The acute illness is usually self-limiting, and treatment rarely is required. However, individuals who are immunocompromised, such as patients with AIDS or transplants, are at risk of developing disseminated toxoplasmosis, as well as toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain (Montoya et al., 2020). Clinical manifestations of congenital toxoplasmosis vary, but classically, a triad of chorioretinitis, hydrocephalus, and cerebral calcifications is seen. Chorioretinitis, which may present decades after exposure, is the most common finding (Kieffer and Wallon, 2013).

The primary treatment of toxoplasmic encephalitis consists of the antifolates *pyrimethamine* and *sulfadiazine* along with *folinic acid* (*leucovorin*) (Montoya et al., 2020). Therapy must be discontinued in about 40% of cases because of toxicity, primarily due to the sulfa compound, and the cost of therapy is substantial (Dunay et al., 2018). *Pyrimethamine-clindamycin* appears to have comparable efficacy to *pyrimethamine-sulfadiazine* for treating toxoplasmosis in immunocompromised patients, but this combination also causes substantial toxicity. Alternative regimens combining *azithromycin*, *clarithromycin*, *atovaquone*, or *dapsone* with either *trimethoprim-sulfamethoxazole* or *pyrimethamine* are less toxic, but also less effective (Rajapakse et al., 2013). For severe, sight-threatening ocular toxoplasmosis, the addition of *prednisone* to decrease inflammation is recommended. *Spiramycin*, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in early pregnancy to prevent transmission to the fetus (Kieffer and Wallon, 2013). *Spiramycin* is available through the investigational new drug process at the U.S. Food and Drug Administration (FDA) (Kimberlin et al., 2018). If fetal infection occurs, the combination of *pyrimethamine*, *sulfadiazine*, and *folinic acid* is administered to the mother (only after the first 12–14 weeks of pregnancy) and to the newborn postnatally for 1 year (Kimberlin et al., 2018).

Cryptosporidiosis

Cryptosporidia are coccidian protozoan parasites that cause diarrhea. *Cryptosporidium parvum* and *Cryptosporidium hominis* appear to account for almost all infections in humans (White, 2020). Infectious oocysts in feces are tolerant to chlorination and may be spread either by direct human-to-human contact or by contaminated recreational or drinking water. Productive infection requires ingestion of as few as 10 oocysts (Wetzel et al., 2005). Groups at particular risk include travelers, children in day care, men who have sex with men, animal handlers, and veterinary or healthcare personnel. After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells (Wilhelm and Yarovinsky, 2014). In many individuals, infection is self-limited. However, in patients with AIDS and other immunocompromising conditions, such as patients with solid organ transplants or hyper-IgM syndrome, the severity of diarrhea or other complications may require hospitalization (White, 2020).

Nitazoxanide is used to treat cryptosporidiosis in immunocompetent children and adults (Kimberlin et al., 2018). It has questionable efficacy in children and adults with HIV/AIDS or other immunocompromising conditions, even when given for prolonged courses. The most effective therapy for cryptosporidiosis in immunocompromised patients is restoration of immune function (e.g., through initiation of antiretroviral therapy in patients with AIDS) (White, 2020).

Trypanosomiasis

African trypanosomiasis, or "sleeping sickness," is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossina* (Kennedy, 2019). Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is almost always fatal unless treated. Sleeping sickness is found in 36 countries in Africa, but the caseload has dropped significantly due to renewed control efforts, and fewer than 1000 cases were reported in 2019 (Neau et al., 2020; WHO, 2020d).

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or

lymph without central nervous system (CNS) involvement (stage 1); stage 2 disease is characterized by involvement of the CNS (Kennedy, 2019; WHO, 2020d). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. There are two types of human African trypanosomiasis (HAT): The East African (Rhodesian; *T. brucei rhodesiense*) variety produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; the West African type (Gambian; *T. brucei gambiense*) causes illness characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, sensory deficits, psychiatric signs, disruption of the sleep cycle, and eventual progression to coma and death.

Treatments for Gambian HAT have evolved dramatically in recent years (Dickie et al., 2020; Neau et al., 2020). A new drug, *fexinidazole*, was added to the WHO list of essential medicines in 2019 and is now the recommended front-line treatment in Europe and Africa in adults for early-stage *T. brucei gambiense* and for less severe late-stage disease (disease with CNS involvement) (Lindner et al., 2020; WHO, 2019). *Nifurtimox-eflornithine* combination therapy (NECT) is still recommended for more severe late-stage disease, in the U.S., and for late-stage disease in children aged 6 years or less or with a body weight less than 20 kg. *Fexinidazole* replaces *pentamidine* for early-stage *T. brucei gambiense*, with the exception of the previously mentioned group of children. Importantly, the availability of both *fexinidazole* and NECT eliminates the need to treat the CNS phase of Gambian HAT with *melarsoprol*, a highly toxic agent that causes a fatal reactive encephalopathy in 2% to 10% of treated patients. Recommendations have not yet changed for *T. brucei rhodesiense* HAT, where *suramin* remains the drug of choice for early-stage disease and *melarsoprol* (available from the U.S. Centers for Disease Control and Prevention [CDC]) remains the only drug approved for the CNS phase of the disease.

Fexinidazole is a nitroheterocycle from the same drug class as *nifurtimox*, which is used as a combination agent (NECT treatment) for HAT and for treatment of *T. cruzi* as a single agent. *Fexinidazole* is the first orally available drug for the treatment of HAT. It is also the first that can be used for treatment of both early-stage and late-stage disease (Lindner et al., 2020; WHO, 2019). Its efficacy in treating both stages eliminates the need for lumbar puncture, except for severe late-stage disease. *Fexinidazole* is a prodrug that is activated by NADH-specific nitroreductase in a two-electron reduction of the NO_2 group, with the mechanism of action likely to be caused by the action of this highly reactive species on multiple cellular targets (Dickie et al., 2020). The antitrypanosomal activity of *fexinidazole* was first described in the 1980s, but concerns over toxicity of the drug class and lack of full efficacy in mouse models derailed its development. The success of *nifurtimox* as part of NECT therapy led to renewed interest, and after testing of a small library of nitroimidazoles, *fexinidazole* was selected as the most promising and was shown to be effective if used in more extended dosing schemes (Neau et al., 2020). It was incorporated into the WHO interim treatment guidelines in 2019 after having received a favorable European Medicines Agency scientific opinion (Lindner et al., 2020; WHO, 2019). It is not yet approved in the U.S. It is administered in tablets with food over 10 days, with a higher loading dose given for 4 days followed by a 6-day maintenance dose.

Eflornithine (available from the CDC), an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism, remains an important agent for the treatment of late-stage Gambian HAT (DeKoning, 2020; WHO, 2019). It has efficacy against both early and late-stages of human *T. brucei gambiense* infection; however, it is thought to be ineffective as monotherapy for infections of *T. brucei rhodesiense*. Notably, *eflornithine* has significantly fewer side effects than *melarsoprol* and is more effective than *melarsoprol* for treatment of late-stage Gambian trypanosomiasis. NECT allows shorter exposure to *eflornithine* with good efficacy and a reduction in adverse events; it remains the treatment of choice for severe infections of late-stage *T. brucei gambiense* in adults, for children under 6 years of age, or in cases where *fexinidazole* is not recommended (Lindner et al., 2020; WHO, 2019).

While drug therapies for HAT have notably improved in recent years, *fexinidazole* is not yet recommended for severe cases of late-stage CNS disease, NECT is difficult to administer in a rural setting, and the lack of an alternative to *melarsoprol* to treat *T. brucei rhodesiense* is concerning. One additional orally available agent, *acoziborole (SCYX-7158)*, has just completed a phase III human efficacy study. *Acoziborole*, which appears to target the RNA cleavage and polyadenylation specificity factor subunit 3 (CPSF3), has the potential to offer a single-dose cure for the treatment of both early- and late-stage Gambian trypanosomiasis (Dickie et al., 2020). If the safety and efficacy data from this study support authorization for clinical use, this compound has the potential to have a high impact on HAT treatment options.

American trypanosomiasis, or *Chagas disease*, is a zoonotic infection caused by *Trypanosoma cruzi* (Bern et al., 2019). The WHO estimates that Chagas affects about 6 to 7 million people worldwide (WHO, 2020b). The spread of Chagas disease is primarily confined to Latin America, but due to immigration, a number of cases are now seen outside that region. Blood-sucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission may also occur. Within the Western Hemisphere, the U.S. is estimated to have the sixth-highest caseload (~300,000 cases), representing a significant public health concern because the parasite can also be transmitted by blood transfusion and organ transplantation (Bern et al., 2019; Hotez et al., 2013). Although most cases in the U.S. arise through immigration, the parasite and its vector are endemic in the southern half of the U.S. and transmission within the U.S. has been documented (Bern et al., 2019). Seven states include Chagas disease as a reportable condition, and local transmission has been reported in Arizona, Louisiana, Mississippi, Tennessee, and Texas. While the U.S. blood supply is now being monitored, lack of awareness of the disease can lead to suboptimal care of those infected.

The clinical outcome of an infected patient can vary widely from asymptomatic to severe disease (Bern et al., 2019). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death (Nunes et al., 2018). Common findings of Chagas heart disease include arrhythmias, myocardial abnormalities, aneurysms, and thromboembolism. End-stage heart failure is usually the result of progressive dilated cardiomyopathy. Chagas heart disease is typically managed in accordance with American College of Cardiology/American Heart Association guidelines for treatment of heart failure (Nunes et al., 2018).

Two nitroheterocyclic drugs, *benznidazole* and *nifurtimox* (both available from the CDC), are used to treat *T. cruzi* infection, and the better-tolerated *benznidazole* has recently been approved by the FDA for children 2 to 12 years of age (Kratz et al., 2018; Meymandi et al., 2018). Both agents suppress parasitemia and can cure the acute, congenital, and early chronic phases of Chagas disease. Treatment should also be offered to any patient with reactivated disease after immunosuppression. While clinical benefit of treatment has also been reported for chronic indeterminate cases, a recent study found no clinical benefit for treatment of patients with advanced cardiomyopathy, even though parasite levels were decreased (Morillo et al., 2015). Both *nifurtimox* and *benznidazole* are toxic and must be taken for long periods, though *benznidazole* is better tolerated in children than adults. Increased awareness among physicians, better drugs, and better diagnostic methods are badly needed to help combat this disease. *Fexinidazole* is currently under evaluation as a treatment for Chagas disease (Meymandi et al., 2018).

Leishmaniasis

Leishmaniasis is a complex vector-borne zoonosis caused by about 20 different species of intramacrophage protozoa of the genus *Leishmania*. Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of female phlebotomine sandflies (WHO, 2020c). Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. The sandfly vector has also spread into the U.S.; there have been documented cases of endemic acquisition in humans in

Oklahoma and Texas, where it is a reportable condition (McIlwee et al., 2018). Flagellated extracellular free *promastigotes*, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. These transform into *amastigotes*, which reside and multiply within phagolysosomes. Amastigotes then propagate the infection by entering more macrophages. Amastigotes taken up by feeding sandflies then transform back into promastigotes (Aronson et al., 2017).

In increasing order of systemic involvement and clinical severity, major syndromes of human leishmaniasis are classified into *cutaneous, mucocutaneous, diffuse cutaneous*, and *visceral* (*kala azar*) forms (WHO, 2020c). The disease syndrome manifested depends on the species of infecting parasite, the distribution of infected macrophages, and the host immune response (Podinovskaia and Descoteaux, 2015). As such, leishmaniasis is recognized as an AIDS-associated opportunistic infection (van Griensven et al., 2014). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring 3 to 18 months after infection, but can leave disfiguring scars. Mucocutaneous, diffuse cutaneous, and visceral leishmaniasis do not resolve without therapy. Visceral disease caused by *Leishmania donovani* is fatal unless treated (Sundar and Chakravarty, 2015).

The classic therapy for all species of *Leishmania* is with *pentavalent antimony compounds* such as *sodium stibogluconate* (sodium antimony gluconate); resistance is widespread, particularly in India (WHO, 2020c). Recently, treatment of leishmaniasis has undergone major changes owing to the success of the first orally active agent, *miltefosine,* which has been FDA-approved for cutaneous, mucocutaneous, and visceral disease (Aronson et al., 2017). *Miltefosine* also can be used to treat dogs, an important animal reservoir of the disease (Alvar et al., 2006). However, its teratogenic effects prevent its use in women of childbearing age (Aronson et al., 2017). As an alternative, *liposomal amphotericin B* is a highly effective agent for visceral leishmaniasis and is now recommended therapy in the U.S. in treatment guidelines (Aronson et al., 2017). In addition, *paromomycin* has been used with some success as a parenteral agent for visceral disease, and topical formulations of *paromomycin* have also been used for cutaneous disease (Aronson et al., 2020). Finally, azole antifungals such as *fluconazole* can be employed, but have only an approximate 50% success rate depending on species, thus limiting their utility to mild cases (Aronson et al., 2017).

Other Protozoal Infections

Just a few of the many less-common protozoal infections of humans are highlighted in this section.

Babesiosis

Babesiosis, caused by either *Babesia microti* or *B. divergens*, superficially resembles malaria in that the parasites invade erythrocytes and produce a febrile illness, hemolysis, and hemoglobinuria. This tick-borne zoonosis can be acquired in the upper Midwest and the Northeast in the U.S. or via blood transfusion. Although this infection usually is mild and self-limiting, it can be severe or even fatal in asplenic or severely immunocompromised individuals (Vannier and Gelfand, 2020). Therapy is with a combination of *clindamycin* and *quinine* for severe disease or the combination of *azithromycin* and *atovaquone* for mild or moderate infections (Kimberlin et al., 2018).

Balantidiasis

Balantidiasis, caused by the ciliated protozoan *Balantidium coli*, is an infection of the large intestine that may be confused with amebiasis. Unlike amebiasis, this infection usually responds to *tetracycline* therapy, although balantidiasis can also be treated with *metronidazole* (Suh et al., 2020).

Other Coccidia

Cyclospora cayetanensis (Szumowski and Troemel, 2015) causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in immunocompromised individuals. *Cystoisospora belli,* formerly known as *Isospora belli,* causes diarrhea in patients with AIDS. Both *Cyclospora* and *Cystoisospora* respond to *trimethoprim-sulfamethoxazole* (Suh et al., 2020).

Microsporidia

Microsporidia are spore-forming, unicellular, eukaryotic organisms that were once thought to be parasites but are now classified as fungi (Szumowski and Troemel, 2015). As such, treatments are discussed in Chapter 61 (Antifungal Agents).

Antiprotozoal Drugs

For ease of reference, the myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

Amphotericin B

The pharmacology, formulation, and toxicology of *amphotericin B* are presented in Chapter 61.

Antiprotozoal Effects

Amphotericin B is a highly effective antileishmanial agent that cures more than 90% of visceral leishmaniasis cases and is the drug of choice for antimonial-resistant cases (WHO, 2020c). It is the recommended agent for visceral leishmaniasis in the U.S. (Aronson et al., 2017). *Amphotericin B* also treats cutaneous or mucosal leishmaniasis and is effective for immunocompromised patients (Aronson et al., 2020). Lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions (WHO, 2020c).

Mechanism of Action

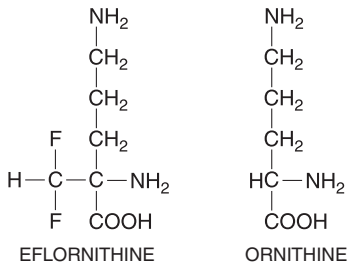
Amphotericin's activity against *Leishmania* is similar to its antifungal effects (see Figure 61–2). *Amphotericin* complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell (McCarthy et al., 2020). *Leishmania* has similar sterol composition to fungi, and *amphotericin* binds fungal sterols preferentially over host cholesterol (Moen et al., 2009).

Therapeutic Uses

Typical regimens of 10 to 20 mg/kg total dose given in divided doses over 10 to 20 days by intravenous infusion have yielded cure rates of more than 95%. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1 to 5, 14, and 21 for a total dose of 21 mg/kg to treat visceral leishmaniasis or 3 mg/kg per day for 7 to 10 days to treat cutaneous disease (Aronson et al., 2017). Shorter courses of the drug for treatment of visceral leishmaniasis have demonstrated good efficacy and provide a potential cost-saving alternative, although only a limited number of patients have been tested (Monge-Maillo and Lopez-Velez, 2013). In addition, combining antileishmanial drugs may be effective; further studies are still needed for such regimens (Sundar and Chakravarty, 2013).

Eflornithine

Eflornithine (DFMO, α-D,L-difluoromethylornithine) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first step in the biosynthesis of polyamines (putrescine, spermidine, and spermine) that are required for cell division and for normal cell differentiation (Phillips, 2018). In trypanosomes, spermidine is required for the synthesis of trypanothione, a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite. *Eflornithine* is transported into the cell via the amino acid transporter *Tb* AAT6.



Eflornithine in combination with *nifurtimox* (NECT) is currently the drug of choice for treatment of severe late-stage (CNS involvement) West African (Gambian) trypanosomiasis caused by *T. brucei gambiense* (Lindner et al., 2020). This includes patients with a white blood cell (WBC) count in the cerebrospinal fluid (CSF) of 100/μL or greater and patients whose clinical presentation meets criteria for evaluation by lumbar puncture. *Fexinidazole* has recently supplanted NECT as the front-line therapy for early-stage disease and for patients with noncomplicated presentations of the CNS stage. *Eflornithine* is thought to be less effective against East African trypanosomiasis and thus is not recommended for this application. *Eflornithine* is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request from the CDC.

Antitrypanosomal Effects

Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion (Phillips, 2018). These include reduced levels of spermidine, which is required for hypusine modification of the essential eukaryotic translation factor eIF5A, and depletion of the trypanosomatid-specific redox cofactor trypanothione. The parasite and human enzymes are equally susceptible to inhibition by *eflornithine*; however, the mammalian enzyme turns over rapidly, whereas the parasite enzyme is stable, and this difference is thought to be one factor that contributes to selective toxicity.

ADME

Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins, is well distributed, and penetrates into the CSF, where estimated concentrations of at least 50 μM must be reached for parasite clearance (Burri and Brun, 2003). The mean $t_{1/2}$ is 3 to 4 h, and renal clearance after intravenous administration is rapid (2 mL/min/kg), with more than 80% of the drug cleared by the kidney largely in unchanged form (Sanderson et al., 2008).

Therapeutic Uses

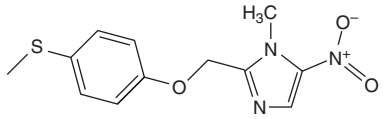
Eflornithine in combination with *nifurtimox* (NECT) is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gambiense*. The combination is logistically easier to administer and better tolerated than *eflornithine* alone. NECT is safer and more efficacious than *melarsoprol* for late-stage gambiense sleeping sickness, and importantly, compared to *eflornithine* alone, NECT achieves a higher cure rate (96.5% vs. 91.5%) (Priotto G et al., 2009). NECT also showed better efficacy than *fexinidazole* in a randomized, phase II/III noninferiority trial (98% vs. 91% cure) of patients with late-stage Gambian HAT and had fewer side effects (Mesu et al., 2018). However, the need for lumbar puncture to evaluate the disease stage before use and the requirement for hospital administration and IV *eflornithine* dosing led to the recommendation that *fexinidazole* should become the front-line therapy with exceptions. NECT remains the recommended drug for severe cases of late-stage disease (WBCs in the cerebral spinal fluid of ≥100/μL) or for young children (<6 years or <20 kg) (Lindner et al., 2020; WHO, 2019). Dosing is as follows: 200 mg/kg IV every 12 h by 2-h infusion for 7 days plus *nifurtimox* (orally at 15 mg/kg per day in three divided doses [every 8 h]) for 10 days (Priotto S et al., 2009).

Toxicity and Side Effects

Eflornithine causes adverse reactions that are generally reversible on withdrawal of the drug. Abdominal pain and headache are the predominant complaints, followed by reactions at the injection sites. Tissue infections and pneumonia have also been reported. The most severe reactions for *eflornithine* alone were reported to include fever peaks (6%), seizures (4%), and diarrhea (2%) (Balasegaram et al., 2009; Priotto S et al., 2009). For NECT, severe adverse events were reduced compared to *eflornithine* alone (14% vs. 29%), and treatment-related deaths were also fewer (0.7% vs. 2%) (Priotto S et al., 2009). The case fatality rates for *eflornithine* (0.7%–1.2%) and for NECT (0.2%) are significantly lower than for *melarsoprol* (4.9%), and overall, either *eflornithine* alone or NECT is superior to *melarsoprol* with respect to both safety and efficacy. The more recent clinical study comparing NECT to *fexinidazole* found that NECT was well tolerated, with the most common side effects being vomiting (29%), nausea (19%), and headache (24%), and these occurred at a lower frequency than for *fexinidazole* (Mesu et al., 2018). Reversible hearing loss can occur after prolonged therapy with oral doses but was not reported in the NECT trials. Therapeutic doses of *eflornithine* are large and require coadministration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients.

Fexinidazole

Fexinidazole is the first oral treatment for West African (Gambian) trypanosomiasis caused by *T. brucei gambiense,* and it is the first drug to be recommended for treatment of both early and late (CNS) stages of the disease (Lindner et al., 2020). The effectiveness of *fexinidazole* on both early- and late-stage disease alleviates the need to perform lumbar puncture to stage the disease, except in the most severe late-stage cases, and thus greatly simplifies HAT treatment. *Fexinidazole* received a positive review from the European Medicines Agency in 2018, and it was added to the WHO essential medicines list in 2019 (Neau et al., 2020).



FEXINIDAZOLE

Antitrypanosomal Effects

Mechanism of Action. *Fexinidazole* is a 5-nitroimidazole from the same drug class as *nifurtimox*. These compounds are prodrugs that are bioactivated by a bacterial-like type 1 nitroreductase (NTR1) in trypanosomatids that uses NADH as a reductive cofactor to perform 2e⁻ electron oxidation reactions (Patterson and Wyllie, 2014). This chemistry leads to the formation of a Michael acceptor in the form of an unsaturated open-chain nitrile. Cell toxicity is believed to result from the interaction of these reactive molecules with multiple targets in the cell including reports of DNA modification. This mechanism of activation provides a basis for species-selective toxicity as there is no mammalian homolog of this enzyme.

Parasites that were 6-fold resistant to *fexinidazole* could be selected *in vitro*, and this resistance was associated with mutations in the 3′ flanking region of the *NTR1* gene, which led to reduced expression, while knockout of a single NTR1 allele also led to partial resistance (Dickie et al., 2020). Overexpression of the *L. donovani* NTR led to 18-fold increased drug sensitivity (Wyllie et al., 2013). These studies show the importance of NTR1-mediated bioactivation in the mechanism of action of the 5-nitroimidazoles. The findings of both common mechanisms of bioactivation and drug resistance for *fexinidazole* and *nifurtimox* underscore a vulnerability in the current treatment strategy. Resistance generated to one in the field through changes in NTR1 expression levels could lead to clinical resistance to both compounds, thus putting at risk both front-line treatments for Gambian HAT.

ADME. *Fexinidazole* is given orally in tablet form and is a Biopharmaceutical Classification class III drug. Pharmacokinetic studies (Tarral et al., 2014) showed that absorption is rapid and the parent compound is quickly metabolized to the sulfoxide (t_{max} = 2–5 h) and the sulfone (t_{max} = 18–24 h). A fed state significantly increases plasma concentrations (C_{max} and area under the curve [AUC]) of the parent and the two metabolites by 4- to 5-fold. The two major metabolites (sulfoxide and sulfone) have been observed after oral dosing in both mice and humans, and the pharmacokinetic data in both species support the conclusion that they are responsible for most of the trypansomatid killing *in vivo* (Kaiser et al., 2011; Tarral et al., 2014). In humans under fed conditions, the two metabolites reach peak plasma concentrations and AUCs that are 5- to 7-fold higher than the parent drug, and exposure levels of the metabolites are sustained for significantly longer, with the sulfone providing the most

prolonged exposure (Tarral et al., 2014). Accumulation over multiple dosing did not occur for the parent or the sulfoxide, but an accumulation ratio of approximately 7 was observed for the sulfone. *Fexinidazole* elimination was almost entirely extrarenal (renal clearance of 1.2–6.0 mL/h vs. oral clearance of 80 L/h).

Therapeutic Uses

Fexinidazole is the currently recommended drug of choice for early-stage Gambian HAT and for uncomplicated late-stage disease including in adults and children aged 6 years or older and weighing 20 kg or more (WHO, 2019). For children who do not meet these criteria, *pentamidine* should still be used for early-stage disease, while NECT is recommend for late-stage disease. NECT is also still recommended for adults with severe late-stage disease. A phase II/III, open-label, noninferiority trial was conducted with *fexinidazole* in comparison to NECT, and *fexinidazole* was curative in 91% of patients compared to a cure rate of 98% in patients who received NECT (Mesu et al., 2018). Follow-up studies demonstrated a 98.7% treatment success rate in early-stage Gambian HAT for adults aged 15 or older; the success rate in children aged 6 to 14 was 97.6% across all stages (Neau et al., 2020). *Fexinidazole* showed inferiority to NECT (86.9% vs. 98.7%, respectively) in adults with severe meningoencephalitic late-stage disease in which patients had a baseline WBC count in the CSF of 100/μL or greater. Thus for patients with severe late-stage disease who have WBC levels above this threshold, or if lumbar puncture is unavailable or inconclusive, NECT therapy is recommended (Lindner et al., 2020; WHO, 2019). Additional contraindications for treatment with *fexinidazole* include patients at risk for QT prolongation or those with jaundice (WHO, 2019).

The dose of *fexinidazole* in patients aged 15 years and older (and 35 kg) is 1800 mg (3 × 600 mg) on days 1 to 4, followed by 1200 mg (2 × 600 mg) on days 5 to 10, administered once daily as 600-mg oral tablets, with the initial higher dose providing a loading dose, followed by a lower maintenance dose (WHO, 2019). For body weight of 20 to 34 kg, the loading phase dose is reduced to 1200 mg (2 tablets) and the maintenance phase dose is 600 mg (1 tablet). The dose must be taken with food to increase drug exposure. The food effect on bioavailability is significant, and if a dose is taken without food, it should be considered as a missed dose.

Toxicity and Side Effects

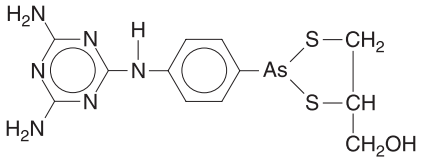
The most common reported side effects in the phase II/III study were nervous system (headache 35%, tremor 22%, and dizziness 19%) and gastrointestinal (GI) disorders (vomiting 28%, nausea 26%, and decreased appetite 21%) (Mesu et al., 2018; Tarral et al., 2014). Vomiting was more frequent in children than adults. Treatment-related adverse events were reported in this study at a similar rate for *fexinidazole* and NECT (81% vs. 79%), but the incidence of neuropsychiatric adverse reactions was higher for *fexinidazole* than for NECT.

8-Hydroxyquinolines

The halogenated 8-hydroxyquinolines *iodoquinol* (diiodohydroxyquin) and *clioquinol* (iodochlorhydroxyquin) can be used as luminal agents to eliminate intestinal colonization with *E. histolytica* and combined with *metronidazole* to treat amebic colitis or amebic liver abscess (WHO, 2020a). Because of its superior adverse event profile, *paromomycin* is preferred as the luminal agent for amebiasis (Petri et al., 2020). However, *iodoquinol*, the safer of the two 8-hydroxyquinolones, is available for use in the U.S. and is a reasonable alternative. When used at appropriate doses (never to exceed 2 g/day) for short periods of time (not greater than 20 days in adults), adverse effects are unusual (Haque et al., 2003). However, using these drugs at high doses for long periods carries significant risk. The most important toxic reaction, ascribed primarily to *clioquinol*, is subacute myelo-optic neuropathy (Meade, 1975). Administering *iodoquinol* in high doses to children with chronic diarrhea is associated with optic atrophy and permanent vision loss (Escobedo et al., 2009). Peripheral neuropathy is a less severe manifestation of neurotoxicity from these drugs (Haque et al., 2003). For adults, the recommended dose of *iodoquinol* is 650 mg orally three times daily for 20 days, whereas children receive 30 to 40 mg/kg body weight orally, divided three times a day (not to exceed 1.95 g/day) for 20 days (Kimberlin et al., 2018).

Melarsoprol

Despite the fact that it causes an often-fatal encephalopathy in 2% to 10% of the patients treated with it, *melarsoprol* is the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by *T. brucei rhodesiense* (Kennedy, 2019). Although *melarsoprol* is also effective against late-stage West African trypanosomiasis caused by *T. brucei gambiense*, NECT and *fexinidazole* have become the first-line treatments of this disease (Lindner et al., 2020).



MELARSOPROL

Melarsoprol is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

Mechanism of Action; Antiprotozoal Effects

Melarsoprol is metabolized to melarsen oxide, the active drug (Barrett et al., 2007; Barrett and Croft, 2012). Arsenoxides react avidly and reversibly with vicinal sulfhydryl groups and thereby inactivate many enzymes. *Melarsoprol* reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of *melarsoprol* to trypanothione results in a melarsen oxide–trypanothione adduct that inhibits trypanothione reductase. Treatment failure owing to resistance of trypanosomes to *melarsoprol* has risen sharply, and some of the resistant strains are an order of magnitude less sensitive to the drug. Resistance to *melarsoprol* arises due to transport defects linked to the aquaglyceroporin pore-forming protein (Munday et al., 2015).

ADME

Melarsoprol is always administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. *Melarsoprol* is a prodrug and is metabolized rapidly (<30 min) to melarsen oxide, the active form of the drug (Barrett et al., 2007; Barrett and Croft, 2012). Bioassays show that the active metabolite has a terminal $t_{1/2}$ of 43 h. A small but therapeutically significant amount of the drug enters the CSF and clears trypanosomes infecting the CNS.

Therapeutic Uses

Melarsoprol remains the recommended drug for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is nearly 100% fatal if untreated (Kennedy, 2019). The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with *T. brucei rhodesiense* who relapse after a course of *melarsoprol* usually respond to a second course of the drug. *Melarsoprol* is also effective against late-stage *T. brucei gambiense* but because both *fexinidazole* and NECT are safer and more effective, *melarsoprol* is no longer recommended for this application.

Dosing is 2.2 mg/kg per day IV for 10 days for both *T. brucei gambiense* (Pepin and Mpia, 2006) and *T. brucei rhodesiense* (Kuepfer et al., 2012).

Encephalopathy develops more frequently in patients with *T. brucei rhodesiense* compared to *T. brucei gambiense*. Concurrent administration of *prednisolone* is frequently employed throughout the treatment course to reduce the prevalence of encephalopathy.

Toxicity and Side Effects

Treatment with *melarsoprol* is associated with significant toxicity and morbidity (Kennedy, 2019). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs 9 to 11 days after treatment starts in about 5% to 10% of patients, leading

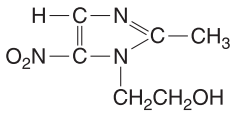
to death in about half of these. Peripheral neuropathy occurs in about 10% of patients receiving *melarsoprol*. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and evidence of renal or hepatic damage may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting *melarsoprol* slowly into the supine, fasting patient.

Precautions and Contraindications

Melarsoprol should be given only to patients under hospital supervision. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of *melarsoprol* to leprous patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. The drug may be used safely in pregnancy.

Metronidazole and Tinidazole

Metronidazole is active *in vitro* against a wide variety of anaerobic protozoal parasites and anaerobic bacteria. Other clinically effective 5-nitroimidazoles closely related in structure and activity to *metronidazole* include *tinidazole*, *secnidazole*, and *ornidazole*. Among these, only *tinidazole* is available in the U.S. *Metronidazole* is clinically effective in trichomoniasis, amebiasis, and giardiasis. *Metronidazole* manifests antibacterial activity against all anaerobic cocci; anaerobic gram-negative bacilli, including *Bacteroides* spp.; anaerobic spore-forming, gram-positive bacilli such as *Clostridium*; and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria (Lofmark et al., 2010). Please refer to Chapter 57 for additional details about the use of *metronidazole* in bacterial infections.



METRONIDAZOLE

Mechanism of Action

Metronidazole is a prodrug requiring reductive activation of the nitro group by susceptible organisms. Unlike their aerobic counterparts, anaerobic and microaerophilic pathogens (e.g., the amitochondriate protozoa *T. vaginalis, E. histolytica*, and *G. lamblia* and various anaerobic bacteria) contain electron transport components that have a sufficiently negative redox potential to donate electrons to *metronidazole*. The single-electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA (McCarthy et al., 2020). *Metronidazole* is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O_2 inhibit *metronidazole*-induced cytotoxicity because O_2 competes with *metronidazole* for electrons. Thus, O_2 can both decrease reductive activation of *metronidazole* and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to *metronidazole* derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by PFOR (pyruvate-ferredoxin oxidoreductase), produces electrons that reduce ferredoxin, which in turn catalytically donates its electrons to biological electron acceptors or to *metronidazole* (Lamp et al., 1999).

Resistance

Clinical resistance to *metronidazole* is well documented for *T. vaginalis, G. lamblia*, and a variety of anaerobic and microaerophilic bacteria. Resistance correlates with impaired oxygen-scavenging capabilities, leading to higher local O_2 concentrations, decreased activation of *metronidazole*, and futile recycling of the activated drug. Other resistant strains have lowered levels of PFOR and ferredoxin, perhaps explaining why they may still respond to higher doses of *metronidazole* (Townson et al., 1994).

ADME

Preparations of *metronidazole* are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake and distributed to a volume approximating total body water; less than 20% of the drug is bound to plasma proteins. A linear relationship between dose and plasma concentration pertains for doses of 200 to 2000 mg. Repeated doses every 6 to 8 h result in some drug accumulation. The $t_{1/2}$ of *metronidazole* in plasma is about 8 h. With the exception of the placenta, *metronidazole* penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF. After an oral dose, more than 75% of labeled *metronidazole* is eliminated in the urine, largely as metabolites formed by the liver from oxidation of the drug's side chains, a hydroxy derivative and an acid; about 10% is recovered as unchanged drug.

Two principal metabolites result. The hydroxy metabolite has a longer $t_{1/2}$ (~12 h) and has approximately 50% of the antitrichomonal activity of *metronidazole*. Small quantities of reduced metabolites are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of *metronidazole* is induced by *phenobarbital, prednisone, rifampin*, and possibly ethanol and is inhibited by *cimetidine* (Lamp et al., 1999; Martinez and Caumes, 2001).

Therapeutic Uses

Trichomoniasis. *Metronidazole* cures genital infections with *T. vaginalis* in more than 90% of cases. The preferred treatment regimen is 2 g *metronidazole* as a single oral dose for both males and females. *Tinidazole*, which has a longer $t_{1/2}$ than *metronidazole*, is also used as a 2-g single dose and appears to provide equivalent or better responses (Kimberlin et al., 2018). When repeated courses or higher doses of the drug are required, it is recommended that intervals of 4 to 6 weeks elapse between courses. Leukocyte counts should be obtained before, during, and after each course. Treatment failures owing to the presence of *metronidazole*-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner (Schwebke and Bachmann, 2020). In addition to oral therapy, the use of a 500- to 1000-mg vaginal suppository may be beneficial in refractory cases (Muzny and Schwebke, 2013).

Amebiasis. *Metronidazole* is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500 to 750 mg *metronidazole* taken orally three times daily for 7 to 10 days (WHO, 2020a) or, for children, 35 to 50 mg/kg per day given in three divided doses for 7 to 10 days (Kimberlin et al., 2018). Amebic liver abscess has been treated successfully by short courses of *metronidazole* or *tinidazole*. *E. histolytica* persists in most patients who recover from acute amebiasis after *metronidazole* therapy, so it is recommended that all such individuals also be treated with a luminal amebicide (Petri et al., 2020).

Giardiasis. *Tinidazole* is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy (Nash and Bartlet, 2020). Although *metronidazole* has never been FDA-approved for treatment of giardiasis in the U.S., there are many years of experience with its use (Kimberlin et al., 2018).

Toxicities and Contraindications

Metronidazole is intensely bitter, and the liquid formulation is often refused by pediatric patients (Kimberlin et al., 2018). Common side effects are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Dysuria, cystitis, and a sense of pelvic pressure have been reported. Dizziness, vertigo, and, very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant drug discontinuation. *Metronidazole* also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete (McCarthy et al., 2020).

Urticaria, flushing, and pruritus indicate drug sensitivity and can require withdrawal of *metronidazole* (Lofmark et al., 2010). *Metronidazole*

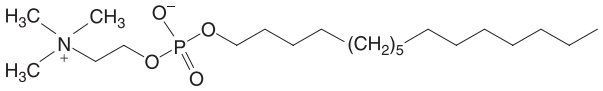
is a rare cause of Stevens-Johnson syndrome, which may be more common among individuals receiving high doses of *metronidazole* and concurrent therapy with the antihelminthic *mebendazole* (Chen et al., 2003).

Drug Interactions

Metronidazole has a *disulfiram*-like effect: some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy (Jang and Harris, 2007). *Metronidazole* and *disulfiram* or any *disulfiram*-like drug should not be taken together because confusional and psychotic states may occur. *Metronidazole* should be used cautiously in patients with active disease of the CNS because of potential neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of *lithium*. *Metronidazole* can prolong the prothrombin time of patients receiving therapy with *warfarin* anticoagulants. The dosage of *metronidazole* should be reduced in patients with severe hepatic disease. *Metronidazole* use during the first trimester of pregnancy generally is not advised (Lofmark et al., 2010).

Miltefosine

Miltefosine is an alkylphosphocholine analogue developed originally as an anticancer agent. Its antiprotozoal activity was discovered in the 1980s as it was being evaluated for cancer chemotherapy. In 2002, it was approved in India as the first orally active treatment available for visceral leishmaniasis (WHO, 2020c). It is highly curative against visceral leishmaniasis and also is effective against the cutaneous forms of the disease (Aronson et al., 2020). Its main drawback is its teratogenicity; consequently, it must not be used in pregnant women (Aronson et al., 2017).



MILTEFOSINE

Antiprotozoal Effects

Miltefosine is the first consistently effective orally available therapy for leishmaniasis. It is a safe and effective treatment of visceral leishmaniasis and has shown greater than 90% efficacy against some species of cutaneous leishmaniasis, although significant strain variation has been noted in clinical trials (Sundar and Chakravarty, 2015). The mechanism of action of *miltefosine* is not understood. Studies suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis (Dorlo et al., 2012). A transporter for *miltefosine* has been cloned by functional rescue of a laboratory-generated resistant strain of *L. donovani*. The transporter is a P-type ATPase that belongs to the aminophospholipid translocase subfamily. The basis for the drug resistance appears to be a point mutation in this transporter that leads to decreased drug uptake and thereby confers drug resistance (Sundar and Chakravarty, 2015).

ADME

Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that *miltefosine* has a long $t_{1/2}$ (1–4 weeks). Plasma concentrations are proportional to the dose (Miltefosine [Impavido] for leishmaniasis, 2014).

Therapeutic Uses

In the U.S., the recommended dose for oral *miltefosine* for both visceral and cutaneous disease for adults over 45 kg is 150 mg/kg per day for 28 days, given in three divided doses, and for patients weighing 30 to 45 kg, the dose is 100 mg/kg per day, given in two divided doses (Aronson et al., 2017; Kimberlin et al., 2018). The compound cannot be given intravenously because it has hemolytic activity (Dorlo et al., 2012). It is also used to treat infections due to *Acanthamoeba, Balamuthia,* and *Naegleria*.

Toxicity and Side Effects

Vomiting and diarrhea are reported as frequent side effects, in up to 60% of patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible. Because of its teratogenic potential, *miltefosine* is contraindicated in pregnant women. In fact, guidelines for *miltefosine* use in the U.S. state that adequate contraception must be used during treatment and for 5 months after therapy is complete (Aronson et al., 2017).

Nifurtimox and Benznidazole

Nifurtimox and *benznidazole* are used to treat American trypanosomiasis caused by *T. cruzi*; *nifurtimox* is also used in combination with *eflornithine* for treatment of *T. brucei* (see previous discussion). *Nifurtimox*, a nitrofuran analogue, and *benznidazole*, a nitroimidazole analogue, can be obtained in the U.S. from the CDC.

Antiprotozoal Effects and Mechanisms of Action

Nifurtimox and *benznidazole* are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi* (Bern et al., 2019; Meymandi et al., 2018). *Nifurtimox* also has activity against *T. brucei* and can be curative against both early- and late-stage diseases (see previous discussion of NECT). The trypanocidal effects of *nifurtimox* and *benznidazole* derive from their activation by an NADH-dependent mitochondrial nitroreductase to nitro radical anions that are thought to account for the trypanocidal effects (Wilkinson et al., 2011). The generated nitro anion radicals form covalent attachments to macromolecules, leading to cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA. Reduced nitroreductase expression through single-allele gene knockout experiments or through drug selection leads to drug resistance (Wilkinson et al., 2011).

ADME

Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after about 3.5 h. Less than 0.5% of the dose is excreted in urine (Paulos et al., 1989). The elimination $t_{1/2}$ is about 3 h. *Nifurtimox* undergoes rapid biotransformation, probably via a presystemic first-pass effect; high concentrations of several unidentified metabolites are found. *Nifurtimox* crosses the blood-brain barrier in mice (Jeganathan et al., 2011).

Benznidazole is absorbed rapidly and reaches peak plasma levels within 3 h; the terminal elimination half-life is 12 h (Raaflaub and Ziegler, 1979). Recent population studies suggest that, in adults, a dose of 2.5 mg/kg/24 h maintains the trough concentration above the therapeutic range of 3 to 6 mg/L, indicating that the current recommended dose of 2.5 mg/kg/12 h may be higher than needed (Soy et al., 2015). In children, drug levels were found to be lower than in adults, with excellent efficacy nonetheless (Altcheh et al., 2014).

Therapeutic Uses

Nifurtimox and *benznidazole* are employed in the treatment of American trypanosomiasis (Chagas disease) caused by *T. cruzi* (Bern et al., 2019; Meymandi et al., 2018). *Nifurtimox* is also used in combination with *eflornithine* (NECT) for treatment of late-stage African sleeping sickness (see *eflornithine* section for discussion) (Lindner et al., 2020). Because of toxicity concerns, *benznidazole* is the preferred treatment of Chagas disease. *Benznidazole* is FDA-approved for children 2 to 12 years old; *nifurtimox* is FDA-approved for children from birth to 18 years of age. In patients older than 50 years, the benefits of treatment are complicated by lowered drug tolerability. Treatment in all age groups is most effective if started early before the disease progresses to the chronic stage or to the point of organ damage. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas disease, with parasitological cures obtained in more than 80% of these cases, although the clinical response of the acute illness to drug therapy varies with geographic region (Messenger et al., 2015). In the chronic form of the disease, parasitological cures are still possible, but the drug is less effective than in the acute stage. In chronic Chagas patients treated with 150 mg *benznidazole* twice daily for 60 days, 94% remained polymerase chain reaction negative after 10 months (Molina et al., 2014a, 2014b). Current recommendations are that patients with acute or congenital disease should be treated (Pan American Health Organization, 2019). For patients with chronic disease, children and women of childbearing age should be treated (Kimberlin et al., 2018), whereas for adults

with chronic disease and specific organ damage, treatment is not recommended (Pan American Health Organization, 2019). Therapy is encouraged for patients who will receive immunosuppressive therapy or who are HIV positive. Therapy with *nifurtimox* or *benznidazole* should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both *nifurtimox* and *benznidazole* are given orally with doses as recommended by Kimberlin and colleagues (2018). For *nifurtimox,* adults (>17 years) with acute infection should receive 8 to 10 mg/kg per day in three to four divided doses for 90 days; children 1 to 10 years old should receive 15 to 20 mg/kg per day in three to four divided doses for 90 days; for individuals 11 to 16 years old, the daily dose is 12.5 to 15 mg/kg given according to the same schedule.

For *benznidazole*, the recommended treatment for adults (>13 years) is 5 to 7 mg/kg per day in two divided doses for 60 days, with children 2 to 12 years old receiving 5 to 8 mg/kg per day in two divided doses for 60 days. However, some studies have suggested that total doses exceeding 300 mg/day are less well tolerated. If gastric upset and weight loss occur during treatment, dosage should be reduced. The ingestion of alcohol should be avoided.

Toxicity and Side Effects

Side effects are common and range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications referable to the GI tract and both the peripheral nervous system and CNS (Ribeiro et al., 2012). Nausea and vomiting are common, as are myalgia and weakness. For *benznidazole*, the most common adverse event (occurring in 30% of patients in the first week of treatment) is urticarial dermatitis, which can be treated with antihistamines or corticosteroids. However, treatment often has to be discontinued in patients with this reaction. Bone marrow suppression can occur early during therapy, so blood cell counts should be measured every 2 to 3 weeks, and treatment stopped if suppression is observed. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. *Benznidazole* should be given with food to minimize GI effects. Because of the seriousness of Chagas disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

Nitazoxanide

Nitazoxanide (*N*-[nitrothiazolyl] salicylamide) is an oral, synthetic, broad-spectrum antiparasitic agent (see Chapter 68). *Nitazoxanide* is FDA-approved for the treatment of cryptosporidiosis and giardiasis in adults and immunocompetent children (Kimberlin et al., 2018).

Antimicrobial Effects

Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites and oocytes of *C. parvum*, as well as the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis in vitro* (McCarthy et al., 2020). *Nitazoxanide* also has activity against intestinal helminths (van den Enden, 2009). Although *nitazoxanide* is sometimes provided to immunocompromised and/or severely ill patients with GI viral infections, the mechanism by which it could be effective remains unclear, and there is minimal evidence to support its use under these circumstances.

Mechanism of Action

Nitazoxanide interferes with the PFOR enzyme-dependent electron-transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species (Raether and Hanel, 2003).

ADME

Following oral administration, *nitazoxanide* is hydrolyzed rapidly to its active metabolite, tizoxanide, which undergoes conjugation to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum plasma concentrations of the metabolites occur 1 to 4 h following administration. Tizoxanide is more than 99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces; tizoxanide glucuronide is excreted in the urine and bile (Raether and Hanel, 2003).

Therapeutic Uses

In the U.S., *nitazoxanide* is approved for the treatment of *G. intestinalis* infection (therapeutic efficacy of 85%–90%) (Nash and Bartlet, 2020) and for the treatment of diarrhea caused by *Cryptosporidium* (therapeutic efficacy, 56%–88%) in adults and children more than 1 year of age (White, 2020). *Nitazoxanide* has decreased efficacy in immunocompromised patients with *Cryptosporidium* infection, leading to extension of treatment courses (Kimberlin et al., 2018).

Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). Effective parasite clearance after *nitazoxanide* treatment was shown for *G. intestinalis, E. histolytica, Blastocystis hominis, C. parvum, C. cayetanensis, I. belli, Hymenolepis nana, Trichuris trichiura, Ascaris lumbricoides*, and *Enterobius vermicularis*, although more than one course of therapy was required in some cases. *Nitazoxanide* also has been used to treat infections with *G. intestinalis* resistant to *metronidazole* and *albendazole* (McCarthy et al., 2020).

To treat cryptosporidiosis, for children ages 12 to 47 months, the recommended dose is 100 mg *nitazoxanide* every 12 h for 3 days; for children ages 4 to 11 years, the dose is 200 mg *nitazoxanide* every 12 h for 3 days. A 500-mg tablet, suitable for adult dosing every 12 h for 3 days, is also available. Immunocompromised patients may require therapy for 2 weeks or longer (Kimberlin et al., 2018; McCarthy et al., 2020).

Toxicity and Side Effects

Adverse effects are rare with *nitazoxanide*. A greenish tint to the urine can be seen. *Nitazoxanide* is generally considered safe in pregnancy (former FDA pregnancy category B), based on animal teratogenicity and fertility studies (Anderson and Curran, 2007).

Paromomycin

Paromomycin (aminosidine) is an aminoglycoside of the neomycin/kanamycin family (see Chapter 59) that is used as an oral agent to treat *E. histolytica* infection, cryptosporidiosis, and giardiasis (McCarthy et al., 2020). Topical formulations have been used to treat trichomoniasis and cutaneous leishmaniasis; parenteral administration has been used to treat visceral leishmaniasis, both alone and in combination with *antimony compounds* (Sundar and Chakravarty, 2015). However, only oral *paromomycin* is available in the U.S. (Kimberlin et al., 2018).

Mechanism of Action; ADME

Paromomycin shares the same mechanism of action as *neomycin* and *kanamycin* (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. The drug is not absorbed from the GI tract; thus, the actions of an oral dose are confined to the GI tract, with 100% of the oral dose recovered in the feces (Mishra et al., 2007).

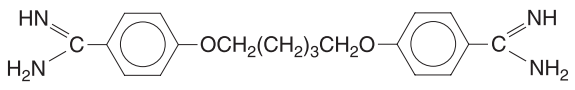
Antimicrobial Effects

Amebiasis. *Paromomycin* is the drug of choice for treating intestinal colonization with *E. histolytica* and is used in combination with *metronidazole* to treat amebic colitis and amebic liver abscess. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Dosing for adults and children is 25 to 35 mg/kg per day in three divided oral doses (Kimberlin et al., 2018).

Giardiasis. *Paromomycin* has been advocated as a treatment of giardiasis when *metronidazole* is contraindicated. It is used in pregnant women and for *metronidazole*-resistant isolates (Wright, 2012).

Pentamidine

Pentamidine, a positively charged aromatic diamine, is a broad-spectrum agent with activity against several species of pathogenic protozoa and some fungi. The di-isethionate salt of *pentamidine* is marketed for injection or as an aerosol (De et al., 1986; Rex and Stevens, 2014).



PENTAMIDINE

Antiprotozoal and Antifungal Effects

Pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection but is ineffective in the treatment of late-stage disease and has reduced efficacy against *T. brucei rhodesiense* (Kennedy, 2019; Lindner et al., 2020). *Fexinidazole* has superseded *pentamidine* as the front-line drug for early-stage Gambian HAT, but *pentamidine* remains the first-line treatment choice for children less than 6 years old or with a body weight of less than 20 kg, in whom insufficient data are currently available to support the use of *fexinidazole*.

Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis (Monge-Maillo and Lopez-Velez, 2013). *Pentamidine* is an alternative agent for the treatment and prophylaxis of pneumonia caused by *Pneumocystis jirovecii* (PJP), formerly known as *Pneumocystis carinii* (PCP). See Chapter 61 on antifungal agents for additional details.

Mechanism of Action and Resistance

The mechanism of action of the diamidines is unknown. The compounds display multiple effects on any given parasite and act by disparate mechanisms in different parasites. Multiple transporters contribute to *pentamidine* uptake. A single high-affinity transporter from the aquaglyceroporin gene family (TbAQP2) is responsible for cross-resistance between *pentamidine* and *melarsoprol* and represents the major route for the uptake of *pentamidine* (Munday et al., 2015).

ADME

Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent $t_{1/2}$ of several minutes to a few hours; maximum plasma concentrations after intramuscular injection occur at 1 h. The $t_{1/2}$ of elimination is long (weeks to months); the drug is 70% bound to plasma proteins (Bronner et al., 1995). This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining its ineffectiveness against late-stage trypanosomiasis.

Therapeutic Uses

African Trypanosomiasis. *Pentamidine* isethionate is used for the treatment of early-stage *T. brucei gambiense* in children who do not fit criteria for treatment with *fexinidazole* and is given by intramuscular or intravenous injection in doses of 4 mg/kg daily for 7 days (Lindner et al., 2020; WHO, 2019).

Leishmaniasis. *Pentamidine* can be used in doses of 2 to 3 mg/kg IV or IM daily or every second day for four to seven doses to treat cutaneous leishmaniasis (Kimberlin et al., 2018). This compound provides an alternative to *antimonials*, lipid formulations of *amphotericin B*, or *miltefosine*, but it is overall the least well tolerated (Monge-Maillo and Lopez-Velez, 2013).

Toxicity and Side Effects

Approximately 50% of individuals receiving the drug at recommended doses show some adverse effect (Barrett et al., 2007; Barrett and Croft, 2012). Intravenous administration of *pentamidine* may be associated with hypotension, tachycardia, and headache. These effects can be ameliorated by slowing the infusion rate. Hypoglycemia, which can be life threatening, may occur at any time during *pentamidine* treatment. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. *Pentamidine* is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises, it may be necessary to withhold the drug temporarily or change to an alternative agent (Rex and Stevens, 2014). Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic enzymes (Salamone and Cunha, 1988). Intramuscular administration of *pentamidine* is associated with the development of sterile abscesses at the injection site, which can become infected secondarily; most authorities recommend intravenous administration (Cheung et al., 1993).

Sodium Stibogluconate

Antimonials were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal infections since then. The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was *antimony potassium tartrate* (tartar emetic), which was both toxic and difficult to administer. *Tartar emetic* and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was *sodium stibogluconate* ($C_{12}H_{35}Na_3O_{26}Sb_2$; sodium antimony gluconate), a pentavalent antimonial compound that has been the mainstay of the treatment of leishmaniasis. Increasing resistance to antimonials has reduced their efficacy (WHO, 2020c). In the U.S., *sodium stibogluconate* can be obtained from the CDC (Aronson et al., 2016).

Mechanism of Action

Multiple mechanisms of action have been postulated. The most commonly invoked is that pentavalent antimonials act as prodrugs that are reduced to the more toxic Sb^{3+} species that kill amastigotes within the phagolysosomes of macrophages. Following reduction, the drugs seem to interfere with the trypanothione redox system. Sb^{3+} induces a rapid efflux of trypanothione and glutathione from the cells and also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells (Aronson et al., 2016).

ADME

The drug is given intravenously or intramuscularly; it is not active orally. The agent is absorbed rapidly and distributed in an apparent volume of about 0.22 L/kg. Elimination occurs in two phases, the first with a $t_{1/2}$ of about 2 h, the second with a much longer half-time (33–76 h). The prolonged terminal elimination phase may reflect conversion of the Sb^{5+} to the more toxic Sb^{3+} that is concentrated in and only slowly released from tissues. The drug is eliminated in the urine (Aronson et al., 2016).

Therapeutic Uses

The standard course is 20 mg/kg per day IV for 20 days for cutaneous disease and for 28 days for visceral leishmaniasis (Aronson et al., 2020). Increased resistance has greatly compromised the effectiveness of antimonials, and *sodium stibogluconate* is now obsolete in India. Previously, *liposomal amphotericin B* was the recommended alternative, but now the orally effective compound *miltefosine* is used (Sundar and Chakravarty, 2015). Intralesional treatment has also been advocated as a safer, alternative method for treating cutaneous disease (Monge-Maillo and Lopez-Velez, 2013). Patients who respond show clinical improvement within 1 to 2 weeks of initiating therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals (Sundar and Chakravarty, 2015). Patients infected with HIV often relapse after therapy (Sundar, 2015).

Toxicity and Side Effects

In general, regimens of *sodium stibogluconate* are tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Adverse effects include chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression, manifested by decreased red cell, white cell, and platelet counts; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death (Aronson et al., 2016).

Suramin

Research into the trypanocidal activity of the dyes *trypan red*, *trypan blue*, and *afridol violet* led to the introduction of *suramin* into therapy in 1920. Today, the drug is used primarily for treatment of early-stage African trypanosomiasis caused by *T. brucei rhodesiense*, though it has been studied for a broad range of applications (Wiedemar et al., 2020); it has no clinical utility against American trypanosomiasis.

Suramin sodium is a water-soluble trypanocide; solutions deteriorate quickly in air, and only freshly prepared solutions should be used. In the U.S., *suramin* is available only from the CDC.

Antiparasitic Effects

Suramin is a relatively slow-acting trypanocide (>6 h *in vitro*) with high clinical activity against both *T. brucei gambiense* and *T. brucei rhodesiense*. Its mechanism of action is unknown (Wiedemar et al., 2020). *Suramin* inhibits many trypanosomal and mammalian enzymes and receptors, and the lack of any significant field resistance suggests multiple points of action. Selective toxicity is likely to result from selective uptake by the parasite.

ADME

Because it is not absorbed after oral intake, *suramin* is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections (Kaur et al., 2002). After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination $t_{1/2}$ of 41 to 78 days. *Suramin* is not appreciably metabolized; renal clearance accounts for elimination of about 80% of the compound from the body. Very little *suramin* penetrates the CSF, consistent with its polar character and lack of efficacy once the CNS has been invaded by trypanosomes.

Therapeutic Uses

Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection (Kennedy, 2019). Because only small amounts of the drug enter the brain, *suramin* is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Treatment of active African trypanosomiasis should not be started until 24 h after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). *Suramin* is given by slow intravenous injection as a 10% aqueous solution. The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 100 mg initially to detect sensitivity, after which the normal dose is given intravenously (e.g., on days 1, 3, 5, 14, and 21). The pediatric test dose is 2 mg/kg followed by a dose of 20 mg/kg, given according to the same schedule as adults. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after *suramin* therapy should be treated with *melarsoprol*.

Toxicity and Side Effects

The most serious immediate reaction, consisting of nausea, vomiting, shock, and loss of consciousness, is rare (~1 in 2000 patients) (Kaur et al., 2002). Malaise, nausea, and fatigue are also common immediate reactions. The most common problem encountered after several doses of *suramin* is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less-prevalent reactions include vomiting, diarrhea, stomatitis, chills, abdominal pain, and edema. Patients receiving *suramin* should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency.

Drug Facts for Your Personal Formulary: *Antiparasitic Agents: Protozoal Infections Other Than Malaria*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Amebiasis		
Metronidazole	• Amoebic colitis and liver abscess	• Always followed by luminal agent • Orally administered ≥80% bioavailable • Common side effects = headache and metallic taste • Can have disulfiram-like effect
Tinidazole	• Amoebic colitis and liver abscess	• Always followed by luminal agent
Paromomycin	• Luminal agent (eradicates *E. histolytica* from gut)	• Drug of choice due to side effects of 8-hydroxyquinolones • Side effects of paromomycin: GI (nausea/vomiting/diarrhea)
Iodoquinol	• Luminal agent	• Use less than 2 g/day for less than 20 days to avoid neurotoxicity
Giardiasis		
Metronidazole	• Giardiasis	• 5-day course • Not FDA-approved for giardiasis but long experience supports its use
Tinidazole	• Giardiasis	• Single dose sufficient
Paromomycin	• Giardiasis	• Used in pregnancy
Nitazoxanide	• Giardiasis	• Orally bioavailable • Can treat resistant infections • Adverse events are rare
Trichomoniasis		
Metronidazole	• Trichomoniasis	• Drug of choice • 2 g once • If failure, give second dose in 4–6 weeks
Tinidazole	• Trichomoniasis	• 2 g once • Can be used for resistant infection

Drug Facts for Your Personal Formulary: *Antiparasitic Agents: Protozoal Infections Other Than Malaria (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Toxoplasmosis		
Pyrimethamine	• Acute or congenital toxoplasmosis	• Combine with sulfadiazine or clindamycin • Give with folinic acid (leucovorin) • Can cause marrow suppression
Sulfadiazine	• Acute or congenital toxoplasmosis	• Combine with pyrimethamine and folinic acid • Can cause bone marrow suppression
Clindamycin	• Acute toxoplasmosis	• Combine with pyrimethamine • Use if cannot tolerate sulfa agent
Spiramycin	• Acute toxoplasmosis during early pregnancy	• Prevent fetal transmission • Available through FDA investigational new drug process
Cryptosporidiosis		
Nitazoxanide	• Drug of choice for cryptosporidiosis	• Restore immune function in immunocompromised patients
Leishmaniasis		
Pentavalent antimony compounds (sodium stibogluconate)	• Cutaneous, mucocutaneous leishmaniasis • Visceral leishmaniasis (not in India)	• 20 days IV/IM for cutaneous disease • 28 days IV/IM for visceral disease • Side effects: pancreatitis, elevated hepatic transaminases, bone marrow suppression • Can cause hemolytic anemia and renal failure
Amphotericin B	• Visceral leishmaniasis • Second-line agent for cutaneous disease	• Used for antimony-resistant cases • Used during pregnancy • Side effects: renal toxicity, low potassium
Miltefosine	• Cutaneous leishmaniasis • Visceral leishmaniasis	• Only oral agent for leishmaniasis • GI side effects (vomiting/diarrhea) • Teratogenic—do not use in pregnancy
Trypanosomiasis—African sleeping sickness		
Suramin	• Early-stage *T. brucei rhodesiense* • Second-line agent for early-stage *T. brucei gambiense* (only if pentamidine and fexinidazole contraindicated)	• Immediate reactions: malaise, nausea, and fatigue • Side effects of multiple doses: renal toxicity, delayed neurological complications (headache, metallic taste, paresthesias, peripheral neuropathy)
Fexinidazole	• Early and late-stage *T. brucei gambiense* • First-line treatment for early-stage (before CNS involvement) • Late-stage *T. brucei gambiense* if noted criteria met	• Added to the WHO list of essential medicines in 2019 • Recommended for adults and children ≥6 years and ≥20 kg that can be managed without lumbar puncture (LP) or for patients in whom WBC count in CSF is <100/μL • Can be used for pregnant women after the first trimester • Most common side effects: vomiting/nausea, headache, insomnia, and anxiety. These were reported at a higher frequency than with NECT
Pentamidine	• Early-stage *T. brucei gambiense* ***before CNS involvement*** • Second-line to fexinidazole except for young children	• Remains front-line treatment for children <6 years or body weight <20 kg • IV administration associated with hypotension, tachycardia, and headache • Hypoglycemia occurs; monitor blood glucose • Nephrotoxic, can cause renal failure
Nifurtimox-eflornithine combination therapy (NECT)	• Late-stage *T. brucei gambiense* • Front-line treatment for severe late-stage disease and for other patients who do not meet criteria for fexinidazole	• Remains front-line treatment for patients in severe second stage with WBC in CSF ≥100/μL and for patients requiring stratification by LP who are unable to receive it or for whom results are unreliable • Remains front-line treatment for children <6 years or body weight <20 kg • Requires hospitalization and skilled healthcare professionals to administer • Safer and more effective than melarsoprol or eflornithine alone • Most common side effects: vomiting/nausea and headache
Melarsoprol	• Late-stage *T. brucei rhodesiense* • Last-line treatment for late-stage *T. brucei gambiense* (only if NECT and fexinidazole contraindicated)	• Fatal encephalopathy: 2%–10% of patients • Coadministration with prednisolone can reduce the prevalence of encephalopathy

Drug Facts for Your Personal Formulary: *Antiparasitic Agents: Protozoal Infections Other Than Malaria (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Trypanosomiasis—Chagas disease		
Benznidazole	• Drug of choice for Chagas	• Requires 60 days of treatment • Urticarial dermatitis in 30% of patients; coadministration of antihistamines or corticosteroids can help • Better tolerated in children, less well tolerated in adults >50 years • Most effective if administered early in the course of infection (acute stage) • Efficacy in chronic Chagas is lower • Give with food to minimize GI effects • Monitor blood cell counts
Nifurtimox	• Alternative treatment for Chagas	• Requires 60 days of treatment • Less well tolerated than benznidazole
Other Protozoal Infections		
Clindamycin and quinine	• Severe babesiosis	• Quinine—monitor for cardiac effects (prolonged QT interval)
Azithromycin and atovaquone	• Mild-moderate babesiosis	
Tetracycline	• Balatinidiasis	• Drug of choice
Trimethoprim-sulfamethoxazole	• Cyclosporiasis, isosporiasis	• Drug of choice

Chapter 68 Chemotherapy of Helminth Infections

Jennifer Keiser, James McCarthy, and Peter Hotez

ANTHELMINTIC DRUGS

- Benzimidazoles
- Diethylcarbamazine
- Doxycycline
- Ivermectin
- Praziquantel
- Niclosamide
- Oxantel and Pyrantel Pamoate
- Tribendimidine
- Moxidectin
- Levamisole
- Nitazoxanide

Helminths are invertebrates featuring elongated, flat or round bodies. According to their morphology and the host organ they inhabit, they are classified as flatworms or platyhelminths, which include flukes (lung flukes [*Paragonimus* spp.], liver flukes [*Fasciola* spp., *Clonorchis sinensis*, *Opisthorchis* spp.], intestinal flukes, or blood flukes [*Schistosoma* spp.]), tapeworms (cestodes [including *Taenia solium*, *T. saginata*], *Diphyllobothrium latum*, *Hymenolepis nana*, and *Echinococcus* spp.), and roundworms (nematodes). The nematodes of major medical importance include the soil-transmitted helminths (STHs) (*Ascaris lumbricoides*, *Trichuris trichiura*, *Necator americanus*, *Ancylostoma duodenale*, *Strongyloides stercoralis*) and the filarial worms. Lymphatic filariasis is caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. Subcutaneous filariasis is caused by *Loa loa*, *Mansonella streptocerca*, and *Onchocerca volvulus*. *Mansonella perstans* and *Mansonella ozzardi* are the causative helminths for serous cavity filariasis.

The blood flukes and nematodes are bisexual, while all other flukes and tapeworm species infecting humans are hermaphroditic. The development of all helminths includes egg, larval (juvenile), and adult stages, but the life cycles greatly differ. The prevalence of helminth infection worldwide is quite extensive (Figure 68–1).

Anthelmintic Drugs

Although a large number of anthelmintic drugs have been approved for human use, only a small number are widely used. These include two drugs in the benzimidazole (BZ) class, *albendazole* and *mebendazole*, which are widely used in intestinal nematode and cestode infections; the macrocyclic lactone *ivermectin*, used to treat a variety of nematode and ectoparasite infections; and *praziquantel*, which is used to treat trematode and some cestode parasites. Because of their role in programs of mass drug administration (MDA), these drugs are among the most commonly used agents worldwide. The World Health Organization (WHO) estimated that through MDA approximately 1.24 billion people received one or more anthelmintic drugs in 2019 (WHO, 2020). In many resource-poor developing countries, several different anthelmintic drugs can be provided together through integrated programs of MDA in order to simultaneously target intestinal and filarial nematodes and trematodes (Webster et al., 2014). A number of clinical trials have been undertaken to ensure that there are not unknown pharmacokinetic interactions or toxicologic consequences of coadministration of these drugs. This is especially the case for *ivermectin*, *diethylcarbamazine*, and *albendazole*, which have been shown to have synergistic activity as treatment for lymphatic filariasis (King et al., 2018; Weil et al., 2019).

Benzimidazoles

Although a large number of drugs in the BZ class have been synthesized and several have undergone clinical development for treatment of parasitic infections of humans, only two are currently in wide use, namely *albendazole* and *mebendazole*, with *triclabendazole* being reserved for treatment of liver fluke infection caused by *Fasciola hepatica*. *Thiabendazole* was formerly recommended for treatment of strongyloidiasis, but *ivermectin* is more effective and better tolerated, and it is now of historical interest only.

Chemistry

Albendazole, *mebendazole*, and *triclabendazole* are all poorly water soluble and only slightly soluble in methanol. Figure 68–2 shows the chemical structures of these drugs.

Mechanism of Action

The primary mechanism of action of the BZs is thought to be inhibition of microtubule polymerization by binding to β-tubulin (Prichard, 1994). The selective toxicity of these agents against helminths results from their increased affinity for parasite β-tubulin than for the same target in higher eukaryotes. A range of other biochemical changes occur in nematodes following BZ exposure, including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation.

ADME

Mebendazole. The low systemic bioavailability (22%) of *mebendazole* results from a combination of poor absorption and rapid first-pass metabolism at the intestinal wall and in the liver. Coadministration of *cimetidine* increases plasma levels of *mebendazole*, possibly due to inhibition of first-pass hepatic metabolism mediated by CYPs (cytochrome P450). The small proportion of *mebendazole* that is absorbed is approximately 95% bound to plasma proteins and is extensively metabolized. *Mebendazole*, rather than its metabolites, appears to be the active drug form (Gottschall et al., 1990). A new chewable formulation of *mebendazole* has recently been developed to facilitate use in pediatric populations (Friedman et al., 2012). Although this formulation is more palatable for administration to children and its systemic bioavailability may be higher (Friedman et al., 2012), its efficacy for treatment of STHs appears to be equivalent to the old formulation (Palmeirim et al., 2020). Conjugates of *mebendazole* and its metabolites have been found in bile, but little unchanged *mebendazole* appears in the urine.

Albendazole. *Albendazole* is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods

Abbreviations

AUC: area under the curve
BZ: benzimidazole
CDC: U.S. Centers for Disease Control and Prevention
CYP: cytochrome P450
dADT: p-(1-dimethylamino ethylimino) aniline
DEC: diethylcarbamazine
GABA: γ-aminobutyric acid
GI: gastrointestinal
MDA: mass drug administration
STH: soil-transmitted helminth
TPAC: terephalic acid
TPAL: terephthalaldehyde
WHO: World Health Organization

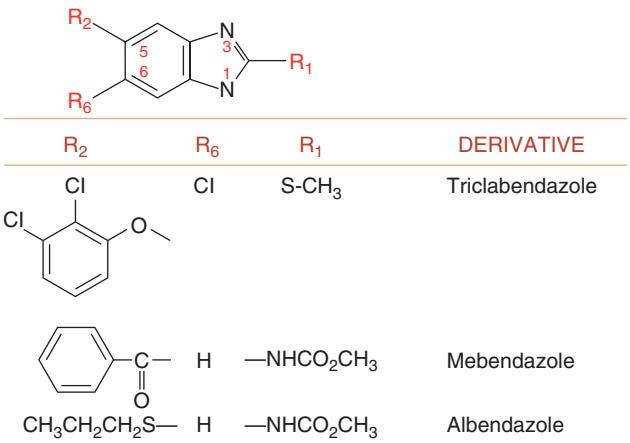

Figure 68–2 *Structure of benzimidazole anthelmintics.*

and possibly by bile salts. Administration following food, especially a fatty meal, enhances absorption by up to 5-fold in humans (Dayan, 2003). The activity of *albendazole* against tissue-dwelling helminths is attributable to its active metabolite *albendazole sulfoxide*. The better bioavailability of the parent drug and the activity of *albendazole sulfoxide* explain why *albendazole* is more active than *mebendazole* against tissue-dwelling helminths. The level of *albendazole sulfoxide* is enhanced 3.2-fold by ingestion of grapefruit juice. However, grapefruit juice shortens the drug's half-life by 46%. Data from indirect experiments suggest that *albendazole* is metabolized by CYP3A4 in the intestinal mucosa, a process that grapefruit juice inhibits (Nagy et al., 2002). In hookworm infected adolescents, *alebendazole* had a half-life of 1.5 h; the metabolites had a half-life of 7–8 h (Schultz et al. 2019).

Both the (+) and (−) enantiomers of *albendazole sulfoxide* are formed; the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (−) form. *Albendazole sulfoxide* is approximately 70% bound to plasma proteins and has a highly variable plasma $t_{1/2}$ of 4 to 15 h (Marques et al., 1999). It is well distributed into various tissues including hydatid cysts, where it reaches a concentration of approximately 20% that in plasma (Morris et al., 1987). Oxidation of the sulfoxide derivatives to the nonchiral sulfone metabolite of *albendazole*, which is pharmacologically inactive, is probably rate limiting

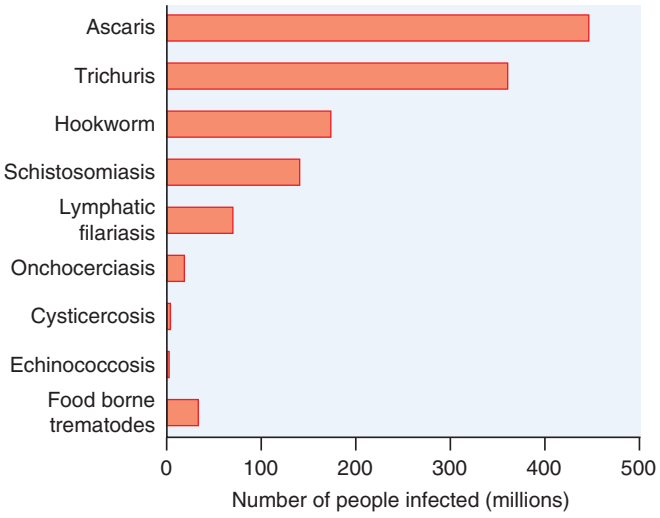

Figure 68–1 *Relative incidence of helminth infections worldwide.*

in determining the clearance and therefore the plasma half-life of the bioactive (+) sulfoxide metabolite. In animal models, BZs can induce their own metabolism. *Albendazole* metabolites are excreted mainly in the urine.

Triclabendazole. Administration of *triclabendazole* after food enhances its absorption, which might be due to the stimulation of gastric acid secretion, food-induced increase in drug solubility, and/or altered gastrointestinal (GI) motility and transit time. After oral administration, *triclabendazole* is rapidly oxidized into two major metabolites, *triclabendazole sulfoxide* and *triclabendazole sulfone* and only low concentrations of the parent drug can be detected in plasma. *Triclabendazole sulfoxide* is the metabolite active against *F. hepatica* (Keiser et al., 2005).

Therapeutic Uses

Albendazole is a safe and highly effective therapy for infections with GI nematodes, including *A. lumbricoides*, *T. trichiura*, and hookworms. For programmatic control of soil-transmitted helminth infections (enterobiasis, ascariasis, trichuriasis, and hookworm), *albendazole* is administered as a single oral 400-mg dose for adults and children greater than 2 years of age. Cure rates for light to moderate *Ascaris* infections typically are greater than 97%, although heavy infections may require therapy for 2 to 3 days. A 400-mg dose of *albendazole* appears to be superior to a 500-mg dose of *mebendazole* for curing hookworm infections and reducing egg counts (Keiser and Utzinger, 2008). A 3-day regimen of *albendazole* outperforms single-dose treatments against hookworm and *T. trichiura* infections. When administered at a dose of 400 mg daily for 3 days, *albendazole* shows some efficacy in treatment of strongyloidiasis but is less effective than *ivermectin* for treatment of this infection (Marti et al., 1996).

Albendazole is the drug of choice for chemotherapy of cystic hydatid disease caused by *Echinococcus granulosus*. Although prolonged treatment with the drug leads to only a modest cure rate, it is useful as adjunctive treatment in the perioperative period to reduce the risk of disseminated infection resulting from spillage of cyst contents at the time of surgery or with nonoperative puncture, aspiration, injection, and reaspiration procedures (Horton, 1997). A typical dosage regimen for adults is 400 mg given twice a day (for children, 15 mg/kg per day with a maximum of 800 mg) for 1 to 6 months. Although it is the only drug available with useful activity against alveolar echinococcosis caused by *Echinococcus multilocularis*, it is parasitostatic rather than parasiticidal, and lifelong therapy with or without surgical intervention is usually required to control this infection.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of *T. solium* (Garcia and Del Brutto, 2000).

The recommended dosage is 400 mg given twice a day for adults for 8 to 30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum: 800 mg) in two doses for 8 to 30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating *albendazole* therapy and continued for several days after commencement of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of *albendazole sulfoxide*. Prior to initiating chemotherapy of neurocysticercosis, consideration should be given to close observation or the administration of presumptive anticonvulsant therapy. Possible complications include arachnoiditis, vasculitis, cerebral edema, damage to the orbit or spinal cord, and the need for surgical intervention should obstructive hydrocephalus occur. A randomized trial indicated that *albendazole* in combination with *praziquantel* showed superior efficacy against neurocysticercosis compared to *albendazole* alone, either in standard or high dose (Garcia et al., 2014).

Albendazole, 400 mg/day, also has shown efficacy for therapy of certain microsporidial intestinal infections in patients with AIDS. Infection with *Capillaria philippinensis* can be treated with a 10-day treatment regimen of *albendazole* (400 mg/day).

The combination of *ivermectin*, *diethylcarbamazine*, and *albendazole* is highly effective for treatment of lymphatic filariasis, with a trial in Papua New Guinea showing that a single dose of the combination cleared microfilaria from the blood for at least 3 years in 96% of 60 participants (King et al., 2018). To avoid serious reactions to dying microfilariae, the *ivermectin/diethylcarbamazine/albendazole* combination is not recommended in locations where filariasis coexists with either onchocerciasis or loiasis.

Mebendazole is an effective drug for treatment of some GI nematode infections. It is only administered orally, with the same dosage schedule applying to adults and to children greater than 2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken; a second dose should be given after 2 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of *mebendazole* taken in the morning and evening for 3 consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. A 3-day *mebendazole* regimen is more effective than single doses of either *mebendazole* (500 mg) or *albendazole* (400 mg).

Triclabendazole is used for the treatment of fascioliasis and represents an alternative to *praziquantel* for treatment of paragonimiasis. *Triclabendazole* is administered at 10 mg/kg with a repeated dose administered when patients have high infection intensities (Keiser et al., 2005).

Adverse Effects and Drug Interactions

Albendazole and *mebendazole* have very good safety profiles when administered in short courses. Overall, side effects, primarily mild GI symptoms, occur in only 1% of treated children. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness. *Mebendazole* does not cause significant systemic toxicity in routine clinical use due to its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infection and expulsion of intestinal worms. *Albendazole* produces few side effects when used for short-term therapy of intestinal helminth infections, even in patients with heavy worm burdens. In long-term therapy of cystic hydatid disease and neurocysticercosis, *albendazole* is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely, jaundice may be noted, but liver enzymes return to normal after therapy is completed. Liver function tests should be monitored during protracted *albendazole* therapy; the drug is not recommended for patients with cirrhosis. The safety of *albendazole* in children less than 2 years of age has not been established. Long-term *albendazole* therapy can occasionally cause marrow toxicity, so blood counts should be monitored in this setting as well.

The BZs as a group display few clinically significant interactions with other drugs. *Albendazole* may induce its own metabolism; plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly *praziquantel*. Due to theoretical considerations, caution is advised when using high doses of *albendazole* together with drugs that inhibit the hepatic CYPs, such as *ritonavir*. Coadministration of *cimetidine* can increase the bioavailability of *mebendazole*.

Pediatric and Geriatric Indications and Problems

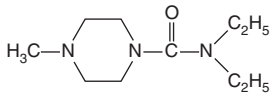
Although neither *albendazole* nor *mebendazole* is recommended for use in pregnancy, a review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects. Hookworm infections occur in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa. Because of the increased morbidity conferred by iron deficiency anemia in pregnancy, monthly BZ treatment has been recommended by the WHO during the second and third trimesters of pregnancy on the basis that improved iron status due to eradication of hookworm infection has a demonstrable benefit for both mother and child. Nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy. There is no evidence that maternal BZ therapy presents a risk to breastfed infants.

The BZs have not been extensively studied in children less than 2 years of age. The recommended dose is 200 mg of *albendazole* in children between the ages of 12 and 24 months. The WHO concluded that BZs may be used in children less than 1 year old if the risks from adverse consequences caused by STHs are justified.

Diethylcarbamazine

Chemistry

Diethylcarbamazine (DEC) (*N,N*-diethyl-4-methylpiperazine-1-carboxamide) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. The drug is soluble in water. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of fortified table salt containing 0.2% to 0.4% by weight of the base. The drug is commercially available outside the U.S.; in the U.S., it is supplied by the U.S. Centers for Disease Control and Prevention (CDC).



DIETHYLCARBAMAZINE

Mechanism of Action

The mechanisms of action of DEC against filarial species are unknown. Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *W. bancrofti, B. malayi*, and *L. loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *O. volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult life cycle stages of *W. bancrofti*, *B. malayi,* and *L. loa* but negligible activity against adult *O. volvulus*.

ADME

DEC is absorbed rapidly from the GI tract. Peak plasma levels occur within 1 to 2 h; the plasma $t_{1/2}$ varies from 2 to 10 h, depending on the urinary pH. Alkalinizing the urine can elevate plasma levels, prolong the plasma $t_{1/2}$, and increase both the therapeutic effect and toxicity of DEC. Dosage reduction may be required for people with renal dysfunction. Metabolism is rapid and extensive; a major metabolite, DEC-*N*-oxide, is active.

Therapeutic Uses

Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

W. bancrofti, B. malayi, and B. timori. The standard regimen for the treatment of lymphatic filariasis traditionally has been a 12-day, 6 mg/kg per day course of DEC. In the U.S., it is common practice to administer small test doses of 50 to 100 mg (1–2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg reportedly has comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen. Single-dose therapy may be repeated every 6 to 12 months, as necessary. Although DEC does not reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent progression of lymphatic damage. For mass treatment to interrupt transmission, effective strategies have included the introduction of DEC into table salt (0.2%–0.4% by weight of the base). As noted above, DEC, when given in combination with *albendazole* and *ivermectin*, is more effective for treatment of lymphatic filariasis than when given alone.

O. volvulus and L. loa. DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions (Molyneux et al., 2003), and *ivermectin* is the preferred drug for this infection. DEC is the drug of choice for therapy of loiasis with some caveats (below). Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2 to 3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for 2 to 3 weeks. In patients with high-grade microfilaremia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. *Albendazole* may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug. DEC is clinically effective against microfilariae and adult worms of *M. streptocerca*. DEC is no longer recommended as a first-line drug for the treatment of toxocariasis.

Adverse Effects and Drug Interactions

Below a daily dose of 8 to 10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae. Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis and small skin wheals in loiasis. The drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhage and life-threatening encephalopathy. In patients with onchocerciasis, the *Mazzotti* reaction, a florid hypersensitivity reaction to release of parasite antigen after mass death of worms, typically occurs within a few hours after the first dose. No significant drug interactions have been reported with DEC.

Precautions and Contraindications

Population-based therapy with DEC should be avoided where onchocerciasis or loiasis may be endemic in sub-Saharan Africa, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine. DEC appears to be safe for use during pregnancy.

Doxycycline

Filarial parasites, including *W. bancrofti* and *O. volvulus,* harbor bacterial symbionts of the genus *Wolbachia*, against which long courses of *doxycycline* (see Chapter 60 for full discussion of *doxycycline*) (≥6 weeks) in bancroftian filariasis and onchocerciasis are effective. A 6-week regimen of *doxycycline* (100 mg daily), by killing the *Wolbachia,* leads to sterility of adult female *Onchocerca* worms.

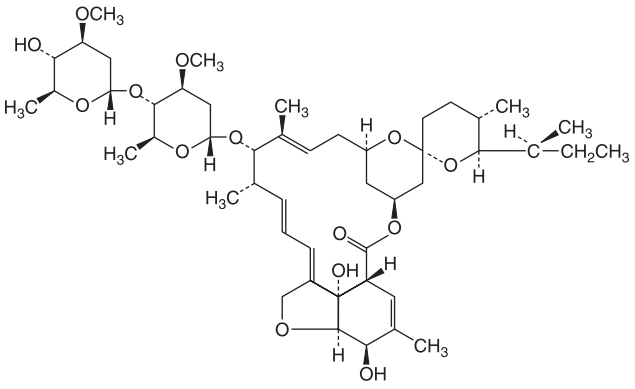
Ivermectin

HISTORY **THE DISCOVERY OF IVERMECTIN: OMURA AND CAMPBELL**

In the mid-1970s, surveys of natural products revealed that a fermentation broth of the soil actinomycete *Streptomyces avermitilis* ameliorated infection with *Nematospiroides dubius* in mice. Isolation of the anthelmintic components from cultures of this organism led to the discovery of the avermectins, a novel class of 16-membered macrocyclic lactones. *Ivermectin* (mectizan; stromectol; 22,23-dihydroavermectin B1a) is a semisynthetic analogue of avermectin B1a (abamectin), an insecticide developed for crop management. *Ivermectin* now is used to treat a broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals (Campbell, 1993). The discoverers of *ivermectin*, Satoshi Omura and William Campbell, won the 2015 Nobel Prize in Physiology/Medicine "for their discoveries concerning a novel therapy against infections caused by roundworm parasites," an award shared with Tu Youyou for "for her discoveries concerning a novel therapy against Malaria."

Chemistry

Ivermectin exists as an odorless off-white powder with high lipid solubility but poor solubility in water. It is a mixture of at least 80% 22,23-dihydroavermectin B1a and no more than 20% 22,23-dihydroavermectin B1b. B1a and B1b have nearly identical antiparasitic activities.



IVERMECTIN

Mechanism of Action

Ivermectin immobilizes affected organisms by inducing a tonic paralysis of the musculature. Avermectins (of which *ivermectin* is a member) induce paralysis by activating a family of ligand-gated Cl^- channels, particularly glutamate-gated Cl^- channels found only in invertebrates. *Ivermectin* probably binds to glutamate-activated Cl^- channels found in nematode nerve or muscle cells and causes hyperpolarization by increasing intracellular chloride concentration, resulting in paralysis. Glutamate-gated Cl^- channels probably are one of several sites of *ivermectin* action among invertebrates. Avermectins also bind with high affinity to γ-aminobutyric acid (GABA)-gated and other ligand-gated Cl^- channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in cestodes and trematodes may explain why these helminths are not sensitive to *ivermectin* (Shoop et al., 1995). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is approximately 100-fold higher. *Ivermectin* interacts with a number of ion channels, Cys-loop receptors, the $P2X_4$ receptor, farnesoid X receptor, and G protein-gated K^+ channel (Chen and Kubo, 2018; Lynagh and Lynch, 2012).

ADME

Peak levels of *ivermectin* in plasma are achieved within 4 to 5 h after oral administration. The long $t_{1/2}$ (~57 h in adults) primarily reflects a low

systemic clearance (~1-2 L/h) and a large apparent volume of distribution. *Ivermectin* is approximately 93% bound to plasma proteins. The drug is extensively metabolized by hepatic CYP3A4 (Zeng et al., 1998). Virtually no *ivermectin* appears in human urine in either unchanged or conjugated form. Although the drug causes significant neurotoxicity in some species such as the beagle dog, in humans, its penetration across the blood-brain barrier is prevented by an efflux pump of the ATP-binding cassette subfamily B member 1 (ABCB1), also known as MDR1 and P-glycoprotein. There is limited experience in the use of a veterinary parenteral preparation of *ivermectin* for treatment of *Strongyloides* hyperinfection.

Therapeutic Uses

Onchocerciasis. *Ivermectin*, administered as a single oral dose (150–200 μg/kg) given every 6 to 12 months, is the drug of choice for onchocerciasis in adults and children 5 years of age or older. Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts for 6 to 12 months; the dose then should be repeated. However, the drug is not curative, because *ivermectin* has little effect on adult *O. volvulus*. Annual doses of the drug are quite safe and substantially reduce transmission of this infection.

Lymphatic Filariasis. *Ivermectin* is as effective as DEC for controlling lymphatic filariasis. As noted above, the combination of *albendazole*, DEC, and *ivermectin* is more efficacious than any of the drugs alone for treatment of lymphatic filariasis. The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms.

Strongyloidiasis. *Ivermectin*, administered as a single dose of 150 to 200 μg/kg, is the drug of choice for human strongyloidiasis (Marti et al., 1996). Although it has been recommended that a second dose be administered a week following the first dose, this has not been demonstrated to improve parasitological response (Buonfrate et al., 2019). *Ivermectin* is more efficacious than a 3-day course of *albendazole*.

Infections With Other Intestinal Nematodes. *Ivermectin* is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection. In the latter two infections, although it is not curative, it significantly reduces the intensity of infection. It also shows efficacy against the zoonotic filarial species *Mansonella ozzardi* when given as a single dose (de Almeida Basano et al., 2018).

Since 2017, *ivermectin* (200 μg/kg) in combination with *albendazole* (400 mg) is on the WHO essential medicine list for the treatment of soil-transmitted helminthiasis (WHO, 2019).

Other Indications. Taken as a single 200-μg/kg oral dose, *ivermectin* is a first-line drug for treatment of cutaneous larva migrans caused by dog or cat hookworms and is an option for treatment of scabies and head lice. In uncomplicated scabies, two doses should be administered 1 to 2 weeks apart. In severe (crusted) scabies, *ivermectin* should be used in repeated doses, with one recommended regimen entailing seven doses of 200 μg/kg given with food on days 1, 2, 8, 9, 15, 22, and 29. The drug formulated as a topical 0.2% lotion is active against human head lice (Pariser et al., 2012).

