been noted during drug interaction trials with ethinyl estradiol–containing hormonal contraception and SOF/VEL/VOX. This effect has also been observed with other HCV protease inhibitors, necessitating caution with the use of this combination.

Pediatric and Geriatric Uses. SOF/VEL/VOX has not been evaluated in children. In SOF/VEL/VOX registrational trials, there was no signal for differences in efficacy or safety in those 65 and older versus younger subjects.

Glecaprevir/Pibrentasvir

Glecaprevir (GLE) is an NS3 protease inhibitor; *pibrentasvir* (PIB) is an NS5A inhibitor.

Mechanism of Action and Resistance. Baseline RASs do not appear to influence the likelihood of achieving SVR with GLE/PIB in patients with HCV genotypes 1, 2, 4, 5, and 6. Among noncirrhotic treatment-naïve genotype 3 patients, 78% of those with the A30K RAS achieved SVR12 with 8 weeks of GLE/PIB. There are insufficient data to characterize the impact of A30K in genotype 3 patients with cirrhosis or prior treatment experience.

ADME. Each fixed-dose combination tablet contains 100 mg of GLE and 40 mg of PIB; patients take three tablets each day. Moderate- and high-fat meals increase GLE 83% to 163% and PIB 40% to 53%. Absolute bioavailabilities of GLE/PIB in humans are unknown. The half-lives for GLE and PIB are 6 and 13 h, respectively. GLE/PIB is eliminated largely via the biliary-fecal route (>92%); renal excretion accounts for less than 1%. Both GLE and PIB are highly protein-bound. In persons with HCV, GLE and PIB exposures are elevated (86% and 54%, respectively) in ESRD, with or without dialysis, compared to subjects with normal renal function. GLE exposures are doubled in Child-Pugh B subjects and 11-fold higher in Child-Pugh C subjects relative to persons with no hepatic impairment. PIB exposures are 26% higher in Child-Pugh B subjects and 114% higher in Child-Pugh C subjects. NS3 protease–containing DAA therapies, such as GLE/PIB, are contraindicated in decompensated cirrhosis. Based on a population pharmacokinetic analysis, PIB exposures are 51% higher in persons without HCV relative to those with HCV, and GLE exposures do not differ in HCV-seropositive versus -seronegative individuals.

Therapeutic Uses. GLE/PIB is pangenotypic. For treatment-naïve individuals, SVR rates of 95% or greater were observed in multiple trials with 8 weeks of dosing, including in compensated cirrhotics. In treatment-experienced patients, SVR rates are 92% and 94% in patients with prior NS3 protease and NS5A failures with 12 and 16 weeks of dosing, respectively. GLE/PIB is a treatment of choice in persons with renal impairment. SVR rates of 97% or greater have been observed in trials of GLE/PIB in patients with chronic kidney disease.

Untoward Effects and Drug Interactions. The most common adverse reactions with GLE/PIB are headache (13%), fatigue (11%), and nausea (8%).

The GLE/PIB combination can act as a perpetrator in drug interactions. GLE/PIB inhibits P-gp, BCRP, and OATP1B1/3, and weakly inhibits CYP3A, CYP1A2, and UGT1A1. As victims of interactions, GLE/PIB are substrates of P-gp and/or BCRP. GLE is a substrate of CYP3A and OATP1B1/3. Thus, drugs that inhibit P-gp, BCRP, or OATP1B1/3 may increase the plasma concentrations of GLE and/or PIB. Potent inducers, such as antiepileptics, St. John's wort (hypericum), *rifampin*, and *efavirenz*, are not recommended with GLE/PIB. Although GLE has pH-dependent absorption and exposures are reduced by 29% to 51% with *omeprazole* 20 to 40 mg daily, clinical data support efficacy even in presence of gastric acid modifiers as long as the *omeprazole* dose equivalent does not exceed 40 mg daily (Flamm et al., 2019). Ethinyl estradiol–containing contraception should not be used during and for 2 weeks after GLE/PIB. Alanine aminotransferase was increased in 5 of 26 women in drug interaction studies of ethinyl estradiol and GLE/PIB. HIV protease inhibitors and *cyclosporine* should not be used with GLE/PIB as the increase in GLE exposures may predispose to hepatotoxicity.

Pediatric and Geriatric Uses. GLE/PIB, at the adult dose, is approved for use in children weighing at least 45 kg. A pediatric formulation of GLE/PIB has proven efficacious and well tolerated in chronic HCV-infected children 3 to < 12 years in a phase 2/3 study (Jonas et al., 2021). Among children ages 3 to 11 years, weight-based doses of small film-coated pellets of GLE/PIB are as follows: 250 mg GLE plus 100 mg PIB (in children weighing ≥30 kg to <45 kg), 200 mg GLE plus 80 mg PIB (≥20 kg to <30 kg), and 150 mg GLE plus 60 mg PIB (12 kg to <20 kg). Pellets are mixed with 1 to 2 teaspoons of a soft food vehicle such as hazelnut spread, yogurt, or peanut butter. Ninety six percent of children ages 3 to 11 years achieved SVR with these weight-based doses (8 weeks of GLE/PIB).

In GLE/PIB licensing trials, no overall differences in safety or effectiveness were observed between subjects over 65 years of age and younger subjects.

Grazoprevir/Elbasvir

Grazoprevir (GZR) is an NS3 protease inhibitor; *elbasvir* (EBR) is an NS5A inhibitor. These drugs are available in a single fixed-dose combination tablet.

Mechanism of Action and Resistance. *Grazoprevir* and EBR are inhibitors of the NS3 and NS5A viral enzymes, respectively. In trials, preexisting NS3 RASs were detected in 57% and 19% of individuals with genotype 1a and 1b, respectively, but the presence of preexisting NS3 RASs does not reduce the likelihood of high SVR rates. The presence of preexisting NS5A RASs did reduce SVR rates in genotype 1a patients. SVR rates were 58% and 68% in genotype 1a treatment-naïve and treatment-experienced patients, respectively, with preexisting NS5A RASs. Adding *ribavirin* and

extending the treatment duration greatly increase SVR rates in patients with preexisting NS5A RASs.

ADME. GZR/EBR is dosed as a single 100-mg/50-mg fixed-dose combination tablet taken once daily without regard to meals, although a high-fat meal will increase the AUC and C_{max} of GZR by 1.5- and 2.8-fold. The bioavailability of EBR is 30%; that of GZR ranges from 10% to 40%. The $t_{1/2}$ of GZR is about 30 h. EBR has a $t_{1/2}$ of 23 h. Less than 1% of GZR and EBR are renally eliminated. Both drugs are extensively (~99%) bound. GZR exposures are increased 62% in those with mild (Child-Pugh A) and 388% in those with moderate (Child-Pugh B) hepatic impairment relative to those with no hepatic impairment. Total concentrations of EBR are 24% and 14% lower in patients with mild and moderate hepatic insufficiency, respectively, likely a reflection of reduced serum protein levels. GZR and EBR pharmacokinetics in individuals with ESRD on hemodialysis are comparable to individuals without hepatic impairment. The AUCs of GZR and EBR are increased, however, by 65% and 86%, respectively, in those with eGFR less than 30 mL/min/1.73 m^2 not receiving dialysis. As with other hepatically metabolized DAAs, this increase may be due to accumulation of uremic toxins, parathyroid hormone, or cytokines that can impair hepatic metabolism. The GZR AUCs are 1.2- to 2.1-fold higher in HCV-infected individuals compared with HCV-uninfected individuals. There are no differences in EBR pharmacokinetics in HCV-seropositive versus -seronegative individuals.

Therapeutic Uses. GZR/EBR is FDA-approved for HCV genotypes 1 and 4 and in those with renal impairment.

Based on clinical trials, 95% of treatment-naïve individuals with primarily genotype 1 disease will achieve SVR after 12 weeks of GZR/EBR (SVR rates: 92% with genotype 1a, 99% with genotype 1b, 100% with genotype 4, and 80% with genotype 6). There are no differences in response between cirrhotics and noncirrhotics, but lower SVR rates (58% vs. 99%) are observed in patients with preexisting NS5A RASs. Thus, NS5A resistance testing needs to be performed for individuals with genotype 1a before starting GZR/EBR. In genotype 1a individuals with preexisting NS5A RASs, adding *ribavirin* and treating for an additional 4 weeks for a total of 16 weeks improves SVR rates. SVR rates are similar in patients with HIV coinfection, but drug interactions with antiretroviral therapy are an important consideration in this population.

Grazoprevir/elbasvir has demonstrated safety and efficacy in the treatment of HCV-infected patients with impaired renal function. In a trial of individuals (14% cirrhotic) with eGFR less than 30 mL/min/1.73 m^2 (76% of whom were hemodialysis dependent), the SVR after 12 weeks of treatment was 94%. The percentage of patients reporting any adverse event (~75%) was similar to studies of GZR/EBR in patients without renal impairment. More serious events occurred in these patients (15% vs. 3%), but many were not considered related to GZR/EBR treatment (Roth et al., 2015).

Untoward Effects and Drug Interactions. The most common side effects with GZR/EBR are headache (17%), fatigue (16%), and nausea (9%–15%). Higher exposures of GZR are associated with liver function test elevations. GZR may increase bilirubin concentrations through inhibition of OATP1B1.

Grazoprevir is a substrate for CYP3A4, P-gp, and OATP1B1. OATP1B1 inhibitors (e.g., HIV protease inhibitors) and moderate/strong CYP3A and P-gp inducers (including *efavirenz*) are not recommended for coadministration with GZR/EBR. EBR is a substrate for CYP3A4 and P-gp and an inhibitor of BCRP and P-gp.

Pediatric and Geriatric Uses. GZR/EBR has not been studied in children, and no dedicated studies have been performed in older patients. No age effect was observed in EBR pharmacokinetics in young (22–45 years) versus elderly (65–78 years) males; elderly females had a 33% higher EBR AUC compared with elderly men even after adjustment for body weight.

Investigational Agents and the Future for Treatment of HCV

Available agents achieve cure in the vast majority of patients; thus, HCV drug development has slowed considerably. The remaining challenges for this disease are testing and diagnosis, linkage to care, increasing access to therapy, and management of special patient populations, including patients with acute HCV, pregnant women, and after transplant for persons who received HCV-positive organs.

Drug Facts for Your Personal Formulary: *Viral Hepatitis (HBV/HCV)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Hepatitis B Therapy		
Pegylated interferon alfa	• Preferred agent • Approved for adult patients with compensated liver disease and evidence of viral replication and liver inflammation • Administered SC weekly for 48–52 weeks	• Adverse reactions (>40%): fatigue/asthenia, pyrexia, myalgia, and headache • May cause fatal neuropsychiatric, autoimmune, ischemic, and infectious disorders • Frequent hematological monitoring required • Contraindicated in advanced liver disease and in pregnancy
Entecavir	• Preferred agent • Approved for individuals ≥2 years old • Indefinite treatment for patients with cirrhosis	• Use higher dose for decompensated cirrhosis and patients with lamivudine or telbivudine resistance • Take on an empty stomach • Monitor for lactic acidosis in decompensated cirrhosis • Adverse reactions (≥3%): headache, fatigue, dizziness, nausea
Tenofovir disoproxil fumarate	• Preferred agent • Approved for individuals ≥2 years old • Indefinite treatment for patients with cirrhosis	• Dose reduction in renal impairment • Monitor renal function • May decrease bone mineral density • Adverse reactions (≥10%) in decompensated cirrhosis: abdominal pain, nausea, insomnia, pruritus, vomiting, dizziness, and pyrexia
Tenofovir alafenamide fumarate	• Preferred agent • Approved for ages 18 and older • Indefinite treatment for patients with cirrhosis	• Avoid drugs that strongly affect P-gp and BCRP • Most common adverse reaction (≥10%) is headache • Monitor renal function • Not recommended for eGFR <15 mL/min/1.73 m^2 • Take with food

Drug Facts for Your Personal Formulary: *Viral Hepatitis (HBV/HCV) (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Adefovir Lamivudine Telbivudine	• Alternative agents due to high incidence of HBV resistance with monotherapy • Indefinite treatment for patients with cirrhosis	• Dose adjust for renal impairment • Abrupt discontinuation causes hepatitis flares • Common adverse reactions: • *Adefovir*: asthenia and impaired renal function • *Lamivudine*: ear, nose, and throat infections; sore throat; and diarrhea • *Telbivudine*: increased creatinine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy
Hepatitis C Therapy		
Sofosbuvir/ledipasvir	• HCV genotypes 1, 4, 5, and 6 • Administered as fixed-dose combination tablet for 8 or 12 weeks • Use with ribavirin for 12 weeks in treatment-experienced patients with cirrhosis • Weight-based dosing approved in children aged ≥3 years with genotype 1, 4, 5, or 6	• Ledipasvir should not be used with potent P-gp inducers • Ledipasvir absorption requires acid gastric pH • Coadministration of sofosbuvir and amiodarone may cause severe bradycardia and fatal cardiac arrest • Adverse reactions (≥10%): fatigue, headache
Sofosbuvir/daclatasvir	• Activity against all genotypes; seldom used in the U.S. due to availability of cheaper fixed-dose combinations • 12-week treatment in patients without cirrhosis • Coadministered with ribavirin in patients with cirrhosis for 12 weeks	• Daclatasvir should not be used with potent CYP3A inducers • Daclatasvir dose reduction needed with strong CYP3A inhibitors • Coadministration of sofosbuvir and amiodarone may cause severe bradycardia and fatal cardiac arrest • Adverse reactions (≥10%): fatigue, headache
Sofosbuvir/velpatasvir	• Approved for use in all HCV genotypes • Administered as fixed-dose combination tablet for 12 weeks • Cirrhotic patients with genotype 3 and Y93H RAS have ↓ SVR and require alternative therapy • Used with ribavirin for patients with decompensated cirrhosis • Approved for use in children ≥6 years or weighing ≥17 kg	• Do not use with potent P-gp or CYP3A inducers • Velpatasvir requires acidic gastric pH • Coadministration of sofosbuvir and amiodarone may cause severe bradycardia and fatal cardiac arrest • Adverse reactions (≥10%): fatigue and headache
Sofosbuvir/velpatasvir/voxilaprevir	• Used for second-line treatment of patients who have previously failed a DAA regimen • All genotypes receive one fixed-dose combination tablet once daily for 12 weeks • Patients with genotype 3 and cirrhosis require the addition of ribavirin	• Do not use with potent P-gp or CYP3A inducers or potent OATP1B1 inhibitors • Do not use with BCRP substrates with narrow therapeutic indices • Velpatasvir requires acidic gastric pH • Coadministration of sofosbuvir and amiodarone may cause severe bradycardia and fatal cardiac arrest • Avoid ethinyl estradiol–containing hormonal contraception during and for 2 weeks after treatment due to potential hepatotoxicity • Adverse reactions (≥10%): headache, fatigue, diarrhea, nausea • Contraindicated in advanced liver disease
Glecaprevir/pibrentasvir	• Approved for use in all HCV genotypes aged >12 years or ≥45 kg • Administered as three fixed-dose combination tablets once a day for 8 weeks • Preferred treatment in renal impairment • Weight-based dosing in children ≥3 years, FDA-approved, June 2021	• Do not use with potent P-gp or CYP3A inducers or potent OATP1B1 inhibitors • Avoid ethinyl estradiol–containing hormonal contraception during and for 2 weeks after treatment due to potential hepatotoxicity • Adverse reactions (≥10%): headache and fatigue • Contraindicated in advanced liver disease
Grazoprevir/elbasvir	• 12-week therapy for patients without baseline NS5A RASs • 16-week combined therapy with ribavirin for patients with baseline NS5A RASs • Preferred treatment in renal impairment	• Should not be used with moderate and strong CYP3A and P-gp inducers • Should not be used with OATP1B1 inhibitors • Adverse reactions (≥10%): headache, fatigue, nausea • Contraindicated in advanced liver disease
Ribavirin	• Used in combination with other HCV regimens to boost therapeutic efficacy	• May cause hemolytic anemia • Teratogenic • Wide tissue distribution • Long half-life (7–10 days) • Dose adjustment needed for renal impairment

Chapter 64 Antiretroviral Agents and Treatment of HIV Infection

Charles W. Flexner

Safe and effective pharmacotherapy to treat and prevent human immunodeficiency virus (HIV) is one of the greatest achievements of science and public health in the past century. Infected individuals who maintain a daily oral regimen now have a normal or near-normal life expectancy. More than 30 approved drugs and dozens of formulations have produced thousands of possible drug combinations, but most patients receive one of a handful of well-tolerated and rigorously tested regimens. Unique features of antiretroviral therapy include the need for lifelong treatment to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly. Although three-drug and two-drug combination oral regimens have radically altered the course of this epidemic, future options will include long-acting injectable and implantable formulations.

Pathogenesis of HIV-Related Disease

Human immunodeficiency viruses are lentiviruses, a family of retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment, there is generally no true period of latency following infection (Deeks et al., 2015). Humans and nonhuman primates are the only natural hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to simian immunodeficiency virus (SIV) and is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar sensitivity to most antiretroviral drugs, although the nonnucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-1 specific and have no activity against HIV-2.

Virus Structure

HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane (Figure 64–1). The viral genome encodes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins of the virus; *pol* overlaps *gag* and encodes three important enzyme activities (an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase); and *env* encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include *tat*, *rev*, *nef*, and *vpu*.

Virus Life Cycle

Understanding the HIV life cycle (Figure 64–1) is crucial to understanding rational therapy of the infection. HIV tropism is controlled by the envelope protein gp160 (*env*). The major target for *env* binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptors CCR5 or CXCR4. CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines. A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of $CD4^+$ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still controversial, but it is possible to develop clinical AIDS without this switch (Deeks et al., 2015).

The gp41 domain of *env* controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA-DNA duplex; the original RNA is degraded by the RNase H activity of reverse transcriptase to allow creation of a full-length double-stranded DNA copy of the virus. Because the HIV reverse transcriptase is error prone and lacks a proofreading function, mutation is frequent and occurs at about three bases for every full-length (9300-base-pair) replication (Coffin, 1995). Virus-derived DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

Following integration, the virus may remain quiescent, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the viral DNA is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid. The envelope and structural proteins assemble at the cell surface, concentrating in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles, so replication can begin immediately after the virus enters a new cell.

How the Virus Causes Disease

Sexual acquisition of HIV infection is likely mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2 to 4 weeks, with $\geq 10^9$ $CD4^+$ cells

Abbreviations

ABC: abacavir
ADME: absorption, distribution, metabolism, excretion
AIDS: acquired immunodeficiency syndrome
5′-AMP: adenosine 5′-monophosphate
AUC: area under plasma concentration-time curve
CBT: cabotegravir
cDNA: complementary DNA
CL_{Cr}: creatinine clearance
CMP: cytidine monophosphate
CNS: central nervous system
CSF: cerebrospinal fluid
CYP: cytochrome P450
dCMP: deoxycytidine monophosphate
ddC: dideoxycytidine
ddI: didanosine
DF: disoproxil fumarate
DRESS: drug reaction with eosinophilia and systemic symptoms
d4T: stavudine
eCL_{Cr}: estimated creatinine clearance
***env*:** envelope protein gp160
FDA: Food and Drug Administration
FTC: emtricitabine
GI: gastrointestinal
HBV: hepatitis B virus
HCV: hepatitis C virus
HIV: human immunodeficiency virus
HTLV: human T-cell lymphotrophic virus
IMP: inosine 5′-monophosphate
InSTI: integrase strand transfer inhibitor
IRIS: immune reconstitution inflammatory syndrome
LA: long-acting
LTR: long terminal repeat
NDP: nucleoside diphosphate
NNRTI: nonnucleoside reverse transcriptase inhibitor
NRTI: nucleos(t)ide reverse transcriptase inhibitor
OATP: organic anion-transporting polypeptide
PI: protease inhibitor
PK: pharmacokinetic
PRPP: phosphoribosyl pyrophosphate
QTc: corrected cardiac QT interval
RNase H: ribonuclease H
RPV: rilpivirine
RT: reverse transcriptase
SIV: simian immunodeficiency virus
$t_{1/2}$: half-life of elimination
TAF: tenofovir alafenamide
TAM: thymidine analogue mutation
3TC: lamivudine
TDF: tenofovir disoproxil fumarate
vRNA: viral RNA
ZDV: zidovudine

becoming infected. This peak is associated with a transient dip in the number of peripheral $CD4^+$ (helper) T lymphocytes. With a balance of new host immune responses and target cell depletion, the number of infectious virions as reflected by the plasma HIV RNA concentration (also known as viral load) declines to a quasi-steady state or set point. This set point reflects the interplay between host immunity and the pathogenicity of the infecting virus (Coffin, 1995). In the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host $CD4^+$ T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm^3, there is an increasing risk of opportunistic diseases and, ultimately, death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical AIDS of 8 to 10 years if the patient is not treated. Some patients, termed long-term nonprogressors, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses.

An important question relevant to treatment is whether AIDS is a consequence of $CD4^+$ lymphocyte depletion alone. Most natural history data suggest that this is true. Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit (Deeks et al., 2015).

Principles of HIV Chemotherapy

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly $CD4^+$ T lymphocytes. *The goal of therapy is to suppress virus replication as much as possible for as long as possible.* The current standard of care is to use three different antiretroviral drugs simultaneously for initial treatment and two to three drugs for the remaining duration of treatment (Flexner, 2019).

Two large randomized clinical trials found substantial clinical benefit from initiating antiretroviral therapy regardless of baseline CD4 count (INSIGHT START Study Group, 2015; TEMPRANO ANRS 12136 Study Group, 2015); thus, the current global standard of care is to offer treatment to all infected individuals whenever possible (World Health Organization, 2021). Substantial evidence confirms the value of antiretroviral therapy in preventing transmission of the virus from person to person (Cohen et al., 2011) and suggests that infected individuals with an undetectable viral load are incapable of transmitting the virus to others.

Drug resistance remains a key problem. There is a high likelihood that all untreated infected individuals harbor viruses with single-amino-acid mutations that confer some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). Thus, a combination of active agents is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (see Chapter 65). Prolonged drug holidays may allow the virus to replicate anew, increasing the risk of drug resistance and disease progression; such breaks in treatment are associated with increased morbidity and mortality and are not generally recommended (Lawrence et al., 2003).

The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA <50 copies/mL) within 24 weeks of starting treatment. In treatment-naïve patients, a regimen containing a nonnucleoside plus two nucleos(t)ide reverse transcriptase inhibitors (NRTIs) is as effective as a regimen containing an additional nucleoside (Shafer et al., 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs may be used simultaneously in patients harboring drug-resistant virus, but the number of agents a patient can tolerate is limited by toxicity and inconvenience. Most patients today can be maintained on a two- or three-drug regimen, even if they are highly treatment experienced.

Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA of greater than 200 copies/mL in a patient with previously undetectable virus, despite continued treatment with that regimen. This is associated with a high probability of resistance to one or more of the drugs in the regimen and necessitates a change in treatment. The selection of new agents is informed by the patient's treatment history and viral resistance testing. Treatment failure indicates the need for a completely new combination of drugs if possible (Department of Health and Human Services, 2019). Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all other drugs

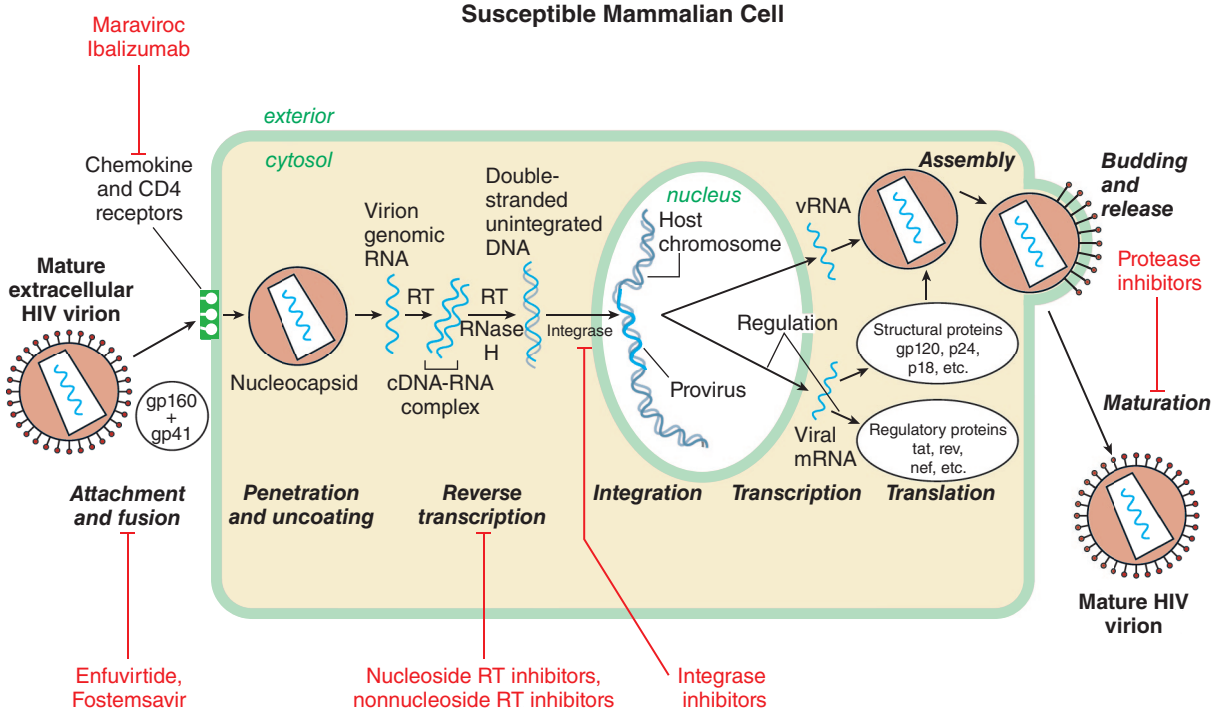

Figure 64–1 *Replicative cycle of HIV-1 showing the sites of action of available antiretroviral agents.* Available antiretroviral agents are shown in red. In this figure, gp120 + gp41 indicates extracellular and intracellular domains, respectively, of envelope glycoprotein.

in the regimen. The risk of failing a regimen also depends on the percentage of prescribed doses taken during a given period of treatment.

As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of great importance. Several approved antiretroviral agents (*lamivudine*, *emtricitabine*, and the integrase strand transfer inhibitors [InSTIs]) have few or no clinically significant toxicities in most patients. Protease inhibitors (PIs) and NNRTIs can produce clinically significant pharmacokinetic drug interactions, since all agents in these two drug classes can act as inhibitors and/or inducers of hepatic CYPs, other drug-metabolizing enzymes, and drug transport proteins (University of Liverpool, 2021; see also Chapters 4 and 5). An uncommon complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections. This immune reconstitution inflammatory syndrome (IRIS) is most commonly seen when initiating therapy in individuals with very low CD4 counts or advanced HIV disease. Infections commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and *Pneumocystis* pneumonia (Manabe et al., 2007).

Drugs Used to Treat HIV Infection

Nucleoside and Nucleotide Reverse Transcriptase Inhibitors

Overview

HIV-encoded, RNA-dependent DNA polymerase, also called reverse transcriptase, converts viral RNA into proviral DNA, which is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogues or nonnucleoside inhibitors (Table 64–1). NRTIs prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nearly all patients starting antiretroviral treatment do so with at least one agent from this class. Figure 64–2 shows the mechanism of action of NRTIs, which involves phosphorylation by host cells to the active inhibitory form. All but one of the drugs in this class (see structures in Figure 64–3) are nucleosides that must be triphosphorylated at the 5′-hydroxyl to exert activity. The sole exception, *tenofovir*, is a nucleoside monophosphate analogue that requires two additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; *emtricitabine*, *lamivudine*, and *tenofovir* are active against hepatitis B virus (HBV; see Chapter 63), whereas *tenofovir* also has activity against herpesviruses (see Chapter 62).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase α and polymerase β, some can inhibit human DNA polymerase γ, which is the mitochondrial enzyme. As a result, the important toxicities common to older representatives of this class of drugs result largely from the inhibition of mitochondrial DNA synthesis (Lee et al., 2003). These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with *stavudine*, *zidovudine*, and *didanosine*. Phosphorylated *emtricitabine*, *lamivudine*, and *tenofovir* have low affinity for DNA polymerase γ and are largely devoid of mitochondrial toxicity.

Table 64–2 summarizes the pharmacokinetic properties of NRTIs approved for treating HIV infection. Figure 64–4 shows the cellular routes that catalyze the activation of NRTIs. In general, the phosphorylated anabolites are eliminated from cells much more gradually than the parent drug is eliminated from the plasma. As a result, available NRTIs are dosed once or twice daily. These drugs are not major substrates for hepatic CYPs. Pharmacokinetic drug interactions involving *tenofovir* and PIs are likely explained by inhibition of OATP and other drug transporters (Chapman et al., 2003; see also Chapter 4). High-level resistance to NRTIs, especially thymidine analogues, occurs slowly by comparison to NNRTIs and first-generation PIs. High-level resistance can occur rapidly with *lamivudine* and *emtricitabine*. Cross-resistance is common but often confined to drugs having similar chemical structures. Several nucleoside analogues have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens (Kuritzkes, 2011).

Zidovudine

Zidovudine is a synthetic thymidine analogue (Figure 64–3) with potent activity against a broad spectrum of retroviruses, including HIV-1,

TABLE 64–1 ■ ANTIRETROVIRAL AGENTS APPROVED FOR USE IN THE U.S.

GENERIC NAME	ABBREVIATION; CHEMICAL NAME
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors	
Zidovudine[a]	ZDV; azidothymidine (AZT)
Didanosine[b]	ddI; dideoxyinosine
Stavudine	d4T; didehydrodeoxythymidine
Zalcitabine[c]	ddC; dideoxycytidine
Lamivudine[a]	3TC; dideoxythiacytidine
Abacavir[a]	ABC; amino-cyclopropylamino-purinylcyclopentenylmethanol
Tenofovir disoproxil[a,d] Tenofovir alafenamide[a,d]	TDF; TAF; phosphono-methoxypropyladenine (PMPA)

Cabotegravir	CBT

[a]A number of fixed-dose coformulations are available; these are described in more detail in the text.
[b]No longer marketed in the U.S.
[c]No longer marketed worldwide.
[d]Tenofovir disoproxil fumarate is a nucleotide prodrug of the nucleoside tenofovir.
[e]Lopinavir is available only as part of a fixed-dose coformulation with ritonavir.
[f]Only available as a coformulation with other antiretroviral agents.

HIV-2, and HTLVs I and II. It was the first FDA-approved antiretroviral drug. *Zidovudine* is active in lymphoblastic and monocytic cell lines but has no impact on cells already infected with HIV. *Zidovudine* appears to be more active in activated than in resting lymphocytes because the phosphorylating enzyme, thymidine kinase, is S-phase specific (Cihlar and Ray, 2010). *Zidovudine* is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission; it was previously recommended for postexposure prophylaxis in HIV-exposed healthcare workers but is rarely used for this indication because of its potential toxicity as compared to alternatives. *Zidovudine* is marketed in oral tablets, capsules, and solution as well as a solution for intravenous injection. *Zidovudine* is available in coformulated tablets with *lamivudine* or with *lamivudine* and *abacavir*. *Zidovudine* is mainly used in pediatric applications and is less commonly used in adults because of its potential toxicity.

Mechanisms of Action and Resistance. Intracellular *zidovudine* is phosphorylated to zidovudine 5′-triphosphate. Zidovudine triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3′-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate formed. Zidovudine triphosphate only weakly inhibits cellular DNA polymerase α but is a more potent inhibitor of mitochondrial polymerase γ. Because the conversion of zidovudine monophosphate to diphosphate is inefficient, high concentrations of the monophosphate accumulate inside cells and may serve as a precursor depot for formation of triphosphate. Consequently, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of triphosphate, and higher plasma concentrations of *zidovudine* do not increase intracellular triphosphate concentrations proportionately.

Resistance to *zidovudine* is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219. These mutations are referred to as thymidine analogue mutations (TAMs) because of their ability to confer cross-resistance to other thymidine analogues, such as *stavudine*. The M184V substitution in the reverse transcriptase gene associated with the use of *lamivudine* or *emtricitabine* greatly restores sensitivity to *zidovudine* (Kuritzkes, 2011). The combination of *zidovudine* and *lamivudine* produces greater long-term suppression of plasma HIV RNA than does *zidovudine* alone.

ADME. *Zidovudine* is absorbed rapidly and reaches peak plasma concentrations within 1 h. Table 64–2 summarizes the drug's pharmacokinetic profile, which is not altered significantly during pregnancy; drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and is also detectable in breast milk, semen, and fetal tissue.

Untoward Effects and Drug Interactions. Patients initiating *zidovudine* often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia; these symptoms usually resolve within a few weeks. Erythrocytic macrocytosis is seen in about 90% of patients but usually is not associated with anemia. Chronic *zidovudine* administration has been associated with nail hyperpigmentation. Skeletal myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase γ. Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal.

Probenecid, fluconazole, atovaquone, and *valproic acid* may increase plasma concentrations of *zidovudine*, probably through inhibition of glucuronosyl transferases. *Zidovudine* is neither a prominent substrate nor potent inhibitor of CYPs. *Zidovudine* can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. *Stavudine* and *zidovudine* compete for intracellular phosphorylation and should not be used concomitantly.

Lamivudine

Lamivudine is a cytidine analogue reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and hepatitis B virus (HBV). *Lamivudine* is

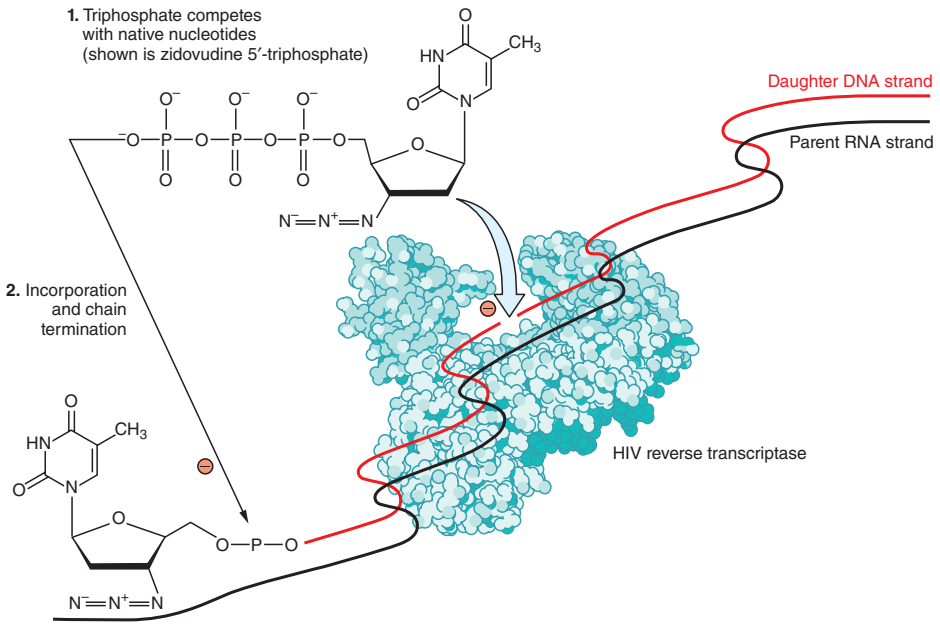

Figure 64–2 *Mechanism of NRTIs. Zidovudine* is depicted; Table 64–1 lists other agents in the NRTI class. Nucleoside and nucleotide analogues must enter cells and be phosphorylated to generate synthetic substrates for reverse transcriptase. The fully phosphorylated analogues block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3′-hydroxyl group.

approved for HIV in adults and children aged 3 months or older. *Lamivudine* has been effective in combination with other antiretroviral drugs in both treatment-naïve and -experienced patients and is a common component of therapy, given its safety, convenience, and efficacy (Cihlar and Ray, 2010). *Lamivudine* is also approved for treatment of chronic HBV (see Chapter 63).

Mechanisms of Action and Resistance. *Lamivudine* enters cells by passive diffusion and is sequentially phosphorylated to lamivudine 5′-triphosphate, which is the active anabolite. *Lamivudine* has low affinity for human DNA polymerases, explaining its low toxicity to the host. High-level resistance to *lamivudine* occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce *in vitro* sensitivity to *lamivudine* as much as 1000-fold. The M184V mutation restores *zidovudine* susceptibility in *zidovudine*-resistant HIV and partially restores *tenofovir* susceptibility in *tenofovir*-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). This effect may contribute to the sustained virologic benefits seen with combinations of *zidovudine* and *lamivudine*.

ADME. Table 64–2 summarizes the pharmacokinetic parameters for this drug. *Lamivudine* is excreted primarily unchanged in the urine; dose adjustment is recommended for patients with a creatinine clearance less than 50 mL/min. *Lamivudine* freely crosses the placenta into the fetal circulation.

Untoward Effects and Precautions. *Lamivudine* is one of the least toxic antiretroviral drugs. Neutropenia, headache, and nausea have

been reported at higher-than-recommended doses. Pancreatitis has been reported in pediatric patients. Because *lamivudine* also has activity against HBV, caution is warranted in using this drug in patients coinfected with HBV or in HBV-endemic areas: Abrupt discontinuation of *lamivudine* may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Abacavir

Abacavir, a synthetic purine analogue, is approved for the treatment of HIV-1 infection in combination with other antiretroviral agents. *Abacavir* is available in a coformulation with *zidovudine* and *lamivudine* for twice-daily dosing, and in a coformulation with *lamivudine*, or *lamivudine* and *dolutegravir*, for once-daily dosing. *Abacavir* is approved for use in adult and pediatric patients aged 3 months or older, with dosing in the latter based on body weight.

Mechanisms of Action and Resistance. *Abacavir* is the only approved antiretroviral that is active as a guanosine analogue. It is sequentially phosphorylated in the host cell to carbovir 5′-triphosphate, which terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3′-hydroxyl group (Cihlar and Ray, 2010). Clinical resistance to *abacavir* is associated with four specific substitutions: K65R, L74V, Y115F, and M184V. In combination, these substitutions can reduce susceptibility by up to 10-fold. K65R confers cross-resistance to all nucleosides except *zidovudine*. An alternate pathway for *abacavir* resistance involves mutations at RT codons 41, 210, and 215 (Kuritzkes, 2011).