Adverse Effects and Drug Interactions

Ivermectin is well tolerated by uninfected humans. In filarial infection, *ivermectin* therapy frequently causes a Mazzotti-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the microfilarial burden. After treatment of *O. volvulus* infections, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which occur in 5% to 35% of people, last just a few days, and are relieved by *aspirin* and antihistamines. Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. *Ivermectin* induces milder side effects than does DEC, and unlike DEC, *ivermectin* seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects, occasionally resulting in permanent disability and encephalopathies in patients with heavy *L. loa* microfilaria. *Loa* encephalopathy is associated with *ivermectin* treatment of individuals with *Loa* microfilaremia levels of greater than or equal to 30,000 microfilariae per milliliter of blood. *Ivermectin* interactions with concurrently administered drugs can occur. For example, increased plasma levels of *ivermectin* have been observed in patients treated concurrently with *ivermectin* and *levamisole* (González Canga, 2008). *Ivermectin* may have significant neurotoxicity in certain susceptible individuals who have specific mutations in the *ABC1* gene conferring loss of activity of the efflux pump (Baudou et al., 2020).

Precautions and Contraindications

Because of its effects on GABA receptors in the CNS, *ivermectin* is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). In programs of MDA where loiasis is coendemic with either onchocerciasis or lymphatic filariasis, *ivermectin* should be used with caution and in consultation with local or international experts.

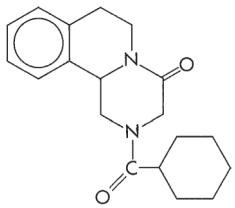
Pediatric and Geriatric Indications and Problems

Ivermectin is not approved for use in children who weigh less than 15 kg or in pregnant or lactating women (low levels of the drug appear in the mother's milk). This is principally due to concerns about the passage of the drug across the immature blood-brain barrier. A recent systematic review and individual patient data analysis showed that *ivermectin* can be safely administered to children who weigh less than 15 kg (Jittamala et al., 2021). Simulations accounting for the higher clearance rates in youth suggest that doses of 300 μg/kg (for ages 2 to 5) and 250μg/kg (for ages 6-12) will achieve ivermectin exposure in children equivalent to that in adults at 200 μg/kg. (Brussee et al., 2019). The safety of *ivermectin* in pregnancy remains to be determined (Westlake and Aronoff, 2021).

Praziquantel

Chemistry

Praziquantel, a pyrazinoisoquinoline derivative, is a racemate, consisting of the biologically active enantiomer, *R-praziquantel* and the inactive distomer *S-praziquantel*. The white crystalline powder is very slightly soluble in water and freely soluble in alcohol and in methylene chloride.



PRAZIQUANTEL

Mechanism of Action

Praziquantel causes Ca^{2+} influx and spastic paralysis of adult worms and rapid vacuolization of the worm surface, activating a schistosome transient receptor potential ion channel (Bais and Greenberg, 2020). The drug is inactive against juvenile schistosomes and therefore is relatively ineffective in early infection.

ADME

Praziquantel is readily absorbed after oral administration (<80%), reaching maximal levels in human plasma in approximately 2 h. The drug is highly protein bound (~80%, nearly exclusive to albumin). *Praziquantel* distributes throughout the body, with highest concentrations measured in the liver and kidneys. It crosses the blood-brain barrier. Breast milk concentrations are approximately 25% of plasma concentrations (Olliaro et al., 2014).

Extensive stereoselective first-pass metabolism takes place. The main metabolite in man is trans-4-hydroxypraziquantel. Plasma $t_{1/2}$ is 2.2 to 8.9 h following 40 mg/kg in healthy fasted adults. In patients with severe liver disease, including those with hepatosplenic schistosomiasis, pharmacokinetic parameters might be altered (Olliaro et al., 2011). About

70% of an oral dose is recovered as metabolites in the urine within 24 h; most of the remainder is eliminated in the bile.

Therapeutic Uses

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. A single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4 to 6 h apart, generally produce cure rates of 70% to 95% and consistently high reductions (>85%) in egg counts (Utzinger and Keiser, 2004). Three doses of 25 mg/kg taken 4 to 8 h apart result in high rates of cure for infections with the liver flukes *C. sinensis* and *Opisthorchis viverrini* or the intestinal flukes *Fasciolopsis buski, Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke, *Paragonimus westermani*. The liver fluke *F. hepatica* is resistant to *praziquantel* and should be treated with *triclabendazole* (Keiser et al., 2005). Low doses of *praziquantel* can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *H. nana* and 10–20 mg/kg for *D. latum, T. saginata*, or *T. solium*). Retreatment after 7 to 10 days is advisable for individuals heavily infected with *H. nana*. Although *albendazole* is preferred for therapy of human cysticercosis, *praziquantel* represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with *dexamethasone* and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

Adverse Effects and Drug Interactions

Abdominal discomfort and drowsiness may occur shortly after taking *praziquantel*; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and may be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2 to 3 days, and respond to analgesics and anticonvulsants. *Praziquantel* is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Driving and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the $t_{1/2}$, requiring dosage adjustment. The bioavailability of *praziquantel* is reduced by inducers of hepatic CYPs such as *carbamazepine* and *phenobarbital*; predictably, coadministration of the CYP inhibitor *cimetidine* has the opposite effect (Dachman et al., 1994). *Dexamethasone* reduces the bioavailability of *praziquantel*. Under certain conditions, *praziquantel* may increase the bioavailability of *albendazole* (Homeida et al., 1994).

Pediatric and Geriatric Indications and Problems

Praziquantel is considered safe in children greater than 4 years old. A pediatric formulation, an oral dispersible tablet based *R-praziquantel*, is under development (Bagchus et al., 2019).

Niclosamide

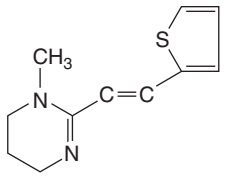
Niclosamide, a halogenated salicylanilide derivative, was introduced for human use as a taeniacide. Niclosamide is no longer approved for use in the U.S. It has some use in intestinal *T. solium* infection where neurocysticercosis is present or cannot be excluded.

Oxantel and Pyrantel Pamoate

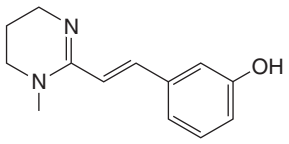
Pyrantel pamoate is a WHO-recommended anthelminthic and widely available; however, *oxantel pamoate* is marketed only in Asia and South America. Efforts are ongoing to register it at a stringent regulatory authority (Palmeirim et al., 2021).

Chemistry

The tetrahydropyrimidine analogue *pyrantel pamoate* and the *m*-oxyphenol analogue of pyrantel, *oxantel pamoate*, are practically insoluble in water and alcohol.



PYRANTEL



OXANTEL

Mechanism of Action

Pyrantel and its analogues are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm. *Pyrantel pamoate* is active at the L type, while *oxantel pamoate* is active at the N subtype, of nicotinic acetylcholine receptors.

Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of *Ascaris* at 1% of the concentration of acetylcholine required to produce the same effect. *Pyrantel* exposure leads to depolarization and increased spike-discharge frequency, accompanied by increases in tension, in isolated helminth muscle preparations (Kopp and Keiser, 2017).

ADME

Pyrantel pamoate and *oxantel pamoate* are poorly absorbed from the GI tract, a property that confines their action to intraluminal GI nematodes. Less than 15% of *pyrantel pamoate* is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.

Therapeutic Uses

Pyrantel pamoate is an alternative to *mebendazole* or *albendazole* for treatment of ascariasis and enterobiasis. High cure rates are achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. *Pyrantel* also is effective against hookworm infections caused by *A. duodenale* and *N. americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. High efficacy against hookworm infections was also observed using a triple combination of *albendazole*, *oxantel pamoate*, and *pyrantel pamoate* (Moser et al., 2018). The drug should be used in combination with *oxantel pamoate* for mixed infections with *T. trichiura*. Indeed, *oxantel pamoate* was shown to have a higher efficacy than the BZs *mebendazole* and *albendazole* against infections with *T. trichiura* (Speich et al., 2016). *Oxantel pamoate* combined with *albendazole* is a highly effective combination in the treatment of ascariasis, trichuriasis, and hookworm infections. For pinworm infections, repeat the treatment after an interval of 2 weeks.

Adverse Events and Drug Interactions

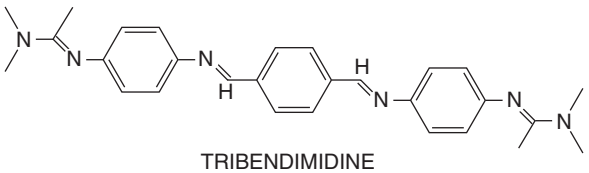
Transient and mild GI symptoms occasionally occur, as do headache, dizziness, rash, and fever. *Pyrantel* and *oxantel pamoate* have not been studied in pregnant women.

Tribendimidine

Tribendimidine is a drug that has been marketed in China for nearly two decades. Given the efforts to introduce the drug to Western markets, it is included in this chapter.

Chemistry

Tribendimidine (a symmetrical diamidine derivative) is a yellow crystalline powder that is soluble in chloroform. It does not dissolve in water and dissolves only marginally in anhydrous ethanol, methanol, or acetone.



TRIBENDIMIDINE

Mechanism of Action

Tribendimidine is an agonist of muscle nicotinic acetylcholine receptors of parasitic nematodes. The drug is more selective for the B-subtype nicotinic acetylcholine receptor (preferentially activated by *bephenium*) than the L-subtype nicotinic acetylcholine receptor (preferentially activated by *levamisole*); thus, *tribendimidine* can activate a specific subset of nematode parasite nicotinic acetylcholine receptors. This relative selectivity might explain why *tribendimidine* exhibits activity on a *levamisole*-resistant isolate of *Oesophagostomum dentatum* and why the spectrum of action of *tribendimidine* is broader (covering also the trematodes *C. sinensis* and *O. viverrini* and cestodes) to that of other cholinergic anthelmintics like *levamisole* (Robertson et al., 2015).

ADME

Tribendimidine pharmacokinetics have been studied in healthy Chinese volunteers (Yuan et al., 2010) and in *O. viverrini*-infected patients (Duthaler et al., 2015). *Tribendimidine* cannot be detected in plasma. It is rapidly and completely broken down to p-(1-dimethylamino ethylimino) aniline (dADT), which is the active metabolite, and to terephthalaldehyde (TPAL). Furthermore, dADT undergoes metabolism to acetylated dADT, and TPAL is transformed into terephalic acid (TPAC). The $t_{1/2}$ of dADT was 4.7 h in healthy volunteers following 400 mg of *tribendimidine*. *Tribendimidine* metabolites are mainly excreted via the urine.

Therapeutic Uses

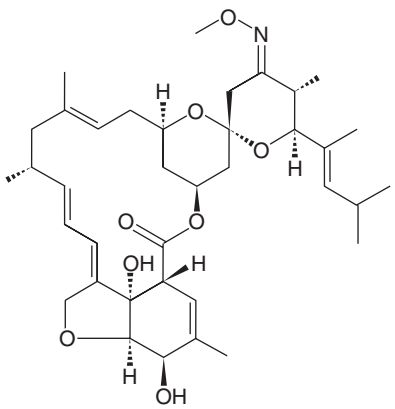
Tribendimidine is given to children younger than 15 years and to adults at doses of 200 mg and 400 mg, respectively. With regard to STH infections, *tribendimidine* has a similar activity profile as *albendazole*: *Tribendimidine* shows high cure and egg reduction rates against *A. lumbricoides*, moderate to good efficacy against hookworm, and low cure rate but moderate egg reduction rates against *T. trichiura*. Against pinworm, infection cure rates with *tribendimidine* were 74.1% (single dose) and 97.1% (two doses) (Xiao et al., 2013). *Tribendimidine* has high activity against *C. sinensis* and *O. viverrini*: Single dosages of *tribendimidine* (200 and 400 mg) show similar efficacy to multiple treatments with *praziquantel* (Qian et al., 2013; Soukhathammavong et al., 2011). The efficacy of *tribendimidine* against *Strongyloides* and cestode infections remains to be studied.

Adverse Events and Drug Interactions

Tribendimidine shows a good safety profile. Adverse events (e.g., dizziness, vertigo, headache, nausea, vomiting, fatigue) are mainly mild and self-limiting. Drug interactions have not yet been studied thoroughly.

Moxidectin

Moxidectin, a macrocyclic lactone related to *ivermectin*, is FDA-approved for the treatment of onchocerciasis due to *O. volvulus* in patients aged 12 years and older.



MOXIDECTIN

Chemistry

Moxidectin, a white or pale-yellow powder, is slightly soluble in water but readily soluble in organic solvents.

Mechanism of Action

The mechanism of action of the avermectins has been described above in the section on *ivermectin*. A different binding activity has been demonstrated between *ivermectin* and *moxidectin* for GABA-gated Cl^- channels. In contrast to *ivermectin*, *moxidectin* is a poor substrate for P-glycoproteins, suggesting a different mechanism or susceptibility to resistance (Cobb and Boeckh, 2009).

ADME

Pharmacokinetic parameters were dose proportional at dosages from 3 to 36 mg. Peak plasma concentrations occur 2 to 6 h after dosing. Administration with food resulted in an increase of over 30% in C_{max} and AUC (integrated area under curve of drug level versus time). In patients with onchocerciasis, *moxidectin* has a very long elimination half-life (mean: 23.3 days) and very large volume of distribution. Following a single dose, *moxidectin* was observed in the breast milk of lactating women (Korth-Bradley et al., 2011). Several hydroxy and oxidative metabolites have been identified *in vitro*; however, in animals, the level of metabolites is low.

Therapeutic Uses

Moxidectin is an effective treatment for *O. volvulus* infections with greater activity than *ivermectin* (Opoku et al., 2018). It also has useful activity in trichuriasis when given with *albendazole* (Keller et al., 2020) and excellent activity in strongyloidiasis (Hofmann et al., 2021) and in an animal model of scabies. The recommended dosage is a single dose of 8 mg (four tablets, each containing 2 mg of *moxidectin*).

Adverse Events and Drug Interactions

Mazzotti reactions, including pruritus, rash, increased pulse rate, and decreased mean arterial pressure, were commonly observed after *moxidectin* treatment (Awadzi et al., 2014). *Moxidectin* can be coadministered with CYP3A4 substrates.

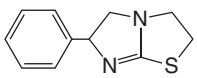
Pediatric and Geriatric Indications and Problems

Moxidectin has not been used in children less than 12 years of age; however, pediatric trials are ongoing.

Levamisole

Chemistry

Levamisole, the levorotatory isomer of the racemic molecule tetramisole, belongs to the imidazole derivatives. The hydrochloride salt is a white powder soluble in water and methanol.



LEVAMISOLE

Mechanism of Action

Levamisole is a cholinergic anthelminthic. The drug is a potent agonist of the L-type nematode nicotinic acetylcholine receptor. Activation of the receptor opens the central channel (see Figures 13–1 and 13–2), producing depolarization, calcium entry, and an increase in sarcoplasmic calcium; this results in spastic muscle contraction, causing the passive elimination of the worms (Martin et al., 2012). *Levamisole* can also inhibit fumarate reductase and hence succinate production, the main source of ATP, which is key for the survival of worms. With regard to mammalian cells, *levamisole* inhibits alkaline phosphatases in most tissues. The drug's immunomodulatory activity has been explained as a stimulation of antibody formation and enhancement of T-cell response by stimulating T-cell activation and proliferation.

ADME

Levamisole is quickly absorbed from the GI tract and C_{Pmax} levels are reached within 2 h. The drug is extensively metabolized in the liver, and its half-life is approximately 4 h (Janssen, 1976).

Therapeutic Uses

Levamisole has excellent activity against *A. lumbricoides* but low to moderate efficacy against *T. trichiura* and hookworm infections (Keiser and Utzinger, 2008). *Levamisole* has also been used for its immunomodulatory effects in cancer. Due to adverse effects (see below), the drug has been withdrawn for human use.

Adverse Events and Drug Interactions

Adverse events mostly occur at high dosages used for immunotherapy. At the single low dosages for anthelminthic therapy, adverse events are minor and include nausea, vomiting, headache, dizziness, or abdominal pain. Severe adverse events such as agranulocytosis have been described following the use of high dosages. In healthy volunteers, increased plasma levels of *ivermectin* and decreased plasma concentrations of *albendazole sulfoxide* were observed when these agents were coadministered with *levamisole* (Awadzi et al., 2004). *Levamisole* has been used as an adulterant in cocaine. *Levamisole*-adulterated cocaine use has been reported to cause neutropenia and agranulocytosis, vasculitis, skin necrosis, and arthralgia, adverse effects that contributed to the withdrawal of *levamisole* for human use (Conrad et al., 2021).

Nitazoxanide

Nitazoxanide (*N*-[nitrothiazolyl] salicylamide) is an oral synthetic broad-spectrum antiparasitic agent that has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). *Nitazoxanide* is approved in the U.S. for treatment of cryptosporidiosis and giardiasis and has activity against *Entamoeba histolytica* (see Chapter 67 for details). In clinical trials, the drug was reported to have activity against a range of STHs, including *A. lumbricoides*, hookworms, *T. trichiura*, *Enterobius vermicularis*, *S. stercoralis*, *H. nana*, and *F. hepatica* (Fox and Saravolatz, 2005). However, subsequent *in vitro* studies and clinical trials have led to some reconsideration of its utility in whipworm and hookworm infection (Speich et al., 2012).

Drug Facts for Your Personal Formulary: *Anthelmintics*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Benzimidazoles: β-Tubulin inhibitors		
Albendazole	• Intestinal nematode infections • Cysticercosis • Cutaneous larva migrans • Toxocariasis • Echinococcosis	• Monitor for liver and hematological toxicity in long-term therapy • Absorption improved with fatty food
Mebendazole	• Intestinal nematode infections	• Poorly absorbed
Triclabendazole	• Fascioliasis	• Available from the CDC under an investigational new drug protocol
Macrocyclic Lactones: Glutamate-gated chloride channel blockers		
Ivermectin	• Onchocerciasis • Lymphatic filariasis • Scabies and head lice • Intestinal nematodes • Strongyloidiasis	• Safety in pregnancy and children <15 kg is uncertain
Moxidectin	• Onchocerciasis • Intestinal nematodes • Strongyloidiasis • Scabies and head lice	• Very long half-life (23 days)
Praziquantel		
	• Schistosomiasis • Food-borne trematode infections (opisthorchiasis and paragonimiasis) • Intestinal tapeworm infections	• Dizziness is a common adverse effect • May impair mental alertness; avoid tasks such as driving
Miscellaneous Anthelmintics		
Diethylcarbamazine	• Lymphatic filariasis	• Contraindicated in onchocerciasis • Available from CDC under an investigational new drug protocol
Niclosamide	• Intestinal tapeworm infection	• Discontinued in the U.S.
Oxantel and pyrantel pamoate	• Pyrantel pamoate is a second-line drug for intestinal nematode infection	• Oxantel pamoate is not licensed for use in the U.S. • Pyrantel pamoate is sold over the counter to treat pinworm infections
Doxycycline	• Filarial infection	• 6-week course of therapy advised
Levamisole		• May cause agranulocytosis at high doses • Discontinued in the U.S.
Nitazoxanide	• Moderately effective against intestinal nematode infection • Antiprotozoal and antiviral activity	• Broad-spectrum antiparasitic agent • Side effects are rare

Chapter 69 General Principles in the Pharmacotherapy of Cancer

Anton Wellstein

Cancer pharmacology has changed dramatically during the recent past, with the improved understanding of cancer biology and an ever-expanding set of new drugs that target vulnerabilities in specific cancers. Effective treatments had been developed earlier for some fatal malignancies, including testicular cancer, lymphomas, and leukemia. Adjuvant chemotherapy and hormonal therapy can extend overall survival and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers; soft-tissue sarcomas; and pediatric solid tumors, thereby allowing for neoadjuvant surgery that is more limited and results in favorable outcomes (Chabner and Roberts, 2005).

In the past 10 years, the ability to harness the power of the immune system in the treatment of cancer has brought about a paradigm shift whereby some of the most feared diseases, such as melanoma and lung cancer and even late-stage metastatic disease, can be eradicated. For some cancers, response rates are surprisingly high: 87% in Hodgkin lymphoma even in heavily pretreated patients (Ansell et al., 2015), and 50% in patients with metastatic melanoma treated with combinations of anti-PD-1 and -CTLA4 immune checkpoint antibodies. Immune checkpoint inhibitors are currently approved for the treatment of over a dozen different cancers that include melanoma and cancers of the bladder, kidneys, liver, lungs as well as Hodgkin lymphoma. In addition to these histologically defined malignancies, any cancers with deficient DNA mismatch repair (e.g., colorectal, ovarian, pancreatic, endometrial cancers) were also approved for treatment.

Despite these major therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than anticancer drugs. A thorough understanding of their mechanisms of action, including clinical pharmacokinetics, drug interactions, and adverse effects, is essential for their safe and effective use. Anticancer drugs are quite varied in structure and mechanism of action. The group includes alkylating agents; antimetabolite analogues of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of small-molecule drugs and antibodies directed at specific molecular targets, such as extracellular receptors, intracellular kinases, or the checkpoints of immune surveillance. Figure 69–1 depicts the cellular targets of these classes of drugs, and Chapters 70 to 73 provide information about them.

Anticancer drugs are increasingly used in a variety of nonmalignant diseases and have become treatment standards, for example, for autoimmune diseases (*rituximab*); rheumatoid arthritis (*methotrexate* and *cyclophosphamide*); Crohn's disease (*6-mercaptopurine*); organ transplantation (*methotrexate* and *azathioprine*); sickle cell anemia (*hydroxyurea*); psoriasis (*methotrexate*); and wet macular degeneration (*ranibizumab* and *aflibercept*).

The Cell Cycle

An understanding of the cell cycle is essential for the rational use of cytotoxic anticancer drugs that target proliferating cells (Figure 69–2). Many cytotoxic agents act by damaging DNA. Their efficacy is thus greatest during S phase, the DNA synthetic phase of the cell cycle. Other agents, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human cancers most susceptible to chemotherapy are those having a high percentage of proliferating cells. However, normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus also susceptible to damage from cytotoxic drugs. In addition, slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or NSCLC) are less responsive to cell cycle–specific drugs.

Although cells from different tumors display differences in the duration of their transit through the cell cycle and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (Figure 69–2):

- A phase that precedes DNA synthesis (G_1)
- A DNA synthesis phase (S)
- An interval following the termination of DNA synthesis (G_2)
- The mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G_1 cells
- A probability of moving into a quiescent state (G_0) for long periods of time

Some anticancer drugs act at specific phases in the cell cycle, mainly at the S and M phases; other drugs are cytotoxic at any point in the cell cycle and are termed *cell cycle phase nonspecific*.

Each transition point in the cell cycle requires the activation of specific cyclin-dependent kinases (*CDKs*), which, in their active forms, couple with corresponding regulatory proteins called *cyclins*. The proliferative impact of CDKs is, in turn, dampened by inhibitory proteins such as $p16^{INK4A}$, a tumor suppressor named for its molecular mass (*p*rotein of *16* kDa) and *in*hibition of CDK*4*. Tumor cells often exhibit changes in cell cycle regulation that lead to relentless proliferation (e.g., mutations or loss of $p16^{INK4A}$ or of other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin, or enhanced CDK activity).

The CDK family consists of over 20 serine/threonine protein kinases that have been among the first pathway targets pursued for the treatment of cancer. However, different tissue selectivities and distinct cell cycle–specific activity periods of the various CDKs provide a challenge for the development of CDK inhibitors. CDK4/6 have become attractive targets because they control cell cycle progression from the G_1 to the

Abbreviations

ABL: Abelson murine leukemia viral oncogene homolog
ALK: anaplastic lymphoma kinase
BCR: breakpoint cluster region
BRAF: B-Raf proto-oncogene ser/thr protein kinase
CAR(T): chimeric antigen receptor T cell
CDK: cyclin-dependent kinase
ctDNA: circulating, cell-free mutant tumor DNA
CTLA4: cytotoxic T lymphocyte–associated protein 4
EGF(R): epidermal growth factor (receptor) [HER1, ErbB-1]
ER: estrogen receptor
FDA: Food and Drug Administration
GI: gastrointestinal
HER1: human EGFR (ErbB-1)
HER2: human EGFR 2 (ErbB-2)
MEK: mitogen-activated protein kinase kinase
MHC: major histocompatibility class (protein)
NCCN: National Comprehensive Cancer Network
NSCLC: non–small cell lung cancer
PARP: poly(ADP-ribose) polymerase
PD-1: programmed cell death 1
PD-L1: programmed cell death ligand 1
SARS-CoV-2: severe acute respiratory syndrome–coronavirus 2
TMB: tumor mutational burden

S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation and inactivation of the retinoblastoma (Rb) protein, followed by the transcription of factors that control transition into the S phase. CDK4/6 inhibition will thus cause a G_1 arrest in susceptible cells that utilize this pathway. CDK4/6 inhibitors were recently approved for the treatment of breast cancer (see Chapter 71).

Because of the central importance of DNA to the identity and functionality of a cell, elaborate cellular mechanisms ("cell cycle checkpoints") have evolved to monitor DNA integrity. At each transition point in the cell cycle, specific proteins, such as p53 and chk-1 and-2, monitor the integrity of DNA and, upon detection of DNA damage, may initiate DNA repair processes, or in the presence of massive damage, direct cells down a pathway of cell death (apoptosis). If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G_1/S or G_2/M boundary. However, if the p53 gene product or other checkpoint proteins are mutated or absent or the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will then emerge as a mutated and potentially drug-resistant subpopulation (see Figure 69–3A).

Cancer Evolution and Drug Discovery

The rapidly expanding knowledge of cancer biology and the ability to analyze cancer genome alterations in thousands of patient samples have led to a better understanding of the molecular evolution of cancer and the discovery of cancer-specific drug targets: growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity,

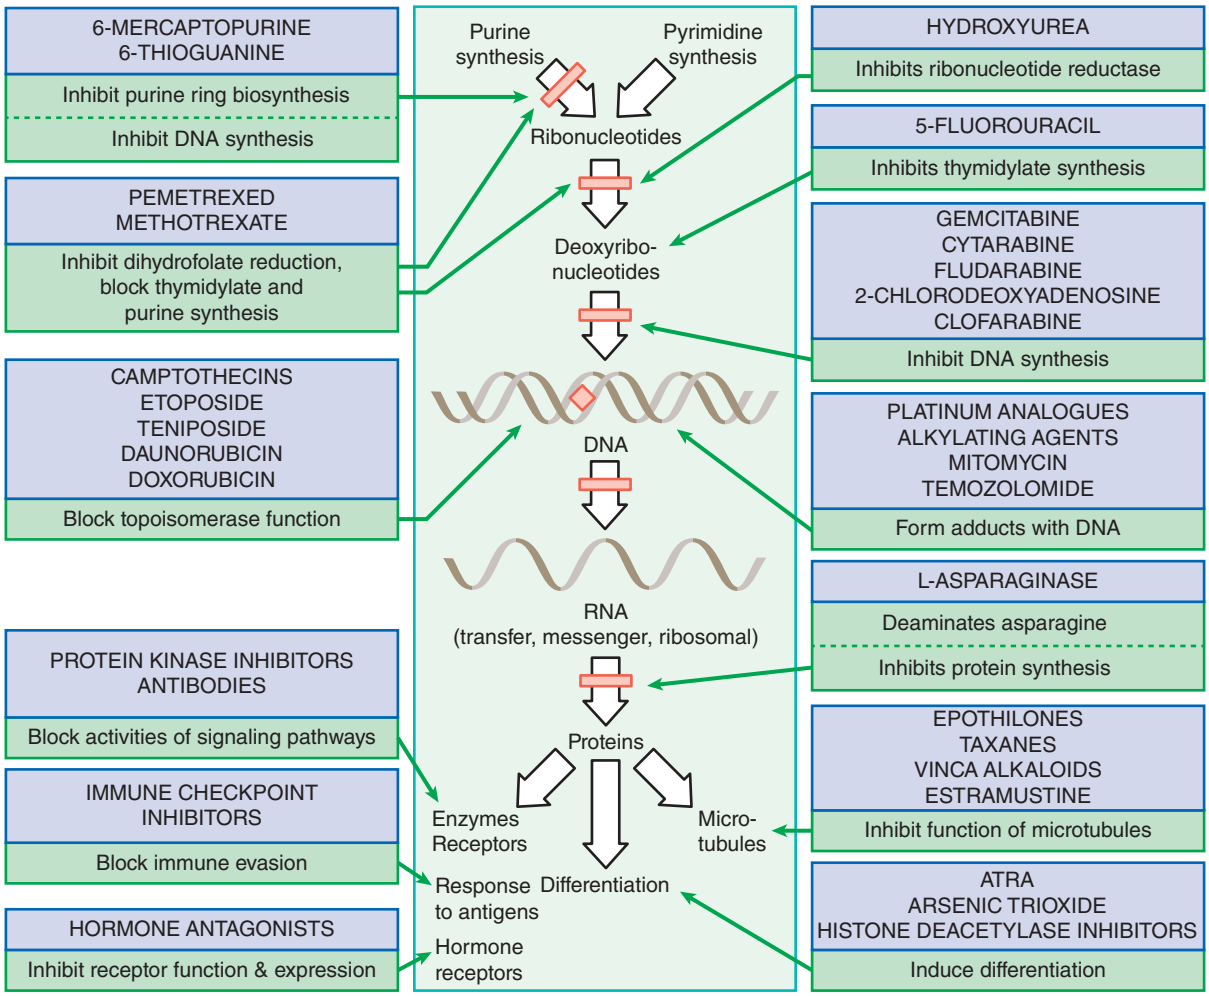

Figure 69–1 *Mechanisms and sites of action of some of the drugs used in the treatment of cancer.*

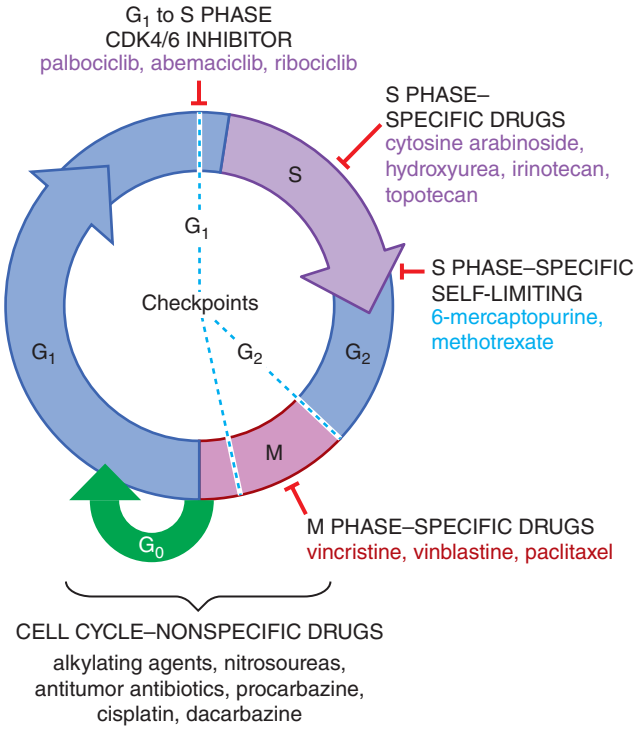

Figure 69–2 *Cell cycle specificity of drugs used in the treatment of cancer.*

DNA repair defects, cell death pathways, and immune escape mechanisms (Hanahan and Weinberg, 2011). Human malignancies are a highly diverse group of diseases that vary even within defined classifications such as organ of origin (lung, breast, prostate, colon, etc.), histology, or molecular marker. Also, the tumor cell population constituting a given cancer at the time of diagnosis has evolved over many years from a few precursor cells that accumulated mutations over time, generating heterogeneity within the primary tumor and at metastatic sites (Figure 69–3).

Clinically detectable cancer lesions represent approximately 1 g of tumor tissue or 10^9 cells and can contain a multitude of subpopulations and a wide variety of genetic alterations (see legend of Figure 69–3). The dynamic evolution of individual cancer genomes and its implications for the development of therapies were established from the analyses of specimens from diverse cancers (Yates and Campbell, 2012). This dynamic was exemplified in a detailed analysis of a series of multiple parallel biopsies from different sites in patients with metastatic melanoma during treatment with inhibitors of mutant BRAF. The genomic analysis of the biopsies revealed complex and distinct evolutionary branching architectures due to the selection of drug-resistant subpopulations during treatment (Shi et al., 2014).

Nevertheless, in many tumors, proliferation and survival of the majority of subpopulations depend on a shared (ancestral) constitutive activity of a single growth factor pathway, or so-called oncogene addiction. Inhibition of that pathway leads to cell death of the sensitive populations. Thus, *imatinib* attacks the unique and specific *bcr-abl* translocation in chronic myelocytic leukemia. *Imatinib* also inhibits *c-kit* and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of *c-kit*. Monoclonal antibodies effectively target tumor-associated antigens such as the amplified *HER2* receptor in breast cancer cells (Slamon et al., 2001). Protein kinase inhibitors targeting mutant EGFR or mutant ALK in lung cancers improve disease outcomes over the use of conventional chemotherapy.

These examples emphasize that new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. One response to the oncogene addiction paradigm has been to group cancers by shared vulnerabilities, include patients in so-called basket trials that evaluate a drug based on its target rather than particular disease entities, and consider sensitivity and resistance to treatments in that context.

However, in the foreseeable future, targeted drugs and cytotoxics will continue to be used in combination. For instance, cytotoxics in combination with monoclonal antibodies such as *trastuzumab* or *bevacizumab* improve efficacy. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better antinausea

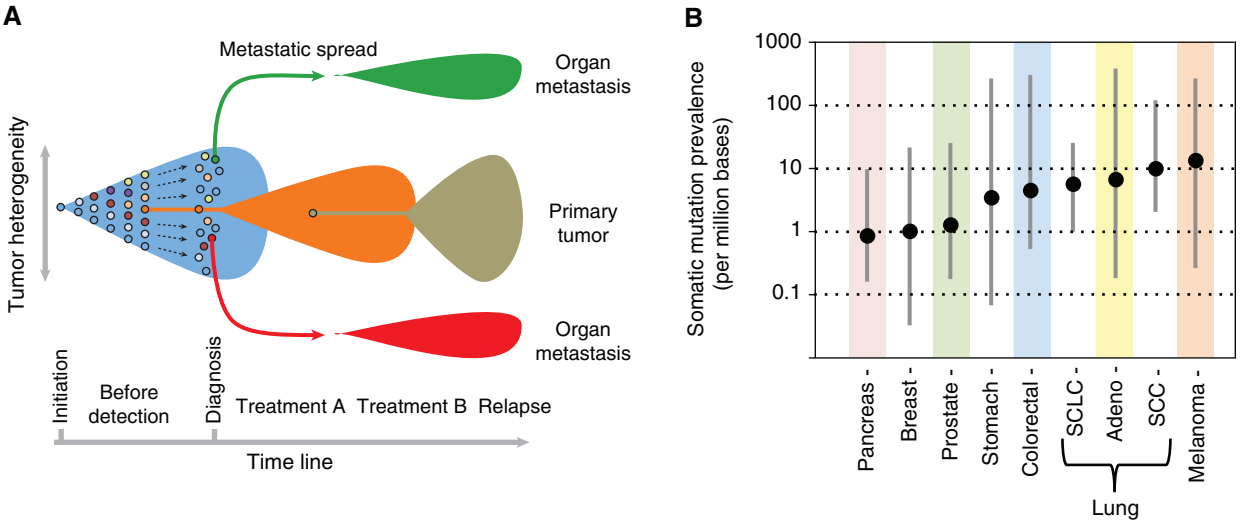

Figure 69–3 *Evolution of treatment resistance; mutational load of human cancers.* **A.** *Treatment resistance.* Cancers accumulate mutations during their evolution. Cancer cell subpopulations are selected based on their growth capacity, adaptation to the tumor microenvironment at the primary or metastatic site, and the evasion of immune surveillance. Drug treatment adds evolutionary pressure and selects for resistant subpopulations. Differently colored dots indicate tumor subpopulations of different genetic or epigenetic makeup. **B.** *Mutational load.* Data are median values ± range of numbers of somatic mutations per million bases observed for some major cancers. Note that the ordinate is a logarithmic scale. In 7042 cancer specimens, between 100 and 1,000,000 mutations were detected per tumor specimen, with a 30- to 1000-fold range among individual specimens from a single cancer type (see original data in Alexandrov et al., 2013). A tumor mutational burden (TMB) of 10 somatic mutations per megabase (= 30,000 mutations in the human genome of 3×10^9 base pairs) results in approximately 150 mutations in amino acid sequences that can alter protein function, drug sensitivity, and antigenicity. In many cancer types, higher TMB is associated with poorer survival. On the other hand, the formation of tumor-specific neoantigens due to DNA mutations permits the immune system to distinguish between tumor and normal cells and contributes to the efficacy of cancer immunotherapy (Schumacher and Schreiber, 2015). Thus, in patients treated with immune checkpoint inhibitors, higher TMB is associated with longer survival. Adeno, adenocarcinoma; SCC, squamous cell carcinoma; SCLC, small cell lung cancer.

medications (see Chapter 54) and with granulocyte colony-stimulating factor to restore bone marrow function (see Chapters 45 and 71).

Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting prosurvival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., *bevacizumab*) normalize blood flow and interstitial pressure, improve drug delivery, and can thus synergize with cytotoxic drugs in the treatment of lung, colon, and other cancers. It is also thought that the combination of cytotoxic drugs or pathway inhibitors can induce tumor cell death and antigen release and thus enhance responses to immune checkpoint inhibitors or other immune modulators. This concept is part of a recommendation for the treatment of patients with melanoma (Kaufman et al., 2013) and should be relevant for a range of cancers (Sharma and Allison, 2015). The ongoing development of activating and inhibitory drugs for additional immune checkpoint pathways (Anderson et al., 2016) will provide new options for drug combinations.

Drug Resistance

Resistance remains the major obstacle to successful cancer treatment. Resistance results from a variety of molecular changes acquired during evolution of a given cancer that can defeat the best-designed treatments. Mechanisms of drug resistance include poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets (Holohan et al., 2013). The processes of resistance are best understood for pathway-targeted drugs. Tumors developing resistance to *bcr-abl* inhibitors and to inhibitors of the EGFR typically express mutations in the target enzyme. Cells exhibiting drug-resistant mutations preexist in a patient's tumor prior to drug treatment and are selected by drug exposure (see Figure 69–3A). Resistance to inhibitors of the EGFR may also develop through expression of an alternative receptor, *c-met*, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2007). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may contribute to resistance to cytotoxic drugs, and a loss of apoptotic pathways can lead to resistance to both cytotoxic and pathway-targeted drugs.

Resistance to immune checkpoint inhibitory drugs appears to follow patterns that are distinct from those of other anticancer drugs, as evidenced by their efficacy in some heavily pretreated patients. One recognized tumor variable of treatment sensitivity is the >30-fold range of the tumor mutational burden (TMB) among patient specimens from a given cancer type (Figure 69–3); TMB is thus used as one marker to assess the likelihood of response or resistance to immunotherapy (Table 69–1). Surprisingly, the composition of the gut microbiome as well as alterations by antibiotic treatment were found to be related to the response of different cancers to immune checkpoint inhibitory drugs, suggesting a potential vulnerability (Finlay et al., 2020; see also Chapter 6). Indeed, recent studies in patients with melanoma suggest that fecal microbiota transplant from appropriate donors may overcome resistance to immunotherapy (Woelk and Snyder, 2021). A major challenge in immunotherapy is the

TABLE 69–1 ■ DIAGNOSTIC TESTS OF CANCER SPECIMENS TO GUIDE TREATMENT DECISIONS

INDIVIDUAL MOLECULAR MARKER (*DNA, mRNA,* PROTEIN)	TARGET: drugs	CANCER INDICATION	CHAPTER
ALK translocation	ALK: alectinib, ceritinib, crizotinib	Lung NSCLC	71

[b]See Figure 69–3.

poor predictability, in individual patients, of the immune responses that govern the success of the treatment. mRNA-based vaccines that contain the coding sequences of antigenic mutations detected in a given tumor are the most recently developed approach to elicit an immune response and enhance the efficacy of immune checkpoint inhibitor treatments (Sahin and Türeci, 2018; Sahin et al., 2020). It is noteworthy that this mRNA-based vaccine approach was also used to generate the first successful vaccines against SARS-CoV-2 (COVID-19).

Finally, T cells carrying chimeric antigen receptors (CARs) can be directed against cancer cells that express specific antigens. CARs are engineered to contain an antigen recognition domain of a monoclonal antibody in the extracellular portion and intracellular signaling domains capable of activating T cells independently of the physiological pathway of antigen presentation by an MHC molecule (see Figures 72–6, 38–2, and 38–4). CD19-targeted CAR T cells reached a 70% to 90% response rate in patients with previously treated, relapsed B-cell leukemias (Khalil et al., 2016), indicating a lack of cross-resistance with conventional therapies. This result is consistent with the requirement for effective combination therapies, that is, complementary mechanisms of action and no overlap in major toxicities. Combinations of immune modulating therapies with pathway-targeted drugs and cytotoxic agents are currently evaluated in national and international trials to generate effective treatment combinations (Hughes et al., 2016).

Molecular Testing to Select Appropriate Drugs

Clinical trials and patient treatments increasingly employ results from biomarker analysis to identify patients likely to benefit from particular treatments and individuals at the greatest risk of toxicity. Some of the tests have been FDA-approved as "companion diagnostics" in conjunction with specific drug therapies (see Table 69–1). Pretreatment testing of tumor specimens is standard practice in selecting patients for antihormonal therapy of breast cancer and for treatment with antibodies such as *trastuzumab* (anti-HER2). Detection of a mutated *KRAS* gene indicates that the tumor of a patient with colorectal cancer will not respond to anti-EGFR antibodies; in patients with lung cancers and EGFR mutations, treatment with *erlotinib*, *gefitinib*, or *afatinib* results in response rates of 70%, and in patients with ALK translocations, the response rates are similar for treatment with the ALK inhibitors *crizotinib* and *ceritinib*. A T790M "gatekeeper" mutation in EGFR (Kobayashi et al., 2005) accounts for about 60% of acquired resistance to first- and second-generation inhibitors but is sensitive to *osimertinib*, a third-generation EGFR inhibitor (Thomas et al., 2015). Overall, introduction of molecular analysis and appropriate choice of pathway-targeted inhibitors in the treatment of NSCLC has increased median survival of patients from less than 1 year to over 3 years and the response rate from 30% to 80% (Ke and Wu, 2016).

Inherited differences in protein sequence polymorphisms or levels of RNA expression can also influence toxicity and antitumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of *5-fluorouracil*, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of *5-fluorouracil*, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual that is homozygous for the polymorphic genes (Van Kuilenburg et al., 2002).

Gene expression profiling, in which the levels of messenger RNA from thousands of genes are surveyed using gene arrays, has revealed tumor profiles that are highly associated with poor outcomes and that warrant adjuvant chemotherapy (Sotiriou and Pusztai, 2009). As an alternative to this broad analysis, small sets of informative genes can be identified and used clinically. One example is a set of 21 genes used in the analysis of samples from patients with early-stage breast cancer. Based on the known association between the expression pattern of the 21 genes and disease outcomes, the analysis of patient samples can predict the risk of disease relapse. Thus, one can identify the patients at a high risk who will benefit from adjuvant chemotherapy (Paik et al., 2004).

Molecular Analysis and Tumor Heterogeneity

One of the caveats to conclusions drawn from the molecular analysis of tumor tissue specimens is the dynamic evolution of cancers noted above (see Figure 69–3). Clinically important mutations in subclones may be missed due to geographically inadequate sampling and may provide the wrong guidance to treatment decisions. Treatment responses of different subpopulations in a tumor or in different metastatic lesions present a further challenge and would require multiple-site tissue biopsies (Shi et al., 2014). The molecular analysis of serially collected blood samples ("liquid biopsies") provides an alternative approach for treatment monitoring.

Liquid Biopsies

More recent technology advances have made it possible to sequence and quantitate circulating, tumor-derived DNA (ctDNA) in blood samples from patients with cancer ("liquid biopsies"), as first demonstrated for the changing abundance of mutant *KRAS* during colon cancer treatment (Diehl et al., 2008). The analysis of ctDNA has shown that during antiestrogen therapy of breast cancer the appearance of mutant estrogen receptor coincides with subsequent resistance to aromatase inhibitor treatment (Schiavon et al., 2015). Furthermore, mutant *KRAS* DNA in the circulation was increased during the treatment of patients with colon cancer with EGFR antibodies but surprisingly reverted to baseline values after cessation of the treatment. This observation demonstrates the dynamic evolution of cancer subpopulations during drug treatment, as indicated in Figure 69–3 (Siravegna et al., 2015). As a consequence of these technological developments, the FDA approved a test for the presence of mutant *EGFR* DNA in blood samples of patients with NSCLC to select candidates for treatment with *erlotinib* or *osimertinib* and thus circumvent the need for a tissue biopsy. The incorporation of liquid biopsies into treatment monitoring can provide additional molecular insights into drug efficacy and adverse effects and reveal the onset of resistance to a chosen treatment (Kilgour et al., 2020).

Achieving Therapeutic Integration and Efficacy

The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size. Pathway-targeted agents, however, may only slow or halt tumor growth, so their effects may be measured in the assessment of time to disease progression; however, for some immune checkpoint inhibitors, tumor lesions may initially increase in size due to cytotoxic lymphocyte infiltration, so called pseudo-progression. Thus, one of the great challenges is to assess efficacy and adjust drug regimens to achieve a therapeutic but nontoxic outcome. Treatment of patients with cancer requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and radiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drug treatment and radiation.

Individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs of the primary choice, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less-quantifiable considerations, such as the natural history of the tumor, the patient's willingness to undergo difficult and potentially dangerous treatments, and the patient's physical and emotional tolerance for adverse effects enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient. In particular, the long-term adverse effects of cytotoxic drugs have been related to the induction of cellular senescence in different organs that resemble symptoms of premature aging and can adversely affect organ function and the overall well-being of patients long after completion of the treatments (Childs et al., 2015; Couzin-Frankel, 2019). The choice of treatment regimen should

 take all of this into account. Finally, in terminally ill patients, the treatment choices must be weighed carefully; the maximal length and highest quality of life may be achieved with palliative care and may reduce the need for chemotherapy (Temel et al., 2010).

A Cautionary Note

Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis: *The pharmacokinetics and toxicities of cancer drugs vary amongst individual patients.* It is imperative to *recognize toxicities early*, to *alter doses or discontinue offending medication* to relieve symptoms and reduce risk, and to *provide vigorous supportive care*. Toxicities affecting the heart, lungs, nervous system, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for each drug's use.

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, among other advances. As a consequence, this chapter and the four that follow present relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the National Comprehensive Cancer Network (NCCN). Table 71–1 provides examples that illustrate the complexities of current therapeutic regimens for two cancers.

Chapter 70 Cytotoxics and Antimetabolites

Anton Wellstein and Edward A. Sausville

Abbreviations

ABVD: ***a***driamycin (doxorubicin), ***b***leomycin, ***v***inblastine, ***d***acarbazine
ADA: adenosine deaminase
ALL: acute lymphoblastic leukemia
AML: acute myeloid leukemia; acute myelocytic leukemia
APL: acute promyelocytic leukemia
Ara-C: cytarabine, cytosine arabinoside
Ara-U: ara-uridine
L-ASP: L-asparaginase
ATO: arsenic trioxide
ATRA: all-*trans* retinoic acid
AUC: area under the curve
BCNU: carmustine [1,3-*bis*-(2-chloroethyl)-1-nitrosourea]
BCRP: breast cancer resistance protein
CCNU: 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine)
CDK: cyclin-dependent kinase
CHOP: *c*yclophosphamide, doxorubicin (***H***), vincristine (***O***), and *p*rednisone
CL_{Cr}: creatinine clearance
CLL: chronic lymphocytic leukemia
CML: chronic myelocytic leukemia; chronic myelogenous leukemia
CSF: cerebrospinal fluid
CTCL: cutaneous T-cell lymphoma
dCK: deoxycytidine kinase
dFdC: 2′,2′-difluorodeoxycytidine, gemcitabine
5′-dFdU: 5′-deoxyfluorodeoxyuridine
DHFR: dihydrofolate reductase
DPD: dihydropyrimidine dehydrogenase
FdUMP: fluorodeoxyuridine monophosphate
FOLFIRINOX: FOLFOX plus irinotecan
FOLFOX: *fol*inic acid, 5*F*U and *ox*aliplatin
5FU: 5-fluorouracil
FUdR: fluorodeoxyuridine or floxuridine or 5-FUdR
GART: glycinamide ribonucleotide transformylase
G-CSF: granulocyte colony-stimulating factor
HbF: hemoglobin (fetal)
HDM-L: high-dose MTX with leucovorin rescue
HGPRT: hypoxanthine guanine phosphoribosyl transferase
HMG: high-mobility group
HRD: homologous recombination DNA repair
HU: hydroxyurea
IMP: inosine monophosphate
MESNA: 2-***m***ercapto***e***thane***s***ulfonate-***Na***$^+$
MGMT: ***O***^{6}-alkyl, **m**ethyl **g**uanine **m**ethyl**tr**ansferase
MMR: mismatch repair
MOPP: nitrogen ***m***ustard, ***o***ncovin (vincristine), ***p***rocarbazine, and ***p***rednisone
6MP: 6-mercaptopurine
MRP: multidrug resistance-associated protein
MTIC: methyl-triazeno-imidazole-carboxamide
MTX: methotrexate
Nab-paclitaxel: albumin-bound nanoparticle solution of paclitaxel
NER: nucleotide excision repair
PG: polyglutamate
Pgp: P-glycoprotein
PML: promyelocytic leukemia
PRPP: 5-phosphoribosyl-1-pyrophosphate
RAR: retinoic acid receptor
RNR: ribonucleoside diphosphate reductase
ROS: reactive oxygen species
TEM: triethylenemelamine
TEPA: triethylenephosphoramide
6TG: 6-thioguanine
Thiotepa: triethylenethiophosphoramide
TPMT: thiopurine methyltransferase
TS: thymidylate synthase
TTP: thymidine triphosphate
VOD: veno-occlusive disease

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, among other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the National Comprehensive Cancer Network (NCCN.org). Table 71–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

I. Alkylating Agents and Platinum Coordination Complexes

HISTORY OF ALKYLATING ANTICANCER DRUGS

The discovery and initial development of alkylating anticancer drugs are based on observations of the effects of chemical warfare in World War I (Chabner and Roberts, 2005). The pervasively toxic sulfur mustard gas that caused topical burns to skin, eyes, lungs, and mucosa also caused aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract (Krumbhaar, 1919). In 1942, Louis Goodman and Alfred Gilman, the originators of this text, demonstrated the activity of nitrogen mustards against mouse lymphoma. Their clinical studies of intravenous nitrogen mustards in patients with lymphoma launched the modern era of cancer chemotherapy (Gilman and Philips, 1946).

Actions Common to Alkylating Drugs

Six major types of alkylating agents are used in the chemotherapy of cancer: *nitrogen mustards*, *ethyleneimines*, *alkyl sulfonates, nitrosoureas, triazenes*, and *methylhydrazines*. Because of similarities in their mechanisms of action and resistance, *platinum complexes* are also discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines

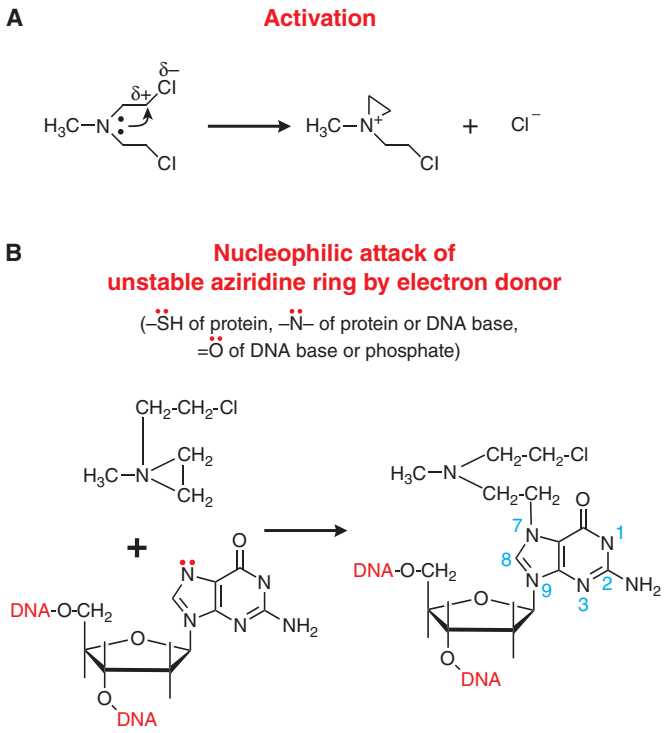

Figure 70–1 *Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard.* **A.** *Activation reaction.* **B.** *Alkylation of N7 of guanine.* With bifunctional drugs such as nitrogen mustards (see Figure 70–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or a nucleic acid to a protein.

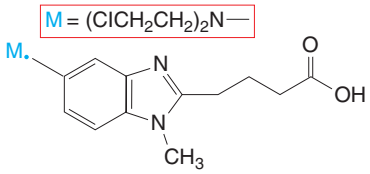
their biological effects (Figure 70–1). Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulfhydryl groups of proteins and the sulfhydryls of glutathione. The general mechanisms of alkylating agents on DNA are illustrated in Figure 70–1 using *mechlorethamine* (nitrogen mustard).

With the bifunctional alkylating agents such as nitrogen mustard and its derivatives that are used therapeutically (Figure 70–2), the second 2-chloroethyl side chain can undergo a similar cyclization reaction and alkylate a second guanine residue or another nucleophilic moiety, resulting in the cross-linking of two nucleic acid chains or the linking of a nucleic acid to a protein, alterations that cause a major disruption in nucleic acid function. Any of these effects can contribute to both the mutagenic and the cytotoxic effects of alkylating agents. The extreme cytotoxicity of the bifunctional alkylators correlates closely with interstrand cross-linkage of DNA.

The ultimate cause of cancer cell death related to drug-induced DNA damage is not known. However, cancer cells depend on mitogenic lesions that drive uncontrolled cell cycle progression but also bring them substantially closer to the threshold at which apoptosis can be triggered by cytotoxic drugs. This contrasts with normal cells that receive their growth and survival cues from their orthotopic environment keeping them far above the apoptosis threshold (Lowe et al., 2004). Genomic instability and the consequent acquisition of tumor mutations are recognized as "enablers" of the neoplastic phenotype (Hanahan and Weinberg, 2011). Such defects in DNA repair defects can render cancer cells more susceptible to death after exposure to DNA-damaging drugs (Costa de Almeida et al., 2021). Specific cellular responses to DNA-damaging agents include cell-cycle arrest and attempts to repair DNA. For example, faulty DNA damage repair mechanisms and mutations of p53 can lead to resistance to alkylating drugs (Kastan, 1999). The process of recognizing and repairing DNA generally requires an intact nucleotide excision repair (NER) complex but may differ with each drug and with each tumor. The specific repair enzyme complex utilized will depend on two factors: the chemistry of the adduct formed and the repair capacity of the cell involved. For example, defects in homologous recombination DNA repair (HRD) can convey relative sensitivity to platinum agents (Stover et al., 2020), and characterization of HRD present in clinical tumors has entered clinical practice as a means of selecting patients who might benefit from specific chemotherapeutic agents.

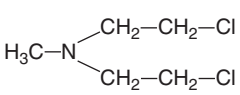
Structure-Activity Relationships

Although alkylating agents share the capacity to alkylate biologically important molecules, modification of the basic backbone structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which determine drug activity *in vivo*. Several of the most used agents (e.g., *cyclophosphamide* and ifosfamides) are prodrugs, and the active alkylating moieties are generated *in vivo* through hepatic metabolism (Figure 70–3) (Arnold et al., 1958; Wagner, 1994).

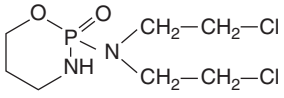


BENDAMUSTINE

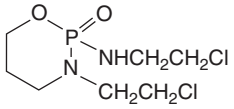
The more recently approved alkylating agent, ***bendamustine***, differs from the other cross-linking agents by having the typical chloroethyl reactive groups in nitrogen mustard (M) attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and is approved for treatment of chronic lymphocytic leukemia (CLL) and large-cell lymphomas refractory to standard alkylators. Newer investigational alkylating agents include *fotemustine*, which is approved in Europe, and *evofosfamide,* a hypoxia-activated prodrug (Yan et al., 2020).



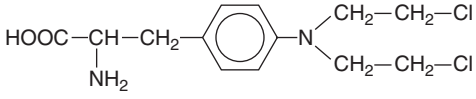
MECHLORETHAMINE



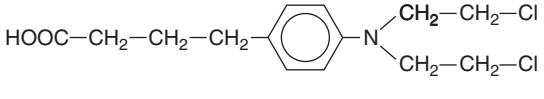
CYCLOPHOSPHAMIDE



IFOSFAMIDE



MELPHALAN



CHLORAMBUCIL

Figure 70–2 *Nitrogen mustards employed in therapy.*

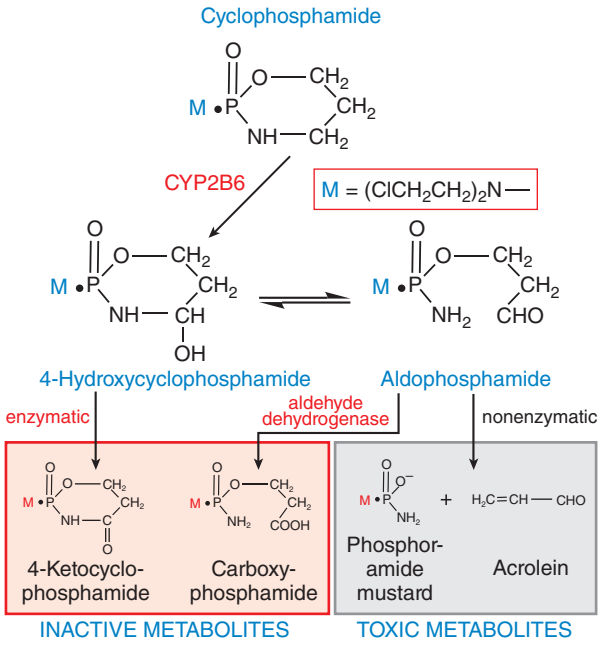


Figure 70–3 *Activation and metabolism of cyclophosphamide. Cyclophosphamide* is activated (hydroxylated) by CYP2B6, with subsequent transport of the activated intermediate to the sites of action. The selectivity of *cyclophosphamide* for some cancer types results from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways and the lack thereof in cancer cells. *Ifosfamide* is structurally similar to *cyclophosphamide* (see Figure 70–2); whereas *cyclophosphamide* has two chloroethyl groups on the exocyclic nitrogen atom, one of the 2-chloroethyl groups of *ifosfamide* is on the cyclic phosphoramide nitrogen of the oxazaphosphorine ring. *Ifosfamide* is activated by hepatic CYP3A4 and proceeds more slowly than activation of *cyclophosphamide*, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of *ifosfamide* required for equitoxic effects, the greater neurotoxicity of *ifosfamide*, and perhaps differences in the antitumor spectra of *cyclophosphamide* and *ifosfamide*.

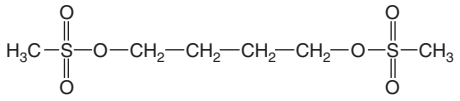
One class of alkylating agents transfers methyl rather than ethyl groups to DNA: The *triazene* derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually called *dacarbazine* or DTIC, is prototypical of methylating agents. *Dacarbazine* requires initial activation by hepatic CYPs through an *N*-demethylation reaction. In the target cell, spontaneous cleavage of the metabolite, methyl-triazeno-imidazole-carboxamide (MTIC), yields an alkylating moiety, a methyl diazonium ion. A related triazene, *temozolomide*, undergoes spontaneous, nonenzymatic activation to MTIC. It is able to cross the blood-brain barrier and has been shown to have significant activity against gliomas.

The *nitrosoureas,* which include compounds such as 1,3-*bis*-(2-chloroethyl)-1-nitrosourea (*carmustine* [BCNU]), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (*lomustine* [CCNU]), and its methyl derivative (*semustine* [methyl-CCNU]), as well as the antibiotic *streptozocin*, exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion. As with the nitrogen mustards, interstrand DNA cross-linking appears to be the primary lesion responsible for the cytotoxicity of nitrosoureas. The reactions of the nitrosoureas with macromolecules are shown in Figure 70–4. The use of nitrosoureas is presently limited to brain tumors due to their lipophilicity, except for *streptozocin*, which is uniquely useful in pancreatic islet cell tumors, perhaps reflecting the selective uptake of the carbohydrate portion of the drug into these tumor cells.

Stable ethyleneimine derivatives have antitumor activity; *triethylenemelamine* (TEM) and *thiotepa* have been used clinically. In standard doses, *thiotepa* produces mostly myelosuppression; it is used for high-dose chemotherapy regimens in transplants for hematological malignancies, in which it causes both mucosal and CNS toxicity. *Altretamine* (hexamethylmelamine, HMM) is chemically similar to TEM and has been used to treat ovarian cancer. The methylmelamines are *N*-demethylated by hepatic microsomes with the release of formaldehyde; there is a direct relationship between the degree of the demethylation and their antitumor activity in model systems.

Esters of alkane sulfonic acids alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.



BUSULFAN

General Pharmacological Actions

Cytotoxic Actions

The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes); effects in these tissues usually are delayed. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. In nondividing cells, DNA damage activates a checkpoint that depends on the presence of a normal *p53* gene. Cells thus blocked in the G_1/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent *p53* fail to suspend cell-cycle progression, do not undergo apoptosis, and can exhibit resistance to these drugs.

Distinction Between Mono- and Bifunctional Agents

Although DNA is the ultimate target of all alkylating agents, there is a crucial distinction between the bifunctional agents, in which cytotoxic

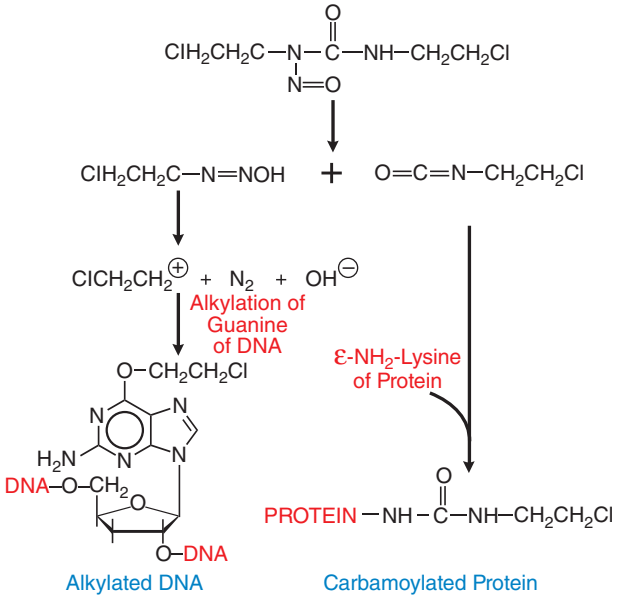


Figure 70–4 *Generation of alkylating and carbamylating intermediates from carmustine (BCNU).* The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate guanine, cytidine, and adenine bases. Displacement of the halogen atom can then lead to interstrand or intrastrand cross-linking of DNA. The formation of cross-links after the initial alkylation reaction proceeds slowly and can be reversed by the DNA repair enzyme MGMT, which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas and to other methylating agents, including *dacarbazine*, *temozolomide*, and *procarbazine*.

effects predominate, and the monofunctional methylating agents (*procarbazine*, *temozolomide*), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. Conversely, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify a DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as *procarbazine*, are highly carcinogenic.

Adduct recognition systems and DNA repair systems play important roles in removing adducts and thereby determine the selectivity of action against particular cell types and the acquisition of resistance to alkylating agents. Alkylation of a single strand of DNA (monoadducts) is repaired by the NER pathway. The less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the potentially error-free HRD pathway. After drug infusion in humans, monoadducts appear rapidly and peak within 2 h of drug exposure, while cross-links peak at 8 h. The $t_{1/2}$ for repair of adducts varies amongst normal tissues and tumors; in peripheral blood mononuclear cells, both monoadducts and cross-links disappear with a $t_{1/2}$ of 12 to 16 h.

The repair process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as *mitomycin*, *cisplatin*, or classical alkylators. Other repair enzymes are specific for removing methyl and ethyl adducts from the O6 of guanine (methyl guanine methyltransferase [MGMT]) and for repair of alkylation of the N3 of adenine and N7 of guanine (3-methyladenine-DNA glycosylase). High expression of MGMT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the MGMT gene in brain tumors are associated with clinical response to BCNU and *temozolomide* (Hegi et al., 2008). *Bendamustine* differs from classical chloroethyl alkylators in activating base excision repair, rather than the more complex double-strand break repair or MGMT. It impairs physiological arrest of adduct-containing cells at mitotic checkpoints, leads to mitotic catastrophe rather than apoptosis, and does not require an intact p53 to cause cytotoxicity.

Recognition of DNA adducts is an essential step in promoting attempts at repair and ultimately leading to apoptosis. The Fanconi pathway, consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation. Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, *cisplatin* and *carboplatin*, and thiopurine analogues, the mismatch repair (MMR) pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.

Mechanisms of Resistance to Alkylating Drugs

Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include the following:

- Decreased permeation of actively transported drugs (e.g., *mechlorethamine* and *melphalan*)
- Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates
- Increased activity of DNA repair pathways, which may differ for the various alkylating agents
- Increased rates of metabolic degradation of the activated forms of *cyclophosphamide* and *ifosfamide* to their inactive keto and carboxy metabolites by aldehyde dehydrogenase (see Figure 70–3) and detoxification of most alkylating intermediates by glutathione transferases
- Loss of ability to recognize adducts formed by nitrosoureas and methylating agents, as the result of defective MMR protein capability, confers resistance, as does defective cell-cycle checkpoint function, for virtually all alkylating drugs
- Impaired apoptotic pathways, with overexpression of bcl-2 as an example, confer resistance

Adverse Effects of Alkylating Drugs

Alkylating agents differ in their patterns of the tissue specificity and severity of their adverse effects, which are summarized next.

Bone Marrow

Most alkylating agents cause dose-limiting toxicity to marrow cells and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., *melphalan*, *chlorambucil*, *cyclophosphamide*, and *ifosfamide*) cause myelosuppression, with a nadir of the peripheral blood granulocyte count at 6 to 10 days and recovery in 14 to 21 days. *Cyclophosphamide* has lesser effects on peripheral blood platelet counts than do the other agents. *Busulfan* suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogenic bone marrow transplantation. *Temozolomide*, *carmustine*, and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4 to 6 weeks after drug administration and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have, therefore, been used to treat various autoimmune diseases. Immunosuppression is reversible at usual doses, but opportunistic infections may occur with extended treatment.

Mucosa, Hair Follicles

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia. Mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow transplantation, as they predispose to bacterial sepsis arising from the GI tract. In these protocols, *cyclophosphamide*, *melphalan*, and *thiotepa* have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, other toxicities become limiting (Table 70–1).

Nervous System

Nausea and vomiting commonly follow administration of nitrogen mustard or BCNU. *Ifosfamide* is the most neurotoxic of the alkylating agents

TABLE 70–1 ■ DOSE-LIMITING EXTRAMEDULLARY TOXICITIES OF SINGLE ALKYLATING AGENTS

DRUG	MTD[a] mg/m²	FOLD INCREASE OVER STANDARD DOSE	MAJOR ORGAN TOXICITIES
Cyclophosphamide	7000	7	Cardiac, hepatic VOD
Ifosfamide	16,000	2.7	Renal, CNS, hepatic VOD
Thiotepa	1000	18	GI, CNS, hepatic VOD
Melphalan	180	5.6	GI, hepatic VOD
Busulfan	640	9	GI, hepatic VOD
Carmustine (BCNU)	1050	5.3	Lung, hepatic VOD
Cisplatin	200	2	PN, renal
Carboplatin	2000	5	Renal, PN, hepatic VOD

GI, gastrointestinal; PN, peripheral neuropathy; VOD, veno-occlusive disease.
[a]Maximum tolerated dose (cumulative) in treatment protocols.

and may produce altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects result from the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of *ifosfamide*. High-dose *busulfan* can cause seizures in up to 10% of patients without prophylaxis.

Other Organs

All alkylating agents, including *temozolomide*, have caused pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing *busulfan* or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver (see Table 70–1), an often-fatal side effect that is successfully reversed by *defibrotide*. *Defibrotide* is an oligonucleotide mixture with profibrinolytic properties that is FDA-approved for the treatment of adult and pediatric patients with hepatic VOD but may cause hemorrhage as an adverse effect. The nitrosoureas and *ifosfamide*, after multiple cycles of therapy, may lead to renal failure. *Cyclophosphamide* and *ifosfamide* release a nephrotoxic and urotoxic metabolite, acrolein, which causes severe hemorrhagic cystitis in high-dose regimens. This adverse effect can be prevented by coadministration of MESNA (2-mercaptoethanesulfonate-Na^+), which conjugates acrolein in urine. *Ifosfamide* in high doses for hematopoietic stem cell transplant causes a chronic, and often irreversible, renal toxicity; its nephrotoxicity correlates with the total dose of drug received and increases in frequency in children younger than 5 years. The syndrome may be due to chloroacetaldehyde or acrolein excreted in the urine.

The more unstable alkylating agents (e.g., *mechlorethamine* and the nitrosoureas) have strong vesicant properties, damage veins with repeated use, and, if extravasated, produce ulceration. All alkylating agents have toxic effects on the male and female reproductive systems, causing an often-permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

Leukemogenesis

Alkylating agents have a high capacity to induce leukemia. Acute nonlymphocytic leukemia, induced by treatment, is often associated with a higher incidence of p53 mutations, partial or total deletions of chromosome 5 or 7, and reduced response to chemotherapy. Incidence peaks about 4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia. *Melphalan*, the nitrosoureas, and the methylating agent *procarbazine* have the greatest propensity to cause leukemia, which is less common after *cyclophosphamide*.

Clinical Pharmacology of Nitrogen Mustards

Mechlorethamine

Mechlorethamine HCl was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of cutaneous T-cell lymphoma (CTCL) as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by *cyclophosphamide*, *melphalan*, and other more stable alkylating agents.

Cyclophosphamide

ADME

Cyclophosphamide is well absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 70–3). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxycyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells, where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramide mustard and acrolein. Phosphoramide mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with *cyclophosphamide*.

Pretreatment with CYP inducers such as *phenobarbital* enhances the rate of activation of the azoxyphosphorenes but does not alter total exposure to active metabolites over time and does not affect toxicity or efficacy. *Cyclophosphamide* can be used in full doses in patients with renal dysfunction because it is eliminated by hepatic metabolism. Patients with significant hepatic dysfunction should receive reduced doses. Maximal plasma concentrations are achieved about 1 h after oral administration; the $t_{1/2}$ of parent drug in plasma is about 7 h.

Therapeutic Uses

Cyclophosphamide is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and doses of *cyclophosphamide* in combination with other chemotherapeutic agents should be consulted. The neutrophil nadir of 500 to 1000 cells/mm^3 generally serves as a lower limit for dosage adjustments in prolonged therapy.

The clinical spectrum of activity for *cyclophosphamide* is broad. It is an essential component of many effective drug combinations for non-Hodgkin lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions have been reported when *cyclophosphamide* was given as a single agent for Burkitt lymphoma. It frequently is used in combination with *doxorubicin* and a taxane as adjuvant therapy after surgery for breast cancer. Because of its potent immunosuppressive properties, *cyclophosphamide* has been used to treat autoimmune disorders, including Wegener granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for nonneoplastic conditions, not only because of its toxic effects but also because of its potential for inducing premature menopause, sterility, teratogenic effects, and leukemia.

Adverse Effects

Phosphoramide mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with *cyclophosphamide*. Patients should receive vigorous intravenous hydration during high-dose treatment. Hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening and may require cystectomy for control of bleeding. Inappropriate secretion of antidiuretic hormone has been observed (usually at doses greater than 50 mg/kg) and can lead to water intoxication because these patients usually are vigorously hydrated. In addition to the cystitis (counteracted by MESNA and diuresis), GI, pulmonary, renal, hepatic, and cardiac toxicities (hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses greater than 200 mg/kg.

Ifosfamide

Ifosfamide is an analogue of cyclophosphamide. Severe urinary tract and CNS toxicity initially limited the use of *ifosfamide*, but adequate hydration and coadministration of MESNA have reduced its bladder toxicity. CNS toxicity is handled with methylene blue (Pelgrims et al., 2000).

ADME

Ifosfamide has a plasma elimination $t_{1/2}$ of approximately 1.5 h after doses of 3.8 to 5 g/m^2 and a somewhat shorter $t_{1/2}$ at lower doses; its pharmacokinetics are highly variable due to variable rates of hepatic metabolism (see legend to Figure 70–3).

Therapeutic Uses

Ifosfamide is approved for treatment of patients with relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric or adult patients with sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue. In nonmyeloablative regimens, *ifosfamide* is infused intravenously

over at least 30 min at a dose of 1.2 g/m^2 per day or less for 5 days. Intravenous MESNA is given as bolus injections in a dose equal to 20% of the *ifosfamide* dose concomitantly and an additional 20% again 4 and 8 h later, for a total MESNA dose of 60% of the *ifosfamide* dose. Alternatively, MESNA may be given concomitantly in a single dose equal to the *ifosfamide* dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3 to 4 weeks.

Adverse Effects

Ifosfamide has a similar toxicity profile as *cyclophosphamide*, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and urothelial damage. In high-dose regimens (i.e., total doses of 12–14 g/m^2), it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 h to 7 days after beginning the *ifosfamide* infusion. This toxicity may result from a metabolite, chloroacetaldehyde. *Ifosfamide* also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

Melphalan

The alkylating agent *melphalan* primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation. The general pharmacological and cytotoxic actions of *melphalan* are similar to those of other bifunctional alkylators.

ADME

Oral *melphalan* is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a plasma $t_{1/2}$ of about 45 to 90 min; 10% to 15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

Therapeutic Uses and Adverse Effects

Melphalan for multiple myeloma is administered orally for 4 to 7 days every 28 days, with *dexamethasone* or *thalidomide*. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. *Melphalan* also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. The toxicity of *melphalan* is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction. The drug is not a vesicant.

Chlorambucil

The cytotoxic effects of *chlorambucil* on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, *chlorambucil* is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or greater.

ADME

Oral absorption of *chlorambucil* is adequate and reliable. The drug has a $t_{1/2}$ in plasma of about 1.5 h and is hydrolyzed to inactive products.

Therapeutic Uses and Adverse Effects

Chlorambucil historically was used almost exclusively in treating CLL; modern approaches to CLL frequently employ as first-line treatments noncytotoxic approaches such as modulators of B-cell antigen receptor signaling (see Chapter 71). When these agents are not available or not tolerated or as treatment for relapsed disease, *chlorambucil* may be given once daily and continued for 3 to 6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy often is required to maintain clinical response. *Chlorambucil* treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Marked hypoplasia of the bone marrow may be induced with excessive doses, but the myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of acute myeloid leukemia (AML) and other tumors was noted when *chlorambucil* was used historically in the treatment of patients with polycythemia vera and as adjuvant chemotherapy after primary removal of breast cancers.

Bendamustine

Bendamustine is approved for treatment of CLL and non-Hodgkin lymphoma. *Bendamustine* is given as a 30-min intravenous infusion on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pretreated patients. *Bendamustine* is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules; less than 5% of the parent drug is excreted in the urine intact. *N*-Demethylation and oxidation produce metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a plasma $t_{1/2}$ of about 30 min. The clinical toxicity pattern of *bendamustine* is typical of alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable.

Ethyleneimines and Methylmelamines

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, other alkylators such as ethyleneimines with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

Altretamine

Altretamine is structurally similar to TEM. Its precise mechanism of cytotoxicity is unknown, although it can alkylate DNA and proteins. It is a palliative treatment of patients with persistent or recurrent ovarian cancer following *cisplatin*-based combination therapy. The usual dosage of *altretamine* as a single agent in ovarian cancer is 260 mg/m^2 per day in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

ADME

Altretamine is well absorbed from the GI tract; its elimination $t_{1/2}$ is 4 to 10 h. The drug undergoes rapid demethylation in the liver; the principal metabolites are pentamethylmelamine and tetramethylmelamine.

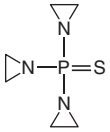
Adverse Effects

The main toxicities of *altretamine* are myelosuppression and neurotoxicity. *Altretamine* causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate on discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage if the white cell count falls to less than 2000 cells/mm^3 or the platelet count falls to less than 75,000 cells/mm^3 or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, *altretamine* should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive monoamine oxidase inhibitors, *amitriptyline*, *imipramine*, or *phenelzine* concurrently with *altretamine*.

Thiotepa

Thiotepa consists of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Hepatic CYPs rapidly convert

thiotepa to its desulfurated primary metabolite, triethylenephosphoramide (TEPA). Both *thiotepa* and TEPA form DNA cross-links.



ADME

Within hours of *thiotepa* administration, TEPA becomes the predominant form of the drug present in plasma. The parent compound has a plasma $t_{1/2}$ of 1.2 to 2 h; TEPA has a longer $t_{1/2}$, 3 to 24 h. *Thiotepa* pharmacokinetics essentially are the same in children as in adults at conventional doses (≤80 mg/m^2), and drug and metabolite $t_{1/2}$ are unchanged in children receiving high-dose therapy of 300 mg/m^2 per day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite.

Adverse Effects

Toxicities include myelosuppression and, to a lesser extent, mucositis. Myelosuppression tends to develop somewhat later than with *cyclophosphamide*, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high doses, *thiotepa* may cause neurotoxic symptoms, including coma and seizures.

Alkyl Sulfonates

Busulfan

Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of *imatinib mesylate*, was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. *Busulfan* now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic VOD are important toxicities.

ADME

Busulfan is well absorbed after oral administration and has a plasma $t_{1/2}$ of 2 to 3 h. The drug is conjugated to glutathione by GSTA1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. In high doses, children less than 18 years of age clear the drug two to four times faster than adults and tolerate higher doses. *Busulfan* clearance varies considerably among patients. VOD is associated with high area under the curve (AUC; >1500 μM × min) and slow clearance, leading to recommendations for dose adjustment based on drug-level monitoring. A target steady-state concentration of 600 to 900 ng/mL in plasma in adults or AUC of less than 1000 μM × min in children achieves an appropriate balance between toxicity and therapeutic benefit.

Therapeutic Uses

The use of *busulfan* in initially treating Philadelphia chromosome–positive chronic myelocytic leukemia (CML) has been essentially supplanted by inhibitors of the oncogenic protein tyrosine kinase bcr-abl (see Chapter 71). However, where those agents are not available or not tolerated, the initial oral dose of *busulfan* varies with the total leukocyte count and the severity of the disease; daily doses are adjusted to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to 10,000 cells/mm^3 or less. A decrease in the leukocyte count usually is not seen during the first 10 to 15 days of treatment, and the leukocyte count may actually increase during this period. Because the leukocyte count may fall for more than 1 month after discontinuing the drug, it is recommended that *busulfan* be withdrawn when the total leukocyte count has declined to about 15,000 cells/mm^3. A normal leukocyte count usually is achieved within 12 to 20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches about 50,000 cells/mm^3.

In high-dose therapy as preparation for stem cell transplants, anticonvulsants must be used concomitantly with busulfan to protect against acute CNS toxicities, including tonic-clonic seizures that may occur several hours after each dose. Although *phenytoin* is a frequent choice, *phenytoin* induces the glutathione S-transferases that metabolize *busulfan*, reducing its AUC by about 20%. In patients requiring concomitant antiseizure medication, non–enzyme-inducing benzodiazepines such as *lorazepam* and *clonazepam* are recommended as an alternative to *phenytoin*. If *phenytoin* is used concurrently, plasma *busulfan* levels should be monitored and the *busulfan* dose adjusted accordingly (Salinger et al., 2010).

Adverse Effects

The toxic effects of *busulfan* are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use is associated with pulmonary fibrosis (*busulfan* lung) and leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose *busulfan* causes VOD of the liver in 10% or fewer of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and *metronidazole*, possibly through inhibition of the clearance of *busulfan* or its toxic metabolites.

Nitrosoureas

The nitrosoureas, except *streptozocin*, have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and *lomustine* (CCNU, not discussed in detail) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of *streptozocin*, nitrosoureas cause profound and delayed myelosuppression, with recovery 4 to 6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially *semustine* (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylating moieties (see Figure 70–4).

Carmustine (BCNU) and Lomustine (CCNU)

Carmustine's major action is its alkylation of DNA at the O6-guanine position, an adduct repaired by MGMT. Methylation of the MGMT gene promoter inhibits its expression in about 30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, *carmustine* (BCNU) produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia. With repeated treatment courses at even conventional doses, its orally administered monochloroethyl analog *lomustine* (CCNU), can be associated with pulmonary dysfunction and prolonged bone marrow toxicity.

ADME

Carmustine (BCNU) is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable $t_{1/2}$ of 15 to 90 min or more. Approximately 30% to 80% of the drug appears in the urine within 24 h as degradation products. The alkylating metabolites enter rapidly into the CSF, and their concentrations in the CSF reach 15% to 30% of the concurrent plasma values.

Therapeutic Uses

Carmustine (BCNU) is administered intravenously over 1 to 2 h and repeated every 6 weeks. *Lomustine* (CCNU) is orally bioavailable. Because of their ability to cross the blood-brain barrier, BCNU and CCNU have been used in the treatment of malignant gliomas. An implantable

carmustine (BCNU) wafer is available for use as an adjunct to surgery for recurrent glioblastoma multiforme.

Streptozocin

Streptozocin (or streptozotocin) has a methylnitrosourea moiety attached to the C2 of glucose. The drug has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

ADME

Streptozocin is rapidly degraded following intravenous administration. The $t_{1/2}$ of the drug is about 15 min. Only 10% to 20% of a dose is recovered intact in the urine.

Therapeutic Uses

Streptozocin is used in the treatment of human pancreatic islet cell carcinoma and carcinoid tumors. It is administered intravenously once daily for 5 days; this course is repeated every 6 weeks. Alternatively, a higher dose can be given weekly for 2 weeks, and the weekly dose then can be increased as tolerated.

Adverse Effects

Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in fewer than 10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. *Streptozocin* should not be given with other nephrotoxic drugs. Hematological toxicities (anemia, leukopenia, thrombocytopenia) occur in 20% of patients.

Triazenes

Dacarbazine (DTIC)

Dacarbazine functions as a methylating agent after metabolic activation in the liver to the monomethyl triazeno metabolite MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O6-guanine bases in DNA by MGMT activity.

ADME

Dacarbazine is administered intravenously. After an initial rapid phase ($t_{1/2}$ of ~20 min), *dacarbazine* is cleared from plasma with a terminal $t_{1/2}$ of about 5 h. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion.

Therapeutic Uses

The primary clinical indication for *dacarbazine* is in the chemotherapy of Hodgkin disease. In combination with other drugs for Hodgkin disease, *dacarbazine* is given on days 1 and 15 and repeated every 4 weeks for up to six cycles. It is modestly effective against malignant melanoma and adult sarcomas. *Dacarbazine* for malignant melanoma is given for a 10-day period, repeated every 28 days; alternatively, it can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. Its use in patients with melanoma has largely been replaced by immune checkpoint inhibitors and agents targeting the typically activated mitogen-activated protein kinase pathway (see Chapters 71 and 72).

Adverse Effects

Dacarbazine induces nausea and vomiting in more than 90% of patients; vomiting usually develops 1 to 3 h after treatment and may last up to 12 h. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1 to 2 weeks. A flu-like syndrome may occur. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

Temozolomide

Temozolomide is the standard agent, in combination with radiation therapy, for initial treatment of patients with high-grade malignant gliomas. *Temozolomide*, like *dacarbazine*, forms the methylating metabolite MTIC, but without the need for hepatic metabolism, and kills cells in all phases of the cell cycle. It is more active in MGMT-deficient tumors.

ADME

Temozolomide is administered orally and has a bioavailability approaching 100%. Plasma levels of the parent drug decline with a $t_{1/2}$ of 1 to 2 h. The primary active metabolite MTIC reaches a maximum plasma concentration (150 ng/mL) 90 min after a dose and declines with a $t_{1/2}$ of 2 h. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide.

Adverse Effects

The toxicities of *temozolomide* mirror those of DTIC. Hematological monitoring is necessary to guide dosing adjustments.

Methylhydrazines

Procarbazine

Procarbazine is used in malignant brain tumors and in combination regimens for patients with Hodgkin disease.

Mechanisms of Action

The antineoplastic activity of *procarbazine* results from its conversion by CYP-mediated hepatic oxidative metabolism to highly reactive alkylating species that methylate DNA. Activated *procarbazine* can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to *procarbazine* develops rapidly when it is used as a single agent; one mechanism of resistance results from increased expression of MGMT, which repairs methylation of guanine.

ADME

The pharmacokinetic behavior of *procarbazine* has not been thoroughly defined. The drug is extensively metabolized by CYPs to azo, methylazoxy, and benzylazoxy intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In patients with brain cancer, the concurrent use of antiseizure drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug.

Therapeutic Uses

Procarbazine is used in combination regimens such as MOPP (*nitrogen mustard*, Oncovin [*vincristine*], *procarbazine*, and *prednisone*) for Hodgkin disease. It is also used in treating gliomas as part of the PVC (*procarbazine*, *vincristine*, and CCNU) regimen.

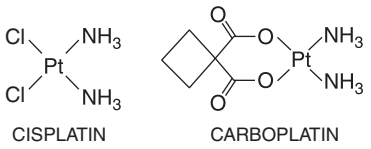
Adverse Effects

The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5% to 10% of cases. Behavioral disturbances also have been reported. Because *procarbazine* augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is a weak monoamine oxidase inhibitor; it blocks the metabolism of catecholamines, sympathomimetics, and dietary tyramine and thus may provoke hypertension in patients concurrently exposed to these. *Procarbazine* has *disulfiram*-like actions; therefore, the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5% to 10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. *Procarbazine* is a potent immunosuppressive agent. It causes infertility, particularly in males.

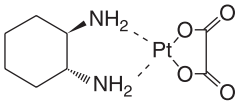
Platinum Coordination Complexes

The growth-inhibitory effect of *cisplatin* was discovered during studies of bacterial growth in electrical fields that were generated by platinum electrodes; *cisplatin* generated from corroding platinum electrodes was then found to be an effective anticancer drug in mouse models

(Rosenberg et al., 1969) and gained FDA approval for cancer treatment in 1978. Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. Although *cisplatin* and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.



CISPLATIN CARBOPLATIN



OXALIPLATIN

Mechanisms of Action

Cisplatin, *carboplatin*, and *oxaliplatin* enter cells by the high-affinity Cu^{2+} transporter CTR1 (SLC31A1, a member of the solute carrier family; see Chapter 5) and in doing so contribute to the degradation of the transporter. The compounds are actively extruded from cells by ATP7A and ATP7B copper exporters and by MRP1; variable expression of these transporters may contribute to clinical resistance, along with a variety of other proteins and epigenetic phenomena (Shen et al., 2012). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the analogues are displaced by water molecules, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins.

Aquation of *cisplatin* is favored at the low concentrations of Cl^- inside the cell and in the urine. High concentrations of Cl^- stabilize the drug, explaining the effectiveness of Cl^- diuresis in preventing nephrotoxicity. The activated platinum complexes can react with electron-rich regions, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and, if recognized by p53 and other cell-cycle checkpoint proteins, cause induction of apoptosis. Adduct formation is an important predictor of clinical response (Reed, 1998). The analogues differ in the conformation of their adducts and the effects of adduct on DNA structure and function. *Oxaliplatin* and *carboplatin* are slower to form adducts. The *oxaliplatin* adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from *cisplatin* adducts in the pattern of hydrogen bonding to adjacent segments of DNA (Sharma et al., 2007).

Unlike the other platinum analogues, *oxaliplatin* exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of high-mobility group (HMG) proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to *cisplatin*. Basal-type breast cancers, such as those with *BRCA1* and *BRCA2* mutations, lack *HER2* amplification and hormone-receptor expression and appear to be uniquely susceptible to *cisplatin* both through their upregulation of apoptotic pathways governed by p63 and p73 (Deyoung and Ellisen, 2007) and defective DNA repair mechanisms including those directed at double-strand breaks, interstrand cross-links, and replication gaps (Li and Heyer, 2008; Panzarino et al., 2021). The cell-cycle specificity of *cisplatin* differs among cell types; the effects of cross-linking are most pronounced during the S phase. The platinum analogues are mutagenic, teratogenic, and carcinogenic. *Cisplatin*- or *carboplatin*-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

Resistance to Platinum Analogues

Resistance to the platinum analogues likely is multifactorial; the compounds differ in their degree of cross-resistance. *Carboplatin* shares cross-resistance with *cisplatin* in most experimental tumors, while *oxaliplatin* does not.

A number of factors influence sensitivity to platinum analogues, including intracellular drug accumulation and intracellular levels of glutathione and other sulfhydryls, such as metallothionein, that bind to and inactivate the drug and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to *cisplatin* in patients with ovarian cancer, while overexpression of NER components is associated with poor response to *cisplatin*- or *oxaliplatin*-based therapy in lung, colon, and gastric cancer (Paré et al., 2008).

Resistance to *cisplatin*, but not *oxaliplatin*, appears to be partly mediated through loss of function in the MMR proteins. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of copper efflux transporters ATP7A and ATP7B correlates with poor survival after *cisplatin*-based therapy for ovarian cancer (Shen et al., 2012).

Cisplatin

ADME

Cisplatin is given only intravenously. To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1 to 2 L of normal saline prior to treatment. The appropriate amount of *cisplatin* then is diluted in a solution containing dextrose, saline, and *mannitol* and administered intravenously over 4 to 6 h. Because aluminum inactivates *cisplatin*, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration. After intravenous administration, *cisplatin* has an initial plasma elimination $t_{1/2}$ of 25 to 50 min; concentrations of total (bound and unbound) drug fall thereafter, with a $t_{1/2}$ of 24 h or more. More than 90% of the platinum in the blood is covalently bound to plasma proteins. High concentrations of *cisplatin* are found in the kidney, liver, intestine, and testes; *cisplatin* penetrates poorly into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 h; by 24 h, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of *cisplatin* is minimal.

Therapeutic Uses

Cisplatin, in combination with *bleomycin*, *etoposide*, or with *ifosfamide* and *vinblastine*, cures 90% of patients with testicular cancer. Used with *paclitaxel*, *cisplatin* or *carboplatin* induces complete responses in the majority of patients with carcinoma of the ovary. *Cisplatin* produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with radiation therapy.

Adverse Effects

Cisplatin-induced nephrotoxicity can be ameliorated by forced pretreatment hydration and chloride diuresis. *Amifostine*, a thiophosphate cytoprotective agent, reduces renal toxicity associated with repeated administration of *cisplatin*. Ototoxicity caused by *cisplatin* is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. Marked nausea and vomiting occur in almost all patients and usually can be controlled with serotonin ($5HT_3$) receptor antagonists, neurokinin (NK_1) receptor antagonists (e.g., *aprepitant*), and high-dose corticosteroids (see Chapters 50 and 54).

At higher doses or after multiple cycles of treatment, *cisplatin* causes a progressive peripheral motor and sensory neuropathy that may worsen

after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. *Cisplatin* causes mild-to-moderate myelosuppression, with transient leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg^{2+} concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of *epinephrine* and with corticosteroids or antihistamines. *Cisplatin* has been associated with the development of AML, usually 4 years or more after treatment.

Carboplatin

The mechanisms of action and resistance and the spectrum of clinical activity of *carboplatin* are similar to *cisplatin*. However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

ADME

Because *carboplatin* is much less reactive than *cisplatin*, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a $t_{1/2}$ of about 2 h. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a $t_{1/2}$ of 5 days or more.

Therapeutic Uses

Carboplatin and *cisplatin* are equally effective in the treatment of patients with suboptimally debulked ovarian cancer, non–small cell lung cancer, and extensive-stage small cell lung cancer; however, *carboplatin* may be less effective than *cisplatin* in the treatment of patients with germ cell, head and neck, and esophageal cancers. *Carboplatin* is an effective alternative for responsive tumors in patients unable to tolerate *cisplatin* because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. *Carboplatin* is administered as an intravenous infusion over at least 15 min and is given once every 21 to 28 days; current approaches to defining the overall dose of *carboplatin* use a regimen-specific target AUC (area under the concentration × time elimination curve) that takes into account the patient's creatinine clearance (CL_{Cr}) (Calvert et al., 1989).

Adverse Effects

Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than *cisplatin*. The dose-limiting toxicity of *carboplatin* is myelosuppression, primarily thrombocytopenia. It may cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

Oxaliplatin

ADME

Oxaliplatin has a short $t_{1/2}$ in plasma, probably as a result of its rapid uptake by tissues and its reactivity; the initial $t_{1/2}$ is about 17 min. No dose adjustment is required for hepatic dysfunction or for patients with a CL_{Cr} greater than or equal to 20 mL/min.

Therapeutic Uses

Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. *Oxaliplatin's* effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects. It also suppresses expression of thymidylate synthase (TS), the target enzyme of *5-fluorouracil* (5FU) action, which may promote synergy of these two drugs (Fischel et al., 2002). In combination with 5FU, it is approved for treatment of patients with colorectal cancer.

Adverse Effects

The dose-limiting toxicity of *oxaliplatin* is peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias or dysesthesias in the upper and lower extremities, mouth, and throat. A second type relates to cumulative dose and has features similar to *cisplatin* neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m^2 experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias; nausea is well controlled with serotonin ($5HT_3$) receptor antagonists. *Oxaliplatin* may cause leukemia and pulmonary fibrosis months to years after administration. *Oxaliplatin* may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

II. Antimetabolites

Folic Acid Analogues

Folic acid is an essential dietary factor that is converted by enzymatic reduction to FH_4 cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines) (Wilson et al., 2014). Folic acid analogues such as *methotrexate* (MTX) interfere with FH_4 metabolism (Figure 70–5), reducing the cellular capacity for one-carbon transfer and methylation reactions in the synthesis of purine ribonucleotides and TMP (thymidine monophosphate), thereby inhibiting DNA replication.

HISTORY OF ANTIFOLATE CHEMOTHERAPY

Antifolate chemotherapy produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, MTX played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with "rescue" of host toxicity by the reduced folate *leucovorin* (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N^5-formyl FH_4) further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Recognition that MTX, an inhibitor of dihydrofolate reductase (DHFR), also directly inhibits the folate-dependent enzymes of *de novo* purine synthesis and thymidylate synthesis led to development of antifolate analogues that specifically target these other folate-dependent enzymes. New congeners have greater capacity for transport into tumor cells (*pralatrexate*) and exert their primary inhibitory effect on TS (*raltitrexed*), early steps in purine biosynthesis (*lometrexol*), or both (the multitargeted antifolate *pemetrexed*).

Mechanism of Action

The primary target of folic acid analogues, such as MTX, is the enzyme DHFR (Figure 70–6). To function as a cofactor in one-carbon transfer reactions, folate must be reduced by DHFR to FH_4. Inhibitors such as MTX, with a high affinity for DHFR (K_i ~0.01–0.2 nM), cause partial depletion of N^{5-10} methylene FH_4 and N^{10} formyl FH_4 cofactors that are required for the synthesis of thymidylate and purines. In addition, MTX, like cellular folates, undergoes addition of a series of polyglutamates (MTX-PGs) in both normal and tumor cells (see Figure 70–5). These PGs

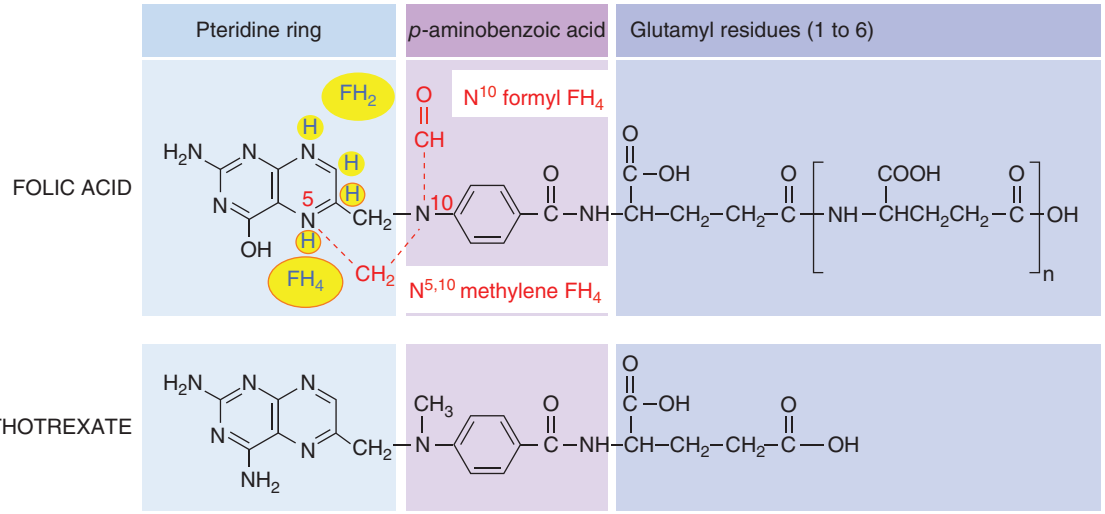


Figure 70–5 *Folic acid, metabolic intermediates, and MTX.* The shading identifies common structural features and areas of modification. Yellow highlights indicate sites modified by DHFR to FH_2 (DHF) and to FH_4 (THF, tetrahydrofolate); red atoms and bonds indicate metabolic intermediates that serve as single-carbon donors (see pathways in Figure 70–6).

constitute intracellular storage forms of folates and folate analogues that dramatically increase inhibitory potency of the analogue for additional targets, including TS and two early enzymes in the purine biosynthetic pathway. The FH_2 PGs that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (see Figure 70–6) (Allegra et al., 1987b).

Selective Toxicity; Rescue

As with most antimetabolites, MTX is only partially selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly. The toxic effects of MTX may be terminated by administering *leucovorin*, a fully reduced folate coenzyme that repletes the intracellular pool of FH_4 cofactors (see Figure 70–6). *Levoleucovorin,* approved in 2018, contains the active isomer and shows similar efficacy and adverse effects as racemic *leucovorin*.

Cellular Entry and Retention

Because folic acid and many of its analogues are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells:

1. A folate receptor, which has high affinity for folic acid but much lower ability to transport MTX and other analogues
2. The reduced folate transporter, the major transit protein for MTX, *raltitrexed*, *pemetrexed*, and most analogues
3. A transporter that is active at low pH

The reduced folate transporter is highly expressed in the hyperdiploid subtype of ALL, which has extreme sensitivity to MTX (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthase. Because these higher PGs are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of ion trapping within

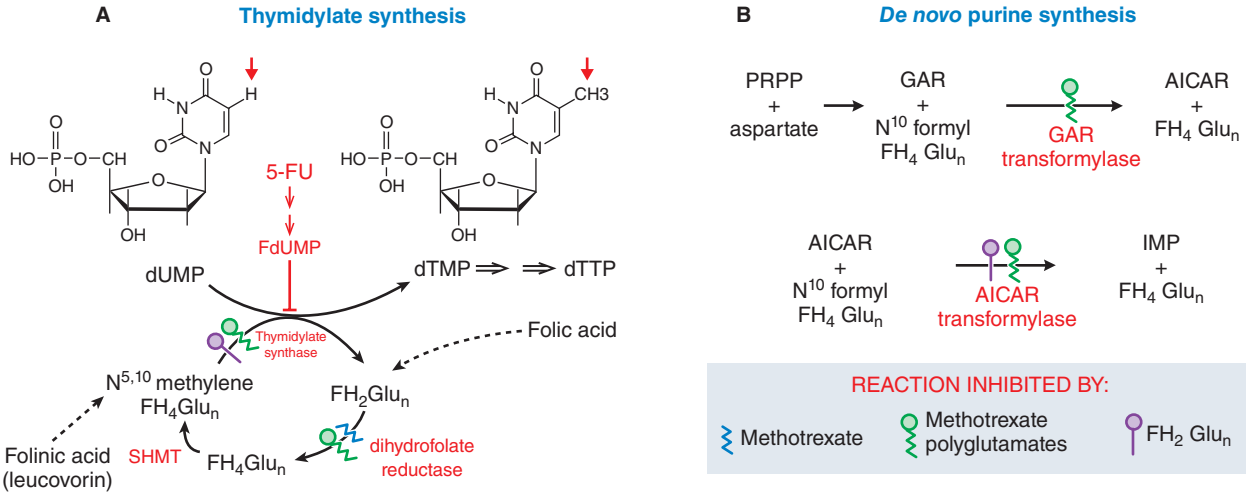

Figure 70–6 *Folate metabolism and the actions of 5FU, MTX, and MTX polyglutamates.* **A.** *Thymidylate synthesis* (for composition of folates, see Figure 70–5). **B.** *De novo purine synthesis.* GAR transformylase provides the C8 and AICAR transformylase the C2 in the purine ring biosynthesis (see Figure 70–1 for numbering of purine ring atoms). AICAR, aminoimidazole carboxamide ribonucleotide is an intermediate in the generation of inosine monophosphate (IMP); dUMP, deoxyuridine monophosphate; FH_2Glu_n, dihydrofolate polyglutamate; FH_4Glu_n, tetrahydrofolate polyglutamate; GAR, glycinamide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate; TMP, thymidine monophosphate.

the cell. The polyglutamation may also account for the prolonged retention of MTX in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamyl folates and analogues have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

Newer Congeners

New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. *Trimetrexate*, a lipid-soluble analogue that lacks a terminal glutamate, has modest antitumor activity, primarily in combination with *leucovorin* rescue. However, it is beneficial in the treatment of *Pneumocystis jirovecii* (*Pneumocystis carinii*) pneumonia, for which *leucovorin* provides differential rescue of the host but not the parasite (Allegra et al., 1987a). The folate analogue, MTA (multitargeted antifolate) or *pemetrexed*, is a pyrrole-pyrimidine structure. It is avidly transported into cells via the reduced folate carrier and is converted to PGs that inhibit TS and glycinamide ribonucleotide transformylase (GART), as well as DHFR (see Figure 70–6). It has activity against ovarian cancer, mesothelioma, and adenocarcinomas of the lung. *Pemetrexed* and its PGs have a somewhat different spectrum of biochemical actions. Like MTX, *pemetrexed* inhibits DHFR, but as a PG, it even more potently inhibits TS and GART. Unlike MTX, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion also differs; it causes a greater fall in thymidine triphosphate (TTP) than in other triphosphates. Like MTX, it induces p53 and cell-cycle arrest, but this effect does not depend on induction of p21. A newer congener, *pralatrexate*, is more effectively taken up and polyglutamated than MTX and is approved for treatment of CTCL.

Mechanisms of Resistance to Antifolates

Resistance to MTX can involve alterations in each known step in MTX action, including

- Impaired transport of MTX into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize MTX-PGs
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

The DHFR levels in leukemic cells increase within 24 h after treatment of patients with MTX, probably as a result of induction of DHFR synthesis. Unbound DHFR protein may bind to its own message and reduce its own translation, while the DHFR-MTX complex is ineffective in blocking DHFR translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated, homogeneously staining chromosomal regions or amplicons (Schimke et al., 1978). Similar gene amplification target proteins have been implicated in the resistance to other antitumor agents, including 5FU and *pentostatin* (2′-deoxycoformycin), and observed in patients with lung cancer (Curt et al., 1985).

High doses of MTX may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of MTX in concentrations that inactivate high levels of DHFR. The understanding of resistance to *pemetrexed* is incomplete. In various cell lines, resistance seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

ADME

Methotrexate is readily absorbed from the GI tract at doses of less than 25 mg/m^2; larger doses are absorbed incompletely and are routinely administered intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance ($t_{1/2}$ of about 2–3 h). A third phase has a $t_{1/2}$ of about 8 to 10 h. This terminal phase of disappearance, if prolonged by renal failure, may be responsible for major toxic effects of the drug on the bone marrow, GI epithelium, and skin. Distribution of MTX into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of MTX binds to plasma proteins and may be displaced from plasma albumin by myriad drugs, including sulfonamides, salicylates, *tetracycline*, *chloramphenicol*, and *phenytoin*; caution should be used if these drugs are given concomitantly. Up to 90% of a given dose of MTX is excreted unchanged in the urine, mostly within the first 8 to 12 h. Metabolism of MTX usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-MTX, which is potentially nephrotoxic. Renal excretion of MTX occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., nonsteroidal anti-inflammatory drugs), that are nephrotoxic (e.g., *cisplatin*), or that are weak organic acids (e.g., *aspirin*) can delay drug excretion and lead to severe myelosuppression. In patients with renal insufficiency, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided. Concentrations of MTX in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of MTX are given, cytotoxic concentrations of MTX reach the CNS beyond the blood-brain barrier. MTX is retained in the form of PGs for long periods (e.g., weeks in the kidneys, several months in the liver).

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates N^{5-10} methylene FH_4, the cofactor for TS, and thereby increases MTX toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to MTX and might also modulate the toxicity and therapeutic effect of *pemetrexed*, a TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression and, by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines (Pui et al., 2004).

Therapeutic Uses

Methotrexate is a critical drug in the management of childhood ALL. High-dose MTX is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-h infusion of relatively large doses of MTX may be employed every 2 to 4 weeks but only when *leucovorin* rescue follows within 24 h of the MTX infusion. For maintenance therapy, it is administered at a lower dose, orally every week. Outcome of treatment in children correlates inversely with the rate of drug clearance. During MTX infusion, high steady-state levels are associated with a lower leukemia relapse rate. MTX is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis.

The intrathecal administration of MTX has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of MTX in the CSF and also is effective in patients whose systemic disease has become resistant to MTX. The treatment is repeated every 4 days until malignant cells no longer are evident in the CSF. *Leucovorin* may be administered to counteract the potential toxicity of MTX that escapes into the systemic circulation, although this generally

is not necessary. Because MTX administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular catheter system in the treatment of active intrathecal disease. MTX is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in about 75% of advanced cases treated sequentially with MTX and *dactinomycin* and in more than 90% when early diagnosis is made. For choriocarcinoma, MTX is administered intramuscularly every other day for four doses, alternating with *leucovorin*. Courses are repeated at 3-week intervals, toxicity permitting, and urinary β-human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt and other non-Hodgkin lymphomas. MTX is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose MTX with *leucovorin* rescue (HDM-L) is a standard approach for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalinization of urine pH are required prior to drug administration. If MTX values measured 48 h after drug administration are 1 μM or higher, higher doses (100 mg/m^2) of *leucovorin* must be given until the plasma concentration of MTX falls to less than 50 nM. With appropriate hydration and urine alkalinization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is less than 2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing MTX levels. Continuous-flow hemodialysis can eliminate MTX at about 50% of the clearance rate in patients with intact renal function. Alternatively, an MTX-cleaving enzyme, *glucarpidase*, is FDA approved for the treatment of MTX toxicity. *Glucarpidase* is a recombinant bacterial carboxypeptidase G2 that converts MTX into glutamate and 2,4-diamino-N(10)-methylpteroic acid. These metabolites are less toxic and are excreted by the liver. MTX concentrations in plasma fall by 99% or more within 5 to 15 min following enzyme administration. However, systemically administered carboxypeptidase G2 has little effect on MTX levels in the CSF.

Methotrexate is used in the treatment of severe, disabling psoriasis (see Chapter 75), given orally for 5 days, followed by a rest period of at least 2 days, or intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis. MTX inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogeneic bone marrow and organ transplantation and for the treatment of dermatomyositis, Wegener granulomatosis, and Crohn's disease (see Chapters 39 and 55). MTX is also used as an abortifacient, generally in combination with a *prostaglandin* (see Chapter 48).

Adverse Effects

The primary toxicities of antifolates are on the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely *pemetrexed*) must be reduced in proportion to any reduction in CL_{Cr}. Additional toxicities of MTX include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose MTX may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of MTX often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Note that *leucovorin* does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of MTX, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. *Dexamethasone*, 4 mg twice daily on days –1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with *pemetrexed*, seen especially in patients with preexisting homocystinemia, largely is eliminated by concurrent administration of low dosages of folic acid, 350 to 1000 mg/day, beginning 1 to 2 weeks prior to *pemetrexed* and continuing while the drug is administered. Patients should receive intramuscular vitamin B_{12} (1 mg) with the first dose of *pemetrexed* to correct possible B_{12} deficiency. These small doses of folate and B_{12} do not compromise the therapeutic effect.

Pyrimidine Analogues

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogues (*6-mercaptopurine* [6MP] and *6-thioguanine* [6TG]) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogues, become incorporated into DNA and block its further elongation and function (Wilson et al., 2014). Other inhibitory effects of these analogues may contribute to their cytotoxicity and their capacity to induce differentiation.

Cellular Actions of Pyrimidine Antimetabolites

Four bases (Figure 70–7) form DNA: two pyrimidines (thymine and cytosine) and two purines (guanine and adenine). RNA differs in that it incorporates uracil instead of thymine as one of its bases. Strategies for inhibiting DNA synthesis are based on the ability to create analogues of these precursors that readily enter tumor cells and become activated intracellularly. As an example, the pyrimidine analogue 5FU is converted to a fluorodeoxyuridine monophosphate (FdUMP), which in turn blocks TS, an enzyme required for the physiological conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP),

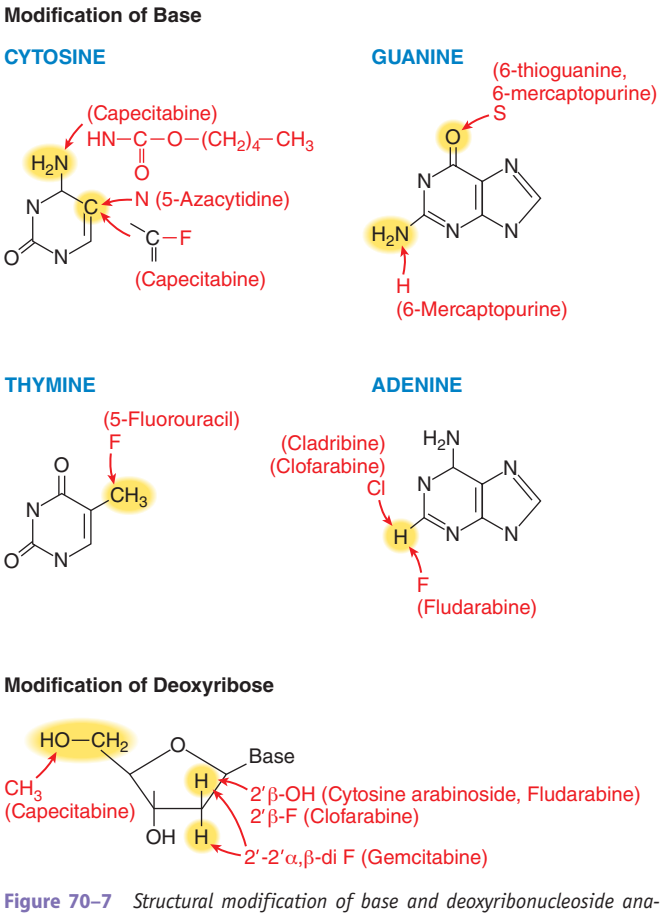

Figure 70–7 *Structural modification of base and deoxyribonucleoside analogues. Yellow ellipses* indicate sites modified to create antimetabolites. Specific substitutions are noted in red for each drug. Modifications occur in the base ring systems, in their amino or hydroxyl side groups, and in the deoxyribose sugar found in deoxyribonucleosides. See structures in Figure 70–8.

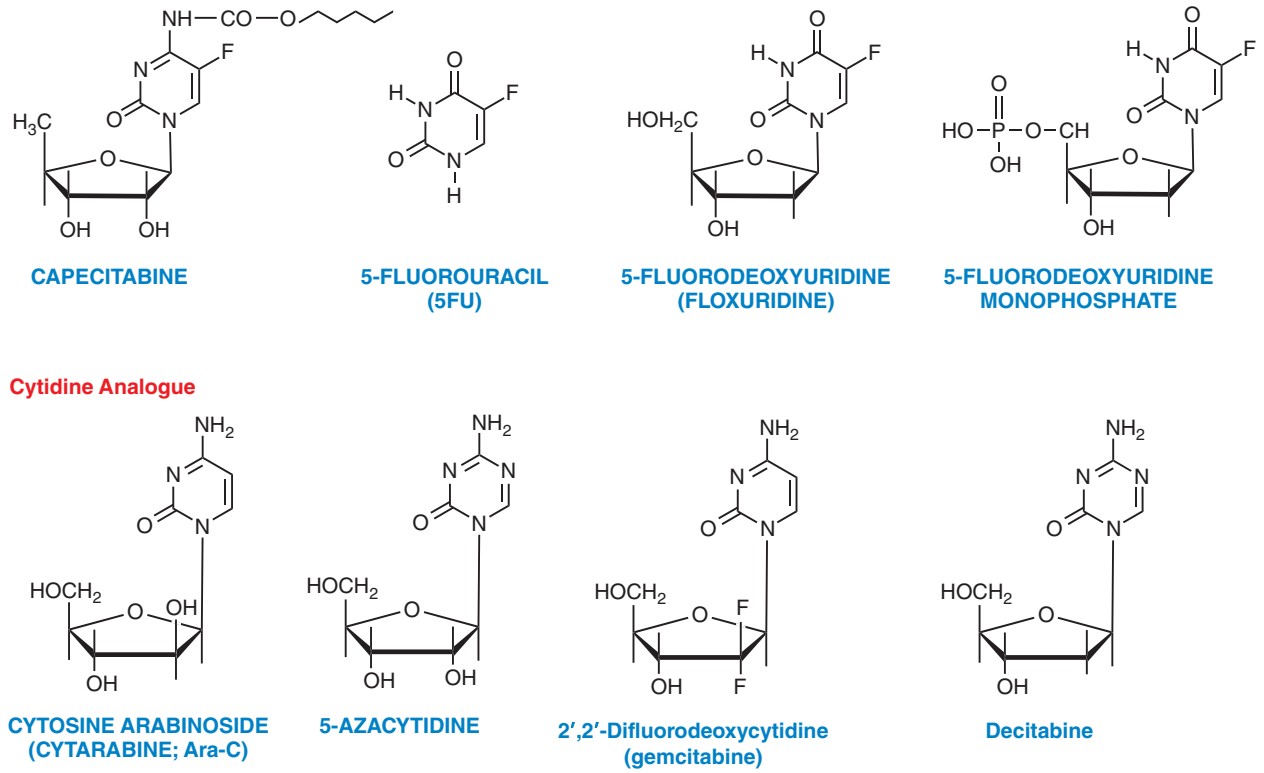

Figure 70–8 *Pyrimidine analogues.*

a component of DNA (see Figure 70–6). Other analogues incorporate into DNA itself and thereby block its function (Wilson et al., 2014).

Cells can make the purine and pyrimidine bases *de novo* and convert them to their active triphosphates (deoxynucleotide triphosphates [dNTPs]), providing substrates for DNA polymerase. Alternatively, cells can salvage free bases or their deoxynucleosides from the bloodstream. Thus, cells can take up uracil, guanine, and their analogues and convert them to (deoxy)nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogues of these bases (5FU, 6TG) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine and their analogues can only be used as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinase. Thus, *cytarabine* (cytosine arabinoside [Ara-C]), *gemcitabine*, *5-azacytidine*, and adenosine analogues (*cladribine*) (Figures 70–7 and 70–8) are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA.

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogues may differ from the physiological bases in a variety of ways: by altering the purine or pyrimidine ring; by altering the sugar attached to the base, as in the arabinoside, Ara-C; or by altering both the base and sugar, as in *fludarabine phosphate* (see Figure 70–7). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

Fluorouracil, Floxuridine, Capecitabine

Fluorouracil is available as 5FU, as the derivative fluorodeoxyuridine (FUdR) (not often used in clinical practice), and as a prodrug, *capecitabine*, which is ultimately converted to 5FU.

Mechanisms of Action

5-Fluorouracil requires enzymatic conversion (ribosylation and phosphorylation) to the nucleotide form to exert its cytotoxic activity. As the triphosphate 5-fluorouridine triphosphate (FUTP), the drug is incorporated into RNA. Alternative reactions can produce the deoxy derivative FdUMP; FdUMP inhibits TS and blocks the synthesis of deoxythymidine triphosphate (dTTP), a necessary constituent of DNA (see Figure 70–6). The folate cofactor, 5,10-methylene FH_4, and FdUMP form a covalently bound ternary complex with TS. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

5-Fluorouracil is incorporated into both RNA and DNA. In 5FU-treated cells, both fluorodeoxyuridine triphosphate (FdUTP) and deoxyuridine triphosphate (dUTP; which accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. Presumably, such incorporation into DNA calls into action the excision-repair process, which can lead to DNA strand breakage because DNA repair requires TTP, which is lacking as a result of TS inhibition. 5FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and the functions of RNA.

Mechanisms of Resistance

Resistance to the cytotoxic effects of 5FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5FU, amplification of TS, mutation of TS to a form that is not inhibited by FdUMP, and high levels of the degradative enzymes dihydrouracil dehydrogenase and thymidine phosphorylase. TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5FU.

Combination with Leucovorin

Some malignant cells appear to have insufficient concentrations of 5,10-methylene FH_4 and thus cannot form maximal levels of the inhibited

ternary complex with TS. Addition of exogenous folate in the form of *leucovorin* increases formation of the complex and enhances responses to 5FU. A number of other agents have been combined with 5FU in attempts to enhance the cytotoxic activity through biochemical modulation. MTX, by inhibiting purine synthesis and increasing cellular pools of 5-phosphoribosyl-1-pyrophosphate (PRPP), enhances the activation of 5FU and increases antitumor activity of 5FU when given prior to but not following 5FU. The combination of *cisplatin* and 5FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is unclear. A combination with *oxaliplatin*, which downregulates TS expression, is commonly used with 5FU and *leucovorin* for treating patients with metastatic colorectal cancer; the combination is abbreviated as FOLFOX. Addition of *irinotecan* (see discussion that follows) is abbreviated as FOLFIRINOX and used in the treatment of patients with colorectal or pancreatic cancer. A most important interaction is the enhancement of radiation therapy by fluoropyrimidines, the basis for which is unclear. 5FU with simultaneous radiation is effective in patients with anal cancer and enhances local tumor control in patients with head, neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

ADME

5-Fluorouracil is administered parenterally because absorption after oral ingestion of the drug is unpredictable and incomplete. 5FU is inactivated by reduction of the pyrimidine ring in a reaction carried out by dihydropyrimidine dehydrogenase (DPD), which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). DPD deficiency can be detected by either enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5FU to its metabolite, 5-fluoro-5,6-dihydrouracil.

Plasma clearance is rapid ($t_{1/2}$ about 10–20 min). Only 5% to 10% of a single intravenous dose of 5FU is excreted intact in the urine. The dose does not have to be modified in patients with hepatic dysfunction, presumably because of sufficient degradation of the drug at extrahepatic sites. 5FU enters the CSF in minimal amounts.

Therapeutic Uses

5-Fluorouracil. *5-Fluorouracil* produces partial responses in 10% to 20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5FU in combination with *leucovorin* and *oxaliplatin* or *irinotecan* (FOLFOX or FOLFIRINOX) in adjuvant therapy is associated with a survival advantage for patients with colorectal cancers. For average-risk patients in good nutritional status with adequate hematopoietic function, the dosage regimen employs *leucovorin* once each week for 6 of 8 weeks. Other regimens use daily doses for 5 days, repeated in monthly cycles. When used with *leucovorin*, doses of daily 5FU for 5 days must be reduced because of mucositis and diarrhea. 5FU increasingly is used as a biweekly infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer. Also, topical application of 5FU is effective in the treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

Floxuridine. Fluorodeoxyuridine is converted directly to FdUMP by thymidine kinase. The drug is administered primarily by continuous infusion into the hepatic artery for treatment of patients with metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate of intrahepatic infusion (40%–50%) is twice that of intravenous administration. Intrahepatic arterial infusion for 14 to 21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7 to 14.

Capecitabine. *Capecitabine*, an orally administered prodrug of 5FU, is approved for the treatment of patients with (1) metastatic breast cancer who have not responded to a regimen of *paclitaxel* and an anthracycline; (2) metastatic breast cancer when used in combination with *docetaxel* in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer.

The recommended dosage is given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. *Capecitabine* is well absorbed orally. It is rapidly deesterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5′-deoxyfluorodeoxyuridine (5′-dFdU), which disappears with a $t_{1/2}$ of about 1 h. The conversion of 5′-dFdU to 5FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5FU levels are less than 10% of those of 5′-dFdU, reaching a maximum of 0.3 mg/L or 1 μM at 2 h. Liver dysfunction delays the conversion of the parent compound to 5′-dFdU and 5FU, but there is no consistent effect on toxicity.

Combination Therapy. Higher response rates are seen when 5FU or *capecitabine* is used in combination with other agents (e.g., with *cisplatin* in head and neck cancer, with *oxaliplatin* or *irinotecan* in colon cancer). The combination of 5FU and *oxaliplatin* or *irinotecan* has become the standard first-line treatment of patients with metastatic colorectal cancer (FOLFOX and FOLFIRINOX). The use of 5FU in combination regimens has improved survival in the adjuvant treatment of breast cancer and, with *oxaliplatin* and *leucovorin*, of colorectal cancer. 5FU also is a potent radiation sensitizer. Beneficial effects have been reported when combined with irradiation as primary treatment of patients with locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck.

Adverse Effects

The clinical manifestations of toxicity caused by 5FU and *floxuridine* are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5FU. The nadir of leukopenia usually occurs 9 to 14 days after the first injection of drug. Thrombocytopenia and anemia also may occur, as may loss of hair (occasionally progressing to total alopecia), nail changes, dermatitis, and increased pigmentation and atrophy of the skin. Hand-foot syndrome, a particularly prominent adverse effect of *capecitabine*, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional than with bolus regimens, while hand-foot syndrome occurs more often with infusional than with bolus regimens. The significant risk of toxicity with fluoropyrimidines requires close supervision by physicians familiar with the drug's effects and possible hazards.

Capecitabine causes a similar spectrum of toxicities as 5FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

Trifluridine

Trifluridine is the 5-trifluoromethyl pyrimidine nucleoside analogue of 5-FUdR (*floxuridine*; Figure 70–8). It is used in eye drops for the treatment of herpes simplex virus (see Table 74–5)) and in a fixed combination with *tipiracil*, a thymidine phosphorylase inhibitor, for the treatment of patients with metastatic colorectal cancers who have previously received other standard combination treatments that included FOLFIRINOX. *Trifluridine* and *tipiracil* are formulated together in a single tablet with *tipiracil* added to prevent rapid breakdown of *trifluridine*. The *trifluridine* mechanism of action mimics that of 5FU (Davidson et al., 2016).

Cytidine Analogues

Cytarabine (Cytosine Arabinoside; Ara-C)

Cytarabine is the most important antimetabolite used in the therapy of AML; it is the single most effective agent for induction of remission in this disease.

Mechanisms of Action

Cytarabine is an analogue of 2′-deoxycytidine; the 2′-hydroxyl in a position *trans* to the 3′-hydroxyl of the sugar (see Figures 70–7 and 70–8) hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via ENT1 (SLC29A1). It is then converted to its active form, the 5′-monophosphate ribonucleotide, by deoxycytidine kinase (dCK), an enzyme that shows polymorphic expression among patients (see discussion that follows). Ara-CMP then reacts with deoxynucleotide kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with deoxycytidine triphosphate (dCTP) for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, in both replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA; incorporation of about 5 molecules of Ara-C per 10^4 bases of DNA decreases cellular clonogenicity by about 50% (Kufe et al., 1984).

In infants and adults with ALL and t(4;11) MLL translocation, usefulness of high-dose Ara-C is mediated by the highly expressed nucleoside transporter ENT1, and its expression correlates with sensitivity to Ara-C (Pui et al., 2004). At extracellular drug concentrations greater than 10 μM (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting. Patients with particular subtypes of AML derive benefit from high-dose Ara-C treatment; these types include t(8;21), inv(16), t(9;16), and del(16).

Mechanisms of Resistance

Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme dCK produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, ara-uridine (Ara-U). Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells lead to a longer duration of complete remission in patients with AML. The capacity of cells to transport Ara-C also may affect response. Clinical studies have implicated a loss of dCK as the primary mechanism of resistance to Ara-C in AML.

ADME

Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only about 20% of the drug reaches the circulation after *oral* Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2 to 50 μM are measurable in plasma after intravenous injection of 30 to 300 mg/m^2 but fall rapidly ($t_{1/2} \approx 10$ min). Less than 10% of the injected dose is excreted unchanged in the urine within 12 to 24 h; most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection but are 10% or less of concentrations in plasma. After *intrathecal* administration of the drug at a dose of 50 mg/m^2, deamination proceeds slowly, with a $t_{1/2}$ of 3 to 4 h, and peak concentrations of 1 to 2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for 24 h or longer. A depot liposomal formulation of Ara-C provides sustained release into the CSF. After a standard dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures.

Therapeutic Uses

Continuous inhibition of DNA synthesis for a duration equivalent to at least one cell cycle or 24 h is necessary to expose most tumor cells during the S phase of the cell cycle. The optimal interval between bolus doses of Ara-C is about 8 to 12 h, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multiday cycle of treatment. In general, children tolerate higher doses than adults. The intrathecal administration of liposomal Ara-C every 2 weeks seems equally effective as the regimen every 4 days with the standard drug. Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of patients with other leukemias, such as acute lymphoblastic leukemia (ALL), CML in the blast phase, acute promyelocytic leukemia (APL), and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intracellular activation, clinicians have employed high-dose regimens every 12 h for 3 to 4 days to achieve 20 to 50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

Adverse Effects

Cytarabine is myelosuppressive and can produce acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. The onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomographic scans may follow 1 to 2 weeks after high-dose Ara-C and may be fatal in 10% to 20% of patients, especially in patients being treated for relapsed leukemia. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose MTX or systemic Ara-C. Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients older than 50 years or patients with poor renal function.

Azacitidine (5-Azacytidine); Decitabine

5-Azacytidine and *decitabine* (2′-deoxy-5-azacytidine; see Figure 70–8) have antileukemic activity as cytotoxic agents and particularly at lower doses induce leukemic cell differentiation by inhibiting DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15% to 20% of patients and reduce the transfusion requirement in one-third of patients. *5-Azacytidine* improves survival.

Mechanism of Action

The aza-nucleosides enter cells by ENT1 (SLC29A1). The drugs incorporate into DNA, where they become covalently bound to the DNA methyltransferase, depleting intracellular enzyme and leading to global demethylation of DNA that results in tumor cell differentiation and apoptosis. *Decitabine* also induces double-strand DNA breaks, perhaps as a consequence of the effort to repair the protein-DNA adduct.

ADME

After subcutaneous administration, *5-azacytidine* undergoes rapid deamination by cytidine deaminase (plasma $t_{1/2}$ ~20–40 min). Due to the formation of intracellular nucleotides that become incorporated into DNA, the effects of the aza-nucleosides persist for many hours.

Therapeutic Use

The usual treatment regimen for *5-azacytidine* in patients with myelodysplastic syndrome is daily for 7 days every 28 days, while *decitabine* is given intravenously every day for 5 days every 4 weeks. Best responses may become apparent only after two to five courses of treatment.

Adverse Effects

The major toxicities of the aza-nucleosides include myelosuppression and mild GI symptoms. *5-Azacytidine* produces severe nausea and vomiting when given intravenously in large doses (150–200 mg/m^2 per day for 5 days).

Gemcitabine

Gemcitabine, a difluoro analogue of *deoxycytidine* (dFdC; see Figure 70–8), is used in the treatment of patients with pancreatic; nonsquamous, non–small cell lung; ovarian; breast; and bladder cancer.

Mechanism of Action

Gemcitabine enters cells via three distinct nucleoside transporters: ENT1 (SLC29A1; the major route), CNT1 (SLC28A1), and a nucleobase transporter found in malignant mesothelioma cells. Intracellularly, dCK phosphorylates *gemcitabine* to the monophosphate (dFdCMP), which is converted to di- and triphosphates (dFdCDP and dFdCTP, respectively). Although *gemcitabine*'s anabolism and effects on DNA in general mimic those of *cytarabine*, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of *cytarabine*, the cytotoxicity of *gemcitabine* is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of ribonucleoside diphosphate reductase (RNR), resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Incorporation of dFdCTP into DNA causes DNA strand termination (Heinemann et al., 1988) and appears resistant to repair. The capacity of cells to incorporate dFdCTP into DNA is critical for *gemcitabine*-induced apoptosis. *Gemcitabine* is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

ADME

Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is 2′,2′-difluorodeoxycytidine (dFdU). In patients with significant renal dysfunction, dFdU and its triphosphate accumulate to high and potentially toxic levels. *Gemcitabine* has a short plasma $t_{1/2}$ (~15 min); women and elderly patients clear the drug more slowly.

Therapeutic Uses

The standard dosing schedule for *gemcitabine* is an intravenous infusion on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication. Conversion of *gemcitabine* to dFdCMP by dCK is saturated at infusion rates of about 10 mg/m^2/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100 to 150 min at a fixed rate of 10 mg/min. The 150-min infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression. The inhibition of DNA repair by *gemcitabine* may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy.

Adverse Effects

The principal toxicity is myelosuppression. Longer duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild, reversible elevation in liver transaminases may occur in 40% or more of patients. Interstitial pneumonitis, at times progressing to acute respiratory distress syndrome, may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients treated for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. *Gemcitabine* is a very potent radiosensitizer and should not be used with radiotherapy.

Purine Analogues

The pioneering studies of Hitchings and Elion identified analogues of naturally occurring purine bases with antileukemic and immunosuppressant properties. Figure 70–9 shows structural formulas of several purine analogues, with *adenosine* for comparison. Other purine analogues that have valuable roles in leukemia and lymphoid malignancies include *cladribine* (standard therapy of hairy cell leukemia), *fludarabine phosphate* (standard treatment of CLL), *nelarabine* (pediatric ALL), and *clofarabine* (T-cell leukemia/lymphoma). The apparent selectivity of these agents may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

6-Thiopurine Analogues

6-Mercaptopurine and 6TG are approved agents for human leukemias and function as analogues of the natural purines hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6MP and 6TG inhibit *de novo* purine synthesis and also become incorporated into nucleic acids (see Figure 55–5).

Mechanism of Action

Hypoxanthine guanine phosphoribosyl transferase converts 6TG and 6MP to the ribonucleotides 6-thioGMP and 6-thioIMP (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase (the enzyme that converts GMP to GDP), T-IMP accumulates intracellularly. T-IMP inhibits the new formation of ribosyl-5-phosphate, as well as conversion of IMP to adenine and guanine nucleotides. The most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the *de novo* pathway. 6TG nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing.

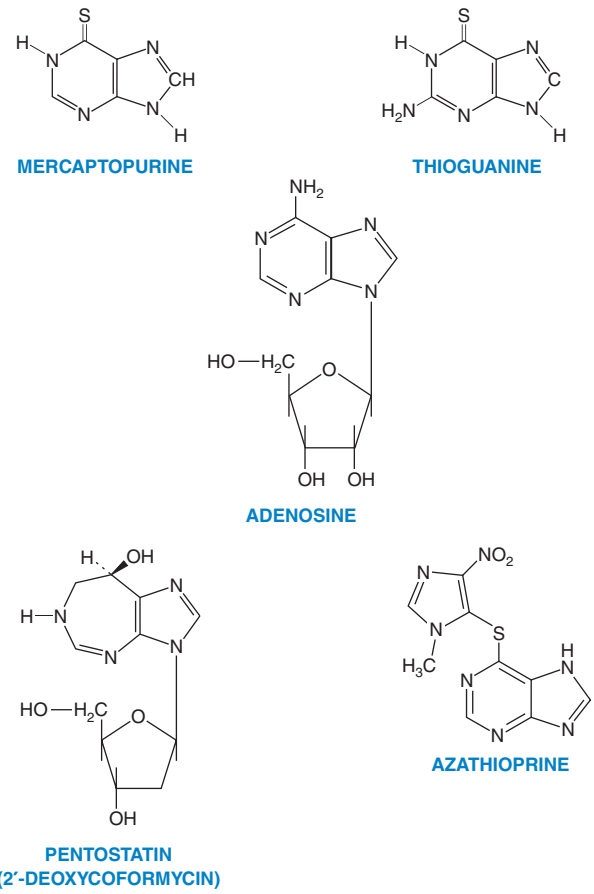

Figure 70–9 *Adenosine and various purine analogues.*

Mechanisms of Resistance

The most common mechanism of 6MP resistance observed *in vitro* is deficiency or complete lack of the activating enzyme HGPRT or increased alkaline phosphatase activity. Other mechanisms for resistance include:

- Decreased drug uptake or increased efflux due to active transporters
- Alteration in allosteric inhibition of ribosylamine 5-phosphate synthase
- Impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6, mutator S homologue 6) of the MMR system (Karran and Attard, 2008)

ADME and Toxicity

Absorption of oral *mercaptopurine* is incomplete (10%–50%); the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when *mercaptopurine* is combined with high-dose MTX. After an intravenous dose, the $t_{1/2}$ of the drug is about 50 min in adults due to rapid metabolic degradation by xanthine oxidase and by thiopurine methyltransferase (TPMT). Restricted brain distribution of *mercaptopurine* results from an efficient efflux transport system in the blood-brain barrier. In addition to the HGPRT-catalyzed anabolism of *mercaptopurine*, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse. In patients with autoimmune disease treated with *mercaptopurine*, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.

A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate. The second major pathway for 6MP metabolism involves its oxidation by xanthine oxidase to 6-thiourate, an inactive metabolite. Oral doses of 6MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor *allopurinol*; no dose adjustment is required for intravenous dosing.

Therapeutic Uses

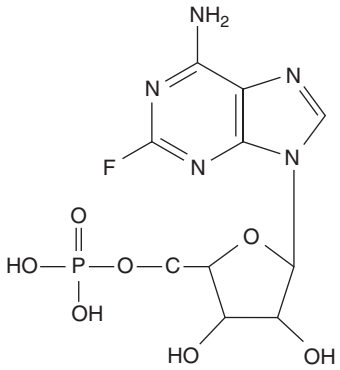
In the maintenance therapy of ALL, an initial daily oral dose of 6MP is adjusted according to white blood cell and platelet counts. The combination of MTX and 6MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, MTX elevates the intracellular concentration of PRPP, a cofactor required for 6MP activation.

Adverse Effects

The principal toxicity of 6MP is myelosuppression. Thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. Dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in about 25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6MP and usually resolve on discontinuation of therapy. 6MP and its derivative *azathioprine* predispose to opportunistic infection (e.g., reactivation of hepatitis B, fungal infection, and *Pneumocystis* pneumonia) and an increased incidence of squamous cell malignancies of the skin. 6MP is teratogenic during the first trimester of pregnancy, and AML has been reported after prolonged 6MP therapy for Crohn's disease.

Fludarabine Phosphate

Fludarabine phosphate is a fluorinated, deamination-resistant, phosphorylated analogue of the antiviral agent *vidarabine* (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas and is also effective as a potent immunosuppressant.



FLUDARABINE PHOSPHATE

Mechanisms of Action and Resistance

The drug is dephosphorylated extracellularly to the nucleoside *fludarabine*, which enters the cell and is rephosphorylated by dCK to the active triphosphate. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996). Incorporation of *fludarabine* into RNA inhibits RNA function, RNA processing, and mRNA translation.

In experimental tumors, resistance to *fludarabine* is associated with decreased activity of dCK (the enzyme that phosphorylates the drug), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of autoimmunity stems from the particular susceptibility of lymphoid cells to purine analogues and the specific effects on the $CD4^+$ subset of T cells, as well as its inhibition of regulatory T-cell responses.

ADME

Fludarabine phosphate is administered both intravenously and orally and is rapidly converted to *fludarabine* in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 h, and oral bioavailability averages 55% to 60%. The $t_{1/2}$ of *fludarabine* in plasma is about 10 h. The compound is eliminated primarily by renal excretion.

Therapeutic Uses

Fludarabine phosphate is approved for intravenous and oral use and is equally active by both routes. The recommended dose interval is daily for 5 days and may be repeated every 4 weeks. Gradual improvement in CLL usually occurs within two to three cycles. Dosage should be reduced in patients with renal impairment in proportion to the reduction in CL_{Cr}. *Fludarabine phosphate* is highly active alone or with *rituximab* and *cyclophosphamide* for the treatment of patients with CLL; overall response rates in previously untreated patients approximate 80%, and the duration of response averages 22 months. The synergy of *fludarabine* with alkylators may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloablative allogeneic bone marrow transplantation.

Adverse Effects

Oral and intravenous therapy cause myelosuppression in about 50% of patients, nausea and vomiting in a minor fraction, and, uncommonly, chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of $CD4^+$ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a rare complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Autoimmune events may occur after *fludarabine* treatment. Patients with CLL may develop an acute hemolytic anemia or pure red cell aplasia during or following *fludarabine* treatment. Prolonged cytopenias probably mediated by autoimmunity, also complicate

fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications. Pneumonitis is an occasional side effect and responds to corticosteroids. In patients with compromised renal function, the initial doses should be reduced in proportion to the reduction in CL_{Cr}.

Cladribine

Cladribine is an adenosine deaminase (ADA)-resistant purine analogue that has potent and curative activity in hairy cell leukemia, CLL, and low-grade lymphomas.

Mechanisms of Action and Resistance

Cladribine enters cells via active nucleoside transport. After phosphorylation by dCK and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme dCK; increased expression of RNR; or increased active efflux by ABCG2 or other members of the ATP binding cassette (ABC) family of transporters.

ADME

Cladribine is absorbed orally (55%) but is routinely administered intravenously. It is excreted by the kidneys, with a terminal $t_{1/2}$ in plasma of 6.7 h. *Cladribine* crosses the blood-brain barrier and reaches CSF concentrations of about 25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

Therapeutic Uses

Cladribine is administered daily for 7 days by continuous intravenous infusion. It is the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

Adverse Effects

The major dose-limiting toxicity of *cladribine* is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased $CD4^+$ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

Clofarabine (2-Chloro-2′-fluoro-arabinosyladenine)

The analogue *clofarabine* (2-chloro-2′-fluoro-arabinosyladenine) incorporates the 2-chloro, glycosylase-resistant substituent of *cladribine* and a 2′-fluoro-arabinosyl substitution, which adds stability and enhances uptake and phosphorylation. The resulting compound is approved for the treatment of pediatric ALL after failure of two prior therapies. *Clofarabine* produces complete remissions in 20% to 30% of these patients. It has activity in pediatric and adult AML and in myelodysplasia. The uptake and metabolic activation of *clofarabine* in tumor cells follow the same path as *cladribine* and the other purine nucleosides, although *clofarabine* is more readily phosphorylated by dCK. *Clofarabine triphosphate* has a long intracellular $t_{1/2}$ (24 h). It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis; *clofarabine* also inhibits RNR.

Therapeutic Uses and Adverse Effects

In children, *clofarabine* is administered as a 2-h infusion daily for 5 days. The primary elimination $t_{1/2}$ in plasma is 6.5 h. Most of the drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in CL_{Cr}. The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachyphemia, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release that necessitate immediate discontinuation of the drug; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia.

Nelarabine (6-Methoxy-arabinosyl-guanine)

Nelarabine (6-methoxy-arabinosyl-guanine) is the only guanine nucleoside in clinical use. It has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in patients with relapsed/refractory disease. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis.

ADME

Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by ADA-mediated cleavage of the methyl group, yielding the phosphorylase-resistant Ara-G, which has a plasma $t_{1/2}$ of 3 h. The active metabolite is transported into tumor cells, where it is activated by dCK to Ara-GTP, which incorporates into DNA and terminates DNA synthesis. The drug and its metabolite Ara-G are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The drug should be used with close clinical monitoring in patients with renal impairment (CL_{Cr} <50 mL/min). Adults are given a 2-h infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose for 5 days, repeated every 21 days.

Adverse Effects

The adverse effects include myelosuppression and liver function test abnormalities, as well as infrequent serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological adverse effects may not be reversible.

Pentostatin (2′-Deoxycoformycin)

Pentostatin (2′-deoxycoformycin; see Figure 70–9), a transition-state analogue of the intermediate in the ADA reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting T-cell and B-cell functions).

Mechanism of Action

Inhibition of ADA by *pentostatin* leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates *S*-adenosyl homocysteine hydrolase. The resulting accumulation of *S*-adenosyl homocysteine is particularly toxic to lymphocytes. *Pentostatin* also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

ADME

Pentostatin is administered intravenously every other week and has a mean terminal $t_{1/2}$ of 5.7 h. After hydration with 500 to 1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of 30 min or less, followed by an additional 500 mL of fluids. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced CL_{Cr}.

Therapeutic Use

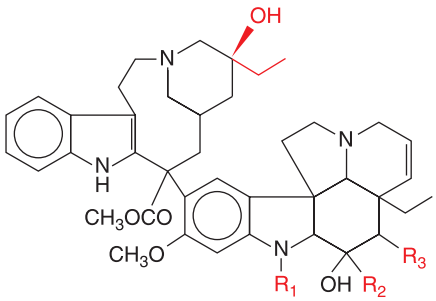
Pentostatin is effective in producing complete remissions (58%) and partial responses (28%) in patients with hairy cell leukemia. It largely has been superseded by *cladribine* (see previous discussion). Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation. At high doses, major renal and neurological complications are encountered. *Pentostatin* in combination with *fludarabine phosphate* may result in severe or even fatal pulmonary toxicity.

Microtubule-Damaging Agents

Structural biology analyses have revealed multiple binding sites of microtubule targeting drugs with different mechanisms of action; the major distinct binding sites are for vinca, taxane, and colchicine (Steinmetz and Prota, 2018).

Vinca Alkaloids

Purified alkaloids from the periwinkle plant, including *vinblastine* and *vincristine*, were among the earliest clinical agents for the treatment of patients with leukemias, lymphomas, and testicular cancer. A closely related derivative, *vinorelbine*, has activity against lung and breast cancer.



Basic structure of vinca alkaloids

Mechanism of Action

The vinca alkaloids are cell-cycle–specific agents and, in common with other drugs, such as *colchicine*, *podophyllotoxin*, the taxanes, and the epothilones, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind to a specific site on β-tubulin and to block its polymerization with α-tubulin into microtubules (Figure 70–10) (Akhmanova and Steinmetz, 2015). The mitotic spindle cannot form, duplicated chromosomes cannot align along the division plate, and cell division arrests in metaphase. Cells blocked in mitosis undergo changes characteristic of apoptosis. Microtubules are found in high concentration in the brain and contribute to other cellular functions, such as movement, phagocytosis, and axonal transport. Adverse effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

Resistance

Despite their structural similarity, the individual vinca alkaloids have unique patterns of clinical efficacy (see discussion that follows). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by P-glycoprotein (Pgp), which confers resistance to a broad range of agents (vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Pgp, also known as MDR1, ABCB1, and CD243, is an ATP-dependent efflux pump with broad substrate specificity that provides a cellular defense mechanism against potentially harmful substances. Chromosomal abnormalities consistent with gene amplification and markedly increased levels of Pgp have been observed in resistant cells in culture. Other membrane transporters, such as the multidrug resistance-associated protein (MRP) and the closely related breast cancer resistance protein (BCRP), may contribute to resistance. Other forms of resistance to vinca alkaloids stem from mutations in β-tubulin or in the relative expression of isoforms of β-tubulin that prevent the inhibitors from effectively binding to their target.

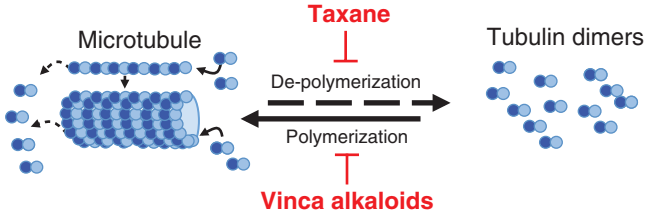


Figure 70–10 *Inhibitors of microtubular function.*

Adverse Effects

The limited myelosuppressive activity of *vincristine* makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of *vinblastine* is a decided advantage in lymphomas and in combination with *cisplatin* against testicular cancer. *Vinorelbine*, which causes mild neurotoxicity and myelosuppression, has an intermediate toxicity profile.

ADME

Hepatic CYPs extensively metabolize all three drugs, and the metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found unchanged in the urine. In patients with hepatic dysfunction (bilirubin >3 mg/dL), a 50% to 75% reduction in dose of any of the vinca alkaloids is advisable. The elimination $t_{1/2}$ is 20 h for *vincristine*, 23 h for *vinblastine*, and 24 h for *vinorelbine*.

Vinblastine

Therapeutic Uses. *Vinblastine sulfate* is given intravenously; special precautions must be taken against subcutaneous extravasation, which may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose, myelosuppression reaches its maximum in 7 to 10 days. If a moderate level of leukopenia (~3000 cells/mm^3) is not attained, the weekly dose may be increased gradually. For testicular cancer, *vinblastine* is administered every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin greater than 1.5 mg/dL. *Vinblastine* is used with *bleomycin* and *cisplatin* in the curative therapy of patients with metastatic testicular cancer, although it has been mainly supplanted by *etoposide* (see further discussion) or *ifosfamide* (see previous material). It is a component of the standard curative ABVD (***a***driamycin [doxorubicin]), *bleomycin*, *vinblastine*, *dacarbazine*) regimen for Hodgkin lymphoma. *Vinblastine* also is active against Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, bladder cancer, carcinoma of the breast, and choriocarcinoma.

Adverse Effects. Maximal leukopenia occurs within 7 to 10 days, after which recovery ensues within 7 days. Other toxic effects of *vinblastine* include mild neurological manifestations. GI disturbances, including nausea, vomiting, anorexia, and diarrhea, may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

Vincristine

Therapeutic Uses. *Vincristine* is a standard component of regimens for treating pediatric patients with leukemias, lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin lymphomas, *vincristine* remains an important agent, particularly when used in the CHOP (*cyclophosphamide*, *doxorubicin*, *vincristine*, and *prednisone*) regimen. *Vincristine*

with glucocorticoids is the treatment of choice to induce remissions in patients with childhood leukemia and in combination with alkylating agents and *anthracycline* for those with pediatric sarcomas. The common adult intravenous dosage for *vincristine* is 1.4 mg/m² of body surface area at weekly or longer intervals, with a maximum dose of 2 mg at each periodic administration. *Vincristine* is tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require lowering of the dose. Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid extravasation during intravenous administration. Doses should be reduced for patients with elevated plasma bilirubin.

Adverse Effects. The clinical toxicity of *vincristine* is mostly neurological. Severe neurological manifestations may be reversed by suspending therapy or reducing the dosage at the first sign of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by laxatives and hydrophilic (bulk-forming) agents. Reversible alopecia occurs in about 20% of patients. Modest leukopenia may occur. Thrombocytopenia, anemia, and the syndrome of inappropriate secretion of antidiuretic hormone are less common. Inadvertent injection of *vincristine* into the CSF causes a devastating and often-fatal irreversible coma and seizures.

Vinorelbine

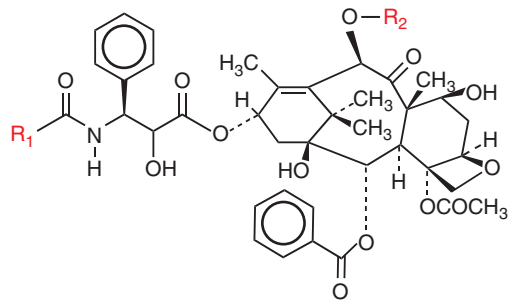
Vinorelbine has activity against non–small cell lung cancer and breast cancer. *Vinorelbine* is administered in normal saline as an intravenous infusion over 6 to 10 min or as an oral capsule formulation. When used alone, it is given intravenously at doses of 30 mg/m² either weekly or for 2 of every 3 weeks. When used with *cisplatin* for the treatment of non–small cell lung cancer, it is given at doses of 25 mg/m² either weekly or for 3 of every 4 weeks. A lower dose (20–25 mg/m²) may be required for patients who have received prior chemotherapy and for hematological toxicity. The primary adverse effect of *vinorelbine* is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. *Vinorelbine* may cause allergic reactions and mild, reversible changes in liver enzymes. Doses should be reduced in patients with elevated plasma bilirubin.

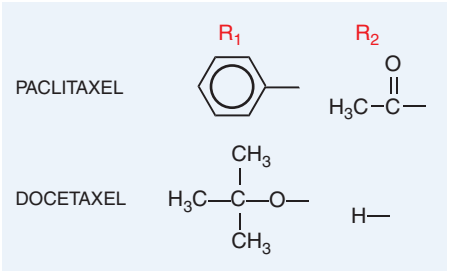
Eribulin

Eribulin is a synthetic analogue of halichondrin, a poly-ether macrolide, originally isolated from the Pacific marine sponge *Halichondria okadai*. The drug binds to the vinca site on β-tubulin and inhibits microtubule assembly. *Eribulin* is a poorer substrate than other microtubule disruptors for the Pgp efflux pump and is effective in drug-resistant tumors that overexpress Pgp. *Eribulin* is approved for the treatment of patients with drug-resistant metastatic breast cancer and liposarcoma. Adverse effects overlap with those of the vinca alkaloids and include neutropenia, neuropathies, and GI toxicities. *Tirbanibulin*, a mitotic inhibitor that binds to the colchicine binding site on β-tubulin, was FDA-approved in 2020 for local treatment of actinic keratosis, a precursor lesion of squamous cell carcinoma.

Taxanes

Paclitaxel was first isolated from the bark of the Western yew tree, *Taxus brevifolia*. *Paclitaxel* and its semisynthetic congeners *docetaxel* and *cabazitaxel* exhibit unique pharmacological properties as inhibitors of mitosis. These taxanes differ from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β-tubulin and promote rather than inhibit microtubule formation (see Figure 70–10), stabilizing tubulin-GDP (Akhmanova and Steinmetz, 2015). The taxanes have a central role in the therapy of patients with ovarian, breast, lung, GI, genitourinary, prostate, and head and neck cancers.





Core structure of taxanes

Mechanism of Action

Paclitaxel binds to the β-tubulin subunit on the inner surface of microtubules and antagonizes their disassembly (see Figure 70–10), with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle (Schiff et al., 1979). Arrest in mitosis follows. Cell death occurs by apoptosis and depends on both drug concentration and duration of drug exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted. The sequence of *cisplatin* preceding *paclitaxel* decreases *paclitaxel* clearance and produces greater toxicity than the opposite schedule. *Paclitaxel* decreases *doxorubicin* clearance and enhances its cardiotoxicity; *docetaxel* has no apparent effect on anthracycline pharmacokinetics.

Resistance to taxanes can be a result of decreased cellular drug accumulation due to increased expression of membrane-bound efflux proteins, including MRP1 and Pgp. *Cabazitaxel* is a poor substrate for Pgp and may therefore be useful for treating multidrug-resistant tumors. Other mechanisms of resistance may include an increase in *survivin*, an antiapoptotic factor; an increase in *α-aurora kinase,* which promotes completion of mitosis; an upregulation of the βIII-isoform of tubulin that lacks taxane-binding capacity; or a direct alteration of the drug target by mutation.

ADME

Paclitaxel has limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil. Hepatic CYPs (primarily CYP2C8, secondarily CYP3A4) extensively metabolize the drug. The primary metabolite is 6-OH paclitaxel, which is inactive; multiple additional hydroxylation products are found in plasma; less than 10% of a dose is excreted in the urine intact. Dose reductions in patients with abnormal hepatic function have been suggested, and 50% to 75% of doses of taxanes should be used in the presence of hepatic metastases larger than 2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as *phenytoin* and *phenobarbital*, or those that inhibit these CYPs, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate; the plasma $t_{1/2}$ is 10 to 14 h. The critical plasma concentration for myelosuppression depends on the duration of exposure but likely is 50 to 100 nM. *Paclitaxel* clearance is markedly delayed by *cyclosporine A* and other drugs that inhibit Pgp.

A nanoparticle albumin-bound *paclitaxel* (*nab-paclitaxel*) is soluble and used for infusion. This form of *paclitaxel* has increased cellular uptake via an albumin-specific mechanism. *Nab-paclitaxel* achieves a higher serum concentration than *paclitaxel*, but the increased clearance of *nab-paclitaxel* results in a similar systemic drug exposure. It is somewhat less neurotoxic than *paclitaxel* and is used in combination treatment of metastatic breast, pancreas, and non–small cell lung cancer. Like the other taxanes, *nab*-paclitaxel should not be given to patients with an absolute neutrophil count below 1500 cells/mm^3.

Docetaxel, somewhat more soluble than *paclitaxel*, is administered intravenously in an emulsifier (polysorbate 80). *Docetaxel* pharmacokinetics are similar to those of *paclitaxel*, with an elimination $t_{1/2}$ of about 12 h. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites.

Therapeutic Uses

The taxanes have become central components of regimens for treating patients with metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. These drugs are administered once weekly or once every 3 weeks. *Cabazitaxel* is a poor substrate for Pgp and is approved for hormone-refractory metastatic prostate cancer previously treated with a *docetaxel*-containing regimen.

Adverse Effects

Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8 to 11 days after a dose and reverses rapidly by days 15 to 21. Used with granulocyte colony-stimulating factor (G-CSF), high doses over 24 h are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving *paclitaxel*. In high-dose schedules or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent *cisplatin* therapy. Mucositis is prominent in 72- or 96-h infusions and in the weekly schedule. Hypersensitivity reactions can occur in patients receiving *paclitaxel* infusions of short duration (1–6 h) but are largely averted by pretreatment with *dexamethasone*, *diphenhydramine*, and histamine H_2 receptor antagonists. Premedication is not necessary with 96-h infusions. Many patients experience asymptomatic bradycardia; occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-h infusions. *Nab-paclitaxel* produces increased rates of peripheral neuropathy compared to the original *cremophor*-delivered *paclitaxel* but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than *paclitaxel* but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of *docetaxel* therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral *dexamethasone*, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, *docetaxel* may cause progressive interstitial pneumonitis and respiratory failure if the drug is not discontinued.

Estramustine

Estramustine combines estradiol and normustine (nornitrogen mustard) through a carbamate link. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, *estramustine* does not function *in vivo* as an alkylating agent; rather, it binds to β-tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions (Tew and Stearns, 1987).

Therapeutic Use

Estramustine is approved for the palliative treatment of patients with progressive or metastatic prostate cancer.

ADME

Following oral administration, at least 75% of a dose of *estramustine phosphate* is absorbed from the GI tract and rapidly dephosphorylated. The drug undergoes extensive first-pass metabolism by hepatic CYPs to an active 17-keto derivative, estromustine, and to multiple inactive products; the active drug forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. *Estramustine* and estromustine have plasma half-lives of 10 and 14 h, respectively, and are excreted as inactive metabolites, mainly in the feces.

Adverse Effects, Drug Interactions

In addition to myelosuppression, *estramustine* also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention); hypercalcemia; acute attacks of porphyria; impaired glucose tolerance; and hypersensitivity reactions, including angioedema. *Estramustine* inhibits the clearance of taxanes.

Epothilones

The epothilones are polyketides discovered as cytotoxic metabolites from a strain of *Sorangium cellulosum*, a myxobacterium isolated from soil on the bank of the Zambezi River in southern Africa (Gerth et al., 1996). One of these, *ixabepilone*, is approved for breast cancer treatment; others are under development (Lee and Swain, 2008).

Ixabepilone

Mechanism of Action; Resistance. Epothilones bind to a β-tubulin pocket located on the luminal side of microtubules, the taxane site (Steinmetz and Prota, 2018), and can trigger microtubule nucleation at multiple sites away from the centriole. This dysfunctional microtubule stabilization triggers cell-cycle arrest at the G_2-M interface and apoptosis. *In vitro* studies suggested that *ixabepilone* is less susceptible to Pgp-mediated export and multidrug resistance than taxanes. Mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and upregulation of isoforms of β-tubulin.

ADME. *Ixabepilone* is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent *cremophor* (polyoxyethylated castor oil/ethanol), which has been implicated as the cause of infusion reactions; such reactions are infrequent when administration is preceded by premedication with H_1 and H_2 antagonists. The drug is cleared by hepatic CYPs and has a plasma $t_{1/2}$ of 52 h.

Therapeutic Uses. In patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes, *ixabepilone* plus *capecitabine* provides an improved progression-free survival of 1.6 months compared to *capecitabine* alone. *Ixabepilone* also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and *capecitabine*. *Ixabepilone* (~40 mg/m^2) is administered as monotherapy or in combination with *capecitabine* over 3 h every 3 weeks. Patients should be premedicated with both an H_1 and an H_2 antagonist before receiving *ixabepilone* to minimize hypersensitivity reactions. In patients with mild-to-moderate hepatic dysfunction who receive *ixabepilone* monotherapy, lower starting doses are recommended due to delayed drug clearance.

Adverse Effects. Epothilones have toxicities similar to those of the taxanes: neutropenia, peripheral sensory neuropathy, fatigue, diarrhea, and asthenia.

Camptothecin Analogues

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme *topoisomerase I*. The lead compound in this class, camptothecin, was isolated from the tree *Camptotheca acuminata*. *Irinotecan* and *topotecan*, currently the only camptothecin analogues approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

	C-10	C-9	C-7
Camptothecin	H	H	H
Topotecan	OH	$(CH_3)_2NHCH_2$	H
Irinotecan		H	CH_2CH_3
SN-38	OH	H	CH_2CH_3

Figure 70–11 *Camptothecin and its analogues.*

Chemistry

All camptothecins have a fused five-ring backbone that includes a labile lactone ring (Figure 70–11). The hydroxyl group and S conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit enhance water solubility and increase potency for inhibiting topoisomerase I. *Topotecan* is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. *Irinotecan* (CPT-11) differs from *topotecan* in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bis-piperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite SN-38 (see Figure 6–6).

Mechanism of Action

The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled to permit replication, repair, and transcription (Pommier, 2013). Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing. Camptothecin analogues inhibit the function of topoisomerase I; other drugs, such as anthracyclines, epipodophyllotoxins, and acridines, inhibit topoisomerase II. The camptothecins bind to and stabilize the normally transient DNA–topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the religation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death.

Camptothecins are *S phase–specific drugs* because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. S phase–specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold for optimal therapeutic efficacy. In fact, low-dose, protracted administration of camptothecin analogues results in less toxicity and equal or greater antitumor activity than shorter, more intense courses.

Mechanisms of Resistance

Decreased intracellular drug accumulation may underlie resistance. The BCRP/xenobiotic exporter ABCG2/BCRP is overexpressed in cultured cells that have become resistant to *irinotecan* after exposure to camptothecins. Cell lines that lack carboxylesterase activity demonstrate resistance to *irinotecan*, but the liver and red blood cells may have sufficient carboxylesterase activity to convert *irinotecan* to the active metabolite SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins *in vitro* and *in vivo*. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance. Finally, exposure of cells to topoisomerase I–targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Topotecan

ADME

Topotecan is approved for intravenous administration. An oral dosage form in development has a bioavailability of 30% to 40% in patients with cancer. *Topotecan* exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation with a $t_{1/2}$ of about 3.5 to 4.1 h. Only 20% to 35% of the total drug in plasma is found to be in the active lactone form. Within 24 h, 30% to 40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in CL_{Cr}. Hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is low (7%–35%), which may explain its relatively greater CNS penetration.

Therapeutic Uses

Topotecan is indicated for previously treated patients with ovarian and small cell lung cancer. Significant hematological toxicity limits its use in combination with other active agents in these diseases (e.g., *cisplatin*). The recommended dosing regimen of *topotecan* for ovarian cancer and small cell lung cancer is a 30-min infusion for 5 consecutive days every 3 weeks. For the treatment of patients with cervical cancer in conjunction with *cisplatin*, *topotecan* is administered on days 1, 2, and 3, repeated every 21 days. The dose of *topotecan* should be reduced in patients with moderate renal dysfunction (CL_{Cr} of 20–40 mL/min); *topotecan* should not be administered to patients with severe renal impairment (CL_{Cr} <20 mL/min). Hepatic dysfunction does not alter *topotecan* clearance and toxicity. A baseline neutrophil count greater than 1500 cells/mm^3 and a platelet count above 100,000 is necessary prior to *topotecan* administration.

Adverse Effects

The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at 1.5 mg/m^2 daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild *topotecan*-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

Irinotecan

ADME

The conversion of *irinotecan* to its active metabolite SN-38 is mediated predominantly by carboxylesterases in the liver (see Figures 5–6 and 5–8). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of *irinotecan*, the AUC of SN-38 is only about 4% of the AUC of *irinotecan*, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. *Irinotecan* exhibits linear pharmacokinetics. In comparison to *topotecan*, a relatively large fraction of both *irinotecan* and SN-38 are present in plasma as the biologically active intact lactone form. The $t_{1/2}$ of SN-38 is 11.5 h, three times that of *topotecan*. CSF penetration of SN-38 in humans has not been characterized.

In contrast to *topotecan*, hepatic metabolism of *irinotecan* and SN-38 represents an important route of elimination for both. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bis-piperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of *irinotecan* was found to be two times greater in patients with brain cancer taking antiseizure drugs that induce hepatic CYPs.

UGT1A1 glucuronidates the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety), producing the inactive glucuronide metabolite SN-38G (see Figures 5–6, 5–8, and 5–9). Biliary excretion

appears to be the primary elimination route of *irinotecan*, SN-38, and metabolites, although urinary excretion also contributes (14%–37%). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after *irinotecan* therapy. UGT1A1 polymorphisms associated with familial hyperbilirubinemia syndromes may have a major impact on the clinical use of *irinotecan*. In patients treated with *irinotecan*, there is a positive correlation between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of *irinotecan* and SN-38. Severe *irinotecan* toxicity has been observed in patients with cancer with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. In patients with the syndrome, elevated levels of unconjugated bilirubin in the bloodstream are due to reduced activity of glucuronyltransferase (Figure 5–7). The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to *irinotecan*'s GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite.

Therapeutic Uses

Single-agent dosage of *irinotecan* is by weekly infusion for 4 of 6 weeks, with a higher dose given every 3 weeks. In patients with advanced colorectal cancer, *irinotecan* is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with *cetuximab* following failure of a 5FU/*oxaliplatin* regimen. It also has activity in small cell lung cancer. An *irinotecan* liposome injection in combination with 5FU and *leucovorin* is FDA-approved for treatment of metastatic pancreatic cancer after disease progression following *gemcitabine* therapy.

Adverse Effects

The dose-limiting toxicity with all dosing schedules is delayed diarrhea (35%), with or without neutropenia. An intensive regimen of *loperamide* (see Chapter 54) reduces this incidence by more than half. However, once severe diarrhea occurs, standard doses of antidiarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common *irinotecan*-associated toxicity is myelosuppression. Severe neutropenia occurs in 14% to 47% of the patients treated with a schedule of administration every 3 weeks and is less frequently encountered among patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by *irinotecan* may occur within the first 24 h after *irinotecan* administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and, less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to *atropine*. Other common toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. There have been case reports of dyspnea and interstitial pneumonitis associated with *irinotecan* therapy.

Antibiotics

Dactinomycin (Actinomycin D)

Actinomycins are chromopeptides isolated from *Streptomyces* soil bacteria. Most contain the same chromophore, the planar phenoxazone actinosin, which is responsible for their yellow-red color. The differences among naturally occurring actinomycins are confined to variations in the structure of the amino acids of the peptide side chains. *Actinomycin D* has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

Mechanism of Action

The capacity of actinomycins to bind to double-helical DNA is responsible for their biological activity and cytotoxicity (Reich, 1963). The planar phenoxazone ring intercalates between adjacent guanine-cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix, resulting in a *dactinomycin*-DNA complex with stability sufficient to block the transcription of DNA by RNA polymerase. The DNA-dependent RNA polymerases are much more sensitive to the effects of *dactinomycin* than are the DNA polymerases. In addition, *dactinomycin* causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II. *Dactinomycin* inhibits rapidly proliferating cells of normal and neoplastic origin and is among the most potent antitumor agents known.

ADME

Dactinomycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal $t_{1/2}$ of 36 h. *Dactinomycin* does not cross the blood-brain barrier.

Therapeutic Uses

Dactinomycin is given intravenously for 5 days, usually in the range of 10 to 15 μg/kg. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2 to 4 weeks, although weekly maintenance doses have been used. The main clinical use of *dactinomycin* is in the treatment of rhabdomyosarcoma and Wilms tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly *vincristine* and *cyclophosphamide*. Ewing, Kaposi, and soft-tissue sarcomas also respond. *Dactinomycin* and MTX form a curative therapy for choriocarcinoma.

Adverse Effects

Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation; the drug is extremely corrosive to soft tissues.

Anthracyclines and Anthracenediones

Anthracyclines are derived from *Streptomyces peucetius* var. *caesius*. *Idarubicin* and *epirubicin* are analogues of the naturally produced anthracyclines *doxorubicin* and *daunorubicin*, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. *Daunorubicin* and *idarubicin* primarily have been used in acute leukemias, whereas *doxorubicin* and *epirubicin* display broader activity against solid tumors. These agents, which possess the potential for generating free radicals, cause an unusual and often-irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent *mitoxantrone* has less cardiotoxicity and is useful against prostate cancer and AML and in high-dose chemotherapy.

	DOXORUBICIN	DAUNORUBICIN	EPIRUBICIN	IDARUBICIN
R_1 =	OCH_3	OCH_3	OCH_3	H
R_2 =	H	H	OH	H
R_3 =	OH	OH	H	OH
R_4 =	OH	H	OH	H

Mechanisms of Action and Resistance

Anthracyclines and anthracenediones can intercalate with DNA, directly affecting transcription and replication. More important is their

capacity to form a heterotrimeric complex with topoisomerase II and DNA (Pommier, 2013). Topoisomerase II produces double-strand breaks at the 3′-phosphate backbone, allowing strand passage and uncoiling of supercoiled DNA. Following strand passage, topoisomerase II religates the DNA strands; this enzymatic function is essential for DNA replication and repair. Formation of the ternary complex with anthracyclines or with *etoposide* inhibits the religation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while altered DNA damage-sensing and DNA repair capacity may contribute to resistance.

The quinone moieties of anthracyclines can form radical intermediates that react with O_2 to produce superoxide anion radicals, which can generate H_2O_2 and •OH that attack DNA and oxidize DNA bases, leading to apoptosis (Serrano et al., 1999). The production of free radicals is significantly stimulated by the interaction of *doxorubicin* with iron. Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as α-tocopherol or by the iron chelator *dexrazoxane*, which protects against cardiac toxicity. Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by ABCG2 (BCRP). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

ADME

Daunorubicin, *doxorubicin*, *epirubicin*, and *idarubicin* are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. Each anthracycline is converted to an active alcohol intermediate that plays a variable role in the therapeutic activity. The plasma disappearance curves for *doxorubicin* and *daunorubicin* are multiphasic, with a terminal $t_{1/2}$ of 30 h. *Idarubicin* has a $t_{1/2}$ of 15 h, and its active metabolite, idarubicinol, has a $t_{1/2}$ of 40 h. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen; they do not cross the blood-brain barrier. Clearance is delayed in the presence of hepatic dysfunction; at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

Idarubicin and Daunorubicin

Therapeutic Use. *Idarubicin* (~12 mg/m² per day for 3 days) is administered by slow intravenous injection (10–15 min) to avoid extravasation. *Idarubicin* has less cardiotoxicity than the other anthracyclines. *Daunorubicin* (also named daunomycin or rubidomycin) is administered (at variable doses according to the regimen, 45–90 mg/m² per day) intravenously for 3 days, with care to prevent extravasation. Total doses greater than 550 mg/m² are associated with a high risk of cardiotoxicity. Radiation therapy to the mediastinum may enhance the risk of anthracycline toxicity. *Daunorubicin* may impart a red color to the urine. *Daunorubicin* and *idarubicin* are used in the treatment of patients with AML in combination with Ara-C.

Adverse Effects. Toxic effects of *daunorubicin* and *idarubicin* include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity of anthracyclines can be acute or chronic and is described in detail next for *doxorubicin*.

Doxorubicin

Therapeutic Uses. The dose (60–75 mg/m²) is administered as a single rapid intravenous infusion that is repeated after 21 days. A *doxorubicin* liposomal product is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 min and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer for treatment at a dose of 50 mg/m² every 4 weeks and as a treatment of multiple myeloma, where it is given as a 30-mg/m² dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine. *Doxorubicin* is effective in malignant lymphomas. In combination with *cyclophosphamide*, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens adjunct of chemotherapy for and metastatic carcinoma of the breast. The drug also is beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

Adverse Effects. Toxicities of *doxorubicin* are similar to those of *daunorubicin*. Myelosuppression is a major dose-limiting complication, with maximal leukopenia usually occurring during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion ("flare") is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity (Rochette et al., 2015) and may take two forms:

- **An acute form, characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias.** This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 h after a single dose, and plasma troponin T may increase in a minority of patients in the first few days following drug administration (Lipshultz et al., 2004). Acute myocardial damage, the "pericarditis-myocarditis syndrome," may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.
- **Chronic, cumulative, dose-related toxicity (usually total doses of ≥550 mg/m²) progressing to congestive heart failure.** The mortality rate in patients with congestive heart failure approaches 50%. The risk of cardiomyopathy increases markedly with dose; estimates run as high as 20% at total doses of 550 mg/m² (a total dose limit of 300 mg/m² is advised for pediatric cases). These total dosages should be exceeded only under exceptional circumstances or with the concomitant use of *dexrazoxane*, a cardioprotective iron-chelating agent (Swain et al., 1997), as the mechanism of cardiotoxicity is thought to derive in part from cardiac lipid peroxidation (Myers et al., 1977) promoted by Fe^{2+} (Zweier, 1984). More recent studies have also proposed that *dexrazoxane* can prevent anthracycline-derived DNA damage by interaction with topoisomerase II in cardiac cells (Lyu et al., 2007). Cardiac irradiation, administration of high doses of *cyclophosphamide* or another anthracycline, or concomitant *trastuzumab* increases the risk of cardiotoxicity (Slamon et al., 2001). Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. Concomitant administration of *dexrazoxane* may reduce troponin T elevations and avert later cardiotoxicity (Lipshultz et al., 2004).

Epirubicin

The anthracycline *epirubicin* is indicated as a component of adjunctive therapy for treatment of breast cancer. It is administered intravenously in doses of 100 to 120 mg/m² every 3 to 4 weeks. Total doses greater than 900 mg/m² sharply increase the risk of cardiotoxicity. Its toxicity profile is the same as that of *doxorubicin*.

Valrubicin

Valrubicin is a semisynthetic analogue of *doxorubicin* used exclusively for intravesicular treatment of bladder cancer. Once a week for 6 weeks, 800 mg are instilled into the bladder. Less than 10% of instilled drug is absorbed systemically. Side effects relate to bladder irritation.

Mitoxantrone

Mitoxantrone is a synthetic anthracenedione derivative topoisomerase II inhibitor that is approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. *Mitoxantrone* has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does *doxorubicin*. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug also causes nausea, vomiting, and alopecia, although less than *doxorubicin*. *Mitoxantrone* is administered by intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m^2 for 3 days with *cytarabine*. It also is used in advanced hormone-resistant prostate cancer in a dose of 12 to 14 mg/m^2 every 21 days.

Epipodophyllotoxins

Podophyllotoxin Derivatives

Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are *etoposide* (VP-16-213) and *teniposide* (VM-26). Although podophyllotoxin binds to tubulin, *etoposide* and *teniposide* have no effect on microtubular structure or function at usual concentrations.

Mechanisms of Action and Resistance

Etoposide and *teniposide* form ternary complexes with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G_2 phases of the cell cycle are most sensitive to *etoposide* and *teniposide*. Resistant cells demonstrate (1) amplification of the *MDR1* gene that encodes the Pgp drug efflux transporter, (2) mutation or decreased expression of topoisomerase II, or (3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

Etoposide

ADME

Oral administration of *etoposide* results in variable absorption that averages about 50%. After intravenous injection, there is a biphasic pattern of clearance with a terminal $t_{1/2}$ of about 6 to 8 h in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in CL_{Cr}. In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces *etoposide* from albumin); guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1% to 10% of those in plasma.

Therapeutic Uses

The intravenous dose of *etoposide* for testicular cancer in combination therapy (with *bleomycin* and *cisplatin*) is 50 to 100 mg/m^2 for 5 days or 100 mg/m^2 on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy (with *cisplatin*) is 100 to 200 mg/m^2/d intravenously for 3 days. Cycles of therapy usually are repeated every 3 to 4 weeks. After relapse, oral administration of 50 mg/m^2 per day for 21 days is one treatment option. When given intravenously, the drug should be administered slowly over a 30- to 60-min period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve *etoposide*.

Etoposide is also active against non-Hodgkin lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with AIDS. *Etoposide* has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with *ifosfamide* and *carboplatin*, it frequently is used for high-dose chemotherapy in total doses of 1500 to 2000 mg/m^2. *Trilaciclib*, a cyclin-dependent kinase (CDK) 4/6 kinase inhibitor, was approved in 2021 for administration prior to cytotoxic chemotherapy to decrease the incidence of myelosuppression in patients receiving a platinum/*etoposide*-containing regimen or *topotecan*-containing regimen for extensive-stage small cell lung cancer (see Chapter 71).

Adverse Effects

The dose-limiting toxicity of *etoposide* is leukopenia (nadir at 10–14 days, recovery by 3 weeks). Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in about 15% of patients. Alopecia is common but reversible. Hepatic toxicity is particularly evident after high-dose treatment. For both *etoposide* and *teniposide*, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug.

A disturbing complication of *etoposide* therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the *MLL* gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of *etoposide*-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1–3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Pui et al., 1995). Patients receiving weekly or twice-weekly doses of *etoposide*, with cumulative doses greater than 2000 mg/m^2, seem to be at higher risk of leukemia.

Teniposide

Teniposide is administered intravenously. It has a multiphasic pattern of clearance from plasma: After distribution, a $t_{1/2}$ of 4 h and another $t_{1/2}$ of 10 to 40 h are observed. Approximately 45% of the drug is excreted in the urine; in contrast to *etoposide*, as much as 80% is recovered as metabolites. Anticonvulsants such as *phenytoin* increase the hepatic metabolism of *teniposide* and reduce systemic exposure. Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. *Teniposide* is available for treatment of refractory ALL in children and is synergistic with *cytarabine*. *Teniposide* is administered by intravenous infusion for 5 days or twice weekly. The drug has limited utility and is given primarily for acute leukemia in children and monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

Trabectedin Analogues

Trabectedin

Trabectedin is derived from the marine invertebrate tunicate *Ecteinascidin turbinate*. *Trabectedin* is an alkylating drug that binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove. The bulky DNA adduct is recognized by the transcription-coupled NER complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. *Trabectedin* has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the ability to repair double-strand DNA breaks through homologous recombination (Soares et al., 2011). Unlike *cisplatin* and other DNA adduct–forming drugs, the activity of *trabectedin* requires the presence of intact components of NER, including xeroderma pigmentosum endonuclease G, which may be important for initiation of single breaks and attempts at adduct removal.

ADME

Trabectedin is administered as a 24-h infusion of 1.3 mg/m^2 every 3 weeks. It is administered with *dexamethasone*, 4 mg twice daily, starting 24 h before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma $t_{1/2}$ of about 24 to 40 h.

Therapeutic Uses

Trabectedin is approved for the treatment of patients with unresectable or metastatic liposarcoma or leiomyosarcoma after an anthracycline-containing regimen and is under study for the treatment of patients with ovarian and pancreatic cancer.