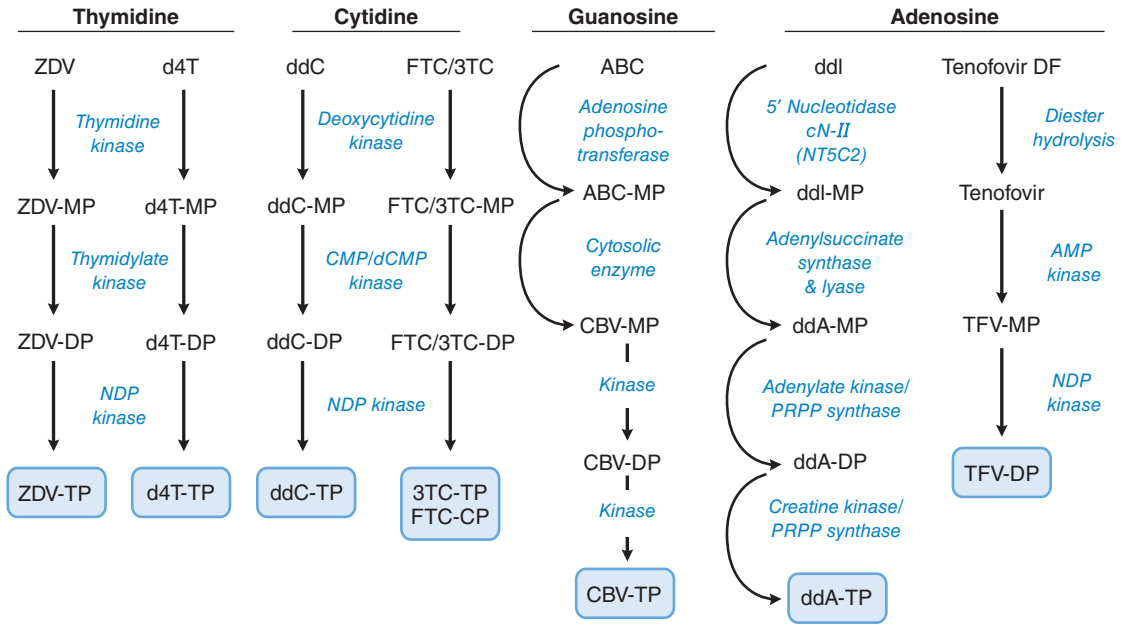

Figure 64–4 *Intracellular activation of nucleoside analogue reverse transcriptase inhibitors.* Drugs and phosphorylated anabolites are abbreviated (see Table 64-1); the enzymes responsible for each conversion are spelled out. The active antiretroviral anabolite for each drug is shown in the blue box. (Adapted with permission from Khoo SH, et al. Pharmacology. In: Boucher CAB, Galasso GAJ, eds. *Practical Guidelines in Antiviral Therapy*. Elsevier, New York, **2002**, 13–35. Copyright © Elsevier.) MP, monophosphate; DP, diphosphate; TP, triphosphate.

ADME. Table 64–2 summarizes the pharmacokinetic parameters for this agent. The presence of food does not affect the oral bioavailability of *abacavir*. *Abacavir* is neither a substrate nor an inhibitor of CYPs. Its CSF/plasma AUC ratio is about 0.3.

Untoward Effects and Drug Interactions. The most important adverse effect of *abacavir* is a unique and potentially fatal hypersensitivity syndrome characterized by fever, abdominal pain, and other GI complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea), musculoskeletal complaints, headache, and paresthesias are less common. The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting *abacavir* is diagnostic and necessitates immediate discontinuation of the drug. Once discontinued for hypersensitivity, *abacavir* must never be restarted. The hypersensitivity syndrome (2%–9% of patients) results from a genetically mediated immune response linked to both the HLA-B*5701 locus and the M493T allele in the heat-shock locus Hsp70-Hom. The *Hsp* gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor α release after exposure of human lymphocytes to *abacavir ex vivo* (White et al., 2015). *Abacavir* should not be used in anyone known to carry the HLA-B*5701 locus (~10% of Caucasians).

Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increases the *abacavir* plasma AUC by 41% and prolongs the elimination $t_{1/2}$ by 26%, possibly owing to competition for alcohol dehydrogenase, which produces the dehydro-metabolite of the drug (see Table 64–2).

Tenofovir

Tenofovir is a derivative of 5′-AMP that lacks a complete ribose ring; it is the only nucleotide analogue currently marketed for the treatment of HIV infection. *Tenofovir* is available as the disoproxil or alafenamide prodrugs, which substantially improve oral absorption. *Tenofovir* is active against HIV-1, HIV-2, and HBV. *Tenofovir disoproxil fumarate* (TDF) is FDA-approved for treating HIV infection in adults and children older than 2 years in combination with other antiretroviral agents and for the treatment of chronic hepatitis B in adults and children older than 12. It is also approved for HIV preexposure prophylaxis (in combination with *emtricitabine*) in adults at high risk of acquiring the infection. TDF is available in a variety of oral coformulations and is the most widely used antiretroviral globally. *Tenofovir alafenamide* (TAF) is FDA-approved for the treatment of HIV and HBV and for HIV prophylaxis in combination with *emtricitabine*. The advantages of TAF over TDF include lower dose and less long-term renal and bone toxicity (Sax et al., 2015). TAF is currently available in coformulation with *elvitegravir, cobicistat*, and *emtricitabine*; with *bictegravir* and *emtricitabine*; with *rilpivirine* and *emtricitabine*; or with *emtricitabine*.

Mechanisms of Action and Resistance. *Tenofovir disoproxil* is hydrolyzed rapidly to *tenofovir*, which is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate, which is actually a triphosphate: The parent drug is a monophosphate (Figure 64–3) (Cihlar and Ray, 2010). The disposition of oral *tenofovir alafenamide* is similar, but it circulates largely as the uncleaved prodrug, which is taken up into cells and then converted to the parent nucleotide; consequently, circulating concentrations of *tenofovir*, which may contribute to renal toxicity, are much lower than produced by the disoproxil fumarate prodrug. Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerase α, polymerase β, and polymerase γ, which is the basis for its selective toxicity.

Specific resistance occurs with a K65R substitution in RT that has been associated with clinical failure of *tenofovir*-containing regimens. *Tenofovir* sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to *zidovudine* or *stavudine*. The M184V mutation associated with *lamivudine* or *emtricitabine* resistance partially restores susceptibility in *tenofovir*-resistant HIV harboring the K65R mutation (Kuritzkes, 2011).

ADME. Table 64–2 shows pharmacokinetic data for *tenofovir*. Following an intravenous dose, 70% to 80% of the drug is recovered unchanged in the urine; thus, doses should be decreased in those with renal insufficiency. *Tenofovir* is not known to inhibit or induce CYPs.

Untoward Effects and Drug Interactions. *Tenofovir* generally is well tolerated, with few significant symptoms reported except for flatulence. Rare episodes of acute renal failure and Fanconi syndrome have been reported, and this drug should be used with caution in patients with preexisting renal disease. *Tenofovir* use is associated with small declines in eCL_{Cr} (estimated creatinine clearance) after months of treatment in some patients; because the dose needs to be reduced in renal insufficiency, renal function (creatinine and phosphorus) should be monitored regularly. Because *tenofovir* also has activity against HBV, caution is warranted in using this drug in patients coinfected with HBV: Abrupt discontinuation of *tenofovir* may be associated with a rebound of HBV replication and exacerbation of hepatitis. *Tenofovir* can increase the AUC of *didanosine*, and the two drugs should not be used together (Cihlar and Ray, 2010).

Tenofovir plasma concentrations are increased by 30% to 50% if combined with the pharmacokinetic enhancers *ritonavir* or cobicistat due to inhibition of renal drug transporters. Similar effects are seen with the HCV NS5A inhibitors *ledipasvir* and *velpatasvir* (see Chapter 63). Regardless, these combinations are generally well tolerated and without producing significant renal injury. However, acute renal insufficiency has been reported when TDF is combined with the oral nonsteroidal *diclofenac*.

Emtricitabine

Emtricitabine is a cytidine analogue that is chemically related to *lamivudine* and shares many of its properties. *Emtricitabine* is active against HIV-1, HIV-2, and HBV. The drug is FDA-approved for treating HIV infection in adults, children, and infants, in combination with other antiretroviral agents, and is available coformulated with TDF with or without *efavirenz* or with either *tenofovir* prodrug plus *elvitegravir* and *cobicistat*; *bictegravir* and *cobicistat*; or *rilpivirine*. *Emtricitabine* is approved for HIV preexposure prophylaxis (in combination with *tenofovir*) in adults at high risk of acquiring the infection.

Mechanisms of Action and Resistance. *Emtricitabine* enters cells by passive diffusion and is sequentially phosphorylated to its active metabolite, emtricitabine 5′-triphosphate. High-level resistance to *emtricitabine* occurs with the same mutations affecting *lamivudine* (mainly M184I/V), although these appear to occur less frequently with *emtricitabine*. The M184V mutation restores sensitivity to *zidovudine* in *zidovudine*-resistant HIV and partially restores sensitivity to *tenofovir* in *tenofovir*-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). The same K65R mutation confers resistance to *emtricitabine* and the other cytidine analogue *lamivudine*, as well as *didanosine*, *stavudine*, and *abacavir*.

ADME. Table 64–2 summarizes pharmacokinetic data for *emtricitabine*. Orally administered drug is rapidly absorbed; the drug can be taken without regard to meals. *Emtricitabine* is excreted primarily unchanged in the urine; thus, the dose should be reduced in patients with CL_{Cr} below 50 mL/min.

Untoward Effects and Drug Interactions. *Emtricitabine* is one of the least-toxic antiretroviral drugs and has few significant adverse effects (Cihlar and Ray, 2010). Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Because *emtricitabine* also has *in vitro* activity against HBV, caution is warranted in using this drug in patients coinfected with HBV and in regions with high HBV seroprevalence; abrupt discontinuation of *emtricitabine* may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to known metabolic drug interactions.

Older NRTIs

Stavudine (d4T) and *didanosine* (ddI) are no longer widely used because of their relative toxicity as compared to other NRTIs. *Dideoxycytidine* (ddC) is no longer marketed for the same reason. Detailed information about these drugs is available in previous editions of this book.

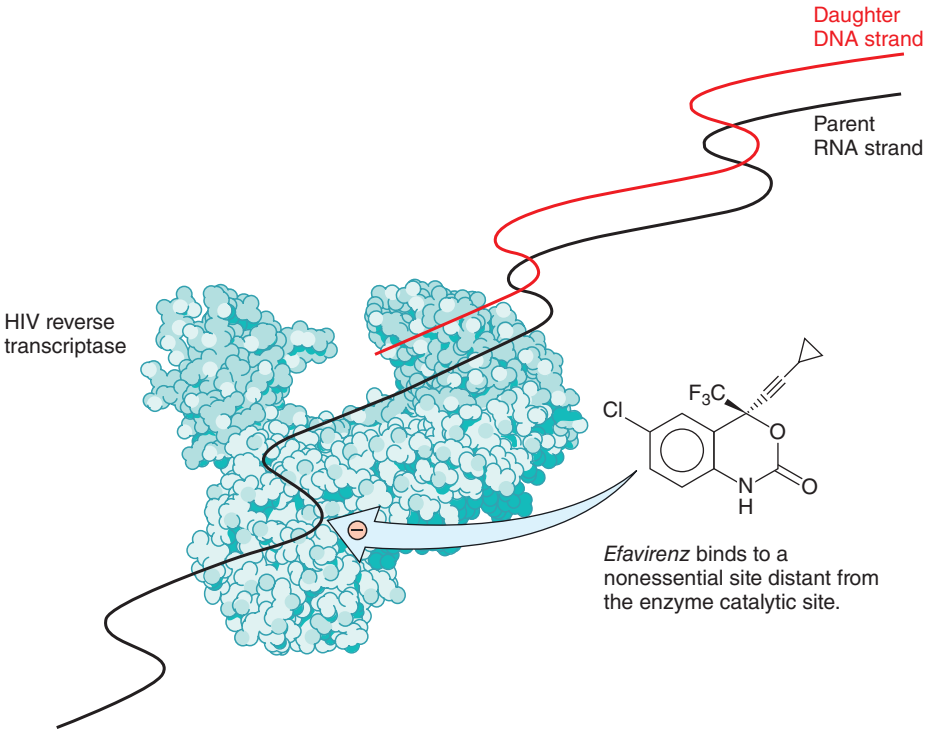

Figure 64–5 *Mechanism of NNRTIs.*

Nonnucleoside Reverse Transcriptase Inhibitors

Overview

The NNRTIs include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase, in a site distant from the active site (Figure 64–5). These compounds induce a conformational change in the three-dimensional structure of the enzyme that greatly reduces its activity, and thus, they act as noncompetitive inhibitors. Because the binding site for NNRTIs is virus-strain specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection. These compounds also have no activity against host cell DNA polymerases (de Bethune, 2010). The six approved NNRTIs are *nevirapine, efavirenz, etravirine, rilpivirine*, *delavirdine*, and *doravirine*. Table 64–3 summarizes their pharmacokinetic properties.

Agents in this class share a number of properties. All approved NNRTIs are eliminated from the body by hepatic metabolism. *Efavirenz, etravirine*, and *nevirapine* are moderately potent inducers of hepatic drug-metabolizing enzymes, including CYP3A4; *delavirdine* is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds. All NNRTIs except *etravirine* and *rilpivirine* are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181; Kuritzkes, 2011). Exposure to even a single dose of *nevirapine* in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman et al., 2004). These agents are potent and highly effective but should be combined with other active agents to avoid resistance. *NNRTIs should never be used as single agents in monotherapy or as the sole addition to a failing regimen.*

NNRTIs in combination with other antiretroviral drugs are associated with favorable long-term suppression of viremia and elevation of $CD4^+$ lymphocyte counts. Rashes occur frequently with all NNRTIs except doravirine, usually during the first 4 weeks of therapy. Rare cases of potentially fatal drug reaction with eosinophilia and systemic symptoms (DRESS) or Stevens-Johnson syndrome have been reported with *nevirapine, efavirenz, rilpivirine*, and *etravirine*. Fat accumulation can be seen after long-term use of some NNRTIs, and fatal hepatitis has been associated with *nevirapine* use (de Bethune, 2010).

TABLE 64–3 ■ PHARMACOKINETIC PROPERTIES OF NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS[a]

Nevirapine

Nevirapine is a dipyridodiazepinone NNRTI with potent activity against HIV-1. The drug is FDA-approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents. *Nevirapine* is approved for use in infants and children 15 days old or older, with dosing based on body surface area. Single-dose *nevirapine* was used widely in pregnant HIV-infected women to prevent mother-to-child transmission, but this practice is declining as more pregnant HIV-infected women are being placed on permanent multidrug antiretroviral regimens (de Bethune, 2010). *Nevirapine* for HIV treatment has largely been replaced by the less toxic *efavirenz* and is less widely used now as more patients begin therapy with or switch to InSTI-based regimens.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. The drug readily crosses the placenta and has been found in breast milk. *Nevirapine* is a moderate inducer of CYPs and induces its own metabolism. To compensate for this, the drug should be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred.

Untoward Effects and Drug Interactions. The most frequent adverse events associated with *nevirapine* are rash (in ~16% of patients) and pruritus. In most patients, the rash resolves with continued administration of drug; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with *nevirapine* use, and this may be more common in women with CD4 counts greater than 250 cells/mm^3, especially during pregnancy (de Bethune, 2010). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

Because *nevirapine* induces CYP3A4, this drug may lower plasma concentrations of coadministered CYP3A4 substrates. *Methadone* withdrawal has been reported in patients receiving *nevirapine*, presumably as a consequence of enhanced *methadone* clearance. Plasma *ethinyl estradiol* and *norethindrone* concentrations decrease by 20% with *nevirapine*; alternative methods of birth control are advised.

Efavirenz

Efavirenz (see structure in Figure 64–5) is an NNRTI with potent activity against HIV-1. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. *Efavirenz* is approved for adult and pediatric patients aged 3 months and older and weighing at least 3.5 kg. *Efavirenz* was widely used because of its convenience, effectiveness, and long-term tolerability. Especially popular was the once-daily, single-pill coformulation of *efavirenz*, TDF, and *emtricitabine* or *lamivudine*. A 400-mg daily dose of *efavirenz* may be equally efficacious and better tolerated than the standard 600-mg dose (ENCORE1 Study Group, 2014). *Efavirenz* can be safely combined with *rifampin* and is useful in patients also being treated for tuberculosis. *Efavirenz* use is likely to decline in the coming years as more patients begin therapy with or switch to InSTI-based regimens.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. *Efavirenz* is well absorbed from the GI tract, but there is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal. *Efavirenz* is more than 99% bound to plasma proteins and, consequently, has a low CSF-to plasma ratio of 0.01. The drug should be taken initially on an empty stomach at bedtime to reduce side effects. The long elimination $t_{1/2}$ permits once-daily dosing.

Untoward Effects and Drug Interactions. The most important adverse effects of *efavirenz* involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but fewer than 5% discontinue the drug for this reason. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy. Rash occurs frequently with *efavirenz* (27%), usually in the first few weeks of treatment, resolving spontaneously and rarely requiring drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome are rare (de Bethune, 2010). Other side effects reported with *efavirenz* include headache, increased hepatic transaminases, and elevated serum cholesterol. *Efavirenz* is the only antiretroviral drug that is teratogenic in primates, but careful clinical studies suggested that it is no more teratogenic in humans than other antiretroviral drugs (Ford et al., 2014).

Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor. *Efavirenz* decreases concentrations of *phenobarbital*, *phenytoin*, and *carbamazepine*; the *methadone* AUC is reduced by 33% to 66% at steady state. *Efavirenz* reduces the *rifabutin* AUC by about 38%. *Efavirenz* has a variable effect on HIV PIs: *Indinavir*, *saquinavir*, and *amprenavir* concentrations are reduced; *ritonavir* and *nelfinavir* concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., *phenobarbital*, *phenytoin*, and *carbamazepine*) would be expected to increase the clearance of *efavirenz* and should be avoided (de Bethune, 2010).

Rilpivirine

Rilpivirine is a diarylpyrimidine NNRTI with potent activity against HIV-1; Table 64–3 presents some of the drug's pharmacokinetic values. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. *Rilpivirine* has one of the best side effect profiles of available NNRTIs and has few or no CNS side effects compared to *efavirenz*. *Rilpivirine* retains efficacy against many HIV strains that are resistant to *efavirenz* and other earlier NNRTIs. However, higher concentrations of *rilpivirine* are associated with prolongation of the QTc interval, and at the approved dose of 25 mg/day, it is less effective than *efavirenz* in patients with baseline viral load greater than 100,000 copies/mL or CD4 count below 200 cells/mm^3 (Sharma and Saravolatz, 2013). Failure of a *rilpivirine*-containing regimen generally results in resistance that precludes the use of other NNRTIs. *Rilpivirine* is approved for adult and pediatric patients 12 years of age and older and weighing at least 35 kg. *Rilpivirine* is also available as once-daily, single-tablet coformulations with TDF and *emtricitabine*, TAF and *emtricitabine*, or *dolutegravir*. A nanocrystalline long-acting injectable formulation of *rilpivirine* was FDA-approved in early 2021 (see section on Long-Acting and Extended-Release Antiretroviral Formulations).

ADME. Table 64–3 summarizes the pharmacokinetic data for *rilpivirine*. Absorption of *rilpivirine* is both food and pH dependent. Bioavailability (AUC) is decreased by 40% in the fasted state or by 50% with a high-protein, low-fat meal; the drug should only be given with food and not with high-protein, low-fat supplements. *Rilpivirine* should not be given with proton pump inhibitors, and H_2 receptor antagonists should be administered 12 h before or 4 h after dosing (Sharma and Saravolatz, 2013). The long elimination $t_{1/2}$ permits once-daily dosing.

Untoward Effects and Drug Interactions. Rash (<5%) occurs less frequently with *rilpivirine* than with other NNRTIs. Although CNS adverse effects are much less common with *rilpivirine* than with *efavirenz*, depressive symptoms have been reported, including in pediatric and adolescent patients. Elevated hepatic transaminases may occur, especially in those with underlying HBV or HCV infection. *Rilpivirine* is considered generally safe in pregnancy (former FDA category B).

Rilpivirine concentrations can be reduced by coadministered CYP inducers, and this drug should not be given with *rifampin*; anticonvulsants such as *carbamazepine, phenobarbital*, or *phenytoin*; or any products containing St. John's wort. At the 25-mg daily dose, *rilpivirine* is not a clinically significant inhibitor or inducer of hepatic enzymes. Because *rilpivirine* can prolong the QTc in a concentration-dependent fashion, caution is advised when combining this drug with any known CYP3A4 inhibitors or other drugs that can increase *rilpivirine* concentrations or with other drugs known to prolong the QTc.

Etravirine

Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1. The drug is unique in its ability to inhibit reverse transcriptase that is resistant to other NNRTIs. *Etravirine* appears to have conformational and

positional flexibility in the NNRTI-binding pocket that allows it to inhibit the HIV-1 RT in the presence of common NNRTI resistance mutations (de Bethune, 2010). *Etravirine* is approved for use only in treatment-experienced adults and children aged 2 years or older and weighing at least 10 kg with viral strains resistant to another NNRTI. NNRTI-experienced patients should not receive *etravirine* plus NRTIs alone.

ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. Food increases the *etravirine* AUC by about 50%; thus, the drug should be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug.

Untoward Effects and Drug Interactions. The only notable side effect of *etravirine* is rash (17% vs. placebo value of 9%), usually occurring within a few weeks of starting therapy and resolving within 1 to 3 weeks if therapy is continued. Severe rash, including Stevens-Johnson syndrome and toxic epidermal necrolysis, have been reported (de Bethune, 2010).

Etravirine is an inducer of CYP3A4 and glucuronosyl transferases and an inhibitor of CYPs 2C9 and 2C19; it can therefore be involved in a number of clinically significant pharmacokinetic drug interactions. *Etravirine* can be combined with *darunavir/ritonavir*, *lopinavir/ritonavir*, and *saquinavir/ritonavir* without the need for dose adjustments. The dose of *maraviroc* should be doubled when these two drugs are combined. *Etravirine* should not be administered with *tipranavir/ritonavir*, *fosamprenavir/ritonavir*, or *atazanavir/ritonavir* in the absence of better data to guide dosing. *Etravirine* should not be combined with other NNRTIs. Unlike other NNRTIs, *etravirine* does not appear to alter the clearance of *methadone*.

Doravirine

Doravirine is a benzonitrile NNRTI with potent activity against HIV-1; Table 64–3 presents some of the drug's pharmacokinetic properties. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. *Doravirine* has the best side effect profile of available NNRTIs and has few or no CNS side effects. *Doravirine* retains efficacy against many HIV strains that are resistant to *efavirenz* and other earlier NNRTIs. However, treatment failure has been associated with the acquisition of V106I, H221Y, and F227C mutations (Blevins et al., 2020). *Doravirine* is approved only for treatment-naïve adults. *Doravirine* is also available as a once-daily, single-tablet coformulation with TDF and *lamivudine*.

ADME. Table 64–3 summarizes the pharmacokinetic data for *doravirine*. *Doravirine* is mainly metabolized by CYP3A4 and is not subject to significant renal clearance. Unlike *rilpivirine*, *doravirine* absorption is not significantly altered by coadministration with food or proton pump inhibitors (Blevins et al., 2020). The long elimination $t_{1/2}$ of 12 to 21 h allows once-daily dosing.

Untoward Effects and Drug Interactions. In comparative clinical studies, *doravirine* was better tolerated than *efavirenz* and had a side effect profile equivalent to or better than that of *darunavir/ritonavir*-containing regimens (Blevins et al., 2020). *Doravirine* is not teratogenic in animals but has not been adequately studied in pregnant women.

Coadministration of CYP inducers will reduce *doravirine* concentrations; thus, this drug should not be given with *rifampin*; anticonvulsants such as *carbamazepine*, *phenobarbital*, or *phenytoin*; or any products containing St. John's wort. *Doravirine* may be administered in patients with tuberculosis taking *rifabutin* if the *doravirine* dose is doubled to 100 mg twice per day (Blevins et al., 2020). At the 100-mg daily dose, *doravirine* is not a clinically significant inhibitor or inducer of hepatic enzymes. Unlike *rilpivirine*, *doravirine* does not significantly prolong the QTc interval.

Delavirdine

Delavirdine, a bisheteroarylpiperazine NNRTI that selectively inhibits HIV-1, is rarely used because it requires for thrice-daily dosing and is more toxic and less convenient than other NNRTIs. A more detailed description of this drug is available in previous editions of this book.

HIV Protease Inhibitors

Overview

The HIV PIs are peptide-like chemicals that competitively inhibit the action of the HIV aspartyl protease (Figure 64–6). This protease is a homodimer consisting of two 99-amino-acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis. The preferred cleavage site for this enzyme is the N-terminal side of proline residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV PIs (Wensing et al., 2010).

Table 64–4 summarizes pharmacokinetic data for these agents. Clearance is mainly through hepatic oxidative metabolism. All except *nelfinavir* are metabolized predominantly by CYP3A4 (and *nelfinavir*'s major metabolite is cleared by CYP3A4). All approved HIV PIs have the potential for metabolic drug interactions. Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with *ritonavir* by far the most potent. It is now a common practice to combine HIV PIs with a low dose of *ritonavir* or *cobicistat* to take advantage of either drug's remarkable capacity to inhibit CYP3A4-mediated metabolism.

"Boosting" PIs With a CYP Inhibitor. The metabolic clearance of HIV PIs is inhibited by *cobicistat*, a ritonavir analogue that lacks antiretroviral activity and that was developed for exclusive use as a pharmacokinetic enhancer (Sherman et al., 2015). *Cobicistat* is a potent and selective inhibitor of CYP3A4 that is better tolerated than *ritonavir* and is not a CYP enzyme inducer. Doses of *ritonavir* of 100 or 200 mg once or twice daily, or *cobicistat* 150 mg daily, are sufficient to inhibit CYP3A4 and increase ("boost") the concentrations of most concurrently administered CYP3A4 substrates. The enhanced pharmacokinetic profile of HIV PIs administered with *ritonavir* or *cobicistat* reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination $t_{1/2}$ of the coadministered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations. Combinations of either *atazanavir*, *darunavir*, *fosamprenavir*, or *lopinavir* with *ritonavir*, or *cobicistat* with *atazanavir* or *darunavir*, are approved for once-daily administration.

A Note on Cobicistat. *Cobicistat* selectively inhibits CYP3A4 with potency similar to that of *ritonavir* but without anti-HIV activity (Sherman et al., 2015). Additional potential advantages compared to *ritonavir* include greater specificity for CYP3A4, better tolerability, reduced impact on plasma lipids, and lack of P450 enzyme induction. However, *cobicistat* can inhibit some drug transport proteins and blocks the tubular transport of creatinine, resulting in a small and reversible increase in serum creatinine. *Cobicistat* is available only in coformulation with *elvitegravir*, *atazanavir*, or *darunavir*.

Other Shared Properties of PIs

Most HIV PIs are substrates for the P-glycoprotein efflux transporter (the multidrug resistance transporter, also known as MDR1 and ABCB1; see Chapter 4). These agents generally penetrate less well into semen than do NRTIs and NNRTIs. HIV PIs have high interindividual serum concentration variability that may reflect differential interactions with intestinal and hepatic CYPs and drug transport proteins. The speed with which HIV develops resistance to unboosted PIs is intermediate between that of nucleoside analogues and NNRTIs. Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs. This relatively favorable resistance profile makes HIV PIs attractive agents for use as second-line therapy in patients who have failed previous antiretroviral regimens (Wensing et al., 2010). Patients failing PI-containing regimens in the clinic often do so without any evidence of resistance to the PI in the regimen. Gastrointestinal side effects, including nausea, vomiting, and

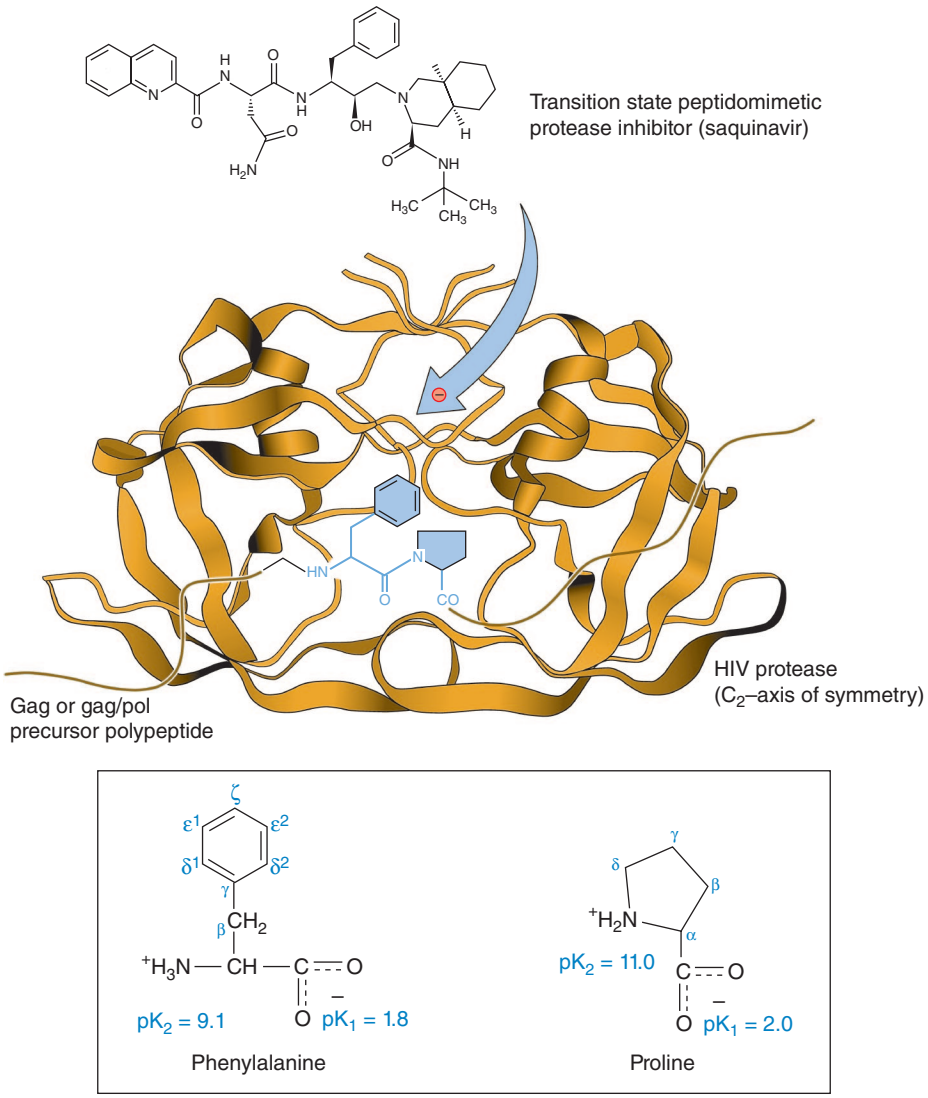

Figure 64–6 *Mechanism of action of an HIV PI.* Shown here is a phenylalanine-proline target peptide sequence (in blue) for the protease enzyme (in golden brown) with chemical structures of the native amino acids (in lower box) to emphasize homology of their structures to that of *saquinavir* (at top).

diarrhea, were common with older HIV PIs but are much less likely to occur with the newer drugs *atazanavir* and *darunavir*.

Ritonavir

Ritonavir is a peptidomimetic HIV PI designed to complement the C2 axis of symmetry of the enzyme active site. *Ritonavir* is active against both HIV-1 and HIV-2 (perhaps slightly less active against HIV-2). Today, *ritonavir* is mainly used as a pharmacokinetic enhancer (CYP3A4 inhibitor); the low doses used for this purpose are not known to induce *ritonavir* resistance mutations in HIV. The drug is used infrequently as the sole PI in combination regimens because of GI toxicity (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of *ritonavir*. Interindividual variability in pharmacokinetics is high, with variability exceeding 6-fold in trough concentrations among patients given 600 mg of *ritonavir* every 12 h as capsules.

Untoward Effects and Drug Interactions. The major side effects of *ritonavir* are GI and include dose-dependent nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. *Ritonavir* also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy.

Ritonavir is one of the most potent known inhibitors of CYP3A4. Thus, *ritonavir* must be used with caution in combination with any CYP3A4 substrate and should not be combined with a drug that is a substrate for CYP3A and has a narrow therapeutic index, such as *midazolam, triazolam, fentanyl*, and ergot derivatives. *Ritonavir* is a mixed competitive and irreversible inhibitor of CYP3A4; its effects can persist for 2 to 3 days after the drug is discontinued (Washington et al., 2003). *Ritonavir* is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as *rifampin* may lower *ritonavir* concentrations and should be avoided or the dosages adjusted. Capsule and solution formulations of *ritonavir* contain alcohol and should not be administered with *disulfiram* or *metronidazole*. *Ritonavir* is also a moderate inducer of CYP3A4, glucuronosyl-S-transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of *ritonavir*. *Ritonavir* reduces the AUC of *ethinyl estradiol* by 40%; thus, alternative forms of contraception should be used.

Use of Ritonavir as a CYP3A4 Inhibitor. *Ritonavir* inhibits the metabolism of all current HIV PIs and is frequently used in combination with most of these drugs (with the exception of *nelfinavir*) to enhance their

[c]Values for lopinavir, tipranavir, and darunavir reflect coadministration with ritonavir.

pharmacokinetic profiles and allow a reduction in their doses and dosing frequencies. *Ritonavir* also overcomes the deleterious effect of food on *indinavir* bioavailability. Low doses of *ritonavir* (100 or 200 mg once or twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600-mg twice-daily dose (Wensing et al., 2010).

Lopinavir

Lopinavir is structurally similar to *ritonavir* but is 3- to 10-fold more potent against HIV-1. This agent is active against both HIV-1 and HIV-2. *Lopinavir* is available only in coformulation with low doses of *ritonavir* (as a CYP3A4 inhibitor). *Lopinavir* has antiretroviral activity comparable with that of other potent HIV PIs and better than that of *nelfinavir*. *Lopinavir* also has considerable and sustained antiretroviral activity in patients who have failed previous HIV PI-containing regimens (Wensing et al., 2010).

Treatment-naïve patients who fail a first regimen containing *lopinavir* generally do not have detectable HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Wensing et al., 2010). For treatment-experienced patients, accumulation of four or more HIV PI resistance mutations is associated with a reduced likelihood of virus suppression after starting *lopinavir*.

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. The adult *lopinavir/ritonavir* dose is 400/100 mg (2 tablets) twice daily or 800/200 mg (4 tablets) once daily. *Lopinavir/ritonavir* should not be dosed once daily in treatment-experienced patients. *Lopinavir/ritonavir* is approved for use in pediatric patients aged 14 days or older, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children older than 6 months of age who reliably demonstrate the capacity to swallow the intact tablet; a pediatric-friendly *lopinavir/ritonavir* oral solution is also available. *Lopinavir* is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability. Although the tablets contain *lopinavir/ritonavir* in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of *lopinavir* to the inhibitory effect of *ritonavir* on CYP3A. Both *lopinavir* and *ritonavir* are highly bound to plasma proteins, mainly to α_1-acid glycoprotein, and have a low fractional penetration into CSF and semen.

Untoward Effects and Drug Interactions. The most common adverse events reported with the *lopinavir/ritonavir* coformulation are GI: loose stools, diarrhea, nausea, and vomiting. Laboratory abnormalities include elevated total cholesterol and triglycerides. It is unclear whether these side effects are due to *ritonavir*, *lopinavir*, or both.

Concomitant administration of agents that induce CYP3A4, such as *rifampin*, may lower plasma *lopinavir* concentrations considerably. St. John's wort is a known inducer of CYP3A4, leading to lower concentrations of *lopinavir* and possible loss of antiviral effectiveness. Coadministration of other antiretrovirals that can induce CYP3A4 (e.g., *amprenavir*, *nevirapine*, or *efavirenz*) may require increasing the dose of *lopinavir*. The liquid formulation of *lopinavir* contains 42% ethanol and should not be administered with *disulfiram* or *metronidazole*. *Ritonavir* is also a moderate CYP inducer at the dose employed in the coformulation and can adversely decrease concentrations of some coadministered drugs (e.g., oral contraceptives). There is no direct proof that *lopinavir* is a CYP inducer *in vivo*; however, concentrations of some coadministered drugs (e.g., *amprenavir* and *phenytoin*) are lower with the *lopinavir/ritonavir* coformulation than would have been expected with low-dose *ritonavir* used alone or in combinations with other PIs.

Atazanavir

Atazanavir is an azapeptide PI that is active against both HIV-1 and HIV-2. A coformulation with *cobicistat* is also available.

Therapeutic Use. *Atazanavir*, with or without *ritonavir*, is approved for treatment of adults and pediatric patients older than 3 months of age and weighing at least 5 kg; in the pediatric population, dosing is based on weight. In treatment-experienced adult patients, *atazanavir* 400 mg once daily without *ritonavir* was inferior to the *lopinavir/ritonavir* coformulation given twice daily. The combination of *atazanavir* and low-dose *ritonavir* had a similar viral load effect as the *lopinavir/ritonavir* coformulation in one study, suggesting that this drug should be combined with *ritonavir* or *cobicistat* in treatment-experienced patients and perhaps in treatment-naïve patients with high baseline viral loads. The primary *atazanavir* resistance mutation occurs at HIV protease codon 50 and confers about 9-fold decreased susceptibility. High-level resistance is more likely if five or more additional mutations are present (Wensing et al., 2010).

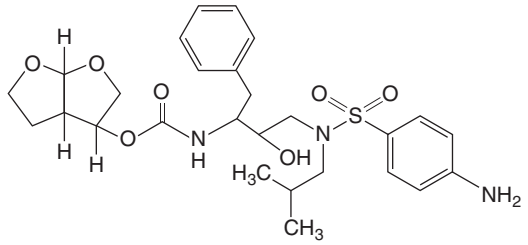
ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. *Atazanavir* is absorbed rapidly after oral administration. A light meal increases the AUC; thus, the drug should be administered with food. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce *atazanavir* concentrations after oral dosing (Wensing et al., 2010). The mean elimination $t_{1/2}$ of *atazanavir* increases with dose, from 7 h at the standard 400-mg once-daily dose to nearly 10 h at a dose of 600 mg. The recommended *atazanavir* dose is 400 mg once daily in adults if given without a pharmacokinetic enhancer (*ritonavir* or *cobicistat*) and 300 mg if given with *ritonavir* 100 mg or *cobicistat* 150 mg. The drug is present in CSF at less than 3% of plasma concentrations but has excellent penetration into seminal fluid.

Untoward Effects and Drug Interactions. *Atazanavir* frequently causes unconjugated hyperbilirubinemia due to inhibition of UGT1A1, although this is not associated with hepatotoxicity. Postmarketing reports include hepatic adverse reactions of cholecystitis, cholelithiasis, cholestasis, and other hepatic function abnormalities. *Atazanavir* can precipitate in urine, causing increased risk of kidney stones. Other side effects reported with *atazanavir* include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinue *atazanavir* because of side effects during 48 weeks of treatment. Patients treated with *atazanavir* have significantly lower fasting triglyceride and cholesterol concentrations than patients treated with *nelfinavir, lopinavir*, or *efavirenz*.

Because *atazanavir* is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., *rifampin*) is contraindicated. *Atazanavir* is also a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. *Atazanavir* is a moderate UGT1A1 inhibitor and increases the *raltegravir* AUC by 41% to 72%. *Ritonavir* significantly increases the *atazanavir* AUC and reduces *atazanavir* systemic clearance. Concomitantly administered proton pump inhibitors reduce *atazanavir* concentrations substantially. Proton pump inhibitors and H_2 receptor antagonists should be avoided in patients receiving *atazanavir* without *ritonavir* (Wensing et al., 2010).

Darunavir

Darunavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. *Darunavir* binds tightly but reversibly to the active site of HIV protease but has also been shown to prevent protease dimerization. At least three *darunavir*-associated resistance mutations are required to confer resistance (Wensing et al., 2010). *Darunavir* in combination with *ritonavir* or *cobicistat* is approved for use in HIV-infected adults and children older than 3 years old. Coformulations with *cobicistat* or with *cobicistat*, TAF, and *emtricitabine* are also available.



DARUNAVIR

ADME. Table 64–4 presents some pharmacokinetic data on this agent. *Darunavir/ritonavir* can be used as a once-daily (800/100-mg) regimen with nucleosides in treatment-naïve adults or as a twice-daily (600/100-mg) regimen in treatment-experienced adults with at least one *darunavir*-associated resistance mutation; this drug should be taken with food. Pediatric dosing is based on body weight. *Darunavir* is absorbed rapidly after oral coadministration with *ritonavir*, with peak concentrations occurring after 2 to 4 h. *Ritonavir* increases *darunavir* bioavailability by up to 14-fold. When combined with *ritonavir*, the mean elimination $t_{1/2}$ of *darunavir* is about 15 h, and the AUC is increased by an order of magnitude; *cobicistat* produces similar results.