Adverse Effects

Without *dexamethasone* pretreatment, *trabectedin* causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reversible. Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

Lurbinectedin

Lurbinectedin is structurally similar to *trabectedin*. It covalently binds to residues in the minor groove of DNA and delays progression through S phase, causing cell cycle arrest in the G2/M phase and cell death. The FDA approved *lurbinectedin* in 2020 for metastatic small cell lung cancer disease progression on or after platinum-based chemotherapy. It has similar adverse effects as *trabectedin*. *Lurbinectedin* can be administered as a 60-min infusion, also every 3 weeks.

Drugs of Diverse Mechanisms of Action

Bleomycin

The bleomycins, an unusual group of DNA-cleaving antibiotics, are fermentation products of *Streptomyces verticillus,* comprising a family of peptide polyketides. The drug currently employed clinically is a mixture of two copper-chelating peptides, bleomycins A_2 and B_2, that differ only in their terminal amino acid. Because their toxicities do not overlap with those of other cytotoxic drugs and because of their unique mechanism of action, *bleomycin* maintains an important role in treating Hodgkin disease and testicular cancer.

Mechanisms of Action and Resistance

Bleomycin's cytotoxicity results from its capacity to cause oxidative damage to DNA. *Bleomycin* is a glycopeptide that has a DNA-binding portion (Chien et al., 1977) and, through a distinct functionality, binds to metal ions. In the presence of O_2, the Fe^{2+}-drug complex becomes activated and transfers electrons from Fe^{2+} to molecular oxygen to produce oxygen radicals, leading to single- and double-stranded breaks with release of free bases from DNA (Sausville et al., 1978). *Bleomycin* causes accumulation of cells in the G_2 phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, fragments, and translocations.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity. Some *bleomycin*-resistant cells contain high levels of hydrolase activity. In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

ADME

Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. Having a high molecular mass, *bleomycin* crosses the blood-brain barrier poorly. The elimination $t_{1/2}$ is about 3 h. About two-thirds of the drug is excreted intact in the urine. Concentrations in plasma are greatly elevated in patients with renal impairment, and doses of *bleomycin* should be reduced in the presence of a CL_{Cr} less than 60 mL/min.

Therapeutic Uses

Bleomycin is given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of 2 units or less is recommended for patients with lymphoma. Myriad regimens are employed clinically, with *bleomycin* doses expressed in units. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity. *Bleomycin* also may be instilled into the pleural cavity in doses of 5 to 60 mg to ablate the pleural space in patients with malignant effusions. *Bleomycin* is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with *cisplatin* and *vinblastine* or *cisplatin* and *etoposide*. It is a component of the standard curative ABVD regimen for Hodgkin disease.

Adverse Effects

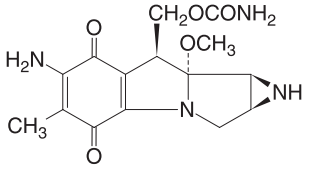
Because *bleomycin* causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, even ulceration, and rarely, Raynaud phenomenon. Skin lesions may recur when patients are treated with other antineoplastic drugs. Rarely, *bleomycin* causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands; this rash responds readily to topical corticosteroids.

The most serious adverse reaction to *bleomycin* is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5% to 10% of patients receiving *bleomycin* develop clinically apparent pulmonary toxicity, and about 1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses greater than 250 mg and in patients more than 40 years of age, in those with a CL_{Cr} less than 80 mL/min, and in those with underlying pulmonary disease; single doses of 30 mg/m^2 or more also are associated with an increased risk of pulmonary toxicity. Administration of high O_2 concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug, in keeping with the clear ability of metallobleomycin complexes to generate O_2-derived radicals. There is no known specific therapy for *bleomycin* lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

Other toxic reactions to *bleomycin* include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and may be related to release of an endogenous pyrogen. This reaction has occurred in about 1% of patients with lymphomas or testicular cancer.

Mitomycin

Mitomycin has limited clinical utility, having been replaced by less toxic and more effective drugs, with the exception of the use in patients with anal cancers, for which it is potentially curative.



MITOMYCIN

Mechanisms of Action and Resistance

After intracellular enzymatic or spontaneous chemical alteration, *mitomycin* becomes a bifunctional or trifunctional alkylating agent. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. *Mitomycin* is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and Pgp-mediated drug efflux.

ADME

Mitomycin is administered intravenously. It has a $t_{1/2}$ of 25 to 90 min. The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulfhydryls. Less than 10% of the active drug is excreted in the urine or the bile.

Therapeutic Uses

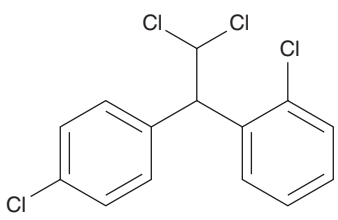
Mitomycin is administered as a single bolus (6–20 mg/m^2) every 6 to 8 weeks. Dosage should be modified based on hematological recovery. *Mitomycin* also may be used by direct instillation into the bladder to treat superficial transitional cell carcinomas. *Mitomycin* is used in combination with 5FU and *cisplatin* for the treatment of anal cancer. *Mitomycin* is also approved for local use as an adjunct to glaucoma surgery to reduce scarring.

Adverse Effects

The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, maximal suppression may be delayed and cumulative, with recovery only after 6 to 8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise also are observed. Patients who have received more than 50 mg/m^2 total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of 70 mg/m^2 or more. There is no effective treatment of the disorder. It must be recognized early, and *mitomycin* must be discontinued immediately. *Mitomycin* causes interstitial pulmonary fibrosis; total doses greater than 30 mg/m^2 have infrequently led to congestive heart failure. *Mitomycin* may potentiate the cardiotoxicity of *doxorubicin*.

Mitotane

Mitotane (*o,p′*-DDD, dichlorodiphenyldichloroethane), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of adrenal cortex carcinoma. The mechanism of action of *mitotane* has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.



MITOTANE (*o,p′*-DDD)

ADME

Approximately 40% of *mitotane* is absorbed after oral administration. Plasma concentrations of mitotane are still measurable for 6 to 9 weeks following discontinuation of therapy. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of *mitotane* found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

Therapeutic Uses

Mitotane initial daily oral doses are 2 to 6 g, usually in three or four divided portions. The maximal tolerated dose may vary from 2 to 16 g/day. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. *Spironolactone* should not be administered concomitantly because it interferes with the adrenal suppression produced by *mitotane*. Treatment with *mitotane* is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30% to 50% of such patients.

Adverse Effects

Although the administration of *mitotane* produces anorexia and nausea in most patients, somnolence and lethargy in about 34%, and dermatitis in 15% to 20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary.

L-Asparaginase

Malignant lymphoid cells depend on exogenous sources of L-asparagine. Thus, L-*asparaginase* (L-ASP) has become a standard agent for treating ALL.

Mechanism of Action

Most normal tissues synthesize L-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthase and derive the required amino acid from plasma. L-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. L-ASP is used in combination with other agents, including MTX, *doxorubicin*, *vincristine*, and *prednisone*, for the treatment of ALL and high-grade lymphomas. Resistance arises through induction of asparagine synthetase in tumor cells.

ADME and Therapeutic Use

Asparaginase is given intramuscularly or intravenously. After intravenous administration, *Escherichia coli*–derived L-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a $t_{1/2}$ of 1 day. The enzyme is given in doses of 6000 to 10,000 IU every third day for 3 to 4 weeks. *Pegaspargase* is a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, resulting in a much longer plasma $t_{1/2}$ (6–7 days); it is administered intramuscularly every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients. *Pegaspargase* has much reduced immunogenicity (<20% of patients develop antibodies) and has been approved for first-line ALL therapy. The conjugated preparation *calaspargase pegol* is administered intravenously every 21 days.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate L-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although the enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, *pegaspargase* produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli* enzyme in relapsed patients. Asparaginase preparations only partially deplete CSF asparagine.

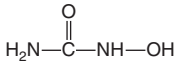
Adverse Effects

The L-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5% to 20% of patients and may be fatal. In these patients, *pegaspargase* is a safe and effective alternative. So-called silent enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk patients with ALL.

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis also has been observed. The clotting problems may take the form of spontaneous thrombosis or, less frequently, hemorrhagic episodes. Brain magnetic resonance imaging studies should be considered in patients treated with L-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of L-ASP treatment is an infrequent but devastating complication. L-ASP also suppresses immune function. L-ASP terminates the antitumor activity of MTX when given shortly after the antimetabolite. By lowering serum albumin concentrations, L-ASP may decrease protein binding and accelerate plasma clearance of other drugs.

Hydroxyurea

Hydroxyurea (HU) inhibits the enzyme ribonuleotide reductase (RNR) and has unique and diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of fetal hemoglobin (HbF) in patients with sickle cell disease. It is orally administered, and its toxicity is modest and limited to myelosuppression.



HYDROXYUREA

Mechanisms of Action and Resistance

Hydroxyurea inhibits RNR, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds non-heme iron atoms that are essential for activation of a tyrosyl radical in the catalytic subunit of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. HU produces arrest at or near the G_1-S interface through both p53-dependent and-independent mechanisms. Because cells are highly sensitive to irradiation at the G_1-S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of deoxynucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as *cisplatin*, alkylating agents, or topoisomerase II inhibitors and facilitates the incorporation of antimetabolites such as Ara-C, *gemcitabine*, and *fludarabine* into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of histone deacetylase (HDAC) inhibitors *in vitro* (Kramer et al., 2008).

Hydroxyurea is the primary drug for improving control of sickle cell (HbS) disease in adults and for inducing HbF in patients with thalassemia HbC and HbC/S. It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. The mechanism of stimulated HbF production is uncertain. HU stimulates nitric oxide production, causing nitrosylation of low-molecular-weight GTPases, a process that stimulates γ-globin production in erythroid precursors. Another property of HU that may be therapeutically relevant is its capacity to reduce L-selectin expression and thereby to reduce adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion. Tumor cells become resistant to HU through increased synthesis of the catalytic subunit of RNR, thereby restoring enzyme activity.

ADME

The oral bioavailability of HU is 80% to 100%; comparable plasma concentrations are seen after oral or intravenous dosing. HU disappears from plasma with a $t_{1/2}$ of 3.5 to 4.5 h. The drug readily crosses the blood-brain barrier; significant quantities appear in human breast milk. From 40% to 80% of the drug is recovered in the urine within 12 h after administration. It is advisable to modify initial doses for patients with renal dysfunction.

Therapeutic Uses

In cancer treatment, HU is used alone or in combination with other drugs with two dosage schedules: (1) intermittent therapy administered orally as a single dose (~80 mg/kg) every third day or (2) continuous therapy administered as a single daily dose (20–30 mg/kg). In patients with essential thrombocythemia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1 to 2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained. Treatment typically is continued for 6 weeks to determine effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocytosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating mutations of Janus kinase 2 (*JAK2*), a gene that is downregulated by HU. In essential thrombocythemia, it is the drug of choice for patients with a platelet count greater than 1.5 million cells/mm^3 or with a history of arterial or venous thrombosis. In CML, HU has been largely replaced by *imatinib* (see Chapter 71). HU is a potent radiosensitizer as a consequence of its inhibition of RNR and has been incorporated into several treatment regimens with concurrent irradiation (i.e., cervical carcinoma, primary brain tumors, head and neck cancer, non–small cell lung cancer).

Adverse Effects

Leukopenia, anemia, and occasionally thrombocytopenia are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, mild dermatological reactions, and, more rarely, stomatitis, alopecia, and neurological manifestations. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in animals and should not be used in women with childbearing potential.

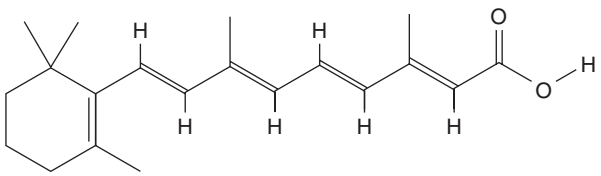
Retinoids

One of the hallmarks of malignant transformation is a block in differentiation. A number of chemical entities (vitamin D and its analogues, retinoids, benzamides and other inhibitors of HDAC [see Chapter 71], various cytotoxic and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines. The most important of these for cancer treatment are retinoids, in particular *tretinoin* (ATRA), which induces a high rate of complete remission in patients with APL as a single agent and, in combination with anthracyclines, cures most patients with this disease. The biology and pharmacology of retinoids are discussed in detail in Chapter 75.

Tretinoin (ATRA)

Mechanism of Action. Under physiological conditions, the retinoic acid receptor (RAR) A dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the transcriptional complex and alters the expression of genes that control differentiation of cells of multiple lineages. Most APLs are

characterized by a chromosomal translocation of the *RARA* gene on chromosome 17 and fusion with the *PML* gene on chromosome 15 that is denoted as t(15;17)(q22;q12). In APL cells, physiological concentrations of retinoid are inadequate to displace the repressor, but pharmacological concentrations are effective in activating the differentiation program and in promoting degradation of the PML-RARA fusion protein (Collins, 2008). The *PML* gene encodes a transcription factor important in inhibiting proliferation and promoting myeloid differentiation. The oncogenic *PML-RARA* gene produces a protein that binds retinoids with much decreased affinity, lacks PML regulatory function, and fails to upregulate transcription factors (C/EBP and PU.1) that promote myeloid differentiation. ATRA also binds and activates RAR-γ and thereby promotes stem cell renewal, and this action may help restore normal bone marrow renewal. Resistance to ATRA arises by further mutation of the fusion gene, abolishing ATRA binding; by induction of the CYP26A1; or by loss of expression of the *PML-RARA* fusion gene.



Tretinoin

Therapeutic Use, ADME and Adverse Effects. Oral administration of ATRA is 45 mg/m^2 per day until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. ATRA in combination with an anthracycline induces remission with 80% or greater relapse-free long-term survival.

ATRA is cleared by a CYP3A4-mediated elimination with a $t_{1/2}$ of less than 1 h. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and resistance to ATRA. Inhibitors of CYPs, such as antifungal imidazoles, block ATRA degradation and may lead to hypercalcemia and renal failure, which respond to diuresis, bisphosphonates, and ATRA discontinuation. When used as a single agent for remission induction, especially in patients with more than 5000 leukemic cells/mm^3 in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15% to 20% of patients. Corticosteroids (e.g., *dexamethasone* 5–10 mg twice daily) and chemotherapy (e.g., hydroxyurea) sharply decrease the occurrence of "retinoic acid differentiation syndrome," which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. The syndrome results from the differentiation of leukemia cells and their migration into peripheral tissues, most notably the lungs. Retinoids also cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia.

Arsenic Trioxide

Arsenic trioxide (As_2O_3), known as ATO, is a highly effective treatment of relapsed APL, producing complete responses in more than 85% of such patients. The chemistry and toxicity of *arsenic* are considered in Chapter 76.

ARSENIC TRIOXIDE

Mechanism of Action

The basis for ATO's antitumor activity remains uncertain. APL cells have high levels of reactive oxygen species (ROS) and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate antiapoptotic proteins such as bcl-2 (see Figure 3–25). ATO's cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including PKB, S6 kinase, and mTOR (see Figure 71–4). ATO also induces differentiation of leukemic cell lines in experimental and human leukemias, with evidence of enhanced degradation of the PML-RARα fusion protein that acts to inhibit normal differentiation of APL cells (Zhang et al., 2010). Recent studies indicate that ATO binding to p53 DNA binding domain mutants restores wild-type transcriptional function to the mutant p53 proteins (Chen et al., 2021).

ADME

Arsenic trioxide is well absorbed orally but in cancer treatment is administered as a 2-h daily intravenous infusion in dosages of 0.15 mg/kg per day for up to 60 days, until remission is documented. The drug enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Multiple methylated metabolites (see Figure 71–9) form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

Adverse Effects

Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Fewer than 10% of patients experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome. Lengthening of the QT interval on the electrocardiogram occurs in 40% of patients, but rarely do patients develop torsade de pointes. Simultaneous treatment with other QT-prolonging drugs should be avoided. Monitoring of serum electrolytes and repletion of serum K^+ in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT (>470 msec), treatment should be suspended, K^+ supplemented, and therapy resumed only if the QT returns to normal.

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Section I: Alkylating Agents and Platinum Coordination Complexes		
Mechanism of action: covalent modification of DNA. Adverse effects of all alkylating drugs: myelosuppression and immunosuppression; toxicity to dividing mucosal cells and hair follicles (e.g., oral mucosal ulceration, intestinal denudation, alopecia); delayed pulmonary fibrosis; reproductive system toxicity (premature menopause, sterility); and leukemogenesis (up to 5%, highest for melphalan, procarbazine, nitrosoureas).		
Nitrogen Mustards: DNA alkylation		
Mechlorethamine	• Hodgkin lymphoma • Topical: cutaneous T-cell lymphoma	• Vascular damage during injection due to vesicant properties
Cyclophosphamide	• Acute and chronic lymphocytic leukemia; Hodgkin lymphoma; non-Hodgkin lymphoma; multiple myeloma; neuroblastoma; breast, ovary, Wilms tumor; soft-tissue sarcoma • Autoimmune disease (Wegener granulomatosis, rheumatoid arthritis, nephrotic syndrome)	• Oral or intravenous administration • Active alkylating moieties generated through hepatic metabolism • Nephrotoxic and urotoxic metabolite, acrolein; severe hemorrhagic cystitis in high-dose regimens; prevented by MESNA • Provide vigorous hydration during high-dose treatment • Elimination not affected by renal dysfunction; reduce dose in patients with hepatic dysfunction
Ifosfamide	• Germ cell testicular cancer • Pediatric and adult sarcoma • High-dose chemotherapy with bone marrow rescue	• See cyclophosphamide • Can cause neurotoxicity (including seizures) • Methylene blue treatment of CNS toxicity possibly useful
Melphalan	• Multiple myeloma	• Oral and intravenous administration
Chlorambucil	• Chronic lymphocytic leukemia	• Oral administration
Bendamustine	• Non-Hodgkin lymphoma • Chronic lymphocytic leukemia	• Lacks cross-resistance with other classical alkylators
Alkyl Sulfonate: DNA alkylation		
Busulfan	• Chronic myelogenous leukemia • High-dose chemotherapy regimen with bone marrow transplantation	• Oral administration • Adverse effects: prolonged (up to years) pancytopenia; suppression of stem cells; seizures; lung fibrosis • Clearance of phenytoin; hepatic VOD
Nitrosoureas: DNA alkylation		
Carmustine (BCNU)	• Malignant gliomas • Hodgkin lymphoma; non-Hodgkin lymphoma	• Vascular damage during injection due to vesicant properties • Profound and delayed myelosuppression
Streptozocin (or streptozotocin)	• Malignant pancreatic insulinoma • Carcinoid	• Frequent renal toxicity, sometimes renal failure
Methylhydrazine Derivatives: Monofunctional DNA alkylation		
Procarbazine (*N*-methylhydrazine, MIH)	• Hodgkin lymphoma • Gliomas	• Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators (e.g., cyclophosphamide)
Triazenes: Methyl transfer to DNA		
Dacarbazine (DTIC)	• Hodgkin lymphoma; soft-tissue sarcomas • Melanoma	• Intravenous administration • Activation by hepatic CYPs • Adverse effects: nausea, vomiting • Rare hepatotoxicity and neurotoxicity
Temozolomide	• Malignant gliomas	• Oral administration • Combined with radiation therapy • Greater capacity for mutagenesis and carcinogenesis than bifunctional alkylators; more active in MGMT-deficient tumors
Platinum Coordination Complexes: Form covalent metal adducts with DNA		

Cisplatin	• Testicular, ovarian, bladder, esophageal, gastric, lung, head and neck, anal, and breast cancer	• Intravenous administration
		• Adverse effects:
		  • Nephrotoxicity (reduce by forced pretreatment hydration, diuresis, and use of *amifostine*)
		  • Ototoxicity (tinnitus, high-frequency hearing loss)
		  • Nausea and vomiting (antidote, *aprepitant*)
		  • Peripheral sensory and motor neuropathy (may worsen after discontinuation; may be aggravated by taxane treatment)
		• Drug resistance due to loss of mismatch repair proteins

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Carboplatin	• Same as above	• Less nausea, neuro-, oto-, and nephrotoxicity than cisplatin • Dose-limiting toxicity: myelosuppression • May cause hypersensitivity reaction
Oxaliplatin	• Colorectal, gastric, and pancreatic cancer	• Peripheral neuropathy is dose limiting • Some nausea • Efficacy not dependent on intact mismatch repair
Section II: Antimetabolites		
Folic Acid Analogues: Inhibit dihydrofolate reductase		
Methotrexate (amethopterin)	• Acute lymphocytic leukemia; choriocarcinoma; breast, head and neck, ovary, bladder, and lung cancers; osteogenic sarcoma • Noncancer use: psoriasis, rheumatoid arthritis	• Oral, intravenous, or intramuscular administration • Adverse effects: myelosuppression, GI toxicity • Leucovorin can reverse toxic effects; used as "rescue" in high-dose therapy • *Glucarpidase*, a methotrexate-cleaving enzyme, is approved to treat toxicity • ↓ Dose in renal insufficiency
Pemetrexed	• Mesothelioma, lung cancer	• Similar effects and side effects as methotrexate • Attenuate toxicity with folate and vitamin B_{12} supplementation
Pyrimidine Analogues		
5-Fluorouracil (5FU) *Thymidylate synthase inhibitor*	• Breast, colon, esophageal, stomach, anal cancer • In FOLFOX or FOLFIRINOX combination to treat pancreatic or colorectal cancer • Combined with cisplatin in head and neck cancer • Premalignant skin lesion (topical)	• Intravenous administration • Nausea, mucositis, diarrhea, myelosuppression, hand and foot syndrome • Combined with leucovorin to enhance efficacy • Enhanced toxicity with DPD deficiency; may rescue with uridine triacetate
Capecitabine *Thymidylate synthase inhibitor*	• Metastatic breast, colorectal cancer	• Orally administered prodrug of 5FU • Similar adverse effects as 5FU; hand and foot syndrome more frequent than with 5FU
Cytarabine (cytosine arabinoside) *Interferes with base pairing in DNA; inhibits DNA polymerase*	• Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin lymphoma	• Intravenous administration • Myelosuppressive; can cause acute, severe leukopenia, thrombocytopenia, anemia • GI disturbances • Noncardiogenic pulmonary edema • Dermatitis
Gemcitabine (difluoro analogue of deoxycytidine) *Inhibits DNA polymerase; causes strand termination*	• Pancreatic, ovarian, lung, bladder cancer	• Intravenous administration • Female and elderly patients clear the drug more slowly • Myelosuppression, hepatic toxicity • Rare posterior leukoencephalopathy syndrome; sometimes interstitial pneumonitis • Radiosensitizer; should be used with caution in radiotherapy
5-Azacytidine (azacitidine) *Inhibits DNA cytosine methyltransferase*	• Myelodysplasia	• Subcutaneous or intravenous administration • Myelosuppression and mild GI symptoms • After intravenous administration, severe nausea possible
Purine Analogues and Related Inhibitors		
6-Mercaptopurine *Inhibits purine nucleotide synthesis and metabolism*	• Acute lymphocytic and myelogenous leukemia; small cell non-Hodgkin lymphoma • Noncancer: Crohn's disease, ulcerative colitis	• Oral absorption incomplete, thus intravenous administration • Reduce oral dose by 75% in patients receiving allopurinol; no adjustment needed for intravenous administration • Myelosuppression; anorexia, nausea, vomiting; GI side effects less frequent in children than adults • Secondary malignancy: squamous cell skin cancer; AML
Fludarabine *A chain terminator when incorporated into DNA; inhibits RNA function and processing*	• Chronic lymphocytic leukemia • Follicular B-cell lymphoma • Allogeneic bone marrow transplant	• Oral or intravenous administration • Frequently myelosuppression • Less frequent: nausea, vomiting; altered mental status; seizures • Secondary myelodysplasia and acute leukemias • Adjust dose for renal dysfunction
Cladribine *Incorporated into DNA, produces strand breaks; inhibits conversion of ribo- to deoxyribonucleotides*	• Hairy cell leukemia • Chronic lymphocytic leukemia • Low-grade lymphoma • CTCL, Waldenström macroglobulinemia	• Intravenous administration • Adjust dose for renal dysfunction • Myelosuppression, opportunistic infections, nausea, high fever, tumor lysis syndrome

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Clofarabine (mechanism as above)	• Acute myelogenous or lymphocytic leukemia	• Intravenous administration • Adjust dose to creatinine clearance • Myelosuppression • Capillary leak syndrome: discontinue drug • Nausea, vomiting, diarrhea
Nelarabine *Incorporated into DNA, terminates DNA synthesis*	• T-cell leukemia, lymphoma	• Intravenous administration • Myelosuppression; liver function abnormalities; infrequent neurologic sequelae
Pentostatin (2′-deoxycoformycin) *Inhibits adenosine deaminase; causes immunodeficiency (T and B cells)*	• Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin lymphoma	• Intravenous administration • Adjust dose for renal dysfunction • Myelosuppression, GI symptoms, skin rashes, opportunistic infections • Renal, neurologic, pulmonary toxicity
Section III: Natural Products		
Vinca Alkaloids: Inhibit tubulin polymerization and microtubule formation		
Vinblastine	• Hodgkin and non-Hodgkin lymphoma • Breast, bladder, lung, testicular cancer • Kaposi sarcoma, neuroblastoma • Part of ABVD combination with doxorubicin (Adriamycin, bleomycin, dacarbazine) for Hodgkin lymphoma	• Administered IV; extravasation causes irritation and ulceration • Reduce dose in patients with impaired liver function • Least neurotoxic vinca alkaloid • Myelosuppressive • GI side effects nausea, vomiting, diarrhea • Vinca alkaloids are substrates of the Pgp efflux pump
Vinorelbine	• Breast cancer • Non–small cell lung cancer	• Intravenous administration • Reduce dose in patients with impaired liver function • Intermediate neurotoxicity among the vinca alkaloids • Myelosuppressive (granulocytopenia)
Vincristine	• Acute lymphocytic leukemia; neuroblastoma; Wilms tumor; rhabdomyosarcoma; Hodgkin and non-Hodgkin lymphoma • Part of CHOP regimen: cyclophosphamide, doxorubicin (H), vincristine (O), prednisone	• Administered IV; extravasation causes irritation and ulceration • Reduce dose in patients with impaired liver function • Least myelosuppressive vinca alkaloid • Dose-limiting neurotoxicity • Better tolerated by children than adults
Eribulin	• Breast cancer, liposarcoma	• Side effects overlap with those of vinca but less sensitive to extrusion by Pgp
Taxanes: Stabilize microtubules, inhibit depolymerization		
Paclitaxel	• Ovarian, breast, lung, prostate, bladder, head and neck cancer	• Intravenous administration • Metabolized by hepatic CYPs, ↓ dose in patients with hepatic dysfunction • Substrate of Pgp efflux pump • Myelosuppressive, alleviated by G-CSF • Peripheral neuropathy is dose limiting • Mucositis
Docetaxel	• Same as above	• No effect on doxorubicin clearance • Pharmacokinetics similar to paclitaxel's • ↓ Neutropenia, ↓ neuropathy than paclitaxel
Camptothecins: Inhibit topoisomerase I; DNA religation is inhibited: accumulation of single-strand breaks		
Topotecan	• Ovarian cancer; small cell lung cancer	• Intravenous or oral administration • Reduce dose in patients with renal dysfunction • Neutropenia, GI side effects, nausea, vomiting • Substrate for Pgp
Irinotecan	• Colorectal cancer, small cell lung cancer • Part of FOLFIRI (leucovorin, 5FU, and irinotecan) or FOLFIRINOX combination for GI tumors	• Intravenous administration • Prodrug activated in the liver; CYP substrate • Diarrhea and neutropenia • Acetylcholinesterase inhibition results in cholinergic syndrome: treat with atropine

Drug Facts for Your Personal Formulary: *Cytotoxic Drugs (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Antibiotics		
Dactinomycin (actinomycin D) *Intercalates between GC base pairs of DNA*	• Wilms tumor; rhabdomyosarcoma; Ewing, Kaposi, and other sarcomas; choriocarcinoma	• Intravenous administration; severe injury on extravasation • Nausea, vomiting; myelosuppression; GI side effects; erythema, inflammation of the skin
Anthracyclines and Anthracenediones: Inhibit topoisomerase II and intercalate DNA		
Daunorubicin (daunomycin, rubidomycin)	• Acute myelogenous and acute lymphocytic leukemia	• Intravenous administration • Imparts a red color to the urine • Myelosuppression, GI side effects • Most important long-term side effect is cardiotoxicity, including tachycardia, arrhythmias, congestive heart failure • Alopecia
Doxorubicin	• Soft-tissue, osteogenic, and other sarcomas; Hodgkin and non-Hodgkin lymphoma; acute leukemia; breast, genitourinary, thyroid, and stomach cancer; neuroblastoma	• See Daunorubicin above
Mitoxantrone (an anthracenedione)	• Acute myelocytic leukemia; breast and prostate cancer	• Similar side effects as above • Less cardiotoxic
Epipodophyllotoxins: Inhibit topoisomerase II and religation of cleaved DNA strand		
Etoposide	• Testicular and lung cancer; Hodgkin lymphoma; non-Hodgkin lymphomas; acute myelogenous leukemia; Kaposi sarcoma	• Oral and intravenous administration • Reduce dose in patients with renal dysfunction • Leukopenia, GI side effects; hepatic toxicity after high doses • Secondary leukemia
Teniposide	• Acute lymphoblastic leukemia in children; glioblastoma, neuroblastoma	• Intravenous administration • Myelosuppression, nausea, vomiting
Drugs With Diverse Mechanisms of Action		
Bleomycin *Binds to DNA, generates free radicals, and induces DNA cleavage via deoxyribose ring damage*	• Testicular cancer; Hodgkin and non-Hodgkin lymphoma; local treatment of bladder cancer • Part of the ABVD regimen (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine)	• IV, IM, or SC administration; instilled into bladder • Reduce dose in patients with renal dysfunction • Most serious: pulmonary toxicity • Cutaneous toxicity (erythema, ulcerations) • Less myelosuppression than other cytotoxics
L-Asparaginase *Hydrolyzes asparagine; deprives leukemia cells that lack asparagine synthase*	• Acute lymphocytic leukemia	• IV and IM administration • Hypersensitivity reactions, anaphylaxis • Hyperglycemia, clotting abnormalities
Hydroxyurea *Inhibits RNR (conversion of ribo- to deoxyribonucleotides)*	• Chronic myelogenous leukemia; polycythemia vera; essential thrombocytosis; sickle cell disease in adults	• Oral administration • Reduce dose in patients with renal dysfunction • Myelosuppression; some GI side effects
Tretinoin (all-*trans* retinoic acid) *Promotes degradation of PML-RARA fusion protein*	• Acute promyelocytic leukemia	• Oral administration • CYP substrate • Leukocyte maturation syndrome, pulmonary distress, effusions, fever, dyspnea • Dry skin, cheilitis • Hypercalcemia and renal failure
Arsenic trioxide *Inhibits thioredoxin and generates reactive oxygen species*	• Acute promyelocytic leukemia	• Oral or intravenous administration • Leukocyte maturation syndrome as above with ATRA • QT prolongation; rare torsade de pointes • See Chapter 76 (section on arsenic)

Note: For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.
Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

Chapter 71

Protein Kinase Inhibitors and Pathway-Targeted Small Molecules

Anton Wellstein and Giuseppe Giaccone

VI. EPIGENETIC MODULATORS: INHIBITORS OF HDAC, HMT, AND IDH1/2

INHIBITORS OF HISTONE DEACETYLASE

- Panobinostat
- Romidepsin
- Vorinostat
- Belinostat

INHIBITORS OF HISTONE METHYLTRANSFERASE

- Tazemetostat

IDH1/2 INHIBITORS

VII. OTHER INHIBITORS (BCL2, NUCLEAR EXPORT, TRANSLATION, CXCR4)

BCL2 INHIBITORS

- Venetoclax

NUCLEAR EXPORT INHIBITOR

- Selinexor

PROTEIN TRANSLATION INHIBITOR

- Omacetaxine

CXCR4 INHIBITOR

- Plerixafor

Abbreviations

ABC: ATP-binding cassette
ABL: Abelson murine leukemia viral oncogene homolog
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia
AML: acute myelocytic leukemia
APML: acute promyelocytic leukemia
ARNT: aryl hydrocarbon receptor nuclear translocator (also known as HIF-1β)
ATO: arsenic trioxide
AUC: area under the curve
BCC: basal cell carcinoma
BCL: B-cell lymphoma
BCR: breakpoint cluster region (chr22)
BCRP: breast cancer resistance protein
BH: BCL2 homology domain
BIM: BCL2-like protein 11
BRCA: breast cancer susceptibility gene
BRK: breast tumor kinase, PTK6
BTK: Bruton tyrosine kinase
CDK: cyclin-dependent kinase
CLL: chronic lymphocytic leukemia
CML: chronic myelocytic leukemia
CRL4-CRBN: cullin-RING ubiquitin ligase cereblon complex
cuSCC: cutaneous squamous cell carcinoma
CXCR4: C-X-C chemokine receptor 4
DNMT: DNA methyltransferase
ECG: electrocardiogram
EGF(R): epidermal growth factor (receptor) = HER1
EML4: echinoderm microtubule-associated protein-like 4
ER: estrogen receptor
ERK: extracellular signal-related kinase = MAPK
FGF(R): fibroblast growth factor (receptor)
FIP1L1: factor interacting with poly (A) polymerase
FKBP12: immunophilin-binding protein for tacrolimus (FK506)
FL: follicular B-cell non-Hodgkin lymphoma
FLT(1 or 4): fms-related tyrosine kinase (1 or 4) (= VEGFR1 or 3)
FMO3: flavin containing monooxygenase 3
GI: gastrointestinal
GIST: gastrointestinal stromal tumor
HDAC: histone deacetylase
HER1/2: human epidermal growth factor receptor; 1 = EGFR; 2 = erbB2
2-HG: 2-hydroxyglutarate
HGF(R): hepatocyte growth factor (receptor) = cMET
HIF-1 or -2: hypoxia-inducible factor 1 or 2
HMT: histone methyltransferase
HSC: hematopoietic stem cell
IFN: interferon
IGF1R: insulin-like growth factor 1 receptor
IκB: inhibitor of nuclear factor kappa B
IL: interleukin
IMiDs: immunomodulatory imide drugs (e.g., thalidomide)
ITK: inducible T-cell kinase
KDR: kinase insert domain receptor = VEGFR2
KIT: feline sarcoma virus oncogene homolog
LCK: lymphocyte-specific kinase
MAPK: mitogen-activated extracellular signal regulated protein kinase = ERK
MCL: mantle cell lymphoma
MCyR: major cytogenetic response
MDS: myelodysplastic syndrome
MEK: mitogen-activated extracellular signal regulated protein kinase kinase = MKK
MET: mesenchymal-epithelial transition factor (= HGFR)
MM: multiple myeloma
mTOR: mammalian or mechanistic target of rapamycin
NCCN: National Comprehensive Cancer Network
NET: neuroendocrine tumor
NF-κB: nuclear factor-κB
NK: natural killer
***NPM*:** nucleophosmin (gene)
NRAS: neuroblastoma RAS virus homolog
NSCLC: non–small cell lung cancer
OATP: organic anion-transporting polypeptide
PARP: poly(ADP-ribose) polymerase
PDGF(R): platelet-derived growth factor (receptor)
Pgp: P-glycoprotein
PI3K: phosphatidylinositol 3-kinase
PIK3CA: PI3K catalytic subunit α gene; codes for the p110α enzyme
PIP2: phosphatidylinositol 4,5-bisphosphate
PIP3: phosphatidylinositol (3,4,5)-trisphosphate
PNET: peripheral neuroendocrine tumor
PPES: palmar-plantar erythrodysesthesia syndrome

PPI: proton pump inhibitor
PROTAC: proteolysis-targeting chimera
PTEN: phosphatase and tensin homolog
Rb: retinoblastoma (protein)
RCC: renal cell carcinoma
RET: "rearranged during transfection" receptor tyrosine kinase
ROS1: orphan receptor tyrosine kinase
SDF: stromal cell-derived factor
SLL: small lymphocytic lymphoma
TGF: transforming growth factor
TIE: tyrosine kinase with Ig and EGF domains
TKI: tyrosine kinase inhibitor
TSC: tuberous sclerosis complex
VEGF(R): vascular endothelial growth factor (receptor)
VHL: von Hippel-Lindau (pVHL = VHL protein)

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the National Comprehensive Cancer Network (NCCN). Table 71–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

Development of targeted therapies for treating cancer relies on the discovery of molecular changes that drive malignant progression of human cancers. A rapidly growing number of drugs are being developed to block oncogenic pathways that lead to dysregulated cancer cell growth and survival and may be combined with cytotoxic cancer drugs described in Chapter 70 to improve efficacy. Growth factor receptors and downstream signaling molecules have been productively targeted by cancer chemotherapeutic agents. Indeed, the use of pathway-targeted therapies has likely contributed to reduced mortality from lung cancer (Howlader et al., 2020). The drivers of cancer growth are oncogenic pathways in malignant cells (e.g., mutant receptors and kinases), the reaction of the tumor microenvironment (e.g., angiogenesis), and the escape of malignant cells from the host's immune surveillance (Hanahan and Weinberg, 2011). The primary tools for targeting oncogenic pathways are *small molecules* (discussed in this chapter) that enter cells and engage intracellular targets (e.g., kinases) and *monoclonal antibodies* (see Chapter 72) that recognize cell surface or shed antigens (e.g., growth factor receptors or receptor ligands). These two classes of drugs have different pharmacological properties (see box titled Two Classes of Pathway-Targeted Drugs Used in Cancer Treatment). The sections of this chapter focus on inhibitory drugs that target these drivers of cancer cell growth and survival:

I. Altered growth factor receptor signaling
II. Activation of intracellular kinases
III. Cancer cell-host interactions and aberrant angiogenesis
IV. Defects in DNA repair
V. Altered protein degradation
VI. Altered epigenetic regulation
VII. Targets that control cancer cell behavior

TABLE 71–1 ■ CANCER TREATMENT REGIMENS: COMPLEXITIES AND RESOURCES

In treating cancers, the selection of the most appropriate treatment(s), dose, and dose intervals and the management of adverse effects require specialized knowledge and a team effort. In addition, cancer treatment regimens are undergoing frequent updates due to findings in ongoing clinical trials. The availability of drugs with new mechanisms of action (e.g., immune checkpoint inhibitors), good target selectivity (e.g., kinase inhibitors), efficacy in specific cancers, and different adverse effect profiles permits the use of new drug combinations and regimens. The chapters on the pharmacotherapy of cancer focus on mechanism of action, ADME, and adverse effects, with less emphasis on treatment regimens. There are several excellent sources of up-to-date treatment information. The U.S. FDA provides authoritative information on approved drugs online (http://www.accessdata.fda.gov/scripts/cder/daf/). Detailed treatment guidelines for most cancers are available from the National Comprehensive Cancer Network (NCCN), a nonprofit alliance of 31 cancer centers that establishes evidence-based guidelines for cancer treatment. The NCCN guidelines are continuously updated to reflect new information that may alter clinical practice. The guidelines can be accessed online (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp).

This table provides examples that illustrate the complexities of current treatment for two cancers: HER2-positive breast cancer and advanced colorectal cancer.

SAMPLE TREATMENT REGIMENS

SUMMARY	DRUGS, SCHEDULE, AND DOSING
HER2-Positive Breast Cancer	
Doxorubicin and cyclophosphamide (AC) followed by paclitaxel, trastuzumab, and pertuzumab	**Day 1:** Doxorubicin 60 mg/m^2 IV **Day 1:** Cyclophosphamide 600 mg/m^2 IV Repeat cycle every 21 days for 4 cycles **Followed by** **Day 1:** Pertuzumab 840 mg IV followed by 420 mg IV **Day 1:** Trastuzumab 8 mg/kg IV followed by 6 mg/kg IV **Days 1, 8, and 15:** Paclitaxel 80 mg/m^2 IV Repeat cycle every 21 days for 4 cycles **Day 1:** Trastuzumab 6 mg/kg IV Repeat cycle every 21 days to complete 1 year of trastuzumab therapy Cardiac monitoring at baseline and 3-month intervals
Advanced or Metastatic Colorectal Cancer RAS Wild-Type	
Oxaliplatin, leucovorin, and 5FU (FOLFOX) plus cetuximab	**Day 1:** Oxaliplatin 85 mg/m^2 IV over 2 h **Day 1:** Leucovorin 400 mg/m^2 IV over 2 h **Days 1–3:** 5FU 400 mg/m^2 IV bolus on day 1, then 1200 mg/m^2 per day × 2 days (total 2400 mg/m^2 over 46–48 h) IV continuous infusion **Repeat cycle every 2 weeks, plus** Cetuximab 400 mg/m^2 IV over 2 h for the first infusion, then 250 mg/m^2 IV over 60 min weekly **OR** **Day 1:** Cetuximab 500 mg/m^2 IV over 2 h every 2 weeks

Source: Data from NCCN.

Two Classes of Pathway-Targeted Drugs Used in Cancer Treatment

Small-molecule inhibitors described in this chapter and **large-molecule drugs** (e.g., monoclonal antibodies) described in Chapter 72 constitute pathway-targeted anticancer drugs. Small molecules (molecular mass <1 kDa) may attack the same targets as monoclonal antibodies but mainly exert their effects by entering cells. A monoclonal antibody (molecular mass of immunoglobulin [Ig] G is ~150 kDa) is generally specific for a single antigen; in contrast, small molecules often inhibit multiple targets (e.g., kinases) with different selectivities and thus are likely to have a broader spectrum of activity and produce a broader spectrum of desired effects, off-target effects, and adverse effects than monoclonal antibodies. Many small-molecule drugs have elimination half-lives of 12 to 24 h and typically require at least daily oral administration, whereas antibodies are typically eliminated with half-lives of many days to weeks and require less frequent administration. For small-molecule drugs that are metabolized by hepatic CYPs, the concomitant use of strong CYP inhibitors (e.g., *ketoconazole*, *nefazodone*, *clarithromycin*, *gemfibrozil*, *cobicistat*) or inducers (e.g., *rifampin*, *phenytoin*, *carbamazepine*, *phenobarbital*, St John's wort) can lead to increased adverse effects due to reduced drug elimination or to reduced efficacy due to accelerated clearance. Syllables contained in the generic names of small-molecule drugs indicate their targeted pathways and are listed in Table 71–2.

I. Inhibitors of Receptor Signaling in Cancer Cells

Tyrosine Kinase Receptors

Inhibitors of Human Epidermal Growth Factor Receptor (EGFR/HER1)

Background

EGFR is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues located in the C-terminal tail of the receptor monomers. These phosphotyrosines provide interaction sites for a variety of adapter proteins, resulting in stimulation of signaling pathways, including the mitogen-activated extracellular signal regulated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K)/Akt pathways (Figure 71–1).

TABLE 71–2 ■ THE NAMING OF SMALL-MOLECULE INHIBITORS

ENDING WITH	INHIBITOR CATEGORY	EXAMPLE
-anib	Angiogenesis	Pazopanib
-ciclib	Cyclin-dependent kinase 4 and 6	Palbociclib
-degib	Hedgehog signaling	Sonidegib
-denib	IDH1 and IDH2	Enasidenib
-lisib	PI3K	Idelalisib
-parib	PARP	Olaparib
-rafenib	BRAF	Vemurafenib
-tinib	Tyrosine kinase	Erlotinib
-zomib	Proteasome	Bortezomib

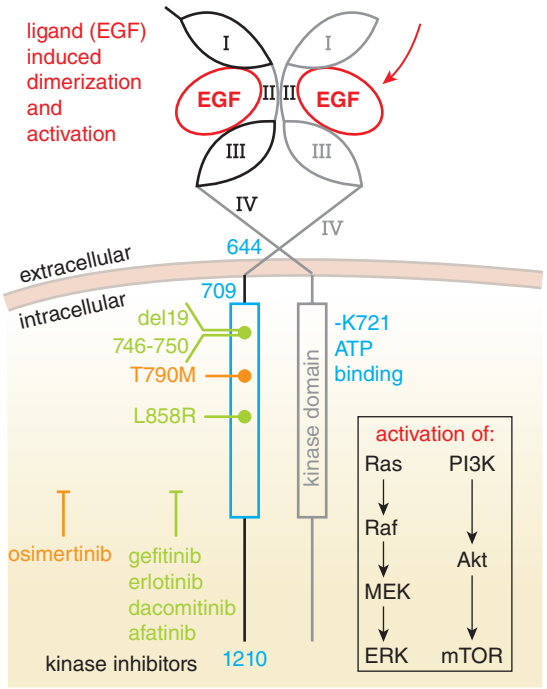

Figure 71–1 *Targeting the EGFR in cancer.* The extracellular portion of the EGFR contains the binding domains for growth factors that include EGF, TGF-α, and amphiregulin. Ligand binding to extracellular domains I and III induces conformational change and receptor dimerization through domains II and IV and activates intracellular signaling by cross-phosphorylation. The intracellular portion contains the tyrosine kinase activity and a C-terminal tail that recruits intracellular substrates after phosphorylation (see Chapter 3). EGFR mutations enhance downstream signaling, which provides a growth and survival advantage for cancer cells and confers sensitivity to treatment with the TKIs *afatinib*, *dacomitinib*, *erlotinib*, *gefitinib*, and *osimertinib*. The most common activating mutations are in-frame deletions in exon 19 (del 19) between E746 and A750 (~45%) and a missense mutation in exon 21 that leads to an L858R substitution (~40%). Lung cancers with these mutations are initially sensitive to first- and second-generation TKIs shown in green font. Resistance develops, however, most commonly via the T790M substitution in exon 20 found in about 50% of resistant tumors. *Osimertinib*, a third-generation inhibitor shown in orange font, is the only TKI that is active against cancers with the T790M mutation. Other insertional mutations in exon 20 are relatively rare and discussed in the text.

Two separate classes of drugs that target the EGFR pathway are important in the therapy of solid tumors: protein tyrosine kinase inhibitors (TKIs) and inhibitors of extracellular ligand binding. EGFR TKIs (*erlotinib*, *gefitinib*, *afatinib*, *osimertinib, dacomitinib*) bind to the intracellular kinase domain and inhibit the enzymatic function of EGFR. Monoclonal antibodies (*cetuximab*, *panitumumab*, *necitumumab*) that recognize the extracellular domain of the EGFR, inhibit ligand-induced signaling, and can elicit an immune response are discussed in Chapter 72. In epithelial cancers, overexpression of the EGFR is a common finding, and mutational activation of the EGFR (e.g., in 10%–40% of non–small cell lung cancers [NSCLCs]) creates a dependence on EGFR signaling. The most common EGFR mutations are in-frame deletions in exon 19 or leucine-to-arginine point mutations (L858R) in exon 21 that cause conformational changes and constitutive activation of the kinase. First-generation (*erlotinib*, *gefitinib*) and second-generation (*afatinib, dacomitinib*) drugs are available that inhibit EGFR kinase activity driven by these mutations. Resistant cancer cell subpopulations that bear the T790M mutation that emerges during treatment with first- and second-generation inhibitors in approximately 50% to 60% of patients are sensitive to the third-generation inhibitor *osimertinib* (see Figure 71–1).

Erlotinib

Mechanism of Action. *Erlotinib* is a reversible inhibitor of the EGFR tyrosine kinase, competitively inhibiting ATP binding at the active site of the kinase. Erlotinib has an IC_{50} of 2 nM for EGFR kinase activity. By comparison, for many protein kinases, the K_d for ATP at the substrate site is in the range of 20 μM.

ADME. *Erlotinib* is about 60% absorbed after oral administration. Peak plasma levels occur after 4 h. *Erlotinib* has a $t_{1/2}$ of 36 h and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1.

Therapeutic Uses. *Erlotinib* is approved for treatment of patients with advanced or metastatic NSCLC after failure of platinum-based chemotherapy treatment. In newly diagnosed NSCLC, *erlotinib* is approved in patients with EGFR mutations only (see Figure 71–1). *Erlotinib* in combination with *gemcitabine* is also approved for the treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer.

Adverse Effects and Drug Interactions. The most common adverse reactions (≥20%) are rash, diarrhea, anorexia, fatigue, dyspnea, nail disorders, nausea, and vomiting. Serious adverse reactions include severe rash (>10%). Fatal interstitial lung disease occurs with a frequency of 0.7% to 2.5%, and fatal hepatic failure has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. *Erlotinib* therapy may cause rare cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton pump inhibitors decreases the bioavailability of *erlotinib* by 50%. Plasma levels can vary due to drug interactions with inducers or inhibitors of CYP3A4. Patients using *warfarin* may experience poorer extrinsic coagulation while taking *erlotinib*. Smoking accelerates metabolic clearance of *erlotinib* and may decrease its antitumor effects.

Gefitinib

Mechanism of Action. *Gefitinib* inhibits the EGFR tyrosine kinase by competitive blockade of ATP binding with an IC_{50} of 15 to 57 nM for the kinase activity.

ADME. Oral bioavailability is about 60%; peak plasma concentrations are achieved within 3 to 7 h. Absorption of *gefitinib* is not significantly altered by food but is reduced by drugs that cause elevations in gastric pH. Metabolism of *gefitinib* is predominantly via CYP3A4, with a terminal $t_{1/2}$ of 41 h. Inducers of CYP3A4 activity decrease *gefitinib* plasma concentrations and efficacy; conversely, CYP3A4 inhibitors increase plasma concentrations.

Therapeutic Uses. *Gefitinib* is approved for treatment of patients with metastatic NSCLC with EGFR mutations (see Figure 71–1).

Adverse Effects and Drug Interactions. Diarrhea and skin reactions occur in more than 20% of patients. In addition to pustular/papular rash, other side effects include dry skin, nail changes, nausea, vomiting, pruritus, anorexia, and fatigue. Most adverse effects occur within the first month of therapy and are manageable with medications. Asymptomatic increases in liver transaminases may necessitate discontinuation of therapy. Respiratory compromise and interstitial lung disease, especially in patients with prior radiation, occurs in fewer than 2% of patients but may have a fatal outcome. Inducers and inhibitors of CYP3A4 will alter plasma concentrations. Patients using *warfarin* should be monitored for poorer extrinsic coagulation while taking *gefitinib*.

Afatinib

Mechanism of Action. *Afatinib* is a second-generation, orally bioavailable, *irreversible* inhibitor of EGFR (HER1) and HER2 receptor kinases with IC_{50} values of 0.5 and 14 nM, respectively.

ADME. The elimination $t_{1/2}$ of *afatinib* is 37 h after repeat dosing in patients with cancer. In patients with severe renal impairment, a dose reduction is recommended. *Afatinib* is a substrate of P-glycoprotein (Pgp), and coadministration of Pgp-modulating drugs can alter drug concentrations of *afatinib*.

Therapeutic Uses. *Afatinib* is approved for the first-line treatment of patients with metastatic NSCLC with EGFR mutations (see Figure 71–1) and patients with metastatic squamous NSCLC that has progressed subsequent to platinum-based chemotherapy.

Adverse Effects and Drug Interactions. Most common adverse effects are diarrhea and skin rash/acneiform dermatitis, stomatitis, and hand-foot skin reactions and nail changes. Also observed are interstitial lung disease, liver function abnormalities, left ventricular dysfunction, and rarely, gastrointestinal perforation (0.2% of patients).

Dacomitinib

Dacomitinib, approved in 2018, is an orally available, second-generation irreversible inhibitor of EGFR indicated for first-line treatment of patients with metastatic NSCLC with EGFR exon 19 deletion or exon 21 L858R substitution mutations. Plasma $t_{1/2}$ of *dacomitinib* is 70 h. Hepatic metabolism is the main route of clearance of *dacomitinib*. There is no impact of hepatic or renal impairment on drug elimination. Adverse effects are similar to *afatinib*, with diarrhea and skin rashes being the most common.

Mobocertinib

Mobocertinib is an irreversible kinase inhibitor that was approved in 2021 for the treatment of patients with advanced NSCLC with EGFR exon 20 insertional mutations progressing after chemotherapy. Exon 20 insertional mutation in EGFR are relatively infrequent (approximately 2%) and are not sensitive to first-, second-, and third-generation EGFR inhibitors. The response rate to mobocertinib is lower (28%) than that of EGFR inhibitors targeting NSCLC with the more common mutations (50%–80%). Adverse effects are similar to the second-generation EGFR inhibitors, in particular skin rash and diarrhea.

Resistance to Gefitinib, Erlotinib, Afatinib, and Dacomitinib

The majority of tumors with activating mutations in the EGFR initially respond to the kinase inhibitors of the first (*gefitinib*, *erlotinib*) and second generation (*afatinib, dacomitinib*). Eventually, however, the tumors progress. Approximately 60% of NSCLCs acquire a second EGFR mutation in the so-called EGFR gatekeeper residue in exon 20, T790M (see Figure 71–1), that reduces binding of these inhibitors to the kinase domain. The second-generation irreversible inhibitors that bind covalently to the kinase can overcome resistance in preclinical models, but their activity against wild-type EGFR exacerbates adverse effects such as skin rash and diarrhea and thus has limited their clinical use. *Osimertinib*, a third-generation inhibitor designed to recognize the T790M-mutant EGFR, is described below. Other mechanisms of resistance include mutational activation of downstream signaling molecules such as *KRAS* or activation of parallel signaling pathways, for example, through *MET* mutation or amplification, *EML4-ALK* translocation (Figure 71–2), and transformation to small cell lung cancer. Anaplastic lymphoma kinase (ALK) and mesenchymal-epithelial transition factor (MET) kinase inhibitors are described further below (Smit and Baas, 2015).

Osimertinib

Mechanism of Action. *Osimertinib* is a third-generation, orally bioavailable, *irreversible* inhibitor of T790M-mutant EGFR, with an IC_{50} value of 10 nM. In addition, *osimertinib* is also a very potent inhibitor of the EGFR mutants that are sensitive to first- and second-generation EGFR inhibitors. The T790M gatekeeper mutation in Exon 20 is often acquired after prior treatment with other EGFR kinase inhibitors (see previous discussion). Very sensitive detection methods can identify the presence of T790M in up to 30% of untreated patients, suggesting preexisting resistant subpopulations (see Chapter 69, Figure 69–3).

ADME. The mean $t_{1/2}$ of *osimertinib* is 48 h. *Osimertinib* is a substrate of CYP3A. The drug is primarily eliminated in the feces and to a lesser extent in the urine. Concurrent administration of inducers of CYP3A4 may necessitate an increase in the dose.

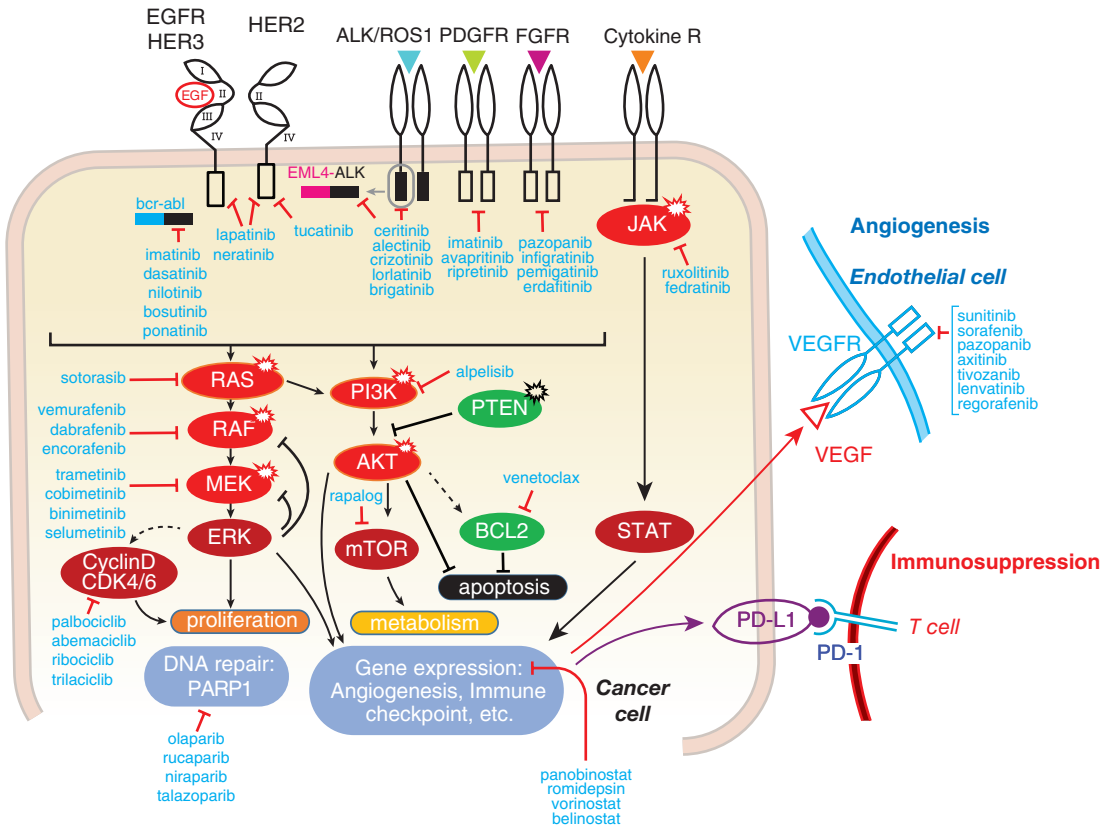

Figure 71–2 *Cancer cell signaling pathways and drug targets.* Extracellular binding of agonist ligands to transmembrane growth factor receptors causes receptor dimerization and activation of a C-terminal protein kinase that initiates intracellular signaling cascades that regulate gene expression and control cancer cell proliferation, apoptosis, metabolism, and metastasis. Crosstalk between cancer cells and the host stroma (including the vasculature and immune cells) is modulated through the release of angiogenic factors and the expression of immune checkpoint proteins. Cancer cell signaling can be altered through increased expression of receptors (e.g., HER2) or ligands, activating mutations in receptors (e.g., ALK, EGFR, FGFR) or in intracellular kinases (e.g., RAS, RAF, MEK, PI3K, AKT, JAK), gene translocations resulting in activated fusion proteins (e.g., bcr-abl, EML4-ALK), and the loss of function of an inhibitor of a pathway (e.g., the PTEN phosphatase) through mutation, gene deletion, or promoter methylation. Inhibitors are shown acting on a cancer cell and an endothelial cell. A T cell is included to represent the crosstalk with the immune system and effects of combination therapies. Inhibitors (in blue) are depicted adjacent to their intracellular target proteins. Proteins within red ellipses provide activating signals, those in green ellipses, inhibitory signals. Star bursts (✸) indicate signaling components in which mutations are common. More details of mechanisms of action are shown below for CDK4/6 inhibitors (Figure 71–3), BTK and PI3Kδ inhibitors in B cells (Figure 71–4), the mTOR pathway (Figure 71–5), HIF-2α inhibition (Figure 71–6), PARP inhibition (Figure 71–7), *thalidomide* congeners (Figures 71–8 and 71–9), and BH3 mimics (Figure 71–10). Immune suppression by mTOR inhibition during organ transplants is discussed in Chapter 39.

Therapeutic Uses. *Osimertinib* is approved for first-line treatment of patients with metastatic NSCLC and adjuvant therapy after resection of NSCLC with EGFR exon 19 deletions or exon 21 L858R mutations; it is also approved in patients with metastatic NSCLC that progressed after prior EGFR TKI treatment and is positive for the EGFR T790M mutation. Genotyping of tumors for the T790M mutation is required after resistance develops and, besides a tumor biopsy, can be done noninvasively from blood samples analyzing DNA shed from tumor cells into the bloodstream (Oxnard et al., 2016). Response rates are greater than 60% in patients with metastatic NSCLC. *Osimertinib* improved survival in patients with NSCLC EGFR T790M mutations and in first-line treatment compared to first-generation inhibitors and thus has become the standard of care irrespective of the presence of the EGFR T790M mutation (Cohen et al., 2021). Acquired resistance after *osimertinib* treatment is manifested by the appearance of a third mutation, C797S, in less than 20% of tumors. The mutation of Cys^{797} to Ser^{797} prevents formation of the potency-conferring covalent bond of the inhibitor (Thress et al., 2015); however, MET amplification is a more common resistance mechanism along with several other mechanisms that have been described. Inhibitors of C797S-mutant EGFR are under development for combination treatment with an EGFR-targeted antibody (Jia et al., 2016).

Adverse Effects and Drug Interactions. The most common adverse effects after *osimertinib* treatment are diarrhea and skin rash; however, these are much less common and severe than for first- and second-generation inhibitors, because the activity on wild-type EGFR is reduced with the third-generation inhibitor. Also observed are interstitial lung disease, QTc prolongation, and left ventricular dysfunction.

Inhibitors of Human Epidermal Growth Factor Receptor 2 (HER2/Neu/ErbB2)

Human epidermal growth factor receptor 2 (also named Neu or ErbB2; see History box) is a member of the HER family, which also includes EGFR (HER1), HER3, and HER4 (see Figure 71–2). The fixed conformation of the extracellular domain of HER2 resembles the ligand-activated state of the other HER family members and explains its unique function as a coreceptor that does not require ligand activation. In addition, due to this conformation, the overexpression of wild-type HER2 is sufficient to activate the intracellular tyrosine kinase and oncogenic signaling even in the absence of activating mutations, coreceptors, or ligands. Overexpression of HER2 is found in 20% to 30% of human breast cancers due to gene amplification on chromosome 17 and results in more aggressive tumors, lower response rates to hormonal therapies, and higher risk of disease recurrence after treatment.

HISTORY **EGFR/HER PATHWAY-TARGETED CANCER THERAPY**

The discovery and analysis of the EGFR (HER1) in 1984 (Ullrich et al., 1984) revealed a remarkable homology of its protein kinase domain to an oncogenic protein in the avian erythroblastosis retrovirus, v-erb (Downward et al., 1984). The first oncogenic protein isolated from the erb virus is a homologue of the thyroid hormone receptor and was named erbA; the second oncogenic protein isolated from v-erb was named erbB, an alternate name for members of the EGFR/HER gene family members. The *HER2* gene was discovered based on its homology to v-erbB in human breast cancer and its oncogenic function in rat ***neu***ral tumors; hence the different names HER2/ErbB2/Neu (King et al., 1985; Schechter et al., 1985). The association of HER2 overexpression with poor prognosis in breast cancer (Slamon et al., 1987) provided the impetus for the development of HER2-targeted therapies and a new concept in the treatment of HER2-positive breast cancers. The most recent addition in 2020 to drugs that target HER2 is *tucatinib*, an HER2-selective, small-molecule kinase inhibitor approved for use in HER2-positive breast cancer.

Lapatinib

Mechanism of Action; ADME. *Lapatinib* is an orally bioavailable, small-molecule inhibitor of the EGFR and HER2 tyrosine kinases with an IC_{50} of about 10 nM for both kinases. *Lapatinib* is metabolized by CYP3A4 with a plasma $t_{1/2}$ of 14 h. Concurrent administration of inducers and inhibitors of CYP3A4 may necessitate adjustment of the dose.

Therapeutic Uses; Adverse Effects. *Lapatinib* in combination with *capecitabine* is approved for the treatment of patients with metastatic HER2-positive *trastuzumab*-refractory breast cancer. *Lapatinib* is also used in combination with the aromatase inhibitor *letrozole* (see Chapter 73) to treat postmenopausal women with hormone receptor–positive, metastatic breast cancer that overexpresses HER2. Frequent adverse effects include acneiform rash, diarrhea, cramping, and exacerbation of gastroesophageal reflux. When *lapatinib* is combined with *capecitabine*, diarrhea is worsened. Cardiac toxicity appears less pronounced than with *trastuzumab*, although *lapatinib* should be used with caution in combination with cardiotoxic drugs. A dose-dependent prolongation of the QT interval has been reported; thus, careful monitoring of patients with heart disease is recommended. Hepatotoxicity that may be severe has been observed.

Neratinib

Neratinib is an orally bioavailable, *irreversible* inhibitor of the HER2 and EGFR protein tyrosine kinase with IC_{50} values of 59 nM and 92 nM, respectively. It is approved as a single agent in early-stage HER2-positive breast cancer following *trastuzumab*–based therapy and in advanced or metastatic HER2-positive breast cancer after two or more anti-HER2–based regimens in combination with *capecitabine*. Diarrhea is the most common and frequent adverse effect, with grade 3 or 4 diarrhea occurring in over one-third of patients (Park et al., 2016); prophylaxis with *loperamide* is recommended. The metabolism is via CYP3A in the liver with an elimination $t_{1/2}$ of 7 to 17 h; concomitant use of *ketoconazole*, a strong inhibitor of CYP3A4 and Pgp, increased maximal plasma concentration by over 2-fold.

Tucatinib

Tucatinib is an orally bioavailable, reversible, highly selective TKI of HER2 with minimal inhibition of EGFR (HER1). *Tucatinib* demonstrated efficacy compared with placebo in progression-free and overall survival of heavily pretreated patients with HER2-positive metastatic breast cancer, including patients with brain metastases (Murthy et al., 2020). In this study, addition of *tucatinib* to the anti-HER2 antibody *trastuzumab* improved outcomes, demonstrating that targeting of the intracellular kinase with a small-molecule inhibitor in addition to targeting the extracellular domain with a monoclonal antibody can be beneficial. The FDA approved its use in 2020 for the treatment of patients with unresectable or metastatic HER2-positive breast cancers, including patients with brain metastases and pretreated patients.

Tucatinib is metabolized mostly by CYP2C8 and less by CYP3A and has an elimination $t_{1/2}$ of 8.5 h. The most common adverse effects are diarrhea and hepatotoxicity. Skin toxicity that is frequently dose limiting and associated with EGFR inhibition is significantly less common with *tucatinib*.

ALK and ROS1

Background

ALK is a membrane monospan with an extracellular domain and an intracellular protein tyrosine kinase domain (see Figure 71–2). The importance of this protein kinase in human cancers is the capacity of the *ALK* gene to form fusion genes that become oncogenic drivers. A 2;5 chromosomal translocation yields an oncogenic fusion gene in which a 3′ portion of *ALK* (chromosome 2) contributes coding for the catalytic domain and is joined to a 5′ region of the *NPM* gene. The extracellular and transmembrane sequences of ALK are absent in the *ALK-NPM* fusion gene, which is the oncogenic driver of malignant progression in anaplastic large cell lymphoma. A similar translocation of the ALK kinase and fusion with EML4 creates the oncogenic driver in a subset of NSCLC (Martelli et al., 2010), as shown in Figure 71–2. *ALK* also fuses with numerous additional 5′ partners (Roskoski, 2017). *Alectinib*, *brigatinib, crizotinib*, *ceritinib*, and *lorlatinib* are small-molecule inhibitors of ALK kinase that are used in the treatment of ALK translocation–positive cancers.

The overall organization of ROS1 (orphan receptor tyrosine kinase) is similar to ALK, and the intracellular kinase portion of ROS1 also can become part of chimeric oncoproteins due to different chromosomal translocation partners most frequently found in glioblastoma and NSCLC but also in other cancers. Several of the kinase inhibitors discussed below also target the ROS1 kinase due to protein sequence homologies in the kinase domains of approximately 70% (reviewed by Drilon et al., 2021). ROS1 inhibition correlates with increased efficacy and improved survival in patients with ROS1-positive NSCLCs (Nokin et al., 2020).

Crizotinib, originally developed as a MET inhibitor, was found to also target ALK and ROS1 and became the first inhibitor to be approved for ALK-positive cancers. The next-generation ALK inhibitors have mostly replaced *crizotinib* due to their improved clinical efficacy in ALK-positive NSCLC.

Crizotinib

Mechanism of Action. *Crizotinib* is an orally bioavailable inhibitor of receptor tyrosine kinases that include ROS1, HGFR/cMET, ALK, and ROS1. IC_{50} values are 0.6, 11, and 24 nM for ROS1, hepatocyte growth factor receptor (HGFR)/cMet, and ALK, respectively.

ADME. *Crizotinib* is predominantly metabolized by CYP3A4/5 and shows a terminal $t_{1/2}$ of 42 h. The typical twice daily dosing is reduced to once daily in patients with severe renal impairment and a creatinine clearance below 30 mL/min.

Therapeutic Uses. *Crizotinib* was initially developed and approved for the treatment of patients with locally advanced or metastatic NSCLC harboring *ROS1* or *ALK* gene rearrangements described above (see Figure 71–2) (Thomas et al., 2015).

Adverse Effects. The most common adverse reactions are GI toxicities including nausea, diarrhea, and vomiting as well as hepatic, respiratory, and ocular toxicity and neuropathy. Also observed are QT prolongation and bradycardia.

Alectinib

Mechanism of Action. *Alectinib* is an orally bioavailable inhibitor of ALK kinase activity with an IC_{50} of 1.9 nM. *Alectinib* shows a higher selectivity for ALK than *crizotinib* and is active against mutant forms of ALK that are found in tumors resistant to *crizotinib*.

ADME. *Alectinib* has an elimination half-life of 33 h and is metabolized by CYP3A4. Coadministration of *alectinib* with CYP3A inhibitors or inducers will alter plasma concentrations.

Therapeutic Uses. *Alectinib* is approved for the treatment of patients with advanced or recurrent NSCLC harboring the ALK fusion gene (ALK^+). Patients with ALK^+ NSCLC who have progressed on treatment with *crizotinib* or are intolerant to *crizotinib* also qualify. *Alectinib* is also approved for first-line treatment of ALK-positive advanced NSCLC.

Adverse Effects. The most common adverse effects are fatigue, constipation, edema, and myalgia. Pneumonitis, GI toxicity, hepatotoxicity, bradycardia, and prolonged QT intervals are also observed (Katayama et al., 2015).

Ceritinib

Ceritinib is an orally bioavailable, competitive inhibitor of the ALK kinase with an IC_{50} of 0.2 nM and is 40-fold selective relative to the homologous insulin-like growth factor 1 receptor (IGF1R) kinase. *Ceritinib* is approved for the treatment of ALK-positive metastatic NSCLC unresponsive to *crizotinib*. *Ceritinib* is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 41 h. Common adverse effects are GI toxicity and hepatotoxicity. Bradycardia and prolonged QT intervals also occur.

Brigatinib

Brigatinib is an inhibitor of the ALK and ROS1 (IC_{50} 0.9 nM) and of IGF1R and FLT3 tyrosine kinases at lower potency. *Brigatinib* is approved for the treatment of ALK-positive metastatic NSCLC, where treatment resulted in a longer progression-free survival and higher response rate (78%) against brain metastases than *crizotinib* (29%) (Camidge et al., 2018). *Brigatinib* is approved for first-line treatment. *Brigatinib* is metabolized by CYP3A and excreted through the urine. Reduced dosing is recommended with hepatic or renal impairment. The elimination $t_{1/2}$ is 25 h. Adverse effects can include the induction of interstitial lung disease/pneumonitis, hypertension, and bradycardia. Blood pressure and heart rate monitoring are recommended.

Lorlatinib

Lorlatinib (originally named PF-06463922) is an orally active, third-generation inhibitor of the ALK and ROS1 kinase with an IC_{50} of less than 1 nM. It was approved in 2018 for the treatment of metastatic, ALK-positive NSCLC who failed 1 or 2 prior ALK inhibitors. In 2021 it was also approved for first-line treatment.

Lorlatinib is metabolized by CYP3A4 and eliminated with a $t_{1/2}$ of 24 h. CNS adverse effects including seizures, cognitive dysfunction, and psychoses or mood changes are a risk during therapy. Potential induction of hypertension requires monitoring of blood pressure. Hepatotoxicity is a further risk.

NRTK/TRK Fusions

Chromosomal rearrangements resulting in in-frame fusions of the kinases with different partners can result in constitutively active chimeric TRK that act as oncogenic drivers, promoting proliferation and survival in tumor cells. Fusions involving one of three TRKs (A, B, or C) occur in diverse cancers (e.g., salivary gland, soft-tissue sarcoma, fibrosarcoma) and define a unique molecular subgroup of advanced tumors. TRK refers to tropomyosin receptor kinase, one of a family of receptor tyrosine kinases encoded by neurotrophic tyrosine receptor kinase (NTRK) gene fusions. Assays to detect TRK fusions are used to identify cancers that contain such a drug-sensitive driver (Nokin et al., 2020).

Larotrectinib

Larotrectinib is an orally available inhibitor of the TRKA, TRKB, and TRKC kinases with IC_{50} values of 5 to 11 nM that showed antitumor activity against constitutively active TRK fusion proteins or TRK overexpression. *Larotrectinib* was not active against mutant TRKA or TRKC. It was approved in 2018 for the treatment of any cancers with TRK gene fusions without resistance mutation (Drilon et al., 2018). Adverse effects include neurotoxicity and hepatotoxicity. It is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 2.9 h.

Entrectinib

Entrectinib is an orally active inhibitor of the TRKA, TRKB, TRKC, ROS1, and ALK kinases with IC_{50} values of 0.1 to 2 nM. It was approved in 2019 for the treatment of any cancers with TRK gene fusions without resistance mutation and for metastatic NSCLC positive for ROS1. Adverse effects include an increased risk for congestive heart failure, cognitive impairment, hepatotoxicity, and prolongation of QT intervals requiring periodic monitoring. It is metabolized by CYP3A with an elimination $t_{1/2}$ of approximately 20 h.

Inhibitors of Platelet-Derived Growth Factor Receptor and KIT

Signaling by the platelet-derived growth factor receptor (PDGFR) plays a significant part in mesenchymal biology, including stem cell growth, and is involved in oncogenesis through aberrant cancer cell signaling, modulation of the tumor microenvironment, and facilitation of angiogenesis and metastasis. Small-molecule protein kinase inhibitors, including *imatinib* (see discussion below), have been used in the treatment of patients with gastrointestinal stromal tumors (GISTs) that carry mutations in *KIT* (feline sarcoma virus oncogene homolog) or *PDGFRA* (see Figure 71–2).

Ripretinib

Ripretinib is an orally bioavailable kinase inhibitor of the PDGFR, wild-type and mutant KIT, and other kinases including VEGFR2 and tyrosine kinase with Ig and EGF domains (TIE) 2 with IC_{50} values of 4 to 18 nM. It was approved in 2020 for the treatment of patients with advanced GIST who have received prior treatment with three or more kinase inhibitors, including *imatinib*. Adverse effects include palmar-plantar erythrodysesthesia syndrome (PPES), nausea, vomiting, constipation, diarrhea, and alopecia. Hypertension and cardiac dysfunction have also been reported. It is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 14.8 h.

Avapritinib

Avapritinib is an orally bioavailable inhibitor of KIT and PDGFRA mutant kinases with IC_{50}s of less than 25 nM. It was approved in 2020 for the treatment of metastatic GIST harboring *PDGFRA* mutations and for advanced systemic mastocytosis and mast cell leukemia. Adverse events include risk of intracranial hemorrhage and cognitive impairment. *Avapritinib* is primarily metabolized by CYP3A. The elimination $t_{1/2}$ ranges from 20 to 57 h.

FGFR Inhibitors

Physiological fibroblast growth factor (FGF) receptor (FGFR) signaling is modulated by 22 human protein ligands that bind to four transmembrane tyrosine kinase receptors expressed as seven distinct splice variant receptors. In approximately 7% of cancers, FGFR genes are mutated or amplified or become part of translocations that lead to constitutively active gene fusions and thus contribute to cancer initiation and malignant progression. *FGFR1* is amplified in NSCLC and breast cancer and mutated in gliomas. FGFR2 is activated by gene fusions in approximately 20% of cholangiocarcinomas, leading to recent approval of kinase inhibitors. The first approval of FGFR kinase inhibitors was based on FGFR3 mutations in metastatic urothelial carcinomas but FGFR3 fusions are also found in brain tumors and bladder cancers. Unusual for tyrosine kinase receptors, the most common FGFR3 mutations occur in the ligand-binding domain, mimicking a constitutive extracellular signaling. A more detailed overview is provided by Facchinetti et al. (2020).

Erdafitinib

Erdafitinib is a selective pan-FGFR kinase inhibitor that also inhibits other kinases including RET, CSF1R, PDGFR, KIT, and VEGFR2. It was approved in 2019 for the treatment of patients with locally advanced or metastatic urothelial carcinoma with FGFR2 or FGFR3 genetic alterations

that has progressed after chemotherapy. Adverse effects include ocular disorders that require monthly ophthalmological monitoring. Hyperphosphatemia as a consequence of FGFR inhibition was observed in 76% of patients with a median onset time of 20 days. About one-third of patients received phosphate binders during treatment. *Erdafitinib* is metabolized by CYP2C9 and CYP3A4 and eliminated with a $t_{1/2}$ of 59 h.

Pemigatinib

Pemigatinib is an orally bioavailable selective FGFR1–3 kinase inhibitor (IC_{50} <1.2 nM; FGFR4 IC_{50} is 30 nM). It was approved in 2020 for the treatment of pretreated, locally advanced, or metastatic cholangiocarcinoma with an FGFR2 fusion or rearrangement. Adverse events include diarrhea, ocular toxicity, and hyperphosphatemia as a consequence of FGFR inhibition, resulting in soft-tissue mineralization and vascular and myocardial calcification. It is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 15.4 h.

Infigratinib

Infigratinib (previously named BGJ398) is an orally bioavailable selective FGFR1–3 kinase inhibitor (IC_{50} <2 nM) approved in 2021 for the treatment of pretreated, locally advanced, or metastatic cholangiocarcinoma with an FGFR2 fusion or rearrangement. Adverse events include diarrhea, ocular toxicity, and hyperphosphatemia as a consequence of FGFR inhibition, resulting in soft-tissue mineralization and vascular and myocardial calcification. It is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 33.5 h.

MET/HGFR Inhibitors

Under physiological conditions, the MET/HGFR transmembrane receptor is activated by HGF ligand binding. Malignant transformation observed in NSCLC and other cancers can lead to alternate MET activation through gene rearrangements that code for constitutively active cytosolic fusion proteins (Nokin et al., 2020). Also, somatic mutations in MET are known to result in aberrant mRNA splicing resulting in increased MET activity: Exon 14 codes for a binding site for the E3 ubiquitin ligase CBL that is responsible for ubiquitination of the MET protein and for its degradation. Skipping of exon 14 thus leads to decreased ubiquitination and results in increased protein levels and activity of MET (Guo et al., 2020) that can be targeted therapeutically (Paik et al., 2015).

Capmatinib

Capmatinib is an orally bioavailable selective inhibitor of the MET kinase (IC_{50} of 0.13 nM) that was approved in 2020 for the treatment of patients with metastatic NSCLC with a mutation that leads to MET exon 14 skipping (see above). Adverse effects include peripheral edema, dyspepsia, and fatigue. *Capmatinib* is predominantly metabolized by CYP3A4 and eliminated with a $t_{1/2}$ of 6.5 h.

Tepotinib

Tepotinib is an orally bioavailable inhibitor of the MET kinase (IC_{50} of 4 nM) approved in 2021 for the treatment of patients with metastatic NSCLC with a mutation that leads to MET exon 14 skipping (see above). Adverse effects include peripheral edema, dyspepsia, fatigue, and musculoskeletal pain. *Tepotinib* is predominantly metabolized by CYP3A4 and eliminated with a $t_{1/2}$ of 32 h.

RET Inhibitors

Physiologically, the RET (rearranged during transfection) transmembrane tyrosine kinase receptor is activated through extracellular interactions with co-receptors and ligands from the glial cell–derived neurotrophic factor family and is involved in development of different organ systems including hematopoiesis, the CNS and the gastrointestinal (GI) tract. Activating RET mutations or gene fusions can become oncogenic drivers in NSCLC (1%–2%), thyroid cancer (10%–20%), and other cancers (Thein et al., 2021).

Selpercatinib

Selpercatinib is an orally bioavailable inhibitor of wild-type and mutated RET isoforms (IC_{50} of 1–4 nM) as well as VEGFRs and FGFRs at higher concentrations. It was approved in 2020 for the treatment of patients with metastatic RET fusion–positive NSCLC and advanced or metastatic RET-mutant medullary thyroid cancer. Adverse effects include the risk of hepatotoxicity that requires close monitoring every 2 weeks; hypertension requiring monitoring; QTc prolongation; impaired wound healing risk after surgery; and tumor lysis syndrome. It is metabolized predominantly by CYP3A4 and eliminated with a $t_{1/2}$ of 32 h.

Pralsetinib

Pralsetinib is an orally bioavailable inhibitor of wild-type and oncogenic RET fusions and mutations (IC_{50} <0.5 nM) that is over 10-fold selective relative to other kinases. It was approved in 2020 for the treatment of patients with metastatic RET fusion–positive NSCLC and advanced or metastatic RET-mutant medullary thyroid cancer. Adverse effects include the risk of severe interstitial lung disease/pneumonitis (10% of patients; 0.5% with fatal reactions) and hypertension (29% of patients; 14% with grade 3) that needs medications. It is metabolized predominantly by CYP3A; elimination $t_{1/2}$ is 15.7 h.

Hedgehog Pathway Inhibitors

The hedgehog signaling pathway was discovered by genetic studies in fruit flies: Mutations resulting in stubby and hairy *Drosophila melanogaster* larvae inspired the naming of the signaling pathway as "hedgehog" or Hh, which is the name of the pathway's polypeptide ligand. The hedgehog pathway controls embryonic cell differentiation in tissues of different species through distinct gradients of hedgehog signaling proteins that are key regulators during development. In adults, hedgehog signaling plays roles in stem cell regulation and tissue regeneration. In mammals, binding of one of three Hh ligands, named Sonic, Indian, and Desert Hh, to Patched-1 (PTCH1), a 12-transmembrane domain cell surface receptor protein, releases the PTCH1-mediated suppression of the seven-transmembrane receptor protein SMO (smoothens hedgehog), resulting in its activation of the glioma-associated (GLI) family of transcription factors that control the expression of Hh target genes. Mutations in PTCH1 are found in patients with Gorlin's syndrome predisposed to basal cell carcinoma (BCC), medulloblastoma, and rhabdomyosarcoma due to increased Hh pathway signaling. Overexpression of Hh ligands occurs in glioblastoma and GI and breast cancers, and abnormal activation of the pathway is seen in BCC and in some hematological malignancies, resulting in increased self-renewal capacity of leukemic cells (Jamieson et al., 2020). Hh pathway inhibitors induce differentiation of stem cells and can thus be used in combination with chemotherapy to target both dormant stem cells and growing cancer cells in the bulk of the tumor (Amakye et al., 2013). Clinical trials in solid tumors and hematological malignancies are ongoing to test the efficacy of such combinations (Jamieson et al., 2020). Three inhibitors of SMO and arsenic trioxide, an inhibitor of GLI transcription factors, are currently FDA-approved for cancer treatment and discussed next.

SMO Inhibitors

Vismodegib

Vismodegib, a 32% orally bioavailable first-in-class hedgehog signaling pathway inhibitor, is approved for the treatment of adult patients with BCC. It acts as a competitive antagonist of SMO and is indicated for patients with metastatic or relapsed BCC. Common adverse effects include GI disorders (nausea, vomiting, diarrhea, constipation), muscle spasms, fatigue, hair loss, and dysgeusia (distortion of the sense of taste). These adverse effects are mostly mild to moderate. *Vismodegib* can cause embryo-fetal death and severe birth defects and thus must not be used during pregnancy. Also, patients are advised not to donate blood for 24 months after the final dose and males not to donate semen during and for 3 months after therapy. The estimated elimination $t_{1/2}$ is 4 days after continuous dosing.

Sonidegib

Sonidegib is a less than 10% orally bioavailable hedgehog pathway inhibitor that binds to and inhibits SMO signal transduction similar to

vismodegib. *Sonidegib* is approved for the treatment of patients with locally advanced BCC that has recurred following surgery or radiation therapy. Warnings and adverse effects are similar to those of *vismodegib*. It is predominantly metabolized by CYP3A and has an elimination $t_{1/2}$ of approximately 28 days.

Glasdegib

Glasdegib is a 77% orally active hedgehog pathway inhibitor that was approved in 2018 for the treatment of patients 75 years of age or older with newly diagnosed acute myelocytic leukemia (AML) in combination with low-dose *cytarabine* if comorbidities preclude use of intensive induction chemotherapy. In addition to the warnings and adverse effects in common with *vismodegib*, *glasdegib* can cause QTc prolongation and thus requires electrocardiogram (ECG) monitoring. *Glasdegib* is metabolized by CYP3A4 and has a mean elimination $t_{1/2}$ of 17.4 h.

GLI Inhibitor

Arsenic Trioxide

Arsenic trioxide (ATO) is administered IV and binds to GLI1 and GLI2, resulting in inhibition of hedgehog target gene expression. ATO is approved in combination with *tretinoin* for the treatment of acute promyelocytic leukemia (APML) with a t(15;17) translocation that fuses PML to the retinoic acid receptor RAR-α. Patients with newly diagnosed, low-risk APML or patients after relapse from retinoid or chemotherapy are eligible. Adverse effects and warnings associated with the treatment include the occurrence of differentiation syndrome, which may be life-threatening and requires high-dose corticosteroids; risk of QTc interval prolongation; complete atrioventricular block; and torsades de pointes that can be fatal and requires ECG and electrolyte monitoring. Patients with ventricular arrhythmias or prolonged QTc should be excluded from treatment. Encephalopathy, including Wernicke's, can occur and requires parenteral thiamine treatment. Hepatic function should be monitored due to potential hepatotoxicity, and patients should be surveyed for new primary malignancies due to the carcinogenic effect of ATO. Patients should also be advised on the potential risk to a fetus and use effective contraception. Other symptoms indicative of adverse effects are nausea, abdominal pain, dyspnea, and pruritus. The elimination $t_{1/2}$ of ATO is 10 to 14 h. Chapter 76 presents aspects of the toxicology of ATO.

II. Inhibitors of Intracellular Protein Kinase Signaling in Cancer Cells

Inhibitors of RAS

The RAS GTPase family is a major switch that transduces extracellular signals from transmembrane receptors to multiple intracellular effectors, including the RAF family of kinases and PI3 kinase. This initiates a cascade of coordinated cellular events required for cell growth and maintenance, including regulation of gene expression and metabolic steady state. The cascade is visualized in Figure 71–2. GTP-bound RAS activates downstream signaling by binding to the RAS-binding domain of effector proteins with the GTPase activity limiting the signal strength and duration. Mutations in codons for glycines G12 or G13 or for glutamine Q61, impact GTP binding and disrupt GTPase activity of RAS proteins. Mutations in codons 12 and 61 decrease the rate of GTP hydrolysis, and mutations in codon 61 also accelerate the rate of GDP-GTP exchange. This results in elevated RAS^{GTP} and dysregulated activation of the downstream effectors characteristic of malignant transformation. Notably, almost all of the components of the downstream pathway can be found mutated in different cancers, and inhibitors are described in this section. RAS mutations occur in a tumor-specific manner for the K-, N-, and HRAS isoforms (reviewed in Moore et al., 2020). *KRAS* is one of the most highly mutated oncogenes in human cancer, occurring in 95% of pancreatic, 50% of colorectal, and 32% of lung adenocarcinomas (Rosen, 2021). Ostrem et al. (2013) developed drugs that bind covalently to the cysteine in the G12C mutant *KRAS* and disrupt downstream signaling of mutant and not wild-type protein. The recently approved KRAS G12C inhibitor *sotorasib* inhibits activation of mutant KRAS by preventing its regeneration from the inactive RAS-GDP state. The promise of mutant RAS inhibition in cancer treatment is supported by the results from the initial *sotorasib* trial. In previously treated patients with NSCLC harboring G12C KRAS mutations, a complete or partial response was observed in 37.1% of patients and disease control was observed in 80.6% of patients (Skoulidis et al., 2021).