Untoward Effects and Drug Interactions. Because *darunavir* must be combined with *cobicistat* or a low dose of *ritonavir*, drug administration can be accompanied by all of the side effects caused by those agents, including drug interactions and GI complaints in up to 20% of patients taking *ritonavir*. *Darunavir*, like *fosamprenavir*, contains a sulfa moiety, and rash has been reported in up to 10% of recipients. *Darunavir/ritonavir* is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with *lopinavir/ritonavir*. *Darunavir* has been associated with episodes of hepatotoxicity.

Because *darunavir* is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., *rifampin*) is contraindicated. The drug interaction profiles of *darunavir/ritonavir* or *darunavir/cobicistat* are dominated by those expected with the pharmacokinetic enhancer. *Darunavir/ritonavir* 600/100 twice daily increases the *maraviroc* AUC by 340%; the *maraviroc* dose should be reduced to 150 mg twice daily when combined *with darunavir* (Wensing et al., 2010).

Older Protease Inhibitors

Saquinavir, indinavir, nelfinavir, fosamprenavir, and *tipranavir* are rarely used because of greater toxicity and intolerability as compared to other PIs. Detailed information about these drugs is available in previous editions of this book.

Entry Inhibitors

Overview

The entry of HIV into targets cells involves sequential binding of the virus to both a main receptor (CD4) and a chemokine co-receptor (CCR5 or CXCR4), followed by membrane fusion and release of virion contents into the cytoplasm (see Figure 64–1). This creates several targets for pharmacologic intervention (Tilton and Doms, 2010).

The four drugs available in this class have different mechanisms of action (see Figure 64–1). *Fostemsavir* binds to the virus envelope protein gp120 and prevents binding to CD4. *Ibalizumab* binds to host CD4 and thus prevents virus from entering target cells. *Maraviroc* is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120. *Enfuvirtide* inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions (Tilton and Doms, 2010).

Fostemsavir

Fostemsavir is a methylphosphate prodrug of *temsavir*. *Fostemsavir* is rapidly hydrolyzed to the parent compound, which binds to the viral envelope protein gp120, preventing attachment to CD4 and subsequent cell entry. *Fostemsavir* is approved only for use in heavily treatment-experienced adults with multidrug-resistant HIV-1 infection. It retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action. Given its relatively short $t_{1/2}$ (7–14 h), *fostemsavir* must be given twice daily. Neither food nor increased gastric pH significantly alters the plasma pharmacokinetic (PK) profile of *fostemsavir* (Hiryak and Koren, 2021).

Fostemsavir resistance is complex and related to polymorphisms in the C1–C5 domains of gp120 (Hiryak and Koren, 2021). Amino acid substitutions that contribute to resistance include S375T, M426L, M434I, S375H/M, and L116P; M426L can be found in up to 15% of populations that have not been treated with *fostemsavir*. In clinical trials in heavily treatment-experienced patients, suppression rates at 48 weeks ranged from 38% to 54%, and 51% of subjects with virologic failure in randomized cohorts had treatment-emergent *temsavir* resistance mutations (Hiryak and Koren, 2021). This may reflect the difficulty of finding effective agents to use in combination with *fostemsavir* or nonadherence issues common in such patients.

ADME. *Temsavir* metabolism is complex and includes contribution from both esterases and CYP3A4. Fifty-one percent of *temsavir* is excreted unchanged in the urine. No clinically significant changes in pharmacokinetic parameters are seen in patients with renal or hepatic impairment, and no dose adjustments are needed in such patients (Hiryak and Koren, 2021).

Untoward Effects and Drug Interactions. *Fostemsavir* is generally well tolerated, but its use has been associated with elevations of hepatic transaminases, particularly in patients with concurrent HBV or HCV infection. In addition, high doses of *fostemsavir* (four times the approved daily dose of 600 mg twice per day) cause QTc prolongation. This drug should therefore be used with caution in patients at risk of QT-associated arrhythmias.

Temsavir is a CYP3A4 and P-glycoprotein substrate and is susceptible to PK drug interactions involving hepatic enzyme inhibitors or inducers. *Fostemsavir* should not be combined with *rifampin* or other potent CYP inducers, but it can be combined with *rifabutin* in patients with tuberculosis. *Temsavir* inhibits OATP1B1 and OATP1B3 and should not be combined with statins that are substrates for these transporters.

Ibalizumab

Ibalizumab is a humanized monoclonal antibody that binds to the CD4 extracellular domain 2, causing steric hindrance of a conformational change in the gp120-CD4 complex necessary for HIV fusion and entry (Chahine and Durham, 2021). *Ibalizumab* does not inhibit gp120 attachment to CD4. The *ibalizumab* binding site on CD4 is separate from the major histocompatibility complex class II binding site, and thus, *ibalizumab* does not interfere with host immune responses. *Ibalizumab* is approved for use in heavily treatment-experienced adults with multidrug-resistant HIV-1 infection who are failing their current antiretroviral regimen. The drug must be given as an intravenous infusion every 2 weeks, limiting its use to this small population of patients (Chahine and Durham, 2021). *Ibalizumab* retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

Resistance to *ibalizumab* can precede exposure to the drug and can develop rapidly if the drug is not combined with other active antiretroviral agents. Resistance is mediated by decreased expression of N-linked glycosylation sites in the V5 loop of gp120 (Chahine and Durham, 2021). *Ibalizumab* has been studied only in small groups of heavily treatment-experienced patients. In one small study, when *ibalizumab* was combined with an optimized background regimen, the percentage of patients with an undetectable viral load (<50 copies/mL of HIV RNA) at week 48 ranged from 47% to 56%, and at week 96, it was 52% (Chahine and Durham, 2021).

Untoward Effects and Drug Interactions. *Ibalizumab* is generally well tolerated with few side effects. The most common adverse effects reported in clinical trials were diarrhea (8%), dizziness (8%), nausea (5%), and rash (5%). Antidrug antibody responses were rarely seen in clinical trial participants and appeared to have no clinical consequences (Chahine and Durham, 2021). Based on its pharmacologic properties, no drug-drug interactions are expected with *ibalizumab*.

Maraviroc

Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine co-receptor (Figure 64–7). *Maraviroc* is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. The drug has no activity against viruses that are CXCR4-tropic or dual-tropic (Tilton and Doms, 2010). *Maraviroc* retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through two distinct pathways. A patient starting *maraviroc* therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4 or dual/mixed tropism predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of *maraviroc*. Alternatively, HIV can retain its CCR5 tropism but gain resistance to the drug through specific mutations in the V3 loop of gp120 that allow virus binding to CCR5 in the presence of inhibitor (Kuritzkes, 2011).

ADME. *Maraviroc* is the only antiretroviral drug approved at three different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other concomitant medications, the starting dose is 300 mg twice daily. Once-daily *maraviroc* has been studied but is not FDA-approved. The oral bioavailability of *maraviroc*, 23% to 33%, is dose dependent. Food decreases bioavailability, but there are no food requirements for drug administration.

Untoward Effects and Drug Interactions. *Maraviroc* is generally well tolerated but can cause dose- and concentration-dependent orthostatic hypotension. Although one case of serious hepatotoxicity with allergic features has been reported, significant (grade 3 or 4) hepatotoxicity was no more frequent with *maraviroc* than with placebo in controlled trials.

Maraviroc is a CYP3A4 substrate and susceptible to pharmacokinetic drug interactions involving CYP3A4 inhibitors or inducers. *Maraviroc* itself is not a CYP inhibitor or inducer *in vivo*, although high-dose *maraviroc* (600 mg daily) can increase concentrations of the CYP2D6 substrate *debrisoquine*.

Enfuvirtide

Enfuvirtide is a 36-amino-acid synthetic peptide that is not active against HIV-2 but is broadly effective against laboratory and clinical isolates of HIV-1. *Enfuvirtide* is FDA-approved for use only in treatment-experienced adults and children weighing 11 kg or more who have evidence of HIV replication despite ongoing antiretroviral therapy. The drug's cost and

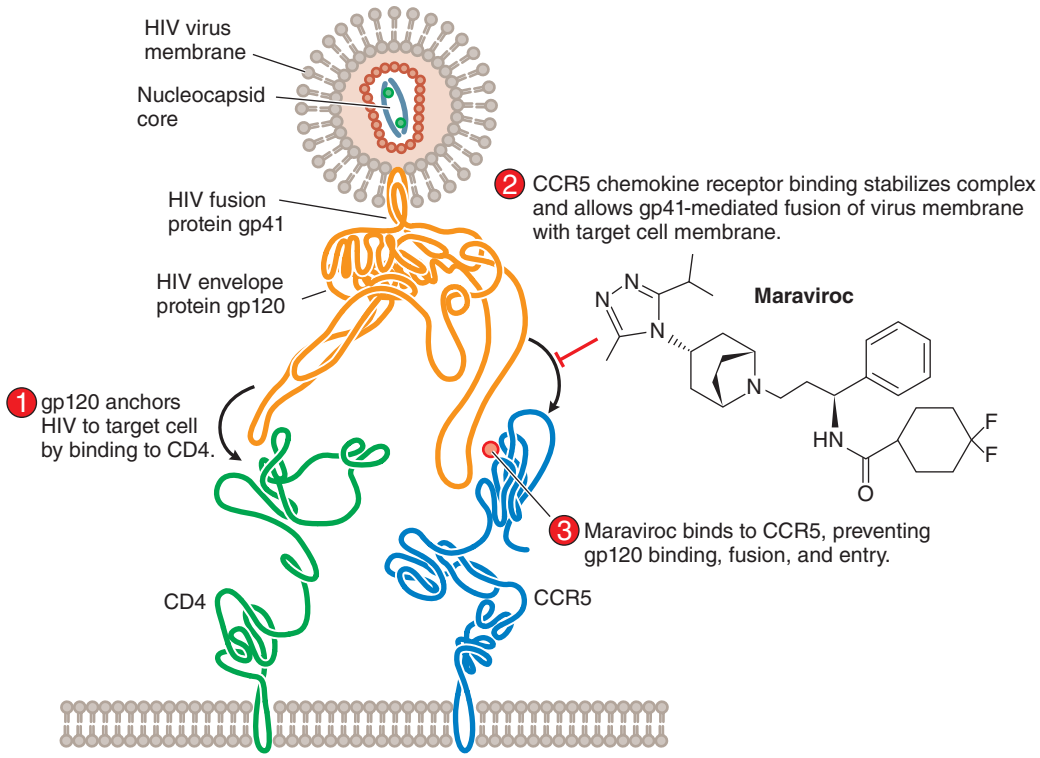


Figure 64–7 *Mechanism of action of the HIV entry inhibitor maraviroc.*

route of administration (subcutaneous injection twice daily) limit its use to those with no other treatment options (Tilton and Doms, 2010).

Mechanisms of Action and Resistance. The amino acid sequence of *enfuvirtide* derives from the transmembrane gp41 region of HIV-1 that is involved in fusion of the viral membrane lipid bilayer with that of the host cell membrane. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell (Tilton and Doms, 2010). *Enfuvirtide* inhibits infection of $CD4^+$ cells by free virus particles. *Enfuvirtide* retains activity against viruses that have become resistant to antiretroviral agents of other classes. HIV can develop resistance to this drug through specific mutations in the *enfuvirtide*-binding domain of gp41.

ADME. The bioavailability of subcutaneous *enfuvirtide* is 84% compared with an intravenous dose. Pharmacokinetics of the subcutaneous drug are not affected by site of injection. The major route of elimination for *enfuvirtide* has not been determined. The mean elimination $t_{1/2}$ of parenteral drug is 3.8 h, necessitating twice-daily administration, which may create adherence issues for the patient.

Untoward Effects and Drug Interactions. The most prominent adverse effects of *enfuvirtide* are injection-site reactions. Most patients (98%) develop local side effects, including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts. Use of *enfuvirtide* has been associated with a higher incidence of lymphadenopathy and pneumonia. *Enfuvirtide* is not known to alter the concentrations of any coadministered drugs.

Integrase Inhibitors

Overview

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency (Figure 64–1). Because human DNA is not known to undergo excision/reintegration, this process is an excellent target for selective antiviral intervention. The HIV integrase inhibitors prevent formation of covalent bonds between host and viral DNA—a process known as strand transfer—presumably by interfering with essential divalent cations in the enzyme's catalytic core (Figure 64–8). In clinical trials, HIV integrase inhibitors produce a more rapid decline in plasma viral RNA over the first 3 to 4 months of therapy than other antiretroviral agents and are generally better tolerated than comparator agents (Scarsi et al., 2020). Because of their unique mechanism of action, these agents retain activity against viruses that have become resistant to antiretroviral agents of other classes.

Integrase inhibitors have radically altered strategies for HIV treatment, given their high degree of efficacy and tolerability and very low propensity for selecting drug-resistant mutations. The coformulation of *dolutegravir* and *lamivudine* is the only two-drug regimen approved for first-line use in treatment-naïve patients.

Raltegravir

Raltegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome (see Figure 64–8). *Raltegravir* has potent activity against both HIV-1 and HIV-2. *Raltegravir* is approved for use in HIV-infected adults and children weighing 2 kg or more. A 400-mg twice-daily oral formulation and a 1200-mg once-daily oral formulation are both available, but the once-daily formulation should be used only in treatment-naïve patients or those already virologically suppressed on the twice-daily formulation.

ADME. Peak concentrations of *raltegravir* occur about 1 h after oral dosing. Elimination is biphasic, with an α phase $t_{1/2}$ of about 1 h and a terminal β phase $t_{1/2}$ of about 12 h, with the α phase predominating. The pharmacokinetics of *raltegravir* are highly variable. Moderate- and high-fat meals increase *raltegravir*'s AUC by as much as 2-fold; a low-fat meal decreases AUC modestly (↓ 46%); however, there are no food requirements for *raltegravir* administration. The drug is 83% protein bound in human plasma. *Raltegravir* is eliminated mainly via glucuronidation by UGT1A1 (Scarsi et al., 2020).

Untoward Effects and Drug Interactions. *Raltegravir* generally is well tolerated, with little clinical toxicity. The most common complaints

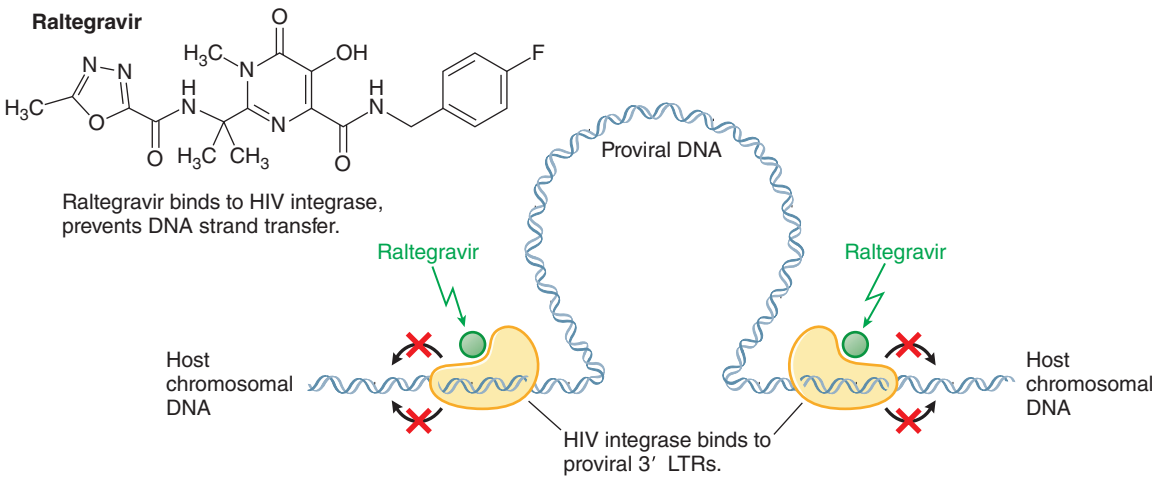

Figure 64–8 *Mechanism of action of the HIV integrase inhibitor raltegravir.*

are headache, nausea, asthenia, and fatigue, which are also associated with coadministered NRTIs. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, as has exacerbation of depression, but their relationship to *raltegravir*'s use is not clear (Scarsi et al., 2020). *Raltegravir* is rarely associated with DRESS (Ripamonti et al., 2014).

As a UGT1A1 substrate, *raltegravir* is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. *Atazanavir*, a moderate UGT1A1 inhibitor, increases *raltegravir*'s AUC by 41% to 72%. *Tenofovir* increases *raltegravir*'s AUC by 49%, but the mechanism for this interaction is unknown. When *raltegravir* is combined with the CYP inducer *rifampin*, the *raltegravir* dose should be doubled to 800 mg twice daily. *Raltegravir* has little effect on the pharmacokinetics of coadministered drugs. Because the mechanism of action of HIV integrase strand transfer inhibitors involves chelation with a divalent cation (Mg^{2+}) in the enzyme active site, chelation by divalent cations may occur in the GI tract following oral administration. To minimize this interaction, any use of magnesium- or aluminum-containing antacids and *sucralfate* must occur 6 h before or 2 h after *raltegravir*. Administration of calcium- and iron-containing supplements should also be separated from *raltegravir* by at least 2 h, unless given with food (Scarsi et al., 2020).

Elvitegravir

Elvitegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome for both HIV-1 and HIV-2. *Elvitegravir* retains activity against viruses that have become resistant to antiretroviral agents of other classes but shares cross-resistance with mutations affecting the HIV integrase inhibitor *raltegravir* (Scarsi et al., 2020). *Elvitegravir* is available only in single-tablet, once-daily coformulations with *cobicistat*, *emtricitabine*, and *tenofovir disoproxil fumarate* (STRIBILD) or *tenofovir alafenamide* (Genvoya). These coformulations are approved for use in HIV-infected adults and children older than 12 years of age.

ADME. Peak concentrations of *elvitegravir* occur about 4 h after oral dosing. The plasma $t_{1/2}$ of *elvitegravir* (administered as STRIBILD) is approximately 13 h. Because light or high-fat meals increase the AUC of *elvitegravir* by 34% or 87%, respectively, *elvitegravir* coformulations should be given with food. The drug is largely (98%–99%) protein bound in human plasma. Unlike *raltegravir* and *dolutegravir*, *elvitegravir* is eliminated mainly by CYP3A4, thus explaining the substantial pharmacokinetic benefit of combining it with *cobicistat*. *Elvitegravir* coformulations should not be given to patients with baseline estimated creatinine clearance below 70 mL/min (for STRIBILD) or 30 mL/min (for Genvoya) because of the potential for reduced clearance of the NRTI components of the tablet (Scarsi et al., 2020).

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, *elvitegravir* is well tolerated. In clinical trials, the only side effects reported in more than 10% of *elvitegravir* recipients were nausea and diarrhea; fewer than 1% of patients discontinued treatment due to adverse drug effects.

Although *elvitegravir* by itself is not likely to cause clinically significant drug-drug interactions, the drug interaction profile of the coformulation is dominated by the effects of *cobicistat*, a potent inhibitor of CYP3A4 and a weak inhibitor of CYP2D6. Caution is warranted in administering *elvitegravir* coformulations with other CYP3A4 substrates with low therapeutic indices or with CYP3A4 inducers that could lower concentrations of *cobicistat* or *elvitegravir*. This includes rifamycins and St. John's wort. As with other integrase inhibitors, *elvitegravir* coformulations are subject to similar restrictions for coadministration of oral divalent cations (Mg^{2+}, Al^{2+}, Ca^{2+}, Fe^{2+}). Because *tenofovir* plus *emtricitabine* is effective suppressive therapy for chronic HBV infection (see Chapter 63), these coformulations should not be discontinued abruptly in coinfected patients because of the risk of rebound HBV replication and acute liver damage.

Dolutegravir

Dolutegravir blocks the catalytic activity of the HIV-encoded integrase of HIV-1 and HIV-2, preventing integration of viral DNA into the host chromosome. *Dolutegravir* retains activity against some viruses that are resistant to *raltegravir* or *elvitegravir*. *Dolutegravir* is approved for use in HIV-infected adults and children older than 4 weeks of age and weighing at least 3 kg. *Dolutegravir* is also available as a single-tablet, once-daily coformulation with *lamivudine*, with *abacavir* and *lamivudine*, with *rilpivirine*, or in a generic form with TDF and *lamivudine*. Given its high efficacy, tolerability, and convenience, *dolutegravir* is increasingly popular as a starting agent in many parts of the world, especially in its generic form (Scarsi et al., 2020). Resistance to *dolutegravir* is rare, and most patients who fail a *dolutegravir*-containing regimen do so without evidence of *dolutegravir* resistance.

ADME. Peak concentrations of *dolutegravir* occur 3 to 4 h after oral dosing without regard to concurrent food. The drug is 99% protein bound in human plasma; its plasma elimination $t_{1/2}$ is about 12 h. Like *raltegravir*, *dolutegravir* is eliminated mainly by UGT1A1. Subjects with UGT1A1 slow metabolism genotypes had a 32% lower clearance of *dolutegravir* and 46% higher AUC, although this is not thought to have clinical significance (Scarsi et al., 2020).

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, *dolutegravir* is generally well tolerated. *Dolutegravir*-containing regimens may be associated with significant long-term weight gain; this effect may be more prominent in women than in men and in individuals of African descent (Scarsi et al., 2020). One large observational study

TABLE 64–5 ■ PHARMACOKINETIC PROPERTIES OF INTEGRASE STRAND TRANSFER INHIBITORS[a]

PARAMETER	RALTEGRAVIR	ELVITEGRAVIR[b]	DOLUTEGRAVIR	BICTEGRAVIR
Oral bioavailability, %	NR	NR	NR	NR
Effect of meals on AUC	↔	↑ 34%–87%	↑ 33%–66%	↑ 24%

[b]Values when elvitegravir is combined with the CYP3A4 inhibitor cobicistat.

found an increased risk of neural tube defects in infants whose mothers were taking *dolutegravir* at the time of conception; more recent data suggests that this risk—if real—is likely to be quite small (Scarsi et al., 2020). Hypersensitivity reactions, including rash and organ dysfunction, have been reported rarely (<1% of recipients). Because *dolutegravir* inhibits the renal organic cation transporter OCT2, it causes small increases in serum creatinine (0.1–0.2 mg/dL) that persist during therapy but are immediately reversible once the drug is stopped.

Dolutegravir has low potential to cause clinically significant drug-drug interactions. Its capacity to inhibit the renal organic cation transporter OCT2 likely explains why it doubles concentrations of coadministered *metformin*. *Dolutegravir* is susceptible to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes, and it should not be coadministered with *etravirine*, *nevirapine*, or St. John's wort. For some enzyme inducers such as *rifampin*, *efavirenz*, and *ritonavir*-boosted HIV PIs, the *dolutegravir* dose can be increased from 50 mg once daily to 50 mg twice daily to counter this effect (Dooley et al., 2013). Similar to other HIV integrase inhibitors, *dolutegravir* should be taken 2 h before or 6 h after cation-containing antacids or laxatives, *sucralfate*, or oral supplements containing Fe^{2+} or Ca^{2+}, unless combined with food (Scarsi et al., 2020). Because *lamivudine* is no longer considered adequate suppressive therapy for chronic HBV infection, the coformulation of *dolutegravir* with *abacavir* and *lamivudine* should not be considered adequate treatment of HBV in coinfected patients (see Chapter 63). If a patient is coinfected with HBV or becomes infected during treatment, abrupt discontinuation of any *dolutegravir* coformulation with *lamivudine* or *tenofovir* may result in rebound HBV replication and acute liver damage. The *dolutegravir/abacavir/lamivudine* combination should not be given to patients who are known to carry the HLA-B*5701 allele because of the risk of *abacavir* hypersensitivity.

Bictegravir

Bictegravir is a close structural analogue of *dolutegravir* and shares many of its pharmacological properties. *Bictegravir* blocks the catalytic activity of the HIV-encoded integrase of HIV-1 and HIV-2, preventing integration of viral DNA into the host chromosome. The drug retains activity against some viruses that are resistant to *raltegravir* or *elvitegravir*. *Bictegravir* is approved for use in HIV-infected adults who are treatment naïve or suppressed on current antiretroviral therapy without known resistance to *bictegravir*, *tenofovir*, or *emtricitabine*. *Bictegravir* is available only as a single-tablet, once-daily coformulation with *tenofovir alafenamide* and *emtricitabine*. Given its high efficacy, tolerability, and convenience, the *bictegravir* coformulation is popular as a starting agent in high-income countries (Scarsi et al., 2020). Resistance to *bictegravir* is rare, and most patients who fail a *bictegravir*-containing regimen do so without evidence of *bictegravir* resistance.

ADME. Peak concentrations of *bictegravir* occur 2 to 4 h after oral dosing with or without food. The drug is 99% protein bound in human plasma; its plasma elimination $t_{1/2}$ is about 17 h. Like *dolutegravir*, *bictegravir* is eliminated mainly by CYP3A4 and UGT1A1.

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, *bictegravir* is generally well tolerated. Because *bictegravir* inhibits the renal organic cation transporter OCT2, it can cause small increases in serum creatinine (0.1–0.2 mg/dL) that persist during therapy but are immediately reversible once the drug is stopped. Long-term *bictegravir* use has not been associated with significant weight gain, although studies of the drug in the international setting are limited. The safety of *bictegravir* in pregnancy is not yet established (Scarsi et al., 2020).

Bictegravir has low potential to cause clinically significant drug-drug interactions. It increases *metformin* concentrations (mean AUC) by about 39%, which is less than the effect seen with *dolutegravir* (79%). *Bictegravir* is more susceptible than *dolutegravir* to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes, and it should not be coadministered with rifamycins, *carbamazepine*, or St. John's wort (Scarsi et al., 2020). As with other HIV integrase inhibitors, *bictegravir* should be taken 2 h before or 6 h after cation-containing antacids or laxatives, *sucralfate*, or oral supplements containing Fe^{2+} or Ca^{2+}, unless given with food. If a patient is coinfected with HBV or becomes infected during treatment, abrupt discontinuation of *bictegravir/tenofovir alafenamide/emtricitabine* may result in rebound HBV replication and acute liver damage.

Long-Acting and Extended-Release Antiretroviral Formulations

Although oral antiretroviral therapy has been a huge success by any measure, 30% or more of HIV-infected persons do not maintain lifelong suppression of HIV with oral regimens, putting them at risk of morbidity and mortality and placing others at risk of drug-resistant infections. The major factor preventing more widespread therapeutic success is suboptimal adherence. Parenteral long-acting (LA) formulations could improve treatment success and help lower rates of HIV transmission. By analogy to other chronic conditions whose management has been transformed with LA formulations (e.g., hormonal contraception, schizophrenia, osteoporosis), LA formulations are often more convenient, are better tolerated, and can radically improve adherence as compared to daily oral therapy. Patient surveys consistently show a high level of interest in and preference for LA treatment regimens (Flexner, 2019).

Most now see InSTI-based oral coformulations as the pinnacle of safety, efficacy, convenience, and tolerability, and difficult to improve upon. Consequently, almost all antiretroviral agents in current development are LA/extended release, a fact likely to continue into the foreseeable future.

The two-drug combination of LA *cabotegravir* and LA *rilpivirine* was approved by the FDA in early 2021 for HIV treatment, and two other LA agents, islatravir and lenacapavir, are in phase III clinical trials (Thornhill and Orkin, 2021).

LA Cabotegravir

Cabotegravir is a close structural analogue of *dolutegravir* and shares many of its pharmacological properties. The chemical structure of *cabotegravir* makes it more suitable for nanoformulation and LA parenteral administration (Scarsi et al., 2020). LA *cabotegravir* is a nanocrystalline suspension of the integrase inhibitor *cabotegravir*, formulated for intramuscular injection. It is available only for combination administration with LA *rilpivirine* in adults with a chronically suppressed plasma HIV RNA (<50 copies/mL) who are stable on an antiretroviral regimen with no history of treatment failure and with no known or suspected resistance to either *cabotegravir* or *rilpivirine*. In two large, prospective, double-blind, randomized trials for HIV prevention, *cabotegravir* injected every 8 weeks was substantially more effective than daily oral coformulated TDF and *emtricitabine*, reducing infections by 68% in men and 89% in women as compared to standard of care.

Cabotegravir blocks the catalytic activity of the HIV-encoded integrase of HIV-1 and HIV-2, preventing integration of viral DNA into the host chromosome. *Cabotegravir* retains activity against viruses that have become resistant to antiretroviral agents of other classes and also remains active against some viruses that are resistant to *raltegravir* or *elvitegravir*. The initial approval of *cabotegravir* required administration of a 30-mg daily oral formulation combined with NRTIs or *rilpivirine* for 28 days to assure tolerability prior to starting injections. Recent data suggest that this oral lead-in may not be required in many settings (Thornhill and Orkin, 2021). Treatment failure with *cabotegravir* drug resistance was rare in clinical trials, but it did occur, and especially in those with subtype A virus.

ADME. Peak concentrations after beginning LA *cabotegravir* occur 7 days after injection. The drug is 99.8% protein bound in human plasma; its elimination $t_{1/2}$ as the injectable nanoformulation ranges from 5.6 to 11.5 weeks, although drug can be detected in many recipients for more than a year after a single injection. Like *dolutegravir*, *cabotegravir* is mainly metabolized by UGT1A1. Despite metabolism, 27% of an oral dose is eliminated unchanged in the urine. Because initial release of drug from the intramuscular depot is slow, a loading dose of 600 mg is required prior to beginning the monthly maintenance dose of 400 mg. Patients who expect to miss a scheduled injection by more than 7 days should resume oral therapy until the next injection.

Untoward Effects and Drug Interactions. The combination of injected *cabotegravir* and injected *rilpivirine* was generally well tolerated. More than 80% of study participants reported injection site reactions, but only 1% discontinued injections as a result. Other reported adverse effects included pyrexia, fatigue, headache, and musculoskeletal pain. Hepatotoxicity and depressive symptoms were also reported with the combination of LA *cabotegravir* and *rilpivirine*.

Cabotegravir is not known to cause clinically significant drug-drug interactions. However, *cabotegravir* is susceptible to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes, and it should not be coadministered with rifamycins, *carbamazepine*, St. John's wort, or other potent inducers. Neither *cabotegravir* nor *rilpivirine* has activity against hepatitis B virus; switching an HBV-coinfected patient from a *tenofovir*-containing regimen to the combination of injectable *cabotegravir* and *rilpivirine* may result in rebound HBV replication and acute liver damage.

LA Rilpivirine

Long-acting *rilpivirine* is a nanocrystalline suspension of the NNRTI *rilpivirine*, formulated for intramuscular injection. It is available only for combination administration with LA *cabotegravir* in adults with a chronically suppressed plasma HIV RNA (<50 copies/mL) who are stable on an antiretroviral regimen and with no history of treatment failure and known or suspected resistance to either *cabotegravir* or *rilpivirine*. Treatment failure with *rilpivirine* drug resistance was rare in clinical trials, but it did occur, especially in those with subtype A virus. For a more complete description of the pharmacology of *rilpivirine*, see the section on oral NNRTIs. *Rilpivirine* has no activity against HIV-2; thus, the combination of injectable *cabotegravir* and *rilpivirine* should not be used as treatment for those infected with HIV-2.

ADME. Peak concentrations after beginning LA *rilpivirine* occur 3 to 4 days after injection. The drug is 99.7% protein bound in human plasma; its elimination $t_{1/2}$ as the injectable nanoformulation ranges from 13 to 28 weeks, and drug can be detected in many recipients for more than a year after a single injection. *Rilpivirine* is mainly metabolized by CYP3A4. Because initial release of drug from the intramuscular depot is slow, a loading dose of 900 mg is required prior to beginning the monthly maintenance dose of 600 mg. Patients who expect to miss a scheduled injection by more than 7 days should resume oral therapy until the next injection.

Untoward Effects and Drug Interactions. The combination of injected *cabotegravir* and injected *rilpivirine* is generally well tolerated. More than 80% of patients report injection site reactions, but only 1% discontinue injections as a result. Adverse effects include pyrexia, fatigue, headache, and musculoskeletal pain. Hepatotoxicity and depressive symptoms are also reported. Hypersensitivity reactions including DRESS have been reported with *rilpivirine*-containing regimens. Rare but serious postinjection reactions have been reported within minutes after receiving LA *rilpivirine*; these have included dyspnea, agitation, abdominal cramping, flushing, sweating, oral numbness, and changes in blood pressure. These events occurred in less than 1% of subjects and began to resolve within a few minutes after the injection. Oral *rilpivirine* is known to produce dose- and concentration-dependent prolongation of the QTc interval, and caution is warranted in using this drug in those otherwise at risk of QT-associated arrhythmias.

Rilpivirine in its injectable form has low potential to cause clinically significant drug-drug interactions. However, *rilpivirine* is susceptible to decreases in plasma concentrations caused by inducers of drug-metabolizing enzymes and should not be coadministered with rifamycins, *carbamazepine*, St. John's wort, or other potent inducers. Neither *cabotegravir* nor *rilpivirine* has activity against hepatitis B virus; switching an HBV-coinfected patient from a *tenofovir*-containing regimen to the combination of injectable *cabotegravir* and *rilpivirine* may result in rebound HBV replication and acute liver damage.

LA Drugs and Formulations in Late-Stage Clinical Development

Two additional LA antiretroviral agents are in phase III clinical trials and likely to be approved as early as 2022. *Islatravir* is an NRTI with a unique mechanism of action. Because its ribose ring contains a 3′-hydroxyl group, it does not act directly as a chain terminator like other NRTIs; rather, it blocks HIV replication by inhibiting translocation of the RT/RNA duplex (Thornhill and Orkin, 2021). *Islatravir* is more potent than existing NRTIs, and its active metabolite, the intracellular triphosphate, has a $t_{1/2}$ of 78 to 128 h, making it suitable for LA strategies. *Islatravir* is under evaluation as a once-monthly oral preparation and a subcutaneous nonerodable implant formulation. The latter can deliver effective concentrations of drug for at least 12 months. Oral *islatravir* is well tolerated in daily combination therapy and has a high genetic barrier to drug resistance (Thornhill and Orkin, 2021).

Lenacapavir is a first-in-class inhibitor of assembly of the HIV capsid protein. Like *islatravir*, this drug is exceedingly potent and, when injected subcutaneously in seronegative volunteers, has a plasma half-life of 38 days (Thornhill and Orkin, 2021). *Lenacapavir* is under evaluation for HIV treatment and prevention at a subcutaneous dose of 900 mg every 6 months. Because of its unique mechanism of action, *lenacapavir* remains active against virus isolates that have developed resistance to any other antiretroviral drug class.

Several other LA drugs and formulations are in advanced clinical development. This includes a number of *broadly neutralizing antiretroviral monoclonal antibodies* that can produce a significant reduction in plasma HIV RNA and may be able to control HIV replication long term if used in combination. A leucine-serine (LS) mutation in the Fc binding domain of these antibodies can extend their plasma half-life to more than

2 months, allowing intravenous administration as infrequently as once every 6 months (Thornhill and Orkin, 2021).

Future Treatment Guidelines

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naïve and treatment-experienced adults and children. In the U.S., the Department of Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents issues regularly updated guidelines that are accessible at https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-arv/whats-new-guidelines (Department of Health and Human Services, 2022).

Treatment recommendations compare various regimens currently available for treatment-naïve patients and address when to change therapy in individuals who are failing their current regimen. The specific drugs recommended may change as new choices become available and clinical research data accumulate. Selection of drugs in treatment-experienced patients will be driven by genotypic and phenotypic resistance testing, when available. However, future treatment guidelines will likely continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus
- Emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication
- Realization of the need for lifelong treatment under most circumstances

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training.

Drug Facts for Your Personal Formulary: *Antiretroviral Agents and Treatment of HIV Infection*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (phosphorylated to active form to prevent infection of susceptible cells; do not eradicate virus from cells with integrated proviral DNA): Active against HIV-1 and HIV-2 and in some cases HBV		
Zidovudine (AZT) (thymidine analogue)	• HIV in adults and children • Preventing mother-to-child transmission	• Adverse effects: bone marrow (anemia, neutropenia) and muscle toxicity (myopathy); inhibits mitochondrial DNA polymerase γ • Do not use with stavudine
Lamivudine (cytidine analogue)	• HIV in adults and children ≥3 months • Chronic hepatitis B (adults, children)	• Essentially nontoxic
Abacavir (only guanosine analogue antiretroviral)	• HIV in adults and children ≥3 months • Not active against HBV	• Bioavailability not affected by food • Adverse effects: hypersensitivity syndrome (fever, abdominal pain, rash), associated with HLA B*5701 genotype; discontinue drug immediately and never use again as this is potentially fatal
Tenofovir (5′-AMP derivative; supplied as prodrugs: TDF or TAF)	• HIV infection (adults, children >2 years, in combination with other antiretrovirals) • Chronic hepatitis B (adults, children >2 years) • HIV preexposure prophylaxis (with emtricitabine) in adults at high risk of infection	• Nephrotoxicity: small decreases in estimated creatinine clearance are common; Fanconi syndrome rare • Decreases in bone mineral density with chronic use
Emtricitabine (cytidine analogue)	• HIV infection (adults, children, in combination with other antiretrovirals) • Chronic hepatitis B (off-label; adults, children) • HIV preexposure prophylaxis (with tenofovir) in adults at high risk of infection	• Generally nontoxic
Nonnucleoside Reverse Transcriptase Inhibitors: Do not require metabolic activation; HIV-1 specific and not active against HIV-2		
Nevirapine	• HIV-1 infection in infants ≥15 days, children, and adults • Single-dose prevention of mother-to-child transmission	• Autoinducer of metabolism • Commonly produces rash that usually resolves with continued treatment • Can rarely produce life-threatening skin eruptions such as Stevens-Johnson syndrome • Rarely produces life-threatening hepatitis
Efavirenz	• HIV-1 infection in children ≥3 months and adults	• Commonly causes CNS toxicity that usually resolves with continued treatment but can be severe enough to warrant discontinuation • Moderate hepatic enzyme inducer
Rilpivirine	• HIV-1 infection in children >12 years and adults	• Must be given with food • Avoid proton pump inhibitors because of reduced absorption • May cause prolonged QTc interval if concentrations are too high
Etravirine	• Treatment-experienced adults and children ≥2 years	• Commonly produces rash that usually resolves with continued treatment • Can rarely produce life-threatening skin eruptions such as Stevens-Johnson syndrome • Moderate inducer of hepatic enzymes
Doravirine	• Treatment-naïve adults	• Avoid coadministration of CYP3A inducers

Drug Facts for Your Personal Formulary: *Antiretroviral Agents and Treatment of HIV Infection (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Protease Inhibitors: Active against HIV-1 and HIV-2; generally used as second-line agents in treatment-experienced patients		
Ritonavir	• Used only as a PK-boosting agent in combination with other PIs	• Commonly causes nausea • Associated with elevated cholesterol and triglycerides at higher doses • Potent inhibitor of CYP3A4 • Moderate hepatic enzyme inducer
Lopinavir	• Treatment-naïve or -experienced HIV-infected adults and children ≥14 days	• Must be combined with ritonavir • Commonly causes nausea and other GI toxicities • Associated with elevated cholesterol and triglycerides in adults with prolonged use
Atazanavir	• Treatment-naïve or -experienced HIV-infected adults and children ≥3 months	• Usually combined with ritonavir or cobicistat • Can be given without a PK booster at a higher dose of 400 mg • Absorption reduced with proton pump inhibitors and H_2 blockers • Commonly causes unconjugated hyperbilirubinemia • Can cause nephrolithiasis and cholelithiasis
Darunavir	• Treatment-naïve or -experienced HIV-infected adults and children ≥3 years	• Must be combined with ritonavir or cobicistat • May cause transient rash • Better tolerated than other PIs
Tipranavir	• Treatment-experienced HIV-infected adults and children ≥2 years, generally those who have failed all other PIs	• Toxicity: rare but potentially fatal hepatotoxicity; rare but potentially fatal bleeding diathesis, including intracranial hemorrhage • Rarely used because of the availability of better-tolerated PIs
Entry Inhibitors: Generally reserved for second-line or salvage therapy		
Maraviroc	• Treatment-naïve or -experienced HIV-infected adults who have evidence of predominantly CCR5-tropic virus	• CYP3A4 substrate susceptible to drug interactions with other antiretrovirals • Adverse effect: dose- and concentration-dependent orthostatic hypotension
Enfuvirtide	• Treatment-experienced HIV-infected adults and children weighing ≥11 kg • Generally reserved for those with no other treatment options	• Injected subcutaneously twice daily • Adverse effects: injection site reactions and subcutaneous nodules are common • Not active against HIV-2
Ibalizumab	• Heavily treatment-experienced adults with multidrug-resistant HIV-1 infection	• Intravenous infusion given every 2 weeks
Fostemsavir	• Heavily treatment-experienced adults with multidrug-resistant HIV-1 infection	• Oral drug that must be given twice daily • Can cause elevation of hepatic transaminases • May prolong QTc interval if given at higher than recommended doses
Integrase Inhibitors: Widely used in treatment-naïve patients because of excellent tolerability, safety, and antiretroviral activity		
Raltegravir	• HIV-infected adults and children weighing ≥2 kg	• Given once or twice daily without the need for a PK-boosting agent • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated
Elvitegravir	• HIV-infected adults and children >12 years of age	• Requires cobicistat as a PK booster • Should be taken with food • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated
Dolutegravir	• HIV-infected adults and children ≥4 weeks of age	• Given once daily without the need for a PK-boosting agent • Reduced bioavailability if given concurrently with divalent cations • May be associated with long-term weight gain • Generally well tolerated
Bictegravir	• HIV-infected adults and children weighing ≥25 kg	• Given once daily without the need for a PK-boosting agent • Reduced bioavailability if given concurrently with divalent cations • Generally well tolerated

Chapter 65

Chemotherapy of Tuberculosis and Nontuberculous Mycobacteria, Including Leprosy

Elisa H. Ignatius and Kelly E. Dooley

Introduction

Mycobacteria have caused epic diseases: Tuberculosis (TB) and leprosy have terrorized humankind since antiquity, and TB is thought to have killed one in seven of humans who have ever lived. Although the burden of leprosy has decreased, TB surpassed human immunodeficiency virus (HIV) as the leading infectious disease killer in 2014, and nontuberculous mycobacteria (NTM) are a growing threat in certain populations (Winthrop et al., 2020). *Mycobacterium abscessus,* a species of NTM, is especially devastating because of its tenacity, lack of response to combination antibiotics, and nearly universal propensity to develop acquired drug resistance. These distinct mycobacterial infections continue to be difficult to treat, owing mainly to three natural barriers:

- **Cell wall.** Mycobacteria are waxy in appearance, due to the composition of the cell walls. More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 3-hydroxy fatty acids with chains made of 76 to 90 carbon atoms. This extraordinary shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.
- **Efflux pumps.** A second layer of defense comes from an abundance of efflux pumps in the cell membrane. These transport proteins pump out potentially harmful chemicals from the bacterial cytoplasm back into the extracellular space and are responsible for the native resistance of mycobacteria to many standard antibiotics (Morris et al., 2005). As an example, ATP binding cassette (ABC) transporters, a group of permeases that transport across membranes, comprise a full 2.5% of the genome of *Mycobacterium tuberculosis* (Braibant et al., 2000).
- **Location in host.** Mycobacterial infections are intracellular and extracellular, with bacilli hiding both inside patients' cells and within necrotic, avascular areas of the lung. Antimicrobials must therefore penetrate the intracellular compartments and into the lesions where mycobacteria reside to be effective.

Summarizing antimycobacterial therapeutics is challenging, but we have taken the approach in this chapter of (1) organizing agents into those developed specifically for TB (or NTM) treatment versus those repurposed for that indication and (2) summarizing therapies for TB versus other types of mycobacteria. In presenting pharmacotherapies for TB, we periodically refer to drug groups A, B, and C, as delineated by the World Health Organization (WHO). This classification is explained fully later in the chapter (see the section on *Definitive Therapy of Drug-Resistant TB* and Table 65–6).

The first-line drugs we use for TB treatment were developed expressly for that purpose (see History). In fact, the first randomized controlled trial with concealed allocation in human history was for the treatment of TB—*streptomycin* versus bed rest. We divide mycobacteria into tuberculous versus nontuberculous mycobacteria; additionally, we often categorize them by their rate of growth on agar—as *rapid* and *slow* growers (see list in Table 65–1). Rapid growers are visible to the naked eye within 7 days; slow growers are visible later. The pharmacology

HISTORY

The first successful drug for treating TB was *para-aminobenzoic acid*, developed by Lehman in 1943. A more dramatic success came when Waksman and Schatz developed *streptomycin*. Further efforts led to development of *thioacetazone* by Domagk in 1946; *isoniazid* by Squibb, Hoffman La Roche, and Bayer in 1952; *pyrazinamide* by Kushner and colleagues in 1952; and rifamycins by Sensi and Margalith in 1957. *Ethambutol* was discovered at Lederle Laboratories in 1961. After a long pause, TB drug development experienced a "second wave" with *bedaquiline* licensed by the FDA in 2012 and *delamanid* receiving marketing approval the following year in Europe. The "third wave" is now here, with multiple compounds in preclinical and clinical development. In addition, pharmacophores in clinical use for other bacteria have been repurposed as antimycobacterial agents, including *moxifloxacin* and *levofloxacin*, oxazolidinones, and β-lactams.

Abbreviations

ABC: ATP binding cassette
ART: antiretroviral therapy
AUC: area under the curve
C_{Pmax}: maximal plasma concentration
CYP: cytochrome P450
ECG: electrocardiogram
FDA: U.S. Food and Drug Administration
FGD1: NADP-dependent glucose-6-phosphate dehydrogenase
GABA: γ-aminobutyric acid
GI: gastrointestinal
G6PD: glucose-6-phosphate dehydrogenase
HIV: human immunodeficiency virus
IC_{50}: concentration causing 50% inhibition
INH: isoniazid
InhA: enoyl acyl carrier protein reductase
KasA: β-ketoacyl-acyl carrier protein synthase
KatG: catalase-peroxidase
MAC: *Mycobacterium avium* complex
MDR-TB: multidrug-resistant TB, or TB resistant to isoniazid and rifampin
MIC: minimum inhibitory concentration
NAT2: *N*-acetyltransferase type 2
NO: nitric oxide
NRPB: nonreplicating persistent bacilli
NTM: nontuberculous mycobacteria
PABA: *para*-aminobenzoic acid
PAS: *para*-aminosalicylic acid
PK: pharmacokinetics
POA: pyrazinoic acid
RR-TB: rifampin-resistant TB
TB: tuberculosis
V_d: volume of distribution
WHO: World Health Organization
XDR-TB: extensively drug resistant (RR-TB or MDR-TB that is also resistant to fluoroquinolones and at least one Group A drug)

of drugs developed against slow growers is discussed in detail in this chapter as these drugs were mostly developed specifically for mycobacteria. Treatment of rapid growers often relies on repurposed drugs, so while this topic is addressed in this chapter, the pharmacology of many of these antibiotics (like macrolides, aminoglycosides, quinolones, and β-lactams) is described more fully elsewhere (see Chapters 57–60). The mechanisms of action of the antimycobacterial drugs are summarized in Figure 65–1. Pharmacokinetic (PK) parameter definitions are presented in Figure 56–1 and Equation 56–1.

Resistance in mycobacteria is chromosomally mediated, with preexisting mutants present in frequencies ranging from less than 1 in 10^6 (for *isoniazid* and nitroimidazoles) to 1 in 10^7 to 10^8 bacilli (for rifamycins). Development of drug resistance is determined by both epistasis, or the interaction between various mutations, and bacterial fitness (Trauner et al., 2014). The fitness cost of various mutations is not fixed, however, and subsequent mutations may compensate, thereby restoring bacterial fitness and potentially enhancing onward transmissibility. Subtherapeutic concentrations, promoted by interindividual variability in PK and suboptimal dosing practices (Pasipanodya et al., 2013; Srivastava et al., 2011), drive early induction of efflux pumps that leads to chromosomal mutations in drug target proteins and efflux pumps (Gumbo et al., 2014; Schmalstieg et al., 2012; Srivastava et al., 2010). Host genetics and immune response may also contribute to the development of drug resistance. The mycobacterial mechanisms of resistance are summarized in Figure 65–2.

TABLE 65–1 ■ PATHOGENIC MYCOBACTERIAL SLOW AND RAPID GROWERS (RUNYON CLASSIFICATION)

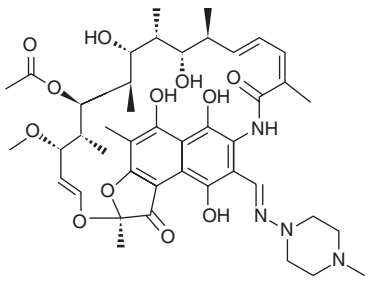
SLOW GROWERS
Runyon I: Photochromogens
Mycobacterium kansasii
Mycobacterium marinum
Runyon II: Scotochromogens
Mycobacterium scrofulaceum
Mycobacterium szulgai
Mycobacterium gordonae
Runyon III: Nonchromogens
Mycobacterium avium complex (*M. avium, M. intracellulare*)
Mycobacterium haemophilum
Mycobacterium xenopi
Mycobacterium ulcerans
RAPID GROWERS
Runyon IV
Mycobacterium fortuitum complex
Mycobacterium chelonae
Mycobacterium smegmatis group
Mycobacterium abscessus

Antimycobacterial Drugs

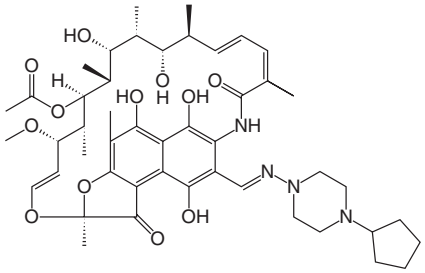
Drugs Developed and Used Primarily for Mycobacterial Infections

First-Line Drugs

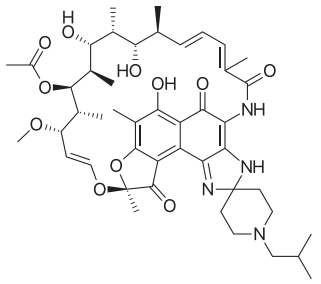
Rifamycins: Rifampin, Rifapentine, and Rifabutin



RIFAMPIN



RIFAPENTINE



RIFABUTIN

Rifamycins, which include *rifampin* (also known as *rifampicin*), *rifapentine*, and *rifabutin*, are macrocyclic antibiotics important in the treatment of most mycobacterial diseases. *Rifaximin*, a nonabsorbed rifamycin, is used for intestinal conditions and is discussed in Chapter 54.

Mechanism of Action. The mechanism of action for rifamycins is typified by *rifampin*'s action against *M. tuberculosis. Rifampin* enters bacilli and binds to the β subunit of DNA-dependent RNA polymerase (*rpoB*) to form a stable drug-enzyme complex (Gumbo et al., 2007a). Drug binding suppresses chain formation in RNA synthesis.

Antibacterial Activity. *Rifampin* inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms, such as *Escherichia coli, Pseudomonas*, indole-positive and indole-negative *Proteus*, and *Klebsiella in vitro*. *Rifampin* is active against *Staphylococcus aureus,* coagulase-negative staphylococci, *Neisseria meningitidis, Haemophilus influenzae,* and *Legionella* species (Thornsberry et al., 1983).

Rifampin inhibits the growth of many mycobacteria, including *M. tuberculosis*, at concentrations of 0.06 to 0.25 mg/L (Heifets, 1991), *Mycobacterium leprae* at less than 1 μg/mL (Bullock, 1983), and *Mycobacterium kansasii* at 0.25 to 1 mg/L. Most strains of *Mycobacterium scrofulaceum, Mycobacterium intracellulare*, and *Mycobacterium avium* are suppressed by concentrations of 4 mg/L. *M. abscessus* harbors innate resistance to rifamycins—it inactivates *rifampin* via an ADP-ribosyltransferase and monooxygenase (Nessar et al., 2012). *Rifapentine* minimum inhibitory concentrations (MICs) are lower than those of *rifampin* (Mor et al., 1995). *Rifabutin* inhibits the growth of many strains of *M. tuberculosis* at concentrations of 0.125 mg/L or less. *Rifabutin* also inhibits the growth of most isolates of *Mycobacterium avium* complex (MAC) at concentrations ranging from 0.25 to 1 mg/L.

Bacterial Resistance. The prevalence of *rifampin*-resistant isolates (1 in every 10^7–10^8 bacilli) is due to an alteration of the target of this drug, *rpoB,* with resistance in 86% of cases due to mutations at codons 526 and 531 of the *rpoB* gene (Somoskovi et al., 2001). Rifamycin monoresistance occurs at higher rates when rifamycins are dosed intermittently, especially among patients with HIV, or when companion drugs are underdosed and are not present at high enough concentrations at the site of disease to protect against the emergence of rifamycin resistance (Burman et al., 2006). Efflux pump induction and mutations in efflux pumps have also been associated with rifamycin resistance (Li et al., 2015). Rifamycin resistance in TB has serious clinical consequences in TB given its unique role as a sterilizing agent; treatment of *rifampin*-monoresistant (RR-) or multidrug-resistant (MDR-) TB is, therefore, often prolonged to 9 to 12 months (World Health Organization, 2019).

ADME. After oral administration, rifamycins are absorbed to variable extents (Tables 65–2 and 65–3) (Burman et al., 2001). Food decreases the *rifampin* maximal plasma concentration (C_{Pmax}) by one-third; a high-fat meal increases the area under the concentration-time curve (AUC) of *rifapentine* by 50%. Food has no effect on *rifabutin* absorption. Thus, *rifampin* is best taken on an empty stomach, whereas *rifapentine* should be taken with food if possible.

Rifamycins are metabolized by microsomal β-esterases and cholinesterases. A major pathway for *rifabutin* elimination is CYP3A. Due to autoinduction, clearance of all three rifamycins increases with repeated administration (Table 65–3) (Dooley et al., 2012). Rifamycins penetrate well into many tissues, with *rifampin* appearing to display better penetration into lung lesions than *rifapentine*. CNS and pericardial fluid penetration are poor (5%–10%) in the absence of inflammation and have

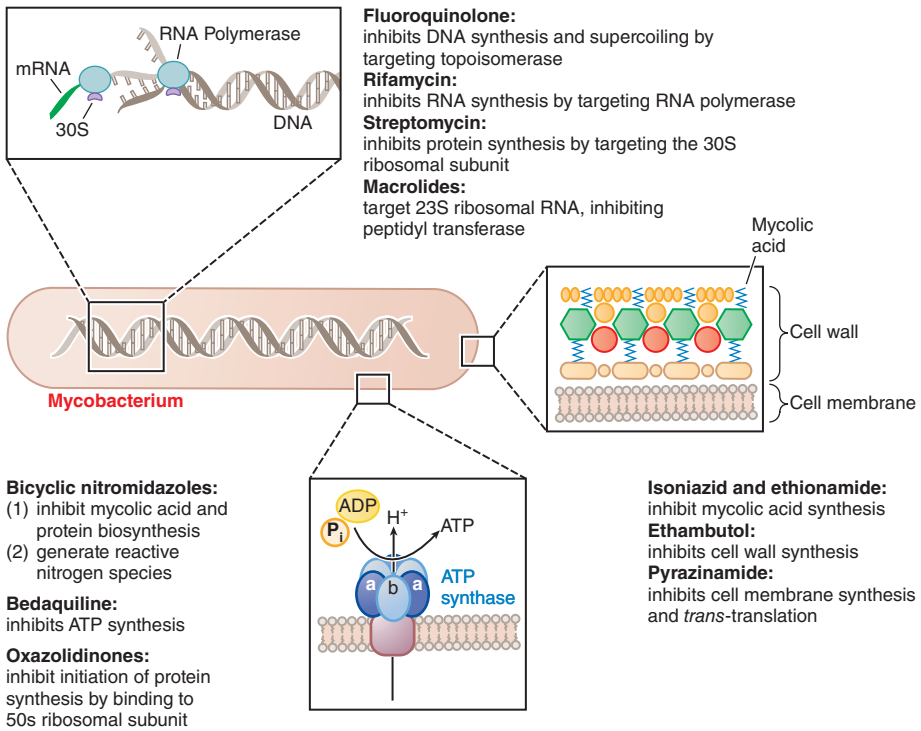


Figure 65–1 *Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections.* Approved drugs for the chemotherapy of mycobacterial diseases may be grouped according to the sites of action indicated by the pictures above that expand regions of the *Mycobacterium*: inhibitors of nucleic acid and protein synthesis; disruptors of cell wall and cell membrane synthesis; inhibitors of membrane transport. Specific antimycobacterial agents and their mechanisms of action are also listed. Rifamycin is used as a generic term for several drugs, of which *rifampin* is used most frequently. *Clofazimine*, whose mode of action is not understood, is omitted.

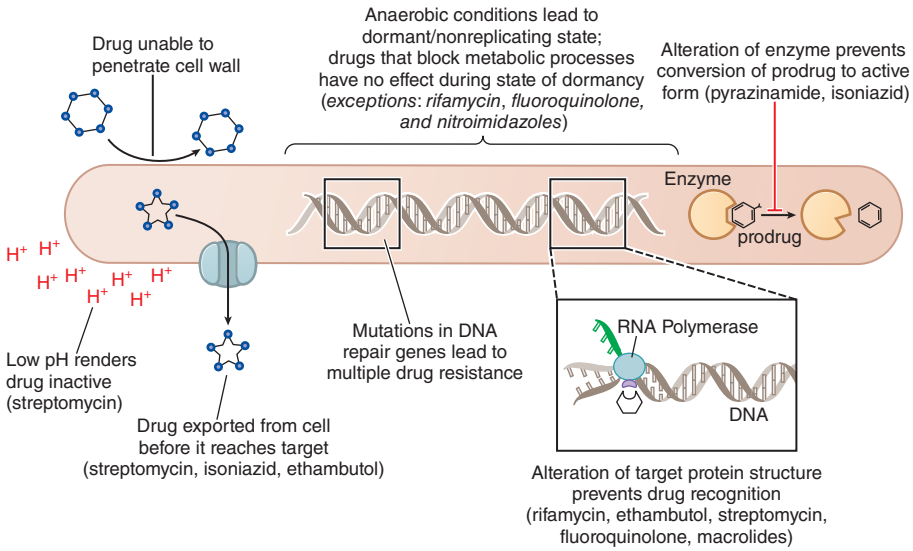

Figure 65–2 *Mechanisms of resistance in mycobacteria.*

only been evaluated for *rifampin* (Nau et al., 1992; Shenje et al., 2015). Nonetheless, rifamycins are a recommended component of therapy for tuberculous meningitis, and *rifabutin* has been shown to be effective in a rabbit model of bacterial meningitis (Schmidt et al., 1997). Rifamycins and their metabolites are excreted by bile and eliminated via feces, with urine being a minor elimination pathway.

The population PK of *rifampin* are best described using a one-compartment model with transit compartment absorption (Wilkins et al., 2008). *Rifampin* displays concentration-dependent clearance and autoinduction of clearance, with dose increases producing more-than-proportional increases in exposures and prolonged dosing resulting in a shorter half-life (Abulfathi et al., 2019; Hibma et al., 2020; Jayaram et al., 2003; Svensson et al., 2018). *Rifapentine*'s PK are best described with a one-compartment model with first-order absorption and elimination (Langdon et al., 2005); this drug also displays autoinduction, but not saturable clearance. Other PK parameters are summarized in Tables 65–2 and 65–3.

In contrast, *rifabutin* disposition is biexponential, and its PK are best described by a two-compartment model with first-order absorption and elimination. *Rifabutin* concentrations are substantially higher in tissue than in plasma due to its lipophilic properties, leading to the very high apparent volumes of distribution (see Table 65–2). As a consequence, C_{Pmax} values for *rifabutin* are lower than other rifamycins. With concomitant *azithromycin* or protease inhibitor administration, central volume of distribution (divided by bioavailability, or V_{dc}/F) increases while peripheral volume of distribution (V_{dp}/F) decreases (Hennig et al., 2016); tobacco smoking increases the V_{dp}/F by 39% (Gatti et al., 1998).

The clearance of all rifamycins is affected by patient weight. A recent systematic review and pooled *rifapentine* PK analysis, however, found that body weight was not predictive of clearance (Hibma et al., 2020); flat

TABLE 65–2 ■ POPULATION PHARMACOKINETIC PARAMETER ESTIMATES FOR ANTIMYCOBACTERIAL DRUGS IN ADULT PATIENTS

	PARAMETER ESTIMATE		
	k_a (h^{-1})	SYSTEMIC CLEARANCE (L/h)	V_d (L)
Rifampin	1.15	19	53
Rifapentine	0.6	2.03	37.8
Rifabutin	0.2	61	231/1050[a]
Pyrazinamide	3.56	3.4	29.2

TABLE 65–3 ■ PHARMACOKINETIC PARAMETERS OF RIFAMPIN, RIFABUTIN, AND RIFAPENTINE

	RIFABUTIN	RIFAMPIN	RIFAPENTINE
Protein binding (%)	71	85	97
Oral bioavailability (%)	20	68	70
t_{max} (h)	2.5–4.0	1.5–2.0	5.0–6.0
C_{max} total (μg/mL)	0.2–0.6	8–20	8–30
C_{max} free drug (μg/mL)	0.1	1.5	0.5
$t_{1/2}$ (h)	32–67	2–5	14–18
Intracellular/extracellular penetration	9	5	24–60
Autoinduction (AUC decrease)	40%	38%	35%
CYP3A induction	Weak	Pronounced	Pronounced
CYP3A substrate	Yes	No	No

dosing of *rifapentine* has since been used in clinical trials (Dorman et al., 2020). For *rifampin*, while weight impacts clearance, its effect is modest, and strict milligram per kilogram dosing results in systematic underdosing of lower-weight patients (Court et al., 2018).

Microbial Pharmacokinetics-Pharmacodynamics. *Rifampin*'s bactericidal and sterilizing effect appears to be largely concentration-dependent, with high AUC or C_{max} associated with optimal sterilizing activity and treatment outcomes in mice and humans (Abulfathi et al., 2019; Jayaram et al., 2003). However, resistance suppression and *rifampin*'s enduring postantibiotic effect are best optimized by high C_{Pmax}/MIC. Recent clinical trials confirm that current dosing is on the steep part of the dose-response curve; better sputum bacillary decline is achieved with up to 3.5 times higher *rifampin* doses than currently used. Such increased doses would increase both AUC/MIC and C_{Pmax}/MIC nonlinearly (Boeree et al., 2015). The safety, tolerability, and efficacy of *rifampin* doses up to 35 mg/kg are being tested in phase III trials (Nabisere et al., 2020), with one recent trial demonstrating that a regimen containing *moxifloxacin* plus high-dose *rifapentine* successfully shortened treatment duration for TB from 6 months to 4 months (Dorman et al., 2021).

Therapeutic Uses. *Rifampin* for oral administration is available alone and as fixed-dose combinations together with *isoniazid*; *isoniazid* and *pyrazinamide*; or *isoniazid*, *pyrazinamide*, and *ethambutol* (not all fixed-dose combinations are available in all countries). A parenteral form of *rifampin* is also available. The standard dose of *rifampin* for treatment of TB disease in adults is 600 mg, given once daily, either at least 1 h before or 2 h after a meal. Children should receive 15 mg/kg (range 10–20 mg/kg), with a maximum dose of 600 mg/day, given in the same way. *Rifabutin* is administered at 300 mg daily. *Rifapentine* is not currently used for treatment of TB disease, but the dose used in the recent successful phase III trial was 1200 mg daily. *Rifampin* and *rifapentine* are used in the treatment of latent tuberculosis infection (see Table 65–5).

Rifampin is also useful for the prophylaxis of meningococcal disease and *H. influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children older than 1 month should receive 10 to 15 mg/kg, to a maximum of 600 mg. Combined with a second antibacterial, *rifampin* may be useful for therapy in selected cases of staphylococcal endocarditis or osteomyelitis, especially for infections associated with prosthetic materials. *Rifampin* may also be indicated for the eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis. In the treatment of brucellosis, *rifampin* 900 mg daily can be combined with *doxycycline* for 6 weeks.

Untoward Effects. Rifamycins are generally well tolerated, although they frequently cause harmless red-orange discoloration of skin, urine, feces, saliva, tears, and contact lenses. Usual doses of *rifampin* result in less than 4% of patients with TB developing significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rifamycins can cause liver disease (mostly cholestasis), with drug-induced liver injury or death due to liver failure rarely observed. Chronic liver disease, alcoholism, and older age appear to increase the incidence of clinically important hepatotoxicity. Gastrointestinal (GI) disturbances have occasionally required discontinuation of the drug.

Hypersensitivity reactions may be encountered. These present with a flu-like syndrome of fever, chills, and myalgias with rare cases progressing to include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Hypersensitivity reaction is more common with intermittent dosing and among female and Asian patients (Yew and Leung, 2006). Light chain proteinuria, thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Although *rifampin* clearance is slightly reduced in pregnancy and does cross the placenta, it is still considered the treatment of choice in pregnancy (Denti et al., 2015). *Rifapentine* has a similar adverse event profile to *rifampin*, including rash, hepatitis, and flu-like symptoms.

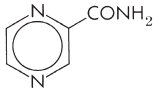
Primary reasons for discontinuation of *rifabutin* therapy include rash (4%), GI intolerance (3%), and neutropenia (2%) (Nightingale et al., 1993). Rarely, thrombocytopenia, flu-like symptoms, hemolysis, myositis, chest pain, and hepatitis develop in patients treated with *rifabutin*. Unique side effects for this rifamycin include polymyalgia, pseudojaundice, and anterior uveitis. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur.

Rifampin overdose is uncommon but can be life threatening. The most prominent symptoms are orange discoloration of skin, fluids, and mucosal surfaces. Treatment consists of supportive measures; there is no antidote.

Drug Interactions. *Rifampin* is a potent inducer of cytochrome P450 (CYP) and phase 2 metabolizing enzymes, as well as transporters such as P-glycoprotein, via its effects on pregnane X receptor (PXR) (see Table 3–3). As a result, its administration often results in higher clearance for concurrently administered medicines subject to these metabolic and transport pathways. The magnitude of the effect on concurrent medications can be large, and therapeutic failures may result. *Rifapentine* displays a similar effect on metabolizing enzymes. *Rifabutin* is a less-potent inducer of CYPs than the other rifamycins; however, *rifabutin* does induce hepatic microsomal enzymes modestly and decreases the $t_{1/2}$ of *zidovudine*, *prednisone*, *digitoxin*, *quinidine*, *ketoconazole*, *propranolol*, *phenytoin*, sulfonylureas, and *warfarin*. Unlike other rifamycins, *rifabutin* is a substrate of CYP3A, and so dose adjustments may be needed (e.g., to 150 mg daily) when this drug is given together with strong CYP3A inhibitors, such as protease inhibitors used to treat HIV.

Pyrazinamide

Pyrazinamide is the synthetic pyrazine analogue of nicotinamide. *Pyrazinamide* was first synthesized at Merck in 1936 in Germany but was first examined as an anti-TB agent in 1952.



PYRAZINAMIDE

Mechanism of Action. Despite clinical use of *pyrazinamide* for decades, only recently has its mechanism of action been elucidated. *Pyrazinamide* is well known to be active only in acidic conditions. The drug passively diffuses into mycobacterial cells, where *M. tuberculosis* pyrazinamidase (encoded by the *pncA* gene) deaminates *pyrazinamide* to pyrazinoic acid (POA^-, in its dissociated form) (Zhang et al., 1999). POA^- binds competitively to the enzyme PanD, essential for coenzyme A biosynthesis in *M. tuberculosis*; this triggers degradation of the protein by a protease called CLPC1-ClpP. An additional target of *pyrazinamide* may be ribosomal protein S1 (encoded by *RpsA*) in the trans-translation process. Blocking RpsA activity leads to accumulation of toxic proteins that kill the bacteria (Gopal et al., 2020; Shi et al., 2011; Sun et al., 2020).

Antibacterial Activity. *Pyrazinamide* exhibits antimicrobial activity *in vitro* only at acidic pH. At pH 5.9, 95% of *M. tuberculosis* clinical isolates have an MIC of 6.25 to 200 mg/L (Gumbo et al., 2014).

Mechanisms of Resistance. There are various mechanisms of drug resistance to *pyrazinamide*. First, mutations in several positions in the *pncA* gene lead to expression of pyrazinamidase with reduced affinity for *pyrazinamide*, leading to decreased conversion of *pyrazinamide* to its active form. In addition, mutations in *RpsA* or *panD* confer *pyrazinamide* resistance (Kuhlin et al., 2021; Zhang et al., 2014). Finally, mutations in *M. tuberculosis* efflux pumps can cause resistance to *pyrazinamide*, as well as other anti-TB drugs (Liu et al., 2019; Zimic et al., 2012).

ADME. The oral bioavailability of *pyrazinamide* exceeds 90%, although some patients absorb *pyrazinamide* more quickly than others (absorption rate constant of 3.56/h vs. 1.25/h) (Wilkins et al., 2006). *Pyrazinamide* is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is then excreted by the kidneys. Clearance and V_d increase with patient mass (0.5 L/h and 4.3 L for every 10 kg above 50 kg), and V_d is larger in males (by 4.5 L) (see Table 65–2). Weight-based dosing is typically employed for *pyrazinamide*, although fixed doses may be more practical, likely to achieve targets, and effective for low-weight individuals (Sahota and Della Pasqua, 2012). *Pyrazinamide* clearance is reduced in renal failure; therefore, the dosing frequency is reduced to three times a week at low glomerular filtration rates. Hemodialysis removes *pyrazinamide*, so the drug should be redosed after each session (Malone et al., 1999b).

Microbial Pharmacokinetics-Pharmacodynamics. The PK parameter that correlates most closely with *pyrazinamide*'s activity is AUC, followed closely by C_{max} (Chigutsa et al., 2015; Gumbo et al., 2009). Higher C_{max} or AUC and lack of genetic resistance markers are associated with shorter time to culture conversion and better clinical outcomes (Kuhlin et al., 2021; Zhang et al., 2021).

Therapeutic Uses. Adding *pyrazinamide* to *isoniazid*- and *rifampin*-containing regimens allows for shortening duration of treatment from 9–12 to 6 months, producing the current "short-course" chemotherapeutic regimen. *Pyrazinamide* is administered at an oral dose of 25 to 35 mg/kg per day.

Untoward Effects. Injury to the liver is the most serious side effect of *pyrazinamide*. Hepatotoxicity appears to be idiosyncratic, up to doses of at least 40 mg/kg, at which time an exposure-toxicity relationship is seen (Pasipanodya and Gumbo, 2010; Sahota and Della Pasqua, 2012; Zhang et al., 2021). At high doses, hepatic disease appears in about 15% of patients, with jaundice in 2% to 3% and death due to hepatic necrosis in rare instances; current dosing regimens are much safer. Prior to *pyrazinamide* administration, all patients should undergo studies of hepatic function, and these studies should be repeated during treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. *Pyrazinamide* should be avoided in individuals with baseline hepatic dysfunction. If *pyrazinamide* cannot be used, "short-course" treatment with *rifampin*, *isoniazid*, and *ethambutol* can still be successful provided treatment duration is prolonged to 9 months from 6 months.

In nearly all patients, *pyrazinamide* inhibits excretion of urate, resulting in hyperuricemia, which may cause acute episodes of gout. Other untoward effects observed with *pyrazinamide* include arthralgias, anorexia, nausea, vomiting, dysuria, malaise, and fever. Although the World Health Organization (WHO) recommends routine use of *pyrazinamide* in pregnancy, the use of *pyrazinamide* is not approved during pregnancy in the U.S. because of inadequate teratogenicity data.

Isoniazid

Isoniazid (*isonic*otinic acid hyd*razide*), also called INH (Figure 65–3), is an important drug for the chemotherapy of drug-susceptible TB and may

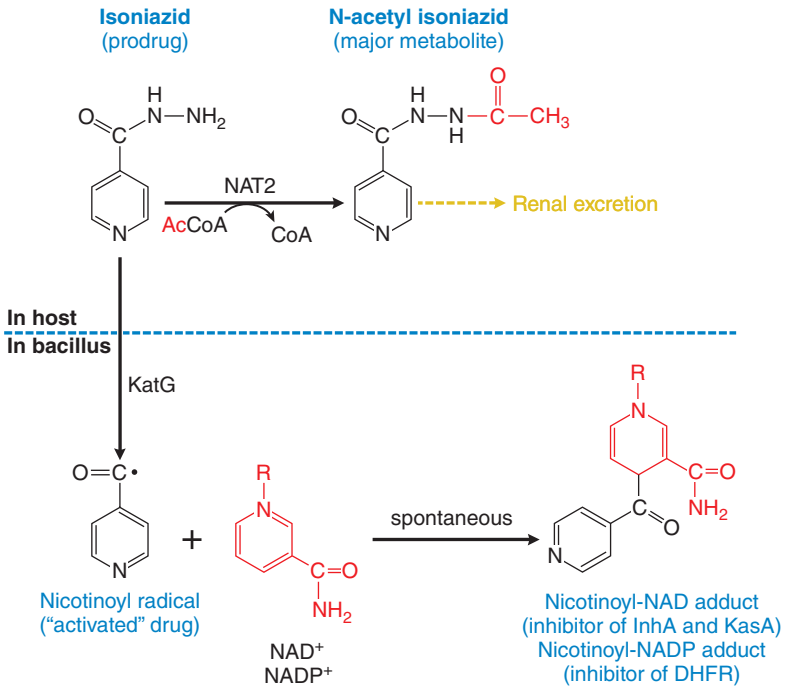


Figure 65–3 *Metabolism and activation of isoniazid.* The prodrug *isoniazid* is metabolized in humans by NAT2 isoforms to its principal metabolite, *N*-acetyl isoniazid, which is excreted by the kidney. *Isoniazid* diffuses into mycobacteria, where it is "activated" by KatG (oxidase/peroxidase) to the nicotinoyl radical. The nicotinoyl radical reacts spontaneously with NAD^+ to produce adducts that inhibit essential enzymes in synthesis of the cell wall and with $NADP^+$ to produce an inhibitor of nucleic acid synthesis.

have a role in some cases of drug-resistant TB. The use of combination therapy (INH + *pyrazinamide* + *rifampin*) provides the basis for short-course therapy and improved cure rates.

Mechanism of Action. *Isoniazid* enters bacilli by passive diffusion. The drug is not directly toxic to the bacillus and must be activated by KatG, a multifunctional catalase-peroxidase. KatG catalyzes the production of an isonicotinoyl radical that subsequently interacts with mycobacterial NAD and NAPD to produce a dozen adducts (Argyrou et al., 2007). One of these, a nicotinoyl-NAD isomer, inhibits the activities of enoyl acyl carrier protein reductase (InhA) and KasA (β-ketoacyl-acyl carrier protein synthase), blocking synthesis of mycolic acid, an essential component of the mycobacterial cell wall, leading to bacterial cell death. Another adduct, a nicotinoyl-NADP isomer, potently inhibits (K_i < 1 nM) mycobacterial dihydrofolate reductase, thereby interfering with nucleic acid synthesis (Argyrou et al., 2006) (see Figure 65–3).

Other products of KatG activation of INH include superoxide, H_2O_2, alkyl hydroperoxides, and the nitric oxide (NO) radical, which may also contribute to the mycobactericidal effects of INH (Timmins and Deretic, 2006). *M. tuberculosis* could be especially sensitive to damage from these radicals because the bacilli have a defect in the central regulator of the oxidative stress response, *oxyR*. Backup defense against radicals is provided by alkyl hydroperoxide reductase (encoded by *ahpC*), which detoxifies organic peroxides. Increased expression of *ahpC* reduces INH effectiveness.

Antibacterial Activity. The INH MICs with clinical *M. tuberculosis* strains vary from country to country. In the U.S., for example, MICs are typically 0.025 to 0.05 mg/L. INH is first-line therapy for *M. kansasii*, has moderate activity against *Mycobacterium bovis*, and poor activity against MAC. It has no activity against any other microbial genus.

Mechanisms of Resistance. The prevalence of INH-resistant mutants is about 1 in 10^6 bacilli. Because TB cavities may contain as many as 10^7 to 10^9 microorganisms, preexisting resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected and amplified by INH monotherapy. Thus, two or more agents are used to treat active TB disease. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, about 1 in 10^{12} ($1 \times 10^6 \times 10^6$), a low probability considering the number of bacilli present.

Resistance to INH is associated with mutation or deletion of KatG (generally conferring high-level resistance), overexpression of the genes for InhA (conferring low-level resistance to INH and some cross-resistance to *ethionamide*) and AhpC, and mutations in the *kasA* and *katG* genes. The most common mechanism of INH resistance in clinical isolates is due to single point mutations in the heme-binding catalytic domain of KatG, especially a serine-to-asparagine change at position 315. Although isolates with this mutation completely lose the ability to form nicotinoyl-NAD^+/$NADP^+$ adducts, they retain good catalase activity and maintain good biofitness. Compensatory mutations in the *ahpC* promoter occur and increase survival of *katG*-mutant strains under oxidative stress. Efflux pump induction by INH has been demonstrated and also confers resistance to *ethambutol* (Colangeli et al., 2005). Studies of the evolution of drug-resistant TB over time in human populations demonstrate that INH resistance has overwhelmingly been the initial acquired resistance mutation, followed by resistance to *rifampin* and other drugs (Cohen et al., 2015).

ADME. The bioavailability of orally administered INH is about 100% for the 300-mg dose. The PK of INH are best described by a two-compartment model, with the PK parameters in Table 65–2 (Pasipanodya and Gumbo, 2013). Approximately 10% of drug is bound to protein. From 75% to 95% of a dose of INH is excreted in the urine within 24 h, mostly as acetylisoniazid and isonicotinic acid.

Isoniazid is metabolized by hepatic arylamine NAT2 (*N*-acetyltransferase type 2), encoded by a variety of *NAT2** alleles (Figure 65–4). A pioneering report in pharmacogenetics elucidated differences in INH clearance by NAT2 acetylator status (Evans and Clarke, 1961). Patients who are slow acetylators of INH have concentrations of the drug that

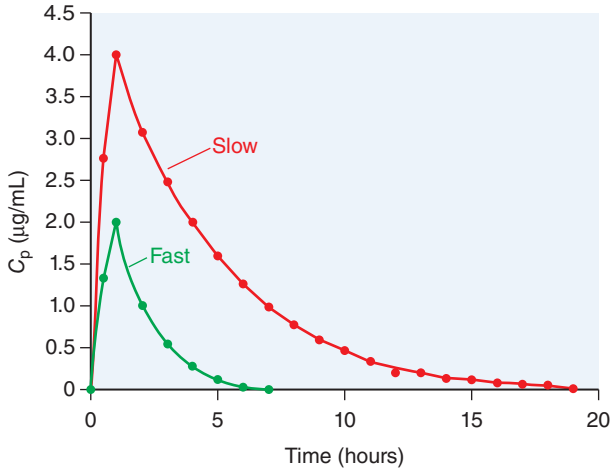

Figure 65–4 *Multimodal distribution of INH clearance due to NAT2 polymorphisms.* A group of matched male volunteers received INH (250 mg orally), and the time courses of plasma drug levels (C_p) were assessed. One-third of the subjects had INH elimination $t_{1/2}$ values less than 1.5 h; these were the *fast acetylators*. Two-thirds had $t_{1/2}$ values ranging from 2.1 to 4.0 h, with a suggestion of multiple groups; these were the *slow acetylators*. Plots of the mean data (C_p vs. time after administration) demonstrate the PK effects of acetylation rate. Both groups reached C_{Pmax} at 1 h. The slow acetylators (red line) achieved a higher C_p (4 μg/mL) with a mean elimination $t_{1/2}$ of 3.0 h; the fast acetylators (green line) reached a lower maximal C_p (2 μg/mL) with a mean elimination $t_{1/2}$ of 1.0 h. The acetylation rate reflects variable expression of active polymorphic forms of NAT2. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procainamide; fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified three elimination subgroups for INH metabolism: *fast*, *slow*, and *intermediate* (codominant fast and slow alleles).

are three times higher than fast acetylators; fast acetylators are at risk for reduced microbial cure, increased relapse, and acquired drug resistance (Pasipanodya et al., 2012). Eighty-eight percent of the variability in INH clearance can be explained by NAT2 status, the distribution of which varies geographically.