HISTORY **THE RAS-RAF-MEK-ERK PATHWAY**

HRAS and *KRAS*, named after ***H***arvey and ***K***irsten ***ra***t ***s***arcoma viruses and discovered in the early 1980s, were the first oncogenes discovered in human tumors. *NRAS* was identified in human ***n***euroblastoma. These oncogenes were found to be mutated and constitutively active in approximately 20% of all cancers, up to 95% in some cancers (pancreatic adenocarcinoma). RAS proteins are GTPases that toggle between the active, GTP-bound and inactive, GDP-bound state. The first *RAF* gene was identified from a murine retrovirus named "***r***apidly ***a***ccelerated ***f***ibrosarcoma" due to its oncogenic effects. Following the discovery of the first human *RAF* gene (*RAF1*, also named *cRAF* = normal cellular *RAF*), the *RAF* genes *ARAF* and *BRAF* were identified; their gene products are ser/thre protein kinases. The signaling cascade of RAS-RAF-MEK-ERK was established by the early 1990s. This pathway plays a central role in cell proliferation and differentiation, is activated in many human cancers, and controls the crosstalk of cancer cells with the tumor microenvironment (see Figure 71–2). Mutations in *RAF* genes can lead to one (BRAF) or two (cRAF, BRAF) changes in amino acids, rendering these gene products oncogenic and resulting in continuous cell proliferation and the development of cancer. Activating mutations of *BRAF* were detected in melanoma and other tumors in 2002. A small-molecule inhibitor targeting mutated BRAF, *vemurafenib*, was approved by the FDA in 2011 for treatment of advanced melanoma; the first inhibitor of MEK, *trametinib*, was approved in 2013; the first inhibitor of mutant $KRAS^{G12C}$, *sotorasib*, was approved in 2021. The role of this pathway for immune crosstalk led to combination trials with the intent of triggering cancer cell death by pathway-targeted inhibitors and promoting cytotoxic T-cell efficacy. Ongoing combination trials have been reviewed a workshop of the National Academy of Sciences (Balogh and Nass, 2019), Hughes et al. (2016), and Petroni et al. (2021).

Sotorasib

Sotorasib (initially named AMG-510) is a first-in-class covalent inhibitor of the RAS GTPase family that targets G12C-mutant oncogenic *KRAS* and was approved in 2021 for the treatment of patients with locally advanced or metastatic NSCLC who have received at least one prior systemic therapy. Approximately 13% of NSCLCs carry mutant KRAS G12C, along with 3% of colorectal cancers and other cancers at lower frequencies. *Sotorasib* forms an irreversible, covalent bond with the unique cysteine in mutant KRAS G12C, locking the protein in an inactive state that prevents downstream signaling. *Sotorasib* showed minimal off-target activity and was associated with antitumor immunity in KRAS G12C preclinical models. Adverse effects include diarrhea, nausea, low-grade hepatotoxicity, and rarely, pneumonitis and dyspnea. The main metabolic pathways of *sotorasib* are nonenzymatic conjugation and metabolism by CYP3A. The mean elimination $t_{1/2}$ is 5 h.

Adagrasib

Adagrasib is a covalent inhibitor of KRAS G12C currently in clinical trials in NSCLC and colorectal cancer (Awad et al., 2021).

Emerging resistance mechanisms to KRAS G12C inhibition by *adagrasib*, an investigational drug still in clinical trials, showed a multitude of resistance pathways in patients with NSCLC and colorectal cancer (Awad et al., 2021). Treatment-resistant cancers contained secondary mutations or amplifications in the targeted KRAS, activation of the signaling pathway without alterations of KRAS itself, and histologic transformation from lung adenocarcinoma to squamous cell carcinoma. Trials exploring various combinations are ongoing to take advantage of this novel pathway inhibitor.

Inhibitors of RAF Kinase: Vemurafenib, Dabrafenib, and Encorafenib

BRAF belongs to the RAF/Mil family of serine/threonine protein kinases and plays a role in regulating signaling via MAPK (also named extracellular signal-related kinase [ERK]) (see Figure 71–2). *RAF* is the most frequently altered gene (7%–10% of all cancers) in the MAPK pathway downstream of RAS.

In melanoma, MAPK signaling can be constitutively activated through alterations in membrane receptors or through mutations of RAS or BRAF. BRAF mutations confer constitutive activation of the kinase pathway independent of RAS activation. BRAF is mutated in about 55% of melanomas, and 90% of these mutations display a substitution of valine to glutamic acid (V600E) or to lysine (V600K), which results in constitutive protein kinase activation (Vultur and Herlyn, 2013). Approximately 8% of other cancers, colon cancer and NSCLC among them, also carry an activating mutation in *BRAF*. The BRAF inhibitors *vemurafenib* and *dabrafenib* are superior to traditional chemotherapy in improving survival in patients with mutant BRAF melanoma and are discussed in the material that follows.

Combination of BRAF and MEK Inhibitors

Since the introduction of BRAF inhibitors in 2011 and MEK inhibitors in 2013 (see below), their combination has shown improved efficacy and is now standard of care in melanoma and NSCLC including *dabrafenib* plus *trametinib*, *vemurafenib* plus *cobimetinib*, and *encorafenib* plus *binimetinib* (Curti and Faries, 2021). Notably, in patients with BRAF-mutant colon cancers, no therapeutic benefit was observed, indicating that colon cancers do not depend on the activated mutant BRAF as a rate-limiting oncogenic driver.

Vemurafenib

Mechanism of Action

Vemurafenib is an orally bioavailable inhibitor of mutated BRAF (V600E). The name *vemuraf*enib is derived from the target, that is, ***V***600***E mu***tated B***RAF***. *Vemurafenib* also is effective against the less common BRAF V600K mutation. Melanoma cells lacking these mutations are not inhibited by *vemurafenib*.

ADME

Following oral administration, the elimination $t_{1/2}$ for *vemurafenib* is 57 h. *Vemurafenib* is a substrate of CYP3A4 and a substrate and an inhibitor of the Pgp exporter. *Vemurafenib* can increase concentrations of CYP1A2 substrates. Thus, concomitant use with the centrally acting α_2 adrenergic receptor agonist *tizanidine*, which has a narrow therapeutic window and is used as a muscle relaxant, should be avoided.

Therapeutic Uses

Vemurafenib is approved for the treatment of patients with metastatic melanoma harboring activating BRAF (V600E/K) mutations. It is not indicated for the treatment of patients with melanoma carrying wild-type BRAF. It is also approved for treatment of patients with Erdheim-Chester disease, a rare blood cancer (600–700 patients worldwide). Half of this slow-growing, histiocyte malignancy carries mutant BRAF as a driver.

Adverse Effects

The most common adverse effects (30%–60% of patients) are cutaneous events. Arthralgia, fatigue, and nausea are also observed but at a lower frequency. Cutaneous squamous cell carcinomas (cuSCCs) and keratoacanthomas that may need surgical removal appear in more than 20% of patients. The median time to the first appearance of these skin lesions is 7 to 8 weeks, and they are caused by a paradoxical stimulation of wild-type BRAF. Increased photosensitivity reactions can be prevented with sunblock. QT prolongation has been observed, necessitating controlling for risk factors and monitoring ECG and electrolytes.

Drug Resistance

Melanoma is one of the most aggressive malignancies, with a high mutation rate that renders these tumors highly heterogeneous and thus prone to the quick development of resistance to drug treatments. After the initial response of melanoma lesions to treatment with *vemurafenib*, resistant cancer cell subpopulations are selected, typically in less than 6 months. Constitutively active mutant *NRAS*; downstream mutations in MEK; overexpression of the growth receptor PDGFR-B; activation of parallel pathways such as PI3K/Akt, mammalian or mechanistic target of rapamycin (mTOR), and STAT3 signaling; or stromal cell secretion of HGF can drive this drug resistance (Chapman et al., 2011). Combination treatment with a MEK inhibitor (see below) that acts downstream of BRAF (see Figure 71–2) can delay development of resistance to single-agent BRAF inhibitors (Robert et al., 2015).

Dabrafenib

Mechanism of Action

Dabrafenib is an orally bioavailable, small-molecule inhibitor of mutated forms of BRAF kinases. *Dabrafenib* can inhibit the proliferation of tumor cells that contain a constitutively active mutated BRAF with *in vitro* IC_{50} values of 0.65, 0.5, and 1.84 nM for the V600E, V600K, and V600D mutations, respectively. At about 5-fold higher concentrations, *dabrafenib* also inhibits wild-type BRAF and cRAF (IC_{50} values of 3.2 and 5.0 nM, respectively). *Dabrafenib*, in combination with *trametinib* (see discussion that follows), is approved for the treatment of patients with unresectable or metastatic melanoma and NSCLC with BRAF mutations. The drug is not indicated for the treatment of patients with wild-type BRAF melanoma.

ADME

The mean terminal $t_{1/2}$ of *dabrafenib* is 8 h after oral administration. *Dabrafenib* is metabolized primarily by CYP2C8 and CYP3A4. Patients should be monitored closely for adverse reactions and for loss of efficacy if treated with drugs that induce CYP2C8 and CYP3A4 activity.

Therapeutic Uses

Dabrafenib was FDA approved as a single-agent treatment of patients with BRAF V600E mutation–positive advanced melanoma in 2013. Resistance to *dabrafenib* and other BRAF inhibitors occurs within about 6 months, but a combination with the MEK inhibitor *trametinib* can delay the development of resistance (see discussion that follows). Thus, the FDA has approved the combination of *dabrafenib* and *trametinib* for the treatment of patients with BRAF V600E/K–mutant metastatic melanoma and BRAF V600E–mutant NSCLC.

Adverse Effects and Drug Interactions

Adverse effects, in order of decreasing frequency, are hyperkeratosis, headache, pyrexia, arthralgia, papilloma, alopecia, and PPES. An increased incidence of cuSCC is expected in about 10% of patients, with a median time of 2 months to the first diagnosis. About one-third of those patients develop more than one lesion with continued administration of *dabrafenib*. With the *dabrafenib-trametinib* combination, the appearance of cuSCC is delayed to a median time of 7 months and occurs in only 3% of patients. Most common adverse reactions (≥20%) for *dabrafenib* in combination with *trametinib* are pyrexia, rash, chills, headache, arthralgia, and cough. Cardiomyopathy has also been reported.

Encorafenib

Encorafenib is an orally active protein kinase inhibitor that targets BRAF V600E, as well as wild-type BRAF and CRAF. It was approved in 2018 in combination with *binimetinib* (a MEK inhibitor) for the treatment of patients with unresectable metastatic melanoma with BRAF mutations. A combination of *encorafenib* and *cetuximab* (anti-EGFR monoclonal antibody; see Chapter 72) is approved for the treatment of patients with metastatic colorectal cancer with a BRAF V600E mutation in whom treatment increased progression-free and overall survival of patients. Adverse events include fatigue, nausea, diarrhea, acneiform dermatitis, abdominal pain, the risk of cuSCC, and dose-dependent QTc interval prolongation. *Encorafenib* is mostly metabolized by CYP3A4, and dosage adjustment is recommended in patients with mild to moderate renal or hepatic impairment. The elimination $t_{1/2}$ of *encorafenib* is 3.5 h.

Inhibitors of MEK: Trametinib, Cobimetinib, Binimetinib, and Selumetinib

The MKKs or MEKs (mitogen-activated extracellular signal regulated protein kinase kinases) are serine/threonine kinases that act downstream of RAF. They provide additional targets for the inhibition of the RAS-RAF-MEK-ERK pathway that is frequently activated in cancer and controls cell survival, differentiation, and growth (see Figure 71–2). Most MEK inhibitors are allosteric kinase inhibitors and their use as a single drug is susceptible to adaptive feedback reactivation of MAPK signaling that can reduce their efficacy (Yaeger and Corcoran, 2019).

Trametinib

Trametinib was the first inhibitor of the MEK family to be FDA-approved.

Mechanism of Action

Trametinib is an orally bioavailable, reversible, allosteric inhibitor of ATP binding to the MEK1/2 kinases. *Trametinib* inhibits MEK1/2 kinase activities with an IC_{50} of about 2 nM.

ADME

Bioavailability of oral *trametinib* is 72% and is reduced if taken with a high-calorie meal. Peak plasma concentrations are achieved 1.5 h postdose. The drug has a relatively long $t_{1/2}$ of 4 to 5 days. *Trametinib* is not a substrate of CYP enzymes, and mild renal or hepatic impairment does not affect exposure to the drug significantly.

Therapeutic Uses

The FDA approved *trametinib* as a monotherapy for patients with mutant BRAF V600E/K melanoma due to improved survival relative to standard therapy. *Trametinib* in combination with the BRAF inhibitor *dabrafenib* is also approved for mutant V600E/K metastatic melanoma and mutant V600E metastatic NSCLC as well as metastatic anaplastic thyroid cancer. *Trametinib* treatment lacks efficacy in patients who received prior treatment with BRAF inhibitors. This suggests that resistance to BRAF and MEK inhibitors involves similar mechanisms (Kim et al., 2013).

Adverse Effects

The most frequent adverse effects are cutaneous rash, acneiform dermatitis, and diarrhea. Fatigue, nausea, and lymphedema also occur. Serious grade 3 to 4 skin toxicity is found in 6% of patients. Other serious adverse effects are cardiomyopathy, hypertension, hemorrhage, interstitial lung disease, and ocular toxic effects. In contrast to the BRAF inhibitors, *trametinib* does not cause cuSCC. Because *trametinib* can cause fetal harm when administered to a pregnant woman, this risk must be weighed against the potential benefit.

Drug Resistance

Activation of alternative signaling pathways that include PI3K/Akt, mTOR, and STAT3 signaling can bypass MEK inhibition and result in drug-resistant tumors. Also, mutations in the allosteric binding pocket and activation loop of MEK1 can inhibit the binding of the inhibitor and cause resistance to *trametinib*. Resistance to single-agent *trametinib* occurs within 6 to 7 months of the initiation of treatment at a rate approaching 50%. As a strategy to overcome resistance, *trametinib* has been combined with the BRAF inhibitor *dabrafenib* for the treatment of patients with BRAF V600E/K–mutant metastatic melanoma (Flaherty et al., 2012). This combination is FDA-approved.

Cobimetinib

Mechanism of Action; ADME

Cobimetinib is an orally bioavailable, reversible inhibitor of MEK1/2 protein kinase activity with an IC_{50} of about 4 nM. Its elimination $t_{1/2}$ ranges from 1 to 3 days. *Cobimetinib* is a substrate for CYP3A, and concomitant treatment with inducers or inhibitors of CYP3A will reduce or increase the systemic exposure of patients.

Therapeutic Uses

A combination of *cobimetinib* and *vemurafenib* is approved for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E/K mutation.

Adverse Effects

The most common adverse effects are diarrhea, photosensitivity reaction, nausea, pyrexia, and vomiting. Major hemorrhagic events can occur with *cobimetinib*; patients should be monitored for signs and symptoms of bleeding. The drug also increases the risk of cardiomyopathy. The safety in patients with decreased left ventricular ejection fraction has not been established.

Binimetinib

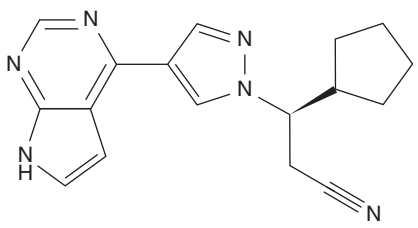
Binimetinib is an orally bioavailable MEK1/2 kinase inhibitor with an IC_{50} of 12 nM that was approved in 2018, in combination with *encorafenib* (see above), for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E or V600K mutation. After moderate to severe hepatic impairment, the area under the curve (AUC) is increased 2-fold. Impaired renal function does not impact drug elimination. The elimination $t_{1/2}$ is 3.5 h.

Selumetinib

Selumetinib is an orally bioavailable inhibitor of MEK1 (IC_{50}, 14 nM) and MEK2 with a lower affinity (IC_{50}, 530 nM). *Selumetinib* was approved in 2020 for the treatment of pediatric patients with neurofibromatosis type 1 and inoperable, plexiform neurofibromas. Warnings include the risk of cardiomyopathy requiring assessment of ejection fraction prior to treatment, ocular and skin toxicity, and possible GI toxicity requiring antidiarrheal treatment and increased fluid intake. Additional adverse reactions (≥40%) are vomiting, rash, and abdominal pain. *Selumetinib* is primarily metabolized by CYP3A4 and eliminated with a $t_{1/2}$ of 6.2 h.

Inhibitors of JAK1 and JAK2

***J**anus **a**ssociated **k**inases* (JAKs) mediate the signaling of cytokines and growth factors in hematopoiesis and immune function (see, for instance, Figure 39–2). Intracellular JAK signaling recruits STATs to cytokine membrane receptors (see Figure 71–2). After STAT activation and subsequent localization to the nucleus, STATs modulate gene expression. JAK signaling is dysregulated in myelofibrosis and polycythemia vera, which prompted the development of JAK inhibitors (JAKinibs). *Ruxolitinib* is the first drug in this class.



Ruxolitinib

Ruxolitinib

Mechanism of Action; ADME

Ruxolitinib is an orally bioavailable (95%) analogue of ATP that inhibits the protein kinase activities of JAK1 and JAK2 (see Figure 72–4) with an IC_{50} of 3 nM and more than 100-fold selectivity over JAK3. The elimination $t_{1/2}$ of *ruxolitinib* is about 3 h; its metabolism is mainly via hepatic CYP3A4, with products excreted largely in the urine. In patients with renal or hepatic impairment, a dose reduction is recommended.

Therapeutic Uses

Ruxolitinib is indicated for the treatment of patients with polycythemia vera who have had an inadequate response to *hydroxyurea* and for the treatment of myelofibrosis and steroid-refractory, acute graft-versus-host disease (>12 years of age).

Adverse Effects and Drug Interactions

The most common adverse reactions, thrombocytopenia and anemia, may require a dose reduction or discontinuation of treatment. Infections should be resolved before treatment with *ruxolitinib*. In a few patients, BCC or squamous cell skin carcinoma may occur, warranting periodic skin examinations during treatment. Strong CYP3A4 inhibitors (e.g., *ketoconazole*, *fluconazole*) increase exposure to *ruxolitinib* and prolong its $t_{1/2}$ to 6 h. Due to the adverse hematopoietic effects, postpartum patients should discontinue nursing during drug treatment.

Fedratinib

Fedratinib is an orally bioavailable JAK2-selective inhibitor (IC_{50} is 3 nM; >35-fold selective vs. JAK1 and JAK3) with activity against wild-type and mutationally activated JAK2 as well as FLT3 (IC_{50} is 15 nM) and RET (IC_{50} is 48 nM). Abnormal activation of JAK2 is associated with myeloproliferative disease and polycythemia vera. *Fedratinib* was approved in 2019 for the treatment of patients with myelofibrosis. Warnings include the risk of serious and fatal encephalopathy requiring monitoring and possibly replenishment of thiamine levels, anemia and thrombocytopenia, as well as GI and hepatic toxicity. Adverse reactions include diarrhea and nausea. The metabolism is through CYP3A with a terminal elimination $t_{1/2}$ of 114 h.

Cyclin-Dependent Kinase (CDK) 4/6 Inhibitors

The CDKs are a family of over 20 serine/threonine protein kinases that modulate intracellular signaling during cell cycle progression (see Figure 71–2). Given their pivotal role in cellular proliferation, CDKs are prime targets for development of inhibitors. However, different tissue selectivity and distinct cell cycle–specific activity periods of different CDKs provide a challenge.

CDK4/6 are attractive targets because they control cell cycle progression from the G_0/G_1 to S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation of the Rb (retinoblastoma) tumor suppressor protein, inactivating Rb and permitting the transcription of factors that control transition into the S phase. Inhibition of CDK4/6 will inhibit the phosphorylation and inactivation of Rb and cause a G_1 arrest in susceptible cells that utilize this pathway, thereby providing the rationale for the use of inhibitors of CDK4/6 (Figure 71–3). This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6, such as $p16^{INK4A}$, a tumor suppressor named for its molecular mass (it is a small protein of 16 kDa) and its capacity to inhibit CDK4. The class of CDK inhibitory drugs is identified by the syllable *ciclib*. CDK4/6 inhibitors with inhibitory profiles similar to that of *palbociclib* include *abemaciclib*, *ribociclib*, and *trilaciclib*, which are now approved for the treatment mostly of patients with breast cancer and are in clinical trials for other cancers. The efficacy and adverse effects of these inhibitors overlap, although differences in the selectivity for the targeted kinases result in different adverse effect profiles and approved uses of these inhibitors (O'Leary et al., 2016).

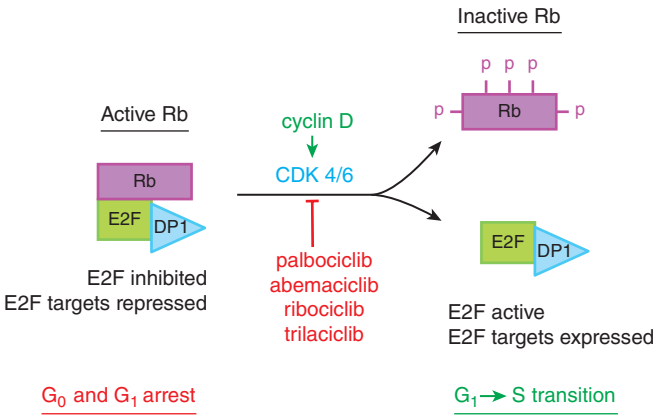


Figure 71–3 *CDK4/6 inhibitors: retinoblastoma protein, cyclin-dependent protein kinases, and the regulation of cell cycle progression.* In quiescent and differentiated cells (in G_0 or in cells arrested in G_1), the Rb protein is active and interacts with a heterodimer of the transcription factor E2F and its dimerization partner DP1, repressing transcription of promoters regulated by E2F. As a cell begins a cycle of division, cyclins activate CDKs that phosphorylate Rb, disrupting the Rb-E2F/DP complexes and permitting accumulation of active E2F complexes that drive transcription. This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6. Hyperphosphorylation of Rb can occur via mutations in Rb or expression of viral oncoproteins targeting Rb, placing the cell in a state of extensive proliferation, with reduced capacity to exit the cell cycle. Inhibition of CDK4/6 can cause G_1 arrest in susceptible cells (Dyson, 2016). CDK inhibitors (in red lettering) are identified by the disyllabic suffix "ciclib."

Palbociclib

Mechanism of Action

Palbociclib is an orally bioavailable, small-molecule inhibitor of CDK4 and CDK6, with IC_{50} values of 11 and 16 nM, respectively, and without inhibitory activity against CDK1, 2, or 5.

ADME

The mean plasma elimination $t_{1/2}$ is 29 h. *Palbociclib* is a substrate and an inhibitor of CYP3A; thus, doses of *palbociclib* or of substrates of CYP3A4 may need to be reduced when they are given concurrently, with special attention to coadministered agents with narrow therapeutic indexes (see the Adverse Effects and Drug Interactions section). The sulfotransferase SULT2A1 also participates in *palbociclib* metabolism.

Therapeutic Uses

Palbociclib is the first CDK inhibitor approved by the FDA (in 2015) for the treatment of advanced or metastatic breast cancer that is estrogen receptor (ER) positive and HER2 negative. *Palbociclib* is used in combination with *letrozole*, an aromatase inhibitor, as initial endocrine-based therapy in postmenopausal women or with the antiestrogen *fulvestrant* in women with disease progression after endocrine-based therapy. *Letrozole* and *fulvestrant* are described in Chapter 73. The inclusion of *palbociclib* with different endocrine-based treatments almost doubles the progression-free survival of patients (Cristofanilli et al., 2016; Finn et al., 2016).

Adverse Effects and Drug Interactions

The most common adverse effects of *palbociclib* are neutropenia, leukopenia, infections, stomatitis, fatigue, nausea, anemia, headache, diarrhea, and thrombocytopenia. The most common grade 3 and 4 adverse effects are neutropenia (>60%), leukopenia (~25%), and anemia (~5%). Patients should avoid breastfeeding while taking *palbociclib*. *Letrozole* and *fulvestrant* do not alter the pharmacokinetics of *palbociclib*. No effect on the QTc interval was observed.

Patients should avoid concomitant use of strong CYP3A inhibitors (e.g., *clarithromycin, indinavir, itraconazole, ketoconazole, lopinavir/ritonavir, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, telithromycin*, and *voriconazole*). Coadministration of a strong

CYP3A inhibitor (e.g., *itraconazole*) can markedly increase exposure to *palbociclib* (by 87% in healthy subjects). Patients should also avoid grapefruit or grapefruit juice. If *palbociclib* coadministration with a strong CYP3A inhibitor cannot be avoided, the dose of *palbociclib* should be reduced.

Coadministration of a strong CYP3A inducer will decrease exposure to *palbociclib*. Thus, concomitant use of *phenytoin*, *rifampin*, *carbamazepine*, *enzalutamide*, and St. John's wort should be avoided.

Palbociclib may increase exposure to coadministered CYP3A substrates with narrow therapeutic indexes (e.g., *midazolam, alfentanil, cyclosporine, dihydroergotamine, ergotamine, everolimus, fentanyl, pimozide, quinidine, sirolimus*, and *tacrolimus*), requiring reduction of *palbociclib* dose.

Abemaciclib

Abemaciclib is an orally bioavailable inhibitor of CDK4/6 approved in 2017 in the treatment of patients with ER-positive and HER2-negative, advanced or metastatic breast cancer. One indication is in postmenopausal women in combination with an aromatase inhibitor (see Chapter 73); a second indication is in patients whose disease progressed following endocrine therapy in combination with the antiestrogen *fulvestrant* (see Chapter 73); a third indication is in patients with disease progression following endocrine therapy and prior chemotherapy in the metastatic setting. Most common adverse reactions (incidence ≥20%) are diarrhea, neutropenia, nausea, abdominal pain, infections, fatigue, anemia, decreased appetite, vomiting, headache, alopecia, and thrombocytopenia.

Abemaciclib is metabolized by CYP3A, and it is recommended to avoid concomitant use of inhibitors (see discussion above on *palbociclib* metabolism). The elimination $t_{1/2}$ of *abemaciclib* is 18.3 h.

Ribociclib

Ribociclib, an orally bioavailable inhibitor of CDK4/6, was approved in 2017 for the treatment of patients with ER-positive and HER2-negative advanced or metastatic breast cancer. One indication is in combination with an aromatase inhibitor (see Chapter 73) for the treatment of pre-, peri-, or postmenopausal patients as initial endocrine-based therapy; a second indication is for the treatment of postmenopausal patients in combination with the antiestrogen *fulvestrant* (see Chapter 73) as initial endocrine-based therapy or following disease progression on endocrine therapy. Recent warnings indicate an increased risk of interstitial lung disease/pneumonitis during treatment. Monitoring of patients for pulmonary symptoms is thus recommended. Other risks are concentration-dependent increases in the QTc interval, with pretreatment and continuous ECG and electrolyte monitoring recommended; severe cutaneous adverse reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis; and neutropenia, with pretreatment and every-2-week monitoring of CBC counts recommended. Common adverse effects (incidence ≥20%) are nausea, fatigue, diarrhea, leukopenia, vomiting, alopecia, headache, rash, and cough. *Ribociclib* is metabolized through CYP3A, and concomitant use of interacting drugs should be avoided (see above discussion for *palbociclib*). The elimination $t_{1/2}$ of *ribociclib* ranges from 29.7 to 54.7 h.

Trilaciclib

Trilaciclib is a CDK4/6 kinase inhibitor that was approved in 2021 to decrease the incidence of chemotherapy-induced myelosuppression in patients receiving a platinum/*etoposide*-containing regimen or *topotecan*-containing regimen (see Chapter 70) for extensive-stage small cell lung cancer. *Trilaciclib* is administered as a single IV 30-min infusion within 4 h prior to chemotherapy on each day of chemotherapy. *Trilaciclib* transiently maintains immune cells and hemopoietic stem and progenitor cells in G_1 cell cycle arrest to reduce bone marrow toxicity of chemotherapy. The elimination $t_{1/2}$ is approximately 14 h, and bone marrow cell cycle arrest lasts for up to 32 h after a single dose. After that time, bone marrow progenitor subsets resume proliferation.

An intriguing possibility is that the intermittent administration of *trilaciclib* may preserve anticancer immune reactivity and contribute to increased efficacy of chemotherapy. This is suggested from a study using *gemcitabine* and *carboplatin* chemotherapy in patients with hormone receptor–negative and HER2-negative ("triple negative") metastatic breast cancer that is not considered responsive to CDK4/6 inhibitors (Tan et al., 2019). An editorial in *Lancet Oncology* (Goel and Tolaney, 2019) speculates that *trilaciclib* before chemotherapy may preserve immune cell function.

Bruton Tyrosine Kinase (BTK) Inhibitors

The BTK protein tyr kinase plays important roles in the signal transduction and normal function of B cells as well as their malignant transformation. B-cell receptor signaling recruits SYK followed by the activation of BTK and PI3Kδ, leading to further downstream responses and multiple cellular effects (Figure 71–4). Integrin signaling and chemokine receptor signaling can modulate the activity of the pathway. A SYK kinase inhibitor, *fostamatinib*, was approved for the treatment of patients with chronic immune thrombocytopenia. BTK inhibitors are discussed next, and inhibitors of the PI3Kδ isoform that is frequently activated in B-cell malignancies are discussed further below. BTK and PI3K inhibitors can disrupt oncogenic B-cell receptor signaling and accelerate tumor cell death (reviewed by Burger and O'Brien, 2018).

Ibrutinib

Mechanism of Action

Ibrutinib is an orally bioavailable, small-molecule inhibitor that inactivates BTK through covalent binding to cys^{481} near the ATP-binding domain.

ADME

Administration with food (vs. on an empty stomach) roughly doubles absorption. The elimination $t_{1/2}$ of *ibrutinib* is 4 to 6 h. It is a substrate of CYP3A; CYP2D6 participates to a minor degree. Metabolites are excreted mainly via the feces; renal excretion is minor. Hepatic impairment is likely to increase *ibrutinib* exposure. *Ibrutinib* is not a substrate for Pgp.

Therapeutic Uses

Ibrutinib inhibits malignant B-cell proliferation and is indicated for the treatment of patients with mantle cell lymphoma (MCL) and marginal zone lymphoma who have received at least one prior therapy and patients with chronic lymphocytic leukemia (CLL), small lymphocytic lymphoma (SLL), Waldenström's macroglobulinemia, and chronic graft-versus-host disease after failure of systemic therapy.

Adverse Effects and Drug Interactions

The most common adverse effects (≥20%) in patients with B-cell malignancies are neutropenia, pyrexia, thrombocytopenia, hemorrhage, anemia, diarrhea, nausea, musculoskeletal pain, rash, and fatigue. The onset of hypertension has been observed within less than a month and up

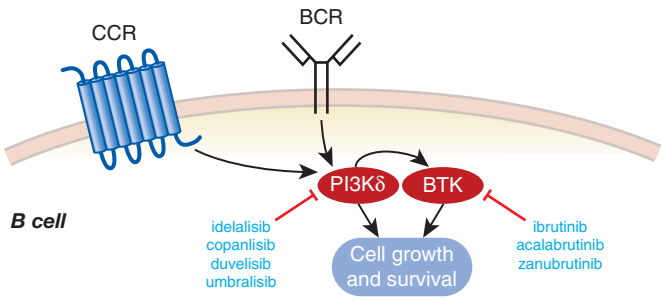

Figure 71–4 *Inhibitors of signaling in B cells.* The signaling by B-cell receptors (BCRs) and chemokine receptors (CCRs) enables the recruitment of intracellular signal transducers, which is followed by the activation of BTK and PI3Kδ. The BTK and PI3K inhibitors indicated can disrupt oncogenic BCR signaling and thus lead to cell death.

to 2 years after the start of *ibrutinib* treatment. Thus, blood pressure should be monitored and antihypertensive treatment initiated or modified. Atrial fibrillation is observed in up to 7% of patients; this requires monitoring and treatment. Second primary malignancies occur in up to 16% of patients, most of them nonmelanoma skin cancers.

Strong (e.g., azole antifungals) and moderate (e.g., *diltiazem, erythromycin*) CYP inhibitors will increase *ibrutinib*'s AUC; thus, dose reduction is recommended when using CYP3A inhibitors concomitantly. The reverse is true for strong and moderate CYP inducers (e.g., *rifampin, efavirenz*), which will decrease *ibrutinib* exposure.

Ibrutinib may cause fetal harm. Pregnant patients and those at risk for pregnancy should be apprised of the drug's hazardous potential.

Acalabrutinib

Acalabrutinib is a second-generation, orally bioavailable, irreversible BTK inhibitor that shows higher selectivity for BTK versus other kinases (e.g., EGFR, ITK [inducible T-cell kinase]) than *ibrutinib*. *Acalabrutinib* was first approved in 2017 and is indicated for the treatment of patients with MCL who have received at least one prior therapy and patients with CLL and SLL. Adverse effects include the risk of infections, hemorrhage, cytopenias, second primary malignancies including nonmelanoma skin cancers, and cardiac arrhythmias. The elimination $t_{1/2}$ is 1 h for *acalabrutinib* and 3.5 h for an active metabolite. Still, dosing every 12 h generates BTK occupancy of 95% or greater in peripheral blood and inactivation of BTK likely due to the covalent binding to a cysteine residue in the active site of the kinase.

Zanubrutinib

Zanubrutinib is an orally bioavailable inhibitor of BTK that forms a covalent bond with a cysteine residue in the BTK active site and shows a higher selectivity for BTK versus other kinases (e.g., ITK, EGFR), resulting in less off-target effects. *Zanubrutinib* was approved in 2019 for the treatment of patients with MCL who have received at least one prior therapy. Adverse events and warnings overlap with those of *acalabrutinib* (above) and include skin cancers as second primary malignancies, hemorrhage, and arrhythmias. The elimination $t_{1/2}$ is 2 to 4 h. Still, BTK occupancy in peripheral mononuclear cells was maintained at 100% over 24 h and at 94% to 100% in lymph nodes.

Inhibitors of the BCR-ABL Kinase

A single molecular event, the Philadelphia chromosome translocation t(9;22), leads to expression of ABL (Abelson murine leukemia viral oncogene homolog) and BCR. This fusion generates a constitutively active protein kinase, BCR-ABL, resulting in continuous and uncontrollable cell division. BCR-ABL drives the malignant phenotype of chronic myelocytic leukemia (CML) (see Figure 71–2).

HISTORY **BCR-ABL KINASE INHIBITORS**

Imatinib mesylate, originally named "sti 571" (signal transduction inhibitor 571), was the first protein kinase inhibitor designed to target a driver mutation in a cancer and to receive FDA approval. It was approved in 2001 under the name *Gleevec* and is now designated as an essential drug by the World Health Organization. *Imatinib* targets the BCR-ABL tyrosine kinase fusion protein that drives CML. Imatinib-resistant ABL mutations were uncovered in 2002 and led to the development of next-generation inhibitors *dasatinib* and *nilotinib*, which overcome the resistance.

Imatinib and the second-generation inhibitors *dasatinib* and *nilotinib* induce clinical and molecular remissions in more than 90% of patients with CML in the chronic phase of disease. Due to its inhibition of other kinases, *imatinib* is also effective in some other tumors, including GISTs (driven by a c-KIT mutation), hypereosinophilia syndrome, and dermatofibrosarcoma protuberans (all driven by activating mutations in the PDGFR; see Figure 71–2).

Imatinib, Dasatinib, and Nilotinib

Mechanisms of Action

These are orally bioavailable, small-molecule kinase inhibitors. *Imatinib* was identified through high-throughput screening against the BCR-ABL kinase. *Dasatinib*, a second-generation BCR-ABL inhibitor, also inhibits the Src kinase, and unlike *imatinib*, it binds both the open (active) and closed (inactive) configurations of the BCR-ABL kinase. *Nilotinib* was designed to have increased potency and specificity compared to *imatinib*. Its structure overcomes mutations that cause *imatinib* resistance. *Imatinib* and *nilotinib* bind to a segment of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP. These three BCR-ABL kinase inhibitors differ in their inhibitory potencies, binding specificities, and susceptibility to resistance mutations in the target enzyme (reviewed by Braun et al., 2020). *Dasatinib* (IC_{50} ~1 nM) and *nilotinib* (IC_{50} ~20 nM) inhibit BCR-ABL kinase more potently than *imatinib* (IC_{50} ~100 nM).

Mechanisms of Resistance

Resistance to these TKIs arises from point mutations in three separate segments of the kinase domain. The contact points between *imatinib* and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. *Nilotinib* retains inhibitory activity in the presence of most point mutations that confer resistance to *imatinib*. Other mutations affect the phosphate-binding region and the "activation loop" of the domain with varying degrees of associated resistance. Some mutations, such as those at amino acids 351 and 355, confer low levels of resistance to *imatinib*, possibly explaining the clinical response of some resistant tumors to dose escalation of *imatinib*.

Molecular studies have detected cells with resistance-mediating kinase mutations *prior* to initiation of therapy, particularly in patients with Ph^+ acute lymphoblastic leukemia (ALL) or CML in blast crisis. This finding indicates that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mechanisms other than BCR-ABL kinase mutations play a minor role in resistance to *imatinib*. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment. The *MDR* gene confers resistance experimentally but has not been implicated in clinical resistance. Ph^- clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML; these may progress to myelodysplastic syndrome (MDS) and AML. Their origin is unclear.

A comparison among secondary mutations in the EGFR, ABL, and KIT kinases following treatment with BCR-ABL kinase inhibitors shows striking differences: The T790M gatekeeper mutation in EGFR (see Figure 71–1) accounts for about 90% of secondary mutations. In contrast, secondary resistance mutations in ABL or KIT after treatment of CML or GIST with *imatinib* are found across the kinase domain and rarely at the analogous gatekeeper residue in ABL (T^{315}) or in KIT (T^{670}).

ADME

Imatinib. *Imatinib* is well absorbed after oral administration and reaches maximal plasma concentrations within 2 to 4 h. The elimination $t_{1/2}$ of *imatinib* and its major active metabolite, the *N*-desmethyl derivative, are about 18 and 40 h, respectively. Food does not influence the pharmacokinetic profile. Doses of more than 300 mg/day achieve trough levels of 1 μM, which correspond to *in vitro* levels required to kill BCR-ABL–expressing cells. In the treatment of GISTs, higher doses may improve response rates. CYP3A4 is the major metabolizer of *imatinib*; thus, drugs that induce or interact with CYP3A4 can alter the pharmacokinetics of *imatinib*. Coadministration of *imatinib* and *rifampin*, an inducer of

 CYP3A4, lowers the plasma *imatinib* AUC by 70%. *Imatinib*, as a competitive CYP3A4 substrate, inhibits the metabolism of *simvastatin* and increases its plasma AUC by 3.5-fold.

Dasatinib. Oral *dasatinib* is well absorbed; its bioavailability is significantly reduced at neutral gastric pH (i.e., after antacids and H_2 blockers) but is unaffected by food. The plasma $t_{1/2}$ of *dasatinib* is 3 to 5 h. *Dasatinib* exhibits dose-proportional increases in AUC, and its clearance is constant over the dose range of 15 to 240 mg/day. *Dasatinib* is metabolized primarily by CYP3A4, with minor contributions by FMO3 (flavin containing monooxygenase 3) and UGT. The major metabolite is equipotent to the parent drug but represents only 5% of the AUC. Plasma concentrations of *dasatinib* are affected by inducers and inhibitors of CYP3A4 in a similar fashion to *imatinib*.

Nilotinib. Approximately 30% of an oral dose of *nilotinib* is absorbed after administration, with peak concentrations in plasma 3 h after dosing. Unlike the other BCR-ABL inhibitors, *nilotinib*'s bioavailability increases significantly in the presence of food. The drug has a plasma $t_{1/2}$ about 17 h, and plasma concentrations reach a steady state only after 8 days of daily dosing. *Nilotinib* is metabolized by CYP3A4, with predictable alteration by inducers, inhibitors, and competitors of CYP3A4. *Nilotinib* is a substrate and an inhibitor of Pgp.

Therapeutic Uses

These protein TKIs have efficacy in diseases in which ABL, *KIT*, or PDGFR has dominant roles in driving tumor growth, reflecting the presence of a mutation that results in constitutive activation of the kinase. *Imatinib* shows therapeutic benefits in patients with chronic-phase CML (BCR-ABL) or GIST and a subset of patients with mucosal or acral lentiginous melanoma (*KIT* mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilia syndrome (FIP1L1-PDGFR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR). It is the agent of choice for patients with metastatic GIST and is used as adjuvant therapy of *c-KIT*–positive GIST. *Dasatinib* is approved for patients with newly diagnosed CML with resistance to or intolerance of *imatinib* in both chronic and advanced phases of disease and for use combined with cytotoxic chemotherapy in patients with Ph^+ ALL who are resistant or intolerant to prior therapies.

Adverse Effects

Imatinib, *dasatinib*, and *nilotinib* cause GI symptoms (diarrhea, nausea, and vomiting) that are usually readily controlled. All three drugs promote fluid retention, edema, and periorbital swelling. Myelosuppression occurs infrequently but may require transfusion support and dose reduction or discontinuation of the drug. These drugs can be associated with hepatotoxicity. *Dasatinib* may cause pleural effusions and pulmonary hypertension in a small subset of patients. *Nilotinib* and *dasatinib* may prolong the QT interval; *nilotinib* has been associated with cardiac and vascular events, including ischemia. Most nonhematological adverse reactions are self-limited and respond to dose adjustments. After the adverse reactions have resolved, the drug may be reinitiated and titrated back to effective doses.

Bosutinib

Bosutinib is another second-generation, orally bioavailable BCR-ABL kinase inhibitor (IC_{50} = 1.2 nM). *Bosutinib* also inhibits activity of Src (IC_{50} = 1 nM) and other members of the Src family. It is FDA approved for the treatment of patients with chronic, accelerated, or blast-phase Ph^+ CML with resistance or intolerance to prior therapy. The most common adverse reactions (incidence >20%) are diarrhea, nausea, thrombocytopenia, vomiting, abdominal pain, rash, anemia, pyrexia, and fatigue.

Ponatinib

Ponatinib is a third-generation BCR-ABL kinase inhibitor. *Imatinib* (first-generation) lacks efficacy for the more advanced disease phases, and cells with mutations in the BCR-ABL tyrosine kinase domain are resistant. Second-generation inhibitors (*nilotinib*, *dasatinib*, *bosutinib*) were developed to address these weaknesses, although they do not inhibit the T315I mutant of BCR-ABL that is found in 15% to 20% of patients with CML.

Mechanism of Action

Ponatinib is a third-generation, orally bioavailable kinase inhibitor that is active against the T315I mutant BCR-ABL and is also effective toward all other known BCR-ABL1 kinase mutants. IC_{50} values (nM) for different kinases are as follows: ABL, 0.37; PDGFR, 1.1; VEGFR2, 1.5; FGFR1, 2.2; and Src, 5.4.

ADME

Peak *ponatinib* concentrations are observed within 6 h and are unaffected by food or fasting. Drug solubility is pH dependent, with higher pH resulting in decreased solubility. Accordingly, drugs that affect gastric pH (e.g., H_2 antagonists, antacids, and proton pump inhibitors [PPIs]) may significantly alter *ponatinib* bioavailability. *Ponatinib* is highly (99%) bound to plasma proteins and is a weak substrate for Pgp and ABCG2 transporters. Metabolism is primarily via CYP3A4 and to a lesser extent by CYPs 2C8, 2D6, and 3A511; esterases; and amidases. Coadministration of CYP3A inhibitors significantly increases *ponatinib* concentrations. The $t_{1/2}$ of *ponatinib* is about 24 h. Unmetabolized *ponatinib* is primarily excreted in the feces (87%), with a small portion (5%) in the urine.

Therapeutic Uses

Ponatinib is approved for resistant CML and Ph^+ ALL. Clinical cytogenetics measurements are a key tool for monitoring the response to therapy, reported as the percentage of Ph^+ karyotypes in 20 bone marrow metaphases (major cytogenetic response [MCyR]). *Ponatinib* produces an overall 54% MCyR in patients with early-phase CML and a 70% MCyR in patients with early-phase CML with the T315I mutation. Because of *ponatinib*'s potency and efficacy against all known BCR-ABL single mutants, trials are under way that may advance this therapy to a first-line treatment.

Adverse Effects

Arterial thrombosis and hepatotoxicity are major adverse effects; thus, appropriate precautions, dose reduction, monitoring, or discontinuation is recommended. Dose-limiting toxicities include elevated lipase and amylase levels and pancreatitis.

Inhibitors of the PI3K/Akt/mTOR Pathway

Background

Activation of PI3K and the consequent activation of signaling events through protein kinase B (Akt) and the mTOR pathway are important in cell growth and survival and in the regulation of cell metabolism (Figures 71–2 and 71–5). Excessive signaling through the PI3K pathway is a frequent aberration in many human cancers; thus, this pathway is an attractive target in cancer therapy. There are three classes of PI3Ks, with the class I being the most important in cancer. The class I PI3K enzymes are heterodimers of a p85 regulatory subunit and a p110 catalytic subunit. The p110 catalytic subunit exists in four identified isoforms: α, β, γ, and δ. The α and β isoforms are ubiquitously expressed, whereas expression of the γ and δ isoforms is restricted to cells of immune lineage. The p110 subunit of the enzyme is a lipid phosphokinase that catalyzes synthesis of phosphatidylinositol (3,4,5)-trisphosphate (PIP3) from the phosphatidylinositol 4,5-bisphosphate (PIP2) substrate, an abundant lipid at the plasma membrane. The different catalytic subunits have distinct roles in normal and malignant cells. The gene coding for PI3Kα (*PIK3CA*) is the most frequently mutated PI3K in human cancer (Fruman and Rommel, 2014). In B-cell malignancies, the PI3Kδ isoform is frequently activated. A PI3Kδ inhibitor, *idelalisib*, is described below followed by the discussion of additional inhibitors of PI3Kδ, *copanlisib*, *duvelisib*, and *umbralisib*, that are approved for the treatment of B-cell lymphoma. An inhibitor of PI3Kα, *alpelisib*, shows a distinct efficacy profile, was approved in 2019 for the treatment of patients with advanced breast cancer, and is described at the end of this section.

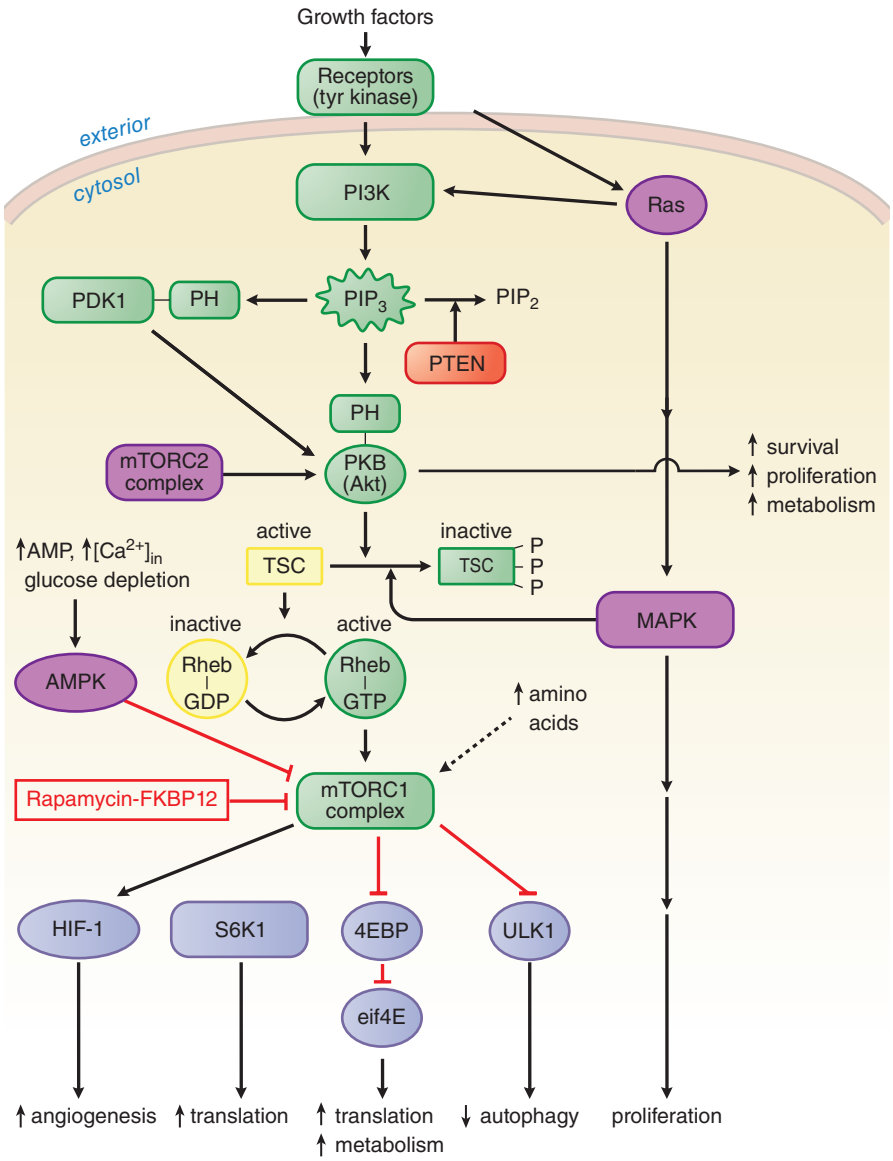

Figure 71–5 *Caveat mTOR: effect of rapamycin on growth factor signaling.* The PI3K-mTOR pathway responds to extracellular signals, the metabolic and nutrient status, and the energy charge of the cell, transmitting signals downstream that drive maintenance and proliferation (Hall, 2016). mTOR activity appears to contribute to resistance to many targeted cancer therapies (Guri and Hall, 2016), and dysregulation of the pathway is implicated in diabetes, cancer, and other pathologies (Dibble and Cantley, 2015). In this simplified version of the PI3K-mTOR pathway, the green shapes show the action pathway from membrane receptor to the mTOR multiprotein complex, mTORC1. Substrates of the mTOR ser/thr protein kinase activity and integrated responses are shown in blue across the bottom of the figure. Red T bars represent inhibitory influence. Signaling through the pathway is initiated by agonist activation of membrane receptors such as IGF1R and stimulation of their tyrosine kinase activities, leading to activation of PI3K, which phosphorylates the inositol ring of the PIP2 in the membrane to produce PIP3. PIP3 recruits to the membrane several proteins containing PH domains, including PKD1 and Akt. Akt, also known as PKB, phosphorylates TSC-2 (a subunit of TSC) at multiple sites. TSC is a GTPase-activating protein (GAP) for Rheb. Phosphorylation of TSC inhibits its GAP activity, thereby reducing the GTPase activity of Rheb and increasing the fraction of Rheb in the GTP-liganded state. Rheb, in its GTP-liganded configuration, activates mTORC1. TSC phosphorylation and PIP3 phosphorylation can be reversed by the phosphatase PTEN. mTORC1 phosphorylates substrates that mediate downstream effects; among them are the following:

- HIF-1, leading to increased angiogenesis. HIF-1 and -2 are overexpressed or upregulated in many cancers.
- S6K1 (ribosomal protein S6 kinase β1), enhancing protein synthesis. Dephospho S6K1 exists in a complex with eIF3; phosphorylation by mTOR dissociates the complex, freeing S6K1 to phosphorylate its targets that promote translation.
- 4EBP, enhancing transcription. The phosphorylation of 4EBP by mTOR reduces the capacity of 4EBP to inhibit eIF4E and slow transcription.
- ULK1, whose phosphorylation reduces autophagic activity. mTOR activity prevents ULK1 activation by disrupting its interaction with AMPK, a key promoter of autophagy. Conversely, inhibition of mTOR will stimulate autophagy.

Rapamycin (*sirolimus*) and the "rapalogs" *everolimus* and *temsirolimus* inhibit mTOR by associating with the intracellular protein FKBP12. The FKBP12-rapalog complex binds directly to mTOR and inhibits its functions in the multiprotein complex mTORC1. mTORC2 remains relatively unaffected by mTORC1 inhibitors and still can respond by upregulating Akt activity.

Impact of PI3K Inhibitors on the Tumor Microenvironment

Tumor angiogenesis is dependent on PI3Kα signaling and its inhibition may contribute to the treatment effects. Also, immune recognition of tumor cells may be enhanced by inhibition of myeloid suppressive cells that are sensitive to PI3Kδ/γ inhibition and macrophages that require PI3Kγ signaling for their suppression of T-cell activation. For further details, see the review by Castel et al. (2021).

Idelalisib

Mechanisms of Action

Idelalisib is an orally bioavailable inhibitor of the PI3Kδ isoform with an IC_{50} of about 19 nM. It is 6-fold selective versus the PI3Kγ and over 200-fold more selective versus the PI3Kα and β isoforms. PI3Kδ is expressed in normal and malignant B cells. *Idelalisib* induces apoptosis and inhibits proliferation in cell lines derived from malignant B cells and in primary tumor cells. *Idelalisib* inhibits several cell signaling pathways, including BCR, C-X-C chemokine receptor (CXCR) 4, and CXCR5 signaling, which are involved in trafficking and homing of B cells to the lymph nodes and bone marrow. Treatment of lymphoma cells with *idelalisib* resulted in inhibition of chemotaxis and adhesion and reduced cell viability.

ADME

Food does not affect absorption of *idelalisib*. The drug is metabolized by aldehyde oxidase, CYP3A, and UGT1A4, yielding an elimination $t_{1/2}$ of 8.2 h. *Idelalisib* inhibits CYP3A and is a substrate of Pgp and of the efflux transporter breast cancer resistance protein (BCRP)/ATP-binding cassette (ABC) G2 *in vitro*. *Idelalisib* increases plasma levels of *midazolam* (a CYP3A substrate) but does not affect plasma levels of *digoxin* (a Pgp substrate) or *rosuvastatin* (an OATP1B1/B3 substrate). Patients receiving strong CYP inhibitors may be at increased risk for *idelalisib* toxicity. Hepatic impairment increases systemic exposure, putting patients at risk for toxicity.

Clinical Use

Idelalisib is approved for the treatment of relapsed or refractory B-cell malignancies in patients who have received at least two prior systemic therapies. This includes CLL in combination with rituximab, follicular B-cell non-Hodgkin lymphoma (FL), and SLL. *Idelalisib* is not indicated and is not recommended for first-line treatment.

Adverse Effects

Idelalisib may cause serious and sometimes fatal adverse effects, including liver toxicity in 16% to 18%, fatal diarrhea or colitis in 14% to 20%, pneumonitis in 4%, or serious infections in 21% to 48% of patients. Patients taking *idelalisib* should avoid other hepatotoxic drugs. Other common side effects include fever, chills, cough, pneumonia, fatigue, nausea, rash, hyperglycemia, and elevated levels of triglycerides and liver enzymes. *Idelalisib* may cause embryofetal toxicity. Breastfeeding during therapy is contraindicated because of the potential for adverse reactions in nursing infants.

Copanlisib

Copanlisib is an inhibitor of PI3Kα (IC_{50} of 0.5 nM) and PI3Kδ (IC_{50} of 0.7 nM) isoforms that are expressed in malignant B cells. Parenterally administered, *copanlisib* was approved in 2017 for the treatment of patients with relapsed FL who have received at least two prior systemic therapies. The efficacy of *copanlisib* has been linked to inhibition of nuclear factor-κB (NF-κB) signaling and reduced release of interleukin (IL)-6 and IL-10. Adverse effects include hyperglycemia, hypertension that may require treatment, pneumonitis, diarrhea, and decreased general strength and energy. *Copanlisib* is a CYP3A substrate and eliminated with a $t_{1/2}$ of 39.1 h.

Duvelisib

Duvelisib is an orally bioavailable inhibitor of PI3Kδ (IC_{50} of 2.5 nM) and PI3Kγ (IC_{50} of 27 nM), which are expressed in normal and malignant B cells. The potency of *duvelisib* against the β (IC_{50} of 85 nM) and α isoforms (IC_{50} of 1602 nM) is lower. *Duvelisib* was approved in 2018 for the treatment of patients with relapsed or refractory CLL, SLL, or FL after at least two prior therapies. Adverse effects include the risk of infections in 31% of patients, diarrhea and colitis in 18%, and pneumonitis in 5%. Metabolism of *duvelisib* is through CYP3A4. The elimination $t_{1/2}$ is 4.7 h.

Umbralisib

Umbralisib is an orally bioavailable inhibitor of PI3Kδ (IC_{50} of 6.2 nM) with a greater than 100-fold selectivity versus PI3Kα, β, or γ. It also inhibits casein kinase ε. *Umbralisib* was approved in 2021 for the treatment of patients with marginal zone lymphoma after at least one prior therapy and for relapsed or refractory FL after three prior therapies. It is in trials for the treatment of other hematological malignancies. Adverse effects include neutropenia, increased risk of infections, diarrhea, noninfectious colitis, and hepatotoxicity. *Umbralisib* is metabolized by CYP2C9, CYP3A4, and CYP1A2. The elimination $t_{1/2}$ is 91 h.

Alpelisib

Alpelisib is an orally bioavailable inhibitor of PI3Kα (IC_{50} of 4.6 nM) with a greater than 50-fold selectivity relative to the other isoforms of PI3K. PIK3CA gene mutations are found in approximately 40% of patients with hormone receptor–positive, HER2-negative advanced breast cancer and indicate a worse prognosis and may mediate resistance to endocrine therapy. *Alpelisib* was approved in 2019 in combination with *fulvestrant* for the treatment of postmenopausal women, and men, with hormone receptor–positive, HER2-negative, PIK3CA-mutated, advanced breast cancer following progression on or after endocrine-based therapy (André et al., 2019). The most frequent adverse events of higher grade are hyperglycemia (36%), rash (10%), and diarrhea (7%). *Alpelisib* is metabolized by CYP3A and has an elimination $t_{1/2}$ of 8 to 9 h.

mTOR Inhibitors: Rapamycin Analogues

Rapamycin (*sirolimus*) is a product from a strain of the soil bacterium *Streptomyces* found on Rapa Nui (Easter Island). It inhibits a serine/threonine protein kinase in mammalian cells named mTOR. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor PTEN (phosphatase and tensin homolog; see Figure 71–2). Activating mutations and amplification of genes in the receptor-PI3K pathway and loss-of-function alterations in PTEN occur frequently in cancer cells, with the result that PI3K signaling is exaggerated and cells exhibit enhanced survival. *Rapamycin* (*sirolimus*) and its congener rapalog *everolimus* are first-line drugs in posttransplant immunosuppression (see Chapter 39) and are used in coronary artery stents to prevent fibrotic growth. Rapalogs have also been approved for the treatment of patients with renal cancer; neuroendocrine tumors (NETs) of pancreatic, GI tract or lung origin; anti–hormone refractory, hormone receptor–positive breast cancer; and tuberous sclerosis complex (TSC)–related tumors.

Mechanism of Action

The rapalogs inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3K pathway (see Figures 71–2 and 71–5). mTOR forms the mTORC1 complex with FKBP12 (immunophilin-binding protein for *tacrolimus* [FK506]), a member of the FK506-binding protein family. The antitumor actions of the rapalogs result from their binding to FKBP12 and preventing activation of mTOR, as detailed in Figure 71–5 and its legend.

ADME

For renal cell cancer, *temsirolimus* is given in weekly intravenous doses. It is metabolized by CYP3A4, with the parent drug elimination $t_{1/2}$ of 30 h and the primary active metabolite *sirolimus* (*rapamycin*) elimination $t_{1/2}$ of 53 h. Because *sirolimus* has equivalent activity as an inhibitor of mTORC1 and has a greater AUC, *sirolimus* is likely the more important contributor to antitumor action in patients. *Everolimus* is administered orally and is metabolized by CYP3A4. *Everolimus* has an elimination $t_{1/2}$

of 30 h and maintains inhibition of mTORC1 for 7 days in white blood cells. Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. For *everolimus*, the dose should be reduced for patients with moderate hepatic impairment; guidelines for dose reduction of *temsirolimus* in such patients have not been established. The drugs' pharmacokinetics do not depend on renal function, and hemodialysis does not hasten *temsirolimus* clearance.

Therapeutic Uses

Both *temsirolimus* and *everolimus* are approved for treatment of patients with advanced renal cell carcinoma. *Everolimus* prolongs survival in patients who had failed initial treatment with antiangiogenic drugs. *Everolimus* is also approved for the treatment of postmenopausal women with advanced hormone receptor–positive, HER2-negative breast cancer in combination with the aromatase inhibitor *exemestane* after failure of treatment with *letrozole* or *anastrozole*. Other indications of *everolimus* are peripheral neuroendocrine tumors (PNETs) and progressive, well-differentiated, nonfunctional NETs of GI or lung origin as well as TSC-related tumors.

Adverse Effects; Resistance

The rapamycin analogues cause similar patterns of adverse effects: a mild maculopapular rash, mucositis, anemia, and fatigue (30%–50%). A few patients develop leukopenia or thrombocytopenia, effects that are reversible if therapy is discontinued. Other, less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving *everolimus* and in a smaller percentage of those treated with *temsirolimus*. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. *Prednisone* may hasten the resolution of radiological changes and symptoms.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapalogs and which can upregulate Akt activity (see Figure 71–5).

Multikinase Inhibitors: Cabozantinib, Vandetanib, Midostaurin, and Gilteritinib

Selectivity of small-molecule protein kinase inhibitors for their targets is dependent on the similarity of the targeted site with sites in other kinases and the chemical composition of the inhibitor. Most inhibitors interact with the ATP-binding site of their target that is relatively conserved within a kinase family; thus, such inhibitors have only relative specificity and will cross-react at higher concentrations with closely related kinases. Nonetheless, inhibition of distantly related kinases is possible. The selectivity of inhibitors for a range of targets in the kinome is determined experimentally using assays with recombinant kinase proteins and *in vivo* using intact cells that express the kinases (Elkins et al., 2015). Inhibitors that target multiple kinase families within the clinically used dose range can be therapeutically efficacious with tolerable adverse effects and are discussed in the material that follows.

Cabozantinib

Mechanism of Action

Cabozantinib is an orally bioavailable, small-molecule inhibitor of several tyrosine kinases; as ranked by the IC_{50} values (in nM) from in vitro assays, these protein kinases are VEGFR2, 0.035; MET, 1.3; RET, 4; KIT, 4.6; AXL, 7; FLT3, 11.3; VEGFR1, 12; and TIE2, 14.3. These receptor tyrosine kinases control normal cellular function and pathologic processes that include maintenance of the tumor microenvironment, tumor angiogenesis, and metastatic spread.

ADME

The elimination half-life of *cabozantinib* is about 99 h. *Cabozantinib* is a substrate of CYP3A4; thus, the dose of *cabozantinib* should be reduced in patients with mild-to-moderate hepatic impairment as well as for concurrent administration of CYP3A4 inhibitors. Conversely, strong inducers of CYP3A4 will reduce exposure to the drug and necessitate increased dosage of *cabozantinib* unless the CYP inducers can be avoided.

Therapeutic Uses

Cabozantinib is indicated for the treatment of patients with advanced RCC and as a first- line treatment in combination with nivolumab; for patients with HCC who have been previously treated with sorafenib and for patients with with progressive, metastatic medullary thyroid cancer.

Adverse Effects

The most commonly reported (≥25%) adverse reactions are diarrhea, fatigue, nausea, PPES, hypertension, vomiting, weight loss, and constipation. Cabozantinib should not be administered to patients with a recent history of bleeding and should be discontinued in patients with thrombotic events, GI perforations and fistulas. Blood pressure should be monitored regularly for the onset of hypertension. Due to the risk of fetal harm, women of childbearing age should use contraception during treatment and for 4 months thereafter.

Vandetanib

Mechanism of Action; ADME

Vandetanib is an orally bioavailable, small-molecule multikinase inhibitor of VEGFRs, the EGFR/HER family, RET, BRK (breast tumor kinase), TIE2, and members of the ephrin receptor and SRC kinase families. These receptor tyrosine kinases are involved in both normal cellular functions and pathological processes (see Figure 71–2). *Vandetanib* is a substrate of CYP3A4. Its median elimination $t_{1/2}$ is 19 days.

Therapeutic Uses

Vandetanib is indicated for the treatment of symptomatic or progressive medullary thyroid cancer that is unresectable, locally advanced, or metastatic. In patients with asymptomatic or slowly progressing disease, *vandetanib* is only indicated after careful consideration of the treatment-related risks.

Adverse Effects and Drug Interactions

The most common adverse effects (>20%) are diarrhea/colitis, rash, acneiform dermatitis, hypertension, nausea, headache, upper respiratory tract infections, decreased appetite, and abdominal pain. Less common are QT prolongation, torsades de pointes, and sudden death. *Vandetanib* should not be used in patients with hepatic impairment or congenital long QT syndrome.

Midostaurin

Midostaurin is an orally bioavailable multikinase inhibitor with activity against mutant FLT3, a driver in AML, as well as other kinases including KIT (wild-type and D816V mutant), PDGFR, SRC, and PKC. It was approved in 2017 for the treatment of patients with newly diagnosed FLT-mutant AML in combination with *cytarabine* and *daunorubicin*. Other indications include systemic mastocytosis with associated leukemia. Major adverse effects of treatment include a risk of prolonged severe leukopenia and thrombocytopenia, mucositis, upper respiratory tract infection, diarrhea, musculoskeletal pain, and QT prolongation. It is metabolized by CYP3A. The parent *midostaurin* has an elimination $t_{1/2}$ of 19 h. Two active metabolites that contribute 28% and 38% of circulating drug are eliminated much more slowly, with $t_{1/2}$ of 32 h and 482 h, respectively.

Gilteritinib

Gilteritinib is an orally bioavailable inhibitor of multiple receptor tyrosine kinases, including wild-type and mutant FLT3 (IC_{50} of 0.29 nM). *Gilteritinib* was approved in 2018 for the treatment of patients with relapsed or refractory AML with an FLT3 mutation. Resistance of leukemic cells to the treatment can be provided by the normal bone marrow microenvironment or by cancer cell intrinsic changes (Joshi et al., 2021) and may

require combinatorial treatment. Serious adverse effects include the risk of posterior reversible encephalopathy syndrome (1% of patients) and differentiation syndrome (3% of patients) that is associated with rapid proliferation and differentiation of myeloid cells and may be life-threatening or fatal if not treated with corticosteroids. Symptoms may be fever, dyspnea, or pulmonary infiltrates. Differentiation syndrome (previously termed "retinoic acid syndrome") is also a risk of ATO treatment (see above). *Gilteritinib* is metabolized through CYP3A, and an increase in the AUC was observed when coadministered with an antifungal, *itraconazole*, that is also a strong CYP3A inhibitor. The elimination $t_{1/2}$ is 113 h.

III. Inhibitors of Tumor Angiogenesis

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells to permit growth and metastasis. Many tumor types overexpress these angiogenic factors, turning on an "angiogenic switch" whereby the tumor cells adopt an invasive phenotype favoring proliferation of endothelial cells and neovascularization. In 1971, Judah Folkman hypothesized that the growth of solid tumors was dependent on angiogenesis and that blockade of the effects of putative angiogenic factors would be a good treatment modality for human cancers (Folkman, 1971). Folkman's hypothesis proved to be correct and led to the characterization of a number of secreted angiogenic factors, including VEGF, FGF, transforming growth factor (TGF)-β, and PDGF. Furthermore, inhibitors of these angiogenic factors have, indeed, become useful therapeutic agents against certain cancers. VEGF is a major driver of angiogenesis, and inhibitors of VEGF signaling comprise an important class of antitumor agents. Beyond nourishing an expanding cancerous lesion, the control of the vascular steady state by growth factors also impacts diseased tissue surveillance by circulating immune cells. Hence, combination therapies of immune checkpoint inhibitors and antiangiogenic drugs are investigated, and some have received approval as indicated below (e.g., *pembrolizumab* and *lenvatinib*) (Huinen et al., 2021). Recent research revealed the modulation of "angiogenic switch" genes by the activities of hypoxia-inducible transcription factors (HIF) that are controlled by oxygen tension in tissues. Indeed, cellular oxygen-sensing mechanisms are essential for the maintenance of complex multicellular life forms (Hammarlund et al., 2020). William G. Kaelin, Jr, Peter J. Ratcliffe, and Gregg L. Semenza shared the 2019 Nobel Prize in Medicine/Physiology "for their discoveries of how cells sense and adapt to oxygen availability." The HIF-2α inhibitor belzutifan, approved in 2021 for the treatment of renal cell carcinoma (RCC), is based on these discoveries (Choueiri and Kaelin, 2020).

Inhibition VEGF and the VEGFR Pathway

Vascular endothelial growth factor initiates endothelial cell proliferation and vascular permeability when it binds to a member of the VEGFR family, a group of highly homologous receptors with intracellular tyrosine kinase domains; these receptors include VEGFR1 (FLT1), VEGFR2 (KDR [kinase insert domain receptor]), and VEGFR3 (FLT4) (see Figure 71–2). The binding of VEGF to its receptors activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and antiapoptotic signaling pathways (Nagy et al., 2007). Antibodies targeting VEGF, such as *bevacizumab*, sterically hinder the interaction of VEGF with its receptor (see Chapter 72). *Aflibercept* acts as a VEGF trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF, basically acting as a "soluble decoy receptor" for VEGF. Several small-molecule drugs that inhibit the protein tyrosine kinase function of VEGFR (*pazopanib*, *sorafenib*, *sunitinib*, and *axitinib*) as well as monoclonal antibodies that target the receptor (*ramucirumab*) have been approved for clinical use. The inhibition of endothelial function by these different approaches results in a similar spectrum of adverse effects.

Antiangiogenic Small-Molecule Kinase Inhibitors

Sunitinib

Mechanism of Action

Sunitinib is a small-molecule, orally bioavailable inhibitor of multiple kinases, including KIT and VEGFR2.

ADME

The typical treatment cycle of *sunitinib* is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of *sunitinib* can be decreased in patients with adverse effects. More recently, a 2-week-on/1-week-off schedule has proven to be better tolerated and as effective as the original treatment schedule. *Sunitinib* is metabolized by CYP3A4 to produce an active metabolite, SU12662, the $t_{1/2}$ of which is 80 to 110 h; steady-state levels of the metabolite are reached after about 2 weeks of daily administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of *sunitinib* are not affected by food intake.

Therapeutic Uses

Sunitinib is approved in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with *interferon* (IFN) or *bevacizumab*. *Sunitinib* is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to *imatinib* as a consequence of *c-KIT* mutations. Specific *c-KIT* mutations correlate with the degree of response to *sunitinib* (e.g., patients with *c-KIT* exon 9 mutations have a response rate of 37%; patients with *c-KIT* exon 11 mutations have a 5% response rate).

Adverse Effects

The main adverse effects of *sunitinib* are shared by antiangiogenic inhibitors that target VEGF and VEGFR signaling and thus impact endothelial cell survival signaling: hypertension, proteinuria, and, uncommonly, bleeding, arterial thromboembolic events, and intestinal perforation. However, because *sunitinib* is a multitargeted TKI, it has a broader adverse effect profile than the monoclonal antibody *bevacizumab* that selectively targets VEGF (see Chapter 72). Fatigue affects 50% to 70% of patients and may be disabling. Hypothyroidism occurs in 40% to 60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils <1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure as a consequence of hypertension, and PPES. It is essential to check blood counts and thyroid function at regular intervals. Monitoring of blood pressure and periodic echocardiograms also are recommended.

Sorafenib

Mechanism of Action and Therapeutic Use

Sorafenib, like *sunitinib*, is an orally bioavailable inhibitor of multiple protein kinases. *Sorafenib* is approved for treatment of patients with thyroid and hepatocellular carcinoma as well as patients with metastatic renal cell cancer, but *sunitinib* and *pazopanib* are generally preferred first-line therapies (see previous discussion and below).

ADME

Sorafenib is given orally every day without treatment breaks. *Sorafenib* is metabolized to inactive products by CYP3A4 with a $t_{1/2}$ of 20 to 27 h; with repeated administration, steady-state concentrations are reached within 1 week.

Adverse Effects

Sorafenib-treated patients can experience the vascular toxicities seen with other antiangiogenic medications described under *sunitinib*. More common adverse effects include fatigue, nausea, diarrhea, anorexia, rash, and palmar-plantar erythrodysesthesias; uncommonly, bone marrow suppression, GI perforation, and cardiomyopathy occur.

Pazopanib

Pazopanib is an orally bioavailable kinase inhibitor of VEGFR-1, -2, and -3 as well as FGFRs, KIT, LCK (lymphocyte-specific kinase), PDGFR,

and other kinases implicated in pathological angiogenesis and cancer progression. *Pazopanib* is approved for the treatment of patients with advanced RCC and advanced soft-tissue sarcoma after prior chemotherapy. It has less toxicity and equivalent efficacy as *sunitinib* in patients with treatment-naïve metastatic renal cancer and therefore has become the preferred first-line treatment. Major adverse effects include hypertension, thrombotic and hemorrhagic events, GI perforation, QT prolongation, and cardiomyopathy. *Pazopanib* carries a black-box warning indicating that it can produce severe and life-threatening hepatotoxicity; as a consequence, *pazopanib* should not be used in elderly patients or those with preexisting liver function test abnormalities. *Pazopanib* is metabolized mostly by CYP3A and eliminated with a $t_{1/2}$ of 31 h.

Axitinib

Axitinib is an orally bioavailable kinase inhibitor of VEGFR-1, -2, and -3, which are implicated in pathological angiogenesis, tumor growth, and cancer progression. *Axitinib* is approved for the treatment of patients with advanced RCC after failure of one prior systemic therapy. Major adverse effects include hypertension, thrombotic and hemorrhagic events, and GI perforation, similar to those of the other VEGFR pathway–targeting drugs (see above). *Axitinib* is metabolized mainly by CYP3A4/5 and eliminated with a variable $t_{1/2}$ of 2.5 to 6.1 h.

Tivozanib

Tivozanib is an orally bioavailable kinase inhibitor of VEGFR-1, -2, and -3 that also inhibits other kinases including c-KIT and PDGFR. *Tivozanib* was approved in 2021 for the treatment of patients with relapsed or refractory advanced RCC following two or more prior systemic therapies. Adverse effects are typical for inhibitors of the VEGFR pathway and include hypertension that requires continuous monitoring and potential treatment as well as monitoring of cardiac function, thromboembolic and hemorrhaging events, diarrhea, decreased appetite, nausea, and dysphonia. *Tivozanib* is mostly metabolized by CYP3A4; it showed an increased AUC with moderately impaired hepatic function and is eliminated with a $t_{1/2}$ of 111 h.

Lenvatinib

Lenvatinib is an orally bioavailable kinase inhibitor of VEGFRs, FGFRs, PDGFR, KIT, and RET and other kinases that are implicated in pathological angiogenesis and cancer progression. *Lenvatinib* is approved for the treatment of patients with recurrent or metastatic differentiated thyroid cancer, in combination with *everolimus* for advanced RCC following one prior antiangiogenic therapy, and for first-line treatment of unresectable hepatocellular carcinoma. In 2021, approval was granted for treatment of patients with endometrial carcinoma that progressed after systemic treatment, in combination with the immune checkpoint inhibitor *pembrolizumab*, even in absence of high levels of microsatellite instability or deficient mismatch repair, which are typical requirements for *pembrolizumab* treatment (see Chapter 72). Adverse effects and warnings are typical for inhibitors of the VEGFR signaling pathway including hypertension, cardiac dysfunction, thromboembolism, and impaired wound healing. Osteonecrosis of the jaw is a rarer adverse effect of treatment. *Lenvatinib* is metabolized by CYP3A and eliminated with a $t_{1/2}$ of 28 h.

Regorafenib

Regorafenib is an orally bioavailable kinase inhibitor of VEGFR1–3, PDGFR, KIT, RET, and RAF1 with IC_{50} values in the low nanomolar range and other kinases including FGFR1/2, TIE2, and ABL. Several of these kinases are implicated in pathological angiogenesis and malignant progression. *Regorafenib* is approved for the treatment of patients with metastatic colorectal cancer after previous chemotherapy, anti-VEGF therapy, or anti-EGFR therapy; for patients with hepatocellular carcinoma who have been previously treated with *sorafenib*; and for patients with locally advanced, unresectable, or metastatic GIST after *imatinib* or *sunitinib*. Major adverse effects include hypertension, thrombotic and hemorrhagic events, hepatotoxicity, GI perforation, QT prolongation, and wound-healing complications. *Regorafenib* is metabolized mostly by CYP3A and eliminated with a $t_{1/2}$ of about 28 h.

Belzutifan

Belzutifan is an orally bioavailable inhibitor of HIF-2α that was approved in 2021 for the treatment of patients with von Hippel-Lindau (VHL) disease and associated RCC, CNS hemangioblastomas, or pancreatic NET. HIF-2α is a transcription factor that plays a role in cellular responses to oxygen levels. Under hypoxic conditions, HIF-2α accumulates in the cytosol and translocates into the nucleus where it heterodimerizes with HIF-1β, resulting in the induction of genes associated with cellular growth and angiogenesis. *Belzutifan* binds to HIF-2α and blocks its heterodimerization with HIF-1β and activation of target genes. Under normoxic conditions, the VHL protein targets HIF-2α for proteasomal degradation, thus preventing its activity. VHL is a subunit of the E3 ubiquitin ligase complex, which mediates the proteasomal degradation of HIF-2α (Figure 71–6). The VHL syndrome is a hereditary condition associated mostly with hemangioblastomas that can arise in multiple organs. Loss of VHL is a crucial oncogenic event in approximately 90% of clear cell RCC, resulting in the accumulation of HIF-2α and induction of cell growth and angiogenesis. HIF-2α also plays a role in the function of immune cells, and combination therapy of *belzutifan* with other cancer therapies is being investigated (Choueiri and Kaelin, 2020) and has shown some promising efficacy in patients with RCC pretreated with immune checkpoint inhibitor and antiangiogenic therapy (Choueiri et al., 2021). Adverse effects of *belzutifan* treatment include anemia due to the reduction of erythropoietin, which occurs within 2 weeks of dosing and can return to baseline values within 3 months of treatment. Monitoring for anemia before initiation and throughout treatment to keep the hemoglobin level at 9 g/dL or greater is required. Blood transfusions may be considered. Other adverse effects include fatigue, headache, and dizziness. *Belzutifan* is primarily metabolized by UGT2B17 and CYP2C19 and to a lesser extent by CYP3A4 and is eliminated with a $t_{1/2}$ of 14 h.

IV. Inhibitors of Poly(ADP-Ribose) Polymerase (PARP)

DNA damage-repair genes are frequently inactivated in human cancer. PARP1 is the product of one such gene. PARP1 is a nuclear protein that transfers ADP-ribose from NAD^+ to target proteins, and this poly(ADP-ribosyl)ation (or PARylation) of nuclear proteins by PARP1 plays a significant role in the DNA damage response (Tallis et al., 2014). Inactive PARP1 associates with chromatin and helps to create a compact chromatin structure in the nucleosome. DNA damage (e.g., strand breaks) mobilizes the enzyme, promoting PARP-mediated PARylation, with the result that chromatin relaxes in the area of damage. The mechanisms of relaxation are the PARylation of PARP1 itself and of histones and other chromatin-associated proteins, resulting in their dissociation from DNA. PARylation produces branching chains up to 200 ADP-ribose units in length. These chains provide docking centers for the localized recruitment of PAR-binding factors, DNA repair enzymes (e.g., DNA polβ, DNA ligase III), and proteins that help to maintain an inactive environment in the open chromatin region while repairs are made to the damaged DNA. The synthesis and degradation of PAR chains *in vivo* are tightly regulated, with the chains having half-lives measured in minutes (Wei and Yu, 2016). Excessive activation of PARP1 leads to depletion of the cellular pool of NAD^+ and to cell death; teleologically, this could be viewed as a means of preserving genomic integrity by removing cells with heavily damaged DNA.

Deficient PARP1 activity leads to defective DNA repair. However, PARP-deficient cells are still able to carry out DNA repair through a different mechanism—homologous recombination. The protein machinery

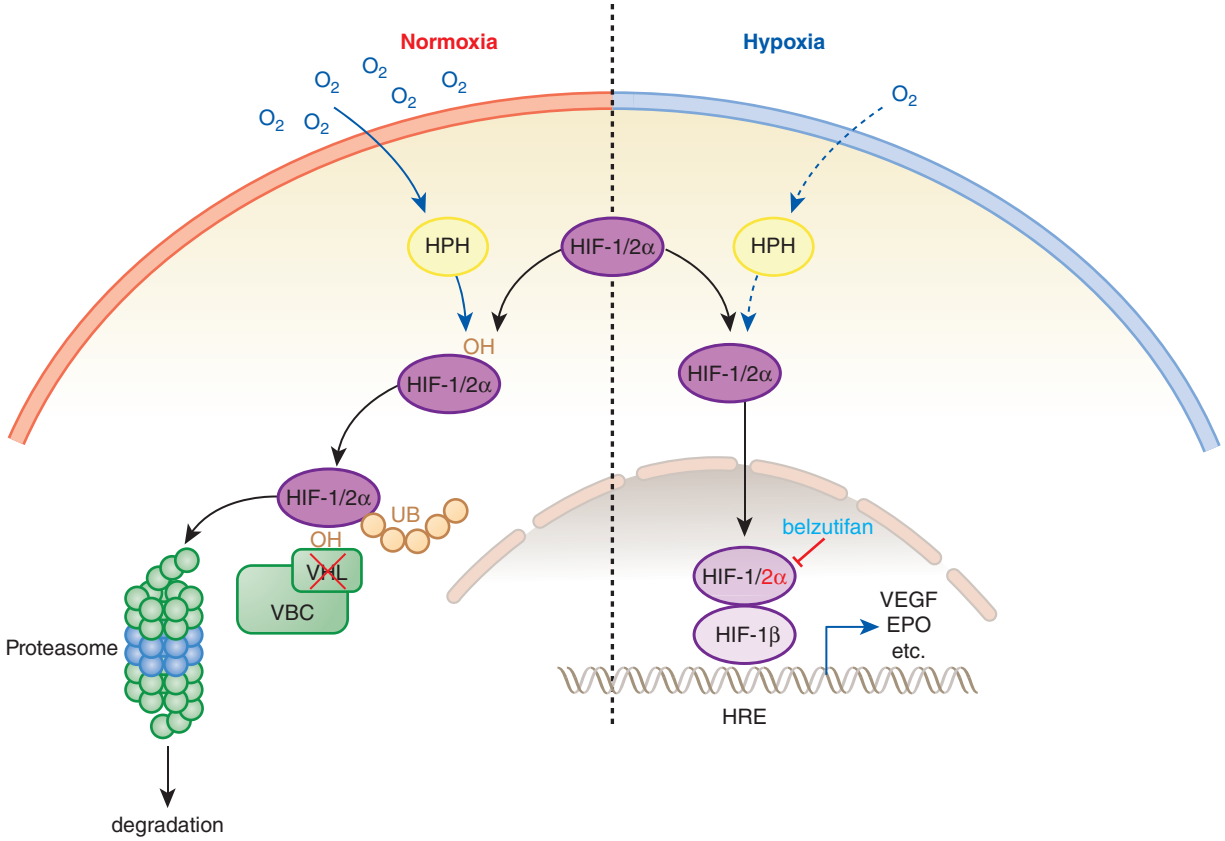

Figure 71–6 *Oxygen-sensing and hypoxia-inducible genes targeted.* Under normoxic conditions, HIF-1α and -2α (HIF-1/2α in short) are hydroxylated (symbolized by the "OH") on proline residues by HIF-prolyl hydroxylases (HPHs) in an oxygen-dependent manner. This allows the VHL protein to recognize and target HIF-1/2α for rapid degradation. VHL is part of an E3 ubiquitin ligase complex of VHL-Elongin B/C-CUL2 (VBC) that transfers ubiquitin (Ub). The ubiquitinated HIF is transported to the proteasome for degradation. In its canonical function depicted here, the VHL protein serves as the substrate recognition component of the VBC protein complex. Under hypoxic conditions, HIF-1/2α are not recognized by VHL and degraded but translocate into the nucleus. In the nucleus HIF-1/2α heterodimerize with HIF-1β (also named aryl hydrocarbon receptor nuclear translocator [ARNT]). The heterodimer binds to hypoxia response element (HRE) DNA sequences and recruits co-activators to drive transcription of hypoxia-inducible genes such as EPO (erythropoietin) and VEGF.

Loss of VHL, symbolized by the red X, is observed in the majority of clear cell RCC and is associated with a pseudohypoxic state that results in the accumulation of HIF-2α and upregulation of HRE target genes that include VEGF. Indeed, inhibition of VEGF and its pathway has shown efficacy and been approved for treatment of clear cell RCC as described in the text. Identification of a binding pocket in HIF-2α led to the development of small molecules that cause conformational changes of HIF-2α and disrupt its heterodimerization with HIF-1β. After successful clinical trials, the HIF-2α inhibitor *belzutifan* was approved in 2021 for the treatment of patients with VHL-deficient cancers (Choueiri et al., 2021).

for homologous recombination repair includes the breast cancer susceptibility genes *BRCA1* and *BRCA2*, suggesting that cells with diminished or absent BRCA1/2 function are unusually susceptible to the inhibition of PARP activity. BRCA1/2 mutations predispose carriers to breast, ovarian, and other cancers that can be resistant to chemotherapy. BRCA-deficient cells are more dependent on PARP1 and base excision repair to maintain genomic integrity. BRCA1/2-deficient cancer cells are less able to carry out repair and ultimately die; inhibition of PARP could accelerate this process (Curtin and Szabo, 2020) and is described in Figure 71–7. PARP inhibitors thus represent a successful example of a molecular medicine application to treatment that takes advantage of DNA repair defects in cancer cells and enhances cancer cell death. Inhibitors of PARP are designed to compete with NAD^+ at its binding site on the PARP enzyme. Catalytic activity is required for repulsion between auto-PARylated PARP1 and DNA, and thus, inhibition of PARP catalytic activity will trap PARP1 and PARP2 on DNA, contributing to the efficacy but also adverse effects and genotoxicity of these inhibitors (Slade, 2020). PARPs catalyze PARylation of a number of proteins that regulate cellular processes beyond DNA damage repair; these extra-chromatin actions may contribute to the clinical efficacy and adverse effects of PARP inhibitors. Different selectivities, subtle differences between the inhibitors, and future drug development in the field were reviewed by Slade (2020). *Olaparib*, *rucaparib*, *niraparib*, and *talazoparib* are currently approved for the treatment of different subsets of patients with ovarian, breast, prostate, and pancreatic cancer, discussed in the below sections.

Olaparib

Olaparib is an orally bioavailable inhibitor of PARP1, -2, and -3 enzymes and was initially approved in 2014 as a monotherapy in patients with BRCA-mutated ovarian cancer who have been treated with three or more prior lines of chemotherapy. The indications have been expanded in 2020 to patients with breast, pancreatic, and prostate cancers with mutant BRCA or DNA repair deficiency. Treatment of these ovarian cancer patients is now approved after first-line platinum-based chemotherapy. Other approvals are in patients with HER2-negative metastatic breast cancer after chemotherapy or after appropriate endocrine therapy for hormone receptor–positive tumors; metastatic pancreatic adenocarcinoma after platinum-based chemotherapy; and metastatic castration-resistant prostate cancer after endocrine therapy with *enzalutamide* or *abiraterone* (see Chapter 73). Adverse effects of treatment include the risk of MDS and AML with mostly fatal outcome in approximately 1.5% of patients after monotherapy. Monitoring of patients for hematological toxicity at baseline and during treatment is required. Pneumonitis with some risk of fatal outcome is another severe risk in 0.8% of patients and requires

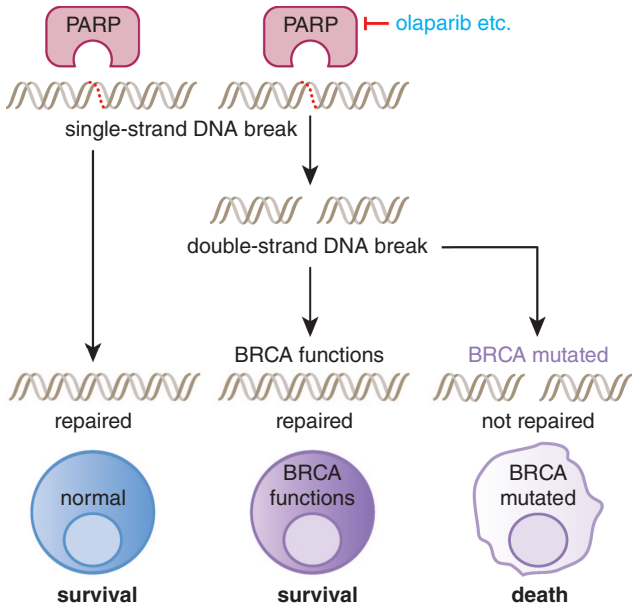

Figure 71–7 *Synthetic lethality from PARP inhibitors in cancer cells that lost BRCA function.* In normal cells, PARP functions in the repair of single-strand breaks in DNA. Without this function of PARP, double-strand DNA breaks accumulate during DNA replication. Cells with functional BRCA can repair these double-strand breaks in DNA through homology-directed repair and thus survive. In contrast, cancer cells with loss of function of BRCA cannot effectively repair double-strand DNA breaks and will become genomically unstable and undergo apoptosis. PARP inhibitors are approved for the treatment of patients with ovarian, breast, prostate, and pancreatic cancer.

monitoring. There is also risk to a fetus, and use of effective contraception is indicated while on treatment. Monitoring for potential venous thromboembolic events including pulmonary embolism is also required. Other adverse effects include nausea and vomiting, loss of appetite, fatigue, muscle and joint pain, low blood cell counts, and anemia. *Olaparib* is rapidly absorbed after oral administration and metabolized primarily by CYP3A4 and eliminated with a $t_{1/2}$ of 14.9 h. Drug exposure is increased or reduced when administered in combination with a CYP3A4 inhibitor or inducer, respectively.