Fast acetylation is found more commonly in Inuit and Japanese populations, while slow acetylation is the predominant phenotype in most Scandinavians, North African whites, and those of Jewish descent. The high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait; fast acetylators of INH are either heterozygous or homozygous.

Microbial Pharmacokinetics-Pharmacodynamics. *Isoniazid*'s microbial kill, as well as protection against emergence of resistance, is concentration dependent and correlates well with AUC_{0-24} or C_{Pmax} (Gumbo et al., 2007b; Jayaram et al., 2004; Pasipanodya et al., 2013).

Therapeutic Uses. *Isoniazid* is available as a pill, as an elixir, and for parenteral administration. The recommended total daily dose of INH is 5 mg/kg with a maximum of 300 mg administered daily.

Untoward Effects. After NAT2 converts INH to acetylisoniazid, it is either excreted by the kidney or is converted to acetylhydrazine (Roy et al., 2008) and then to hepatotoxic metabolites by CYP2E1. Alternatively, acetylhydrazine may be further acetylated by NAT2 to diacetylhydrazine, which is nontoxic. In this scenario, rapid acetylators will rapidly remove acetylhydrazine, while slower acetylation or induction of CYP2E1 or mutations in CYP2E1 that lead to increased enzyme activity may lead to more of the toxic metabolites (Sheng et al., 2014).

Elevated serum aspartate and alanine transaminases are encountered commonly in patients taking INH. However, the enzyme levels often normalize even when INH therapy is continued (Blumberg et al., 2003). Severe hepatic injury occurs in about 0.1% of all patients taking the drug. Hepatic damage is rare in patients less than 20 years old, and the

incidence increases with age. Most cases of hepatitis occur 4 to 8 weeks after the start of therapy.

If *pyridoxine* is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is encountered in about 2% of patients receiving 5 mg/kg INH daily. Neuropathy is more frequent in slow acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may appear during the use of this drug, including euphoria, transient impairment of memory, loss of self-control, and florid psychoses.

Patients may develop hypersensitivity to INH as well as rheumatological conditions. Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms have been attributed to this agent. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported. Miscellaneous reactions associated with INH therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to *pyridoxine* deficiency anemia, the administration of INH may result in dramatic anemia. Treatment of the anemia with large doses of vitamin B_6 gradually returns the blood count to normal.

As little as 1.5 g of INH can be toxic. INH overdose has been associated with the clinical triad of:

- Seizures refractory to treatment with *phenytoin* and barbiturates
- Anion gap metabolic acidosis that is refractory to treatment with sodium bicarbonate
- Coma

The common early symptoms appear within 0.5 to 3 h of ingestion and include ataxia, peripheral neuropathy, dizziness, and slurred speech. The most dangerous are grand mal seizures and coma, encountered when patients ingest 30 mg/kg or more of the drug. Mortality in these circumstances is as high as 20%. Intravenous *pyridoxine* is administered over 5 to 15 min on a gram-to-gram basis with the ingested INH. If the dose of ingested INH is unknown, then 70 mg/kg dose of *pyridoxine* is given. In patients with seizures, benzodiazepines are utilized.

Isoniazid binds to pyridoxal 5′-phosphate to form isoniazid-pyridoxal hydrazones, thereby depleting neuronal pyridoxal 5′-phosphate and interfering with pyridoxal phosphate–requiring reactions, including the synthesis of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Decreased levels of GABA lead to cerebral overexcitability and lowered seizure threshold. The antidote is replenishment of pyridoxal 5′-phosphate.

Drug Interactions. *Isoniazid* is a potent inhibitor of CYP2C19 and CYP3A, a weak inhibitor of CYP1A2, CYP2A6, and CYP2D6, and a weak inducer of CYP2E1 (Desta et al., 2001). Drugs that are metabolized by these enzymes will potentially be affected (Table 65–4).

TABLE 65–4 ■ SOME ISONIAZID-DRUG INTERACTIONS VIA INHIBITION AND INDUCTION OF CYPs

COADMINISTERED DRUG	CYP ISOFORM	ADVERSE EFFECTS
Acetaminophen	CYP2E1 induction	Hepatotoxicity
Carbamazepine	CYP3A inhibition	Neurological toxicity
Diazepam	CYP3A and CYP2C19 inhibition	Sedation and respiratory depression
Ethosuximide	CYP3A inhibition	Psychotic behaviors
Isoflurane and enflurane	CYP2E1 induction	Decreased effectiveness
Phenytoin and fosphenytoin	CYP2C19 inhibition	Neurological toxicity
Theophylline	CYP3A inhibition	Seizures, palpitation, nausea
Vincristine	CYP3A inhibition	Limb weakness and tingling
Warfarin	CYP2C9 inhibition	Possibility of increased bleeding (higher risk with isoniazid doses >300 mg/day)

Ethambutol

Ethambutol hydrochloride is a water-soluble and heat-stable compound. It was discovered in the 1960s and has demonstrated utility in protecting companion drugs against resistance in mice and humans and is generally used for that purpose in tuberculosis.

Mechanism of Action. *Ethambutol* inhibits arabinosyl transferase III, thereby disrupting the transfer of arabinose into arabinogalactan biosynthesis, which in turn disrupts assembly of the mycobacterial cell wall. The arabinosyl transferases are encoded by *embB* genes.

Antibacterial Activity. *Ethambutol* has activity against a wide range of mycobacteria but has no activity against any other genus. *Ethambutol* MICs are 0.5 to 2 mg/L in clinical isolates of *M. tuberculosis*, about 0.8 mg/L for *M. kansasii,* and 2 to 7.5 mg/L for *M. avium*. The following *Mycobacterium* species are also susceptible: *M. gordonae, M. marinum, M. scrofulaceum,* and *M. szulgai*. However, the majority of *M. xenopi, M. fortuitum, M. abscessus,* and *M. chelonae* have been reported as resistant.

Mechanisms of Resistance. *In vitro*, mycobacterial resistance to the drug develops via mutations in the *embB* gene that encodes arabinosyltransferases. In 30% to 70% of clinical isolates that are resistant to *ethambutol*, mutations are encountered in the *ethambutol* resistance–determining region of the *embB* gene. However, mutations in codon 306 (the most common mutation) are also encountered in *ethambutol*-susceptible mycobacteria; therefore, this mutation is necessary, but not sufficient, to confer *ethambutol* resistance (Safi et al., 2008). Enhanced efflux pump activity may induce resistance to both INH and *ethambutol in vitro*.

ADME. The oral bioavailability of *ethambutol* is about 80%. Approximately 10% to 40% of the drug is bound to plasma protein. *Ethambutol* drug concentrations have been modeled using a two-compartment model, with first-order absorption and elimination (Zhu et al., 2004). The decline in *ethambutol* is biexponential, with a $t_{1/2}$ of 3 h in the first 12 h and a $t_{1/2}$ of 9 h between 12 and 24 h due to redistribution of drug. Clearance and V_d are greater in children than in adults on a per-kilogram basis. Slow and incomplete absorption is common in children (Zhu et al., 2004). See Table 65–2 for PK data on this drug.

About 80% of the drug is not metabolized and is renally excreted as parent drug. Therefore, in renal failure, *ethambutol* should be dosed at 15 to 25 mg/kg three times a week instead of daily, including in patients on hemodialysis. The remainder of *ethambutol* (~20%) is oxidized by aldehyde dehydrogenase and excreted as aldehyde and dicarboxylic acid derivatives.

Microbial Pharmacokinetics-Pharmacodynamics. *Ethambutol*'s microbial kill of *M. tuberculosis* is optimized by AUC/MIC, while that against disseminated MAC is optimized by C_{max}/MIC (Deshpande et al., 2010) (see Chapter 56).

Therapeutic Uses. *Ethambutol* is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated MAC, and in *M. kansasii* infection. *Ethambutol* is administered at 15 to 25 mg/kg per day for both adults and children.

Untoward Effects. At standard doses, *ethambutol* produces very few serious untoward reactions: About 1% of patients experience diminished visual acuity, 0.5% a rash, and 0.3% drug fever. Other side effects include pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations.

Therapy with *ethambutol* results in an increased concentration of urate in the blood in about 50% of patients, owing to decreased renal excretion of uric acid.

The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of red-green discrimination. The incidence of this reaction is proportional to the dose and duration of *ethambutol* and is observed in 15% of patients receiving 50 mg/kg per day, in 5% of patients receiving 25 mg/kg per day, and in less than 1% of patients receiving daily doses of 15 mg/kg. While 15 mg/kg may be considered the minimal effective dose (Radenbach, 1973), this is the recommended dose for drug-sensitive TB given its narrow therapeutic window (higher doses are commonly used in drug-resistant TB). Severity of the visual loss is related to the duration of therapy after decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when *ethambutol* is withdrawn but in some cases can be permanent. There are no known clinically important drug interactions involving *ethambutol*.

Second-Line Drugs

Injectable Agents: Aminoglycosides (Streptomycin, Amikacin, Kanamycin) and Capreomycin

While *streptomycin* was commonly used as first-line therapy, and an injectable agent such as *amikacin*, *kanamycin*, or *capreomycin* was recommended as standard of care for MDR-TB until very recently, these drugs have largely been phased out of TB treatment regimens, owing to their dose- and duration-dependent toxicities, which includes irreversible hearing loss and vestibular damage. They are still used in hard-to-treat NTM infections, such as drug-resistant MAC or *M. abscessus*. The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 59.

Capreomycin is an antimycobacterial cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides, as are adverse effects, and *capreomycin* should not be administered with other drugs that damage cranial nerve VIII. Adverse reactions include pain with injection, hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Eosinophilia is common; leukocytosis, leukopenia, rash, and fever have been observed. Severe renal failure is rare.

Bacterial resistance to *capreomycin* develops when it is given alone; such microorganisms show cross-resistance with *kanamycin* and *neomycin*. The recommended daily dose is 1 g (no more than 20 mg/kg) per day for 60 to 120 days, followed by 1 g two or three times a week.

Clofazimine

Clofazimine is a fat-soluble riminophenazine dye initially evaluated as a treatment for TB in 1954, but owing to inconsistent results in early animal models, it was instead developed and first licensed for use in leprosy in 1969. It is now considered a Group A (standard of care, see Definitive Therapy of Drug-Resistant TB section below) drug for the treatment of RR- or MDR-TB in the WHO treatment guideline scheme, is increasingly used in NTM, and is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*.

Mechanism of Action. The mechanism of antimicrobial activity of *clofazimine* against mycobacteria appears to be multifactorial and includes membrane disruption, inhibition of mycobacterial phospholipase A_2, inhibition of microbial K^+ transport, generation of hydrogen peroxide, interference with the bacterial electron transport chain, and efflux pump inhibition. *Clofazimine* has both antibacterial activity and anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

Antibacterial Activity. The MICs for *M. tuberculosis* are 0.06 to 2 mg/L. The MICs for *M. avium* clinical isolates are 1 to 5 mg/L and for *M. abscessus* are 0.25 to 0.5 mg/L (Shen et al., 2010). It has activity against many gram-positive bacteria with an MIC of 1.0 μg/L or less against *S. aureus*, coagulase-negative staphylococci, *Streptococcus pyogenes*, and *Listeria monocytogenes*. Gram-negative bacteria have MICs greater than 32 mg/L.

Bacterial Resistance. Resistance has been associated with mutations in *Rv0678*, a repressor gene that affects the mmpS5-mmpL5 efflux pump; this is associated with cross-resistance to *bedaquiline* (Hartkoorn et al., 2014; Zhang S et al., 2015). Mutations in *pepQ* appear also to confer resistance to both *clofazimine* and *bedaquiline* via effects on drug efflux. Mutations in *Rv1979c* affect *clofazimine* but not *bedaquiline* (Kadura et al., 2020; Xu et al., 2017).

ADME. *Clofazimine* is administered orally at doses up to 300 mg a day. *Clofazimine*'s oral bioavailability is 45% to 60%; it is increased 2-fold by high-fat meals and decreased 30% by antacids (Nix et al., 2004). *Clofazimine*'s PK are best modeled using a three-compartment model. It has a prolonged absorption phase and large volume of distribution (10,000 L for a typical patient) (Abdelwahab et al., 2020). After sustained repeated dosing, the $t_{1/2}$ is about 35 days (see Table 65–2 for PK data). As a result of high penetration into many tissues, a reddish-black discoloration of skin and body secretions may occur and take months to years to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (TB Alliance, 2008). *Clofazimine* is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

Untoward Effects. Gastrointestinal problems are encountered in 40% to 50% of patients. In patients on *clofazimine* who died after complaints of abdominal pain, crystal deposition throughout the intestinal mucosa, liver, spleen, and abdominal lymph nodes was found (TB Alliance, 2008). Ichthyosis and discoloration of skin, eyes, and bodily secretions can be distressing or stigmatizing to patients. *Clofazimine* is also associated with prolongation of the QT interval on electrocardiogram (ECG).

Drug Interactions. The anti-inflammatory effects of *clofazimine* may be inhibited by *dapsone*.

Ethionamide

Ethionamide is a congener of thioisonicotinamide. It is currently considered a Group C drug for the treatment of MDR-TB (to be used only when a regimen cannot be constructed using Group A and B drugs).

Mechanism of Action. Mycobacterial EthA, an NADPH-specific, flavin adenine dinucleotide (FAD)-containing monooxygenase, converts *ethionamide* to a sulfoxide and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. *Ethionamide* inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP (acyl carrier protein) reductase of fatty acid synthase II (Larsen et al., 2002). This is the same enzyme that activated INH inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell wall synthesis.

Antibacterial Activity. The multiplication of *M. tuberculosis* is suppressed by concentrations of *ethionamide* ranging from 0.6 to 2.5 mg/L. A concentration of 10 mg/L or less will inhibit about 75% of photochromogenic mycobacteria; the scotochromogens are more resistant.

Bacterial Resistance. Resistance occurs mainly via changes in the enzyme EthA that activates *ethionamide* or in a transcriptional repressor gene that controls its expression, *etaR*. Mutations in the *inhA* gene or in its promoter lead to resistance to both *ethionamide* and INH (Vilcheze and Jacobs, 2014).

ADME. The oral bioavailability of *ethionamide* approaches 100%. The PK are adequately explained by a one-compartment model with first-order absorption and elimination (Al-Shaer et al., 2020; Zhu et al., 2002) (see PK values in Table 65–2). After oral administration of 500 mg of *ethionamide*, a C_{max} of 1.4 mg/L is achieved in 2 h; $t_{1/2}$ is about 2 h. *Ethionamide* is cleared by hepatic metabolism. Metabolites are eliminated in the urine, with less than 1% of *ethionamide* excreted in an active form.

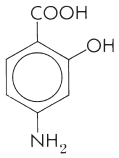
Therapeutic Uses. *Ethionamide* is administered orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/day every

5 days until a dose of 15 to 20 mg/kg per day is achieved up to a daily maximal dose of 1 g. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10 to 20 mg/kg per day in two divided doses, not to exceed 1 g/day.

Untoward Effects. *Ethionamide* is very poorly tolerated. Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurological symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. *Pyridoxine* (vitamin B_6) may relieve or prevent the neurological symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, metallic taste, and alopecia have also been observed. Hepatitis has been associated with the use of the *ethionamide* in about 5% of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

Para-aminosalicylic Acid

Para-aminosalicylic acid (PAS), discovered by Lehman in 1943, was the second effective drug against TB. It is currently a Group C drug, to be used in MDR-TB only when regimens using Group A and B drugs are not possible.



AMINOSALICYLIC ACID

Mechanism of Action. *Para-aminosalicylic acid* is a structural analogue of *para*-aminobenzoic acid (PABA), the substrate of dihydropteroate synthase (*fol*P1/P2). It was previously believed that PAS was a competitive inhibitor of *fol*P1, but recent metabolomics work demonstrated that PAS is a prodrug whose active products block *M. tuberculosis* growth downstream of dihydropteroate synthase (DHPS) (Chakraborty et al., 2013). Mutation of the thymidylate synthase gene (*thyA*) results in resistance to PAS; however, only 37% of PAS-resistant clinical isolates or spontaneous mutants encode a mutation in the *thyA* gene or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009).

Antibacterial Activity. *Para-aminosalicylic acid* is bacteriostatic. *In vitro*, most strains of *M. tuberculosis* are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

Bacterial Resistance. Mutations in *thyA*, *folC*, and *ribD* lead to PAS resistance in up to 61% of resistant isolates (Zhang X et al., 2015). Recently, MDR-TB strains due to deletions of entire *dfrA* and *thyA* have been identified, a surprising finding given the conserved nature of folate synthesis (Moradigaravand et al., 2016).

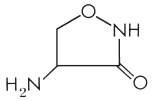
ADME. *Para-aminosalicylic acid* oral bioavailability is more than 90%. PAS PK are described by a one-compartment model (Peloquin et al., 2001) (see PK values in Table 65–2). The C_{max} increases 1.5-fold and AUC 1.7-fold with food compared to fasting (Peloquin et al., 2001). Administration with food also reduces gastric irritation. Protein binding is 50% to 60%. PAS is *N*-acetylated in the liver to *N*-acetyl PAS, a potential hepatotoxin. Over 80% of the drug is excreted in the urine; more than 50% is in the form of the acetylated compound. Excretion of PAS acid is reduced by renal dysfunction; thus, the dose must be reduced in renal dysfunction.

Therapeutic Uses. *Para-aminosalicylic acid* is administered orally in a total daily dose of 12 g. The drug is best administered after meals, with the daily dose divided into three equal portions. Children should receive 150 to 300 mg/kg per day in three or four divided doses.

Untoward Effects. The incidence of untoward effects associated with the use of PAS is about 10% to 30%. GI problems predominate and often limit patient adherence. In the days of TB sanatoria, it is rumored that one could tell which patients were on PAS because many patients threw it out the window, causing discoloration of the grass: the drug turns brown or purple in direct sunlight or if exposed to water. Hypersensitivity reactions to PAS are seen in 5% to 10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities. People with glucose-6-phosphate dehydrogenase (G6PD) deficiency should not take this drug, as it would cause hemolysis.

Cycloserine and Terizidone

Cycloserine is D-4-amino-3-isoxazolidone. It is a broad-spectrum antibiotic produced by *Streptococcus orchidaceous.* It is a Group B drug, used for MDR-TB.



CYCLOSERINE

Mechanism of Action. *Cycloserine* and D-alanine are structural analogues; thus, *cycloserine* inhibits alanine racemase, which converts L-alanine to D-alanine, and D-alanine–D-alanine ligase, thereby stopping reactions in which D-alanine is incorporated into bacterial cell wall synthesis. *Terizidone* is a structural analogue of *cycloserine*, and the two drugs are used interchangeably.

Antibacterial Activity. *Cycloserine* is a broad-spectrum antibiotic. It inhibits *M. tuberculosis* at concentrations of 5 to 20 mg/L. It has good activity against MAC, enterococci, *E. coli, S. aureus, Nocardia* species, and *Chlamydia*.

Mechanisms of Resistance. *Cycloserine* resistance in clinical isolates of *M. tuberculosis* results mostly from mutations in *alr*, which encodes alanine racemase or in the *alr* promoter (Chen et al., 2017; Desjardins et al., 2016).

ADME. Oral *cycloserine* is almost completely absorbed. The population PK are best described using a one-compartment model with first-order absorption and elimination. The drug's $t_{1/2}$ is 9 h. The C_{max} in plasma is reached in 45 min in fasting subjects but is delayed for up to 3.5 h with a high-fat meal. See Table 65–2 for PK values. *Cycloserine* is widely distributed throughout the body, including to the cerebrospinal fluid and brain. About 50% of *cycloserine* is excreted unchanged in the urine in the first 12 h; a total of 70% is recoverable in the active form over a period of 24 h. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of *cycloserine* is removed by hemodialysis, and the drug must be readministered after each hemodialysis session (Malone et al., 1999a).

Therapeutic Uses. *Cycloserine* is available for oral administration. The usual dose for adults is 250 to 500 mg twice daily.

Untoward Effects. Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/day. Because of the prevalence of these occurrences, the drug is sometimes referred to as "psycho-serine." Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideations. Large doses of *cycloserine* or the concomitant ingestion of alcohol increases the risk of seizures. *Cycloserine* is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

Newer Drugs

Bedaquiline

Bedaquiline was discovered by Andries and colleagues in 2005 and was registered with the FDA in 2012 for the treatment of drug-resistant TB. Since then, it has been shown to have potent sterilizing activity and to reduce mortality in patients with MDR-TB (Ndjeka et al., 2018). It is now classified as a Group A drug and considered standard of care for patients with MDR-TB. *Bedaquiline* is a cationic amphiphilic drug, which may account for its high accumulation in tissues.

Mechanism of Action. *Bedaquiline* acts by targeting subunit *c* of the ATP synthase of *M. tuberculosis*, leading to inhibition of the proton pump activity of the ATP synthase, thereby targeting bacillary energy metabolism (Andries et al., 2005; Koul et al., 2007).

Antibacterial Activity. The *bedaquiline* MIC for *M. tuberculosis* is 0.03 to 0.12 mg/L. It has potent activity against MAC, *M. leprae, M. bovis, M. marinum, M. kansasii, M. ulcerans, M. fortuitum, M. szulgai,* and *M. abscessus* (Andries et al., 2005; Huitric et al., 2007).

Bacterial Resistance. The proportion of *M. tuberculosis* mutants resistant to four times the MIC is 5×10^{-7} to 2×10^{-8}. Resistance is associated with mutations in D32V and A63P in the region of the gene encoding the membrane-spanning domain of the ATP synthase *c* subunit. Resistance due to efflux pump mutations and their regulators also occurs and is associated with cross-resistance to *clofazimine*.

ADME. The population PK of *bedaquiline* are well characterized (Svensson et al., 2013, 2016). After oral ingestion, there is a large lag time in absorption, resulting in a t_{max} of 5 h. The PKs are best described using a three-compartment model, with a central compartment and two peripheral compartments. The drug has a very large volume of distribution (>10,000 L) (Svensson et al., 2016) and accumulates intracellularly. Food increases bioavailability 2-fold (van Heeswijk et al., 2014). Clearance is 52% higher in people of African descent and 16% lower in women compared to men. The terminal $t_{1/2}$ is about 5.5 months, mainly driven by redistribution from the tissues. *Bedaquiline* is metabolized by CY3A4 to M2, an *N*-monodesmethyl metabolite, which has approximately 20% of parent drug's activity against *M. tuberculosis*.

Microbial Pharmacokinetics-Pharmacodynamics. Microbial kill of *bedaquiline* is linked to AUC/MIC ratios (Rouan et al., 2012; Svensson and Karlsson, 2017). The PK-pharmacodynamic parameters linked to resistance suppression are not established.

Efficacy and Therapeutic Use. A regimen of *bedaquiline* 400 mg daily for 2 weeks followed by 200 mg three times per week to complete 24 weeks of therapy was added to a background second-line regimen of either *kanamycin* or *amikacin* and *ofloxacin* with or without *ethambutol* in patients with MDR-TB and led to an 8-week sputum conversion of about 50% with *bedaquiline* compared to 9% with background regimen alone (Diacon et al., 2009). This study led to licensing of the drug as part of multidrug therapy for MDR-TB. Subsequent studies confirmed the bacterial activity seen in the initial trial (Diacon et al., 2014). More recently, a 6-month regimen of *bedaquiline* combined with *pretomanid* and *linezolid* proved highly effective against extensively drug-resistant (XDR-) TB (Conradie et al., 2020).

Untoward Effects. *Bedaquiline* is generally well tolerated. The most common side effects include nausea in 26% of patients and diarrhea in 13% of patients, but these are rarely treatment-limiting. *Bedaquiline* causes prolongation of the QT interval, driven by its M2 metabolite; thus, serial ECG monitoring is recommended.

Drug Interactions. Bedaquiline is metabolized by CYP3A4; thus, it is prudent to avoid strong CYP3A4 inducers while taking *bedaquiline*. For patients taking a companion drug that inhibits CYP3A4, if substitution is not possible, then close ECG monitoring should be undertaken. The same is true if *bedaquiline* is taken with other drugs that prolong the QT interval.

Bicyclic Nitroimidazoles: Delamanid and Pretomanid

Pretomanid, discovered by Stover and coleagues in 2000, and *delamanid*, discovered by Matsumoto and colleagues in 2006, are bicyclic nitroimidazopyrans that are being used in the treatment of XDR- and MDR-TB. *Pretomanid* is FDA-approved for the treatment of XDR-TB in combination with *bedaquiline* and *linezolid*. *Delamanid* is licensed by the European Medicines Agency for the treatment of MDR-TB.

Mechanisms of Action. *Pretomanid* has two mechanisms of action. First, under aerobic conditions, it inhibits *M. tuberculosis* mycolic acid and protein synthesis at the step between hydroxymycolate and ketomycolate (Stover et al., 2000). Similar to the structural related *metronidazole*, *pretomanid* requires activation by the bacteria via a nitroreduction step that requires, among other factors, a specific G6PD, FGD1 (NADP-dependent G6PD), and the reduced deazaflavin cofactor F_{420} encoded by Rv3547 (Bashiri et al., 2008). Second, in nonreplicating persistent bacilli (NRPB), it generates reactive nitrogen species such as NO via its des-nitro metabolite, which then augment the kill of intracellular NRPB by the innate immune system (Singh et al., 2008). In addition, direct poisoning of the respiratory complex in the NRPB leads to ATP depletion.

Delamanid is also a prodrug that is activated by the same enzyme encoded by Rv3547 (Xavier and Lakshmanan, 2014). Similarly, it also forms a reactive intermediate metabolite that inhibits mycolic acid production.

Antibacterial Activity. The MICs of *pretomanid* against *M. tuberculosis* range from 0.015 to 0.25 mg/L, but the drug lacks activity against other mycobacteria. Similarly, for *delamanid*, MICs range from 0.006 to 0.012 mg/L (Matsumoto et al., 2006).

Mechanism of Resistance. The proportion of mutants resistant to 5 mg/L of *pretomanid* is 1 in 10^{-6}. Resistance arises from changes in the structure of FGD, which is due to a variety of point mutations in the *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations (Stover et al., 2000). Mutation frequencies for *delamanid* are unclear; however, resistance has also been shown to be due to *fgd1* and *fbiA* mutations (Bloemberg et al., 2015).

ADME. Systemic exposures of *pretomanid* and *delamanid* increase when taken with food. *Delamanid* metabolism involves albumin. *Delamanid* is not metabolized by CYP4s. *Pretomanid* is metabolized approximately 20% by CYP3A; coadministration of *rifampin* reduces *pretomanid* exposures (Dooley et al., 2014; Ignatius et al., 2021). PK parameters of *pretomanid* and *delamanid* are summarized in Table 65–2 (Ginsberg et al., 2009; Ignatius et al., 2021; Salinger et al., 2019; Wang et al., 2020).

Microbial Pharmacokinetics-Pharmacodynamics. Nitroimidazoles display time-dependent activity in mouse models of TB. There are no published analyses evaluating PK-pharmacodynamic relationships for nitroimidazoles in patients with TB.

Therapeutic Uses. *Delamanid* is currently dispensed in 50-mg tablets, and it is taken at a dose of 100 mg twice daily, with food; in the phase III trial among patients with pulmonary MDR-TB, the dose was switched to 200 mg once daily after the initial 2 months of treatment for ease of administration. *Pretomanid* is administered at 200 mg/day and has shown efficacy in phase III trials in combination with *bedaquiline* and *linezolid* for the treatment of MDR- and XDR-TB (Conradie et al., 2020).

Untoward Effects. *Delamanid* can cause headaches and insomnia. It has a modest effect on the QT interval on ECG. *Pretomanid* was registered based on data from just 100 patients, so the safety profile of this drug has not been fully elucidated. This drug has been associated with hepatotoxicity, but the magnitude of the risk and the role of companion drugs in this potential toxicity are still under investigation. Its effects on human male fertility have not been adequately evaluated, but studies are underway.

Drug interactions. *Pretomanid* is metabolized in part by CYP3A, so coadministration with strong or moderate CYP3A inducers should be avoided. *Delamanid* displays low bioavailability, so to maximize absorption, it should be taken with food and separated from dosing of other medications, if possible.

Drugs Repurposed for Use in Mycobacterial Infections

Oxazolidinones: Linezolid, Tedizolid, and Sutezolid

Oxazolidinones have been in clinical use for over a decade for the treatment of gram-positive cocci. *Linezolid* and *tedizolid* are highly efficacious in the treatment of TB (Sotgiu et al., 2012). Several studies have examined

the utility of *linezolid* for the treatment of MDR-TB, finding that *linezolid* significantly increases sputum conversion but causes adverse responses in a large fraction of patients (see, for instance, Tang et al., 2015). *Linezolid* is now considered a Group A drug (standard of care) for MDR-TB by the WHO. It is also a required component of a novel 6-month, three-drug regimen that is FDA-approved for patients with XDR-TB, along with *pretomanid* and *bedaquiline* (Conradie et al., 2020). However, side effects related to mitochondrial toxicity (e.g., bone marrow suppression, peripheral neuropathy, optic neuropathy) are common with prolonged dosing, and so new oxazolidinones such as *sutezolid* are in the development pipeline.

Linezolid is also used in the treatment of more complex NTM cases when an effective regimen cannot be constructed owing to resistance or tolerability challenges, but advice regarding its use has not been incorporated into treatment guidelines.

The pharmacology of oxazolidinones is discussed in Chapter 60.

Fluoroquinolones

Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, and pharmacology are discussed in detail in Chapter 57. Of the C8 methoxy quinolones, *moxifloxacin* and *levofloxacin* have been integrated into the treatment of pulmonary and meningeal TB. They are also sometimes used in the treatment of NTM infections. *Ofloxacin* and *ciprofloxacin* are no longer used for TB treatment.

Microbial Pharmacokinetics-Pharmacodynamics Relevant to TB

Fluoroquinolone microbial kill is best explained by the AUC_{0-24}/MIC ratio. In preclinical models of *M. tuberculosis*, *moxifloxacin* AUC_{0-24}/MIC exposures equivalent to those from the standard 400-mg dose were associated with good microbial kill, and in a recent trial, the addition of *moxifloxacin* at a dose of 400 mg daily to a *rifapentine*-based regimen led to enhanced activity that was sufficient to shorten treatment duration from 6 to 4 months (Dorman et al., 2021). This might be in part due to *moxifloxacin*'s high penetration into the lung lesions that characterize human TB and activity against mycobacteria in both aerobic and anaerobic conditions (Sarathy et al., 2019; Strydom et al., 2019). Whether *levofloxacin* has similar treatment-shortening properties is unknown. Clinical trial simulations have revealed that *moxifloxacin* doses greater than 400 mg daily might better achieve AUC/MIC targets for both bacterial killing and suppression of emergence of resistance (Ginsburg et al., 2003; Gumbo et al., 2004). Whether these benefits outweigh the increase in corrected QT interval on the ECG seen with higher-dose *moxifloxacin* remains to be seen.

Fluoroquinolones have very good penetration into the CNS (Thwaites et al., 2011), unlike *ethambutol* and *streptomycin*. In a phase III study, intensified anti-TB treatment with high-dose *rifampin* plus *levofloxacin* was associated with a higher rate of survival among patients with tuberculous meningitis whose *M. tuberculosis* isolates were isoniazid-resistant (but not among those whose isolates were isoniazid-sensitive) (Heemskerk et al., 2016). This suggests that fluoroquinolones may have a role as a replacement for the highly bactericidal INH in INH-monoresistant TB.

Currently, fluoroquinolones, especially *moxifloxacin*, continue to be standard of care as Group A drugs for the treatment of pulmonary MDR-TB (WHO, 2019), and their use is strongly associated with improvement in treatment outcomes.

Fluoroquinolones are not considered first-line treatment for any NTM but are used when other first-line drugs cannot be.

β-Lactam Antibiotics for the Treatment of TB

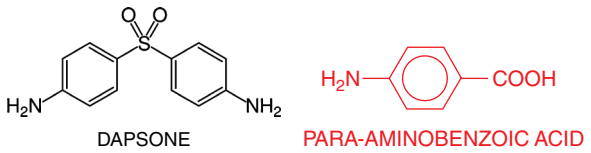
Until recently, it was assumed that β-lactam antibiotics lacked activity against mycobacteria because these bacteria have Ambler class A β-lactamases such as BlacC. Carbapenems, which are poorer substrates of these enzymes, in conjunction with inhibitors such as *clavulanate*, have demonstrated efficacy against *M. tuberculosis*. Compounds such as *faropenem*, which possess both *carbapenem* and *cephalosporin* structures, are effective against *M. tuberculosis* without a β-lactamase inhibitor. The general pharmacology of this class of compounds is discussed in Chapter 58. Patients with MDR-TB have reportedly responded to β-lactam antibiotics such as *ertapenem* (Tiberi et al., 2016). A meta-analysis has identified seven clinical studies in which *ertapenem*, *imipenem*, and *meropenem* were used to treat MDR-TB with sputum conversion rates exceeding 60% (Sotgiu et al., 2016). These data notwithstanding, the role and optimal dosing of β-lactams in the treatment of MDR-TB remain poorly defined.

Macrolides

The pharmacology, bacterial activity, and resistance mechanisms of macrolides are discussed in Chapter 60. *Azithromycin* and *clarithromycin* are used for the treatment of MAC.

Dapsone

Dapsone (diamino-diphenylsulfone) is a broad-spectrum agent with antibacterial, antiprotozoal, and antifungal effects.



Mechanism of Action

Dapsone is a structural analogue of PABA (similar to sulfonamides; see Chapter 57) and a competitive inhibitor of dihydropteroate synthase (*fol*P1/P2) in the folate pathway (Figure 65–5). The anti-inflammatory effects of *dapsone* occur via inhibition of tissue damage by neutrophils (Wolf et al., 2002). *Dapsone* inhibits neutrophil myeloperoxidase activity and respiratory burst, and it inhibits activity of neutrophil lysosomal enzymes. *Dapsone* may act as a scavenger of free radicals generated by neutrophils, and *dapsone* may inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002).

Antimicrobial Effects

Antibacterial. *Dapsone* is bacteriostatic against *M. leprae* at concentrations of 1 to 10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasii* have an MIC of 8 mg/L or lower, but the MICs for *M. tuberculosis* isolates are high. *Dapsone* has little activity against other bacteria.

Antiparasitic. *Dapsone* is also highly effective against *Plasmodium falciparum* with IC_{50} (concentration causing 50% inhibition) of 0.6 to 1.3 mg/L even in *sulfadoxine-pyrimethamine*–resistant strains. *Dapsone* has an IC_{50} of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

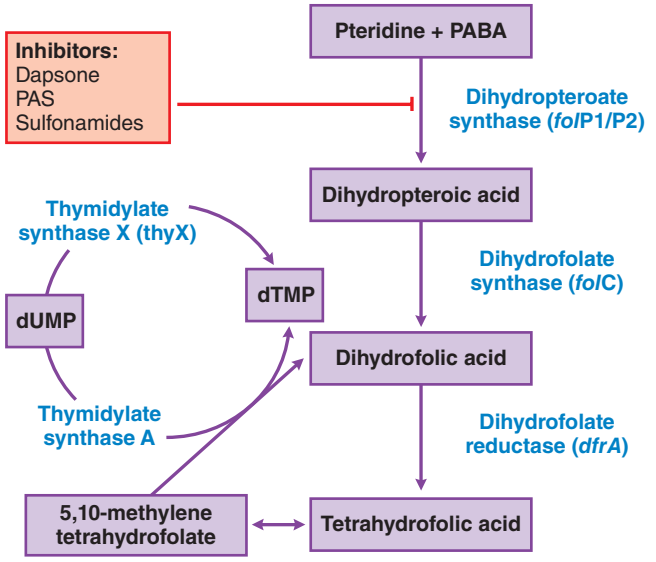


Figure 65–5 *Effects of antimicrobials on folate metabolism and deoxynucleotide synthesis.* dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate.

Antifungal. *Dapsone* is effective at concentrations of 0.1 mg/L against the fungus *Pneumocystis jirovecii*.

Drug Resistance

Resistance to *dapsone* in *P. falciparum*, *P. jirovecii*, and *M. leprae* results primarily from mutations in genes encoding dihydropteroate synthase (see Figure 65–5).

ADME

After oral administration, absorption is complete; the elimination $t_{1/2}$ is 20 to 30 h. Table 65–2 shows the population PK of *dapsone* (Simpson et al., 2006). *Dapsone* undergoes *N*-acetylation by NAT2. *N*-Oxidation to dapsone hydroxylamine is via CYP2E1 and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid-to-plasma ratio is between 0.76 and 2.91; cerebrospinal fluid–to–plasma ratio is 0.21 to 2.01 (Gatti et al., 1997). Approximately 70% to 80% of a dose of *dapsone* is excreted in the urine as an acid-labile mono-*N*-glucuronide and mono-*N*-sulfamate.

Therapeutic Uses

Dapsone is administered as an oral agent. Therapeutic uses of *dapsone* in the treatment of leprosy are described later in this chapter. *Dapsone* is also used for the prophylaxis for *T. gondii* (see Chapter 67). It is no longer used for malaria. The anti-inflammatory effects are the basis for therapy of pemphigoid, dermatitis herpetiformis, linear immunoglobulin A bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A$^-$. *Dapsone*, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of *dapsone* whenever possible.

Other Untoward Effects

Hemolysis develops in almost every individual treated with 200 to 300 mg of *dapsone* per day. Doses of 100 mg or less in healthy persons and 50 mg or less in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of *dapsone*. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis–like syndrome, which may be fatal, occurs occasionally.

Principles of Antituberculosis Chemotherapy

Evolution and Pharmacology

The *M. tuberculosis* complex is comprised of several species with 99.9% similarity at the nucleotide level. The complex includes *M. tuberculosis (typus humanus)*, *M. canettii*, *M. africanum*, *M. bovis*, and *M. microti*. They all cause TB, with *M. microti* responsible for only a handful of human cases.

Antituberculosis Therapy

Following a series of multiple, large, well-designed trials conducted from the 1940s to the 1970s, INH, *pyrazinamide*, *rifampin*, and *ethambutol* were established as first-line antiTB agents that, when used together, could treat TB in 6 months, so-called "short-course" chemotherapy (Fox et al., 1999). Each drug in the regimen has a unique role. INH is highly bactericidal, resulting in rapid reductions in bacilli burden within just a few days of starting TB treatment. This results in rapid improvement in TB symptoms and reduces transmission risk. *Rifampin* is able to kill semi-dormant or dormant bacilli, so-called "persisters" (Dickinson and Mitchison, 1981), and it remains the best sterilizing agent available. It is unparalleled in its ability to kill persister organisms that must be eradicated to cure the patient. *Pyrazinamide* adds sterilizing activity to the first-line regimen, seeming to kill subpopulations of *M. tuberculosis* that reside in acidic conditions inside macrophages and in necrotic lesions; further, it is synergistic with other anti-TB drugs. Use of *pyrazinamide* allows for treatment shortening from 9 to 6 months (Hong Kong Chest Service, 1978). *Ethambutol* is given at its lowest effective dose and does not contribute meaningfully to the antibacterial effects of multidrug regimens; rather, its role is to protect companion drugs against emergence of resistance (Doster et al., 1973). As new drugs are developed for TB, it is critical to consider their roles in multidrug regimens and to ensure that new drug combinations have bactericidal activity, sterilizing activity, and robustness to emergence of resistance (Ignatius and Dooley, 2019). Other considerations include penetration into lung lesions, drug interactions, and overlapping toxicities. Second-line agents are used in case of poor tolerance or resistance to first-line agents.

We use multiple drugs to treat TB because each drug plays a specific role in the regimen. Combination therapy is also mandatory to prevent emergence of clinical resistance. Pretreatment mutation rates to anti-TB drugs are between 10^{-6} and 10^{-10}, so that the probability of resistance is high to any single anti-TB drug in patients with cavitary TB who have about 10^9 colony-forming units of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli will develop mutations to two or more different drugs is the product of two mutation rates (between 1 in 10^{14} and 1 in 10^{20}).

Types of Antituberculosis Therapy

Prophylaxis

After infection with *M. tuberculosis*, about 10% of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction 5 mm or greater who also fall into one of the following categories: household contact of someone with pulmonary TB, HIV co-infection, lung fibrosis, or immunosuppressed due to treatment of rheumatological disease or cancer. If the tuberculin skin test is 10 mm or greater, those with a high risk of TB include recent (≤5 years) immigrants from areas of high TB prevalence, children younger than 4 years, children exposed to adults with TB, people who inject intravenous drugs, as well as residents and employees of high-risk congregate settings. Any person with a skin test greater than 15 mm is also at high risk of developing active TB disease.

In these higher-risk patients, prophylactic treatment with "TB preventive therapy" (TPT) is recommended to prevent active disease. There are now several TPT regimens (Table 65–5). The most tried-and-true regimen is oral INH 300 mg daily (or 10–15 mg/kg daily for children) for 6 to 9 months. While effective, treatment duration is long, and completion rates are poor. *Rifampin* 10 mg/kg daily for 4 months is an alternative regimen. Once-weekly *rifapentine* (900 mg) plus INH (900 mg) given for a total of 12 doses over 3 months (or 3HP) is highly effective, and adherence is generally excellent (Sterling et al., 2011). The newest (and shortest) TPT regimen is 1HP, or once-daily *rifapentine* (10 mg/kg) plus INH (300 mg) given for 28 days (Swindells et al., 2019). To date, published clinical data for this alternative regimen are only available for patients with HIV.

Definitive Therapy of Drug-Susceptible Active TB

All patients with active TB should have sputum collected for genotypic or phenotypic resistance testing. In adults, the current standard regimen for drug-susceptible pulmonary TB consists of INH (5 mg/kg, maximum 300 mg/day), *rifampin* (10 mg/kg, maximum 600 mg/day), *pyrazinamide*

TABLE 65–5 ■ WHO TREATMENT REGIMENS FOR LATENT TUBERCULOSIS INFECTION

REGIMEN	DOSE (PER kg BODY WEIGHT)	DURATION
Daily isoniazid	Adults: 5 mg Children: 10 mg (range 7–15 mg)	6–9 months
Daily rifampin	Adults: 10 mg Children: 15 mg (range 10–20 mg)	3–4 months
Daily isoniazid PLUS rifampin	Adults: 5 mg isoniazid, 10 mg rifampin Children: 10 mg isoniazid, 15 mg rifampin	3–4 months
Weekly rifapentine PLUS isoniazid	≥12 years: isoniazid 15 mg 2–11 years: isoniazid 25 mg Rifapentine: 10.0–14.0 kg = 300 mg 14.1–25.0 kg = 450 mg 25.1–32.0 kg = 600 mg 32.1–50.0 kg = 750 mg >50 kg = 900 mg	3 months (12 doses)

(15–30 mg/kg, maximum of 2 g/day), and *ethambutol* (15–20 mg/kg) given daily for 2 months, followed by 4 months of INH and *rifampin*, to complete 6 months of therapy. Daily therapy is preferred over intermittent dosing, as daily treatment gives the highest chance for cure without relapse (the current regimen is unforgiving to missed doses) (Imperial et al., 2018). Children should receive *rifampin* 15 to 20 mg/kg at a maximum dose of 600 mg/day, *pyrazinamide* 30 to 40 mg/kg per day, and INH 10 to 15 mg/kg at a maximum dose of 300 mg/day. *Rifabutin* can be substituted for *rifampin* in cases where there are drug interactions that preclude use of *rifampin*, for example, among patients with HIV taking second-line antiretroviral therapy containing protease inhibitors, but the *rifabutin* dose should be decreased to 150 mg daily during coadministration (Kendall et al., 2021). *Ethambutol* is only continued until INH susceptibility can be confirmed. Because monitoring of visual acuity is difficult in children younger than 5 years, caution should be exercised in using *ethambutol* in this group.

The first 2 months of the four-drug regimen compose the *initiation phase*, and the last 4 months compose the *continuation phase* of therapy. *Pyridoxine*, vitamin B_6 (10–50 mg/day), should be administered with INH to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, or patients with HIV, diabetes mellitus, high alcohol intake, or renal failure). To support adherence, therapy is typically administered as directly observed therapy (Volmink and Garner, 2007). More patient-centered strategies for adherence support are now endorsed by the WHO and offered as alternatives.

Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is typically treated for longer, 9 to 12 months, although that duration is not evidence based (Jullien et al., 2016), and it is likely that using drugs at doses that reach effective concentrations in the brain and cerebrospinal fluid is more important than prolonging treatment duration. Patients with TB meningitis should also receive steroids as standard of care (Prasad et al., 2016).

The treatment of TB pericarditis is a special case in which the use of steroids has been advocated for many decades. The IMPI trial randomized 1400 patients to examine the effect of *prednisolone* on the composite outcome of death, cardiac tamponade requiring pericardiocentesis, or constrictive pericarditis. There was no significant difference in the primary outcome between patients who received *prednisolone* and those who received placebo, even though the corticosteroids were associated with a 44% decrease in the development of constrictive pericarditis (Mayosi et al., 2014). Free drug concentrations of *rifampin* in pericardial fluid are close to zero, *ethambutol* concentrations are low, and the pH in infected pericardial fluid is around 7.3, which is a pH at which *pyrazinamide* has no effect (Shenje et al., 2015). The optimal regimen for treatment of TB pericarditis thus remains to be identified.

TABLE 65–6 ■ WORLD HEALTH ORGANIZATION GROUPINGS OF DRUGS FOR MDR-/RR-TB

GROUP	DRUG	COMMENTS
A	Levofloxacin or moxifloxacin Bedaquiline Linezolid	Include all three (unless they cannot be used)
B	Clofazimine Cycloserine or terizidone	Add both, unless they cannot be used
C	Ethambutol Delamanid Pyrazinamide Meropenem (plus amoxicillin-clavulanate) Amikacin Ethionamide or prothionamide	Add to complete the regimen and when medicines from Groups A and B cannot be used

Definitive Therapy of Drug-Resistant TB

The WHO has laid out guidance for the treatment of MDR-TB—all three Group A drugs (a fluoroquinolone plus *bedaquiline* and *linezolid*), one or both Group B drugs (*clofazimine* and *cycloserine* or *terizidone*), and one or more Group C drugs (*ethambutol*, *delamanid*, *pyrazinamide*, β-lactam, *ethionamide*, *amikacin*, or PAS), for a total of at least four to five active drugs, should be given (Table 65–6). Treatment duration is 18 to 20 months. If a patient's TB isolate is resistant to one or more of these second-line agents or the patient cannot tolerate a recommended drug, then therapy should be based on evidence of susceptibility and should include at least four drugs to which the pathogen is susceptible. A standardized, shorter MDR-TB regimen of 9 to 12 months is possible for patients whose *M. tuberculosis* isolate is susceptible to fluoroquinolones and comprises *bedaquiline*, a fluoroquinolone, *clofazimine*, *pyrazinamide*, *ethambutol*, high-dose INH, and *ethionamide* (WHO, 2020).

Principles of Therapy for Nontuberculous Mycobacteria

NTM are composed of nearly 200 subspecies and cause both pulmonary and extrapulmonary disease among susceptible individuals. *In vitro* antimicrobial susceptibility can vary widely within and between species; therefore, drug susceptibility testing should be performed on isolates deemed to represent true infection (rather than colonization). The most common species causing human infection are MAC, *M. kansasii, M. xenopi*, and *M. abscessus* (Daley et al., 2020). MAC includes *M. intracellulare, M. avium,* and *M. chimaera,* among others. NTM are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when NTM are isolated from a nonsterile site in a patient's body, one cannot assume they are causing an infection.

Therapy of NTM Pulmonary Infection

Although distinguishing colonization from disease can be challenging, the 2007 American Thoracic Society/Infectious Diseases Society of America guidelines provide clear diagnostic criteria for clinicians. These criteria include pulmonary or systemic symptoms, nodules or cavitations on chest imaging, exclusion of other diagnoses, and either two positive cultures from expectorated sputum or one from either bronchial wash/lavage or biopsy. Once the diagnosis is established,

the decision to commence treatment can be complex, given that many patients experience mild chronic or waxing/waning symptoms and medications may be poorly tolerated (Griffith et al., 2007). Recently updated clinical guidelines, however, advocate treatment for those meeting diagnostic criteria for NTM pulmonary disease over watchful waiting, particularly when there is significant baseline mycobacterial burden (sputum is acid-fast bacilli smear positive) or cavitary disease (Daley et al., 2020).

In newly diagnosed patients with pulmonary MAC, triple-drug therapy is recommended. These drugs include a rifamycin, *ethambutol*, and a macrolide. Either oral *clarithromycin* or *azithromycin* may be used; however, *azithromycin* is favored in the updated 2020 guidelines as it is better tolerated, less frequently dosed, and less prone to drug interactions (Daley et al., 2020). *Rifampin* is often the rifamycin of choice, although *rifabutin* may be substituted to mitigate drug-drug interactions. *Clarithromycin* 1000 mg or *azithromycin* 500 mg is combined with *ethambutol* 25 mg/kg and *rifampin* 600 mg and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are recommended for patients with cavitary disease, but the dosing is *azithromycin* 250 mg, *ethambutol* 15 mg/kg, and *rifampin* 600 mg administered daily. Parenteral *streptomycin* or *amikacin* at 15 mg/kg is recommended as a fourth drug for patients with severe disease or macrolide-resistant MAC. Inhaled *amikacin* liposome inhalation suspension is now recommended for add-on therapy for treatment-refractory MAC (Daley et al., 2020).

Given high rates of sustained cure for pulmonary *M. kansasii* infection, currently guidelines recommend that *rifampin*-sensitive *M. kansasii* be treated with *rifampin*, *ethambutol*, and either INH or a macrolide, without the routine addition of an aminoglycoside. For *rifampin*-resistant *M. kansasii*, a fluoroquinolone may be added in lieu of *rifampin*. Dosing frequency recommendations for *M. kansasii* treated with a macrolide are similar to pulmonary MAC, with daily dosing usually reserved for more severe or cavitary disease. For *M. kansasii* treated with INH (instead of a macrolide), daily triple therapy is recommended.

Current guidelines for treatment of *M. xenopi* recommend daily triple therapy with *rifampin*, *ethambutol*, and either *moxifloxacin* or a macrolide, with the addition of *amikacin* for more severe disease.

M. abscessus is an increasingly recognized and virulent pathogen among those with predisposing factors like structural lung disease, and treatment options are often limited by baseline resistance that is extensive, unpredictable, and, in many cases, identified weeks after the initial *M. abscessus* infection is diagnosed. Given the risk of inducible macrolide resistance caused by a functional *erm*(41) gene, prior guidelines recommended use of macrolides for *M. abscessus* only when there was demonstrable sensitivity; updated guidelines, however, recommend addition of a macrolide in all cases for the macrolide's immunomodulatory properties. Multidrug therapy with three active medications is recommended for *M. abscessus* disease.

Duration of therapy for these pulmonary NTM infections is usually a minimum of 12 months (and often 12 months from culture conversion) for both cavitary and nodular/bronchiectatic disease, although data to support precise treatment durations are scant. For both MAC and *M. abscessus*, macrolide sensitivity correlates with outcomes (Griffith et al., 2006; Jeon et al., 2009; Koh et al., 2011; Moon et al., 2016); therefore, use of a macrolide is highly encouraged, provided the patient can tolerate it. Patients at risk for treatment failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success rates are low. Only half of patients have successful outcomes as defined by both culture conversion and clinical resolution.

Therapy of Disseminated NTM

Although various drugs and combination regimens have been used with success in the treatment of a variety of disseminated NTM infections, there are firm guidelines only for the treatment of disseminated MAC among patients with HIV. In this population, *M. avium* is the most common infecting species and tends to occur in patients with CD4 cell count less than 50/mm^3 who are not on antiretroviral therapy (ART).

The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, diarrhea, elevated serum alkaline phosphatase, and anemia. However, when disease occurs in patients already on ART, it may manifest as focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (Department of Health and Human Services, 2020). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

Prophylaxis against disseminated MAC is no longer recommended for patients with HIV who are taking ART, even those patients newly initiating HIV treatment. For patients with CD4 count below 50 cells/mm^3 who cannot be on suppressive ART, prophylaxis with weekly *azithromycin* 1200 mg, twice-weekly *azithromycin* 600 mg, twice-daily *clarithromycin* 500 mg, or daily *rifabutin* 300 mg should be prescribed.

First-line treatment of disseminated MAC consists of either *clarithromycin* 500 mg twice daily or *azithromycin* 500 to 600 mg daily plus *ethambutol* 15 mg/kg. The addition of a third or fourth drug (*rifabutin* 300 mg, *levofloxacin* 500 mg, *moxifloxacin* 400 mg, *amikacin* 10–15 mg/kg, or *streptomycin* 1 mg IV/IM daily) is recommended for those with high baseline bacterial load (Department of Health and Human Services, 2021). Patients should be continued on multidrug suppressive therapy until all three of the following criteria are met:

- Therapy duration of at least 12 months
- CD4 count greater than 100/mm^3 for at least 6 months
- Asymptomatic from MAC infection

Therapy for Other NTM, Including Leprosy

The global prevalence of leprosy (Hansen disease) has markedly declined, largely due to the global initiative of the WHO to eliminate it as a public health problem by providing multidrug therapy (*rifampin*, *clofazimine*, and *dapsone*) free of charge. Prevalence of the disease has dropped by about 90% since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America.

There are four major clinical types of leprosy, and clinical phenotype determines therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found on smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by disseminated infection and high bacillary burden. Two major intermediate forms of the disease are recognized: (1) borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy; and (2) indeterminate disease, which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy.

M. leprae was discovered by Armauer Hansen in 1873. The *M. leprae* genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). It has a long doubling time (14 days) and is an obligate intracellular pathogen. *M. leprae* is, therefore, difficult to culture on synthetic media, an impediment to basic research on the disease and to its clinical identification.

Types of Antileprosy Therapy

Leprosy is treated with multidrug therapy consisting of *rifampin*, *clofazimine*, and *dapsone*. Combination therapy reduces the development of resistance, overcomes preexisting primary resistance, and reduces the duration of therapy. The most bactericidal drug in current regimens is *rifampin*. Because of its high kill rate resulting in massive release of bacterial antigens, *rifampin* is not often given during a "reversal" reaction (see discussion below) or in patients with erythema nodosum leprosum. *Clofazimine* is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema

TABLE 65–7 ■ PHARMACOTHERAPY FOR SELECT NONTUBERCULOUS MYCOBACTERIA

MYCOBACTERIAL SPECIES	FIRST-LINE THERAPY	ALTERNATIVE AGENTS
M. Avium intracellulare	Macrolide + rifampin + ethambutol	Amikacin; clofazimine; moxifloxacin; linezolid
M. kansasii	Isoniazid + rifampin[a] + ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin
M. fortuitum complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
M. marinum	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
M. ulcerans	Rifampin + streptomycin[b]	Clarithromycin[c]; rifapentine[c]
M. abscessus	Cefoxitin (or imipenem) + amikacin + clarithromycin	Tigecycline; moxifloxacin
M. malmoense	Rifampin + ethambutol ± clarithromycin	Fluoroquinolone
M. haemophilum	Clarithromycin + rifampin + quinolone	—

[a]In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and nonnucleoside reverse transcriptase inhibitors.
[b]For *M. ulcerans*, surgery is the primary therapy.
[c]Based on animal models.

nodosum leprosum. The third major agent in the regimen is *dapsone*. The objective of administering these drugs is total cure.

Definitive Therapy; Standard Therapy

Paucibacillary Leprosy. The WHO regimen consists of once-monthly oral *rifampin* 600 mg, plus once-daily *dapsone* 100 mg for 6 months. In the U.S., the regimen consists of *dapsone*, 100 mg daily, and *rifampin*, 600 mg daily, for 12 months, and then therapy is discontinued (National Hansen's Disease Program, 2018).

Multibacillary Therapy. The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, *clofazimine* 300 mg daily is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary leprosy, with the addition of *clofazimine* 50 mg daily. Treatment is given for 24 months and then discontinued.

Treatment of Reactions in Leprosy

Patients with tuberculoid leprosy may develop "reversal reactions," manifestations of delayed hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or *clofazimine* is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction is often associated with therapy and is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with *clofazimine* or *thalidomide* is effective.

Therapy of Other NTM

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity *in vitro* and drug therapy selected on this basis. Therapy of infections from these organisms is summarized in Table 65–7. In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary. One of the most exciting advances in mycobacterial therapeutics is the successful treatment of Buruli ulcer in mice with ultrashort courses of *telacebec*, an investigational agent (Almeida et al., 2020; Chauffour et al., 2020). *Telacebec* targets the respiratory cytochrome Bc1:aac complex, and unlike *M. tuberculosis*, *M. ulcerans* does not have an alternative pathway for maintaining the electron transport chain. If proven to work clinically, this will transform therapy for this hard-to-treat and disfiguring disease.

Rifamycins (cont.)		
Rifapentine	• Treatment of TB • Prophylaxis of TB disease	• 97% protein bound • Strong inducer of metabolizing enzymes and transporters
Rifabutin	• Used as rifampin replacement to avoid drug interactions of rifampin with other medications, especially in HIV co-infection • Treatment of disseminated MAC in patients with AIDS	• Weaker CYP3A induction than rifampin • Concentrations higher in tissue than plasma • $t_{1/2}$ ~45 h • Neutropenia in 25% of patients with HIV • Primary reasons for therapy discontinuation include rash, GI intolerance, and neutropenia • Uveitis is a unique but rare side effect for this rifamycin
Isoniazid		
Isoniazid	• *M. tuberculosis* infection • *M. kansasii* infection • Prophylaxis of TB disease	• Patients divided into slow, intermediate, and fast acetylators, which has consequences for efficacy and toxicity • Hepatotoxicity, increased above age of 60 years • Peripheral neuritis: should be administered with pyridoxine • Reversible vasculitis • Overdose associated with the clinical triad: (1) seizures refractory to treatment with phenytoin and barbiturates, (2) metabolic acidosis, and (3) coma • Several drug interactions via inhibition and induction of several CYPs
Pyrazinamide		
Pyrazinamide	• TB	• No activity against *M. bovis* • Activated under acidic conditions; synergizes with rifampin • Pyrazinamide clearance reduced in renal failure; reduce dosing frequency to 3 times per week at low glomerular filtration rate • Removed by hemodialysis; redose after each session • Adverse effects: hepatotoxicity and hyperuricemia
Ethambutol		
Ethambutol	• TB • MAC infections • *M. kansasii* infection • Activity against *M. gordonae, M. marinum, M. scrofulaceum,* and *M. szulgai*	• Incidence of optic neuritis leading to decreased visual acuity and loss of red-green discrimination. Test visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter • In renal failure, ethambutol should be dosed at 15–25 mg/kg three times a week instead of daily, even in patients receiving hemodialysis
Bicyclic Nitroimidazoles		
Pretomanid, delamanid	• Treatment of MDR-TB; being tested for regimens used to treat drug-susceptible TB	• Kills both replicating and nonreplicating *M. tuberculosis* • Delamanid: modest QT interval prolongation
Riminophenazines		
Clofazimine	• Treatment of leprosy • Treatment of MDR-TB • Treatment of NTM infection	• GI problems are encountered in 40%–50% of patients • Abdominal pain due to crystal deposition in cavities and tissues • Body secretion, eye, and skin reddish-black discoloration occurs in most patients
Diarylquinoline		
Bedaquiline	• Treatment of MDR-TB; being tested for regimens used to treat drug-susceptible TB	• Apparent volume of distribution >10,000 L • 5-month terminal half-life • QT interval prolongation; ECG monitoring recommended • CYP3A substrate; avoid coadministration with CYP3A inducers
Ethionamide		
Ethionamide	• Treatment of MDR-TB and XDR-TB	• Same mutations in ethionamide-resistant bacteria as for isoniazid-resistant bacteria • 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI toxicity • Adverse effects: postural hypotension, mental depression, drowsiness, asthenia; neurological toxicity • Concomitant administration with pyridoxine is recommended • He atitis in ~5% of cases

Drug Facts for Your Personal Formulary: *Antimycobacterial Drugs (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
***Para*-aminobenzoic Acid Analogues**		
Dapsone	• Treatment of leprosy • Treatment of *Pneumocystis jirovecii* infection and prophylaxis • Prophylaxis of *Toxoplasma gondii* infection • Anti-inflammatory effects for treatment of pemphigoid, dermatitis herpetiformis, linear immunoglobulin A bullous disease, relapsing chondritis, and brown recluse spider bite ulcers	• Test for G6PD deficiency prior to use • NADH-dependent methemoglobin reductase deficiency–associated methemoglobinemia • Hemolysis at doses of 200–300 mg of dapsone per day • Used topically for acne
P-aminosalicylic acid	• Treatment of MDR-TB	• Should be administered with food • Dose must be reduced in renal dysfunction • Adverse events incidence is ~10%–30% • GI problems predominate • Hypersensitivity reactions in 5%–10% of patients
Cycloserine		
Cycloserine	• Treatment of MDR-TB	• Oral second-line drug • "Psycho-serine": 50% of patients develop neuropsychiatric symptoms; headache, somnolence, severe psychosis, seizures, and suicidal ideas • Must be redosed after dialysis

Chapter 66 Chemotherapy of Malaria

Abdoulaye A. Djimde and Steve M. Taylor

Global Impact of Malaria

Malaria remains among the top five causes of death among children younger than 5 years, affects about a quarter of a billion people, and caused over 600,000 deaths in 2021 (World Health Organization, 2021). Malaria transmission occurs in regions of Africa, Latin and South America, Asia, the Middle East, the South Pacific, and the Caribbean (Figure 66–1). This disease is caused by infection with protozoan parasites of the genus *Plasmodium*, five species of which are known to infect humans: *P. falciparum, P. vivax, P. ovale, P. malariae,* and *P. knowlesi. P. falciparum* and *P. vivax* cause most malarial infections worldwide. On the basis of genetic data, *P. ovale* has recently been subdivided in two subspecies, *P. ovale wallikeri* and *P. ovale curtisi. P. falciparum* accounts for the majority of the burden of malaria in sub-Saharan Africa and causes most severe disease and deaths. *P. vivax* accounts for half of the malaria burden in South and East Asia and more than 80% of the malarial infections in the Americas and has been underappreciated as a cause of severe malaria (Baird, 2013).

Over the past half-century, malaria parasites worldwide—primarily *P. falciparum* and *P. vivax*—have become increasingly resistant to antimalarial drugs, including *chloroquine* (Djimde et al., 2001; Fidock et al., 2000; Warhurst, 2001), *mefloquine* (White et al., 2014), *quinine* (White et al., 2014), *sulfadoxine/pyrimethamine* (Artimovich et al., 2015; Plowe et al., 1995; Sibley et al., 2001), and *atovaquone* (Garcia-Bustos et al., 2013; Kessl et al., 2007). In response, new, multipronged international public-private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).

Biology of Malarial Infection

The life cycle of malaria parasites comprises distinct morphological and functional stages. Because these stages have differential susceptibilities to antimalarial drugs, a basic understanding of the stages is critical to understand the chemotherapy for malaria (Figure 66–2). Malaria infections are initiated when an infected female anopheline mosquito injects *Plasmodium* sporozoites during a blood meal (Miller et al., 1998). After entering the dermis, sporozoites enter the bloodstream and, within minutes, arrive at the liver, where they infect individual hepatocytes via cell surface receptor-mediated events (Sinnis et al., 2013). This process initiates the *prepatent period* or *exoerythrocytic stage* of infection, which typically lasts about 1 week and is asymptomatic.

During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver-stage *schizonts*. When an infected hepatocyte ruptures, tens of thousands of *merozoites* are released into the bloodstream to infect red blood cells and initiate the *erythrocytic stage* of infection. During this stage, there are no residual *P. falciparum*, *P. malariae,* or *P. knowlesi* parasites in the liver. In contrast, *P. vivax* and *P. ovale* can, while establishing the erythrocytic stage, also maintain a quiescent hepatocyte infection as a dormant form of the parasite known as the *hypnozoite,* which can emerge to later cause symptomatic disease long after the initial malaria episode is recognized and treated. Erythrocytic forms cannot reestablish infection of hepatocytes. Transmission of human-infecting malarial parasites is maintained in human populations by the persistence of hypnozoites (several months to a few years for *P. vivax* and *P. ovale*), by antigenic variation in *P. falciparum* (probably months), by the putative antigen variation in *P. malariae* (for as long as several decades), and, in *P. knowlesi*, by the ability to infect nonhuman primates.

The *asexual erythrocytic stages* of malarial parasites are responsible for the clinical manifestations of malaria. This part of the *Plasmodium* life cycle is initiated by the recognition of red blood cells by merozoites by a process that is mediated by cell surface receptors that facilitate invasion of red blood cells.

Once inside a red blood cell, the merozoite develops into a ring form, which becomes a hemoglobin-metabolizing trophozoite (feeding stage) that matures into an asexually dividing blood-stage *schizont*. Schizont rupture at the end of the growth-and-division cycle releases 8 to 32 merozoites that invade new red blood cells. The erythrocytic replication cycle lasts for 24 h (for *P. knowlesi*), 48 h (for *P. falciparum, P. vivax,* and *P. ovale*), and 72 h (for *P. malariae*). Although most invading merozoites develop into schizonts, a small proportion becomes *gametocytes*, the form of the parasite that is infective to mosquitoes. These morphologically distinct and sexually dimorphic gametocytes are ingested by the mosquito

during an infectious blood meal; on reaching the midgut of the mosquito, the gametocytes transform into gametes that fertilize to become zygotes. Zygotes mature into ookinetes that invade the mosquito midgut wall and transform into oocysts. Numerous rounds of asexual replication occur in the oocyst to generate sporozoites over 10 to 14 days. Fully developed sporozoites rupture from oocysts and invade the mosquito salivary glands, from which they can initiate a new infection during subsequent mosquito blood meals (Figure 66–2). Thus, aside from *P. knowlesi*, which also infects macaques, the infection cycles from mosquito to human to mosquito.

Plasmodium falciparum has a family of binding proteins that recognize a variety of host cell molecules that this parasite species uses to invade all stages of erythrocytes (Lim et al., 2015; Weiss et al., 2016); high parasitemia may result from this mechanism. In contrast, *P. vivax* preferentially binds to the Duffy chemokine receptor protein as well as reticulocyte-specific proteins (Chitnis et al., 2008; Paul et al., 2015). *P. falciparum* assembles cytoadherence proteins (e.g., PfEMP1) (Weiss et al., 2016), encoded by a highly variable family of *var* genes into structures called knobs that are presented on the erythrocyte surface (Hviid et al., 2015; Ukaegbu et al., 2015). Knobs allow the *P. falciparum*–parasitized erythrocyte to bind to postcapillary vascular endothelium to avoid spleen-mediated clearance and allow the parasite to grow in a low-O_2, high-CO_2 microenvironment.

Clinical Manifestations of Malaria

The cardinal signs and symptoms of malaria are high, spiking fevers (with or without periodicity), chills, headaches, myalgias, malaise, and gastrointestinal (GI) symptoms (White et al., 2014). Severe headache, a characteristic early symptom in malaria caused by all *Plasmodium* spp., often heralds the onset of disease, even before fever and chills. *P. falciparum* causes the most severe disease and may lead to organ failure and death. Placental malaria, of particular danger for primigravidae, is due to *P. falciparum* adherence to CSA (chondroitin sulfate A) in the placenta. This often leads to severe complications, including miscarriage, stillbirth, and intrauterine growth retardation. When treated early, symptoms of malarial infection usually improve within 24 to 48 h. The nonspecific nature of the clinical presentation of malaria renders its signs and symptoms insufficient for accurate diagnosis (Taylor et al., 2010), underscoring the need for diagnostic testing in suspected cases, typically with light microscopy or rapid lateral-flow immunochromatographic tests.

Acute illness due to *P. vivax* infection may appear severe due to high fever and prostration. Indeed, the pyrogenic threshold of this parasite (i.e., "blood stage" parasite burden associated with fever) is lower than that of *P. falciparum*. Nonetheless, *P. vivax* malaria generally has a low mortality rate. *P. vivax* malaria is characterized by relapses caused by the reactivation of latent tissue forms. Clinical manifestations of relapse are the same as those of primary infection. In recent years, severe *P. vivax* malaria from Oceania (Papua New Guinea, Indonesia) and India has shown important similarities to severe malaria caused by *P. falciparum*. These include neurological symptoms (diminished consciousness, seizure) and pulmonary edema. Rare but life-threatening complications can occur, including splenic rupture, acute lung injury, and profound anemia.

Plasmodium ovale causes a clinical syndrome similar to that of *P. vivax* but may be milder with lower levels of parasitemia. It shares with *P. vivax* the ability to form the hypnozoite (dormant liver stage) that may relapse after months to 2 years later. *P. ovale* is more common in sub-Saharan Africa and some islands in Oceania.

Plasmodium malariae generally causes an indolent infection with very low levels of parasitemia and often does not produce clinical symptoms. This parasite can be found in all malaria-endemic areas but is most common in sub-Saharan Africa and the southwest Pacific. Interestingly, *P. malariae* prevalence increases during the dry season and can be found as a coinfection with *P. falciparum*. An uncommon but potentially fatal complication of *P. malariae* is a glomerulonephritis syndrome that does not respond to antimalarial treatment.

Plasmodium knowlesi, previously thought to be restricted to macaques, was often misdiagnosed as *P. malariae* by light microscopy owing to morphological similarity. *P. knowlesi* is distinguished by a shorter erythrocytic cycle (24 h compared with 72 h for *P. malariae*) and higher levels of parasitemia that account for its more severe clinical presentation. Like *P. malariae, P. knowlesi* is generally sensitive to chloroquine, but patients presenting with advanced disease nonetheless may progress to death despite adequate drug dosing.

Despite the above, asymptomatic infections with either *P. falciparum* or *P. vivax* are common in endemic regions and represent important potential reservoirs for malaria transmission. Although different studies are not entirely consistent in the definition of *asymptomatic*, generally this state implies a lack of fever, headache, and other systemic complaints, within a defined time period prior to a positive test for malaria parasitemia. Migration of asymptomatic individuals to areas where malaria is not present but vector mosquitoes are (i.e., anophelism without malaria) is an important mechanism for the introduction or reintroduction of malaria, in addition to facilitating the spread of drug-resistant isolates. Novel approaches to preventing transmission from asymptomatic reservoirs—whether through new drugs or vaccines—will be essential for future malaria control, elimination, and eradication strategies.

Classification of Antimalarial Agents

The various stages of the malarial parasite life cycle in humans differ in their drug sensitivity. Thus, antimalarial drugs can be classified based on their activities during this life cycle as well as by their intended use for either chemoprophylaxis or treatment. The spectrum of antimalarial drug activity leads to several generalizations.

The first relates to chemoprophylaxis: *Because no antimalarial drug kills sporozoites, it is not truly possible to prevent infection; drugs can only prevent the development of symptomatic malaria caused by the asexual erythrocytic forms, either in the bloodstream or as produced within and released by hepatocytes prior to erythrocyte invasion.*

The second relates to the treatment of an established infection: *No single antimalarial is effective against all hepatic and intraerythrocytic stages of the life cycle that may coexist in the same patient. Complete elimination of the parasite infection, therefore, may require more than one drug.*

The patterns of clinically useful antimalarial agents fall into three general categories (Table 66–1):

1. Agents that are not reliably effective against primary or latent liver stages: *artemisinins, chloroquine, mefloquine, quinine* and *quinidine, pyrimethamine, sulfadoxine,* and *tetracycline*. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria.
2. Drugs (e.g., *atovaquone* and *proguanil*) that target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.
3. *Primaquine* and *tafenoquine,* 8-aminoquinolines that are effective against primary and latent liver stages as well as gametocytes. *Primaquine* is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections. *Tafenoquine* is FDA-approved for similar uses.

A. Eastern Hemisphere

Figure 66–1 *Malaria-endemic countries.* **A.** Eastern Hemisphere. **B.** Western Hemisphere. A country is shaded orange even if malaria is endemic in just a portion of that country. Large regions not shown on the maps (e.g., Scandinavia, Russia, Canada, U.S., Tasmania, New Zealand) are nonendemic for malaria. In areas of endemic malaria, the disease is largely *chloroquine* resistant. For up-to-date information, consult the CDC's Malaria Information and Prophylaxis, by Country (https://www.cdc.gov/malaria/travelers/country_table/a.html; accessed January 12, 2022). (Reproduced from Centers for Disease Control and Prevention, https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-related-infectious-diseases/malaria; accessed January 12, 2022).

B. Western Hemisphere

Figure 66–1 (*Continued*)

The relative utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics, efficacy, and safety. *Quinine* and *primaquine*, which have significant toxicity and relatively short half-lives, generally are reserved for the treatment of established infections and are not used for chemoprophylaxis in a healthy traveler. By contrast, *chloroquine*, which is relatively free from toxicity and has a long $t_{1/2}$, is convenient for chemoprophylactic dosing, though there are few regions where *P. falciparum* remains reliably susceptible to chloroquine.

Specific Antimalarial Agents

For ease of reference, detailed information on the antimalarial drugs appears below in alphabetical order by drug name.

Artemisinin and Its Derivatives

Artemisinin and its three major semisynthetic derivatives in clinical use, *dihydroartemisinin*, *artemether*, and *artesunate*, are potent and fast-acting antimalarials. They are optimized for the treatment of severe *P. falciparum* malaria and are also effective against the asexual erythrocytic stages of *P. vivax*. For uncomplicated malaria, the standard treatment approach employs orally administered *artemisinin-based combination therapies* (*ACTs*), in which the rapid-acting and rapidly eliminated *artemisinin* component is paired with a slower-acting and slower-eliminated partner drug with a distinct antiparasitic mechanism of action. Such an approach is required because *artemisinins*, when administered alone, require more than 7 days of therapy to eliminate parasites, but when paired with an effective partner, antimalarial courses of treatment are commonly just 3 days for effective ACT.

The *artemisinin* drugs were discovered as potent antimalarials by Chinese scientists in the 1970s, garnering a Nobel Prize in Medicine/Physiology in 2015 for Tu Youyou "for her discoveries concerning a novel therapy against Malaria." By screening compounds described in ancient Chinese medical texts, an extract of sweet wormwood (*Artemisia annua*) was found to be effective in curing simian and murine *Plasmodium* infections. The pure ingredient in this extract was termed *qinghaosu*, or

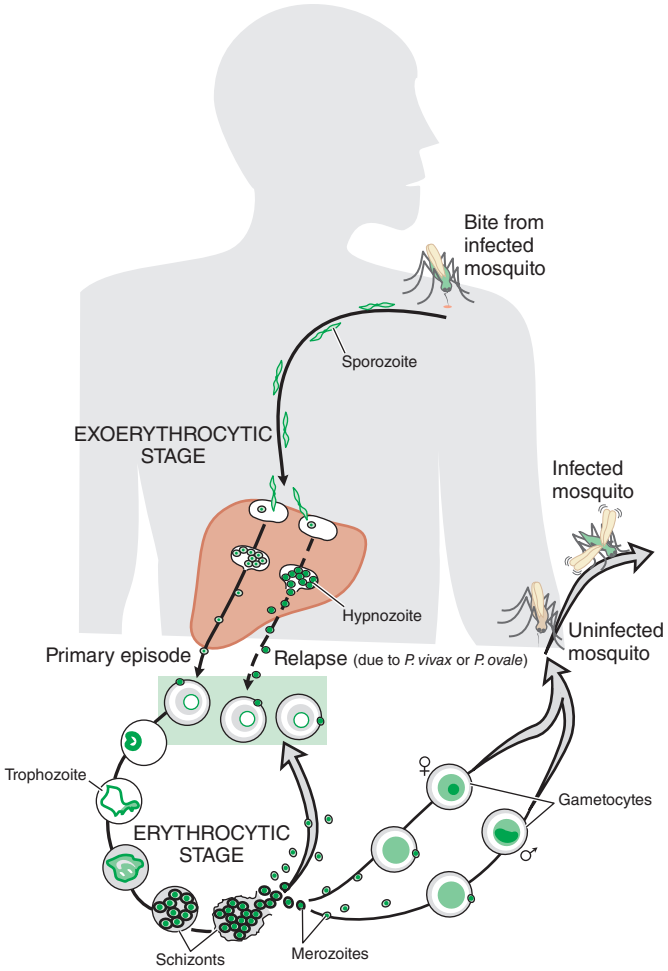

Figure 66–2 *Life cycle of malaria parasites.*

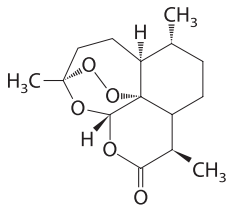
artemisinin (Tu, 2011). After refinement of the chemical structure, sourcing of natural supplies, and formulation of it as a pharmaceutical product, *artemisinin* therapies were successful against *chloroquine*-sensitive and -resistant *P. falciparum* infections in a wide variety of Chinese studies in the 1970s, prior to gaining broader recognition as a potent, novel class of antimalarial by Western science in the 1980s (Klayman, 1985).

The recent emergence of *P. falciparum artemisinin* "resistance" does not indicate classic resistance but rather reflects delayed parasite clearance time on the order of hours following the administration of ACT (Ashley et al., 2014; Huang et al., 2015); mutations in the *P. falciparum* gene *Pfk13* encoding the kelch13 propeller protein confer delayed parasite clearance times, possibly by rendering host hemoglobin inaccessible to *artemisinin* and thereby preventing its activation. True resistance to *artemisinin* has not been reported, and no infection from this parasite has been reported to survive ACT due to delayed clearance times (van Schalkwyk et al., 2015). Nevertheless, although the clinical significance of *P. falciparum artemisinin* resistance/delayed clearance remains unclear (Fairhurst, 2015), when coupled with widespread mutations that confer resistance to partner drugs (e.g., the ACT partner drug *piperaquine*), clinically significant ACT failure is substantial, with recrudescence rates reported to exceed 50% in parts of Asia (Amaratunga et al., 2016; Spring et al., 2015). For this reason, triple ACT strategies are being tested, in which *artemisinin* is paired with two partner drugs, an approach that remains in development. Resistance of non–*P. falciparum* malaria parasites to *artemisinin* class drugs has not been reported.