Rucaparib

Rucaparib is an orally bioavailable inhibitor of PARP1–3. *Rucaparib* was approved in 2016 for the treatment of patients with advanced ovarian cancer with BRCA mutations and is used in the maintenance treatment of these patients after a partial response to platinum-based chemotherapy. Other uses include patients with BRCA-mutated, metastatic, castration-resistant prostate cancer after endocrine and taxane-based therapy. Warnings, adverse effects, and precautions overlap with those for *olaparib* (see previous paragraph) and include the risk for potentially fatal MDS and AML. *Rucaparib* is metabolized primarily by CYP2D6 and to a lesser extent by CYP1A2 and CYP3A4 and can impact metabolism of drugs that are substrates of CYP1A2, CYP3A, CYP2C9, or CYP2C19. If coadministered with *warfarin* (a CYP2C9 substrate), increased monitoring of coagulation parameters is required. The mean terminal $t_{1/2}$ of *rucaparib* is 25.9 h.

Niraparib

Niraparib is an orally bioavailable inhibitor of PARP1 and PARP2, was approved in 2017, and is used for the treatment of patients with BRCA-mutated or homologous recombination–deficient, advanced ovarian cancer after first-line platinum-based chemotherapy as maintenance treatment. Warnings and adverse effects include the risk of MDS, AML, and posterior reversible encephalopathy syndrome, which require discontinuation. Potential hypertension and cardiovascular effects due to the inhibition of the dopamine, norepinephrine, and serotonin transporters require monitoring of blood pressure and heart rate and appropriate treatment or dose adjustment. Nausea, thrombocytopenia, anemia, leukopenia, dyspnea, and diarrhea are common adverse events. *Niraparib* can cause fetal harm. *Niraparib* is metabolized and inactivated by carboxylesterases and eliminated with a $t_{1/2}$ of 36 h.

Talazoparib

Talazoparib is an orally bioavailable inhibitor of PARP1 and PARP2 that was approved in 2018 for the treatment of patients with BRCA-mutated, HER2-negative, locally advanced or metastatic breast cancer. *Talazoparib* is the strongest PARP trapper on DNA among the currently approved PARP inhibitors and has the highest occurrence rate of anemia.

Adverse effects are similar to the other PARP inhibitors and include the risk for MDS and AML (0.3% of patients), myelosuppression with anemia, neutropenia, thrombocytopenia, and potential risk to the fetus. *Talazoparib* is mostly excreted in the urine with minimal hepatic metabolism and eliminated with a $t_{1/2}$ of 90 h.

V. Modulators of Protein Degradation

Targeting Protein Degradation

The selective degradation of target proteins is an attractive approach to expand the druggable proteome. Targeted protein degradation uses proteolysis-targeting chimeras (PROTACs), which bind to a protein of interest and link that to an E3 ligase (Dale et al., 2021). An established example of this concept is the antiestrogen *fulvestrant*, which functions as a monovalent degrader of ERα by occupying the ligand-binding pocket of the receptor, exposing hydrophobic residues with its long aliphatic tail and thus tagging ERα for proteolysis (reviewed by Besten and Lipford, 2020). In 2013, the immunomodulatory imide drugs (IMiDs) *thalidomide* and *lenalidomide*, which contain a CO-NH-CO structure as their signature (see figure with structures and highlight), were discovered to exert their therapeutic effects in a similar manner (Bartlett et al., 2004; Jan et al., 2021). They act as a molecular glue that recruits disease-relevant proteins to an E3 ubiquitin ligase, resulting in proteasomal degradation. *Thalidomide* and its analogues bind to cereblon (CRBN), a component of a cullin-RING E3 ligase (CRL) complex, and their binding to CRBN mediates interaction with transcription factors of the Ikaros zinc finger family (IKZF), leading to their ubiquination and subsequent degradation. Figure 71–8 outlines the mechanism of action. Based on the protein targeted by this class of drugs, they may also be referred to as cereblon modulators (Kannt and Đikić, 2021). Proteasomal degradation of these transcription factors kills multiple myeloma cells. *Thalidomide* is associated with significant toxicity and was mostly replaced by *lenalidomide*, a more potent and less toxic IMiD used in the treatment of multiple myeloma (MM). *Pomalidomide*, a more potent, third-generation IMiD, shows efficacy even in patients with *lenalidomide*-refractory cancers. Also, in del(5q) MDS, *lenalidomide* induces the degradation of CK1α, which preferentially affects del(5q) cells because they express this gene at haploinsufficient levels.

Thalidomide and Lenalidomide

Thalidomide and *lenalidomide* have a most unusual history and a multiplicity of biological and immunological effects (see Chapters 39, 65, and 75). *Thalidomide* originally was used for the treatment of pregnancy-associated morning sickness but was withdrawn from the market due to teratogenicity and dysmelia (stunted limb growth). It reentered clinical practice for treatment of erythema nodosum leprosum (see Chapter 60). Further research revealed its antiangiogenic and immunomodulatory effects. At least four distinct mechanisms have been proposed to explain its antitumor activity, which are summarized in Figure 71–9 and enumerated in its legend.

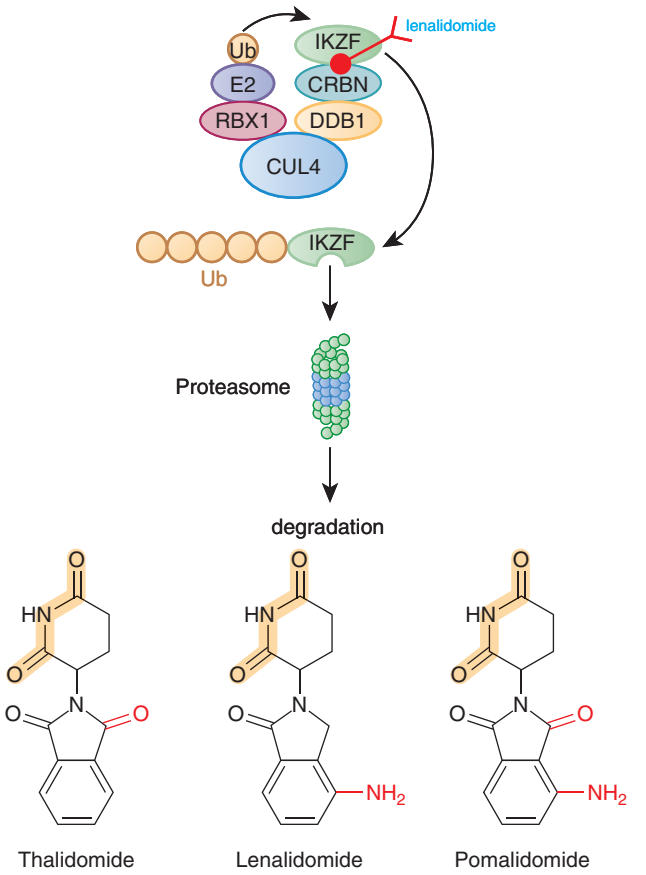

Figure 71–8 *Recruitment of target substrates by lenalidomide.* *Lenalidomide* functions as a molecular "glue" for the recruitment of proteins to the cereblon (CRBN) receptor component of the cullin–RING E3 ubiquitin ligase complex 4 (CRL4) comprising cullin 4 (CUL4), DNA damage-binding protein 1 (DDB1), and E3 ubiquitin–protein ligase RBX1. This recruitment results in protein ubiquitylation and degradation. Due to the structural differences, thalidomide, and its congeners, interact with and lead to the depletion of overlapping but distinct sets of proteins that include IKZF1/3 (Ikaros family zinc finger protein) and CK1α (casein kinase I isoform-α) (Jan et al., 2021).

Both *thalidomide* and *lenalidomide* possess potent activity in patients with newly diagnosed and heavily pretreated relapsed/refractory MM. *Lenalidomide* is also approved for its activity in the 5q– subset [or del(5q) subset] of MDS. A specific gene array profile identifies patients with MDS who lack the 5q– abnormality but respond to *lenalidomide*. A more recently added derivative of *thalidomide* is *pomalidomide*, approved for treatment of patients with MM resistant to *lenalidomide*.

Thalidomide

ADME

Thalidomide exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting nonpolar S(–) and R(+) isomers. Of these mirror image molecules, the *S*-enantiomer is associated with the teratogenic, phocomelia-inducing, and growth control activities, while the *R*-enantiomer accounts for the sedative properties of *thalidomide*. It is noteworthy that the isomers interconvert under biological conditions. When treating MM, doses usually are escalated by 200 mg/day every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) appear. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. *Thalidomide* absorption from the GI tract is slow and highly variable. It distributes throughout most tissues and organs, without significant binding to plasma proteins. The enantiomers are eliminated with a $t_{1/2}$ of about 6 h, mainly due to spontaneous hydrolysis in all body fluids; the *S*-enantiomer is cleared more rapidly than the *R*-enantiomer. *Thalidomide* and its metabolites are excreted in the urine, while the non-absorbed portion of the drug is excreted unchanged in feces. The inactive hydrolysis products undergo CYP-mediated metabolism. Longer plasma $t_{1/2}$ is reported at the highest doses (1.2 g daily). No dose adjustment is necessary in the presence of renal failure.

Lenalidomide

Lenalidomide constitutes the lead compound of immunomodulatory *thalidomide* derivatives. *Lenalidomide* induces the ubiquitination and degradation of target proteins by the E3 ubiquitin ligase CRL4-CRBN (Fink and Ebert, 2015). Target proteins in MM cells are IKZF1/3, which are crucial for cell survival (Lu et al., 2014) (Figure 71–9). In MDS, casein kinase 1A1 is the target protein (Krönke et al., 2015). Cellular effects of *lenalidomide* include direct suppression of tumor cell growth in culture, T-cell and natural killer (NK)-cell activation, suppression of tumor necrosis factor-α and other cytokines, antiangiogenesis, and promotion of HSC differentiation.

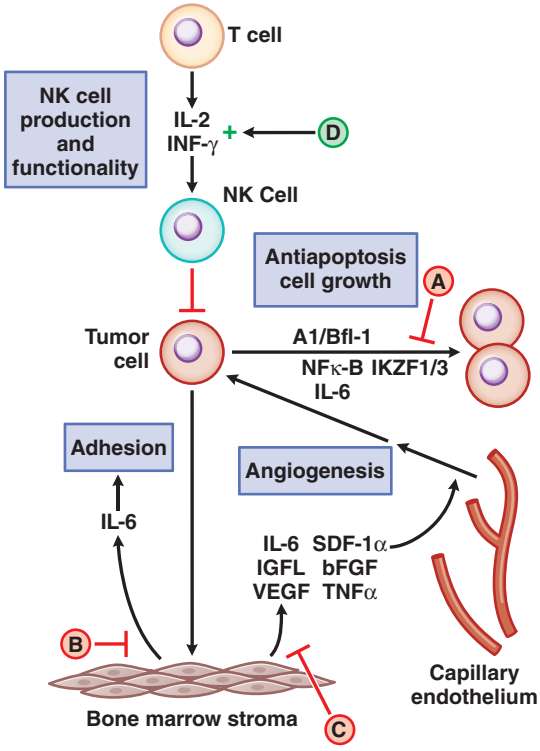

Figure 71–9 *Overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives.* Some biological hallmarks of the malignant phenotype are indicated in blue *boxes*. The proposed sites of action for *thalidomide* (letters inside red and green circles) are hypothesized to also be operative for *thalidomide* derivatives. **A.** Direct anti-MM effect on tumor cells, including G_1 growth arrest or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the antiapoptotic effect of BCL2 family members, blocking NF-κB signaling, and inhibition of the production of IL-6. Mechanistic studies show that *lenalidomide* can kill MM cells by inducing E3 ubiquitin ligase CRL4-CRBN–mediated ubiquitination and degradation of the crucial IKZF1 and -3 (zinc finger transcription factors). **B.** Inhibition of MM cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and IFN-γ, that increase the number and cytotoxic functionality of NK cells.

ADME

The drug is rapidly absorbed following oral administration and eliminated with a $t_{1/2}$ of 9 h. Approximately 70% of the orally administered dose of *lenalidomide* is excreted intact by the kidney. Dose adjustments for reduced creatinine clearance are recommended.

Therapeutic Use

Lenalidomide exhibits antitumor activity in MM, MDS, and CLL; it causes fewer adverse effects and lacks the teratogenicity of *thalidomide*.

Adverse Effects of Thalidomide and Lenalidomide

Thalidomide is well tolerated at doses less than 200 mg daily. Common adverse effects are sedation and constipation. The most serious adverse effect is peripheral sensory neuropathy, which occurs in 10% to 30% of patients with MM or other malignancies in a dose- and time-dependent manner. *Thalidomide*-related neuropathy is an asymmetrical, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. Although symptoms improve upon drug discontinuation, long-standing sensory loss may not reverse. Particular caution should be applied in patients with preexisting neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, *bortezomib*). *Thalidomide* enhances the sedative effects of barbiturates and alcohol and the catatonic effects of *chlorpromazine*. Conversely, CNS stimulants (such as *methamphetamine* and *methylphenidate*) counteract the depressant effects of *thalidomide*.

Adverse effects of *lenalidomide* are less severe; it causes little sedation, constipation, or neuropathy. *Lenalidomide* depresses bone marrow function and is associated with significant leukopenia (20% of patients). Hepatotoxicity and renal dysfunction are rare. In some patients with CLL, *lenalidomide* causes dramatic lymph node swelling and tumor lysis (tumor flare reaction). Patients with renal dysfunction are prone to this reaction; thus, patients with CLL should be started at lower doses of 10 mg/day, with escalation as tolerated. Patients with CLL should receive pretreatment hydration and *allopurinol* to avoid the consequences of tumor swelling and tumor lysis syndrome. A negative interaction with *rituximab*, an anti-CD20 antibody, may result from *lenalidomide*'s downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies.

Thalidomide and *lenalidomide* increase the risk for thromboembolic events, including deep vein thrombosis, stroke, and myocardial infarction, which occur with increased frequency in combination with glucocorticoids and with anthracyclines. Anticoagulation and antiplatelet medication reduce this risk and are indicated in patients with risk factors for clotting.

Pomalidomide

Pomalidomide, a third-generation *thalidomide* congener, was first approved in 2013 and is indicated in combination with *dexamethasone* for the treatment of patients with MM who have received at least two prior therapies including *lenalidomide*. It was also approved in 2020 for the treatment of AIDS-related Kaposi sarcoma. Adverse effects are similar to those of *thalidomide*. *Pomalidomide* is contraindicated during pregnancy and in females who may become pregnant. As a consequence, this drug is available only under a pregnancy control system to ensure that recipients are not pregnant and are using effective birth control.

Proteasome Inhibitors

First Generation

Bortezomib

Bortezomib is a first-generation inhibitor of proteasome-mediated protein degradation that has a central role in the treatment of MM.

Mechanism of Action

Bortezomib binds to the β5 subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. This event disrupts multiple intracellular signaling cascades, leading to apoptosis. An important consequence of proteasome inhibition is its effect on NF-κB, a transcription factor that promotes cell damage response and cell survival. Most cellular NF-κB is cytosolic and bound to IκB (inhibitor of NF-κB); in this form, NF-κB is restricted to the cytosol and cannot enter the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, IκB becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF-κB, which enters the nucleus and transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins) and proliferation (e.g., cyclin D1) or antiapoptosis (e.g., cIAPs, BCL-2). NF-κB is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. *Bortezomib* blocks proteasomal degradation of IκB, thereby preventing the transcriptional activity of NF-κB and downregulating survival responses.

Bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. *Bortezomib* activates the cell's stereotypical "unfolded protein response," in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis.

ADME

The recommended starting dose of *bortezomib* is 1.3 mg/m^2 given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 h should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced by 25%. The drug exhibits a terminal $t_{1/2}$ in plasma of 5.5 h. Peak proteasome inhibition reaches 60% within 1 h and declines thereafter, with a $t_{1/2}$ of about 24 h. *Bortezomib* clearance results from the deboronation of the parent compound (90%), followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

Therapeutic Uses

Bortezomib is used as initial therapy for patients with MM and as therapy for patients with MM after relapse from other drugs. It is also approved for treatment of patients with relapsed or refractory MCL. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., *thalidomide*, *lenalidomide*, liposomal *doxorubicin*, or *dexamethasone*).

Adverse Effects

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, and weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., *thalidomide*) or diabetes or with prolonged use. Dose reductions or discontinuation of *bortezomib* ameliorates the neuropathic symptoms. Injection of *bortezomib* may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. Cardiac toxicity is rare, but congestive heart failure and prolonged QT interval have been reported.

Second Generation

Carfilzomib is a second-generation selective proteasome inhibitor based on a tetrapeptide epoxyketone. It is FDA-approved as a single agent or in combination with *dexamethasone* or *lenalidomide* plus *dexamethasone*

for the treatment of patients with relapsed or refractory MM who have received at least one prior therapy. Frequent adverse effects (>20% of patients) include anemia, thrombocytopenia, diarrhea, dyspnea, and peripheral edema. There is a risk for cardiac, renal, pulmonary, and hepatic toxicity as well as hypertension.

Ixazomib is an orally bioavailable second-generation peptide analogue proteasome inhibitor that interacts with subunit beta type 5 (PSMB5) of the 20S proteasome complex. *Ixazomib* has an elimination $t_{1/2}$ of 9.5 days and is approved for use in combination with *lenalidomide* and *dexamethasone* for the treatment of patients with MM after at least one prior therapy (Moreau et al., 2016). *Ixazomib* can cause diarrhea, peripheral neuropathy, and hepatotoxicity.

VI. Epigenetic Modulators: Inhibitors of HDAC, HMT, and IDH1/2

Inhibitors of Histone Deacetylase

Histone deacetylases (HDACs) are a class of enzymes that catalyze the removal of acetyl groups from acetylated lysine amino acids in histones, thereby altering the transcriptional activation of cellular genes. Thus, HDAC inhibitors produce a broad spectrum of epigenetic effects (Bates, 2020). HDACs can also deacetylate other proteins, including transcription factors. Overexpression of HDACs found in some cancers or aberrant recruitment of HDACs to oncogenic transcription factors can cause hypoacetylation of core nucleosomal histones. This hypoacetylation results in a condensed chromatin structure and repression of gene transcription. In contrast, inhibition of HDAC activity leads to the accumulation of acetyl groups on the histone lysine residues, an open chromatin structure, and activation of target genes that are selectively repressed in tumors. The result of HDAC inhibition can be differentiation with the emergence of a more normal cellular phenotype or cell cycle arrest with expression of endogenous regulators of cell cycle progression. Due to the diversity of the HDAC family of enzymes and their tissue distribution, HDAC inhibitors with different selectivity can induce a wide variety of cellular effects. Beyond the cellular effects, the impact of HDAC inhibitors on the crosstalk of cancer cells and the immune system is currently evaluated in trials using combination treatments with immune checkpoint inhibitors (Hogg et al., 2020). Four HDAC inhibitors, *panobinostat*, *romidepsin*, *vorinostat*, and *belinostat*, have gained FDA approval and are discussed below. An updated review of other epigenetic modulators is provided by Bates (2020).

Panobinostat

Panobinostat is an orally bioavailable, nonselective pan-HDAC inhibitor. The inhibitory activity leads to apoptosis of malignant cells via multiple pathways. *Panobinostat* is approved for the treatment of patients with MM who have received at least two previous treatments, including *bortezomib* and an immunomodulatory agent.

ADME

The oral bioavailability is about 21%. *Panobinostat* is metabolized through CYP3A. It is recommended to avoid concomitant use of strong CYP3A4 inducers or inhibitors; otherwise, dose adjustments will be necessary. The elimination $t_{1/2}$ is approximately 37 h.

Adverse Effects

The most common adverse effects are diarrhea (severe in 25% of patients), fatigue, nausea, peripheral edema, decreased appetite, pyrexia, and vomiting. The most common nonhematologic laboratory abnormalities (incidence ≥40%) are hypophosphatemia, hypokalemia, hyponatremia, and increased creatinine. Common hematological laboratory abnormalities (incidence ≥60%) are thrombocytopenia, lymphopenia, leukopenia, neutropenia, and anemia. Fatal cardiac ischemic events, severe arrhythmias, and ECG changes have occurred in patients receiving *panobinostat*. Arrhythmias may be exacerbated by electrolyte abnormalities. Avoid concomitant use of antiarrhythmic or QT-prolonging drugs. Close cardiac monitoring during treatment is recommended.

Romidepsin

Romidepsin is an HDAC inhibitor used in the treatment of cutaneous and peripheral T-cell lymphoma. Recently, its indication in peripheral T-cell lymphoma has been withdrawn. *Romidepsin* is a natural product obtained from the bacteria *Chromobacterium violaceum* and is also referred to as *depsipeptide*. *Romidepsin* functions as a prodrug. Within cells, a zinc-binding thiol of the drug is reduced and interacts with a zinc atom in the binding pocket of HDAC to block its activity.

ADME

After intravenous administration, the major metabolism is through CYP3A4. Thus, it is recommended to monitor for toxicities related to increased *romidepsin* exposure when coadministering strong CYP3A4 inhibitors. *Rifampin* and other strong CYP3A4 inducers should be avoided. The terminal $t_{1/2}$ is about 3 h.

Adverse Effects

The most commonly observed adverse effects are nausea and vomiting, anemia, thrombocytopenia, and leukopenia, as well as abnormal electrolyte levels and ECG changes.

Vorinostat

Vorinostat is a small-molecule, orally bioavailable HDAC inhibitor; it is also known as SAHA based on its chemical name ***s***uber***a***nilo***h***ydroxamic ***a***cid.

Mechanism of Action

Vorinostat binds to the active site of HDACs and chelates zinc ions in the active site. The resulting inhibition of HDACs causes the accumulation of acetylated histones and other acetylated proteins, among which are transcription factors crucial for cell differentiation. *Vorinostat* inhibits the enzymatic activities of HDAC1, -2, and -3 (class I) and HDAC6 (class II) at nanomolar concentrations (IC_{50} <100 nM). *In vitro*, *vorinostat* induces cell cycle arrest or apoptosis of some cancer cells.

ADME

The absorption of *vorinostat* is slightly improved when taken with a meal. Metabolism is mostly through glucuronidation and hydrolysis. The elimination $t_{1/2}$ is about 2 h.

Therapeutic Use; Adverse Effects

Vorinostat is approved for the treatment of patients with cutaneous T-cell lymphoma with persistent or recurrent disease after two systemic therapies. The most common adverse reactions are diarrhea, fatigue, nausea, thrombocytopenia, anorexia, and dysgeusia. Patients with severe hepatic impairment should be excluded from treatment. Women should be apprised of the potential harm to the fetus.

Belinostat

Belinostat is an HDAC inhibitor developed for the treatment of hematological malignancies and solid tumors. It is approved to treat peripheral T-cell lymphoma and is administered by intravenous infusion. Warnings and adverse effects include the risk of hematological toxicity, infections, and hepatotoxicity. Treatment can also cause fetal harm.

Inhibitors of Histone Methyltransferase

Tazemetostat

Tazemetostat is an orally available, S-adenosyl methionine (SAM) competitive inhibitor of histone methyltransferase (HMT) EZH2 (wild-type and mutant) that was approved in 2020 for the treatment of patients with

metastatic or locally advanced epithelioid sarcoma not eligible for complete resection. Inhibition of EZH2 prevents the methylation of histone H3 lysine 27 (H3K27), alters gene expression patterns associated with cancer pathways, and inhibits growth of EZH2-mutated cancer cells. EZH2 is overexpressed or mutated in a variety of cancer cells and plays a key role in tumor cell proliferation. The most common adverse effects include fatigue, nausea, and decreased appetite. There is an increased risk of developing secondary malignancies and of fetal harm. *Tazemetostat* is metabolized by CYP3A, and coadministration of inhibitors can increase the AUC. The elimination $t_{1/2}$ is 3.1 h.

IDH1/2 Inhibitors

IDH1 and IDH2 mutations result in preferential production of 2-hydroxyglutarate (2-HG) over alpha-ketoglutarate, mimicking the loss-of-function of the ten-eleven translocation (TET) gene that controls DNA demethylation and resulting in DNA hypermethylation; simultaneously, inhibition of lysine demethylases by 2-HG leads to increased histone lysine methylation (Yang et al., 2012). Mutations in DNMT3A, TET2, IDH1, and IDH2 are found in 28%, 14%, 9%, and 10% of AMLs, respectively, with a similar mutation pattern in peripheral T-cell lymphoma. DNMT3A and TET2 mutations have been detected only at lower frequency in solid tumors, whereas IDH1 mutations were detected at higher frequency, including in 78% of low-grade gliomas, 14% of cholangiocarcinomas, and 4% of cutaneous melanomas. Two drugs targeting mutants IDH1 and IDH2 are currently approved and have shown some efficacy in the treatment of AML.

Enasidenib is an orally bioavailable IDH2 inhibitor that was approved in 2017 for the treatment of patients with relapsed or refractory AML with an IDH2 mutation. *Ivosidenib* is an orally bioavailable IDH1 inhibitor approved in 2018 for the treatment of AML with a susceptible IDH1 mutation (DiNardo et al., 2018; Issa and DiNardo, 2021) and recently for cholangiocarcinoma with IDH1 mutations. For both drugs, there is a risk of differentiation syndrome, which can be fatal and requires corticosteroid therapy and hemodynamic monitoring if suspected. For *ivosidenib*, risks include QTc prolongation and Guillain-Barré syndrome.

VII. Other Inhibitors (BCL2, Nuclear Export, Translation, CXCR4)

BCL2 Inhibitors

The B-cell lymphoma (BCL) 2 protein family comprises more than 20 proteins that govern mitochondrial outer membrane permeabilization and control programmed cell death (apoptosis). Proteins in this family can be either *pro-* or *anti*apoptotic depending on their content of BCL2 homology domains (BH1–4). *Proapoptotic* proteins contain a BH3 domain that is necessary for dimerization with other proteins of the BCL2 family. *Antiapoptotic* proteins contain BH1 and BH2 domains. The balance of these interacting proteins controls mitochondrial outer membrane permeabilization, cytochrome c release, and the activation of caspases that leads to apoptosis (Figure 71–10). BCL2 promotes cellular survival by inhibiting proapoptotic proteins like BIM (BCL2-like protein 11), BAX, and BAK and is overexpressed in CLL and some other tumors where it can support tumor cell survival and resistance to cancer treatments.

Venetoclax

Mechanism of Action

Venetoclax is a first-in-class, orally bioavailable, small-molecule inhibitor of BCL2. It was designed as a BH3 mimetic that inhibits BCL2 interaction with the proapoptotic BH3-only family members, such as BIM, BID, and BAD. *In vitro*, *venetoclax* inhibits BCL2 action with an IC_{50} of less than 0.01 nM and with a selectivity of two to three orders of magnitude over other BCL2 family members. In the presence of *venetoclax*, BH3-only proteins can translocate to mitochondria and initiate BAX/BAK-dependent apoptosis. Overexpression of BCL2 occurs in CLL cells, where it supports tumor cell survival and resistance to chemotherapeutic agents. Thus, *venetoclax* helps restore apoptosis in these cells.

Therapeutic Use; Adverse Effects; ADME

Venetoclax is approved for the treatment of patients with CLL or SLL and in combination with *azacitidine*, *decitabine*, or low-dose

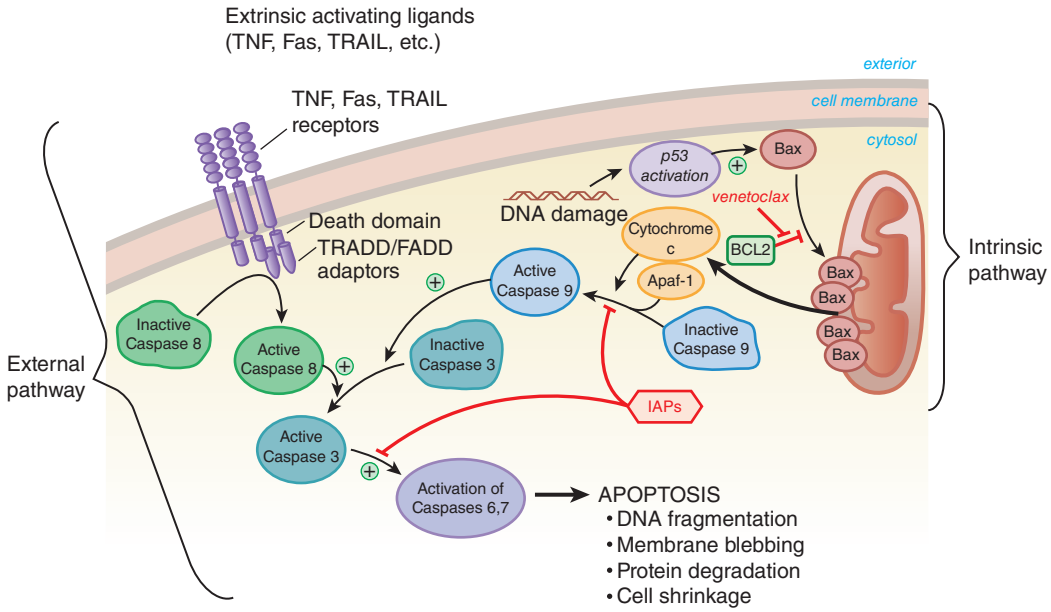

Figure 71–10 *BH3 mimetics enhance apoptosis.* Permeability of the outer mitochondrial membrane to cytochrome c is regulated by proteins required for forming pores, including proapoptotic BAX and BAK. BAK and BAX are rendered inactive by binding to the BH3 domains of antiapoptotic proteins such as BCL2. BH3 mimetic drugs (*venetoclax*) target BCL2 and its interaction with BAX/BAK, reducing the inhibitory effect of BCL2 on apoptosis progression, enhancing cytochrome c release, and sensitizing the cell to apoptosis. Cancer cells may be resistant to apoptosis by overexpression of BCL2; BH3 mimetics such as *venetoclax* release the resultant blockade and promote apoptosis.

cytarabine for the treatment of newly diagnosed AML in patients 75 years or older or with comorbidities that preclude the use of chemotherapy. The most common adverse effects are neutropenia, diarrhea, nausea, anemia, upper respiratory tract infection, thrombocytopenia, and fatigue. *Venetoclax* may cause fetal harm. Oral absorption is significantly improved 3- to 5-fold by administration with a meal. *Venetoclax* is metabolized by CYP3A4/5 and has an elimination $t_{1/2}$ of 18 to 26 h.

Nuclear Export Inhibitor

Selinexor

Selinexor is an orally bioavailable reversible inhibitor of exportin 1 (XPO1). It was approved in 2019 in combination with *bortezomib* and *dexamethasone* for the treatment of patients with MM who have received at least one prior therapy, and for the treatment of patients with relapsed or refractory diffuse large B-cell lymphoma after at least two lines of systemic therapy. Warnings and risks of treatment that require monitoring and management include thrombocytopenia, neutropenia, hyponatremia, and infection. Also, there is a risk of fetal harm. The most common adverse effects are fatigue, nausea, vomiting, decreased appetite, diarrhea, peripheral neuropathy, upper respiratory tract infection, decreased weight, and cataract. *Selinexor* is metabolized by CYP3A4 and eliminated with a $t_{1/2}$ of 6 to 8 h.

Protein Translation Inhibitor

Omacetaxine

Omacetaxine is administered by SC injection and is approved for the treatment of patients with CML with resistance or intolerance to two or more kinase inhibitors. The mechanisms of action include inhibition of protein translation by preventing the initial elongation step of protein synthesis, thereby depleting the cell of short-lived proteins. Warnings include the risk of myelosuppression, bleeding, and fetal toxicity. Adverse effects also include nausea, fatigue, and infections. *Omacetaxine* is hydrolyzed by plasma esterases and eliminated with a $t_{1/2}$ of 14.6 h.

CXCR4 Inhibitor

Plerixafor

Plerixafor is a small-molecule inhibitor of the CXCR4 chemokine receptor and is used in combination with granulocyte colony-stimulating factor to mobilize hematopoietic stem cells (HSC) to the peripheral blood for collection and subsequent autologous transplantation in patients with non-Hodgkin's lymphoma and MM. *Plerixafor* blocks binding of stromal cell-derived factor (SDF)-1α to CXCR4. CXCR4 activity supports homing of HSCs to the bone marrow, and *plerixafor* mobilizes the release and entry of HSCs into the circulation. The combination of granulocyte colony-stimulating factor with *plerixafor* increases the efficacy of HSC mobilization.

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Section I: Inhibitors of Growth Factors and Receptors		
Epidermal Growth Factor Receptor Inhibitors		
Small-Molecule EGFR Kinase Inhibitors: Oral Administration		
Erlotinib	• Advanced NSCLC with mutant EGFR (del exon 19; L858R) • Advanced pancreatic cancer in combination with gemcitabine	• Skin rash, stomatitis, diarrhea, interstitial lung disease • CYP3A4 substrate • Anticoagulant effect of warfarin enhanced • Concurrent use of PPI ↓ bioavailability
Gefitinib	• Advanced NSCLC with mutant EGFR (del exon 19; L858R)	• Side effects similar to erlotinib, but bioavailability not affected by PPI
Afatinib	• Irreversible inhibitor EGFR > HER2 • Advanced NSCLC with mutant EGFR (del exon 19; L858R) • Squamous cell carcinoma of the lung progressing after systemic therapy	• Side effects stronger than gefitinib; can cause hepatotoxicity • Not affected by CYP3A4 modulation • ↓ Dose with renal impairment or Pgp inhibitors
Osimertinib	• Advanced NSCLC with EGFR mutations • Advanced NSCLC that is resistant to other EGFR kinase inhibitors and positive for exon 20 T790M-mutant EGFR	• Similar to gefitinib but less intense side effects; can ↑ QTc interval
Human Epidermal Growth Factor Receptor 2 Inhibitors		
Small-Molecule HER2 Kinase Inhibitors: Oral Administration, Also Inhibit EGFR		
Lapatinib	• HER2-positive breast cancer in combination with capecitabine • HER2-positive, hormone receptor–positive breast cancer in combination with letrozole (aromatase inhibitor)	• Skin rash, diarrhea • Cardiotoxicity (less than trastuzumab), QT interval prolongation • CYP3A4 substrate
Neratinib	• Irreversible inhibitor of EGFR and HER2 • HER2-positive breast cancer in addition to chemotherapy	• Diarrhea is major adverse effect, with one-third of patients with severe grade 3–4 diarrhea

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Section II: Inhibitors of Intracellular Protein Kinases		
Mutant B-RAF Kinase Inhibitors		
Vemurafenib	• BRAF V600E/K mutant melanoma	• Cutaneous adverse effects up to 60%, with squamous cell carcinoma in >20% • Arthralgia, fatigue, nausea less frequently • Can cause QT prolongation • CYP3A4 substrate; CYP1A2 inhibitor
Dabrafenib	• BRAF V600E/K mutant melanoma also in combination with the MEK inhibitor trametinib • BRAF V600E mutant NSCLC with trametinib	• Cutaneous adverse effects include hyperkeratosis and papilloma • cuSCC in ~10% of patients • Combination with trametinib ↓ incidence of cuSCC to 3% and delays onset • CYP2C8 and CYP3A substrate
Mitogen-Activated Protein Kinase Kinase Inhibitors		
Cobimetinib	• BRAF V600E/K mutant melanoma	• Diarrhea, photosensitivity, nausea common • Risk of hemorrhage, cardiomyopathy • CYP3A4 substrate
Trametinib	• BRAF V600E/K mutant melanoma and BRAF V600E mutant NSCLC: with dabrafenib • Ineffective in patients who developed resistance to BRAF inhibitor treatment	• Cutaneous rash, acneiform dermatitis, diarrhea most frequent; serious skin toxicity in 6% • Risk of cardiomyopathy, hypertension, hemorrhage, interstitial lung disease • Reduced absorption after high-calorie meal
Janus-Associated Protein Kinase Inhibitors		
Ruxolitinib	• Polycythemia vera • Myelofibrosis	• Thrombocytopenia, anemia most frequent • Rare basal cell carcinoma or squamous cell carcinoma • ↓ Dose in renal or hepatic impairment • CYP3A4 substrate
Cyclin-Dependent Kinase 4/6 Inhibitors		
Palbociclib	• Advanced ER-positive, HER2-negative breast cancer • Combination with aromatase inhibitor or antiestrogen (fulvestrant)	• Common: neutropenia, leukopenia, infections, stomatitis, anemia, thrombocytopenia, nausea, diarrhea • Substrate and inhibitor of CYP3A4
Abemaciclib and ribociclib	• Same as for palbociclib	• Side effects similar to palbociclib
Bruton Tyrosine Kinase Inhibitors		
Ibrutinib	• Mantle cell lymphoma, CLL, SLL, Waldenström's macroglobulinemia	• Neutropenia, thrombocytopenia, diarrhea, anemia, musculoskeletal pain • Slow onset of hypertension possible: monitor blood pressure • Atrial fibrillation: monitor and treat • Secondary malignancies mostly skin, nonmelanoma • CYP3A4 substrate
BCR-ABL, PDGFR, KIT Kinase Inhibitors		
Imatinib	• Chronic-phase CML; mucosal and acral lentiginous melanoma (KIT mutation positive), GIST (KIT mutation positive), dermatofibrosarcoma protuberans, chronic myelomonocytic leukemia	• GI tract adverse effects: diarrhea, nausea, vomiting • Fluid retention, edema • Rare myelosuppression, hepatotoxicity • CYP3A4 substrate
Dasatinib	• CML resistant to imatinib after prior therapy	• Adverse effects: diarrhea, nausea, vomiting • Fluid retention, edema, pleural effusions • Rare myelosuppression, hepatotoxicity • Bioavailability ↓ after antacids or H_2 blockers • CYP3A4 substrate
Nilotinib	• CML resistant to imatinib after prior therapy	• Adverse effects: diarrhea, nausea, vomiting, fluid retention, edema • May ↑ QT interval; beware vascular events, including ischemia • Rare myelosuppression, hepatotoxicity • Bioavailability ↑ in the presence of food • CYP3A4 and Pgp substrate • Inhibitor of the Pgp
Bosutinib	• CML resistant to prior therapy	• Diarrhea, nausea, thrombocytopenia, vomiting, rash
Ponatinib	• Resistant CML and Ph^+ ALL	• Major adverse effects: thrombosis, hepatotoxicity, pancreatitis • Absorption ↓ by elevated gastric pH (H_2 antagonists, antacids, PPIs) • CYP3A4 substrate

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Anaplastic Lymphoma Kinase Inhibitors		
Alectinib	• Advanced NSCLC with ALK kinase fusion gene • Advanced NSCLC with ALK kinase fusion gene and disease progression on crizotinib	• Fatigue, constipation, edema, and myalgia are common adverse effects • Pneumonitis, GI and hepatic toxicity; bradycardia and prolonged QT intervals observed
Ceritinib, crizotinib	• As above	• As above
PI3K (Phosphatidylinositol-4,5-Bisphosphate 3-Kinase) Inhibitors		
Idelalisib	• Relapsed or refractory B-cell malignancies: CLL (with rituximab), FL, SLL • Not indicated for first-line treatment	• Serious and sometimes fatal adverse effects: hepatotoxicity, colitis, pneumonitis, intestinal perforations, skin toxicity • CYP3A substrate
mTOR (Mechanistic or Mammalian Target of Rapamycin) Inhibitors		
Temsirolimus	• Advanced renal cell carcinoma	• Adverse effects: frequent rash, mucositis, anemia, fatigue (30%–50%); rare leukopenia, thrombocytopenia, interstitial lung disease • Metabolized to a longer-lived active metabolite (sirolimus) by CYP3A4: avoid CYP3A4 inhibitors, including grapefruit juice
Everolimus	• Renal cell carcinoma • Breast cancer: advanced ER positive, HER2 negative in combination with aromatase inhibitor exemestane after failure of other aromatase inhibitors (letrozole, anastrozole) • PNETs • Progressive, well-differentiated, nonfunctional neuroendocrine GIST	• Adverse effects overlap with temsirolimus (see above) • CYP3A4 substrate
Multikinase Inhibitors		
Cabozantinib	• Advanced renal cell carcinoma	• Diarrhea, fatigue, nausea, abdominal pain • Hypertension: monitor blood pressure • Not indicated in patients with recent bleeding history or thromboembolic event • Discontinue in patients with GI perforation, fistulas • CYP3A4 substrate; ↓ dose with hepatic impairment
Vandetanib	• Progressing, locally advanced medullary thyroid cancer	• Diarrhea, colitis, rash • QT interval prolongation, torsades des pointes, sudden death • Do not use in patients with hepatic impairment, long QT syndrome • CYP3A4 substrate
Section III: Inhibitors of Tumor Angiogenesis		
Inhibitor of Hypoxia-Inducible Factor (HIF) Activity		
Belzutifan	• Inhibition of heterodimerization of HIF-2α with HIF-1β transcription factors • Clear cell RCC	Adverse effects: • Anemia due to reduction of erythropoietin • Hypertension
Inhibitors of Vascular Endothelial Growth Factor (VEGFR) and Intracellular Kinases Participating in Angiogenesis		

Sunitinib	• VEGFR2 and multiple other kinases inhibited
	• Metastatic RCC
	• GIST after imatinib resistance
	• Pancreatic neuroendocrine tumors
		• Adverse effects shared with anti-VEGF: bleeding, hypertension, proteinuria (frequent); thromboembolism, GI perforations (rare)
		• Adverse events distinct from anti-VEGF:
		  • Fatigue (50%–70%), hypothyroidism (40%–60%)
		  • Common: bone marrow suppression and diarrhea
		  • Less common: hepatotoxicity, congestive heart failure
		• Check blood pressure, blood counts, and thyroid functions at regular intervals
		• Elimination $t_{1/2}$ ~4 days: regimen in some cancers is 4 weeks on, 2 weeks off vs. continuous daily administration for other cancers

Sorafenib	• Hepatocellular carcinoma • Metastatic RCC (however, sunitinib is the first choice)	• Adverse vascular effects match with those of sunitinib • More common: fatigue, diarrhea, anorexia, rash • Less common: bone marrow suppression, GI perforation, cardiomyopathy
Axitinib	• Inhibition of VEGFR1–3 • Advanced renal cell cancer after failure of prior systemic therapy	• Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation • CYP3A4/5 substrate

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Inhibitors of Vascular Endothelial Growth Factor (VEGFR) and Intracellular Kinases Participating in Angiogenesis (cont.)		
Lenvatinib	• Inhibition of VEGFR1–3, FGFRs, PDGFR • Recurrent or metastatic differentiated thyroid cancer • RCC in combination with everolimus • Endometrial cancer with pembrolizumab	• Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation • In addition: hepatotoxicity, QT prolongation • CYP3A substrate
Pazopanib	• Inhibition of VEGFR1–3, FGFRs, KIT, PDGFR • Advanced RCC and advanced soft-tissue sarcoma after prior chemotherapy	• Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation • In addition: hepatotoxicity, QT prolongation • CYP3A substrate
Regorafenib	• Inhibition of RET, VEGFR1, PDGFR, FGFR, TIE2, RAF1, BRAF, ABL • Metastatic colorectal cancer after previous chemotherapy and anti-VEGF or anti-EGFR • Advanced GIST after imatinib or sunitinib	• Major adverse effects: hepatotoxicity, hypertension, thrombotic and hemorrhagic events, GI perforation, and wound-healing complications • CYP3A substrate
Section IV: PARP Inhibitors		
Poly(ADP-Ribose) Polymerase Inhibitor		
Olaparib	• Ovarian cancer after three or more prior lines of treatment in patients with germline mutant BRCA	• Adverse effects: nausea, vomiting, loss of appetite, muscle and joint pain, anemia; leukemia (rare), potentially fatal MDS (rare), pneumonitis • CYP3A4 substrate
Section V: Modulators of Protein Degradation		
Thalidomide and Congeners		
Thalidomide	• Newly diagnosed multiple myeloma • Relapsed or refractory, pretreated multiple myeloma	• Most serious adverse effect: sensory neuropathy in 10%–30% of patients; may not be reversible after discontinuation of treatment; patients with preexisting neuropathy at higher risk • Teratogenic; do not use in pregnancy • Causes sedation (enhanced by CNS depressants), fatigue, constipation
Lenalidomide	• Multiple myeloma • MDS (5q– MDS) • Chronic lymphocytic leukemia (CLL)	• Marrow suppression and leukopenia (20% of patients), rare hepatic or renal toxicity • Tumor lysis in some patients with CLL → lymph node swelling and tumor flare: start at lower dose in patients with CLL • Downregulates CD20, a target for monoclonal antibody therapy • In contrast to thalidomide: little neuropathy, sedation, or constipation; lack of teratogenicity • Reduce dose in patients with reduced renal function
Pomalidomide	• AIDS-related Kaposi sarcoma	• Teratogenic; available only under a pregnancy control system
Proteasome Inhibitors		
Bortezomib	• Multiple myeloma: initial therapy and after relapse • Mantle cell lymphoma: relapsed or refractory	• Thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%) • Neutropenia, anemia, vomiting, diarrhea, limb pain, weakness • Rare: congestive heart failure and prolonged QT intervals • Metabolized by CYP3A4; beware of drug interactions
Section VI: Epigenetic Modulators		
Panobinostat	• Patients with MM who have received at least two previous treatments, including bortezomib and an immunomodulatory agent	• Fatal cardiac ischemic events, severe arrhythmias, close cardiac monitoring during treatment • CYP3A substrate
Section VII: Other Inhibitors		
BCL2 (Antiapoptotic Protein): Orally Available Inhibitor		
Venetoclax	• CLL with 17p deletion (poor prognosis)	• Neutropenia, thrombocytopenia, diarrhea, nausea • Absorption ↑ 3- to 5-fold with a meal • CYP3A substrate

Note: CYP3A4 substrate: For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.
Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

Chapter 72 Antibodies, CAR T Cells, and Proteins to Treat Cancer

Anton Wellstein and Michael B. Atkins

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, among other advances. As a consequence, this chapter presents only a few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA (drugs@fda) and the NCCN (National Comprehensive Cancer Network). Table 71–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

Development of targeted therapies for treating patients with cancer relies on the continuing process of discovery of molecular changes that drive malignant progression of human cancers. A growing number of drugs are being developed to block oncogenic pathways that lead to dysregulated cancer cell growth and survival. Targeted therapy may be combined with classical cytotoxic cancer drugs described in Chapter 70 for improved efficacy. Growth factor receptors and downstream signaling molecules are among the most actively explored targets for cancer drug discovery. The drivers of cancer growth are oncogenic pathways in malignant cells themselves (e.g., mutant or overexpressed receptors), the reaction of the tumor microenvironment (e.g., angiogenesis), and the escape of malignant cells from the host's immune surveillance (Hanahan and Weinberg, 2011). Chapter 71 describes small-molecule drugs used in targeting pathways altered in cancer. The discussion of drugs in this chapter focuses on large molecules and cell-based therapeutics of cancer and is organized into sections:

I. **Inhibiting growth factors receptors in cancer cells**
II. **Inhibiting tumor angiogenesis**
III. **Activating immune cells**
IV. **Targeting cancer cell surface molecules to engage immune cells**
V. **Cytotoxin conjugates with antibodies or cytokines**
VI. **Cellular therapy and vaccines**
VII. **Other proteins**

The proteins discussed here target oncogenic pathways that contribute to cancer growth and metastatic spread as well as immune evasion and for the most part consist of *monoclonal antibodies* or their derivatives that

Abbreviations

ADC: antibody-drug conjugate
ADCC: antibody-dependent cellular cytotoxicity
ADCP: antibody-dependent cellular phagocytosis
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia
AML: acute myelocytic leukemia
APC: antigen-presenting cell
BCMA: B-cell maturation antigen, tumor necrosis factor receptor superfamily member 17
BiTE: bispecific T-cell–engaging antibody
CAR T: chimeric antigen receptor T cells
CCR: CC motif chemokine receptor
CDC: complement-dependent cytotoxicity
CDR: complementarity-determining regions
CLL: chronic lymphocytic leukemia
CTLA-4: cytotoxic T lymphocyte–associated protein 4
EGF(R): (human) epidermal growth factor (receptor) = HER1
FOLFIRI: folinic acid (leucovorin), 5-fluorouracil, irinotecan
FOLFOX: folinic acid (leucovorin), 5-fluorouracil, oxaliplatin
5FU: 5-fluorouracil
G(M)-CSF: granulocyte(-macrophage) colony-stimulating factor
HER1 or 2: *h*uman *E*GF*R* 1 or 2
HNSCC: head and neck squamous cell carcinoma
IFN: interferon
IL(-2R): interleukin (2 receptor)
JC: John Cunningham
KDR: kinase insert domain receptor = VEGFR2
KIT: feline sarcoma virus oncogene homolog
LAG3: lymphocyte activation gene 3
LVEF: left ventricular ejection fraction
mCRC: metastatic colorectal cancer
MET: mesenchymal-epithelial transition factor (= HGFR)
MHC: major histocompatibility complex protein
MM: multiple myeloma
MMAE/F: monomethyl auristatin E/F
MSI-H: microsatellite instability high
NHL: non-Hodgkin lymphoma
NK: natural killer
NSCLC: non-small cell lung cancer
PAP: prostate acidic phosphatase
PD-1: programmed cell death protein 1
PDGF(R): platelet-derived growth factor (receptor)
PD-L1: programmed cell death ligand 1
RCC: renal cell carcinoma
TCR: T-cell receptor
VEGF(R): vascular endothelial growth factor (receptor)

recognize cell surface proteins on cancer cells or on host cells or antigens shed from cancer cells (see box Antibodies as Cancer Drugs).

Over 40 different antibody-based therapeutics are currently FDA-approved for cancer treatment, many added in the past 5 years (see Figure 1–7 and Table 72–1). Notably, small-molecule inhibitors used to treat cancer impact the efficacy of antibody therapy and are used in treatment combinations that may target the same pathway or parallel and escape pathways. Indeed, triggering cell death in tumors by chemotherapy, pathway-targeted inhibitors, or radiotherapy can promote cytotoxic T-cell infiltration. The efficacy of such combinations is discussed below. Ongoing combination trials have been recently reviewed (Balogh and Nass, 2019; Petroni et al., 2021).

Antibodies as Cancer Drugs

The general concept of harnessing the immune system to treat cancer originated with William B. Coley, a professor of clinical surgery at Cornell University. He suggested that natural immunity becomes lowered during malignancy and thus thought to raise the immune reaction by injecting bacterial toxins into sarcoma (Coley, 1910) with some successes, although also with serious adverse events. The foundation for contemporary antibody-based drugs was laid by Köhler and Milstein who, in 1975, generated the first hybridoma cell lines capable of producing monoclonal antibodies. Georges Köhler, César Milstein, and Niels Jerne shared the 1984 Nobel Prize in Physiology/Medicine "for theories concerning the specificity in development and control of the immune system and the discovery of the principle for production of monoclonal antibodies."

A monoclonal antibody is derived from a single B cell, recognizes a specific antigen, and can mediate cancer cell eradication by different mechanisms: (1) blocking ligands or function of cell surface receptors, (2) recruiting immune cells and complement to an antigen-antibody complex formed, (3) modulating immune cell function, or (4) carrying toxins or radionuclides as cytotoxic payloads to the cells of interest. A monoclonal antibody is generally specific for a single antigen, such as an epitope in a growth factor receptor; has a long plasma $t_{1/2}$ of days to weeks; and requires only intermittent parenteral administration. Immunoglobulin G1 (IgG1), the most frequently approved antibody isotype used in cancer treatment, can activate the complement pathway and interacts with Fcγ receptors on immune cells more potently than IgG2 or IgG4 (see Figure 72–1). Protein or carbohydrate engineering of the Fc region can alter the effector functions and mitigate complement-dependent cytotoxicity (CDC), antibody-dependent cellular cytotoxicity (ADCC), and antibody-dependent cellular phagocytosis (ADCP) (Goydel and Rader, 2021). Further background on monoclonal antibodies is provided in Chapters 38 and 39.

The naming of monoclonal antibodies (Table 72–1): *M*onoclonal *anti*body names end with the syllable "mab" preceded by different morphemes that indicate the characteristics of a given antibody, mostly based on its molecular design: "xi"—fusion of human constant (Fc) and mouse variable (Fv) antibody domains to generate chimeric proteins; "zu"—insertion of antigen-binding regions (complementarity-determining regions [CDRs]) into a human IgG protein scaffold, known as humanization; and "u"—amino acid sequence fully matching the human IgG and generated in transgenic mice that carry human Ig gene loci or *in vitro* (e.g., by phage display of human antibody libraries and their affinity for the target, improved by randomization of amino acid sequences in the CDRs) (see Figure 72–1).

I. Inhibiting Growth Factor Receptors in Cancer Cells

Inhibitors of Epidermal Growth Factor Receptor

Background

The epidermal growth factor receptor (EGFR) belongs to the ErbB family of transmembrane receptor tyrosine kinases also known as ErbB1 or HER1 (*h*uman *E*GF*R 1*). The EGFR is expressed in epithelial tissues, including the skin, and essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein

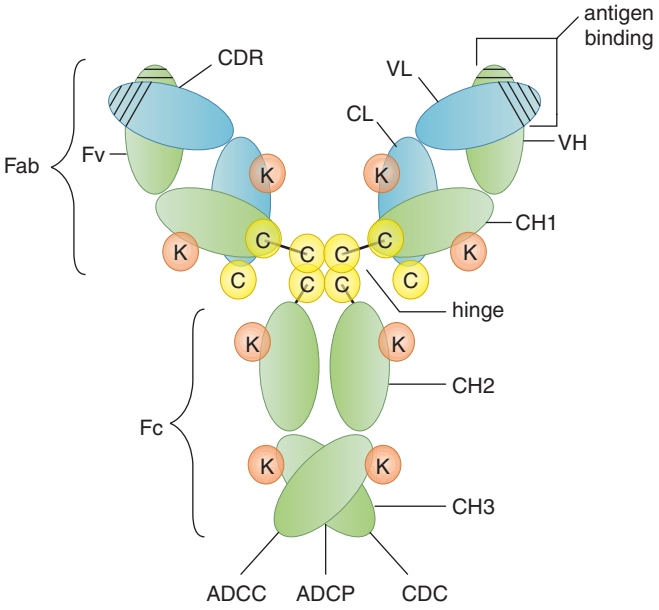

Figure 72–1 *IgG1 elements relevant for their use in cancer treatment.* Constant and variable heavy and light chains (CH, CL, VH, VL) are shown. The Fab domain contains the three complementarity-determining regions (CDR) in each of the variable chains that constitute the antigen binding site (paratope). The Fc domain modulates the effector functions, i.e., antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and antibody-dependent cellular phagocytosis (ADCP). Six disulfide bridges containing cysteine residues (C, yellow) connect the chains. The molecular mass of an IgG1 is approximately 150 kDa. Cytotoxic payloads can be linked to an IgG through the cysteine residues or through a multitude of lysine (K) residues in the different domains.

tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues located in the C-terminal tail of the receptor monomers. These phosphotyrosines provide interaction sites for a variety of adapter proteins, resulting in stimulation of signaling pathways, including MAPK and PI3K/Akt pathways (Figure 72–2).

In epithelial cancers, overexpression of the EGFR is a common finding. Monoclonal antibodies (*cetuximab*, *panitumumab*, *necitumumab*) recognize the extracellular domain of the EGFR, inhibit ligand-induced signaling, and can elicit an immune response.

HISTORY **EGFR/HER PATHWAY-TARGETED CANCER THERAPY**

The discovery and analysis of the EGFR (= HER1) in 1984 revealed a remarkable homology of its protein kinase domain to an oncogenic protein in the avian erythroblastosis retrovirus, v-erb. This oncogenic protein was the second one isolated from v-erb, resulting in "erbB" as an alternate name for "HER" gene family members. The HER2 gene was discovered based on its homology to v-erbB in human breast cancer and its oncogenic function in rat ***neu***ral tumors, hence the different names HER2/ErbB2/Neu (King et al., 1985; Schechter et al., 1985). The association of HER2 overexpression with poor prognosis in breast cancer (Slamon et al., 1987) provided the impetus for the development of HER2-targeted antibodies and a new concept in the treatment of HER2-positive breast cancers. *Trastuzumab* was the first anti-HER2 monoclonal antibody developed based on these discoveries; it was approved in the U.S. in 1998 and in Europe in 2000 for the treatment of patients with HER2-positive breast cancers. A monoclonal antibody targeting EGFR, *cetuximab*, was approved in Switzerland in 2003 and in the U.S. in 2004.

TABLE 72–1 ■ NAMING AND FORMAT OF ANTIBODY-BASED CANCER THERAPEUTICS

Please note that the nomenclature below applies to antibody drug names that were assigned by the WHO through the year 2021.

The nomenclature for future monoclonal antibodies was changed by the WHO in Oct 2021 to accommodate the expansion of this class of drugs that contains 880 "mab" entities. In newly named antibodies the stem "mab" will be replaced by four distinct stems to identify the composition of the antibody and will be indicated in future editions of this textbook and on *AccessMedicine.com* and *AccessPharmacy.com*.

ANTIBODY NOMENCLATURE	DEFINITION	EXAMPLE
"mab"	Names end with this syllable	Bevacizu*mab*
"xi"	Chimeric mAb consisting of human constant (Fc) and mouse variable (Fv) antibody domains	Cetu*xi*mab
"zu"	Humanization by insertion of antigen-binding regions (CDRs) into a human IgG protein scaffold	Trastu*zu*mab
"u"	Fully human amino acid sequence match with human IgG	Nivol*u*mab
"li"	Indicates immunomodulatory function	Cemip*li*mab

ANTIBODY FORMAT	EXAMPLES (TARGETS)	NUMBER BY 2021
IgG1	Bevacizumab (VEGF), cetuximab (EGFR), ipilimumab (CTLA-4), trastuzumab (HER2)	30
IgG2	Panitumumab (EGFR)	1
IgG4	Pembrolizumab, nivolumab (PD-1)	5
Bispecific, linked scFvs	Blinatumomab (CD3 and CD19)	2
CAR T cells	Tisagenlecleucel (CD19)	5

scFv, single-chain antibody fragment of the variable domain.

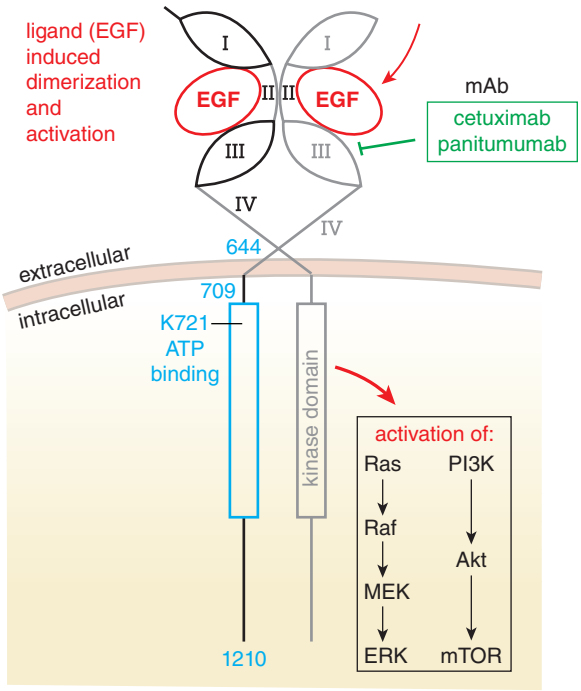

Figure 72–2 *Antibody targeting and domains of EGFR (HER1).* The extracellular portion of the EGFR contains the binding domains for growth factors that include EGF, transforming growth factor-α, and amphiregulin. Ligand binding to extracellular domains I and III induces conformational change and receptor dimerization through domains II and IV and activates intracellular signaling by cross-phosphorylation. The monoclonal antibodies *cetuximab*, *panitumumab*, and *necitumumab* block ligand binding. HER2, HER3, and HER4 share the extracellular domain organization of EGFR. mAb, monoclonal antibody. Amino acid residue numbers are in blue.

Antibody Inhibitors of EGFRs

Cetuximab

Mechanism of Action. *Cetuximab* is a chimeric human/mouse IgG1 antibody composed of the Fv regions of a murine anti-EGFR antibody with human IgG1 heavy and kappa light chain constant regions that bind to the extracellular domain III of EGFR (see Figure 72–2). Binding to EGFR prevents ligand-dependent signaling and receptor dimerization, thereby blocking growth and survival signals in normal and tumor cells. *Cetuximab* can also mediate ADCC against tumor cells that express high levels of EGFR.

ADME. *Cetuximab* exhibits nonlinear pharmacokinetics. A single loading dose of *cetuximab* intravenously is followed by weekly maintenance doses for the duration of treatment. Following intravenous administration, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space. The half-life of *cetuximab* is about 5 days.

Therapeutic Uses. Antibodies targeting EGFR show a different spectrum of antitumor activity than small-molecule EGFR kinase inhibitors (see Chapter 71), in part due to the additional ADCC of antibodies toward tumor cells. *Cetuximab* and related antibodies are used to treat patients with metastatic colon cancers and head and neck squamous cell carcinoma (HNSCC).

In colon cancer, *cetuximab* enhances the effectiveness of chemotherapy in patients with *KRAS* wild-type but not *KRAS*-mutant tumors (Van Cutsem et al., 2009). A combination of *cetuximab* with FOLFIRI (*folinic acid* [*leucovorin*], *5-fluorouracil* [5FU], and *irinotecan*; see Chapter 70) is typically used to treat patients with *KRAS* wild-type tumors that express EGFR. *Cetuximab* is also used as a single agent in patients who cannot tolerate *irinotecan*-based therapy and in patients with cancers that are resistant to *oxaliplatin*, *irinotecan*, and *5FU*.

In HNSCC, *cetuximab* is used in combination with radiation or with platinum complex–based chemotherapy (e.g., *cisplatin*; see Chapter 70) for locally or regionally advanced HNSCC. *Cetuximab* is also indicated as a monotherapy for patients with metastatic or recurrent HNSCC whose disease progresses on platinum-based chemotherapy.

Adverse Effects. Antibodies targeting EGFR have an adverse effect profile similar to that of first-generation EGFR protein tyrosine kinase inhibitors (see Chapter 71). Acneiform rash in the majority of patients, pruritus, nail changes, headache, and less frequently diarrhea are the most common adverse reactions. Rare but serious adverse effects include infusion reactions (~3% of patients), cardiopulmonary arrest in patients with HNSCC receiving radiation or chemotherapy (2%–3%), interstitial lung disease, and serum electrolyte imbalances, including hypomagnesemia. During pregnancy, *cetuximab* may be transmitted to the developing fetus and has the potential to cause fetal harm.

Panitumumab

Panitumumab is a human IgG2κ antibody that binds to the extracellular domain III of the EGFR and prevents ligand-dependent signaling. It is FDA approved for the treatment of EGFR-expressing metastatic colorectal cancer (mCRC) in combination with chemotherapy and as monotherapy after disease progression following chemotherapy regimens containing *fluoropyrimidine*, *oxaliplatin*, and *irinotecan* (Saltz et al., 2006). Although *panitumumab* effectively inhibits EGFR signaling similarly to *cetuximab*, it is less effective at triggering cellular immune mechanisms that may be crucial for effective therapy of HNSCC (Trivedi et al., 2016).

ADME; Adverse Effects. *Panitumumab* exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean $t_{1/2}$ is 7.5 days. Adverse effects of *panitumumab* are similar to those of *cetuximab* and include rash and dermatological toxicity, infusion reactions, pulmonary fibrosis, and electrolyte abnormalities. Dermatological toxicities were reported in 90% of patients and were severe in 15% of patients receiving monotherapy.

Necitumumab

Necitumumab is a human IgG1 monoclonal antibody that binds to the extracellular domain of the EGFR. It is approved for first-line treatment of patients with metastatic, squamous NSCLC in combination with *gemcitabine* and *cisplatin*. *Necitumumab* is administered intravenously every 3 weeks prior to chemotherapy. Adverse effects are similar to those of *cetuximab*.

HER2/Neu Inhibitors

Human epidermal growth factor receptor 2 (HER2, also named Neu or ErbB2; see box on History) is a member of the HER1 to HER4 family, which shares a common extracellular domain organization that is shown in Figure 72–2 for EGFR (HER1). Of note, the fixed conformation of the extracellular domain of HER2 resembles the ligand-activated state of the other HER family members and explains the unique function of HER2 as a coreceptor that does not require ligand activation. In addition, due to this conformation, the overexpression of wild-type HER2 is sufficient to activate the intracellular tyrosine kinase and oncogenic signaling even in the absence of activating mutations, coreceptors, or ligands. Overexpression of HER2 is found in 20% to 30% of human breast cancers due to gene amplification on chromosome 17 and results in more aggressive tumors, lower response rates to hormonal therapies, and higher risk of disease recurrence after treatment. Antibodies targeting HER2 are discussed below; small-molecule kinase inhibitors of HER2 (*lapatinib*, *neratinib*, and *tucatinib*) are discussed in Chapter 71.

Trastuzumab

Mechanism of Action

Trastuzumab is a humanized IgG1 monoclonal antibody that binds to the extracellular domain IV of HER2 (see domain organization in

Figure 72–2), reduces HER2 signaling, and can induce antibody-dependent, immune cell–mediated cytotoxicity. HER2 protein overexpression or gene amplification is predictive of response to HER2-targeted therapies (Wolff et al., 2013).

ADME

Trastuzumab has dose-dependent pharmacokinetics with a mean $t_{1/2}$ of 5.8 days on a weekly maintenance dose with alternative dosing every 3 weeks. Steady-state levels are achieved between 16 and 32 weeks.

Therapeutic Uses

Trastuzumab is approved for HER2-overexpressing breast and gastric cancer. It is used in combination with cytotoxic chemotherapeutics such as taxanes as initial treatment or as a single agent following relapse of disease after cytotoxic chemotherapy (see Chapter 70).

Adverse Effects and Precautions

Acute adverse effects after infusion of *trastuzumab* are typical for monoclonal antibodies and can include fever, chills, nausea, dyspnea, and rashes. The most serious toxicity of *trastuzumab* is heart failure. Cardiotoxicity is caused by interruption of HER2/4 heterodimer signaling in cardiomyocytes, signaling that is essential for the maintenance of contractile function. The cardiotoxic potential was predicted from gene inactivation studies ("knockouts") in mice, which showed that mice lacking HER2, HER4, or HER ligands developed dilated cardiomyopathy and heart failure. Baseline electrocardiogram and cardiac ejection fraction measurement should be obtained before initiating treatment with *trastuzumab* to rule out underlying heart disease. Clinical monitoring for symptoms of congestive heart failure as well as periodic determination of left ventricular ejection fraction (LVEF) during and after the course of therapy are recommended. When *trastuzumab* is used as a single agent, fewer than 5% of patients will experience a decrease in LVEF, and about 1% will have clinical signs of congestive failure. However, left ventricular dysfunction occurs in up to 20% of patients who receive a combination of *doxorubicin* and *trastuzumab*, reflecting the added cardiotoxicity of *doxorubicin* (see Chapter 70). In contrast, the risk of cardiac toxicity is greatly reduced with the recommended combination of *trastuzumab* with taxanes.

Pertuzumab

Mechanism of Action

Pertuzumab is a humanized IgG1 monoclonal antibody directed against the extracellular receptor dimerization domain II of HER2 that is distinct from domain IV targeted by *trastuzumab* (see domain organization in Figure 72–2). *Pertuzumab*, in contrast to *trastuzumab*, prevents ligand-dependent heterodimerization of other HER family members with HER2 and thus inhibits ligand-induced signaling, cell growth, and survival. In addition to the inhibition of receptor heterodimerization, binding of *pertuzumab* to HER2-overexpressing cells can induce ADCC.

ADME

The median half-life of *pertuzumab* is 18 days; after an initial loading dose, maintenance doses are administered every 3 weeks.

Therapeutic Use

Preclinical studies with HER2-overexpressing human tumor cells grown as xenograft tumors in mice showed that the combination of *pertuzumab* and *trastuzumab* enhanced antitumor activity. In patients with HER2-positive metastatic breast cancer, the addition of *pertuzumab* to *trastuzumab* and *docetaxel* increases the median overall survival by over 1 year from 40.8 months to 56.5 months (Swain et al., 2015). Use of *pertuzumab* is approved for the treatment of patients with HER2-positive, locally advanced, inflammatory, or early-stage breast cancer in combination with *trastuzumab* and *docetaxel*.

Adverse Effects

Cardiotoxicity is similar to that of *trastuzumab*, and combinations with cardiotoxic anthracyclines are not indicated (Slamon et al., 2001). On the other hand, the combination of *pertuzumab* and *trastuzumab* does not cause any increase in cardiac toxicity (Swain et al., 2015). Based on its mechanism of action, *pertuzumab* can cause fetal harm when administered to a pregnant woman, and this risk should be weighed against the potential benefit.

Margetuximab

Margetuximab is a chimeric IgG1-targeting HER2 that was approved in 2020 for the treatment of patients with metastatic HER2-positive breast cancer who had received two or more prior anti-HER2 regimens. It is used in combination with chemotherapy and shares the risk of left ventricular dysfunction with *trastuzumab* and *pertuzumab*.

Inhibitors of Platelet-Derived Growth Factor Receptor

Signaling by the platelet-derived growth factor receptor (PDGFR) plays a significant part in mesenchymal biology, including stem cell growth, and is involved in oncogenesis through aberrant cancer cell signaling, modulation of the tumor microenvironment, and facilitation of angiogenesis and metastasis. Small-molecule protein kinase inhibitors, including *imatinib* (see discussion below), have been used in the treatment of patients with gastrointestinal stromal tumors that carry mutations in *KIT* or *PDGFRA* (see Figure 71–2).

Olaratumab

Mechanism of Action

Olaratumab is a human IgG1 monoclonal antibody that binds to PDGFRα and blocks ligand-mediated receptor activation (Tap et al., 2016).

Therapeutic Uses

Olaratumab is indicated, in combination with *doxorubicin*, for the treatment of adult patients with soft-tissue sarcoma with a histological subtype for which an anthracycline-containing regimen is appropriate and which is not amenable to curative treatment with radiotherapy or surgery. Recent studies showed that addition of *olaratumab* to *doxorubicin* doubled the median survival of patients with metastatic soft-tissue sarcoma to 26 months (Judson and van der Graaf, 2016).

Adverse Effects

The most common (≥20%) adverse effects of treatment with *olaratumab* are nausea, fatigue, neutropenia, musculoskeletal pain, inflammation of the mucous membranes (mucositis), alopecia, vomiting, diarrhea, decreased appetite, abdominal pain, neuropathy, and headache. Laboratory abnormalities are lymphopenia, neutropenia, thrombocytopenia, hyperglycemia, elevated activated partial thromboplastin time, hypokalemia, and hypophosphatemia. Other adverse effects include infusion-related reactions (low blood pressure, fever, chills, rashes) and embryofetal harm.

II. Inhibiting Tumor Angiogenesis

HISTORY

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells to permit growth and metastasis. Many tumor types overexpress these angiogenic factors, turning on an "angiogenic switch" whereby the tumor cells adopt an invasive phenotype favoring proliferation of endothelial cells and neovascularization. In 1971, Judah Folkman hypothesized that the growth of solid tumors was dependent on angiogenesis and that blockade of the effects of putative angiogenic factors would be a good treatment modality for human cancers (Folkman, 1971). Folkman's hypothesis proved to be correct and led to the characterization of a number of secreted angiogenic factors, including

vascular endothelial growth factor (VEGF), fibroblast growth factor, transforming growth factor-β, and PDGF. Furthermore, inhibitors of these angiogenic factors have, indeed, become useful therapeutic agents against certain cancers. VEGF is a major driver of angiogenesis, and inhibitors of VEGF signaling comprise an important class of antitumor agents. Most recently, a better understanding of the immunosuppressive features of angiogenesis has prompted the combination of antiangiogenic therapy with immune checkpoint inhibitors to enhance their efficacy, as discussed below (Huinen et al., 2021).

Inhibition of VEGF and the VEGF Receptor Pathway

Vascular endothelial growth factor initiates endothelial cell proliferation and vascular permeability when it binds to a member of the VEGF receptor (VEGFR) family, a group of highly homologous receptors with intracellular tyrosine kinase domains; these receptors include VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4). The binding of VEGF to its receptors activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and antiapoptotic signaling pathways (Nagy et al., 2007). Antibodies targeting VEGF, such as *bevacizumab*, sterically hinder the interaction of VEGF with its receptor. *Aflibercept* acts as a VEGF trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF, basically acting as a "soluble decoy receptor" for VEGF. Several small-molecule drugs that inhibit the protein tyrosine kinase of VEGFR (*axitinib, cabozantinib, lenvatinib, pazopanib*, *sorafenib*, *sunitinib*, and *tivozanib*; see Chapter 71) as well as monoclonal antibodies that target the receptor (*ramucirumab*) have been approved for clinical use. The inhibition of endothelial function by these different approaches results in a similar spectrum of mostly cardiovascular adverse effects.

Bevacizumab

Mechanism of Action

Bevacizumab is a humanized monoclonal IgG1 antibody that binds to VEGF; the antibody contains the antigen-recognition domain of a murine antibody inserted into a human IgG1. *Bevacizumab* prevents the interaction of VEGF with its receptors on the surface of endothelial cells and inhibits receptor signaling that normally increases vascular permeability and angiogenesis. *Bevacizumab* delays progression of renal cell carcinoma (RCC) and, in combination with cytotoxic chemotherapy, is approved in the treatment of patients with mCRC, non–small cell lung cancer (NSCLC), and ovarian or cervical cancer, and also following initial therapy, in patients with glioblastoma, and in combination with *atezolizumab* (anti-PD-L1, see below) for the treatment of unresectable or metastatic hepatocellular carcinoma.

ADME

Bevacizumab is administered intravenously as a 30- to 90-min infusion every 2 weeks in patients with metastatic colon cancer and, in conjunction with combination chemotherapy, in patients with nonsquamous metastatic NSCLC every 3 weeks with chemotherapy. The antibody has a plasma half-life of about 20 days (range, 11–50 days).

Therapeutic Use in Cancer

Bevacizumab is indicated as treatment of various cancers, frequently in combination with other drugs. In metastatic colon cancer, the addition of *bevacizumab* to either FOLFOX (*folinic acid* [*leucovorin*], *5FU*, and *oxaliplatin*) or FOLFIRI (see Chapter 70) increases patient median survival by about 5 months (Hurwitz et al., 2004). In NSCLC, the addition of *bevacizumab* to *carboplatin* and *paclitaxel* increases median survival by about 2 months. Also approved are combinations of *bevacizumab* with cytotoxic chemotherapy in patients with cervical or ovarian cancer and used rarely as a combination with interferon (IFN)-α for the treatment of metastatic RCC. For glioblastoma, *bevacizumab* is approved as a single agent following prior therapy.

Other Therapeutic Uses: Wet Macular Degeneration

Vascular endothelial growth factor is an important mediator of pathologic vascular permeability. Intravitreous administration of anti-VEGF–targeted therapy has become a standard treatment of wet macular degeneration (see also Chapter 74). *Bevacizumab* and a modified fragment of *bevacizumab*, *ranibizumab*, are used. *Ranibizumab* is derived from the *bevacizumab* IgG1 by deletion of the Fc domain and changes in six amino acids in the antigen-recognition domain to increase affinity for VEGF. *Brolucizumab*, a humanized single-chain antibody fragment against VEGF, is also used for the treatment of wet macular degeneration and delivered by intravitreal injection.

Because these drugs are administered by injection into the vitreous cavity of the eye, few systemic adverse effects are observed. A direct comparison of intravitreous *bevacizumab*, *ranibizumab*, and *aflibercept* (the VEGF trap protein; see discussion that follows) in patients with diabetic macular edema showed that all three treatments improved vision, although *aflibercept* appeared more effective in patients with worse baseline levels of visual impairment (Wells et al., 2015).

Adverse Effects

Bevacizumab causes a wide range of serious class-related adverse effects that include hypertension, gastrointestinal perforation, thromboembolic events, and hemorrhage including epistaxis. A major concern is the potential for vessel injury and bleeding in patients with lung cancer. *Bevacizumab* is contraindicated for patients with a history of hemoptysis, brain metastasis, or a bleeding diathesis. In appropriately selected patients, the predicted rate of life-threatening pulmonary hemorrhage is less than 2%, and for arterial thromboembolism (stroke, myocardial infarction) observed during treatments that include *bevacizumab*, the predicted rate is less than 4%.

Other adverse effect characteristics of drugs that target the VEGF pathway include hypertension and proteinuria. A majority of patients require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment. *Bevacizumab* can be associated with congestive heart failure, probably secondary to hypertension, and with reversible posterior leukoencephalopathy in patients with poorly controlled hypertension. Gastrointestinal perforation, a potentially life-threatening complication, has been observed in up to 11% of patients with ovarian cancer. In patients with colon cancer, colonic perforation occurs infrequently (<1%) during *bevacizumab* treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment. Following colon cancer surgery, patients on *bevacizumab* have a higher rate (13% vs. 3.4%) of serious wound-healing complications. Because of the long $t_{1/2}$ of *bevacizumab*, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should not be resumed for at least 4 weeks after surgery.

Ramucirumab

Mechanism of Action

Ramucirumab is a human IgG1 monoclonal antibody that binds to VEGFR2, blocking the binding of VEGFR ligands and thereby inhibiting ligand-induced activity in endothelial cells.

ADME

Ramucirumab is administered intravenously every 2 to 3 weeks. Its mean half-life is 14 days.

Therapeutic Uses

Ramucirumab is used in combination with chemotherapy for the treatment of patients with mCRC with disease progression on or after prior therapy; as a single agent or in combination with *paclitaxel* for treatment of patients with advanced gastric adenocarcinoma with disease progression on or after prior chemotherapy; and in combination with *docetaxel* for treatment of patients with metastatic NSCLC with disease progression on or after chemotherapy.

Adverse Effects

The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, gastrointestinal perforation, and impaired wound healing.

Aflibercept

Mechanism of Action

Ziv-aflibercept acts as a trap for VEGFR ligands. It is a recombinant fusion protein that contains the extracellular VEGF-binding domain of human VEGFR1/2 fused to the Fc portion of human IgG1. *Ziv-aflibercept* acts as a soluble receptor that binds to human VEGFR ligands with high affinity (K_ds of 0.5–40 pM), reducing their plasma concentrations to levels that are too low for significant activation of their cognate receptors.

ADME

The elimination half-life is about 6 days (range, 4–7 days). *Ziv-aflibercept* is administered by intravenous infusion over 1 h every 2 weeks.

Therapeutic Uses

In combination with FOLFIRI, *ziv-aflibercept* is indicated for patients with mCRC that is resistant to or has progressed following an *oxaliplatin*-containing regimen.

Adverse Effects

The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of *bevacizumab* (anti-VEGF; see previous discussion): increased risk of hemorrhage, gastrointestinal perforation, and impaired wound healing.

III. Activating Immune Cells

HISTORY

The discovery of the T-cell receptor (TCR) and of costimulatory signal pathways in the period from 1982 to 1992 defined essential requirements for T-cell activation during antigen presentation: In addition to the antigen-TCR interaction ("signal 1"), CD28 on T cells binds to B7 proteins on antigen-presenting cells (APCs) ("signal 2"; Figure 72–3; see also Figures 38–2, 38–3, and 38–4). The finding, in the mid-1990s, of coinhibitory molecules that can dampen T-cell activation revealed a potential mechanism for drugs to modulate immune checkpoints and alter anticancer immune activity. Tasuku Honjo and James Allison shared the 2018 Nobel Prize in Physiology or Medicine for "for their discovery of cancer therapy by inhibition of negative immune regulation." TCR activation induces expression of the inhibitory cytotoxic T lymphocyte–associated protein 4 (CTLA-4), a CD28 homolog with higher affinity for the B7 ligands than CD28. CTLA-4 inhibits T-cell activation to control autoimmune tissue damage. Programmed cell death 1 (PD-1), an inhibitory molecule expressed on T cells after activation, and PD-L1, the ligand for PD-1, were described in the early 2000s. It became obvious that T cells present in human tumors were being inhibited by factors in the tumor tissues: T cells isolated from cancer patients and activated exogenously showed antitumor efficacy, paving the way for targeting immune inhibition. Improved survival of patients with metastatic melanoma after anti–CTLA-4 treatment led to FDA approval of *ipilimumab* in 2011; anti–PD-1 drugs *pembrolizumab* and *nivolumab* were approved in 2014 for the treatment of patients with metastatic melanoma. Clinical trials in multiple types of cancer have been ongoing since then and have led to the approval of immune checkpoint inhibitors for more than 20 additional indications as described in this section. Milestones in the discoveries and more details can be found in a review by Korman et al. (2021).

Immune Checkpoint Inhibitors

Recent striking successes of cancer immunotherapy have given credence to the long-held hope that the immune system may be unleashed to treat cancer. The conceptual breakthrough is based on the discovery of inhibitory signals that limit T cell activation, so-called immune checkpoints. The discovery of receptors, ligands, and their function in the control of immune cell activity during the past two decades led to the development of clinically effective monoclonal antibodies that enable antitumor T cells to eradicate cancer cells with acceptable adverse effects (Figure 72–3).

Blocking immune checkpoints on cytotoxic T cells enables them to eradicate cancer cells that express antigens recognized by the T cells. Sustained eradication of metastatic melanoma in a significant number of patients was an impressive outcome of initial clinical trials with a monoclonal antibody, *ipilimumab*, which is an immune checkpoint inhibitor (Robert et al., 2013). Note that immune checkpoint inhibition is distinct from conventional approaches such as vaccination with a known antigen (to generate T cells that recognize cells expressing the antigen); nonspecific stimulation of T cells; isolation, *ex vivo* expansion, and administration of tumor-infiltrating lymphocytes; or approaches using antigen-responsive T cells that express a specific chimeric antigen receptor (CAR). The different approaches are described next.

Mechanisms of T Cell Activation

Antigen-mediated activation of T cells is initiated by engagement of the TCR with antigen presented on major histocompatibility complex (MHC) protein on the surface of an APC, "signal 1." In addition, engagement of CD28 costimulatory molecules on T cells is required for effective T-cell activation that includes cell proliferation, migration, and production of cytokines. This "signal 2" is provided by B7 surface proteins on APCs, for example, CD80 (B7-1) or CD86 (B7-2) (see Figures 38–4 and 72–3). T-cell activation is tightly controlled by immune-suppressive cells and cytokines as well as by coinhibitory molecules present on T cells themselves, such as CTLA-4 or PD-1 (see Figure 72–3). CTLA-4 is expressed by activated CD4 and CD8 T cells and competes with costimulatory CD28 for binding to the B7 protein ligands. Binding of CTLA-4 to B7 proteins interrupts the initial CD28 costimulatory signals and serves as an early negative regulator of the T-cell activation responses, that is, an *immune checkpoint*. Additional control of T-cell activity is provided by later inhibitory signals through other molecules, such as PD-1 that binds the ligand PD-L1. PD-1 is mainly expressed by activated CD4 and CD8 T cells as well as B cells and macrophages.

Blocking monoclonal antibodies to CTLA-4, PD-1, or PD-L1 are currently used to neutralize coinhibitory receptors during T-cell priming (CTLA-4), to maintain cancer antigen-specific T-cell function, and to provide a sustained T-cell response (PD-1) that includes increased production of cytokines such as tumor necrosis factor-α and IFN-γ, as well as granzyme B. Antibodies that target different checkpoint molecules are discussed in the following sections: *ipilimumab* (anti–CTLA-4); *atezolizumab, avelumab, durvalumab* (anti–PD-L1); *nivolumab, pembrolizumab, cemiplimab, dostarlimab* (anti–PD-1); and *relatlimab* (anti-LAG3).

Inhibitors of CTLA-4

CTLA-4 is upregulated during the antigen priming of T cells and binds B7 on APCs to attenuate the T-cell response and thus reduce the risk for chronic autoimmune-dependent inflammation (see Figure 72–3).

Ipilimumab

Ipilimumab is a human IgG1 monoclonal antibody that binds to CTLA-4 and was the first immune checkpoint inhibitor approved for cancer treatment.

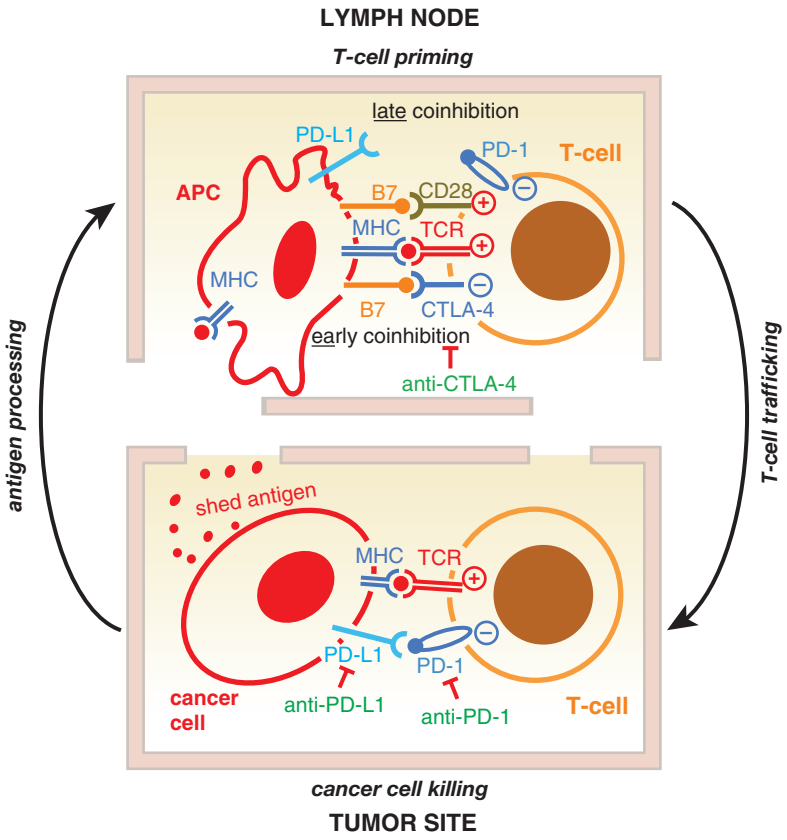

Figure 72–3 *Targeting of immune checkpoints.* Antigens shed from dead cancer cells are captured and processed by APCs. APCs travel to the regional lymph nodes and present the antigen bound to MHC to stimulate TCRs (+). Costimulatory signals leading to T-cell activation are provided by the interaction between CD28 on T cells and B7 (CD80, CD86) on APCs. Inhibitory molecules, including cytotoxic T lymphocyte–associated protein 4 (CTLA-4) and programmed cell death 1 (PD-1), are induced during immune responses and represent a "checkpoint" to dampen T-cell hyperactivation. Sequence homology within the extracellular binding domains of CTLA-4 and CD28 allows binding to the B7 ligands. Higher affinity and avidity of CTLA-4 for the ligands leads to a dampening of the immune response. Human PD-1 is expressed on T cells after TCR stimulation and binds the B7 homologues PD-L1 (B7-H1) and PD-L2 (B7-DC) on APCs but can be induced in nonhematopoietic cells (e.g., by cytokines). Activated T cells also upregulate PD-1 on their surface. (Figures 38–3 and 38–4 show additional details of T-cell activation.)