ARTEMISININ

Artemisinin is a revolutionary medicinal product. *Artemisinin* compounds cause a significant reduction of the parasite burden, with a 4-$\log_{10}$ reduction in the parasite population for each 48-h cycle of intraerythrocytic invasion, replication, and egress. Three to four cycles (6–8 days) of treatment are required to remove all the parasites from the blood. In addition, *artemisinin* treatment sharply decreases gametocyte carriage, which may possibly mitigate onward parasite transmission.

Mechanism of Action

Artemisinin and derivatives are activated by an interaction with intraparasitic heme, which is produced inside the highly acidic digestive vacuole of the parasite as it digests hemoglobin. This interaction cleaves the molecule's endoperoxide bridge to produce free radicals, which promiscuously alkylate a wide variety of parasite proteins (Meshnick, 1994). The site of action of the putatively toxic heme adducts is unclear. In addition, activated *artemisinin* might in turn generate free radicals that alkylate and oxidize macromolecules in the parasite.

TABLE 66–1 ■ SUSCEPTIBILITY TO DRUGS OF MALARIAL PARASITES AT VARIOUS DEVELOPMENTAL STAGES

ADME

The *semisynthetic artemisinins* have been formulated for oral (*dihydroartemisinin*, *artesunate*, and *artemether*), intramuscular (*artesunate* and *artemether*), intravenous (*artesunate*), and rectal (*artesunate*) routes. Bioavailability after oral dosing typically is 30% or less. Peak serum levels occur rapidly with *artemisinins* and in 2 to 6 h with intramuscular *artemether*. Both *artesunate* and *artemether* have modest levels of plasma protein binding, ranging from 43% to 82%. These derivatives are extensively metabolized and converted to *dihydroartemisinin*, which has a plasma $t_{1/2}$ of 1 to 2 h. Drug bioavailability via rectal administration is highly variable among individual patients. With repeated dosing, *artemisinin* and *artesunate* induce their own CYP-mediated metabolism, primarily via CYPs 2B6 and 3A4, which may enhance clearance by as much as 5-fold.

Therapeutic Uses

Given their rapid and potent activity against even multidrug-resistant parasites, the *artemisinins* are invaluable for the treatment of severe *P. falciparum* malaria, for which parenteral *artesunate* was FDA-approved in 2020. Other than this use of parenteral *artesunate* for the initial treatment of severe malaria, as a rule, *artemisinins* are not used as monotherapy. When combined with partner drugs as ACT, *artemisinins* are highly effective for the first-line treatment of malaria. *Artemisinins* should not be used for chemoprophylaxis because of their short $t_{1/2}$ values.

Toxicity and Contraindications

In pregnant rats and rabbits, *artemisinins* can cause increased embryo lethality or malformations in the early postconception period. Preclinical toxicity studies have identified the brain (and brainstem), liver, and bone marrow as the principal target organs. However, no systematic neurological changes have been attributed to treatment in patients 5 years of age or older. Patients may develop dose-related and reversible decreases in reticulocyte and neutrophil counts and increases in transaminase levels. About 1 in 3000 patients develops an allergic reaction. Although studies of *artemisinin* treatment during the first trimester have found no evidence of adverse effects on fetal development, use of ACTs is not recommended during the first trimester of pregnancy or for the treatment of children weighing 5 kg or less. Accumulating clinical evidence for the safety of *artemether* (when combined with *lumefantrine*) in the first trimester may herald a broader use of this or other ACTs safely in early pregnancy.

ACT Partner Drugs

Partner drugs for ACT are chosen for potency and $t_{1/2}$ that substantially exceeds that of the *artemisinin* partner. The primary ACT regimens that are well tolerated in adults and children weighing 5 kg or more are *artemether-lumefantrine*, *artesunate-amodiaquine*, *artesunate-pyronaridine*, and *dihydroartemisinin-piperaquine*. In the U.S., *artemether-lumefantrine* is FDA-approved and is arguably the first choice for all malaria cases if oral drug treatment is appropriate (see Centers for Disease Control and Prevention [CDC] treatment tables at https://www.cdc.gov/malaria/resources/pdf/Malaria_Treatment_Table.pdf).

- ***Lumefantrine*** shares structural similarities with the arylamino alcohol drugs *mefloquine* and *halofantrine* and is formulated with *artemether*. *Artemether-lumefantrine* is highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of *lumefantrine* include a large apparent volume of distribution and a terminal elimination $t_{1/2}$ of 4 to 5 days. Administration with a high-fat meal is recommended because it significantly increases absorption. A sweetened dispersible formulation of *artemether-lumefantrine* has been approved for treatment of children.
- ***Amodiaquine*** is a congener of *chloroquine* that is no longer recommended in the U.S. for chemoprophylaxis of *P. falciparum* malaria because of toxicities (hepatic and agranulocytosis) associated with its prophylactic use. *Amodiaquine* is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma $t_{1/2}$ of 9 to 18 days and reaches a peak concentration of about 500 nM 2 h after oral administration of the recommended dose. By contrast, *amodiaquine* has a $t_{1/2}$ of about 3 h, attaining a peak concentration of about 25 nM within 30 min of oral administration. Clearance rates of *amodiaquine* vary widely among individuals (78–943 mL/min/kg). The ACT *artesunate-amodiaquine* is a highly effective therapy for uncomplicated malaria and is first-line treatment in many African countries.
- ***Piperaquine*** is a potent and well-tolerated bisquinoline structurally related to *chloroquine*. It is rapidly absorbed, with a t_{max} (time to peak plasma drug concentration) of 2 h after a single dose. *Piperaquine* has a large volume of distribution and reduced rates of excretion after multiple doses. *Piperaquine* has the longest plasma $t_{1/2}$ (5 weeks) of all ACT partner drugs, a factor that could reduce the likelihood of reinfection following treatment. Reduced efficacy of *piperaquine* in combination with *dihydroartemisinin* in Cambodia has been reported, primarily associated with copy number amplifications of *P. falciparum* plasmepsin-2 (*pfpm2*) owing to unknown mechanisms. These mutations have undermined the efficacy of *dihydroartemisinin-piperaquine* in Southeast Asia, though its efficacy in African settings remains high (West African Network for Clinical Trials of Antimalarial Drugs, 2018).
- ***Pyronaridine***, an antimalarial structurally related to *amodiaquine*, is well tolerated and potent against both *P. falciparum* and *P. vivax*. *Pyronaridine* has a peak plasma concentration 2 to 8 h after administration, distributes widely to tissues, and is eliminated slowly with a $t_{1/2}$ in adults of 14 to 18 days. This drug, highly efficacious in clinical trials against *P. falciparum* or *P. vivax* when partnered as *pyronaridine-artesunate*, has not yet been licensed by the FDA but is available globally.

In addition, there are two antimalarials that are used both alone and in combination as ACT:

- ***Sulfadoxine+Pyrimethamine*** **(SP)**, partnered as *artesunate*-SP
- ***Mefloquine,*** partnered as *artesunate-mefloquine*

Details of these ACT partner drugs are in the alphabetical listing below.

Atovaquone

A fixed combination of *atovaquone* with *proguanil hydrochloride* is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated *P. falciparum* malaria in adults and children.

Mechanism of Action, Selective Toxicity, Antimalarial Action, and Resistance

Atovaquone is a lipophilic analogue of ubiquinone (coenzyme Q), the electron acceptor for the parasite's cytochrome bc_1 ($cytbc_1$) complex. $Cytbc_1$, situated on the inner mitochondrial membrane, supplies oxidized ubiquinone for dihydroorotate dehydrogenase, an essential enzyme in pyrimidine biosynthesis in the parasite. In addition, $cytbc_1$ is part of the respiratory chain and transports H^+ into the intramembranous space of mitochondria. By binding at the Q_o site of $cytbc_1$, atovaquone inhibits electron transport, collapses the mitochondrial membrane potential, and inhibits regeneration of ubiquinone. The selective toxicity of *atovaquone* for the *Plasmodium* genus and not the human host may stem from structural differences in the amino terminal regions of plasmodial and human cytochrome b (Capper et al., 2015).

The drug is highly active against *P. falciparum* asexual blood-stage parasites and the liver stages but is not active against *P. vivax* liver-stage hypnozoites. Synergy between *proguanil* and *atovaquone* results from the ability of nonmetabolized *proguanil* to enhance the mitochondrial toxicity of *atovaquone*. Resistance to *atovaquone* alone in *P. falciparum* develops easily and is conferred by single, nonsynonymous nucleotide polymorphisms in the cytochrome b gene located in the mitochondrial genome. Addition of *proguanil* markedly reduces the frequency of appearance of *atovaquone* resistance. However, once *atovaquone* resistance is present, the synergy of the partner drug *proguanil* diminishes.

ADME

Atovaquone absorption is slow and variable after an oral dose; absorption improves when the drug is taken with a fatty meal. More than 99% of the drug is bound to plasma protein; levels in the cerebrospinal fluid are

less than 1% of those in plasma. Profiles of drug concentration versus time often show a double peak, the first at 1 to 8 h and the second 1 to 4 days after a single dose; this pattern suggests enterohepatic circulation. Humans do not metabolize *atovaquone* significantly. The drug is excreted in bile, and more than 94% of the drug is recovered unchanged in feces. *Atovaquone* has a reported elimination $t_{1/2}$ from plasma of 2 to 3 days in adults and 1 to 2 days in children.

Therapeutic Uses

A tablet containing a fixed dose of 250 mg *atovaquone* and 100 mg *proguanil hydrochloride*, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate infections due to *chloroquine*- or SP-resistant *P. falciparum* malaria. The same regimen followed by a *primaquine* course is effective in the treatment of *P. vivax* malaria. *Atovaquone-proguanil* is a standard agent for malaria chemoprophylaxis. Experience in prevention of non–*P. falciparum* malaria is limited. *P. vivax* infection may occur after drug discontinuation, indicating imperfect activity against exoerythrocytic stages of this parasite.

Toxicity

Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. *Atovaquone* occasionally causes transient elevations of serum transaminase or amylase.

Precautions and Contraindications

Although *atovaquone* is generally considered to be safe, it needs further evaluation in children weighing less than 11 kg, pregnant women, and lactating mothers. *Atovaquone* may compete with certain drugs for binding to plasma proteins. Therapy with *rifampin* reduces plasma levels of *atovaquone* substantially; the mechanism of this effect is not clear. Coadministration with *tetracycline* is associated with a 40% reduction in plasma concentration of *atovaquone*.

Diaminopyrimidines

Sulfadoxine+Pyrimethamine was a primary treatment of uncomplicated *P. falciparum* malaria, especially against *chloroquine*-resistant strains. Due to widespread resistance, it is no longer recommended for the treatment of uncomplicated malaria, except in some settings when paired with *artesunate*, as noted below (see Therapeutic Uses).

Antimalarial Action and Resistance

Pyrimethamine is a slow-acting blood *schizonticide* with antimalarial effects *in vivo* resulting from inhibition of *folate biosynthesis* in *Plasmodium,* similar to *proguanil*. The efficacy of *pyrimethamine* against hepatic forms of *P. falciparum* is less than that of *proguanil*. At therapeutic doses, *pyrimethamine* fails to eradicate *P. vivax* hypnozoites or gametocytes of any *Plasmodium* species. The drug increases the number of circulating *P. falciparum* mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.

Synergy of *pyrimethamine* and the sulfonamides or sulfones results from inhibition of two metabolic steps in folate biosynthesis in the parasite:

- The utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides
- The reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by *pyrimethamine* (see Figure 57–2)

Dietary *p*-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Resistance to *pyrimethamine* has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of *pyrimethamine*.

ADME

Oral *pyrimethamine* is slowly but completely absorbed, reaching peak plasma levels in 2 to 6 h. The compound is significantly distributed in the tissues and is about 90% bound to plasma proteins. *Pyrimethamine* is slowly eliminated from plasma, with a $t_{1/2}$ of 85 to 100 h. Concentrations that are suppressive for responsive *Plasmodium* strains remain in the blood for about 2 weeks. *Pyrimethamine* also enters the milk of nursing mothers.

Therapeutic Uses

Due to increasing drug resistance, SP is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis. However, SP is still used as prevention in malaria-endemic areas, monthly during pregnancy starting in the second trimester as part of intermittent preventive treatment in pregnancy in parts of Africa, and paired with *amodiaquine* for monthly administration to children for seasonal malaria chemoprevention in the Sahel belt of Africa.

Toxicity, Precautions, and Contraindications

Antimalarial doses of *pyrimethamine* alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folinic acid. At high doses, *pyrimethamine* is teratogenic in animals, and in humans, the related combination, *trimethoprim-sulfamethoxazole*, may cause birth defects.

Sulfonamides or sulfones, rather than *pyrimethamine*, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of *pyrimethamine* and *sulfadoxine* causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness–type reactions, urticaria, exfoliative dermatitis, and hepatitis. SP is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants less than 2 months of age. Administration of *pyrimethamine* with *dapsone*, a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

Proguanil

The antimalarial activity of *proguanil* (chloroguanide) is ascribed to *cycloguanil*, a cyclic triazine metabolite (structurally related to *pyrimethamine*) and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase–thymidylate synthetase that is crucial for parasite *de novo* purine and pyrimidine synthesis.

Antimalarial Action and Resistance

In drug-sensitive *P. falciparum* malaria, *proguanil* exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute episode and usually eradicating the infection. *Proguanil* is also active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. *Proguanil* treatment does not destroy gametocytes, but oocysts in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors. A series of amino acid changes near the dihydrofolate reductase–binding site have been identified that cause resistance to *cycloguanil*, *pyrimethamine*, or both. The presence of *Plasmodium* dihydrofolate reductase is not required for the intrinsic antimalarial activity of *proguanil* or *chlorproguanil*; however, the molecular basis for this alternative activity is unknown. *Proguanil* accentuates the mitochondrial membrane potential–collapsing action of *atovaquone* against *P. falciparum* but displays no such activity by itself. In contrast to *cycloguanil*, resistance to the parent drug, *proguanil*, either alone or in combination with *atovaquone*, is not well documented.

ADME

Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, t_{max} is approximately 5 h. The mean plasma elimination $t_{1/2}$ is about 180 to 200 h or longer. The drug's activation and metabolism

involve the CYP2C subfamily; about 3% of Caucasians are deficient in this oxidation phenotype, contrasted with about 20% of Asians and Kenyans. *Proguanil* is oxidized to two major metabolites, the active *cycloguanil* and an inactive 4-chlorophenyl biguanide. On a daily dosage regimen of 200 mg daily, plasma levels of *cycloguanil* in extensive metabolizers exceed the therapeutic range, whereas *cycloguanil* levels in poor metabolizers do not. *Proguanil* itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells, where its concentration is about three times that in plasma. In humans, 40% to 60% of the absorbed *proguanil* is excreted in urine, either as the parent drug or as the active metabolite.

Therapeutic Uses

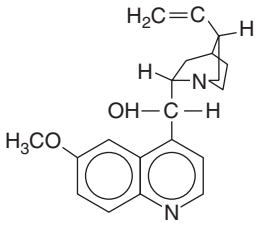
Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of *P. falciparum* resistant to *proguanil* emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of *proguanil* to its active antimalarial metabolite. *Proguanil* is effective and well tolerated when administered with *atovaquone* once daily for 3 days to treat drug-resistant strains of *P. falciparum* or *P. vivax* (see section on *atovaquone*). *P. falciparum* readily develops clinical resistance to monotherapy with either *proguanil* or *atovaquone*; however, resistance to the combination is uncommon unless the strain is initially resistant to *atovaquone*.

Toxicity and Side Effects

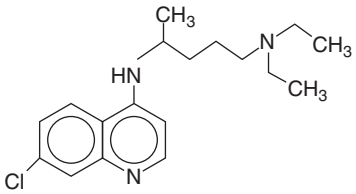
In chemoprophylactic doses of 200 to 300 mg daily, *proguanil* causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Doses as high as 700 mg twice daily have been taken for more than 2 weeks without serious toxicity. *Proguanil* is safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs.

Quinolines and Related Compounds

Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree. Structure-activity analysis of the cinchona alkaloids provided the basis for the discovery of more recent antimalarials, such as mefloquine.



QUININE



CHLOROQUINE

Antimalarial Action

Asexual malarial parasites flourish in host erythrocytes by digesting hemoglobin; this generates free radicals and iron-bound heme as highly reactive by-products. Heme is sequestered as an insoluble, chemically inert malarial pigment termed *hemozoin*. Quinolines interfere with heme sequestration. Failure to inactivate heme and drug-heme complexes is thought to kill the parasites via oxidative damage to membranes or other critical biomolecules.

Chloroquine and Hydroxychloroquine

Chloroquine is a 4-aminoquinoline derived from a precursor compound that was originally synthesized by German chemists in the 1930s. This precursor found purchase against a variety of *Plasmodium* species in early human studies during World War II. The compound and these data were delivered to Allied forces following the capture of Tunis in 1943, prompting American industrial-academic-military complex to synthesize and test additional 4-aminoquinolines. This process begat *chloroquine* as the most effective and safe antimalarial against *P. falciparum* and *P. vivax*. *Chloroquine*, a weak base, concentrates in the highly acidic digestive vacuoles of susceptible *Plasmodium*, where it binds to heme and disrupts its sequestration. *Hydroxychloroquine*, in which one of the *N*-ethyl substituents of *chloroquine* is β-hydroxylated, is essentially equivalent to *chloroquine* against *P. falciparum* malaria.

Resistance. Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially *chloroquine*, now is widespread. *Chloroquine* resistance results from mutations in the polymorphic gene *pfcrt* (*P. falciparum chloroquine* resistance transporter) that encodes a putative transporter that resides in the membrane of the acidic digestive vacuole, the site of hemoglobin degradation and *chloroquine* action. In addition to PfCRT, the P-glycoprotein transporter encoded by *pfmdr1*, and other transporters, including *P. falciparum* multidrug resistance-associated protein (PfMRP), may play a modulatory role in *chloroquine* resistance. *Chloroquine* resistance among *P. vivax* has also been reported; the resistance manifests clinically as early recurrences of infection following treatment and is associated mechanistically with overexpression of the *P. vivax chloroquine* resistance transporter (*pvcrt*).

ADME

Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. This drug extensively sequesters in tissues, particularly liver, spleen, kidney, lung, and to a lesser extent, brain and spinal cord. *Chloroquine* binds moderately (60%) to plasma proteins. The actions of hepatic CYPs produce two active metabolites, desethylchloroquine and bisdesethylchloroquine. Renal clearance of *chloroquine* is about half of its total systemic clearance. Unchanged *chloroquine* and desethylchloroquine account for more than 50% and 25% of the urinary drug products, respectively, and their renal excretion is increased by urine acidification. To avoid potentially lethal toxicity, parenteral *chloroquine* is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. *Chloroquine* is safer when given orally because the rates of absorption and distribution are more closely matched. Peak plasma levels are achieved in about 3 to 5 h. The $t_{1/2}$ of *chloroquine* increases from a few days to weeks as plasma levels decline. The terminal $t_{1/2}$ ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

Therapeutic Uses. *Chloroquine* is highly effective against the erythrocytic forms of *P. vivax* in most settings, *P. ovale, P. malariae*, *P. knowlesi*, and chloroquine-sensitive strains of *P. falciparum*. For infections caused by *P. ovale* and *P. malariae,* it remains the agent of choice for treatment. For *P. falciparum,* ACTs have largely replaced *chloroquine*.

The utility of *chloroquine* has declined across most malaria-endemic regions of the world because of the spread of *chloroquine*-resistant

BOX 66–1 ■ Quinine: From Tree Bark to Tonic Water

The powdered bark of the South American cinchona tree was ingested by the Quechua people of Peru as a treatment for rigors. Jesuit missionaries in the 17th century adopted this practice and popularized the bark's use in Europe, where it became known as "Jesuit powder," among other names. For several centuries, cinchona was a widespread therapy for syndromes consistent with malaria, as well as a highly valued commodity, begetting plantations of cinchona plants to supply the global demand. It was not until the early 19th century that quinine was isolated from the bark, and only in the mid-20th century that industrial synthesis was established, although by this time, *quinine*'s routine use had been largely eclipsed by other antimalarials.

Quinine is now ingested socially as a carbonated beverage. The FDA has set an upper limit for the *quinine* content of tonic water: 83 mg/L.

P. falciparum. Except in areas where resistant strains of *P. vivax* are reported (e.g., Papua New Guinea and Indonesia), *chloroquine* is effective in chemoprophylaxis or treatment of acute attacks of malaria caused by *P. vivax, P. ovale*, and *P. malariae*. *Chloroquine* has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, *primaquine* can either be given with *chloroquine* or used after a patient leaves an endemic area. *Chloroquine* rapidly controls the clinical symptoms and parasitemia of acute malaria. Most patients become completely afebrile within 24 to 48 h after receiving therapeutic doses. If patients fail to respond during the second day of *chloroquine* therapy, resistant strains should be suspected and therapy instituted with *quinine* plus *tetracycline* or *doxycycline* or with *atovaquone-proguanil*, *artemether-lumefantrine*, or *mefloquine* if the others are not available. In comatose children, *chloroquine* is well absorbed and effective when given through a nasogastric tube. Tables 66–2 and 66–3 provide information about recommended chemoprophylactic and therapeutic dosage regimens involving *chloroquine*. *Chloroquine* and its analogues are also used to treat certain nonmalarial conditions, including hepatic amebiasis.

Toxicity and Side Effects. Taken in proper doses and for recommended total durations, *chloroquine* is safe, but its margin of safety is narrow; a single dose of 30 mg/kg may be fatal. Acute *chloroquine* toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma may also result from overdose. *Chloroquine* doses of more than 5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, *epinephrine*, and *diazepam* may be lifesaving.

Doses of *chloroquine* used for oral therapy of acute malaria may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as

TABLE 66–2 ■ CHEMOPROPHYLAXIS FOR PREVENTION OF MALARIA IN NONIMMUNE INDIVIDUALS

DRUG (USAGE)	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone/proguanil (Prophylaxis in all areas)	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride; 1 adult tablet orally, daily	Pediatric tablets (62.5 mg atovaquone/25 mg proguanil HCl) 5–8 kg: 1/2 ped tab/day >8–10 kg: 3/4 ped tab/day >10–20 kg: 1 ped tab/day >20–30 kg: 2 ped tab/day >30–40 kg: 3 ped tab/day >40 kg: 1 adult tab daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Contraindicated in persons with severe renal impairment (creatinine clearance <30 mL/min). Take with food or a milky drink. Not recommended for prophylaxis for children weighing less than 5 kg, pregnant women, and women breastfeeding infants weighing less than 5 kg.
Chloroquine phosphate (Prophylaxis in areas with chloroquine-sensitive malaria)	300 mg base (500 mg salt) orally, once/week	5 mg/kg base (8.3 mg/kg salt) orally, once/week, up to maximum adult dose (300 mg base)	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas. May exacerbate psoriasis.
Doxycycline (Prophylaxis in all areas)	100 mg orally, daily	≥8 years of age: 2 mg/kg up to adult dose of 100 mg/day	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 4 weeks after leaving such areas. Contraindicated in children less than 8 years of age and pregnant women.
Hydroxychloroquine sulfate (Alternative to chloroquine for prophylaxis in areas with chloroquine-sensitive malaria)	310 mg base (400 mg salt) orally, once/week	5 mg/kg base (6.5 mg/kg salt) orally, once/week, up to maximum adult dose (310 mg base)	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas.
Mefloquine (Prophylaxis in areas with mefloquine-sensitive malaria)	228 mg base (250 mg salt) orally, once/week	≤9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week >9–19 kg: 1/4 tab weekly >19–30 kg: 1/2 tab weekly >31–45 kg: 3/4 tab weekly ≥45 kg: 1 tablet weekly	Begin 1–2 weeks before travel to malarious areas. Take weekly on same day of the week while in malarious area and for 4 weeks after leaving such areas. Contraindicated in persons allergic to mefloquine or related compounds (e.g., quinine, quinidine) and in persons with active depression, recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a previous history of depression. Not recommended for persons with cardiac conduction abnormalities.
Primaquine (Prophylaxis for short-duration travel to areas with principally *P. vivax*)	30 mg base (52.6 mg salt) orally, daily	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily	Begin 1–2 days before travel to malarious areas. Take daily at same time each day while in malarious area and for 7 days after leaving such areas. Contraindicated in persons with G6PD[a] deficiency and during pregnancy and lactation (unless the infant being breastfed has documented normal G6PD level).

(Continued)

TABLE 66–2 ■ CHEMOPROPHYLAXIS FOR PREVENTION OF MALARIA IN NONIMMUNE INDIVIDUALS (*CONTINUED*)

DRUG (USAGE)	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Primaquine (For presumptive antirelapse therapy [terminal prophylaxis] to decrease the risk of relapses [*P. vivax*, *P. ovale*])	30 mg base (52.6 mg salt) orally, once/day for 14 days after departure from the malarious area	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, once/day for 14 days after departure from the malarious area	Indicated for persons who have had prolonged exposure to *P. vivax* and *P. ovale* or both. Contraindicated in persons with G6PD[a] deficiency and during pregnancy and lactation (unless the infant being breastfed has documented normal G6PD level).
Tafenoquine (Prophylaxis for travel to all areas)	200 mg daily (before travel) or weekly (during/after travel)	NA	Begin daily dosing for 3 days before travel to malarious areas. Then take weekly during travel, starting 1 week after last pretravel dose, then a final dose 1 week after travel. Contraindicated in people with G6PD[a] deficiency or unknown G6PD status, pregnant women, women breastfeeding an infant with G6PD deficiency or unknown G6PD status, people <18 years old, or people with history of psychotic disorder.
Tafenoquine (For antirelapse therapy [terminal prophylaxis] to reduce the risk of relapses [*P. vivax, P. ovale*])	300 mg, single dose	NA	Coadminister on the first or second day of therapy with the primary treatment for *P. vivax* or *P. ovale*. Contraindicated in people with G6PD[a] deficiency or unknown G6PD status, pregnant women, women breastfeeding an infant with G6PD deficiency or unknown G6PD status, people <16 years old. Use with caution in those with a history of a psychotic disorder.

NA, not applicable; ped, pediatric; tab, tablet.
These regimens are based on published recommendations of the U.S. Centers for Disease Control and Prevention. These recommendations may change over time. Up-to-date information should be obtained from https://wwwnc.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the last, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.
[a]All persons who take primaquine or tafenoquine should have a documented normal G6PD level before starting the medication.

TABLE 66–3 ■ AGENTS FOR PRESUMPTIVE SELF-TREATMENT OF MALARIA[a]

DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone-Proguanil			
Adult tablet: 250 mg atovaquone and 100 mg proguanil *Pediatric tablet*: 62.5 mg atovaquone and 25 mg proguanil	4 adult tablets, orally as a single daily dose for 3 consecutive days	Daily dose to be taken for 3 consecutive days: 5–8 kg: 2 pediatric tabs 9–10 kg: 3 pediatric tablets 11–20 kg: 1 adult tablet 21–30 kg: 2 adult tablets 31–40 kg: 3 adult tablets >41 kg: 4 adult tablets	Contraindicated in people with severe renal impairment (creatinine clearance <30 mL/min). Not recommended for people on atovaquone-proguanil prophylaxis. Not recommended for children weighing <5 kg, pregnant women, and women breastfeeding infants weighing <5 kg.

DRUG	DOSE	COMMENTS
Artemether-Lumefantrine		
A tablet contains 20 mg artemether and 120 mg lumefantrine	A 3-day treatment schedule with a total of 6 oral doses is recommended for both adult and pediatric patients *based on weight*. The patient should receive the initial dose, followed by the second dose 8 h later, then 1 dose twice daily for the following 2 days. 5 to <15 kg: 1 tablet per dose 15 to <25 kg: 2 tablets per dose 25 to <35 kg: 3 tablets per dose ≥35 kg: 4 tablets per dose	Not for people on mefloquine prophylaxis. Not recommended for children weighing <5 kg, pregnant women, and women breastfeeding infants weighing <5 kg.

[a]If used for presumptive self-treatment, medical care should be sought as soon as possible.
Source: Modified from https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-related-infectious-diseases/malaria; accessed June 21, 2022.

headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. *Chloroquine* may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines. Irreversible retinopathy and ototoxicity can result from high daily doses (>250 mg) of *chloroquine* or *hydroxychloroquine*, leading to cumulative total doses of more than 1 g/kg. Retinopathy presumably is related to drug accumulation in melanin-containing tissues and can be avoided if the daily dose is 250 mg or less. Prolonged therapy with high doses of *chloroquine* or *hydroxychloroquine* also can cause toxic myopathy, cardiopathy, and peripheral neuropathy. These reactions improve if the drug is withdrawn promptly. Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. *Chloroquine* is not recommended for treating individuals with epilepsy or myasthenia gravis and should be used cautiously, if at all, in the presence of advanced liver disease or severe GI, neurological, or blood disorders. The dose should be reduced in renal failure. In rare cases, *chloroquine* can cause hemolysis in patients with a deficiency of glucose-6-phosphate dehydrogenase (G6PD). *Chloroquine* should not be prescribed for patients with psoriasis or other exfoliative skin conditions. It should not be used to treat malaria in patients with porphyria cutanea tarda; however, it can be used in lower doses for treatment of manifestations of this form of porphyria.

Chloroquine inhibits CYP2D6 and thus can interact with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with *mefloquine* because of increased risk of seizures. *Chloroquine* opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when coadministered with *amiodarone* or *halofantrine*. By increasing plasma levels of *digoxin* and *cyclosporine*, *chloroquine* can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose therapy should undergo ophthalmological and neurological evaluations every 3 to 6 months.

Quinine and Quinidine

Oral *quinine* is FDA-approved for the treatment of uncomplicated *P. falciparum* malaria. *Quinidine*, a stereoisomer of *quinine*, is more potent as an antimalarial and more toxic than *quinine*.

Antimalarial Action and Resistance. *Quinine* acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than *chloroquine* against malarial parasites susceptible to both drugs. Compared to *artemisinin* class therapy, *quinine* produces poorer clinical outcomes. However, *quinine*, along with its stereoisomer *quinidine*, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*. Because of its toxicity and short $t_{1/2}$, *quinine* is generally not used for chemoprophylaxis. The antimalarial mechanism of *quinine* is presumably similar to that of *chloroquine*. The basis of *P. falciparum* resistance to *quinine* is complex. Patterns of *P. falciparum* resistance to *quinine* correlate in some strains with resistance to *chloroquine* yet in others correlate more closely with resistance to *mefloquine* and *halofantrine*. A number of transporter genes may confer resistance to *quinine*.

Action on Skeletal Muscle. *Quinine* not only increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. *Quinine* can antagonize the actions of *physostigmine* on skeletal muscle. *Quinine* may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis.

ADME. *Quinine* is readily absorbed when given orally or intramuscularly. Oral absorption occurs mainly from the upper small intestine and is more than 80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3 to 8 h and, after distributing into an apparent volume of about 1.5 L/kg, decline with a $t_{1/2}$ of about 11 h. The pharmacokinetics of *quinine* may change with severe malarial infection: the apparent volume of distribution and the systemic clearance of *quinine* decrease, such that the average elimination $t_{1/2}$ increases to 18 h. The high levels of plasma α_1-acid glycoprotein produced in severe malaria may prevent toxicity by binding *quinine* and thereby reducing the free fraction of drug. Concentrations of *quinine* are lower in erythrocytes (33%–40%) and cerebrospinal fluid (2%–5%) than in plasma, and the drug readily reaches fetal tissues. The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus, only about 20% of an administered dose is excreted in an unaltered form in the urine. The major metabolite of *quinine*, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of *quinine* itself is more rapid when the urine is acidic.

Therapeutic Uses. Although *quinine* and *quinidine* have long been treatments of choice for drug-resistant and severe *P. falciparum* malaria, the advent of oral and intravenous *artemisinin* therapy has changed this situation. Standard of care for severe illness, and only until *artemisinin* therapy can be started, is the prompt use of loading doses of intravenous *quinine* (or *quinidine*, discontinued in the U.S. in 2017), which can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5 to 7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizonticides such as *tetracyclines* or *clindamycin* are given concurrently to enhance *quinine* efficacy. Formulations of *quinine* and *quinidine* and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in the Drug Facts table. Note that in the U.S. *quinine* and *quinidine* have been eclipsed by parenteral *artesunate* for the treatment of severe malaria. Parenteral *artesunate* was FDA-approved in 2020 and is available both commercially and through an expanded access investigational new drug program accessible through the CDC Malaria Hotline (770-488-7788 or 855-856-4713).

The therapeutic range for "free" *quinine* is 0.2 and 2 mg/L. Regimens needed to achieve this target vary based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. Dosage regimens for *quinidine* are similar to those for *quinine*, although *quinidine* binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination $t_{1/2}$ than *quinine*.

Nocturnal Leg Cramps. It is commonly believed that night cramps are relieved by *quinine* (200–300 mg) taken at bedtime. The FDA has required drug manufacturers to stop marketing over-the-counter *quinine* products for nocturnal leg cramps, stating that data supporting safety and efficacy of *quinine* for this indication were inadequate and that risks outweighed the potential benefits.

Toxicity and Side Effects. The fatal oral dose of *quinine* for adults is about 2 to 8 g. *Quinine* is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses: cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism (consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension) occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rare and most often is associated with excessively rapid intravenous infusions of *quinine* or *quinidine*. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations. GI symptoms (nausea, vomiting, abdominal pain, and diarrhea) result from the local irritant action of *quinine*, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and angioedema, especially of the face. *Quinine* and *quinidine*, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded. QTc prolongation is mild and does not

appear to be affected by concurrent *mefloquine* treatment. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias, such as sinus arrest, junctional rhythms, atrioventricular block, and ventricular tachycardia and fibrillation. *Quinidine* is even more cardiotoxic than *quinine*. Cardiac monitoring of patients on intravenous *quinidine* is advisable where possible.

Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from *quinine* may occur more rarely. "Blackwater fever"—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and in some instances death—is a rare hypersensitivity reaction to *quinine* therapy that can occur during treatment of malaria. *Quinine* occasionally may cause milder hemolysis, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura also is rare but can occur even in response to ingestion of tonic water, which has about 4% of the therapeutic oral dose per 12 oz ("cocktail purpura"). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

Research in model systems indicated that *quinine* can inhibit a number of transport proteins, including Tat2p, which transports tryptophan, the precursor of serotonin (5HT). *Quinine* also competitively inhibits the rate-limiting step in 5HT biosynthesis, tryptophan hydroxylase (Islahudin et al., 2014; Khozoie et al., 2009). Whether these data relate to adverse effects of *quinine* in humans remains to be determined.

Precautions, Contraindications, and Drug Interactions. *Quinine* must be used with considerable caution, if at all, in patients who manifest hypersensitivity. *Quinine* should be discontinued immediately if evidence of hemolysis appears. This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of *quinine* requires the same precautions as for *quinidine*. *Quinine* appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

Quinine and *quinidine* are highly irritating to tissues and should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of *quinine* from the GI tract. *Quinine* and *quinidine* can delay the absorption and elevate plasma levels of cardiac glycosides, *warfarin*, and related anticoagulants. The action of *quinine* at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. *Prochlorperazine* can amplify *quinine*'s cardiotoxicity, as can *halofantrine*. The renal clearance of *quinine* can be decreased by *cimetidine* and increased by urine acidification and by *rifampin*.

Mefloquine

Mefloquine was discovered through the Experimental Therapeutics Division of the U.S. Walter Reed Army Institute of Research in the 1970s and found to be safe and effective against drug-resistant strains of *P. falciparum*.

Mechanisms of Action and Resistance. *Mefloquine* is a highly effective blood schizonticide. *Mefloquine* associates with intraerythrocytic hemozoin, suggesting similarities to the mode of action of *chloroquine*. However, increased *pfmdr1* copy numbers are associated with both reduced parasite susceptibility to *mefloquine* and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites, suggesting that the drug's target resides outside this vacuolar compartment. The (−)-enantiomer is associated with adverse effects in the CNS (central nervous system); the (+)-enantiomer retains antimalarial activity with fewer side effects. *Mefloquine* can be paired with *artesunate* to reduce the selection pressure for resistance. This combination has proved efficacious for the treatment of *P. falciparum* malaria, even in regions with high prevalence of *mefloquine*-resistant parasites.

ADME. *Mefloquine* is taken orally because parenteral preparations cause severe local reactions. The drug is absorbed rapidly but with marked variability. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of *mefloquine* rise in a biphasic manner to their peak in about 17 h. *Mefloquine* has a variable and long $t_{1/2}$ (13–24 days), reflecting its high lipophilicity, extensive tissue distribution, and extensive binding (~98%) to plasma proteins. The slow elimination of *mefloquine* fosters the emergence of drug-resistant parasites. *Mefloquine* is extensively metabolized in the liver by CYP3A4; this CYP can be inhibited by *ketoconazole* and induced by *rifampin*. Excretion of *mefloquine* is mainly by the fecal route; about 10% of *mefloquine* appears unchanged in the urine.

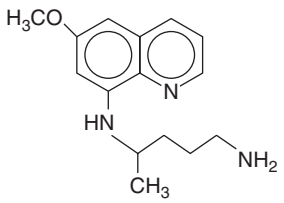
Therapeutic Uses. *Mefloquine* should be reserved for the prevention and treatment of malaria caused by known or suspected drug-resistant *P. falciparum* and *P. vivax*; it is no longer considered first-line treatment of malaria. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks to years in areas where these infections are endemic and have not yet acquired significant resistance (see Table 66–2). In areas where drug-resistant strains of *P. falciparum* are circulating widely, *mefloquine* is more effective when used in combination with an *artemisinin* compound.

Toxicity and Side Effects. While oral *mefloquine* is generally well tolerated at chemoprophylactic dosages, the FDA in 2013 added a "black-box" warning to *mefloquine* labeling, noting the drug's potential to cause severe, possibly permanent, neurological and psychiatric adverse effects. Vivid dreams are common; significant neuropsychiatric signs and symptoms can occur in 10% or more of people receiving treatment doses, but serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour. After treatment of malaria with *mefloquine*, CNS toxicity can be as high as 0.5%; symptoms include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms are reversible on drug discontinuation. Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Drug Interactions. At very high doses, *mefloquine* is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with *mefloquine* use, especially during the first trimester. Pregnancy should be avoided for 3 months after *mefloquine* use because of the prolonged $t_{1/2}$ of this agent. This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder, and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials. Although this drug can be taken safely 12 h after a last dose of *quinine*, taking *quinine* shortly after *mefloquine* can be hazardous because the latter is eliminated so slowly. Treatment with or after *halofantrine* or within 2 months of prior *mefloquine* administration is contraindicated. Controlled studies suggest that *mefloquine* does not impair performance in persons who tolerate the drug; nonetheless, some advise against the use of *mefloquine* for patients in occupations that require focused concentration, dexterity, and cognitive function.

Primaquine

Primaquine, in contrast to other antimalarials, acts on exoerythrocytic tissue stages of *Plasmodium* spp. in the liver to prevent and cure relapsing malaria. Patients should be screened for G6PD deficiency prior to therapy with this drug.



PRIMAQUINE

Antimalarial Action and Parasite Resistance. The mechanism of action of the 8-aminoquinolines has not been elucidated. *Primaquine* acts against primary and latent hepatic stages of *Plasmodium* spp. and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocytocidal activity against *P. falciparum* and other *Plasmodium* species. However, *primaquine* is inactive against asexual blood-stage parasites, rendering it unsuitable as the principal treatment for an acute episode of malaria.

ADME. Absorption of *primaquine* from the GI tract approaches 100%. Peak plasma concentration occurs within 3 h and then falls with a variable $t_{1/2}$ averaging 7 h. *Primaquine* is metabolized rapidly; only a small fraction of a dose is excreted as the parent drug. Importantly, *primaquine* induces CYP1A2. The major metabolite, carboxyprimaquine, is inactive.