Activated effector T cells capable of killing cancer cells traffic from the lymph node to the tumor site, where they recognize cancer cells by the interaction of the TCR with the MHC-antigen complex and kill cancer cells through cytolysis (release of perforin and granzyme). This triggers additional antigen release that can induce subsequent rounds of anticancer immunity. Release of IFN-γ upon TCR recognition of the MHC-neoantigen complex induces upregulation of PD-L1 on the surface of tumor cells. PD-L1 binds to PD-1 on the surface of activated T cells, dampening the immune response in the tumor microenvironment.

T-cell checkpoint inhibitors can enhance T-cell priming through blockade of CTLA-4 (*ipilimumab*) or by T-cell activation in the tumor via blocking the PD-1/PD-L1 interaction with antibodies to PD-1 (*cemiplimab, dostarlimab, nivolumab, pembrolizumab*) or PD-L1 (*atezolizumab, avelumab, durvalumab*). Antibodies that block inhibitory immune checkpoints allow a sustained T-cell response that also includes an increased production of cytokines and T-cell proliferation. (Reviewed in Waldman et al. [2020].)

Mechanism of Action

Ipilimumab blocks the interaction of CTLA-4 with B7 ligands on APCs and thereby augments T-cell activation (see Figure 72–3). Inhibition of CTLA-4 signaling can also expand the T-cell repertoire (Cha et al., 2014) and inhibit regulatory T-cell function that dampens cytotoxic T-cell activity and thus increases the antitumor immune response further (Mellman et al., 2011) as well as induce T-cell memory (Felix et al., 2016) that prolongs the immune response.

ADME

Ipilimumab is administered intravenously and shows linear pharmacokinetics in the dose range of 0.3 to 10 mg/kg, with a terminal half-life of 15.4 days.

Therapeutic Uses

A pivotal trial in patients with metastatic melanoma showed improved median overall survival after *ipilimumab* treatment (Hodi et al., 2010). This trial led to FDA approval of *ipilimumab* for the treatment of patients with metastatic melanoma. Further studies showed that some patients had clinical responses that lasted for 10 or more years (Schadendorf et al., 2015). The tumor response can take several months to manifest, and tumors may increase in size during this period, in part due to the evolving inflammatory reaction (Mellman et al., 2011). *Ipilimumab* is approved for treatment of patients with advanced melanoma as a single agent or in combination with *nivolumab*; other approved indications in combination with *nivolumab* are advanced RCC; colorectal cancer with high microsatellite instability (MSI-H) or mismatch repair deficient; pretreated hepatocellular carcinoma; metastatic NSCLC with no EGFR or anaplastic lymphoma kinase (ALK) genomic aberrations; and malignant pleural mesothelioma. Recommended dosing of *ipilimumab* is 3 mg/kg intravenously over 90 min every 3 weeks for a maximum of four doses.

Adverse Effects

Blockade of CTLA-4 compromises immune tolerance to some normal tissue antigens and provokes inflammatory toxicities, mostly in the skin, pituitary gland, thyroid, intestine, and liver. The activation of T-cell responses by *ipilimumab* treatment leads to immune-related toxicities in

the majority of patients (73.6%), with 18.6% reaching grade 3 to 4 toxicity (Callahan et al., 2016). Adverse effects on the skin (pruritus, rash, vitiligo) and gastrointestinal tract (diarrhea, colitis) are the most frequent, whereas immune-mediated hepatitis, hypophysitis, and hypo- or hyperthyroidism are less frequent. Withholding treatment because of moderate adverse reactions until return to baseline and high-dose corticosteroids for severe immune-mediated reactions are recommended (Dougan et al., 2021; Esfahani et al., 2020).

Tremelimumab

Tremelimumab (formerly *ticilimumab*) is a human IgG2 monoclonal antibody that targets CTLA-4; it is under investigation in several clinical trials and received orphan drug designation by the FDA for the treatment of malignant mesothelioma.

Inhibitors of PD-1

Activation of the PD-1 checkpoint pathway in T cells by PD-L1 or PD-L2 evokes a negative regulatory immune response and inactivates T cells (see Figure 72–3). Tumor cells can exploit this pathway by presenting the PD-L1 ligand to tumor-infiltrating T cells and thus shield the tumor from T cell–mediated destruction. Presentation of PD-L1 to activated T cells results in T-cell exhaustion, whereas antibody-mediated blockade of PD-1 can restore or maintain T-cell antitumor response.

Nivolumab

Mechanism of Action

Nivolumab is a human monoclonal IgG4 antibody that blocks the interaction between PD-1 and its ligands.

ADME; Clinical Use

Nivolumab is administered as an intravenous infusion every 2 (or 4) weeks until the time of disease progression or unacceptable toxicity. The drug has an elimination half-life of 26.7 days. *Nivolumab* is FDA approved as a single agent for the treatment of a variety of cancers, including advanced or resected high-risk melanoma, previously treated advanced NSCLC, RCC, advanced head and neck cancer, MSI-H or mismatch repair–deficient colorectal cancer, hepatocellular carcinoma, and relapsed/refractory classical Hodgkin lymphoma. Quite strikingly, *nivolumab* provided an overall response rate of 87% in patients with Hodgkin lymphoma who had failed treatment with *brentuximab vedotin* (see discussion that follows).

Adverse Effects

The most common adverse effect of treatment in patients with melanoma is a rash (>20%); in patients with advanced squamous NSCLC, the adverse effects are fatigue, dyspnea, pneumonitis, musculoskeletal pain, decreased appetite, cough, nausea, and constipation. Immune-mediated adverse reactions are much less common than with CTLA-4 antibodies; corticosteroids are recommended based on the severity of the reaction. For pneumonitis, colitis, hepatitis, nephritis, and renal dysfunction, withhold treatment if the adverse effects are moderate and discontinue treatment if the effects are severe (Dougan et al., 2021; Esfahani et al., 2020).

Pembrolizumab

Pembrolizumab (formerly called *lambrolizumab* or MK-3475) is a humanized monoclonal IgG4κ isotype antibody that blocks interaction between PD-1 and its ligands. This humanized antibody has a mouse variable region grafted onto a human antibody framework and shows high affinity toward PD-1 receptors of humans and other primates but no appreciable affinity for mouse or rat PD-1.

ADME; Clinical Use

The recommended treatment schedule for *pembrolizumab* is 2 mg/kg as an intravenous infusion over 30 min every 3 weeks (or a flat dose of 200 mg every 3 weeks or 400 mg every 6 weeks). The elimination half-life is 26 days. In clinical trials, *pembrolizumab* demonstrated an overall response rate of 26% in patients with *ipilimumab*-pretreated and refractory advanced melanoma (Hamid et al., 2013; Robert et al., 2014). *Pembrolizumab* is more effective and less toxic than *ipilimumab* in patients with either treatment-naïve or BRAF inhibitor–pretreated melanoma. *Pembrolizumab* is currently approved for the treatment of 18 different cancers that include advanced and high-risk and intermediate risk resected melanoma, NSCLC (either prior to or after platinum-containing chemotherapy), head and neck cancer, urothelial cancer, Merkel cell carcinoma, Hodgkin lymphoma, triple-negative breast cancer and intermediate-high risk RCC. The approval for *pembrolizumab* includes any cancer with DNA mismatch repair deficiency or MSI-H that leads to a higher mutation load followed by the generation of mutant protein antigens by cancer cells that can activate the immune system. This first cancer tissue–agnostic approval extends immune checkpoint inhibitor treatment to subsets of patients with hereditary colorectal cancer due to Lynch syndrome (MSI-H) and up to 20% of patients with sporadic colon cancer. The frequency is less in endometrial, ovarian, and pancreatic cancers and requires testing of each patient's tumor to assess suitability of the treatment. More recently, the tissue-agnostic approval for *pembrolizumab* was broadened to advanced cancers with high tumor mutational burdens of 10 or more mutations per megabase, which includes a large fraction of solid tumors, as described in Chapter 69 (see Figure 69–3).

Adverse Effects

The most common adverse effects, experienced by more than 20% of patients, are fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgia, and diarrhea. Serious adverse events include immune-mediated inflammation, specifically pneumonitis, colitis, hepatitis, hypophysitis, and both hyper- and hypothyroidism. Withholding treatment and administration of systemic corticosteroids for grade 2 or higher grade adverse events or discontinuing treatment with more severe adverse effects is recommended. Because human IgG4 can cross the placenta, the benefit from *pembrolizumab* treatment should be balanced with the potential fetal risk in a pregnant woman.

Cemiplimab

Cemiplimab is a human IgG4 monoclonal antibody that binds to PD-1 and blocks the pathway. It was approved in 2018 for treating patients with advanced cutaneous squamous and in 2021 for the treatment of patients with basal cell carcinoma as well as first-line treatment of those with locally advanced or metastatic NSCLC with high PD-L1. Adverse effects are typical for PD-1 blockade and include immune-related inflammation of different organs.

Dostarlimab

Dostarlimab is a humanized IgG4 monoclonal PD-1–blocking antibody approved in 2021 for the treatment of patients with mismatch repair–deficient chemotherapy-resistant endometrial cancer.

Antagonists of PD-L1

Programmed cell death 1 has two known ligands, PD-L1 (B7-H1) and PD-L2 (B7-DC), each with a distinct expression profile. The PD-L1 ligand is expressed on APCs, T cells, B cells, and nonhematopoietic cells, which can include cancer cells (see Figure 72–3). Expression of PD-L2 is restricted to APCs, macrophages, myeloid dendritic cells, and mast cells. PD-L1 is expressed in many cancers and thus can suppress the activation of cytotoxic T cells that enter the tumor. Anti–PD-L1 antibodies can block this inhibitory effect and promote an effective antitumor response. *Atezolizumab, durvalumab*, and *avelumab* are approved antibody inhibitors of PD-L1 with similar profiles.

Atezolizumab

Mechanism of Action

Atezolizumab, also known as MPDL3280A, is a humanized IgG1 monoclonal antibody to PD-L1 approved in 2016.

ADME

Atezolizumab is administered as an intravenous infusion over 60 min every 3 weeks. The terminal half-life is 27 days.

Clinical Use

Atezolizumab is approved for the treatment of different advanced or metastatic cancers: urothelial cancer, NSCLC, small cell lung cancer (with *carboplatin* and *etoposide*, see Chapter 70), triple-negative breast cancer (with *paclitaxel*, see Chapter 70), hepatocellular carcinoma (with *bevacizumab*), and melanoma (with *cobimetinib* and *vemurafenib*, see Chapter 71). High PD-L1 expression is a prerequisite for several of these indications.

Adverse Effects

The most common adverse effects in 20% or more of patients with metastatic NSCLC are fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, and constipation. Patients with urothelial carcinoma may report urinary tract infection. Possible immune-related adverse effects include hepatitis, colitis, hypophysitis, thyroid disorders, adrenal insufficiency, and rarely, type 1 diabetes mellitus, pancreatitis, myasthenia gravis, Guillain-Barré syndrome, and ocular inflammation; these may require discontinuation of treatment. Due to potential embryofetal toxicity, female patients should be advised accordingly.

Durvalumab

Durvalumab is a human IgG1κ monoclonal antibody to PD-L1 and was initially approved in 2017 for the treatment of metastatic urothelial cancer. It is currently approved for advanced NSCLC and for first-line treatment of small cell lung cancer (with *etoposide* and either *carboplatin* or *cisplatin*, see Chapter 70).

Avelumab

Avelumab is a human IgG1κ monoclonal antibody to PD-L1 and was approved in 2017 for the treatment of metastatic urothelial and Merkel cell cancer. It is also approved for RCC as first-line treatment in combination with *axitinib*, a VEGFR kinase inhibitor (see Chapter 71).

Combination of Anti–PD-1 and Anti–CTLA-4

Because anti–CTLA-4 and anti–PD-1 target distinct immune checkpoints during T-cell activation, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to effects of single agents (Curran et al., 2010). In patients with advanced melanoma, the combination of *ipilimumab* and *nivolumab* produces a tumor response in more than 50% of the patients, and 5-year overall survival is highest in the combination treatment group, with 52% survival versus 44% with *nivolumab* only and 26% with *ipilimumab* only (Larkin et al., 2019). Immune-related adverse effects are similar, but more frequent than with the single agent, although combination therapy increases the rate of rare but fatal myocarditis (combination 0.17%; nivolumab <0.01%) (Johnson et al., 2016). Autoimmune reactions can be managed by dose delays, glucocorticoid treatment, and immunosuppressant treatment reviewed by Dougan et al. (2021) and Esfahani et al. (2020). Immune checkpoint inhibitors also induce regression of melanoma metastases at intracranial and visceral sites in over half of the patients, and integration of immune checkpoint inhibitors with other treatment approaches for melanoma can further improve this (Atkins et al., 2021; Curti and Faries, 2021). Combinations of immune checkpoint inhibitors with other cancer therapies are being evaluated in numerous international clinical trials and are becoming the standard of care in solid and hematological malignancies (Balogh and Nass, 2019).

Immune Checkpoint Targeting Beyond CTLA-4 and PD-1: Anti-LAG3

LAG3 (lymphocyte activation gene 3), TIM3 (T cell immunoglobulin and mucin domain-3), and TIGIT (T cell immunoreceptor with Ig and ITIM domains) are other cell surface receptors that negatively regulate the responsiveness of immune cells and are thus potential targets for immune modulatory therapies (Kraehenbuehl et al., 2022). LAG3 targeting enhanced anti-PD-1 efficacy in preclinical models and was evaluated recently in a Phase III trial in patients with untreated advanced melanoma. Addition of *relatlimab* (anti-LAG3, human IgG4) to *nivolumab* (anti-PD-1) treatment improved median progression-free survival of the patients from 4.6 to 10.1 months. Adverse events increased in frequency and matched those known for anti-PD-1 treatment (Tawbi et al., 2022). This establishes the validity of dual immune checkpoint inhibition beyond the combination of anti-PD-1 and anti-CTLA-4 discussed above.

Impact of the Microbiome on Immune Checkpoint Inhibitor Therapy

Most recently, the impact of the composition of the gut microbiome on the efficacy of immune checkpoint inhibitor treatment of cancer has become an active area of research. Fecal transplants are one tool applied in ongoing clinical trials and are reviewed by Woelk and Snyder (2021); see also Chapter 6.

Cytokines to Stimulate Immune Responses

Interleukin-2

Of the 70 or so proteins and glycoproteins that are classified as cytokines, only IFN (see Chapters 38 and 39) and interleukin (IL)-2 are in routine clinical use, often for actions against cancer.

Activated $CD4^+$ T cells are the primary producers of IL-2. The functions of IL-2 are myriad; among other roles, IL-2 promotes the growth of T cells and natural killer (NK) cells, stimulates the proliferation of and antibody production by B cells, and drives the development of regulatory T cells (mediators of tolerance and suppression). As noted by Liao and colleagues (2013), "IL-2 has broad essential biological actions, not only driving T cell proliferation and modulating effector cell differentiation, but also limiting potentially dangerous autoimmune reactions." This statement provides a general rationale for the clinical use of IL-2 and the likelihood that IL-2 administration might also engender adverse effects.

Mechanism of Action

Interleukin-2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells.

Interleukin-2 is a 133–amino acid glycoprotein (molecular weight ~15 kDa) produced by activated T cells and NK cells; it promotes activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2 receptor (IL-2R). The receptor comprises three independently expressed membrane monospans, α, β, and γ, which can assemble in several combinations to produce working receptors of varying affinities. These monospans are variously expressed in lymphohematopoietic cells, lack C-terminal protein kinase activities, and transduce signals via coupling to Jak proteins (Figure 72–4). In contrast, nearly all types of cancer cells lack receptor expression and are unresponsive to IL-2.

ADME

Interleukin-2 (as recombinant IL-2, *aldesleukin*) is administered intravenously. The serum $t_{1/2}$ of IL-2 after intravenous administration has an

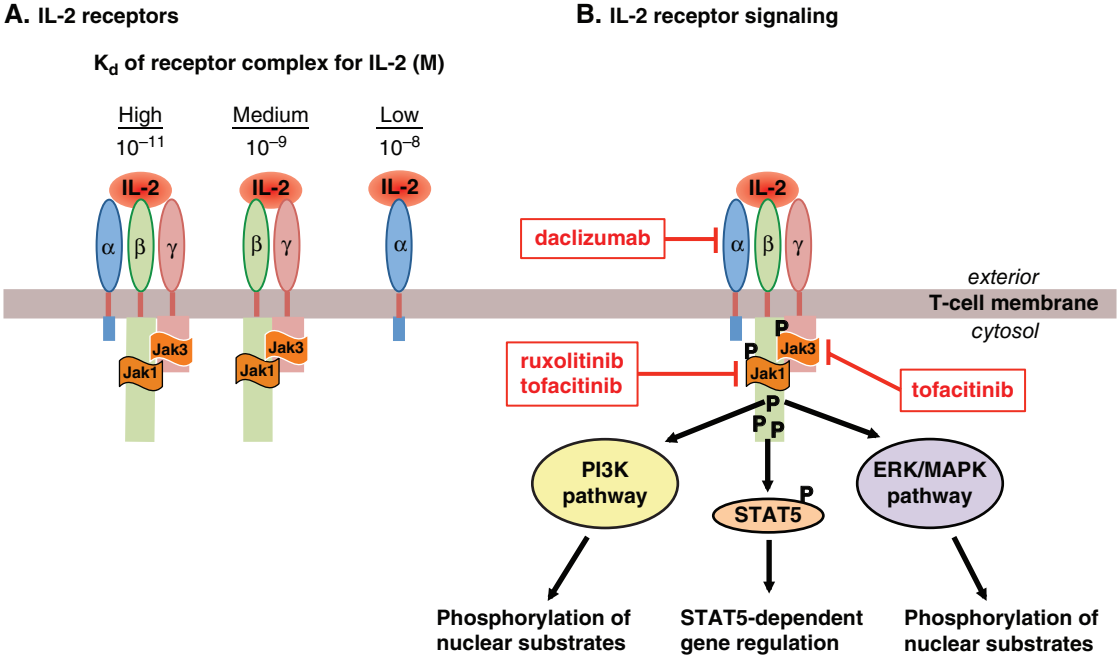

Figure 72–4 *A pharmacologist's view of IL-2 receptors, their cellular signaling pathways, and their inhibition.* **A.** *IL-2 receptors.* The IL-2 receptor has three components: an α chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; a β chain, a 75-kDa protein that binds to Jak1; and a γ chain, a 64-kDa protein that signals via Jak3. These components combine as shown to produce receptors of varying affinities and with different capacities for intracellular signaling. The γ chain is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). Resting T cells have a low density of IL-2Rα; however, activation of the TCR (see Figure 38–2) and IL-2, itself, induce IL-2Rα expression. IL-2Rα can also be induced by a large variety of cytokines, viruses, and activators of protein kinase C. The β and γ monospans are constitutively expressed on many lymphohematopoietic cells, and their expression can also be regulated. Tumor cells generally lack receptor expression and are unresponsive to IL-2. **B.** *IL-2 receptor signaling.* The formation of the quaternary complex of IL-2 and the α, β, and γ units of IL-2R suffice to activate intracellular signaling. The IL-2R monospans shown in **A** lack the protein tyrosine kinase activities common to many monospanning hormone receptors. Rather, these receptors respond to IL-2 binding at the extracellular domain by differentially recruiting Jak1 and Jak3 to their cytosolic domains, Jak1 at IL-2Rβ and Jak3 at IL-2Rγ. Heterodimerization of β and γ cytosolic domains leads to activation of Jak1 and Jak3. The Jaks transactivate and also phosphorylate key tyrosines on IL-2Rβ. These phosphotyrosines (**P**) permit important protein-protein interactions that direct downstream signaling:

- Binding of an SHC adapter/scaffolding protein that is the platform for activation of the Ras/MAPK pathway and the PI3K pathway
- Recruitment and phosphorylation of STAT5 (to a lesser extent STATs 1 and 3), leading to STAT-dependent gene regulation

IL-2/IL-2R signaling can be therapeutically targeted by inhibitors that interact with IL-2Rα, Jak1, and Jak3 (red boxes and T bars), as is discussed in Chapters 39, 71, and 75.

α phase of about 13 min and a β phase of about 90 min. IL-2 is excreted in the urine as an inactive metabolite.

Therapeutic Uses

Aldesleukin possesses the biological activities of native human IL-2. The drug is approved for use in patients with metastatic RCC and metastatic melanoma. High-dose IL-2 produces an overall response rate of 15% to 25% in patients with RCC; 8% achieve a complete response. In patients with metastatic melanoma, high-dose IL-2 induces an overall response rate of 16% to 22%, and 6% achieve a complete response. In both instances, responses last a median of about 5 years. Low-dose IL-2 also produces responses, but few are complete responses, and the duration appears less than with high-dose IL-2.

Adverse Effects

Interleukin-2 toxicities are dominated by the capillary leak syndrome, in which intravascular fluid leaks into the extravascular space, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems. Other adverse effects include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, lymphopenia and eosinophilia. Most patients develop a pruritic skin rash. Hypothyroidism may occur. Cardiac arrhythmias are a rare complication. These toxicities can be life threatening, yet nearly all are reversible within 24 to 48 h of discontinuing therapy. Patients should have normal renal and hepatic function, adequate respiratory reserve (FEV1 > 2 L), and a normal exercise tolerance test before beginning therapy and should be closely supervised in an inpatient facility capable of care at the intensive care unit level during drug administration.

IV. Targeting Cancer Cell Surface Molecules to Engage Immune Cells

HISTORY

The first therapeutic antibody approved for oncology patients in 1997, *rituximab*, is a chimeric mouse/human monoclonal antibody that binds to the CD20 surface antigen on B cells and has improved outcomes for patients with B-cell malignancies. CD20 is a glycosylated tetra-transmembrane phosphoprotein with intracellular N- and C-terminal regions and a small and a large extracellular loop expressed on developing B cell and many B-cell malignancies. *Rituximab* binds to the large extracellular loop, whereas *ofatumumab*, approved in 2009, binds to a distinct epitope on the large extracellular loop as well as sites on the small loops. *Obinutuzumab*, approved in 2013, is derived from *rituximab* with modifications of its glycosylation to

improve immune effector effects. *Bi*specific *T*-cell–*e*ngaging (BiTE) antibody targeting of cancer cell surface molecules is based on antibody engineering concepts that won first approval with *blinatumomab* in 2014: *Blinatumomab* bridges cytotoxic T cells and cancer cells independent of MHC-bound antigen recognition. BiTE antibodies are under development for the treatment of a range of cancers; other bifunctional antibody approaches under development have been reviewed by Goebeler and Bargou (2020). See also Chapter 38.

CD19, CD20, CD52, CD38, CCR4, GD2, and SLAMF7

Rituximab (CD20)

Rituximab is a chimeric murine/human monoclonal IgG1 antibody that targets the CD20 B-cell surface antigen. On binding to the large extracellular loop of CD20, *rituximab* mediates B-cell lysis mostly through CDC and ADCC. In patients with non-Hodgkin lymphoma (NHL), administration of *rituximab* depletes circulating and tissue-based B cells within the first 3 weeks, with sustained depletion for 6 to 9 months after treatment in a majority of patients. Median B-cell levels return to normal by 12 months.

ADME

The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy. *Rituximab* has a $t_{1/2}$ of about 22 days. As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3 to 6 months. In combination regimens, the drug may be administered every 3 to 4 weeks, with chemotherapy, for up to eight doses. The rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Pretreatment with antihistamines, *acetaminophen*, and glucocorticoids decreases the risk of hypersensitivity reactions. Patients with large numbers of circulating tumor cells (as in chronic lymphocytic leukemia [CLL]) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m^2 on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis.

Therapeutic Uses

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with chemotherapy for the initial treatment of diffuse large B-cell lymphoma. *Rituximab* improves response rates when added to combination chemotherapy for other indolent B-cell NHLs, including CLL, mantle cell lymphoma, Waldenström macroglobulinemia, and marginal zone lymphomas. Maintenance of remission with *rituximab* delays time to progression and improves overall survival in indolent NHL. It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease, and multiple sclerosis.

Resistance and Adverse Effects

Resistance to *rituximab* may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels. Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation may predict the clinical response to *rituximab* monotherapy in patients with follicular lymphoma but not in CLL. *Rituximab* infusion reactions can be life threatening, but with pretreatment, reactions are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. *Rituximab* may cause reactivation of hepatitis B virus or, rarely, JC (John Cunningham) virus (with progressive multifocal leukoencephalopathy). Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may appear 1 to 5 months after administration.

Ofatumumab (CD20)

Ofatumumab is a human IgG1 that binds to CD20 at sites on the large and small extracellular loops of CD20, distinct from the site targeted by *rituximab*. Antibody binding results in B-cell lysis via CDC and ADCC. *Ofatumumab* is approved for treating patients with CLL after failure of *fludarabine* and *alemtuzumab* (see below). A complex dosing scheme is used, beginning with small (300-mg) doses on day 1, followed by higher doses (up to 2 g per week) later. *Ofatumumab*'s primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored in hepatitis B carriers.

Obinutuzumab (CD20)

Obinutuzumab is a humanized IgG1 that binds to CD20. Antibody binding mediates B-cell lysis through CDC and ADCC. Glycosylation of the Fc portion of *obinutuzumab* is altered to enhance binding of effector immune cells. This is the first glycoengineered antibody approved by the FDA and is used for the treatment of patients with CLL and follicular lymphoma in combination with chemotherapy.

Alemtuzumab (CD52)

Alemtuzumab is a humanized IgG1 that binds to CD52 found on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most B and T cell lymphomas. Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a potential target for unconjugated monoclonal antibodies. *Alemtuzumab* can induce tumor cell death through ADCC and CDC.

ADME

Alemtuzumab is administered intravenously in dosages of 30 mg/day, three times per week. Premedication with *diphenhydramine* and *acetaminophen* should precede drug infusion. Dosing should begin with a low-dose infusion, followed by an increased dose 2 days later and, if well tolerated, the highest dose 2 days later. The drug has an initial mean $t_{1/2}$ of 1 h, but after multiple doses, the $t_{1/2}$ extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment.

Therapeutic Uses

Alemtuzumab is approved as a single agent for the treatment of B-cell CLL. Clinical activity has been demonstrated in both B and T cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogues. In chemotherapy-refractory CLL, overall response rates are about 40%, with complete responses of 6% in multiple series. Response rates in treatment-naïve patients with CLL are higher (overall response rates of 83% and complete responses of 24%). *Alemtuzumab* is also approved for the treatment of patients with relapsing forms of multiple sclerosis under a different label.

Adverse Effects

Serious toxicities include acute infusion reactions and depletion of normal neutrophils and T cells. Myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or autoimmune responses. Immunosuppression leads to a significant risk of fungal, viral, and other opportunistic infections, particularly in patients who have previously received purine analogues. Patients should receive prophylaxis against *Pneumocystis carinii* and herpesvirus during treatment and for at least 2 months following therapy with *alemtuzumab*. Because reactivation of cytomegalovirus infections

may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. $CD4^+$ T-cell counts may remain profoundly depleted (<200 cells/μL) for 1 year.

Tafasitamab (CD19)

Tafasitamab is directed to CD19, a B-cell surface antigen, and carries a modified Fc domain (IgG1/2 hybrid) to enhance Fc-mediated cytotoxic function (ADCC and ADCP) toward B-cell malignancies. It was approved in 2020 for use in combination with *lenalidomide* (see Chapter 71).

Naxitamab (GD2)

Naxitamab is a humanized IgG1 that binds to the sialic acid–containing glycosphingolipid GD2 (disialoganglioside) overexpressed on the surface of neuroblastoma and other peripheral and central nervous system neuroectodermal cells. Binding to GD2 induces cell death through CDC and ADCC. *Naxitamab* was approved in 2020 for the treatment of relapsed neuroblastoma in combination with granulocyte-macrophage colony-stimulating factor (GM-CSF). Severe neurotoxicity, including neuropathic pain, is a potential adverse effect.

Dinutuximab (GD2)

Dinutuximab is a chimeric human/mouse IgG1 that targets GD2 and has a similar activity and adverse effect profile as *naxitamab* (above). It is used in combination with GM-CSF, IL-2, and retinoic acid (RA) for the treatment of neuroblastoma.

Daratumumab (CD38)

Daratumumab is a human IgG1 that binds to CD38, a transmembrane glycoprotein expressed on the surface of hematopoietic cells, including multiple myeloma (MM); binding to CD38-expressing tumor cells induces cell death through CDC and ADCC. *Daratumumab* was approved for the treatment of patients with MM in combination with other agents such as *lenalidomide* or *bortezomib* and *dexamethasone* (see Chapter 71). The most frequent adverse effects are upper respiratory tract infection, neutropenia, and thrombocytopenia.

Isatuximab (CD38)

Isatuximab is a chimeric human/mouse IgG1 that binds to CD38 with an activity profile and adverse effects similar to *daratumumab* (see above). It was approved in 2020 for the treatment of patients with MM.

Elotuzumab (SLAMF7)

Elotuzumab is a humanized IgG1 that targets SLAMF7 (CD319), a cell surface glycoprotein expressed on MM and NK cells. Binding of *elotuzumab* to the antigen on myeloma cells induces ADCC-dependent tumor cell lysis. ADCC is enhanced by stimulation of the SLAMF7 pathway in NK cells by *elotuzumab*. It is approved for the treatment of patients with MM who have received one to three prior therapies and used in combination with *lenalidomide* and *dexamethasone*.

Mogamulizumab (CCR4)

Mogamulizumab is a humanized IgG1 antibody that targets CCR4, a G protein–coupled receptor that regulates trafficking of lymphocytes and is expressed in some T-cell malignancies. It was approved in 2018 for treatment of relapsed or refractory mycosis fungoides and Sézary disease, types of cutaneous T-cell lymphomas. Adverse effects include moderate to severe rashes and potential bone marrow suppression.

Bispecific Antibodies: CD19 and CD3; EGFR and MET

The introduction of *blinatumomab*, discussed below, opened a distinct category—BiTE antibody targeting of cancer cell surface molecules. Notably, *blinatumomab* bridges cytotoxic T cells and cancer cells independent of MHC-bound antigen recognition. *Amivantamab* is a recently approved bispecific antibody that targets two receptors on cancer cells, EGFR and MET (mesenchymal-epithelial transition factor), and is discussed further below. Bifunctional antibody approaches under development are reviewed by Goebeler and Bargou (2020).

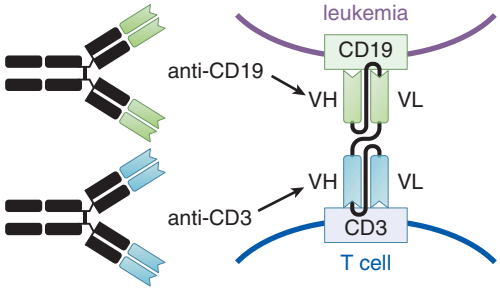

Figure 72–5 *The bispecific T-cell–engaging (BiTE) fusion antibody, blinatumomab.* *BiTE* consists of the VL and VH domains of an anti-CD19 IgG joined via an amino acid link with the VL and VH domains of an anti-CD3 IgG, resulting in a molecular mass of 54 kDa (IgGs are ~150 kDa). The bispecific antibody generates a "synapse" between cytotoxic T cells and leukemia cells that express CD19 on their surface.

Blinatumomab (CD19 and CD3)

Blinatumomab is a first-in-class bispecific antibody that recognizes sites on the surfaces of B cells and T cells, thereby enabling a patient's T cells to recognize malignant B cells (Figure 72–5). To generate this fusion protein, the VH and VL antigen binding domains in IgG1s raised against CD3 (part of the TCR) and against CD19 were isolated. The domains that bind to CD3 were linked to the domains that recognize CD19 on B cells. Due to this bispecific targeting, *blinatumomab* can mediate the formation of a cytotoxic connection between CD19-expressing tumor cells and T cells, resulting in the lysis of CD19-positive cells, release of inflammatory cytokines, and proliferation of T cells. *Blinatumomab* was approved in 2014 for the treatment of acute lymphoblastic leukemia (ALL) including minimal residual disease. Major adverse effects are cytokine release syndrome, neurological toxicities, neutropenic fever, and sepsis.

Amivantamab (EGFR and MET)

Amivantamab is a bispecific IgG1 that binds to the extracellular domains of EGFR and MET. Binding can disrupt ligand signaling through the receptors and initiate targeting of cancer cells by the immune system through ADCC. *Amivantamab* was approved in 2021 for the treatment of patients with locally advanced or metastatic NSCLC with EGFR exon 20 insertion mutations. Adverse effects include pneumonitis, dermatological reactions, and ocular toxicity.

V. Cytotoxin Conjugates With Antibodies or Cytokines

HISTORY

The concept of a "magic bullet," the translation of "Zauberkugel," was introduced by Paul Ehrlich in 1913 to describe his goal of developing cytotoxic drugs that selectively target and destroy cancer cells without impacting healthy tissues. Anticancer drugs developed in the century since Ehrlich's work still aim for this goal (Strebhardt and Ullrich, 2008). The drugs discussed below follow this concept: Cytotoxic drugs are linked to monoclonal antibodies to form antibody-drug conjugates (ADCs) that direct toxic payloads to cancer cells that overexpress the antibody target. Binding of an ADC to the surface antigen

on targeted cells can lead to its internalization, intracellular cleavage of the conjugate, and the release of the cytotoxic payload. This will result in the death of the targeted cancer cells. As a "bystander" effect, the release of the cytotoxic payload may impact cells in the immediate tumor microenvironment for additional therapeutic benefit (Jabbour et al., 2021). For details of ADCs, see Figure 38-10 and Table 38-2.

Antibody-Drug Conjugates (ADCs)

Gemtuzumab Ozogamicin (CD33)

Mechanism of Action

Gemtuzumab ozogamicin is a first-generation humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of *calicheamicin*, a potent antitumor antibiotic that induces double-strand DNA breaks and causes cell death. The CD33 antigen is present on most hematopoietic cells, on more than 80% of acute myelocytic leukemia (AML) cells, and on most myeloid cells in patients with myelodysplastic syndrome. Other normal cell types lack CD33 expression, making this attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, *gemtuzumab ozogamicin* undergoes endocytosis; cleavage of *calicheamicin* from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death. *Ozogamicin* is conjugated to *gemtuzumab* through surface lysine residues (see Figure 72–1) at an average ratio of two to three cytotoxic molecules per antibody.

ADME

The antibody conjugate produces a 30% complete response rate in patients with relapsed AML when administered at a dose of 9 mg/m^2 for up to three doses at 2-week intervals. The $t_{1/2}$ of total and unconjugated *calicheamicin* are 41 and 143 h, respectively. Following a second dose, the $t_{1/2}$ of drug-antibody conjugate increases to 64 h. Most patients require two to three doses to achieve remission.

Therapeutic Use

The drug was initially approved in 2000, withdrawn due to toxicity, and approved in 2020 for CD33-positive AML. Primary toxicities include myelosuppression and hepatocellular damage in 30% to 40% of patients, manifested by hyperbilirubinemia and enzyme elevations. This agent also causes a syndrome that resembles hepatic veno-occlusive disease when patients subsequently undergo myeloablative therapy or when treatment follows high-dose chemotherapy.

Ado-trastuzumab Emtansine (HER2)

Ado-trastuzumab emtansine is a first-generation antibody-cytotoxic drug conjugate that was approved in 2013. *Ado-trastuzumab-DM1* combines the HER2-targeted properties of *trastuzumab* with the antimicrotubule agent DM1 (derived from *maytansine*), allowing preferential intracellular cytotoxic drug delivery to cancer cells in the treatment of HER2-positive breast cancer. The complex binds to HER2 and enters the cell by receptor-mediated endocytosis. The DM1 (*emtansine*) is conjugated to surface lysine residues on the antibody (see Figure 72–1) and released into the cytosol as the complex is cleaved by proteases in lysosomes. The DM1 disrupts microtubule-dependent events, causing mitotic arrest, disruption of intracellular trafficking, and apoptosis. The adverse effects of treatment include cardiac dysfunction as described for unconjugated *trastuzumab*. Hepatotoxicity is an additional risk as well as bone marrow suppression.

Fam-trastuzumab Deruxtecan (HER2)

Fam-trastuzumab deruxtecan is an HER2-targeted antibody conjugated to a *camptothecin* derivative (topoisomerase I inhibitor) via the hinge cysteine residues (see Figure 72–1). It was approved for the treatment of patients with locally advanced or metastatic HER2-positive breast or gastric cancer in 2019 and 2021, respectively. Interstitial lung disease and pneumonitis, including fatal cases, have been reported as serious adverse effects as well as cardiotoxicity.

Inotuzumab Ozogamicin (CD22)

Inotuzumab ozogamicin is a humanized anti-CD22 antibody-cytotoxic drug conjugate approved in 2017 for the treatment of relapsed or refractory ALL. After binding to CD22-positive tumor cells and cellular uptake, the cytotoxic is released via hydrolytic cleavage. Ozogamicin, a derivative of calicheamicin, binds to the minor grove in DNA, induces double-strand breaks, and causes cell death; conjugation to the antibody is via surface lysine residues (see Figure 72–1). Adverse effects include hepatotoxicity, including hepatic veno-occlusive disease, and bone marrow suppression.

Brentuximab Vedotin (CD30)

Brentuximab vedotin is an anti-CD30 IgG1 monoclonal antibody linked with the microtubule-disrupting agent monomethyl auristatin E (MMAE). CD30 is expressed on a number of malignant cells and is especially prevalent in Hodgkin and anaplastic lymphoma. Binding of the antibody to CD30-expressing cells is followed by internalization and the intracellular release of MMAE via proteolytic cleavage. MMAE disrupts the microtubule network, inducing cell cycle arrest and apoptotic cell death. MMAE is mostly metabolized by CYP3A, and coadministration with CYP3A4 inhibitors will increase exposure to the MMAE toxin. Coadministration with CYP3A4 inducers (e.g., *rifampicin*) reduces exposure. The most common adverse reactions are neutropenia, peripheral sensory neuropathy, fatigue, nausea, anemia, upper respiratory tract infection, diarrhea, pyrexia, rash, thrombocytopenia, cough, and vomiting.

Belantamab Mafodotin (BCMA)

Belantamab mafodotin is a humanized IgG1 targeted to B-cell maturation antigen (BCMA) and conjugated via cysteine residues (see Figure 72–1) to the cytotoxic monomethyl auristatin F (MMAF). Upon binding to BCMA, *belantamab mafodotin* is internalized and MMAF is released. MMAF can bind to tubulin and disrupt the microtubule network and cause cell death. It was approved 2020 for the treatment of patients with relapsed or refractory MM. Adverse effects include damage to the corneal epithelium that impacts vision and may cause loss of vision.

Polatuzumab Vedotin (CD79b)

Polatuzumab vedotin is a CD79b-directed antibody conjugated with the antimitotic MMAE via cysteine residues (see Figure 72–1). It was approved in 2019 for the treatment of patients with relapsed or refractory diffuse large B-cell lymphoma in combination with *bendamustine* (see Chapter 70) and *rituximab*.

Enfortumab Vedotin (Nectin4)

Enfortumab vedotin is a Nectin4-directed antibody conjugated with the antimitotic MMAE via cysteine residues (see Figure 72–1). It was approved in 2019 for the treatment of locally advanced or metastatic urothelial cancer.

Sacituzumab Govitecan (Trop-2)

Sacituzumab govitecan is a Trop-2–directed antibody conjugated to a *camptothecin* derivative (topoisomerase I inhibitor) via the hinge cysteine residues (see Figure 72–1). It was approved in 2020 for the treatment of metastatic triple-negative breast cancer and metastatic urothelial cancer. It can cause severe neutropenia and severe diarrhea.

Moxetumomab Pasudotox (CD22)

Moxetumomab pasudotox is a CD22-directed antibody fused to a truncated form of the *Pseudomonas* exotoxin A. Upon entering cells, the exotoxin inhibits protein synthesis through ADP-ribosylation of elongation

factor 2 and causes cell death. It was approved in 2018 for the treatment of relapsed or refractory hairy cell leukemia.

Radioimmunoconjugates (CD20)

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells. ^{131}Iodine (^{131}I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The γ particles emitted by ^{131}I can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free ^{131}I and ^{131}I-tyrosine into the blood and thus present a health hazard to people in contact with the patient. The β-emitter ^{90}Y (yttrium) has emerged as an alternative to ^{131}I, based on its higher energy and longer path length. Thus, it may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with ^{131}I (tositumomab) or ^{90}Y (ibritumomab). Both drugs have shown response rates in relapsed lymphoma of 65% to 80%. Adverse effects include antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias. Both radioconjugates targeting CD20 on lymphomas have been approved; however, concerns over toxicity have limited their use.

Cytokine-Cytotoxin Conjugates

Tagraxofusp

Tagraxofusp is a fusion protein of human IL-3 and truncated diphtheria toxin that is directed to cells expressing the IL-3 receptor (CD123), where it will inhibit protein synthesis and cause cell death. CD123 is overexpressed in leukemic stem and more differentiated cells from ALL, AML, hairy cell leukemia, and Hodgkin lymphoma as well as plasmacytoid dendritic cell neoplasm, the malignancy it was FDA-approved in 2018. Potentially life-threatening capillary leak syndrome is the major adverse event.

VI. Cellular Therapy and Vaccines

RATIONALE

To meet the challenge of poorly immunogenic cancers, the potential of T-cell–based therapies is harnessed by genetically engineering T cells to redirect them to tumor cell surface antigens (Carpenito et al., 2009). The engineered T cells contain a chimeric antigen receptor (CAR) that consists of the antigen-binding domain of a monoclonal antibody to confer recognition of the targeted tumor antigen coupled to intracellular domains capable of activating T cells (Figure 72–6). When expressed in T cells harvested from the patient, these CARs recognize cell surface antigens and activate T cells independent of antigen presentation by an MHC molecule. In initial studies, CAR-expressing T cells were targeted to NY-ESO-1, a tumor antigen of the cancer/testis family that is highly expressed on many poor-prognosis melanoma cells. The CAR T cells showed long-lasting efficacy (>3 years) in some patients with metastatic melanoma. CAR targeting CD19, a B-cell antigen, also resulted in striking efficacy in patients with B-cell leukemias (Klebanoff et al., 2016). The FDA approved CD19 CAR T cells (*tisagenlecleucel-T*; previously named CTL019) in 2017 based on data showing >80% remission rate for relapsed or refractory B-cell ALL during treatment. Modification of CAR constructs to improve antigen recognition, efficacy, and safety of engineered T cells is an area of active research (Hou, 2021). In addition to this genetic engineering of T cells, the technique of isolating and expanding immune cells that recognize cancer antigens is used in adoptive, cell-based immunotherapy (Restifo et al., 2012).

The names for CAR T-cell therapies contain the syllables "gen" for genetic modification, "leu" for leukocytes as the targeted cell type, and "cel" for cell-based therapy (e.g., tisa*gen*lec*leucel*).

CAR T Cells

Five CAR T therapies have been approved by the FDA, with four of them targeting CD19 in relapsed or refractory B-cell ALL or B-cell NHL and one targeting BCMA. CAR T-cell treatment is not approved for the treatment of central nervous system lymphoma.

Tisagenlecleucel

Tisagenlecleucel, FDA-approved in 2017, was the first CD19 CAR-expressing autologous T cell–based immunotherapy (see Figure 72–6) for the treatment of patients with ALL that is refractory or in second or later relapse. The CAR is composed of a murine single-chain antibody fragment that recognizes CD19 and is fused to intracellular signaling domains from 4-1BB (CD137) and CD3 zeta. The CD3 zeta component is critical for initiating T-cell activation and antitumor activity, while 4-1BB enhances the cell expansion and survival (Ellis et al., 2021). Other CD19-directed CAR T immunotherapies approved since 2017 are *lisocabtagene maraleucel*, *brexucabtagene autoleucel*, and *axicabtagene ciloleucel.*

Adverse Effects

The most common adverse effects of CAR T therapy are cytokine release syndrome (indicated by fever, nausea, headache, rapid heartbeat, low blood pressure, and dyspnea) and potentially life-threatening neurological toxicities. *Tocilizumab*, a humanized IgG1 against the IL-6 receptor, blocks signaling of the IL-6 cytokine that is implicated in the pathogenesis of cytokine release syndrome. IL-6 plays an important role in inflammatory disease and is discussed in Chapter 39; *tocilizumab* is approved for treatment of CAR T cell–induced severe cytokine release syndrome and may be used in combination with corticosteroids.

Resistance to Anti-CD19 CAR T Treatment

Loss of the CD19 antigen is a frequent cause of treatment resistance. Because CD22 expression is typically retained after the loss of CD19 from the tumor cell therapy with anti-CD19, CAR T cells can be used to overcome the resistance (Fry et al., 2018).

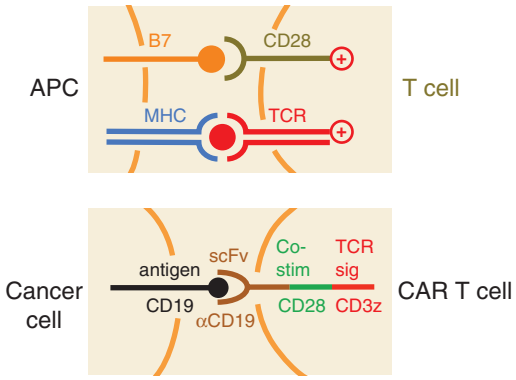

Figure 72–6 *Chimeric antigen receptor (CAR) T-cell activation by a target antigen on cancer cells.* T cells are harvested from a cancer patient and transduced with a CAR expression vector. Elements in a CAR include an extracellular, single-chain antibody fragment of the variable domain (scFv) that recognizes the targeted antigen; intracellular costimulatory domain (e.g., from CD28); and intracellular signaling domain of the TCR. CD19 is shown as an antigen example. APC-mediated stimulation of T cells is depicted for comparison (see Figure 72–3).

Idecabtagene Vicleucel

Idecabtagene vicleucel is an anti-BCMA CAR T immunotherapy that was FDA-approved in 2021 for the therapy of MM.

Sipuleucel-T

Sipuleucel-T is a cell-based approach designed to induce an immune cell response against prostate acidic phosphatase (PAP), which is expressed in most prostate cancers. This cellular immunotherapy is designed to harness a T-cell response from a patient's peripheral blood cells, which are isolated by leukapheresis. The cells are exposed to a human recombinant protein, PAP–GM-CSF. APCs present among the blood cells are thought to take up and process PAP and direct the immune response toward the antigen. A patient receives the treated cells by infusion on three occasions at 2-week intervals. The approach is modeled on adoptive immunotherapy (Restifo et al., 2012). The treatment is approved for patients with minimally symptomatic, hormone-refractory, metastatic prostate cancer. Adverse effects include acute infusion reactions, which can be reduced by premedication with acetaminophen and antihistamine.

Lifileucel

Lifileucel is an adoptive cellular therapy approach that uses tumor-infiltrating lymphocytes isolated from patients. The approach is technically challenging, and clinical trials in patients with melanoma and other cancers in combination with immune checkpoint inhibitors as well as IL-2 are ongoing (Curti and Faries, 2021).

Cancer Vaccines

Vaccination against cancer antigens remains an area of active research. mRNA-based vaccines that code for neoantigens prevalent in a given cancer type or are tailored to the neoantigen composition of each patient's cancer hold significant promise, especially in combination with immune checkpoint inhibitor treatment (Sahin and Türeci, 2018; Sahin et al., 2020). It is noteworthy that the development of mRNA-based approaches in cancer immunotherapy over the past decade (Pastor et al., 2018) was the basis for the rapid generation of highly effective vaccines against COVID-19 that helped to blunt the worldwide pandemic. Currently, only an oncolytic herpesvirus, *T-VEC*, that functions as a cancer vaccine is FDA approved, in this case for the treatment of patients with metastatic melanoma.

T-VEC

T-VEC (*talimogene laherparepvec*) is an oncolytic herpesvirus that replicates within tumors and expresses GM-CSF. Tumor antigens are released after virally induced cell death, and the presence of GM-CSF can promote an antitumor immune response. T-VEC was approved in 2015 for the local treatment of unresectable but injectable cutaneous and nodal lesions in patients with melanoma. T-VEC may synergize with immune checkpoint inhibitor treatment; the combination therapy is under study. Adverse effects are influenza-like symptoms and injection site pain.

VII. Other Proteins

Colony-Stimulating Factors

Many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression can limit the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) has advanced the ability to use combination therapy or high-dose cytotoxic therapy with diminished complications such as febrile neutropenia (see Chapter 70) or erythropenia when treating von Hippel-Lindau (VHL)-related disease using the HIF-2 inhibitor *belzutifan* (see Chapter 71). Chapter 45 presents the basic pharmacology of hematopoietic growth factors.

Asparaginase

L-Asparaginase

Bacterial *L-asparaginase* hydrolyzes the amino acid asparagine. It has been used in the treatment of ALL since initial approval in 1978. Some leukemic cells depend on exogenous asparagine because they lack asparagine synthase and cannot survive asparagine depletion, whereas most normal cells can synthesize asparagine from glutamine. Treatment reduces circulating asparagine levels by greater than 90%. Available formulations of *asparaginase* are isolated from *Escherichia coli*, including a polyethylene glycol modified enzyme with prolonged duration of activity, and the enzyme from *Erwinia chrysanthemi* (approved June 2021) for patients who have developed hypersensitivity to *E. coli*–derived *asparaginase*. Adverse reactions include hepatic toxicity and pancreatitis.

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Section I: Growth Factors and Receptors		
Epidermal Growth Factor Receptor (EGFR)		
Monoclonal Antibody EGFR Inhibitors: Intravenous Administration		
Cetuximab *(chimeric human/mouse IgG1)*	• Metastatic colorectal cancer with wild-type KRAS in combination with chemotherapy • HNSCC in combination with radiation or cisplatin	• Skin rash, diarrhea, interstitial lung disease • Rare: infusion reaction, cardiopulmonary arrest, hypomagnesemia
Panitumumab *(human IgG2)*	• Metastatic colorectal cancer with wild-type KRAS in combination with chemotherapy	• Side effects similar to those of cetuximab
Necitumumab *(human IgG1)*	• Metastatic NSCLC in combination with chemotherapy	• Side effects similar to those of cetuximab
Human Epidermal Growth Factor Receptor 2 (HER2)		
Monoclonal Antibody HER2 Inhibitors: Intravenous Administration		
Trastuzumab *(humanized IgG1)*	• HER2-positive breast cancer and gastric cancer • Combination with taxanes possible as chemotherapy	• Congestive heart failure (<5% reduced LVEF; <1% symptomatic); ↑ to 20% in combination with doxorubicin due to cardiotoxicity; monitor LVEF during and after • Acute infusion reaction, nausea, dyspnea, rashes
Pertuzumab *(humanized IgG1)*	• HER2-positive breast cancer in combination with trastuzumab and taxane	• Targets different HER2 domain than trastuzumab; prevents dimerization with other HERs • Side effects similar to those of trastuzumab
Platelet-Derived Growth Factor Receptor Inhibitors		
Olaratumab *(human IgG1)*	• Soft-tissue sarcoma in combination with doxorubicin	• Nausea, fatigue, gastrointestinal toxicity • Neutropenia, thrombocytopenia, elevated activated partial thromboplastin time, hypokalemia, hypophosphatemia
Section II: Tumor Angiogenesis		
Vascular Endothelial Growth Factor Inhibitors		
Bevacizumab *(humanized IgG1)*	• Metastatic colorectal cancer combined with chemotherapy (FOLFOX or FOLFIRI) • NSCLC combined with carboplatin and paclitaxel • Ovarian cancer combined with chemotherapy • RCC combined with interferon-α • Glioblastoma following prior therapy	• Hypertension, related congestive heart failure: monitor blood pressure and treat hypertension • Impaired wound healing: delay elective surgery for 1 month after the last dose; do not resume treatment for at least 1 month after surgery • Spontaneous gastrointestinal perforation
Ramucirumab *(human IgG1 to VEGFR2)*	• Metastatic colorectal cancer, advanced gastric adenocarcinoma, and NSCLC with disease progression on or after prior therapy as a single drug or in combination with chemotherapy	• Hypertension, diarrhea • Hemorrhage, gastrointestinal perforations • Impaired wound healing
Aflibercept *(extracellular domain of VEGFR1/2 fused to Fc portion of human IgG1)*	• Metastatic colorectal cancer in combination with FOLFIRI chemotherapy following FOLFOX	• Soluble trap for VEGF receptor ligands • Hypertension, diarrhea, impaired wound healing • Increased risk of hemorrhage, gastrointestinal perforation • Pathophysiology: increased circulating extracellular domain of VEGFR and decreased VEGF are hallmarks of preeclampsia
Section III: Activating Immune Cells		
Immune Checkpoint Inhibitors		
Ipilimumab *(anti–CTLA-4 human IgG1)*	• Metastatic melanoma as single agent or in combination with nivolumab (anti-PD-1) • Clinical trials with different cancers are ongoing	• Autoimmune inflammatory toxicities in majority of patients (>70%) • Adverse effects: skin (pruritus, rash, vitiligo), GI tract (diarrhea, colitis) • Less frequent: hepatitis, pneumonitis, hypophysitis, hypo- or hyperthyroidism, myocarditis
Tremelimumab *(anti–CTLA-4 human IgG2)*	• Clinical trials with different cancers are ongoing	• See above

Drug Facts for Your Personal Formulary: *Pathway-Targeted Therapies (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Nivolumab *(anti–PD-1 human IgG4)*	• Advanced melanoma that progressed after ipilimumab (anti–CTLA-4) • Previously treated NSCLC • Advanced RCC • Relapsed/refractory Hodgkin lymphoma	• Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation • Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism
Pembrolizumab *(anti–PD-1 humanized IgG4)*	• Advanced melanoma that progressed after ipilimumab (anti–CTLA-4) • NSCLC that expresses PD-L1 and progressed under chemotherapy • NSCLC with wild-type EGFR and ALK and disease progression after chemotherapy • HNSCC with disease progression after chemotherapy	• Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation • Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism
Atezolizumab *(anti–PD-L1 human IgG1)*	• NSCLC that is treatment resistant • Urothelial cancer that is locally advanced or metastatic	• Adverse effects: fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, constipation • In patients with urothelial cancer: urinary tract infections • Immune-related pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypo- and hyperthyroidism, hypophysitis, adrenal insufficiency, pancreatitis, Guillain-Barré syndrome, severe infections
Section IV: Targeting Cancer Cells to Engage Immune Cells		
Antibodies Targeting Cell Surface Antigens		
Rituximab *(chimeric human/mouse IgG1 anti-CD20)*	• NHL • CLL • Rheumatological and other autoimmune disease, including multiple sclerosis	• Infusion-related toxicity with fever, rash, and dyspnea; B-cell depletion; late-onset neutropenia; risk of hypersensitivity reaction: use slow increase in infusion rate and antihistamines • Rare: severe mucocutaneous skin reaction, including Stevens-Johnson syndrome • Risk of tumor lysis syndrome in patients with high tumor burden in the circulation: use lower dose initially • Reactivation of hepatitis B virus or JC polyomavirus
Ofatumumab *(human IgG1 anti-CD20)*	• CLL after treatment failure	• Immunosuppression and opportunistic infections, hypersensitivity reaction during infusion and myelosuppression: monitor blood counts during treatment
Obinutuzumab *(humanized IgG1 anti-CD20)*	• CLL in combination with chemotherapy	• Frequent adverse effects: cytopenia, fever, cough, musculoskeletal disorders
Alemtuzumab *(Campath* or *Lemtrada; humanized IgG1 anti-CD52)*	• CLL (label: *Campath*) • Multiple sclerosis (label: *Lemtrada*)	• Infusion-related toxicity, T-cell depletion with increased infection; myelosuppression with pancytopenia • Antibiotic prophylaxis
Dinutuximab *(chimeric human/mouse anti-GD2)*	• High-risk neuroblastoma	• Infusion reaction • Nerve damage
Daratumumab *(human IgG1 anti-CD38)*	• MM in combination with lenalidomide or bortezomib	• Infusion reactions • Peripheral sensory neuropathy, upper respiratory tract infection
Elotuzumab *(humanized IgG1 anti-CD319)* (SLAMF7)	• MM after one to three prior therapies	• Infusion reaction
Blinatumomab *(bispecific anti-CD19 and anti-CD3)*	• Ph-negative relapsed or refractory B-cell precursor ALL	• Cytokine release syndrome, neurological toxicity, neutropenic fever

Chapter 73 Hormones, Hormone Receptor Antagonists, and Related Agents in the Therapy of Cancer

Claudine Isaacs, Kerry L. Burnstein, and Anna T. Riegel

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, among other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA (drugs@fda) and the NCCN (National Comprehensive Cancer Network). Table 71–1 provides the details and focuses on the complexities of treatment of two cancers.

Introduction to Hormone-Regulated Cancers

The growth of a number of cancers is hormone-dependent or regulated by hormones. Therapies that employ estrogen and androgen receptor antagonists, steroid hormone synthesis inhibitors, and gonadotropin-releasing hormone (GnRH) analogues or antagonists extend survival and delay or prevent tumor recurrence of both breast and prostate cancer. These molecules interrupt the normal feedback controls regulating steroid hormone synthesis, inhibit androgen and estrogen production, or inhibit binding of these hormones to their cognate receptors, which are ligand-activated transcription factors. By inhibiting the activation and actions of androgen and estrogen receptors, these drugs block or reduce expression of genes and gene networks that ultimately promote tumor growth and survival. Glucocorticoids are used for their antiproliferative and lympholytic properties in hematologic malignancies and, in other oncological settings, to mitigate untoward responses to other treatments as well as some cancer-related symptoms.

The pharmacology of the estrogens and androgens is described in detail in Chapters 48 and 49. Decreasing the actions of these steroid hormones is the therapeutic goal in certain cancers, most notably those of the prostate and breast, because these organs are dependent on steroid hormones for their growth, function, and morphological integrity.

Endocrine Therapy of Breast Cancer

The presence of the estrogen receptor (ER) and/or progesterone receptor (PR) (ER+/PR+) in female breast cancer tissue identifies the subset of hormone receptor–positive cancers with a greater than 60% likelihood of responding to endocrine therapy. The response rate to antiestrogen treatment is somewhat lower in the subset of patients with tumors that are ER+ or PR+ but also positive for human epidermal growth factor receptor (HER2)/neu amplification. In contrast, ER-negative and PR-negative (ER–/PR–) carcinomas do not respond to endocrine therapy. Antiestrogen approaches for the therapy of ER+/PR+ breast cancer include the use of selective estrogen receptor modulator (SERMs), selective estrogen receptor downregulators (SERDs), and aromatase inhibitors (AIs) (Table 73–1 and Figure 73–1A). Historically, high doses of estrogen have been recognized as effective treatment of breast cancer. The growth inhibitory effect of estrogens may be related to their ability to induce apoptosis in endocrine-resistant breast cancer (reviewed in Jordan, 2015). However, interruption of estrogen-induced signaling with SERMs, SERDs, and drugs that reduce estrogen production such as AIs and GnRH/luteinizing hormone–releasing hormone (LHRH) analogues are more effective and better tolerated. These drugs have largely replaced estrogens or progestins for the treatment of breast cancer, although estrogen and progesterone are used occasionally. Male breast cancer is rare and predominantly (>90%) ER+/PR+. Treatment is directed at inhibiting ER with *tamoxifen*. There is a paucity of data on the use of AIs or SERDs in males.

Initial or acquired resistance to endocrine therapies (*tamoxifen* or AIs) frequently occurs. Multiple mechanisms contribute to endocrine resistance in breast cancer (reviewed in Fan and Jordan, 2019); these mechanisms include loss of ER expression, changes in transcriptional coregulator expression or activity, and hormone-independent activation of the ER by stress kinase or growth factor–activated cellular kinase

Abbreviations

ADT: androgen deprivation therapy
AI: aromatase inhibitor
ALL: acute lymphoblastic leukemia
AR: androgen receptor
AUC: area under the curve
BAT: bipolar androgen deprivation therapy
BCRP: breast cancer resistance protein
CDK: cyclin-dependent kinase
CLL: chronic lymphocytic leukemia
CRPC: castration-resistant prostate cancer
CYP: cytochrome P450
ER: estrogen receptor
ERE: estrogen-response element
FSH: follicle-stimulating hormone
GnRH: gonadotropin-releasing hormone
GR: glucocorticoid receptor
HER: human epidermal growth factor
HL: Hodgkin lymphoma
HR: hormone receptor
LH(RH): luteinizing hormone (–releasing hormone)
MM: multiple myeloma
mTOR: mechanistic (or mammalian) target of rapamycin
NHL: non-Hodgkin lymphoma
OATP: organic anion transporting polypeptide
Pgp: P-glycoprotein
PR: progesterone receptor
PROTAC: proteolysis targeting chimeras
SERD: selective estrogen receptor downregulator
SERM: selective estrogen receptor modulator
UGT: UDP-glucuronosyltransferase

pathways. In particular, cross talk between the ER and the HER2/neu pathway has been implicated in *tamoxifen* resistance. In a significant portion of metastatic breast cancers, estrogen deprivation therapy can lead to selection of cancer cells expressing an ER with mutations that allow hormone-independent activation. Acquired ER mutations also contribute to endocrine therapy–resistant breast cancer growth (reviewed in Jeselsohn et al., 2017). Targeting endocrine-resistant disease harboring ER mutations with SERDs and SERMs is an active area of drug investigation and development (reviewed in McDonnell et al., 2021).

Androgen Deprivation Therapy of Prostate Cancer

Androgens are essential for the development and maintenance of the prostate gland. The critical role of androgens in promoting prostate cancer growth was demonstrated in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles Huggins. Huggins's findings established androgen deprivation therapy (ADT) as the mainstay of treatment for patients with advanced prostate cancer, an approach still used today. ADT is accomplished by surgical castration (bilateral orchiectomy) or "medical" castration, using long-acting GnRH agonist formulations to downregulate GnRH receptors in the anterior pituitary or with GnRH antagonists that directly block GnRH receptor-ligand interaction to achieve more rapid suppression of the major circulating androgen, testosterone (Table 73–2 and Figure 73–1B). ADT results in castrate levels (≤50 ng/dL) of testosterone and hence subsequent reduction of the testosterone metabolite, dihydrotestosterone, which binds with highest affinity to the androgen receptor (AR). Thus, ADT limits the action of the AR in prostate and other sensitive tissues (see Chapter 49).

In localized, high-risk or advanced prostate cancer (prior to metastasis or after metastatic progression), the combination of ADT and AR antagonists or androgen synthesis inhibitors is the standard of care but not a curative treatment. Disease progression commonly occurs despite this "combined androgen blockade" and signifies the development of castration-resistant prostate cancer (CRPC). In CRPC, the target of combined androgen blockade, AR, is typically "reactivated" through a variety of mechanisms (reviewed in Desai et al., 2021; Einstein et al., 2019; Luo et al., 2018; Nakazawa et al., 2017) including increased AR levels, expression of constitutively active AR splice variants that lack the ligand binding domain, or acquisition of somatic *AR* gene gain-of-function mutations that render AR promiscuous for activation by other steroid hormones (including weak adrenal androgens or glucocorticoids) and, in rare cases, by AR antagonists. Increased expression or activity of AR coactivators and pioneer transcription factors (e.g., FOXA1) or decreased AR corepressor proteins may also participate in continued AR activity in CRPC. Another mechanism that may drive persistent AR signaling in CRPC is local production of sufficient quantities of androgens by CRPC tumors to activate AR. Therefore, second-generation, highly potent AR antagonists and inhibitors of androgen synthesis are employed concurrently with GnRH agonists or antagonists as frontline or second-line therapies following progression to CRPC (reviewed in Mitsiades and Kaochar, 2021). Combining ADT with a newer generation AR antagonist or an androgen synthesis–directed drug is associated with improvements in symptoms and prolongation of survival.

Use of Glucocorticoids in Hematological Malignancies

Glucocorticoids act by binding to a specific glucocorticoid receptor (GR) that is a member of the nuclear receptor family of transcription factors. Agonist-liganded GR translocates to the nucleus and induces complex gene expression changes (see Chapter 50) that lead to antiproliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in 30% of children. However, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. Thus, therapy is initiated with *prednisone* and *vincristine* (see Chapter 70), often followed by an anthracycline or *methotrexate* (see Chapter 70), and *L-asparaginase* (see Chapter 72). Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin disease, non-Hodgkin lymphoma, multiple myeloma, and chronic lymphocytic leukemia (CLL). Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

Endocrine Therapy for Other Malignancies

Endocrine therapies are occasionally used in other malignancies. *Tamoxifen* and *medroxyprogesterone acetate* have activity in metastatic endometrial carcinoma, particularly in low-grade tumors. Use of endocrine therapy in ovarian cancer has also been considered.

Drugs That Target GnRH/LHRH

GnRH Agonists

Synthetic GnRH analogues (e.g., *triptorelin*, *goserelin*, *leuprolide*, *histrelin*, and *nafarelin*) have amino acid substitutions at key residues of the

TABLE 73–1 ESTROGEN RECEPTOR (ER)–TARGETED THERAPY IN ER+ BREAST CANCER

DRUG (DAILY STANDARD DOSE)	THERAPEUTIC APPROACH IN DISEASE SETTING					
	CHEMOPREVENTION		ADJUVANT THERAPY		METASTATIC DISEASE	
	PREMENOPAUSAL	POSTMENOPAUSAL	PREMENOPAUSAL	POSTMENOPAUSAL	PREMENOPAUSAL	POSTMENOPAUSAL
Tamoxifen (20 mg PO)	Yes (5 years)	Yes (5 years)	Yes (5–10 years)	Yes (before AI for 2–5 years)	Yes	Yes
Raloxifene (60 mg PO)		Yes (5 years)				
Fulvestrant (500 mg IM day 1, day 15, day 29, then once per month)						Yes
Anastrozole (1 mg PO)		Yes (5 years)		Yes (5–10 years) (up front or after tamoxifen)		Yes
Letrozole (2.5 mg PO)				Yes (5–10 years) (up front or after tamoxifen)		Yes
Exemestane (25 mg PO)		Yes (5 years)		Yes (5–10 years) (up front or after tamoxifen)		Yes
GnRH agonist in addition to one of above given monthly			Yes (with tamoxifen or AI)		Yes (with tamoxifen, AI, or fulvestrant)	

naturally occurring decapeptide GnRH that increases analogue binding affinity to the GnRH receptor and reduces susceptibility to enzymatic degradation. These GnRH agonists are 100-fold more potent than the native decapeptide. Administration of long-acting GnRH agonists downregulates GnRH receptors in the anterior pituitary gland in both women and men.

In women, the downregulation of GnRH receptors suppresses the release of the gonadotropins follicle-stimulating hormone (FSH) and LH from the pituitary and prevents follicular maturation in the ovary. Serum estrogen levels are reduced to those seen in postmenopausal women or in women after oophorectomy. GnRH agonists are used in the adjuvant treatment of breast cancer or metastatic disease for women who have functioning ovaries; typically, they are used in combination with either *tamoxifen* or AIs.

In treating prostate cancer, the most common form of ADT involves chemical suppression of pituitary gland function with long-acting GnRH agonists (*leuprolide*, *goserelin*, *buserelin*). ADT is given to patients with localized intermediate- to high-risk prostate cancer in conjunction with radiation therapy or in some cases following surgical removal of the prostate gland. GnRH agonists cause an initial release of both LH and FSH and a subsequent increase in testosterone production termed "testosterone flare" from testicular Leydig cells. After 1 week of therapy, GnRH receptors are downregulated on the gonadotropin-producing cells, causing a decline in the pituitary response. The fall in serum LH leads to a decrease in testosterone production to castrate levels within 3 to 4 weeks of the first treatment. Subsequent treatments maintain testosterone at castrate levels.

ADME

GnRH agonists are administered as an injection once a month or every 3, 4, or 6 months. There is in an initial rise in LH and FSH levels, but after 14 to 21 days of therapy, a sustained decrease in serum LH and estrogen n women or testosterone in men is observed.

Therapeutic Use in Breast and Prostate Cancer. In the adjuvant setting, studies have demonstrated a further reduction in the risk of recurrence when GnRH agonists are given in conjunction with either AIs or *tamoxifen*, when compared to *tamoxifen* alone, in very young or higher-risk premenopausal women (Pagani et al., 2020). In addition, these drugs can be given with *tamoxifen*, AIs, or *fulvestrant* in premenopausal women with metastatic breast cancer. In men with metastatic prostate cancer, ADT may be used in conjunction with chemotherapy (e.g., *docetaxel*). Alternatively, ADT is typically combined with potent newer generation AR antagonists or the androgen synthesis inhibitor *abiraterone acetate* in what is referred to as "combined androgen blockade." The advantage of combined androgen blockade is that the GnRH agonist (or GnRH antagonist) will deplete testicular androgens, while the competitive AR antagonist component competes at the AR with residual androgens made by the adrenal glands. When the steroid synthesis inhibitor *abiraterone* is used for combined androgen blockade, there is a decrease in androgens made by the adrenal glands. Numerous trials showed a benefit in survival in metastatic castration-sensitive prostate cancer following ADT combined with either *abiraterone* or *docetaxel*, but these treatments are associated with higher costs (and, in the case of *docetaxel*, significantly higher toxicities) compared to ADT alone (Wang L et al., 2021).

Toxicity

Side effects in women are generally related to hypoestrogenism (i.e., hot flashes, vaginal dryness, decreased libido, osteoporosis, amenorrhea, and dyspareunia). The side effects of GnRH agonists are often reversible on cessation of therapy. AI use in premenopausal women combined with ovarian suppression with GnRH analogues increases menopausal symptoms and sexual dysfunction, and thus, benefits and risks should be carefully considered with each patient (Burstein et al., 2016).

In men, during the transient rise in LH, the resultant testosterone surge or "flare" may induce acute stimulation of prostate cancer growth

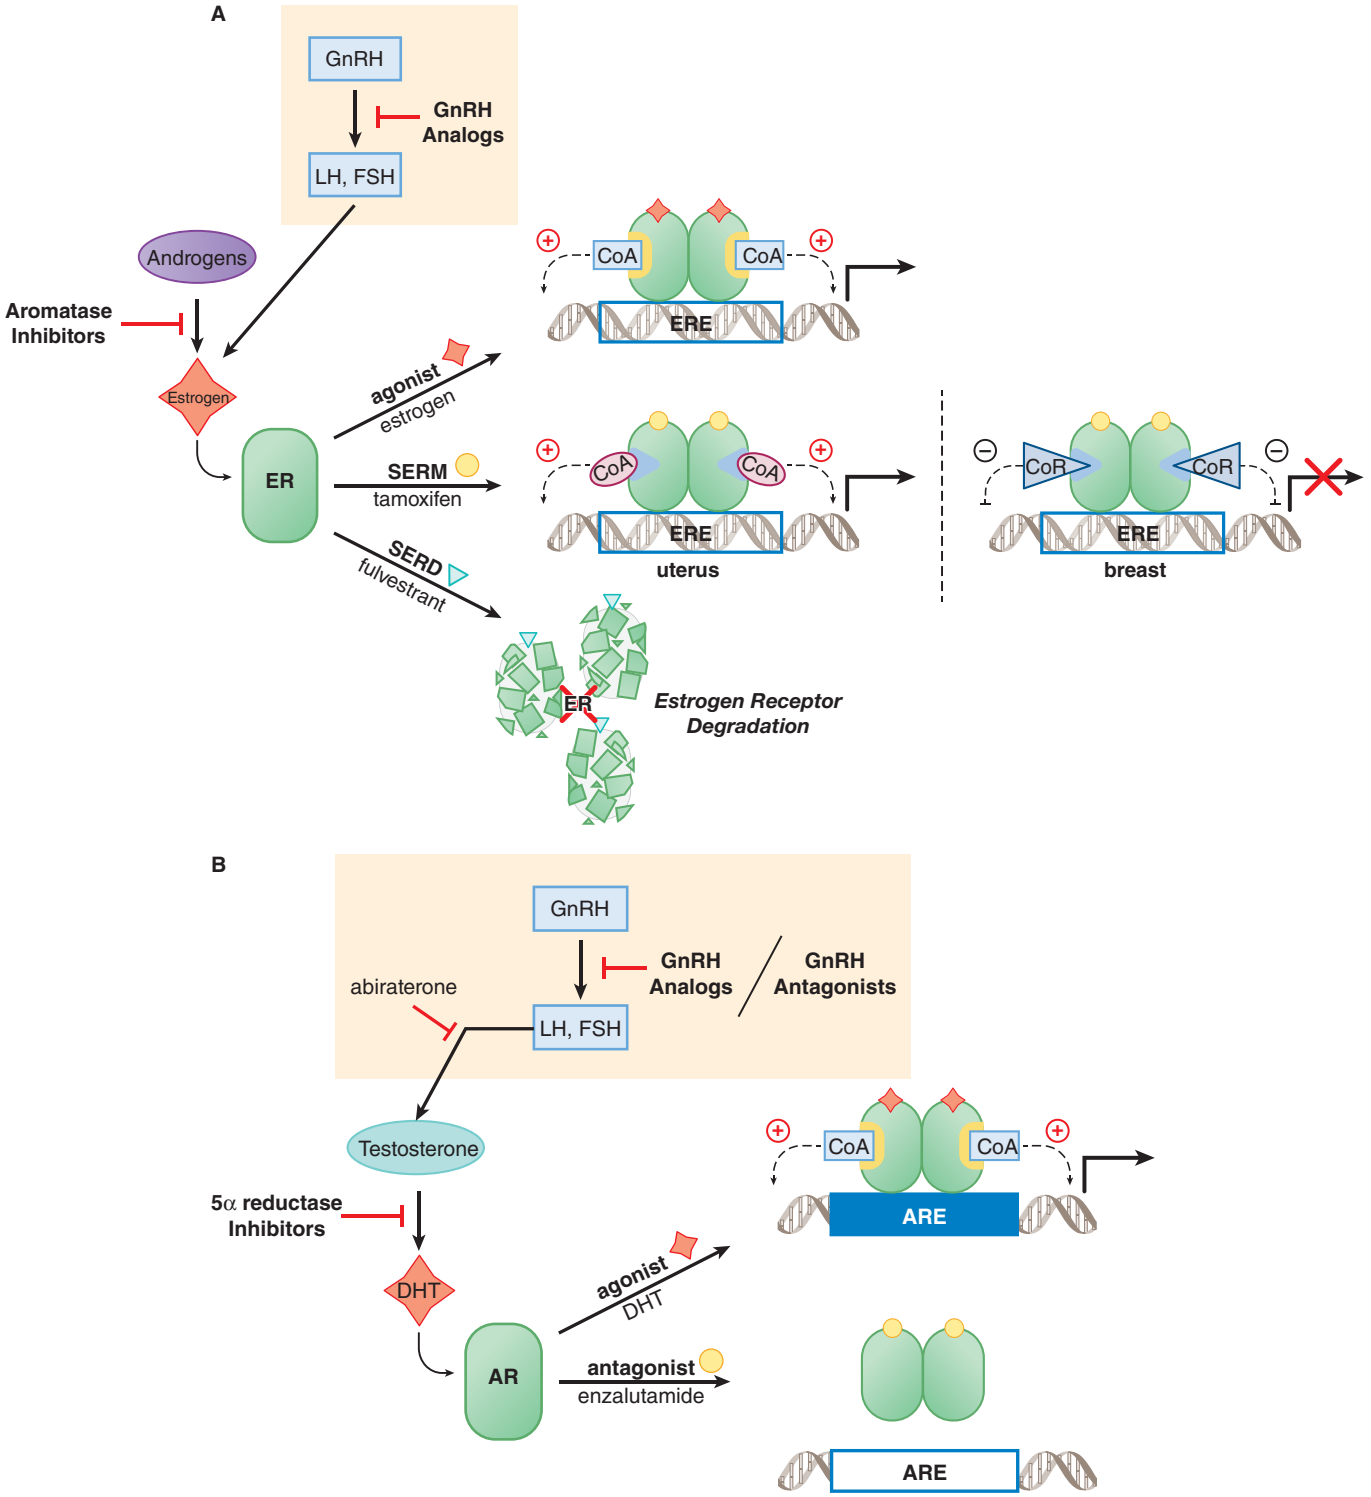

Figure 73–1 **A.** *Targets of agents that interrupt estrogen receptor signaling in females.* GnRH promotes the release of LH and FSH (Figure 46–1), which regulate ovarian production of estrogen and progesterone and can stimulate estrogen production. Aromatase converts the estrogen precursors androstenedione, dihydroepiandrostenedione, and testosterone to estrogens (see Figures 48–1 and 48–2). Estrogen signaling can be interrupted by inhibiting hormone production (GnRH analogues, aromatase inhibitors), by antagonizing the effects of estrogen at the estrogen receptor (ER) with a SERM, or by destabilizing the ER and promoting its degradation with a SERD (e.g., *fulvestrant*). The effects of SERMs (e.g., *tamoxifen*) on organs are dependent on a number of factors including the activity and relative expression levels of transcriptional coactivators (CoA) and corepressors (CoR) in a particular tissue. In the breast, *tamoxifen* is an antagonist; a corepressor effect on gene transcription predominates. On the other hand, in the uterus, *tamoxifen* can drive estrogenic effects, after binding ER, by utilizing coactivators of gene transcription. **B.** *Targets of agents that interrupt androgen receptor signaling in males.* GnRH promotes the release of LH and FSH, which stimulates adrenal and testicular androgen production. GnRH receptors can be inhibited by long-acting GnRH analogues that downregulate GnRH receptors or by GnRH antagonists. *Abiraterone acetate* is a steroid synthesis inhibitor that blocks the conversion of pregnenolone and progesterone to androgen precursors. Androgen signaling is inhibited by androgen receptor (AR) antagonists (e.g., *enzalutamide*), which competitively bind the AR and inhibit binding and activation by androgens, particularly dihydrotestosterone (DHT). AR bound to *enzalutamide* (instead of DHT) has diminished interaction with coactivators and androgen response elements (AREs) on DNA.

TABLE 73–2 ■ ANDROGEN RECEPTOR–TARGETED THERAPY FOR PROSTATE CANCER

DRUG (DAILY STANDARD DOSE)	CASTRATION-SENSITIVE		CASTRATION-RESISTANT	
	NON-METAST	METAST	NON-METAST	METAST
Bicalutamide (one 50-mg tablet daily in combination with ADT)[a]	Yes	Yes	Yes	Yes
Enzalutamide (four 40-mg tablets once daily)		Yes	Yes	Yes
Apalutamide (four 60-mg tablets once daily)		Yes	Yes	
Darolutamide (two 300-mg tablets twice daily)			Yes	
Abiraterone acetate (4×250 mg or 2×500 mg tablets daily) plus prednisone: 5-mg tablet once daily (metastatic castration-sensitive prostate cancer) or 5-mg tablet twice daily (metastatic CRPC)		Yes		Yes
ADT consisting of bilateral orchiectomy, GnRH agonist, or GnRH antagonist in addition to one of above agents	Yes	Yes	Yes	Yes

Metast, metastatic.

[a]Bicalutamide dose as monotherapy is higher.

and symptoms from stimulation of metastatic deposits in bone. Patients may experience an increase in bone pain, spinal cord compression, or obstructive bladder symptoms lasting for 2 to 3 weeks. The flare phenomenon can be effectively counteracted with concurrent administration of 2 to 4 weeks of oral AR antagonist therapy, which may inhibit the action of the increased serum testosterone levels. Common side effects of ADT include vasomotor instability, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased insulin sensitivity, altered lipid profiles, osteoporosis and fractures, and loss of muscle mass (Formenti et al., 2021). Skeletal-related events due to ADT may be mitigated by bisphosphonate therapy (see Chapter 52). Studies have shown a small but significant increase in the risk of diabetes and coronary heart disease in patients taking GnRH agonists (Gupta et al., 2018). Because of these concerns, GnRH agonists have undergone FDA review since 2010.

GnRH Antagonists

GnRH antagonists are a class of agents used in the treatment of prostate cancer. They antagonize the GnRH receptor by reversible competition with GnRH, resulting in rapid reduction in LH and FSH secretion from the pituitary and concomitant loss of testosterone production to castrate levels from the testes. *Degarelix* is a small peptide-based GnRH antagonist used in prostate cancer treatment. The recently FDA-approved *relugolix* is an orally available, nonpeptide antagonist used for treatment of prostate cancer (Shore et al., 2020).

ADME

After an initial subcutaneous loading dose (240 mg in two doses of 120 mg), *degarelix* is given as a monthly injection (80 mg). C_{max} is achieved after 2 days, and excretion is mainly through the hepatobiliary system. *Relugolix* is given orally as an initial loading dose (360 mg), followed by one tablet (120 mg) daily for prostate cancer. Steady-state levels are achieved after 7 days. Food can diminish oral bioavailability by 50%.

Absorption and distribution of *relugolix* are influenced by its interaction with the efflux transporter P-glycoprotein (Pgp) and CYP3A4 (the predominant metabolizer of the drug). Oral coadministration with agents that inhibit Pgp (e.g., *erythromycin*) increases the C_{Pmax} and area under the curve (AUC) of *relugolix*; coadministration with *rifampicin* (an inducer of intestinal Pgp and hepatic CYP3A4) will decrease C_{Pmax} and AUC. Metabolites of *relugolix* are excreted mainly in feces.

Degarelix distributes slowly from a subcutaneous depot to total body water. As a peptide, *degarelix* does not interact with Pgp and is not metabolized by hepatic CYPs. Rather, hepatic/biliary hydrolysis of the drug produces peptide fragments that are excreted in the bile/feces (~75%), with approximately 25% of the original dose appearing in the urine.

Therapeutic Use

GnRH antagonists are used in the treatment of advanced and metastatic prostate cancer. Besides avoidance of the initial increase in testosterone seen with GnRH agonists, GnRH antagonists are reported to be more effective at suppressing FSH and have fewer cardiovascular side effects than GnRH agonists (Dearnaley et al., 2020; Shore et al., 2020).

Toxicity

Degarelix is associated with higher rates of injection site reactions compared with GnRH agonists. ADT may cause prolongation of the cardiac QT/QTc interval, a serious side effect of both *relugolix* and *degarelix*. The most common side effects of *relugolix* include hot flushes, increased blood glucose levels, increased triglyceride levels, musculoskeletal pain, anemia, increased liver enzymes, tiredness, constipation, and diarrhea. *Relugolix* causes reproductive and fetal harm in animal toxicity tests; thus, caution is warranted, and male patients with female partners of reproductive potential should use contraception during and for 2 weeks following the last dose of *relugolix*.

The early GnRH antagonists *cetrorelix* and *abarelix* (no longer marketed), although effective, are now rarely used for prostate cancer because of the risk for severe systemic allergic reactions. Later generation GnRH peptide antagonists are not associated with systemic allergic reactions.

Drugs That Target the Estrogen Receptor

Estrogen Antagonists

Selective Estrogen Receptor Modulators

The SERMs bind to the ER and exert either estrogenic or antiestrogenic effects, depending on the specific organ (see Chapter 48). *Tamoxifen* is one of the most widely studied antiestrogenic drugs used in the treatment of breast cancer. *Tamoxifen* also exerts estrogenic agonist effects on nonbreast tissues, which influences the side effect profile of the drug. Therefore, several novel antiestrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with *tamoxifen* have been developed. These novel antiestrogens can be divided into *tamoxifen* analogues (e.g., *toremifene*, *droloxifene*, *idoxifene*); "fixed-ring" compounds (e.g., *raloxifene*, *bazedoxifene*, *lasofoxifene*, *arzoxifene*, *miproxifene*, *levormeloxifene*); and the SERDs (e.g., *fulvestrant*), the latter also termed "pure antiestrogens" (McDonnell et al., 2021).

Tamoxifen. *Tamoxifen* was developed as an oral contraceptive but instead was found to induce ovulation and to have antiproliferative effects on estrogen-dependent breast cancer cell lines (reviewed in Abderrahman and Jordan, 2019). *Tamoxifen* is prescribed for the adjuvant therapy of

early-stage breast cancer and for the therapy of advanced breast cancer. *Tamoxifen* and other SERMs such as *raloxifene* are also used for the prevention of breast cancer in high-risk patients such as those with a strong family history or prior nonmalignant breast pathology (Visvanathan et al., 2013). The uses, pharmacology, and mechanism of action of *raloxifene* are discussed in Chapter 48.

Mechanism of Action. *Tamoxifen* is a competitive inhibitor of the binding of estrogens (e.g., 17β-estradiol) to the ER and antagonizes estrogen-induced proliferation of human breast cancer.

There are two subtypes of ERs: ERα and ERβ, which have different tissue distributions and can either homo- or heterodimerize. ERα plays a major role in breast cancer progression and is a prognostic marker; the role of ERβ is unclear. Binding of estrogen and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. Coregulator proteins interact with the liganded receptor to act as corepressors or coactivators of gene expression (see Chapter 48). Elegant studies of the crystal structure of ERα bound to different ligands indicate that, when an ER agonist is bound to the ER, a conformational change occurs in the ligand-binding pocket that enables helix 12 in this region to provide a docking site for p160 transcriptional coactivators, thereby increasing transcription of target genes.

Conversely, the interaction of an estrogen antagonist such as 4-hydroxytamoxifen bound to the ligand binding domain of ER causes a structural rearrangement of helix 12. This alteration in structure reduces transcriptional coactivator binding and favors binding of transcriptional corepressors. The net result is inhibition of estrogen-induced gene transcription (reviewed in Legare and Basik, 2016; Nettles and Greene, 2005). Differences in tissue distribution of the ER subtypes and the relative abundance and activities of different transcriptional coactivators and corepressors likely explain the antagonist response to tamoxifen in ER+ breast cancer and its partial agonist activities in noncancerous tissues (see Figure 73–1A) (reviewed in Abderrahman and Jordan, 2019; Green and Carroll, 2007).

Organs displaying agonist effects of *tamoxifen* include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer); the coagulation system (thromboembolism); bone metabolism (increase in bone mineral density, which can slow development of osteoporosis); and liver (*tamoxifen* lowers total serum cholesterol, low-density lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A1 levels).

ADME. *Tamoxifen* is given orally once (20 mg) per day. It is readily absorbed following oral administration, with peak concentrations measurable after 3 to 7 h and steady-state levels reached at 4 to 6 weeks. Metabolism of *tamoxifen* is complex and principally involves CYPs 3A4/5 and 2D6 in the formation of *N*-desmethyl tamoxifen and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 73–2). Both metabolites can be further converted to 4-hydroxy-*N*-desmethyltamoxifen (endoxifen), which retains high affinity for the ER. The parent drug has a terminal $t_{1/2}$ of 7 days. After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal. Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of the potent metabolites 4-OH tamoxifen and endoxifen, but whether this leads to inferior efficacy of *tamoxifen* treatment and higher risk of disease relapse is unclear (reviewed in Hertz and Rae, 2016; Tamura et al., 2020). While drugs that inhibit CYP2D6 activity, such as antidepressants, have been postulated to minimize *tamoxifen* activity in breast cancer, more recent studies do not suggest a clinically significant impact (Haque et al., 2016).