Therapeutic Uses. *Primaquine* is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually *chloroquine*, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal chemoprophylaxis, *primaquine* regimens should be initiated shortly before or immediately after a subject leaves an endemic area (see Table 66–2). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection or during an acute attack. Simultaneous administration of a schizonticidal drug plus *primaquine* is more effective than sequential treatment in promoting a radical cure. Limited studies demonstrated efficacy in prevention of *P. falciparum* and *P. vivax* malaria when *primaquine* was taken as chemoprophylaxis. *Primaquine* is generally well tolerated when taken for up to 1 year.

The role of *primaquine* has expanded owing to its unique gametocidal activity. Because most standard treatments for an episode of *P. falciparum* malaria effectively remove asexual blood stages but allow gametocytes to persist, treated patients may fuel onward transmission to mosquitos. For low transmission areas, the World Health Organization (WHO) recommends the use of single-dose *primaquine* at a dose of 0.25 mg/kg as adjunct to ACT in nonpregnant people over age 6 months with *P. falciparum* malaria. Owing to the use of a single dose, G6PD testing is not required.

Toxicity and Side Effects. *Primaquine* has few side effects when given in the usual therapeutic doses. *Primaquine* can cause mild-to-moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60–240 mg daily) worsen the abdominal symptoms. Methemoglobinemia can occur even with usual doses of *primaquine* and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase (NADH-cytochrome b5 reductase [diaphorase 1]). *Chloroquine* and *dapsone* may synergize with *primaquine* to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.

Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency. Primaquine is the prototype of more than 50 drugs, including antimalarial tafenoquine and sulfonamides, that causes hemolysis in G6PD-deficient individuals.

Precautions and Contraindications. When used for terminal chemoprophylaxis or radical cure, G6PD deficiency should be ruled out prior to administration of *primaquine*. *Primaquine* has been used cautiously in subjects with the A form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks, but should not be used in patients with more severe deficiency. If a daily dose of more than 30 mg *primaquine* base (>15 mg in potentially sensitive patients) is given, then blood counts should be followed carefully. Patients should be counseled to look for dark or blood-colored urine, which would indicate hemolysis. *Primaquine* should not be given to pregnant women; in treating lactating mothers, *primaquine* should be prescribed only after ascertaining that the breastfeeding infant has a normal G6PD level. *Primaquine* is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia (e.g., active forms of rheumatoid arthritis and lupus erythematosus). *Primaquine* should not be given to patients receiving drugs capable of causing hemolysis or depressing the myeloid elements of the bone marrow.

Tafenoquine

Tafenoquine is a derivative of *primaquine* that was discovered in the 1970s by the Walter Reed Army Institute of Research. As a derivative of *primaquine*, *tafenoquine* presumably has the same mechanism of action as *primaquine*; its reported toxicities and side effects are the same, particularly with relation to G6PD deficiency. Absorption after dosing is nearly complete but delayed over about 12 h in healthy volunteers (Charles et al., 2007). The main differences between *primaquine* and *tafenoquine* relate to ADME. There are no reported detectable QTc effects with *tafenoquine*. This agent has not been tested in pregnant women or children.

ADME. After oral administration (no parenteral formulation is available) *tafenoquine* is slowly absorbed, with maximum plasma concentrations occurring about 12 h after dosing in fasting healthy subjects; absorption and elimination are first order (Brueckner et al., 1998). The elimination $t_{1/2}$ of *tafenoquine* is about 14 days (Brueckner et al., 1998; Charles et al., 2007). The drug has a large volume of distribution and low clearance. *In vivo* metabolism of the parent drug and resultant metabolites is not well understood. Mild GI side effects include heartburn, gas, vomiting, and diarrhea. Methemoglobinemia, hemolytic anemia, thrombocytopenia, or changes in white blood cell counts or electrocardiograms are not observed in healthy fasting subjects without G6PD deficiency (Brueckner et al., 1998; Charles et al., 2007).

Therapeutic Uses. *Tafenoquine* is FDA-approved for the prevention of malaria and for the radical cure of *P. vivax* malaria. For the prevention of malaria, *tafenoquine* may be used for up to 6 months, with a loading regimen of 200 mg daily for 3 days prior to travel followed by 200 mg weekly thereafter. For the radical cure of *P. vivax* or *P. ovale*, a single dose of 300 mg is used, usually concomitantly with the therapy that is directed against the blood stage parasite.

Toxicity and Side Effects. The most common side effects in clinical trials of *tafenoquine* were headache, dizziness, back pain, diarrhea, nausea, motion sickness, depression, anxiety, abnormal dreams, and an elevated alanine aminotransferase level. Methemoglobinemia is a known side effect, and people with NADH-dependent methemoglobin reductase deficiency should undergo monitoring. Vortex keratopathy was reported at a high prevalence in two trials that included ophthalmic evaluations, although these were not accompanied by functional visual deficits or retinal changes.

Precautions and Contraindications. G6PD deficiency or unknown G6PD status is a contraindication to the use of *tafenoquine* owing to the risk of hemolytic anemia; therefore, G6PD testing is mandatory prior to *tafenoquine* administration. In males, qualitative G6PD tests are sufficient, although females often require quantitative G6PD testing. Psychosis or psychotic symptoms are also a contraindication, and their development while on preventive treatment should prompt evaluation and possible drug withdrawal. Because of the chemical similarity to *primaquine*, a hypersensitivity to *primaquine* is also a contraindication to *tafenoquine* use.

Sulfonamides and Sulfones

The sulfonamides and sulfones are slow-acting blood schizonticides and are more active against *P. falciparum* than *P. vivax*.

Mechanism of Action

Sulfonamides are *p*-aminobenzoic acid analogues that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action. See Figure 57–2 and neighboring text for details of these agents.

Drug Resistance

Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene. These *sulfadoxine* resistance mutations, when combined with mutations of dihydrofolate reductase that confer *pyrimethamine* resistance, greatly increase the likelihood of SP treatment failure. These mutations are widespread throughout global parasite populations, rendering SP unsuitable as a treatment for acute malaria. However, SP, given intermittently during the second and third trimesters of pregnancy as chemoprevention, is a routine component of antenatal care throughout Africa, an indication for which it retains a positive effect on newborn outcomes. Generally, one can anticipate that, in the absence of novel antifolates effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

Tetracyclines and Clindamycin

Tetracycline and *doxycycline* are useful in malaria treatment, as is *clindamycin*. These agents are slow-acting blood schizonticides that can be used alone for short-term chemoprophylaxis in areas with *chloroquine*- and *mefloquine*-resistant malaria (only *doxycycline* is recommended for malaria chemoprophylaxis).

These antibiotics act via a delayed-death mechanism resulting from their inhibition of protein translation in the parasite apicoplast (an organelle evolutionarily derived from plant chloroplasts). This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity. Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. Dosage regimens for tetracyclines and *clindamycin* are listed in the Drug Facts table. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or to children younger than 8 years. For details of these agents, see Chapter 60.

Antimalarials in Development

With resistance to *arteminisins* growing in Asia and appearing in sub-Saharan Africa, development of novel antimalarial drugs, ideally of a different class, is critical. Two such candidate drugs are currently the most advanced in clinical development: *ganaplacide* (KAF 156) and *cipargamin* (KAE 609). *Ganaplacide* is an imidazolopiperazine that is active on asexual forms as well as gametocytes. It is also active on *P. vivax* in addition to *P. falciparum*. It is currently in phase II clinical trials in several sites in combination with a new formulation of *lumefantrine* termed *lumefantrine* solid dispersible form (Ashley et al., 2018). *Cipargamin* (KAE 609) is a spiroindolone active as blood schizonticide on *P. falciparum*. It is under development as a single-dose single agent and is in field trials.

Ferroquine is a 4-aminoquinoline that retains *in vitro* efficacy against *chloroquine*-resistant and *piperaquine*-resistant *P. falciparum*. It is under clinical development in combination with *artefenomel*, which is a synthetic analogue of the *artemisinins* (Ashley et al., 2018).

Novel approaches using monoclonal antibodies are under development. Neutralizing human monoclonal antibody that targets epitopes in the *P. falciparum* circumsporozoite protein (PfCSP) were shown to be protective from malaria infection. This novel malaria prevention approach is now in phase I clinical trial Gaudinski et al., 2021).

Principles and Guidelines for Chemoprophylaxis and Chemotherapy of Malaria

Pharmacological prevention of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the human deaths from malaria, has become progressively more resistant to available antimalarial drugs. Oral *artemether-lumefantrine* is likely appropriate as first-line antimalarial treatment of uncomplicated malaria. *Chloroquine* remains effective against malaria caused by *P. ovale*, *P. malariae*, *P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum*. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions (see Figure 66–1). Extensive geographic overlap also exists between *chloroquine* resistance and resistance to SP. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to *mefloquine* or *quinine*. The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are provided in Tables 66–2 and 66–3.

Drugs should not replace simple, inexpensive measures for malaria prevention. Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding of the anopheline species of mosquitos that transmit malaria parasites. Others include using insect repellents containing at least 30% DEET (*N,N′*-diethylmetatoluamide) and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin.

Malaria Chemoprophylaxis

Regimens for malaria chemoprophylaxis include primarily three drugs: *atovaquone-proguanil* and *doxycycline*, which can both be used in all areas, and *mefloquine*, which can be used in areas with *mefloquine*-sensitive malaria. Other available options are *chloroquine* or *hydroxychloroquine* (but their use is restricted to the few areas with *chloroquine*-sensitive malaria) and *primaquine* or *tafenoquine* (for short-duration travel to areas with principally *P. vivax*). In general, dosing should be started before exposure, ideally before the traveler leaves home (see Table 66–2).

In those few areas where *chloroquine*-sensitive strains of *P. falciparum* are found, *chloroquine* is still suitable for chemoprophylaxis. In areas where *chloroquine*-resistant malaria is endemic, *mefloquine* and *atovaquone-proguanil* are the regimens of choice for chemoprophylaxis. For chemoprophylaxis in long-term travelers, *chloroquine* is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with *chloroquine* is recommended because of ocular toxicity. *Mefloquine* and *doxycycline* are well tolerated. *Mefloquine* is the best-documented drug for malaria prophylaxis in long-term travelers and, if well tolerated, can be used for prolonged periods. *Atovaquone-proguanil* has been studied for prophylactic use up to 20 weeks but probably is acceptable for years based on experience with the individual components.

Self-Treatment of Presumptive Malaria for Travelers

The CDC provides travelers' guidelines for self-treatment of presumptive malaria with appropriate drugs (*atovaquone-proguanil*, *artemether-lumefantrine*; as described in Table 66–3) when professional care is not available within 24 h. In such cases, medical care should be sought immediately after treatment. These recommendations may change over time and with specific locations. Consult the CDC Yellow Book (https://wwwnc.cdc.gov/travel/page/yellowbook-home).

Diagnosis and Treatment of Malaria

The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial. Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown in Figure 66–3, with details of the available agents summarized in Table 66–3. More information is available online (https://www.cdc.gov/malaria/resources/pdf/Malaria_Treatment_Table.pdf) and from the CDC Malaria Hotline (770-488-7100 and 855-856-4713).

Children and pregnant women are the most susceptible to severe malaria. The treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose) (see the Drug Facts table

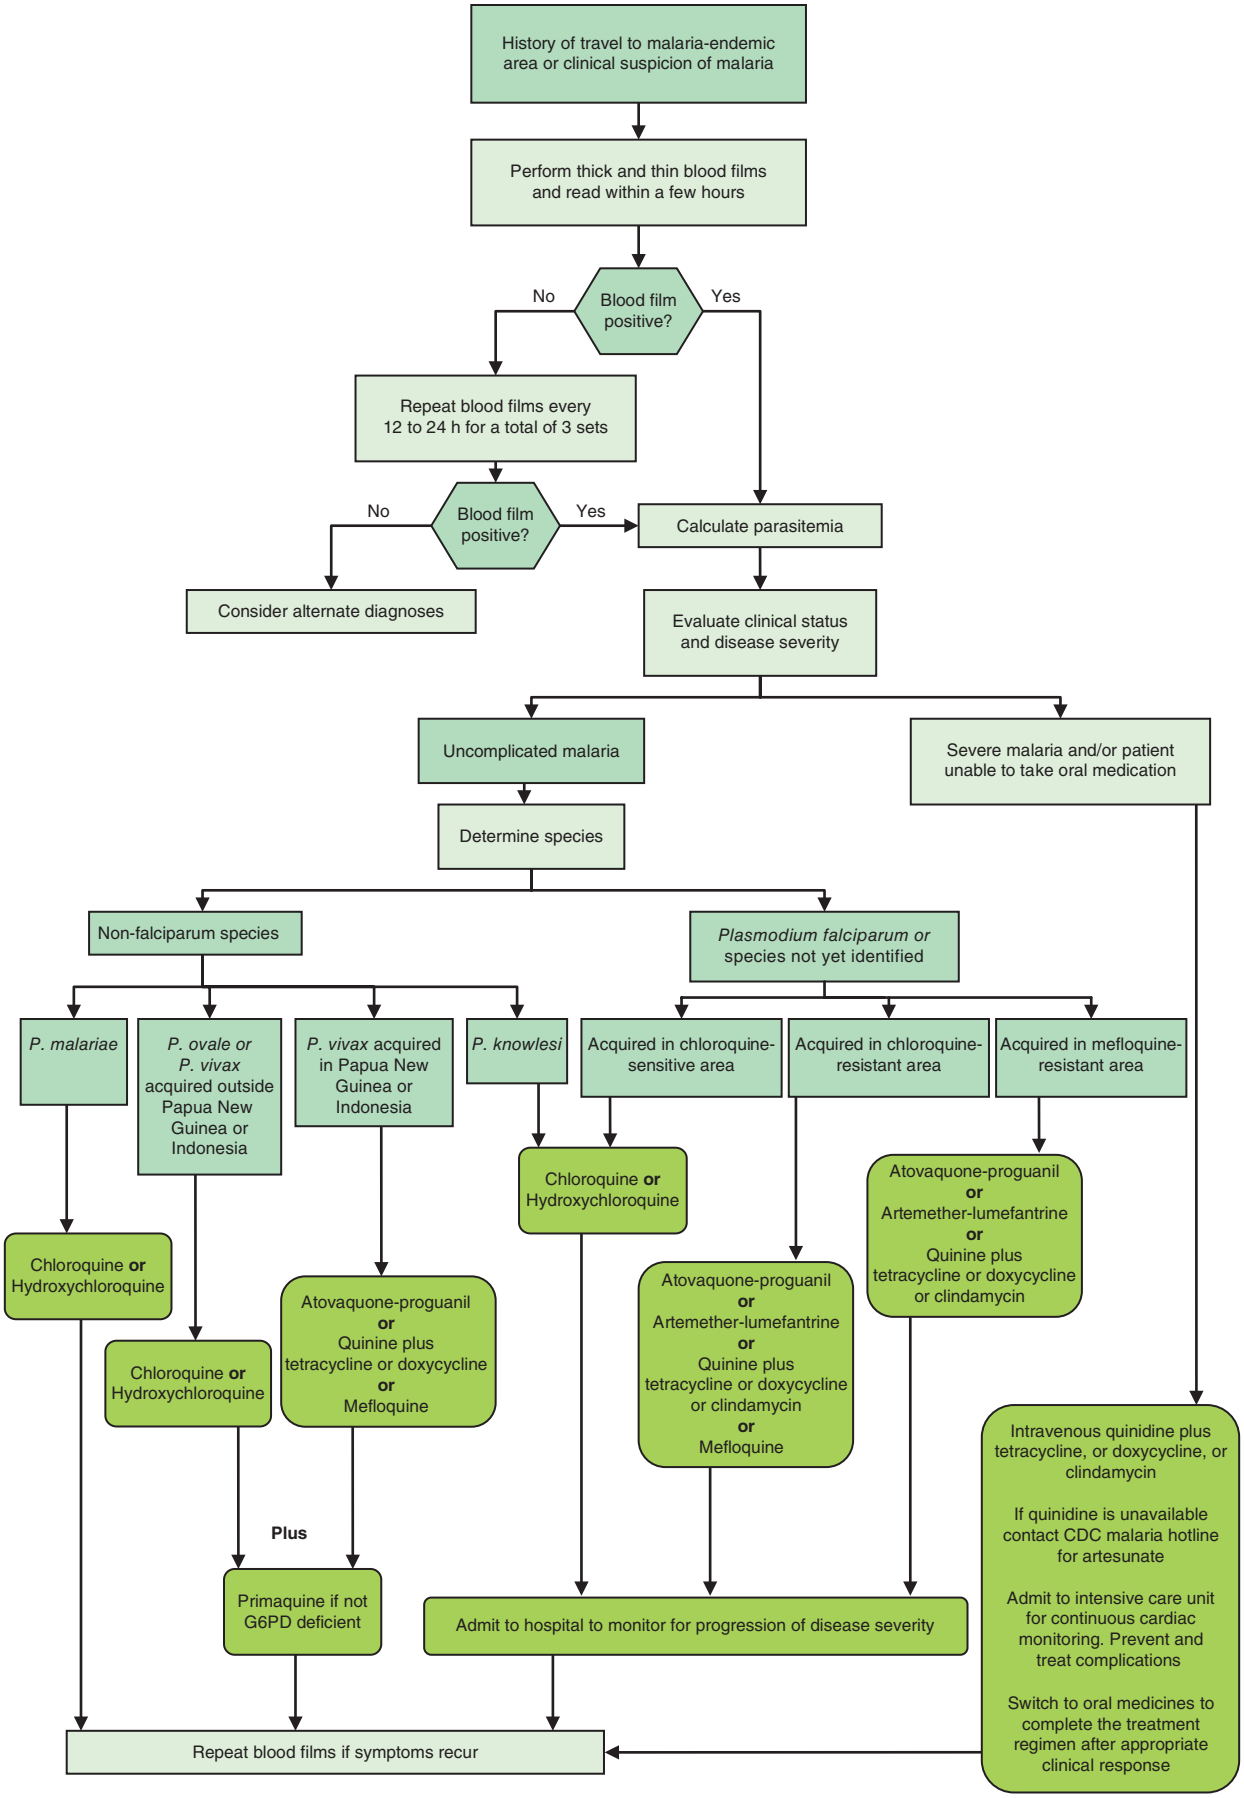


Figure 66–3 *Decision algorithm for the treatment of malaria.* *Atovaquone-proguanil*, *mefloquine*, *artemether-lumefantrine*, *tetracycline*, and *doxycycline* are not indicated during pregnancy (pregnancy category C). *Tetracycline* and *doxycycline* are not indicated in children younger than 8 years. (Modified from Centers for Disease Control and Prevention. Available at: http://www.cdc.gov/malaria/resources/pdf/alg_for_hcp.pdf; accessed June 21, 2012.)

at the end of the chapter). However, tetracyclines should not be given to children less than 8 years of age except in an emergency, and *atovaquone-proguanil* as treatment has been approved only for children weighing more than 5 kg.

Chemoprophylaxis and Treatment During Pregnancy

Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situations. Severe malaria during pregnancy should be treated with an intravenous antimalarial agent according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy. In lactating mothers, treatment with most compounds is acceptable, although *chloroquine* and *hydroxychloroquine* are the preferred agents. The use of *atovaquone-proguanil* is not recommended unless breastfeeding infants weigh more than 5 kg. Also, the breastfeeding infant should be shown to have a normal G6PD level before receiving *primaquine*.

Targeting the Mosquito Rather Than the Infected Human

The requisite transmission of parasites between human hosts by *Anopheles* spp. mosquitos renders sustained malaria transmission vulnerable to effective vector control. Controlling vectors through larval source management, indoor residual spraying of domiciles with mosquitocidal compounds, and use of long-lasting insecticide-treated bed nets are common vector-directed interventions that directly reduce the frequency of contact between humans and vectors.

A new approach to transmission reduction is the indirect targeting of mosquitos with the endectocide ivermectin. Ivermectin is a semisynthetic member of the avermectin class of macrocyclic lactones (see Chapter 68). The direct activity of ivermectin against *Plasmodium* spp. parasites is only mild; its application in malaria control results from its activity against the *Anopheles* spp. vectors when they take a blood meal from a host following the administration of ivermectin. The aspiration of serum ivermectin along with the blood meal delivers a potentially lethal dose to the vector and, in surviving mosquitos, renders them less efficient at supporting parasite development and less efficient at obtaining further blood meals. Given the vulnerability of malaria transmission to even slight reductions in vector efficiency, these effects have, in clinical trials of the administration of monthly doses of ivermectin to adult community members, reduced the incidence of *P. falciparum* malaria in children. Mathematical modeling supports the potential for this as a new tool to indirectly control malaria and sharply reduce transmission in some settings, and further trials of ivermectin delivery modes are underway.

In addition, antimalaria chemotherapies may be adapted to kill the parasite in the mosquito. In a proof-of-concept study, atovaquone, an inhibitor of parasite cytochrome B, was delivered to *Anopheles* spp. mosquitos across their cuticle when landing and inhibited the subsequent development of *P. falciparum* in the mosquito midgut. Should other conventional antiparasitics also be capable of incorporation into bednets and be successful at arresting parasite development in the mosquito, these compounds may find a new application beyond therapy in humans.

Recent technological developments seem likely to revolutionize mosquito control and mosquito susceptibility to malarial parasites. Isaacs et al. (2011) engineered resistance to infection by *P. falciparum* in mosquitoes by having the mosquitoes express single-chain antibodies that targeted antigens on the parasite's surface and inhibited the parasite's capacity to invade the midgut and salivary glands of the mosquito, effects that would reduce or eliminate the capacity of the mosquito to infect humans in the course of a blood meal.

The development of gene editing using CRISPR/cas9 (see Chapters 3 and 7) has opened up a new avenue for high-efficiency expression of resistance genes for treating the spread and prevalence of malaria. Gantz and Bier (2015) have described a "mutagenic chain reaction" based on CRISPR/cas9 that can spread a mutation from one chromosome to its homologous chromosome, converting heterozygous mutations to homozygosity in most germline and somatic cells in *Drosophila*. This gene drive system works in mosquitoes as well (Gantz et al., 2015), introducing anti-*Plasmodium* effector genes into the germline and thence into the progeny with very high frequency. Other CRISPR/cas9 endonuclease constructs have driven genes in the malarial vector *Anopheles gambiae,* targeting female reproduction and holding the promise of reducing the mosquito population in malarious areas to levels that will not support transmission of the disease (Hammond et al., 2016). Research on the use of gene-drive technology to control populations of mosquitoes continues to advance (Adolfi et al., 2020). The use of this technology among wild populations is not without concern, and the WHO has released revised guidance for the application of genetically modified mosquitoes into the wild (Benedict et al., 2021). As noted in a recent review, "These scientific advances, combined with ethical and social considerations, will facilitate the transparent and responsible advancement of these technologies towards field implementation" (Bier, 2022).

Drug Facts for Your Personal Formulary: *Regimens for Malaria Treatment*

Drug Indication	Adult Dosage	Pediatric Dosage[a]	Potential Adverse Effects	Comments
Artemether-lumefantrine *P. falciparum* from chloroquine-resistant or unknown areas	Tablet: 20 mg artemether, 120 mg lumefantrine. Dose: 4 tablets. Day 1: 2 doses separated by 8 h; thereafter 1 dose twice daily × 2 days	Weight (kg) 5–15: 1 tablet/dose 15–25: 2 tablets/doses 25–<35: 3 tables/doses >35: 4 tablets/doses Use same 3-day schedule as adults	Adults: headache, anorexia, dizziness, asthenia, arthralgia, myalgia Children: fever, cough, vomiting, loss of appetite, headache	Take with food or whole milk. If patient vomits within 30 min, repeat dose. Contraindicated in pregnancy.
Artesunate (IV) Severe malaria; see CDC guidelines	IV: 2.4 mg/kg doses at 0, 12, and 24 h each with reassessment for subsequent oral treatment with artemether-lumefantrine, atovaquone-proguanil, doxycycline, or mefloquine		See Artemether	See Artemether CDC guidelines (https://www.cdc.gov/malaria/diagnosis_treatment/artesunate.html).

Drug Facts for Your Personal Formulary: *Regimens for Malaria Treatment* (*continued*)

Drug Indication	Adult Dosage	Pediatric Dosage[a]	Potential Adverse Effects	Comments
Atovaquone-proguanil *P. falciparum* from chloroquine-resistant areas; *P. vivax*	Adult tablet: 250 mg atovaquone/100 mg proguanil; 4 adult tablets orally per day × 3 days	Pediatric tablet: 62.5 mg atovaquone/25 mg proguanil 5–8 kg: 2 pediatric tablets orally/day × 3 days >8–10 kg: 3 pediatric tablets daily × 3 days >10–20 kg: 1 adult tablet daily × 3 days >20–30 kg: 2 adult tablets daily × 3 days >30–40 kg: 3 adult tablets daily × 3 days >40 kg: 4 adult tablets daily × 3 days	Abdominal pain, nausea, vomiting, diarrhea, headache, rash, mild reversible elevations in liver aminotransferase levels	Not indicated for use in pregnant women due to limited data. Contraindicated if hypersensitivity to atovaquone or proguanil; severe renal impairment (creatinine clearance <30 mL/min). Should be taken with food to increase absorption of atovaquone.
Chloroquine phosphate *P. falciparum* from chloroquine-sensitive areas; *P. vivax* from chloroquine-sensitive areas; all *P. ovale*; all *P malariae*; all *P. knowlesi*	600 mg base (1000 mg salt) orally immediately, followed by 300 mg base (500 mg salt) orally at 6, 24, and 48 h Total dose: 1500 mg base (2500 mg salt)	10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus	Safe in children and pregnant women. Give for chemoprophylaxis (500 mg salt orally every week) in pregnant women with chloroquine-sensitive *P. vivax*. Contraindicated if retinal or visual field change or hypersensitivity to 4-aminoquinolines. Use with caution in those with impaired liver function since the drug is concentrated in the liver.
Clindamycin (oral or IV) *P. falciparum* from chloroquine-resistant areas; *P. vivax* from chloroquine-resistant areas	Oral: 20 mg base/kg/day orally divided 3 times daily × 7 days IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (as above) as soon as patient can take oral meds; duration = 7 days	Oral: 20 mg base/kg/day orally divided 3 times daily × 7 days IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 days	Diarrhea, nausea, rash	Always use in combination with quinine-quinidine. Safe in children and pregnant women.
Doxycycline (oral or IV) *P. falciparum* and *P. vivax* from chloroquine-resistant areas	Oral: 100 mg orally twice daily × 7 days IV: 100 mg IV every 12 h and then switch to oral doxycycline (as above) as soon as patient can take oral medication; treatment course = 7 days	Oral: 2.2 mg/kg orally every 12 h × 7 days IV: Only if patient is not able to take oral medication; for children <45 kg, give 2.2 mg/kg IV every 12 h and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication; for children >45 kg, use same dosing as for adults; duration = 7 days	Nausea, vomiting, diarrhea, abdominal pain, dizziness, photosensitivity, headache, esophagitis, odynophagia. Rarely hepatotoxicity, pancreatitis, and benign intracranial hypertension seen with tetracycline class of drugs.	Always use in combination with quinine or quinidine. Contraindicated in children <8 years old, pregnant women, and persons with known hypersensitivity to tetracyclines. Food, milk, and Ca^{2+} antacids decrease absorption and decrease GI disturbances. To prevent esophagitis, take tetracyclines with large amounts of fluids (patients should not lie down for 1 h after taking the drugs). Barbiturates, carbamazepine, or phenytoin may cause reduction in C_p of doxycycline.
Hydroxychloroquine (oral) Secondary alternative for treatment of *P. falciparum* and *P. vivax* from chloroquine-sensitive areas; all *P. ovale*; all *P. malariae*	620 mg base (800 mg salt) orally immediately, followed by 310 mg base (400 mg salt) orally at 6, 24, and 48 h Total dose: 1550 mg base (2000 mg salt)	10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus	Safe in children and pregnant women. Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines. Use with caution in those with impaired liver function.

Drug Facts for Your Personal Formulary: *Regimens for Malaria Treatment* (*continued*)

Drug Indication	Adult Dosage	Pediatric Dosage[a]	Potential Adverse Effects	Comments
Mefloquine[b] *P. falciparum* from chloroquine-resistant areas, except Thailand-Burmese and Thailand-Cambodian border regions; *P. vivax* from chloroquine-resistant areas	684 mg base (750 mg salt) orally as initial dose, followed by 456 mg base (500 mg salt) orally given 6–12 h after initial dose Total dose = 1250 mg salt	13.7 mg base/kg (15 mg salt/kg) orally as initial dose, followed by 9.1 mg base/kg (10 mg salt/kg) orally given 6–12 h after initial dose Total dose = 25 mg salt/kg	Nausea, vomiting, diarrhea, abdominal pain; dizziness, headache, somnolence, sleep disorders; myalgia, mild skin rash, and fatigue; moderate-to-severe neuropsychiatric reactions; electrocardiogram changes (sinus arrhythmia, sinus bradycardia, first-degree atrioventricular block, QTc prolongation, and abnormal T waves	Contraindicated if hypersensitive to the drug or to related compounds; cardiac conduction abnormalities; psychiatric disorders; and seizure disorders. Do not administer if patient has received related drugs (chloroquine, quinine, quinidine) less than 12 h ago.
Primaquine phosphate Radical cure of *P. vivax* and *P. ovale* (to eliminate hypnozoites)	30 mg base orally per day × 14 days	0.5 mg base/kg orally per day × 14 days	GI disturbances, methemoglobinemia (self-limited), hemolysis in persons with G6PD deficiency	Must screen for G6PD deficiency prior to use. Contraindicated in persons with G6PD deficiency; pregnant women. Should be taken with food to minimize GI adverse effects.
Quinine sulfate (oral) *P. falciparum* from chloroquine-resistant areas; *P. vivax* from chloroquine-resistant areas	542 mg base (650 mg salt)[d] orally 3 times daily × 3 days (infections acquired outside Southeast Asia) to 7 days (infections acquired in Southeast Asia)	8.3 mg base/kg (10 mg salt/kg) orally 3 times daily × 3 days (infections acquired outside Southeast Asia) to 7 days (infections acquired in Southeast Asia)	Cinchonism,[e] sinus arrhythmia, junctional rhythms, atrioventricular block, prolonged QT interval, ventricular tachycardia, ventricular fibrillation (these are rare and more commonly seen with quinidine), hypoglycemia	Combine with tetracycline, doxycycline, or clindamycin, except for *P. vivax* infections in children <8 years old or pregnant women. Contraindicated in hypersensitivity, including history of blackwater fever, thrombocytopenic purpura, or thrombocytopenia associated with quinine or quinidine use; many cardiac conduction defects and arrhythmias[f]; myasthenia gravis; optic neuritis.
Quinidine gluconate[c] (intravenous) Severe malaria (all species, independently of chloroquine resistance); patient unable to take oral medication; parasitemia >10%	6.25 mg base/kg (10 mg salt/kg) loading dose IV over 1–2 h, then 0.0125 mg base/kg/min (0.02 mg salt/kg/min) continuous infusion for at least 24 h Note alternative regimen[g]	Same as adult	Cinchonism, tachycardia, prolongation of QRS and QTc intervals, flattening of T wave (effects are often transient). Ventricular arrhythmias, hypotension, hypoglycemia	Combine with tetracycline, doxycycline, or clindamycin. Contraindicated in hypersensitivity, history of blackwater fever, thrombocytopenic purpura, or thrombocytopenia associated with quinine/quinidine use; many cardiac conduction defects and arrhythmias[f]; myasthenia gravis; optic neuritis.
Tafenoquine (oral) Radical cure of *P. vivax* and *P. ovale* (to eliminate hypnozoites)	300 mg single dose	Not defined	GI disturbances, methemoglobinemia (self-limited), hemolysis in persons with G6PD deficiency	Must screen for G6PD deficiency prior to use. Contraindicated in persons with G6PD deficiency; pregnant women.
Tetracycline (oral or IV) *P. falciparum* and *P. vivax* from chloroquine-resistant areas (with quinine/quinidine)	Oral: 250 mg 4 times daily × 7 days IV: dosage same as for oral	25 mg/kg/day orally, divided, 4 × daily × 7 days IV: dosage same as for oral	See doxycycline	See doxycycline.

These regimens are based on published recommendations of the U.S. CDC. Although current at the time of writing, these recommendations may change over time. Up-to-date information should be obtained from the CDC website at https://wwwnc.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the last, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

[a]Pediatric dosage should never exceed adult dosage.

[b]Mefloquine should not be used to treat *P. falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

[c]Extrapolated from chloroquine literature.

[d]Quinine sulfate capsule manufactured in the U.S. is in a 324-mg dose; therefore, two capsules should be sufficient for adult dosing.

[e]Nausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

[f]Refer to https://www.accessdata.fda.gov/drugsatfda_docs/label/2008/021799s008lbl.pdf; accessed January 12, 2022.

[g]Alternative dosing hypoglycemia optic neuritis regimen for quinidine gluconate (IV): 15 mg base/kg (24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density <1% and patient can take oral medication, complete treatment with oral quinine, dose as above. Quinidine or quinine course is 7 days in Southeast Asia (3 days in Africa or South America).

Chapter 67

Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

Dawn M. Wetzel and Margaret A. Phillips

PROTOZOAL INFECTIONS OF HUMANS

- Amebiasis
- Giardiasis
- Trichomoniasis
- Toxoplasmosis
- Cryptosporidiosis
- Trypanosomiasis
- Leishmaniasis
- Other Protozoal Infections

ANTIPROTOZOAL DRUGS

- Amphotericin B
- Eflornithine
- Fexinidazole
- 8-Hydroxyquinolines
- Melarsoprol
- Metronidazole and Tinidazole
- Miltefosine
- Nifurtimox and Benznidazole
- Nitazoxanide
- Paromomycin
- Pentamidine
- Sodium Stibogluconate
- Suramin

Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs, or from one person to another. The immune system plays a crucial role in protecting against the pathological consequences of many protozoal infections. Thus, opportunistic infections with protozoa are prominent in patients with suppressed or underdeveloped immune systems, such as infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced human immunodeficiency virus (HIV) infection. Because effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. Satisfactory agents for treating important protozoal infections such as African trypanosomiasis (sleeping sickness) and chronic Chagas disease still are lacking. Many effective antiprotozoal drugs are toxic at therapeutic doses; this problem is exacerbated by increasing drug resistance (McCarthy et al., 2020). For a list of drugs and doses used to treat these diseases, see Kimberlin et al. (2018) and McCarthy et al. (2020).

Protozoal Infections of Humans

Amebiasis

Amebiasis affects about 10% of the world's population, causing invasive disease in about 50 million people and death in about 100,000 of these annually (Stanley, 2003). Amebiasis is seen most commonly among individuals living in poverty, crowded conditions, and areas with poor sanitation. Multiple morphologically identical but genetically distinct species of *Entamoeba*—such as *E. histolytica, E. dispar*, *E. bangladeshi*, and *E. moshkovskii*—exist (Petri et al., 2020). However, the major species that requires treatment is *E. histolytica*, a leading cause of mortality by parasitic infection (World Health Organization [WHO], 2020a).

Humans are the only known hosts for these protozoa, which are transmitted by the fecal-oral route. Ingested *E. histolytica* cysts survive acidic gastric contents and transform into *trophozoites* that reside in the large intestine (Petri et al., 2020). The outcome of *E. histolytica* infection is variable; both host and parasite factors influence the course and severity of the disease (Marie and Petri, 2014). Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, *E. histolytica* trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). This bloody diarrhea may result from a phenomenon termed trogocytosis ("trogo" means "nibble"), where the parasite acquires required nutrients by "nibbling" on human cells (Ralston and Petri, 2011). In a small proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess (Haque et al., 2003).

The cornerstone of therapy for amebiasis causing colitis or liver abscess is metronidazole or its analogue tinidazole (Petri et al., 2020). Because *metronidazole* is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen. The drug is also less effective against cysts. Therefore, patients with amebic colitis or amebic liver abscess should receive a luminal agent after the course of *metronidazole* has been completed to eradicate any *E. histolytica* trophozoites residing within the gut lumen (Kimberlin et al., 2018). Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside *paromomycin*, the 8-hydroxyquinoline compound *iodoquinol,* and *diloxanide furoate* are effective luminal agents (Haque et al., 2003). In addition, *nitazoxanide*, which is approved in the U.S. for treatment of cryptosporidiosis and giardiasis, has activity against *E. histolytica* (Petri et al., 2020). Since no treatment is 100% effective at eliminating infection from the intestinal tract, follow-up stool examination is recommended. In addition, all household members/close contacts of an index patient should have stool examinations performed, and they should be treated with a luminal agent if positive, even if they are asymptomatic (Kimberlin et al., 2018).

Giardiasis

Giardiasis, caused by the flagellated protozoan *Giardia intestinalis*, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the U.S. Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food. Cysts shed from animals or infected humans can contaminate

Abbreviations

AUC: area under the curve
CDC: U.S. Centers for Disease Control and Prevention
CSF: cerebrospinal fluid

NTR: nitroreductase
PFOR: pyruvate-ferredoxin oxidoreductase
WBC: white blood cell
WHO: World Health Organization

recreational and drinking water supplies (Fletcher et al., 2012). Human-to-human transmission is common among children in day-care centers, institutionalized individuals, and men who have sex with men (Escobedo et al., 2014). Infection with *Giardia* results in one of three syndromes:

- An asymptomatic carrier state
- Acute self-limited diarrhea
- Chronic diarrhea, characterized by signs of malabsorption (steatorrhea) and weight loss (Nash and Bartlet, 2020)

Chemotherapy with a 5- to 7-day course of *metronidazole* usually is successful, although sometimes therapy may have to be repeated or prolonged, particularly in patients who are immunocompromised. A single dose of *tinidazole* may be superior to *metronidazole* (Kimberlin et al., 2018). *Paromomycin* can be used to treat pregnant women to avoid any possible mutagenic effects of the other drugs (Hill and Nash, 2014). *Nitazoxanide* is also approved for the treatment of giardiasis in adults and immune-competent children less than 12 years of age (Kimberlin et al., 2018).

Trichomoniasis

Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis* (Meites, 2013). This organism inhabits the human genitourinary tract, where it causes vaginitis in women and, less commonly, urethritis in men. Trichomoniasis essentially can only be transmitted by sexual contact; it is the most common nonviral sexually transmitted infection (Kimberlin et al., 2018). Infection with this organism is associated with an increased risk of acquiring HIV and adverse pregnancy outcomes in pregnant women (Kissinger, 2015). Only *trophozoite* forms of *T. vaginalis* have been identified in infected secretions. *Metronidazole* remains the drug of choice for treating trichomoniasis (Schwebke and Bachmann, 2020). *Tinidazole*, another nitroimidazole, appears to be better tolerated than *metronidazole* and has been used successfully to treat *metronidazole*-resistant *T. vaginalis* (Kimberlin et al., 2018). Because there is a high reinfection rate, retesting is recommended for all sexually active women within 3 months after initial treatment.

Toxoplasmosis

Toxoplasmosis is a zoonotic infection caused by the obligate intracellular protozoan *Toxoplasma gondii*. Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been recovered from all mammalian species examined. Common routes of infection in humans are as follows:

- Ingestion of undercooked meat containing tissue cysts
- Ingestion of contaminated vegetable matter containing infective *oocysts*
- Oral inoculation with feces of cats shedding oocysts
- Transplacental fetal infection with *tachyzoites* from acutely infected mothers (Woodhall et al., 2014)
- Donor-acquired infection and/or reactivation in transplant recipients (particularly cardiac transplant recipients) (Kimberlin et al., 2018)