Therapeutic Uses. *Tamoxifen* is used for the treatment of women with ER+ metastatic breast cancer or following primary excision of an ER+ tumor as an adjuvant treatment to prevent recurrence and extend overall survival. For the adjuvant treatment of premenopausal women, *tamoxifen* is given for at least 5 years (see Table 73–1). *Tamoxifen* may also be used for postmenopausal women, but AIs are preferred as they are associated with further reductions in the risk of recurrence (Early Breast

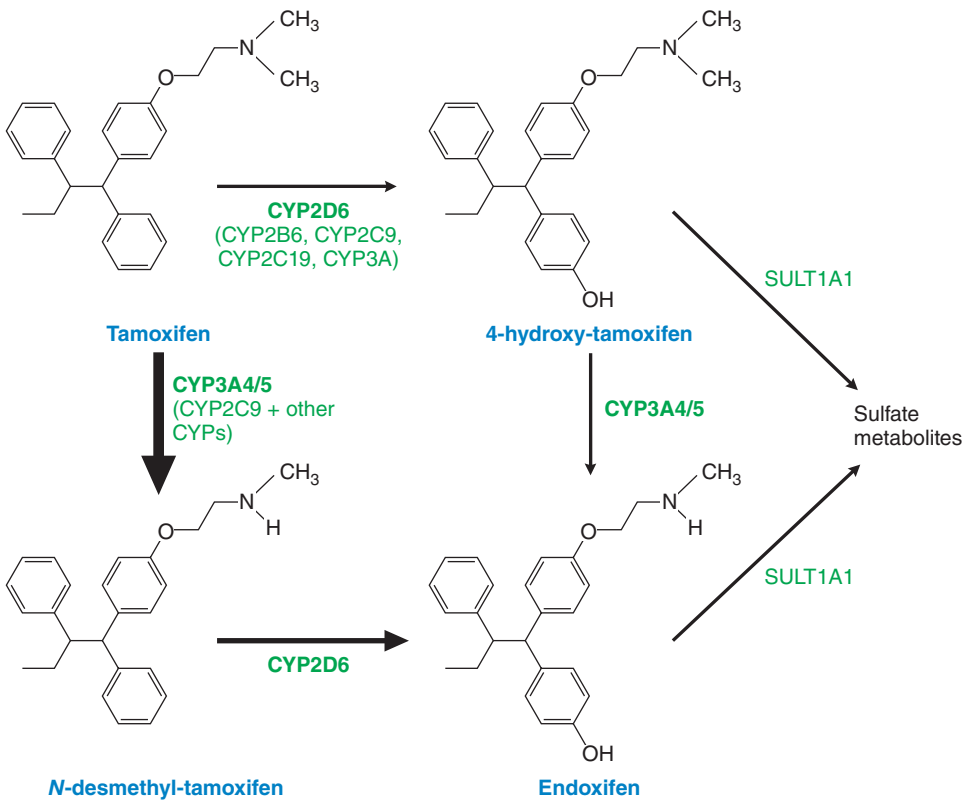

Figure 73–2 *Tamoxifen and its metabolites.*

Cancer Trialists' Collaborative Group, 2015). Recent studies indicate that patients with breast cancer derive modest additional benefit, in terms of disease-free survival, overall survival, and decrease in contralateral breast cancer risk, if *tamoxifen* is taken for up to 10 years or AIs are continued for 5 to 10 years after completion of 5 years of *tamoxifen* (Burstein, 2020; Davies et al., 2013; Goss et al., 2016). Although taken for a finite time, *tamoxifen* has persisting long-term benefits (Ekholm et al., 2016). *Tamoxifen* may be taken as sole adjuvant therapy or after adjuvant chemotherapy (see Table 73–1). Alternative or additional antiestrogen strategies in the adjuvant treatment of premenopausal women with ER+ breast cancer include oophorectomy or suppression of ovarian function with GnRH analogues in combination with either *tamoxifen* or an AI. These combinations, used in premenopausal women, further reduce estrogen stimulation of breast cancer and result in lower rates of disease recurrence in very young women and in higher risk patients receiving chemotherapy (Francis et al., 2015; Pagani et al., 2020). Some studies suggest improved response rates with these combinations in patients with metastatic disease. *Tamoxifen* also is effective (a 40%–50% reduction in tumor incidence) in preventing breast cancer in women at increased risk. In the preventive setting, *tamoxifen* reduces only ER+ tumors, not ER– tumors and does not affect overall mortality. In patients with metastatic cancer, responses to hormonal therapy may not be apparent clinically or by imaging for 8 to 12 weeks. The medication typically should be continued until the disease progresses or unwanted toxicities develop.

Adverse Effects. The common adverse reactions to *tamoxifen* include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, menstrual irregularities, vaginal bleeding and discharge and pruritus vulvae, these occur with increasing severity in postmenopausal women. The partial agonist activity of *tamoxifen* increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive *tamoxifen* for more than 2 years, although the absolute risk remains low. The increase in risk of thromboembolic events is slight and increases with the age of a patient and during the perioperative period. Hence, it often is advisable to temporarily halt *tamoxifen* prior to elective surgery. *Tamoxifen* is associated with fatty liver disease (although rarely clinically significant), a small increase in risk of cataracts, and, rarely, retinal deposits and decreased visual acuity. The FDA has assigned a boxed warning to *tamoxifen* based on uterine malignancies and thromboembolic events associated with its use, noting that for breast cancer patients, the benefits of *tamoxifen* outweigh these risks.

Toremifene. *Toremifene* is a triphenylethylene derivative of *tamoxifen* and has a similar pharmacological profile, clinical efficacy, and safety. *Toremifene* is used occasionally in the metastatic setting for the treatment of breast cancer in postmenopausal women with tumors that are ER+ or of unknown receptor status. It can also be used for the treatment of desmoid tumors. In rare cases, *toremifene* can cause heart rhythm problems through prolongation of the QT interval.

Selective Estrogen Receptor Downregulators

The SERDS, also termed *pure antiestrogens*, include *fulvestrant* and a number of agents in experimental trials. SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

Fulvestrant. *Fulvestrant* is currently the only FDA-approved SERD, either as a single agent or in combination with *palbociclib*, a CDK4/6 inhibitor (see Chapter 71), for postmenopausal women with ER+/PR+ metastatic breast cancer that has progressed on antiestrogen therapy.

Mechanism of Action. *Fulvestrant* is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of *tamoxifen*. The drug not only inhibits the binding of estrogen but also alters the receptor structure and exposes a region that leads to targeting of the protein for proteasomal degradation (see Figure 73–1A); *fulvestrant* also may inhibit receptor dimerization. Unlike *tamoxifen*, which stabilizes or even increases ER expression, *fulvestrant* reduces the number of ER molecules in cells; as a consequence of this downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes.

ADME. *Fulvestrant* (500-mg dose) is given intramuscularly with initial biweekly loading doses in the first month followed by once-monthly injections thereafter. Using this dosing regimen, steady-state levels are achieved within the first month (see Table 73–1). C_{Pmax} is reached approximately 7 days after intramuscular administration; the plasma $t_{1/2}$ is approximately 40 days. There is rapid distribution and extensive protein binding of this highly lipophilic drug. Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), metabolize *fulvestrant*. CYP3A4 appears to be the major CYP isoenzyme involved in the metabolism of *fulvestrant*. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of antiestrogenic activity (~22% that of *fulvestrant*). Less than 1% of the parent drug is excreted intact in the urine.

Therapeutic Uses. *Fulvestrant* is used in postmenopausal women or in premenopausal women receiving GnRH agonists as antiestrogen therapy of ER+/PR+ metastatic breast cancer typically after progression on first-line antiestrogen therapy such as *tamoxifen* or an AI. *Fulvestrant* is at least as effective in this setting as the third-generation AI *anastrozole* (Robertson et al., 2016). Endocrine-resistant breast cancer that harbors ERα mutations retains some sensitivity to *fulvestrant*. Newer SERDs are also being developed for the treatment of advanced endocrine-resistant disease (McDonnell et al., 2021). A variety of agents that promote ER degradation such as proteolysis targeting chimeras (PROTACs) are also active areas of investigation (Wang Z et al., 2021).

Toxicity and Adverse Effects. Fulvestrant generally is well tolerated, the most common adverse effects being nausea, asthenia, pain, hot flashes, arthralgias, and headache. The risk of injection site reactions, seen in almost 10% patients, is reduced by giving the injection slowly.

Drugs That Decrease Estrogen Levels

Aromatase Inhibitors

Aromatase converts androgens to estrogens (e.g., androstenedione to estrone). AIs (Figure 73–3) block this enzymatic activity, thereby reducing estrogen production (Figure 73–4). AIs are now considered the standard of care for adjuvant treatment of postmenopausal women with ER+ breast cancer, either as initial therapy or after *tamoxifen* (Dowsett et al., 2010) as well as in higher-risk premenopausal women in combination with GnRH agonists. AIs are also approved in the initial treatment of metastatic ER+/PR+ breast cancer, often in combination with CDK4/6 inhibitors, in postmenopausal women and in combination with GnRH agonists in premenopausal women.

Aromatase (CYP19A1) converts adrenal androgens and gonadal androstenedione and testosterone to the estrogens estrone (E1) and estradiol (E2), respectively (see Figures 73–3 and 73–4; reactions catalyzed by aromatase are noted by a green "A" beside the reaction arrow in Figure 73–4). In postmenopausal women, this conversion occurs in nonovarian tissues (fat, liver, muscle, brain, breast, and breast tumors) and is the primary source of circulating estrogens. In premenopausal women, estrogen is primarily produced in the ovaries. AIs increase gonadotropin production in premenopausal women, which reduces their ability to inhibit ovarian estrogen production. As a result, AIs are not effective in premenopausal women without additional ovarian suppression (e.g., with GnRH analogues; see previous section). In postmenopausal women, AIs suppress most peripheral aromatase activity, leading to profound estrogen deprivation. AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AIs according to their structure and mechanism of action (see Figure 73–3). Type 1 inhibitors are steroidal analogues of androstenedione that bind covalently and irreversibly to the same site on the aromatase molecule. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

Third-Generation Aromatase Inhibitors. First- and second-generation (e.g., *aminoglutethimide*, *formestane*) AIs are no longer used for breast

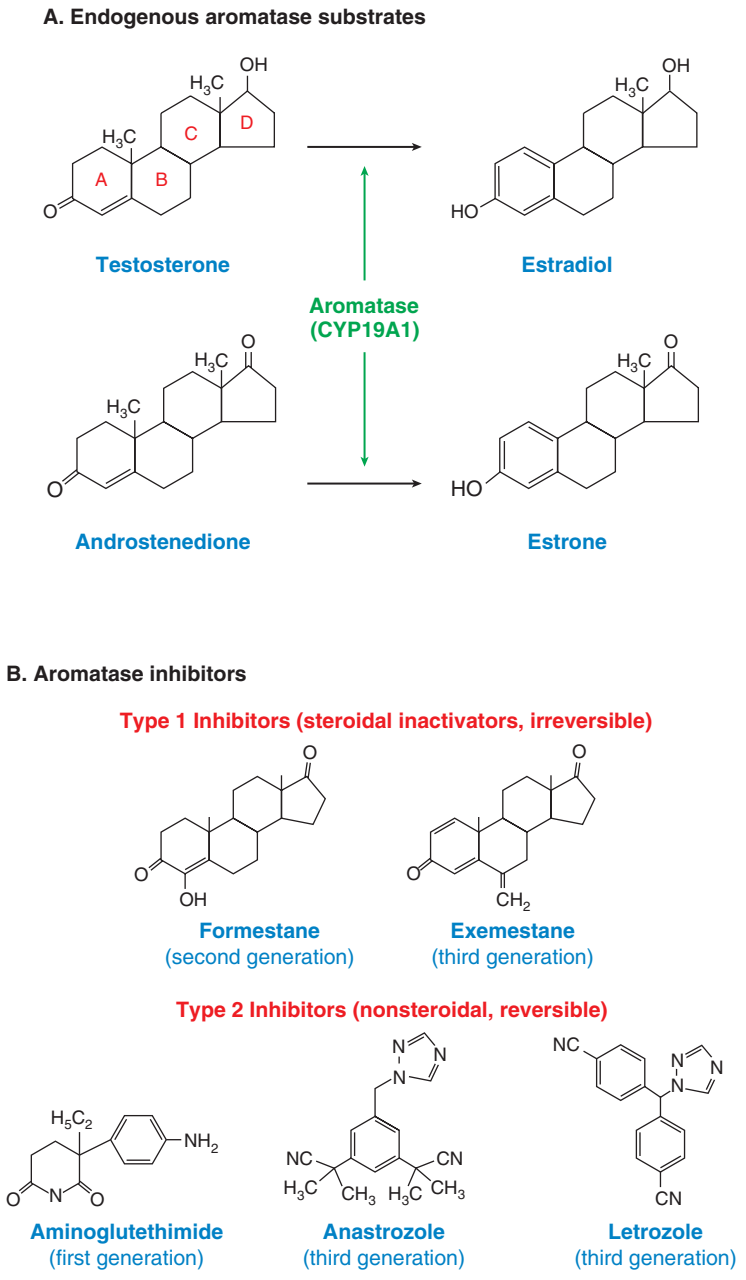

Figure 73–3 *Aromatase and its endogenous substrates and inhibitors.* **A.** Aromatization of endogenous substrates. In a multistep reaction, aromatase trihydroxylates the methyl group at C19, eliminating it as formate and aromatizing the A ring of the androgen substrate. Not shown are cofactors (NADPH, O_2) and other reaction products (H_2O, formate). **B.** Aromatase inhibitors (AIs). Type 1 AIs are steroidal analogues of androstenedione that bind covalently and irreversibly to the steroid substrate site on the enzyme and are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal, bind reversibly to the heme group of the enzyme, and produce reversible inhibition.

cancer treatment because of their side effects. Third-generation inhibitors include the type 1 steroidal agent *exemestane* and the type 2 nonsteroidal imidazoles *anastrozole* and *letrozole*; they are FDA approved for use in postmenopausal women. Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (see Table 73–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using *anastrozole* as a prototype. For *letrozole* and *exemestane*, additional drug-specific information is given. Daily administration of AIs (see dosages in Table 73–1) reduces total-body androgen aromatization by more than 95% after 1 month of treatment. AIs also reduce aromatization within large ER+ breast tumors.

Anastrozole. *Anastrozole* is a potent and selective triazole AI. *Anastrozole*, like *letrozole*, binds competitively and specifically to the heme of the CYP19.

ADME. *Anastrozole* is absorbed rapidly after oral administration; food slows the rate but not the overall extent of absorption. Steady state is attained after 7 days of repeated dosing. *Anastrozole* is metabolized by hepatic *N*-dealkylation, hydroxylation (CYP3A4 mainly), and glucuronidation (UGT1A4); the main circulating metabolite of *anastrozole*, triazole, is inactive. The hepatic metabolites account for 85% of the administered dose and are excreted via bile/feces; approximately 10% of the drug is excreted in the urine as the unmetabolized parent compound. The elimination $t_{1/2}$ is approximately 50 h. The pharmacokinetics of

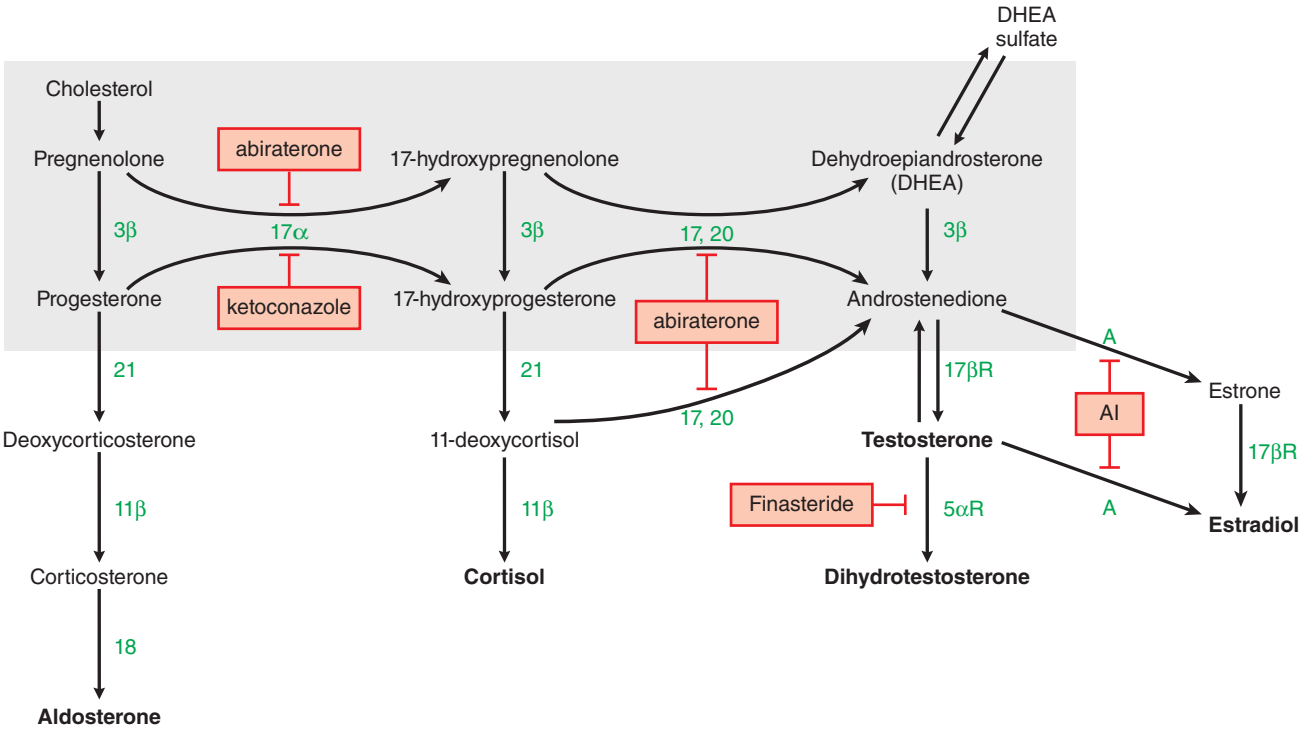

Figure 73–4 *Steroid synthesis pathways.* The shaded area contains the pathways used by the adrenal glands and gonads and clinically used agents that inhibit the pathways. Enzymes are labeled in green, inhibitors in red. Abbreviations pertaining to this figure only: *A*, aromatase; AI, aromatase inhibitor; *3β*, 3β-hydroxysteroid dehydrogenase; *5αR*, 5α-reductase; *11β*, 11β-hydroxylase; *17,20*, 17,20-lyase (CYP17A1); *17α*, 17α-hydroxylase (also CYP17A1); *17βR*, 17β-reductase; *18*, aldosterone synthase; *21*, 21-hydroxylase.

anastrozole, which can be affected by drug interactions via CYP3A4, are decreased 27% by coadministration of *tamoxifen* or *cimetidine*. *Anastrozole* is a substrate for the multidrug resistance transporter (Pgp/ABCB1) but not for the breast cancer resistance transporter (BCRP/ABCG2) (Miyajima et al., 2013).

Therapeutic Uses. AIs are approved for up-front adjuvant hormonal therapy for 5 to 10 years or following prior *tamoxifen* in postmenopausal women with early-stage breast cancer and as treatment of advanced and metastatic breast cancer. In early-stage breast cancer, *anastrozole* is significantly more effective than *tamoxifen* in delaying time to tumor recurrence and decreasing the odds of a new primary contralateral tumor. AIs are combined with ovarian suppression as adjuvant treatment of breast cancer in premenopausal women less than 35 years of age and in those requiring chemotherapy. This combination is associated with significant reduction in risk of recurrence compared to *tamoxifen* alone (Pagani et al., 2020). In postmenopausal women with ER+ or PR+ metastatic breast cancer, AIs are typically used as first-line therapy, as studies have shown them to be superior to *tamoxifen* and *megestrol acetate*. In premenopausal women with advanced disease, AIs are also used but must be given with a GnRH agonist to suppress ovarian function.

Adverse Effects and Toxicity. Most adverse effects are related to estrogen depletion. In postmenopausal women, compared to *tamoxifen*, *anastrozole* causes a lower incidence of hot flashes, vaginal bleeding, vaginal discharge, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep venous thrombosis/pulmonary embolism. *Anastrozole* is associated with a higher incidence of symptomatic arthralgias, vaginal dryness, and sexual dysfunction than *tamoxifen*. In addition, the estrogen depletion caused by AIs results in loss of bone mineral density. Compared with *tamoxifen*, treatment with *anastrozole* results in significantly lower bone mineral density in the lumbar spine and total hip and has been associated with increased fracture risk. Bisphosphonates (see Chapter 52) prevent AI-induced loss of bone mineral density in postmenopausal women.

Letrozole. The clinical uses and side effect profile of the type 2 AI *letrozole* are similar to those detailed in the previous section for *anastrozole* (see Table 73–1). *Letrozole*-specific information is as follows.

ADME. *Letrozole* is rapidly absorbed after oral administration, with a bioavailability of 99.9%. Steady-state plasma concentrations of *letrozole* are reached after 2 to 6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, *letrozole* is eliminated as an inactive metabolite mainly via the kidneys and has a $t_{1/2}$ of approximately 41 h.

Therapeutic Uses. *Letrozole* is used to treat breast cancer in the same manner as *anastrozole* (see Table 73–1). In addition, improved progression-free survival is observed when ER+/PR+ advanced-stage breast cancer is treated with *letrozole* in combination with a CDK4/6 inhibitor (see Chapter 71) (Finn et al., 2016; Hortobagyi et al., 2016).

Exemestane. *Exemestane* is a more potent, orally administered analogue of the endogenous aromatase substrate androstenedione and lowers estrogen levels more effectively than does its predecessor, *formestane*. *Exemestane* irreversibly inactivates aromatase and is a "suicide substrate" type 1 inhibitor of aromatase. The clinical uses and side effect profile of *exemestane* are similar to those detailed in the section for the AI *anastrozole*.

ADME. Orally administered *exemestane* is rapidly absorbed from the gastrointestinal tract; its absorption is increased by 40% after a high-fat meal. *Exemestane* has a terminal $t_{1/2}$ of approximately 24 h. It is extensively metabolized in the liver, ultimately to inactive metabolites; one metabolite, 17-hydroxyexemestane, has weak androgenic activity that may contribute to antitumor activity. Although metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

Therapeutic Uses. The clinical indications for use of *exemestane* in breast cancer treatment are the same as for *anastrozole* (see Table 73–1). In addition, the use of the mechanistic (or mammalian) target of rapamycin (mTOR) inhibitor *everolimus* (see Chapter 71) with *exemestane* has

been approved for treatment of advanced-stage breast cancer that has progressed on nonsteroidal type 2 AIs (Piccart et al., 2014).

Toxicity and Adverse Reactions. The side effects are similar to those described for *anastrozole*. *Exemestane* causes fetal toxicities and abortion in preclinical animal experiments and is considered unsafe for administration to pregnant women; women of childbearing potential should use contraception during AI treatment and for a month thereafter.

Drugs That Target the Progesterone Receptor

Progestational agents are mainly used as secondary agents in hormonal therapy for metastatic hormone-dependent breast cancer and are also used in the management of endometrial carcinoma previously treated by surgery and radiotherapy. Progesterone binds to the PR present in target tissues, such as breast and the endometrium. Activation of the PR by progestins in the endometrium is antiproliferative. Chapter 48 covers the mechanisms and uses of hormones and drugs that interact with the PR.

Medroxyprogesterone acetate is available for oral administration; an alternative oral progestational agent is *megestrol acetate.* These agents provide beneficial effects in one-third of patients with endometrial cancer. The response of breast cancer to *megestrol* is predicted by both the presence of ER and PR and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose-dependent, with some patients demonstrating second responses following dose escalation of *megestrol*. Clinical use of progestins in breast cancer has been largely superseded by *tamoxifen* and AIs. Additional uses of progestins are as treatment of metastatic endometrial cancer and to stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS.

Drugs Combined With Agents That Antagonize the Estrogen Receptor

The addition of several agents used in cancer (see Chapter 71) when combined with SERMs, SERDs, or AIs improves the therapeutic outcome of breast cancer patients.

CDK4/6 Inhibitors

There are currently three CDK4/6 inhibitors—*palbociclib*, *ribociclib*, and *abemaciclib*—that have been approved for use in combination with ER antagonists (SERDs and AIs). These combinations result in significantly improved outcomes in ER+ HER2-advanced breast cancer (Finn et al., 2016; Goetz et al., 2017; Hortobagyi et al., 2016; Slamon et al., 2020; Sledge et al., 2020; Turner et al., 2018).

A major effect of CDK4/6 inhibitors is to prevent progression through the G_1/S cell cycle checkpoint by inhibiting the activation of D-type cyclins and thereby reducing the production of phosphorylated retinoblastoma-associated protein and E2F transcriptional activity (see Figure 71–3). In ER+ breast cancer, the G_1-to-S checkpoint is a therapeutic target since cyclin D is frequently overexpressed. The presence of the ER in a breast cancer is currently the best predictive marker of response to CDK4/6 inhibitors. While there are questions about the optimal sequence and choice of ER antagonists with CDK4/6 inhibitors, recent trials demonstrate no difference in outcome in the first-line setting whether an AI or *fulvestrant* is used with a CDK4/6 inhibitor (Slamon et al., 2020; Sledge et al., 2020; Turner et al., 2018).

PI3 Kinase (PI3K) and mTOR Inhibitors

The PI3K inhibitor *alpelisib* and the mTOR inhibitor *everolimus* (see Chapter 71) are approved for use in combination with *fulvestrant* and *exemestane*, respectively, in treating advanced-stage breast cancer (Andre et al., 2019; Piccart et al., 2014). The mTOR, a kinase in the phosphoinositide-3-kinase (PI3K)/AKT signaling pathway, controls cell growth and proliferation (see Figure 71–5). In breast cancer, the PI3K/AKT/mTOR pathway modulates the growth of breast cancer through ER-mediated signaling as well as through the HERs (human epidermal growth factor receptors) and mediates the clinical sensitivity to ER antagonists. Breast cancers that harbor activating mutations in PI3K can be resensitized to endocrine therapies by treatment with inhibitors of PI3K or mTOR.

Drugs That Target the Androgen Receptor

AR Antagonists

AR antagonists competitively inhibit the binding of testosterone and dihydrotestosterone to the AR, thereby reducing AR nuclear translocation, chromatin binding, and AR-mediated gene transcription (see Figure 73–1B). Unlike castration, AR antagonist therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with AR antagonists maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration. However, AR antagonist therapy is typically given in combination with ADT (described above). AR antagonists include the newer second-generation drugs *enzalutamide, apalutamide*, and *darolutamide*, and the earlier generation antagonists *bicalutamide, flutamide*, and *nilutamide*. Table 73–2 summarizes dosing and conditions for the use of these agents in treating prostate cancer.

Enzalutamide

Enzalutamide is a second-generation, nonsteroidal competitive AR antagonist that has 5- to 8-fold higher binding affinity for the AR compared to the older antagonist *bicalutamide* (Tran et al., 2009). Similar to other AR antagonists, *enzalutamide* prevents binding of androgens to the AR, thereby decreasing receptor-mediated transcriptional activity. *Enzalutamide* is approved for use in nonmetastatic and metastatic CRPC as well as in metastatic castration-sensitive prostate cancer. *Enzalutamide* prolongs survival in patients with metastatic CRPC when given to chemotherapy-naïve patients or after *docetaxel* therapy (Paschalis and de Bono, 2020). *Enzalutamide* combined with ADT, compared with ADT alone, also prolongs metastasis-free and overall survival in men with nonmetastatic castration-resistant disease and rapidly rising circulating prostate-specific antigen (indicative of more aggressive disease and increased risk of progression) (Hussain et al., 2018; Sternberg et al., 2020).

ADME. *Enzalutamide* has improved efficacy and potency compared to older, first-generation AR antagonists. *Enzalutamide* is given orally once daily. Median time to reach C_{Pmax} is 1 h. Its $t_{1/2}$ is approximately 6 days; steady-state levels are achieved in 28 days. CYP2C8 and CYP3A4 metabolize *enzalutamide*. Therefore, concomitant treatment with *enzalutamide* and strong CYP2C8 inhibitors such as *gemfibrozil* or *pioglitazone* may raise levels of *enzalutamide*. Conversely, strong inducers of CYP2C8 or CYP3A4 (e.g., *rifampin*) may reduce plasma *enzalutamide*. *Enzalutamide* can induce multiple hepatic CYPs, including 3A4, 2C9, and 2C19 and thereby has the potential to affect the metabolism of up to 50% of drugs (reviewed in Del Re et al., 2017). Coadministration with substrates of these CYPs (including *fentanyl*, *nifedipine*, *disopyramide*, *quetiapine*, *quinidine*, and *warfarin*) should be avoided as *enzalutamide* may decrease levels of these drugs (Benoist et al., 2018).

Adverse Effects and Toxicity. The most frequently reported side effects are fatigue, back pain, hot flush, constipation, arthralgia, decreased appetite, diarrhea, and hypertension. Fractures, falls, and cognitive impairment have been reported (Fizazi et al., 2020a; Sternberg et al., 2020). A population-based retrospective study showed that *enzalutamide* use is associated with an increased risk of short-term mortality in elderly prostate cancer patients with preexisting cardiovascular comorbidities compared to similar patients without cardiovascular disease (Lu-Yao et al., 2020). *Enzalutamide* crosses the blood-brain barrier; seizures occur infrequently (0.5%–2.2% of patients).

Apalutamide

Apalutamide is a second-generation, nonsteroidal AR antagonist that is approved for use in nonmetastatic castration-resistant and metastatic castration-sensitive prostate cancer (Smith et al., 2021).

ADME. *Apalutamide* is given orally once daily as four tablets, taken with or without food. Mean absolute oral bioavailability is approximately

100%. Median time to achieve peak plasma concentration (t_{max}) is 2 h and may be increased with a high-fat meal. Mean elimination $t_{1/2}$ is 3 to 4 days. Steady state is achieved by approximately 4 weeks. *Apalutamide* is a strong inducer of CYP3A4 and CYP2C19 and a weak inducer of CYP2C9. Concomitant use of *apalutamide* and drugs that are substrates of these CYPs should be avoided as lower exposure to these CYP substrates may result. Coadministration of *apalutamide* and substrates of UDP-glucuronosyltransferase (UGT), Pgp (e.g., *fexofenadine*), breast cancer resistance protein (BCRP), or organic anion transporting polypeptide 1B1 (OAT1B1) (e.g., *rosuvastatin*) may result in decreased exposure to these medications.

Toxicity. *Apalutamide* has a similar toxicity profile as *enzalutamide* and can cause fatigue, hypertension, rash, nausea, hot flush, weight loss, arthralgia, falls, decreased appetite, diarrhea, fracture, and peripheral edema. Hypothyroidism has been reported. *Apalutamide* can increase the QT interval. Seizures occurred in 0.2% of patients receiving *apalutamide*, possibly related to interaction of the drug with the $GABA_A$ receptor.

Darolutamide

Darolutamide is a second-generation, nonsteroidal AR antagonist that is used in the treatment of nonmetastatic CRPC. Addition of *darolutamide* to ongoing ADT significantly increases time to metastasis-free survival in men with nonmetastatic prostate cancer (Fizazi et al., 2020b).

ADME. *Darolutamide* is given orally twice daily and should be given with food. The $t_{1/2}$ is approximately 20 h. C_{Pmax} is reached approximately 4 h after administration of a single 600-mg oral dose. In contrast to *enzalutamide* and *apalutamide*, *darolutamide* does not induce CYPs. Use of *darolutamide* concurrently with inhibitors of Pgp and strong-to-moderate CYP3A inducers may decrease *darolutamide* exposure. Concurrent use of *darolutamide* with inhibitors of Pgp and strong CYP3A4 inhibitors may increase *darolutamide* exposure. *Darolutamide* inhibits BCRP transporter, and therefore, concurrent use of *darolutamide* and BCRP substrates (e.g., *prazosin*, *glyburide*, *cimetidine*, *sulfasalazine*, *rosuvastatin*, and nucleoside and nucleotide analogues such as *zidovudine* and *lamivudine*) may increase BCRP substrate toxicity. *Darolutamide* inhibits OATP1B1 and OATP1B3 transporters. Concomitant use of *darolutamide* and OAT1B1 or OATP1B3 substrates (e.g., statins, taxanes, *cisplatin*) may increase concentrations of drugs that are substrates of OAT1B1 and OATP1B3. Post-hoc analysis of a phase III trial of *darolutamide* reported a low incidence of clinically relevant drug-drug interactions (Shore et al., 2019).

Adverse Effects and Toxicity. *Darolutamide* is structurally distinct from *enzalutamide* and *apalutamide* and is not associated with an increase in adverse events such as falls, seizures, cognitive disorders, mental impairment disorders, and hypertension compared to ADT alone (Fizazi et al., 2020b). The most common adverse reactions are fatigue, pain in extremities, and rash. Significant adverse reactions in patients taking *darolutamide* include ischemic heart disease, heart failure, urinary retention, pneumonia, and hematuria. Of the newer generation AR antagonists, seizures appear to be least frequent with *darolutamide*, which does not penetrate the blood-brain barrier.

Older AR Antagonists

These nonsteroidal agents are still in use but are being supplanted by the more potent second-generation AR antagonists.

Bicalutamide. The agent *bicalutamide* is given once daily in conjunction with a GnRH agonist, usually to combat tumor flare. *Bicalutamide* has a $t_{1/2}$ of 5 to 6 days; it undergoes glucuronidation to inactive metabolites, and the parent compound and metabolites are eliminated in bile and urine. The $t_{1/2}$ of *bicalutamide* is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. *Bicalutamide* is well tolerated at higher doses and has reduced toxicity and improved tolerability and pharmacokinetic profiles relative to *flutamide* and *nilutamide*. Daily *bicalutamide* is significantly inferior compared to surgical or medical castration and should not be used as monotherapy of prostate cancer. *Bicalutamide* inhibits CYP3A4, and therefore, coadministration of *bicalutamide* and CYP3A4 substrates should be monitored. Use of *bicalutamide* in patients receiving anticoagulants requires monitoring since *bicalutamide* may displace coumarin anticoagulants from binding sites.

Nilutamide. *Nilutamide* is given orally once daily. It has an elimination $t_{1/2}$ of 45 h and is metabolized to five products that are all excreted in the urine. Common side effects include mild nausea, alcohol intolerance (5%–20%), and diminished ocular adaptation to darkness (25%–40%); rarely, interstitial pneumonitis occurs.

Flutamide. *Flutamide* is given orally three times per day. It has a $t_{1/2}$ of 5 h; its major metabolite, hydroxyflutamide, is biologically active. Common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur. Rare reports of fatal hepatotoxicity have been observed. It is used infrequently as it has the least favorable toxicity profile of the antiandrogens.

Resistance to AR Antagonists, Including to Second-Generation Drugs

Resistance to these agents develops frequently through mechanisms that primarily but not exclusively enhance AR activity, as noted above (reviewed in Schmidt et al., 2021). In an effort to overcome resistance to current antiandrogen therapies, studies are ongoing with a variety of new agents, including those that promote AR degradation such as PROTACs (Salami et al., 2018) and small-molecule receptor degraders (Mohler et al., 2021).

Drugs That Inhibit Androgen Synthesis

As discussed above, even in conditions of castration levels of circulating testosterone, persistent AR activity in CRPC cells may support tumor growth. Synthesis of extragonadal androgens occurs in the adrenal glands or CRPC tumors themselves (see Figure 73–4). Androstenedione, produced by the adrenal glands, is converted to testosterone and dihydrotestosterone in peripheral tissues and prostate tumors. Intratumoral *de novo* androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation. Thus, inhibitors of androgen synthesis combined with ADT have proven useful in reducing AR signaling in CRPC.

Abiraterone Acetate

Abiraterone, with *prednisone*, is used for the treatment of metastatic prostate cancer in patients who are chemotherapy naïve or in those who have received previous *docetaxel*. In both settings, *abiraterone* prolongs survival (reviewed in Paschalis and de Bono, 2020). The combination of *abiraterone* and *prednisone*, in conjunction with ADT, also prolongs overall survival in men with metastatic castration-sensitive prostate cancer (Virgo et al., 2021; Wang L et al., 2021). Resistance to *abiraterone*, similar to that to *enzalutamide*, can occur through a variety of mechanisms mainly involving the AR (discussed above). AR antagonists and abiraterone in additional prostate cancer clinical settings is being evaluated in ongoing clinical trials.

Mechanism of Action. *Abiraterone* is an irreversible inhibitor of 17α-hydroxylase and 17,20-lyase (CYP17A1) activity in testicular, adrenal, and prostatic cancer tissue (see Figure 73–3). Inhibition of CYP17A1 reduces the conversion of pregnenolone and progesterone to their 17α-OH derivatives and their subsequent enzymatic conversion to dehydroepiandrosterone and androstenedione. Thus, circulating levels of testosterone drop to almost undetectable levels after *abiraterone* administration. *Abiraterone* also has some activity as an AR antagonist and inhibitor of other steroid synthetic enzymes and CYPs. Overall, *abiraterone* has greater potency and selectivity than *ketoconazole*, which is described below.

ADME. Abiraterone is the active metabolite of *abiraterone acetate*. With continuous administration, *abiraterone* increases adrenocorticotropic hormone levels, resulting in mineralocorticoid excess. Oral *abiraterone* acetate is administered with *prednisone* to counteract adrenal suppression. *Abiraterone* should be taken on an empty stomach due to the effect of food to increase both C_{max} and AUC of the drug. Alternatively, the National Comprehensive Cancer Network lists low-dose *abiraterone* (250 mg/day) with a low-fat breakfast as an alternative treatment option to 1000 mg/day of *abiraterone* taken on an empty stomach (Szmulewitz et al., 2018)

Abiraterone is metabolized by CYP3A4; thus, concomitant use of drugs that are strong CYP3A4 inducers (e.g., *carbamazepine*, *rifampicin*, St. John's wort, several reverse transcriptase inhibitors) should be avoided. *Abiraterone acetate* inhibits the highly polymorphic CYP2D6 and CYP2C8; thus, concomitant use of drugs that are substrates of these CYPs (e.g., 2D6 substrates: *risperidone*, *metoprolol*, *nebivolol*, *imipramine*-based antidepressants, *fluoxetine*, *tamoxifen*, *codeine*, *hydrocodone*, *oxycodone*, *tramadol*; 2C8 substrates: *amiodarone*, *carbamazepine*, *cerivastatin*, *diclofenac*, *ibuprofen*, *paclitaxel*, *rosiglitazone*) requires careful monitoring for toxicity and possibly dose adjustment.

Toxicity. The most common side effects include fatigue, arthralgia, hypertension, nausea, edema, hypokalemia, hot flush, diarrhea, vomiting, upper respiratory tract infection, cough, and headache. As was observed with enzalutamide in the same study, use of *abiraterone* is associated with an increased risk of short-term mortality in elderly men with preexisting cardiovascular comorbidities (Lu-Yao et al., 2020). Laboratory abnormalities that are most common include anemia, elevated alkaline phosphatase, hypertriglyceridemia, lymphopenia, hypercholesterolemia, hyperglycemia, and hypokalemia.

Ketoconazole

Ketoconazole is an antifungal agent that also inhibits both testicular and adrenal steroidogenesis by blocking CYP17 (17α-hydroxylase), CYP11A, and other P450 cytochrome enzymes. *Ketoconazole* can be administered off-label in conjunction with ADT to reduce adrenal androgen synthesis in CRPC. Oral *ketoconazole* is coadministered with *hydrocortisone* to compensate for inhibition of adrenal steroidogenesis. *Ketoconazole* has limited use in practice due to its toxicity and inferiority compared to *abiraterone acetate*. Chapter 61 presents the basic and clinical pharmacology of the azoles.

Prostate Cancer Chemoprevention (5α-Reductase Inhibitors)

5α-Reductase catalyzes the conversion of testosterone to dihydrotestosterone, the most potent endogenous androgen. Two inhibitors of 5α-reductase, *finasteride* and *dutasteride*, have been studied for prostate cancer chemoprevention. The results have been controversial: two clinical trials indicated decreased risk of low-grade prostate cancer but increased incidence of high-grade disease in the drug treatment arms. However, longer-term follow-up and other studies (Goodman et al., 2019) revealed no elevated incidence for high-grade prostate cancer or mortality from prostate cancer in the *finasteride*-treated subjects; the initial results in higher grade prostate cancer may have resulted from detection bias or may have been related to the study design (reviewed in Chau and Figg, 2018).

Bipolar Androgen Deprivation Therapy

Since CRPC typically becomes resistant to AR-directed therapies such as *enzalutamide* and *abiraterone*, investigators have examined whether bipolar androgen deprivation therapy (BAT) might resensitize tumors to AR-directed drugs. With prolonged deprivation of stimulation by androgens, prostate cancer cells may adapt via upregulation of the AR, thereby becoming resistant to treatment. BAT is rapid cycling between extremes of high and low (castrate) circulating testosterone in order to disrupt the process by which prostate cancer cells adapt to a low androgen milieu. A randomized study compared BAT versus *enzalutamide* in men with CRPC whose disease had progressed following *abiraterone*. Although there was no significant difference between the treatment arms in terms of progression-free survival, BAT did improve the extent and duration of response in the crossover arm in which BAT was the intervening therapy between *abiraterone* and *enzalutamide*. This study underscores the need to define optimal sequencing of BAT and different AR-targeted therapies (Denmeade et al., 2021).

Drugs That Target the Glucocorticoid Receptor

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapters 50, 74, and 75. Only the applications of these drugs in the treatment of neoplastic disease are considered here.

A number of glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 50). *Prednisone*, for example, usually is administered orally in doses up to 100 mg for the first few days and gradually reduced to the lowest possible effective dose. Side effects of these agents include glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 50). *Dexamethasone* is one of the preferred agents for remission induction in multiple myeloma, typically in combination with *bortezomib*, *anthracyclines*, or *lenalidomide*. Glucocorticoids, particularly *dexamethasone*, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Frequent lower doses (4–6 mg every 6 h) can have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. However, acute changes in *dexamethasone* dosage can lead to a rapid recrudescence of symptoms. *Dexamethasone* should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. *Dexamethasone* is also frequently used as part of an antiemetic regimen in patients receiving chemotherapy.

Drug Facts for Your Personal Formulary: *Hormones and Related Agents in Cancer Therapy*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Glucocorticoid Receptor Agonists		
Dexamethasone Prednisone Others	• Treatment of malignant hematologic disorders (ALL, CLL, MM, HL, NHL) • Symptom palliation in various cancer types (antiemetic; ↓ edema due to spinal cord compression, brain metastases)	• Major toxicities: Cushing syndrome, glucose intolerance, immunosuppression, osteoporosis, psychosis, insomnia • Acute reduction in dosing can lead to recurrence of symptoms • Drug interactions: concomitant use of CYP3A4 inhibitors or inducers. Concomitant use of erythropoietin-stimulating agents or estrogens increases risk of thromboembolism
Selective Estrogen Receptor Modulators: Antiestrogens in breast cancer therapy		
Tamoxifen	• Adjuvant therapy for pre- and postmenopausal women with HR+ breast cancer • Treatment of advanced or metastatic HR+ breast cancer in pre- and postmenopausal women • Breast cancer prevention in pre- and postmenopausal women • Rarely used to treat metastatic endometrial cancer	• SERM with partial agonist and antagonist action. Antagonist of ER in breast. Long $t_{1/2}$. Steady-state levels reached in 3–4 weeks • Some major toxicities due to ER agonism (endometrial carcinoma, thromboembolic events) or ER antagonism (vasomotor symptoms, menstrual irregularities) • Other adverse effects: cataracts • Drug interactions: strong CYP3A/4 inducers (rifampin) reduce AUC and C_{max}. Inhibitors of CYP2D6 increase metabolism (e.g., paroxetine) but it has not been established that this changes clinical efficacy. Increases anticoagulant effect of warfarin
Toremifene	• Postmenopausal metastatic HR+ breast cancer	• Pharmacology, clinical efficacy, and adverse effects similar to those of tamoxifen • Rare: prolongs QT interval, increased risk of torsades de pointes • Drug interactions: with agents that prolong QT. CYP3A/4 inducers/inhibitors change AUC and C_{max}. Use with caution with CYP2C9 substrates (warfarin, phenytoin)
Selective Estrogen Receptor Downregulators: Antiestrogens in breast cancer therapy		
Fulvestrant	• Advanced or metastatic HR+ breast cancer (+/– CDK4/6 inhibitors or +/– PI3K inhibitor alpelisib) in postmenopausal women who have disease progression after antiestrogen therapy	• Binds to ER, blocks estrogen action, and causes degradation of the ER • No estrogen agonist effects • IM loading then monthly dosing; steady state achieved in first month • Side effects: injection site reaction, nausea, weakness, bone and back pain, fatigue, vasomotor symptoms, headache • Drug interactions: no major interactions noted
Aromatase Inhibitors: Antiestrogen in breast cancer therapy		
Anastrozole, letrozole (nonsteroidal, competitive inhibitors) Exemestane (steroidal, irreversible inhibitor)	• Adjuvant treatment of postmenopausal (natural or in conjunction with OFS) women with HR+ breast cancer • Treatment of postmenopausal women (natural or in conjunction with OFS) with HR+ advanced and metastatic breast cancer (+/– CDK4/6 inhibitors) (exemestane +/– mTOR inhibitor) • Breast cancer prevention in postmenopausal women	• AIs significantly lower serum estrogens • Contraindicated in premenopausal women with ovarian function • Major side effects: vasomotor symptoms, arthralgia, loss of bone mineral density, osteoporosis, fractures, vaginal dryness, dyspareunia • Drug interactions: concomitant use with tamoxifen reduces plasma levels 27% (anastrazole). Estrogen coadministration reduces AI efficacy. CYP3A/4 inducers decrease exemestane exposure
Progesterone Receptor Agonists		
Megestrol acetate	• Treatment of endometrial cancer and rarely of breast and prostate cancer • Appetite stimulant in patients with AIDS or cancer-associated cachexia	• Adverse effects: weight gain, nausea, vomiting, edema, breakthrough bleeding, shortness of breath, thrombophlebitis, pulmonary embolism • Drug interactions: coadministration reduces exposure to HIV protease inhibitor indinavir
Medroxyprogesterone acetate	• Management of advanced-stage endometrial carcinoma • Therapy of metastatic hormone-dependent breast cancer	• Adverse effects: hot flashes, weight gain, depression, amenorrhea • With long-term use, bone loss is possible • Drug interactions: CYP3A/4 inducers reduce plasma levels
Gonadotropin-Releasing Hormone Analogues: Chemical castration in cancer therapy		
Prostate Cancer *GnRH agonists*: Leuprolide Goserelin Buserelin Histrelin Triptorelin	• Androgen deprivation therapy: ↓ pituitary release of LH and FSH, ↓ testicular testosterone production • Treatment of all forms of advanced prostate cancer • In combination with radiation therapy or surgery for management of moderate-/high-risk locally confined prostate cancer • In combination with androgen receptor antagonists or androgen synthesis inhibitors for combined androgen blockade	• Can cause initial testosterone surge and tumor flare. Administered with androgen receptor antagonists to reduce initial side effects from testosterone surge • Side effects related to low testosterone: vasomotor symptoms, loss of libido, osteoporosis, fatigue, impotence, gynecomastia, loss of muscle mass • Small but significant increase in risk of diabetes or development of cardiovascular disease • Drug interactions: no major interactions noted

Drug Facts for Your Personal Formulary: *Hormones and Related Agents in Cancer Therapy (continued)*

Drug	Therapeutic Use	Clinical Pharmacology and Tips
GnRH antagonists: Degarelix (cetrorelix) Relugolix	• Treatment of all forms of advanced prostate cancer • Cetrorelix less used, requires more frequent injection, higher cost	• No initial testosterone surge; rapid suppression of serum testosterone and prostate-specific antigen levels • Side effect profile in men similar to GnRH agonists above • More effectively decreases FSH compared to GnRH agonists • Relugolix is given orally • Fewer major cardiovascular events (relugolix compared to leuprolide) • Prolonged QT interval with relugolix (rare) • Drug interactions: relugolix interacts with Pgp and CYP3A4. Coadministration with strong CYP3A/4 inducers (rifampin) reduces AUC and C_{max}; Pgp inhibitors (erythromycin) increase AUC and C_{max}
Breast Cancer *GnRH agonist*: Goserelin Leuprolide	• Suppression of ovarian estrogen and progesterone production in pre- and perimenopausal women • With antiestrogens as adjuvant therapy or for metastatic disease	• Adverse effects due to hypoestrogenism: vasomotor symptoms, ↓ libido, osteoporosis, tumor flare, fatigue, vaginal dryness, dyspareunia • Drug interactions: No major interactions noted
Nonsteroidal Androgen Receptor Antagonists: Antiandrogens in prostate cancer therapy		
Enzalutamide	• In conjunction with ADT (or bilateral orchiectomy) for treatment of metastatic castration-sensitive prostate cancer, nonmetastatic and metastatic CRPC	• Adverse effects related to AR antagonism: sexual dysfunction, gynecomastia, breast pain, fatigue, diarrhea, headache, musculoskeletal pain, vasomotor symptoms, hot flashes, hypertension • Increase risk of cardiovascular disease (particularly in elderly men with preexisting conditions) • Rare: seizures (likely due to central "off-target" effects) • Drug interactions: enzalutamide may affect metabolism of many drugs through induction of multiple CYPs. Strong CYP2C8 inhibitors (e.g., the fibrate gemfibrozil) will raise enzalutamide levels. Strong inducers of CYP2C8 or CYP3A4 (e.g., rifampin) will reduce plasma enzalutamide
Apalutamide	• In conjunction with ADT (or bilateral orchiectomy), for treatment of metastatic castration-sensitive prostate cancer and nonmetastatic CRPC (not yet FDA approved for metastatic CRPC)	• Adverse effects related to AR antagonism • Drug interactions: apalutamide strongly induces CYP3A4 and CYP2C19. Concomitant use with substrates of these CYPs should be avoided. Coadministration of apalutamide with substrates of UGT, Pgp, BCRP, and OATP1B1 may decrease exposure to these medications
Darolutamide	• In conjunction with ADT (or bilateral orchiectomy), for treatment of nonmetastatic CRPC	• Adverse effects related to AR antagonism • Drug interactions: concomitant use with Pgp inhibitors and CYP3A inducers may decrease darolutamide exposure. Use with Pgp inhibitors and CYP3A inhibitors may increase darolutamide exposure. BCRP transporter inhibited by darolutamide; coadministration with BCRP substrates may increase substrate toxicity. Darolutamide inhibits OATP1B1 and OATP1B3; concomitant use with OATP substrates may increase concentration of these medications
Bicalutamide	• Older generation AR antagonist used with GnRH analogues to treat all forms of advanced prostate cancer. Current use mainly to ameliorate GnRH agonist flare	• Adverse effects related to AR antagonism • Favorable toxicity and pharmacokinetic profile relative to flutamide or nilutamide • Drug interactions: coadministration of bicalutamide and CYP3A4 substrates should be monitored. Bicalutamide may displace coumarin anticoagulants from binding sites, and therefore, use in patients receiving anticoagulants requires caution
Inhibitors of Steroidogenesis: Antiandrogens in prostate cancer therapy		
Abiraterone	• Treatment of metastatic prostate cancer (castration-sensitive and castration-resistant) • Used in combination with prednisone or dexamethasone (to compensate for adrenal insufficiency induced by abiraterone)	• Irreversibly inhibits CYP17A1, ↓ testosterone and other androgens • Fluid retention, hypertension, hypokalemia, hepatotoxicity, fatigue, joint swelling, vasomotor symptoms, diarrhea, arrhythmia • Increase risk of cardiovascular disease (particularly in elderly men with preexisting conditions) • Should be taken on empty stomach; or reduced dose with low-fat breakfast • Drug interactions: strong CYP3A4 inducers decrease abiraterone plasma levels. Plasma levels of substrates of CYP2D6 and CYP2C8 may increase by coadministration with abiraterone

OFS, ovarian function suppression.

Chapter 74

Ocular Pharmacology

Upneet K. Bains, Zeba A. Syed, Jeffrey D. Henderer, and Christopher J. Rapuano

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers. As a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties.

Extraocular Structures

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 74–1). In the orbit, connective (i.e., *Tenon's capsule*) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or *globe*). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon, and peribulbar or retrobulbar injections.

The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the *fornix*, located superiorly and inferiorly behind the upper and lower eyelids, respectively. Topical medications usually are placed in the inferior fornix, also known as the *inferior cul-de-sac*.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 74–2). The secretory system is composed of the main *lacrimal gland*, which is located in the temporal outer portion of the orbit, and accessory glands located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 74–1 and Chapter 10). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 18), antihistamines (see Chapter 43), and drugs used in the management of Parkinson's disease (see Chapter 21). Muscarinic cholinergic and α adrenergic receptors that mediate responses of several pupillary muscles from autonomic nerves also provide means of dilating the pupil for examination of posterior structures.

Tears constitute a functionally trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior tear layer is composed primarily of lipids, produced by the meibomian glands located at the eyelid margin. The middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes about 98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea. The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (see Figure 74–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nasal cavity. The nasal cavity is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

Ocular Structures

The eye is divided into anterior and posterior segments (Figure 74–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm's canal), iris, lens, ciliary zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

Anterior Segment

Cornea and Drug Access

The cornea is a transparent and avascular tissue organized into five (or six, depending on definitions used) layers (Figure 74–3B). The hydrophobic epithelial layer is five or six cells thick and is an important barrier to foreign material, including drugs. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman's layer, a distinct sheet of collagen fibers. Constituting about 90% of the corneal thickness, the stroma, a hydrophilic layer, is organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet's membrane, the basement membrane of the corneal endothelium. An additional corneal

layer, Dua's layer, has been proposed—a distinct thin, but strong, collagen layer between the stroma and Descemet's membrane (Dua et al., 2013). Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal dehydration by active transport processes and serve as a hydrophobic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic-hydrophilic-hydrophobic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1- to 2-mm wide) called the *limbus*. Limbal structures include the corneal epithelial stem cells, conjunctival epithelium, Tenon's capsule, episclera, corneoscleral stroma, canal of Schlemm, and trabecular meshwork (see Figure 74–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds about 250 µL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, with about 50 µL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber. It exits the eye primarily by the trabecular meshwork and canal of Schlemm, thence to an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80% to 95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see Glaucoma section in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: *open-angle glaucoma*, which is by far the most common form of glaucoma in the U.S., and *angle-closure* or *closed-angle glaucoma*. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production or increasing aqueous outflow. In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the force vectors between the iris and the lens. The aqueous humor is prevented from passing from the posterior chamber through the pupil to the anterior chamber through a ball (lens)-valve (pupil) type mechanism. The change in the lens-pupil relationship leads to an increase in pressure in the posterior chamber, causing an anterior bowing of the iris. The iris root is pushed against the angle wall, thereby covering the trabecular meshwork, closing the filtration angle, and markedly elevating the intraocular pressure (IOP). This can happen slowly over time and result in chronic angle-closure glaucoma, or it can happen suddenly, in which case the result is known as an acute attack of pupillary-block angle-closure glaucoma. The preferred management for angle-closure glaucoma is to create another pathway for aqueous humor to pass from the posterior to the anterior chamber. This equalizes pressure across the pupil, flattens the iris, and if the iris is not adherent to the trabecular meshwork, opens the angle, reestablishes outflow, and lowers the intraocular pressure. This is done by making a hole in the peripheral iris by either laser (laser iridotomy) or incision (surgical iridectomy), but short-term medical management may be necessary to reduce the acute IOP elevation and decrease corneal edema prior to surgery. Long-term surgical IOP reduction may be necessary, especially in chronic angle-closure glaucoma where the peripheral iris has permanently covered the trabecular meshwork.

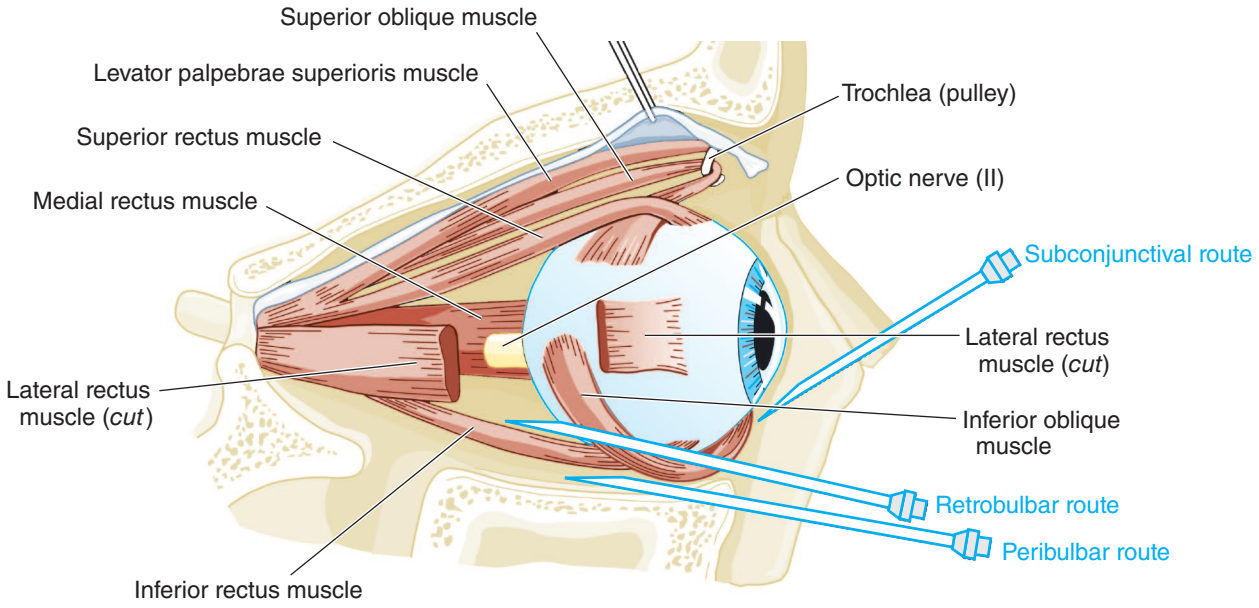

Figure 74–1 *Anatomy of the globe in relation to the orbit and eyelids.* Routes of administration of anesthesia are represented by the blue needles.

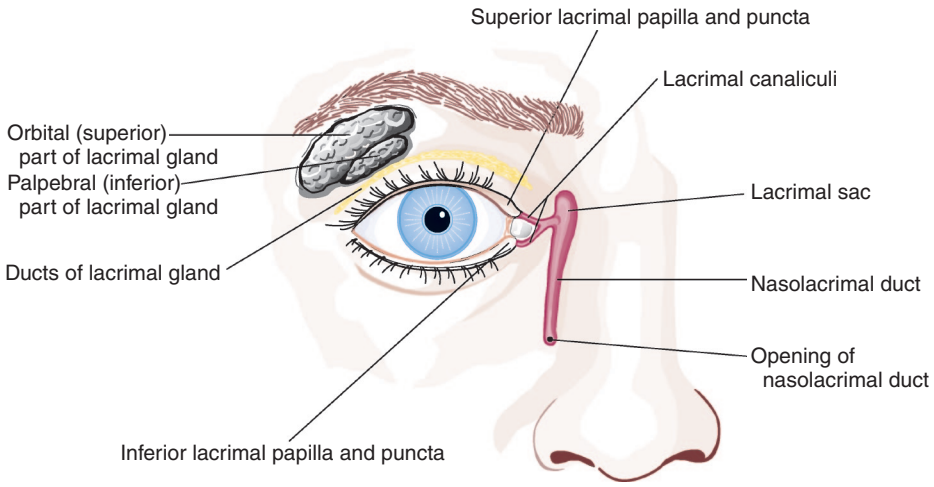

Figure 74–2 *Anatomy of the lacrimal system.*

Iris and Pupil

The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes and their melanosomes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding and side effect profile if melanogenic. The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 74–4), which causes *mydriasis* (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes *miosis* (constriction). The use of pharmacological agents to dilate normal pupils and to evaluate the pharmacological response of the pupil is summarized in Table 74–2. Agents affecting sympathetic neurotransmission in the eye are also used for the diagnostic evaluation of Horner syndrome and anisocoria.

Ciliary Body

The ciliary body serves two very specialized roles:

- Production and secretion of aqueous humor by the epithelial bilayer
- Accommodation by the ciliary muscle

The anterior portion of the ciliary body (*pars plicata*) comprises 70 to 80 ciliary processes with intricate folds. The posterior portion is the *pars plana*. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonular fibers suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as *accommodation*, permits focusing on near objects and may be pharmacologically *blocked* by muscarinic cholinergic antagonists through a process called *cycloplegia*. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This last effect accounts for at least some of the IOP-lowering properties of directly acting and indirectly acting parasympathomimetic drugs. Blockade of β adrenergic receptors of the ciliary epithelium decreases production of aqueous humor, as does blockade of carbonic anhydrase enzymes.

Lens

The lens is suspended by the *ciliary zonular fibers,* specialized strands emanating from the ciliary body. The lens is about 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as

TABLE 74–1 ■ AUTONOMIC PHARMACOLOGY OF THE EYE AND RELATED STRUCTURES

	ADRENERGIC RECEPTORS		CHOLINERGIC RECEPTORS	
TISSUE	SUBTYPE	RESPONSE	SUBTYPE	RESPONSE
Corneal epithelium	β_2	Unknown	M[a]	Unknown
Corneal endothelium	β_2	Unknown	Undefined	Unknown
Iris radial muscle	α_1	Mydriasis		
Iris sphincter muscle			M_3	Miosis
Trabecular meshwork	β_2	Unknown		
Ciliary epithelium[b]	α_2/β_2	Aqueous production		
Ciliary muscle	β_2	Relaxation[c]	M_3	Accommodation
Lacrimal gland	α_1	Secretion	M_2, M_3	Secretion
Retinal pigment epithelium	α_1/β_2	H_2O transport/unknown		

[a]Although acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of acetylcholine in this tissue is unknown.
[b]The ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium.
[c]Although β_2 adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.

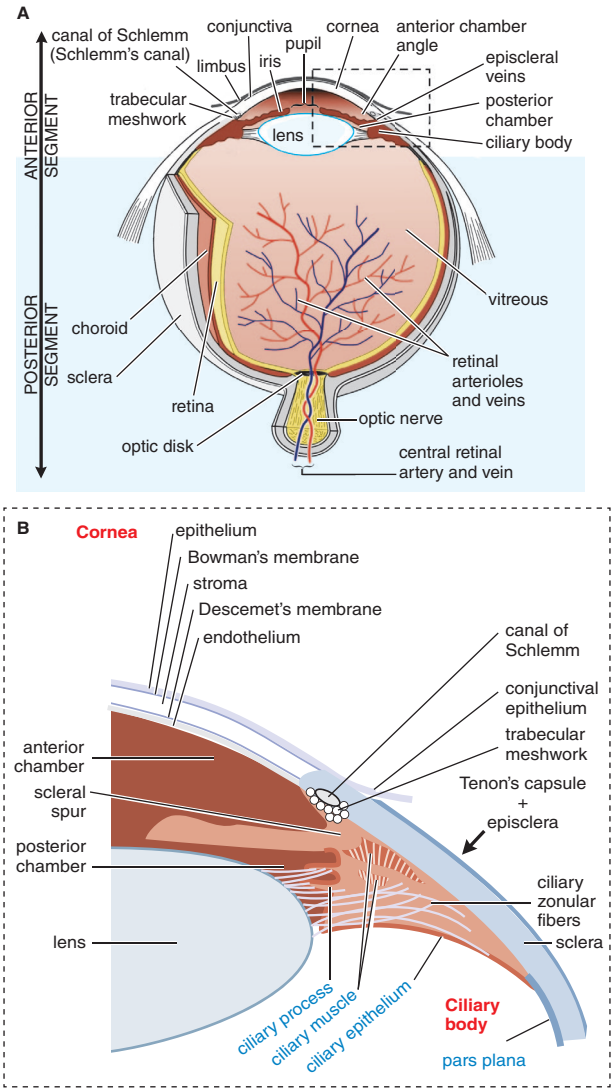

Figure 74–3 **A.** *Anatomy of the eye.* **B.** *Enlargement of the anterior segment, revealing the cornea, angle structures, lens, and ciliary body.* (Adapted with permission from Riordan-Eva P. Anatomy and embryology of the eye. In: Riordan-Eva P, Whitcher JP, eds. *Vaughan & Asbury's General Ophthalmology*. 17th ed. McGraw-Hill, New York, **2008**. corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a *cataract*.

Posterior Segment

Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye's posterior pole is particularly challenging.

Sclera and Choroid

The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, Tenon's capsule, and the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial sclera. Numerous blood vessels pierce the sclera through emissaria to supply and drain the choroid, ciliary body, optic nerve, and iris. Inside the scleral shell, a capillary network (vascular choroid) nourishes the outer retina. The choroid can be a location of abnormal neovascular membranes and is the target of therapy with vascular endothelial growth factor (VEGF) inhibitors. Between the outer retina and the capillary network lie Bruch's membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A

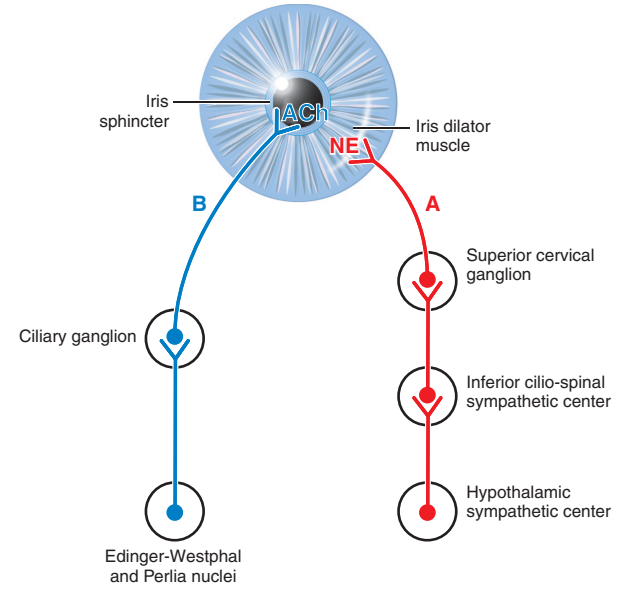

Figure 74–4 *Sympathetic (**A**) and parasympathetic (**B**) efferent pathway of pupil dilation and constriction.* Norepinephrine (NE) and acetylcholine (ACh) are the respective neurotransmitters.

metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

Retina

The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels; it contains the photoreceptors and the rhodopsin-based G protein signaling system. The elevated IOP of glaucoma damages and causes the death of the retinal ganglion cells whose axons comprise the optic nerve that connect the retina and the brain. Glutamate, acting on *N*-methyl-D-aspartate receptors, can stimulate this process (Sucher et al., 1997). In theory, this offers a target for neuroprotective

TABLE 74–2 ■ EFFECTS OF PHARMACOLOGICAL AGENTS ON THE PUPIL

CLINICAL SETTING	DRUG	PUPILLARY RESPONSE
Normal	Sympathomimetic drugs	Dilation (mydriasis)
Normal	Parasympathomimetic drugs	Constriction (miosis)
Horner syndrome	Cocaine 4%–10% Apraclonidine 0.5%	No dilation Marked dilation[a]
Preganglionic Horner syndrome	Hydroxyamphetamine 1%	Dilation
Postganglionic Horner syndrome	Hydroxyamphetamine 1%	No dilation
Adie's pupil	Pilocarpine 0.05%–0.1%[b]	Constriction
Normal	Opioids (oral or intravenous)	Pinpoint pupils

Topically applied ophthalmic drugs unless otherwise noted.
[a]This is a result of the adrenergic receptor supersensitivity in a Horner pupil that gives a dominant alpha-1 effect in an otherwise alpha-2–dominant medication.
[b]This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie's pupil manifests a denervation supersensitivity and is responsive to this dilute cholinergic agonist.

agents to protect against cell death, but to date, no treatment other than IOP lowering has demonstrated any benefit in treating glaucoma.

Vitreous

Approximately 80% of the eye's volume is the vitreous, a clear medium containing collagen type II, hyaluronic acid, proteoglycans, glucose, ascorbic acid, amino acids, and a number of inorganic salts. The vitreous is adherent to the retina and optic nerve, which can result in traction on these vital structures, and has been the target of enzymatic lysis.

Optic Nerve

The optic nerve is a myelinated nerve conducting the retinal output to the CNS. It comprises an intraocular portion, visible as the optic disk in the retina; an intraorbital section; an intracanalicular portion; and an intracranial segment. The nerve is sheathed in meninges continuous with the brain. It is susceptible to a variety of insults, ranging from traumatic to toxic (ethambutol, methanol, ethanol) to nutritional (vitamin B_{12} and folic acid deficiency) to infectious, neoplastic, vascular, and inflammatory. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, arteritic ischemic optic neuropathy (giant cell arteritis) is best treated with systemic glucocorticoids and optic neuritis with intravenous glucocorticoids (Beck and Gal, 2008; Volpe, 2008). Glaucomatous optic neuropathy is medically managed by decreasing IOP.

Pharmacokinetics and Toxicology of Ocular Therapeutic Agents

Drug Delivery Strategies

There are a number of formulations of agents and routes of drug administration that are unique to the eye (Figure 74–1 and Table 74–3).

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, soft contact lenses, and collagen shields. Prolonging the time a drug remains in the cul-de-sac beneath the eyelid enhances drug absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Drug molecules may also be encapsulated in nanoparticles for controlled release on the ocular surface.

ADME

The ADME pharmacokinetic principles determine the time course of drug action in the eye; however, the routes of ocular drug administration, the flow of ocular fluids, and the architecture of the eye introduce other variables specific to the eye. Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon's, intracorneal, intracameral, intravitreal, and peribulbar or retrobulbar routes.

Absorption. After topical instillation of a drug, the rate and extent of absorption are determined by the dwell time of the drug in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug's dwell time may be prolonged by changing its formulation or vehicle. Dwell time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used frequently or chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 74–5.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug's diffusion are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process; the cornea resembles a trilaminar "fat-water-fat" structure corresponding to the epithelial, stromal, and endothelial layers, respectively. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, an amphipathic agent with both hydrophilic and lipophilic properties is best suited for transcorneal absorption. Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed.

Distribution. Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly via local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (see Figure 74–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α adrenergic agonists is slower in onset in humans with darkly pigmented irides compared to those with lightly pigmented irides; drug-melanin binding is a potential reservoir for sustained drug release. Another clinically

TABLE 74–3 ■ SOME CHARACTERISTICS OF OCULAR ROUTES OF DRUG ADMINISTRATION

ROUTE	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Topical	Prompt, depending on formulation	Convenient, economical, relatively safe	Compliance, corneal and conjunctival toxicity, nasal mucosal toxicity, systemic side effects from nasolacrimal absorption
Subconjunctival, sub-Tenon's, peribulbar, and retrobulbar injections	Prompt or sustained, depending on formulation	Anterior segment infections, posterior uveitis, cystoid macular edema	Local toxicity, tissue injury, globe perforation, optic nerve trauma, central retinal artery or vein occlusion, direct retinal drug toxicity with inadvertent globe perforation, ocular muscle trauma, prolonged drug effect
Intraocular (intracameral) injection	Prompt	Anterior segment surgery, infections	Corneal toxicity, intraocular toxicity, relatively short duration of action, adjacent tissue injury from injection
Intravitreal injection or device	Absorption circumvented, immediate local effect, potentia' sustained effect	Endophthalmitis, retinitis, age-related macular degeneration	Retinal toxicity, adjacent tissue injury from injection

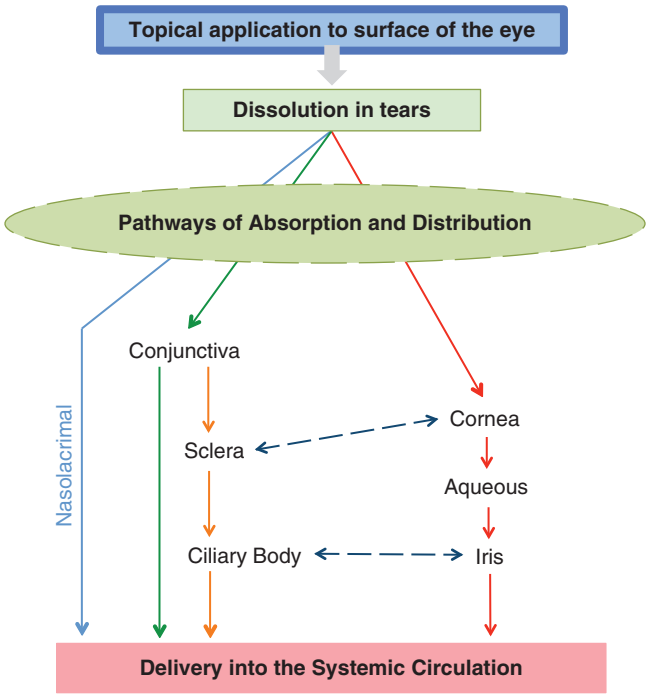

Figure 74–5 *Drugs applied to the surface of the eye have multiple routes to the systemic circulation.*

important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of *chloroquine* (see Chapter 66) causes a toxic retinal lesion known as a "bull's-eye" maculopathy, which is associated with a decrease in visual acuity. To reduce the risk of retinal toxicity from *chloroquine* and related substances (e.g., *hydroxychloroquine*), patients receiving chronic therapy should receive periodic eye exams, and lifetime cumulative doses should generally be limited to 2.3 mg/kg per day of *chloroquine* and 5 mg/kg per day of *hydroxychloroquine* (Melles and Marmor, 2014).

Metabolism. Biotransformation of ocular drugs may be significant; a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, glutathione conjugating enzymes, catechol-*O*-methyltransferase, monoamine oxidase, and 11β-hydroxysteroid dehydrogenase, are found in the eye. The esterases are of particular interest, permitting development of ester prodrugs for enhanced corneal permeability (e.g., *latanoprost* is a prodrug for prostaglandin [PG] $F_{2\alpha}$ used for glaucoma management; *loteprednol* is a *prednisolone* analogue engineered to have limited systemic effects due to metabolic inactivation within the eye).

Excretion. Ocular drugs are excreted from the eye through multiple routes. Lacrimal tearing dilutes and reduces the concentration of medications from the ocular surface. Additionally, nasolacrimal drainage contributes to the elimination of drugs from the ocular surface, redirecting topically administered medications to the nasal cavity and to systemic absorption. Once introduced into the systemic circulation, the drug is distributed to other parts of the body followed by metabolism and excretion.

Toxicity

Most local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eye drops and contact lens solutions commonly contain antimicrobial preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and, rarely, thimerosal. Benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy. All ophthalmic medications are potentially absorbed into the systemic circulation (see Figure 74–5), so systemic side effects may occur.

Ophthalmic Uses of Drugs

Chemotherapy of Microbial Diseases in the Eye

Bacterial Infections

Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (e.g., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics may be administered in addition to topical medications. A number of antibiotics are formulated for topical ocular use (Table 74–4).

Dacryoadenitis, an infection of the lacrimal gland, is most common in children and young adults; it may be bacterial (typically *Staphylococcus aureus, Streptococcus* spp.) or viral (seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

Dacryocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *S. aureus, Streptococcus* spp., diphtheroids, *Candida* spp., and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the eyelids include *hordeolum* and *blepharitis*. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands in the eyelids. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotics (gel, drops, or ointment). Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, usually associated with *Staphylococcus* spp. Local hygiene is the mainstay of therapy, although topical antibiotics frequently are used. Systemic *tetracycline*, *doxycycline*, *minocycline*, *erythromycin*, and *azithromycin* often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

Conjunctivitis is an inflammatory or infectious process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include allergies, viruses, environmental irritants, contact lenses, and chemicals. Less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. Commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus) and bacterial (e.g., *Neisseria* spp., *Streptococcus pneumoniae, Haemophilus* spp., *S. aureus, Moraxella lacunata*, and chlamydial spp.) sources. *Rickettsia*, fungi, and parasites, in both cystic and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation or infection, can occur at any level of the cornea. Myriad microbial agents may cause infectious keratitis, including bacteria, viruses, fungi, spirochetes, and parasites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, peripheral, and visually insignificant infections usually are not cultured, and the eyes are treated with frequent broad-spectrum topical antibiotics. In more severe, central, visually significant infections, corneal scrapings for cultures and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. When pathogens are not identified using corneal scrapings, the clinician may perform a corneal biopsy. A commercially available broad-spectrum antibiotic may be given, but in severe infections, specially formulated fortified antibiotics are often used. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance

TABLE 74–4 ■ TOPICAL ANTIBACTERIAL AGENTS COMMERCIALLY AVAILABLE FOR OPHTHALMIC USE

AGENT	FORMULATION[a]	TOXICITY	INDICATIONS FOR USE
Azithromycin	1% solution	H	Conjunctivitis
Bacitracin	500 units/g ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, blepharoconjunctivitis, meibomianitis, dacryocystitis
Besifloxacin	0.6% suspension	H	Conjunctivitis, keratitis
Chloramphenicol (not available in the U.S.)	1% ointment	H, BD	Conjunctivitis, keratitis
Ciprofloxacin	0.3% solution, 0.3% ointment	H, D-RCD	Conjunctivitis, keratitis, keratoconjunctivitis, blepharitis, blepharoconjunctivitis, meibomianitis, dacryocystitis
Erythromycin	0.5% ointment	H	Superficial ocular infections involving the conjunctiva or cornea; prophylaxis of ophthalmia neonatorum
Gatifloxacin	0.3% and 0.5% solutions	H	Conjunctivitis, keratitis
Gentamicin	0.3% solution, 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis, keratoconjunctivitis, blepharoconjunctivitis, meibomianitis, dacryocystitis
Levofloxacin	0.5% solution	H	Conjunctivitis, keratitis
	1.5% solution	H	Keratitis
Moxifloxacin	0.5% solution	H	Conjunctivitis, keratitis
Ofloxacin	0.3% solution	H	Conjunctivitis, keratitis
Sulfacetamide	10% solution, 10% ointment	H, BD	Conjunctivitis, other superficial ocular infections
Polymyxin B combinations[b]	Various solutions and ointments	H	Conjunctivitis, blepharitis, keratitis
Tobramycin[c]	0.3% solution, 0.3% ointment	H	External infections of the eye and its adnexa

Toxicity: BD, blood dyscrasia; D-RCD, drug-related corneal deposits; H, hypersensitivity.
[a]For specific information on dosing, formulation, and trade names, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*, which is published annually.
[b]Polymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, dexamethasone, hydrocortisone or trimethoprim. See Chapters 56–60 for further discussion of these antibacterial agents.
[c]Tobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate.

of corneal perforation and visual debilitation. The initial medication selection and dosage are adjusted according to the clinical response and culture/sensitivity results. In the case of culture-proven bacterial keratitis that has been treated with appropriate topical antibiotics for several days but still has significant inflammation, judicious topical steroids can be used with close follow-up to decrease corneal scarring.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis usually is caused by bacteria or fungi or, rarely, by spirochetes. The typical case occurs during the early postoperative course after intraocular surgery, following trauma, or rarely by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap (often sent for smears and cultures) and empirical injection of intravitreal antibiotics. Systemic antibiotics are helpful in reducing the risk of endophthalmitis following a traumatic open-globe injury (Ahmed et al., 2012). In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source. Vitrectomy (i.e., specialized surgical removal of the vitreous) is indicated in some cases (Endophthalmitis Vitrectomy Study Group, 1995; Schiedler et al., 2004).

Viral Infections

Antiviral drugs used in ophthalmology are summarized in Table 74–5 (see Chapter 62 for details of these agents). The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There currently are no antiviral agents indicated for the treatment of viral conjunctivitis caused by adenoviruses, which usually have a self-limited course and typically are treated by symptomatic relief of irritation, but topical *ganciclovir* gel may be of some benefit (Yabiku et al., 2011).

Viral keratitis, an infection of the cornea that may involve the epithelium, stroma, or endothelium, is most commonly caused by herpes simplex type I and varicella-zoster viruses. These viruses also may present with eyelid or periocular skin lesions. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and cytomegalovirus (CMV). The topical antiviral agents *trifluridine*, *acyclovir*, and *ganciclovir* are indicated for the treatment of epithelial disease due to herpes simplex infection, but *trifluridine* is more toxic to the corneal epithelium than the other two. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform (or endothelial) keratitis (predominantly a cell-mediated immune reaction), topical glucocorticoids often accelerate recovery. For recurrent herpetic stromal keratitis, there is clear benefit from treatment with an oral antiviral such as *acyclovir* in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1997, 1998; Young et al., 2010).

Herpes zoster ophthalmicus is a latent reactivation of a varicella-zoster infection in the first division of the trigeminal cranial nerve. Systemic *acyclovir*, *valacyclovir*, and *famciclovir* are effective in reducing the severity and complications of herpes zoster ophthalmicus (Cohen and Kessler, 2016).

Viral retinitis may be caused by herpes simplex virus, CMV, and varicella-zoster virus. With antiretroviral therapy (see Chapters 62 and 64), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal *ganciclovir*, injected or implanted as an insert, is an effective alternative to systemic use. The *ganciclovir* intravitreal implant provides a *zero-order* rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a prolonged period of time rather than as a bolus. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella-zoster virus, can be

TABLE 74–5 ■ ANTIVIRAL AGENTS FOR OPHTHALMIC USE

GENERIC NAME	ROUTE OF ADMINISTRATION	OCULAR TOXICITY	INDICATIONS FOR USE
Trifluridine	Topical (1% ophthalmic solution)	Punctate keratopathy, hypersensitivity	Herpes simplex keratitis and keratoconjunctivitis Dosed initially 9 times a day Corneal toxicity can occur
Ganciclovir	Topical (0.15% ophthalmic gel) Intravenous infusion, intravitreal injection[a]	Punctate keratopathy, conjunctival hyperemia	Herpes simplex keratitis Cytomegalovirus retinitis
Acyclovir	Oral (200-mg capsules, 400- and 800-mg tablets), intravenous	Punctate keratopathy	Herpes zoster ophthalmicus Herpes simplex keratitis, iridocyclitis
Valacyclovir	Oral (500- and 1000-mg tablets)		Herpes simplex keratitis[a] Herpes zoster ophthalmicus
Famciclovir	Oral (125-, 250-, and 500-mg tablets)		Herpes simplex keratitis[a] Herpes zoster ophthalmicus
Foscarnet	Intravenous Intravitreal[a]	Visual disturbance, conjunctivitis, hypersensitivity	Cytomegalovirus retinitis
Valganciclovir	Oral (450-mg tablets)	Retinal detachment, macular edema	Cytomegalovirus retinitis
Cidofovir	Intravenous	Decreased intraocular pressure, uveitis, blindness, cataract, conjunctivitis, corneal lesion, diplopia	Cytomegalovirus retinitis

[a]Off-label use. For additional details, see Chapter 62.

treated by combinations of oral, intravenous, and intravitreal administration of antiviral medications (Newman and Gooding, 2013).

Fungal Infections

The only currently available topical ophthalmic antifungal preparation is *natamycin*, a polyene. Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, intracorneal, intracameral, or intravitreal routes of administration (Table 74–6; see also Chapter 61). As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Fungal infections can involve the cornea, sclera, intraocular structures, canaliculi, and orbit. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection. Treatment for fungal keratitis is typically prolonged due to the generally poor ocular penetration of these medications and more resistant nature of these pathogens to antimicrobial agents. Consequently, topical antifungal therapy is frequently supplemented with systemic antifungal drugs to improve access to deeper infections.

Protozoal Infections

Parasitic infections involving the eye usually manifest themselves as a form of *uveitis*, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis. In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba*. Risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines—*propamidine isethionate* in topical aqueous and ointment forms (not commercially available in the U.S.)—have been used successfully to treat this relatively resistant infectious keratitis. The cationic antiseptic agent *polyhexamethylene biguanide* also is used in drop form for *Acanthamoeba* keratitis. Alternatively, topical *chlorhexidine* can be used. Both drugs need to be prepared by a specialty compounding pharmacy. Although initially FDA-approved to treat leishmaniasis, oral *miltefosine* has also been used adjunctively in the treatment of *Acanthamoeba* keratitis. Oral imidazoles (e.g., *itraconazole*, *fluconazole*, *ketoconazole*, *voriconazole*) are sometimes used in addition to topical medications. Resolution of *Acanthamoeba* keratitis often requires many months of treatment (Chew et al., 2011; Hoti and Tandon, 2011).

Treatment of *toxoplasmosis* is indicated when inflammatory lesions encroach on the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) *pyrimethamine*, *sulfadiazine*, and *folinic acid* (*leucovorin*); (2) *pyrimethamine*, *sulfadiazine*, *clindamycin*, and *folinic acid*; (3) *sulfadiazine* and *clindamycin*; (4) *clindamycin*; and (5) *trimethoprim-sulfamethoxazole* with or without *clindamycin*. Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminth infections are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections (Maenz et al., 2014; see Chapter 67, *Chemotherapy of Protozoal Infections*).

Ophthalmic Use of Autonomic Agents, Prostanoids, and Carbonic Anhydrase Inhibitors

Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology and the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 74–7. Table 74–8 presents some characteristics of prostanoids used in ophthalmology.

Glaucoma

Glaucoma is characterized by progressive loss of retinal nerve fiber layer tissue with corresponding visual field loss. The optic nerve acquires a characteristic loss of the neuroretinal rim, frequently referred to as "cupping." The prevalence of the disease is growing as populations age around the world (Tham et al., 2014). Risk factors include increased IOP, positive family history of glaucoma, African American heritage, and possibly myopia, diabetes, and hypertension. Reducing IOP can delay or prevent glaucomatous nerve or field damage. Although markedly elevated IOPs

TABLE 74–6 ■ ANTIFUNGAL AGENTS FOR OPHTHALMIC USE

DRUG CLASS AGENT	METHOD OF ADMINISTRATION	INDICATIONS FOR USE
Polyenes		
Amphotericin B[a]	0.1%–0.5% (typically 0.15%) topical solution	Yeast and fungal keratitis and endophthalmitis
	0.8–1 mg subconjunctival	Yeast and fungal endophthalmitis
	2–10 μg intracorneal and intracameral	Yeast and fungal keratitis
	5–10 μg intravitreal injection	Yeast and fungal endophthalmitis
	Intravenous	Yeast and fungal endophthalmitis
Natamycin	5% topical suspension	Yeast and fungal blepharitis, conjunctivitis, keratitis
Imidazoles		
Fluconazole[a]	Oral, intravenous	Yeast keratitis and endophthalmitis
Itraconazole[a]	Oral	Yeast and fungal keratitis and endophthalmitis
Ketoconazole[a]	Oral	Yeast keratitis and endophthalmitis
Miconazole[a]	1% topical ophthalmic solution	Yeast and fungal keratitis
	5–10 mg subconjunctival	Yeast and fungal endophthalmitis
	10 μg intravitreal injection	Yeast and fungal endophthalmitis
Voriconazole	Oral, intravenous, intravitreal	Yeast and fungal keratitis and endophthalmitis
	50 μg intracorneal and intracameral	Yeast and fungal keratitis

[a]Off-label use. Only natamycin is commercially available and labeled for ophthalmic use. All other antifungal drugs are not labeled for ophthalmic use and must be extemporaneously formulated for the given method of administration. For further dosing information, refer to the *Physicians' Desk Reference for Ophthalmic Medicines*. For additional discussion of these antifungal agents, see Chapter 61.

(e.g., >30 mmHg) usually will lead to optic nerve damage, the optic nerves in certain patients (*ocular hypertensives*) can tolerate IOPs in the mid-to-high 20s. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range; this form of the disease sometimes is called *normal-tension* or *low-tension* glaucoma. Regardless of the initial level, reducing the IOP delays or prevents disease progression (Collaborative Normal-Tension Study Group, 1998a, 1998b; Ederer et al., 2004; Heijl et al., 2002; Kass et al., 2002; Miglior et al., 2005). At present, the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood. Current pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways.

There is no consensus on the best IOP-lowering algorithm, but a stepwise approach depends on the patient's health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. For many ophthalmologists, a stepwise medical approach may begin with a *topical PG* analogue (see Table 74–8).

Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogues have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The PG analogues consist of *latanoprost* (Figure 74–6), *travoprost*, *bimatoprost*, and *tafluprost*. $PGF_{2\alpha}$ reduces IOP but has intolerable local side effects. Modifications to the chemical structure of $PGF_{2\alpha}$ have produced PG analogues with a more acceptable side effect profile. $PGF_{2\alpha}$ and its analogues (prodrugs that are hydrolyzed to $PGF_{2\alpha}$) bind to receptors for $PGF_{2\alpha}$ (FP receptors, FPr) that link to the $G_{q/11}$-PLC-IP_3-Ca^{2+} pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by $PGF_{2\alpha}$ range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts. *Latanoprostene bunod* is a newer PG analogue with a nitric oxide donating moiety that enhances traditional outflow through the trabecular meshwork by inducing relaxation of cytoskeleton in addition to the effect of the *latanoprost* backbone on the uveoscleral pathway (Cavet and DeCory, 2018).

The *β receptor antagonists* (see Table 74–7) are currently the next most common topical medical treatment. Nonselective β blockers bind to both β_1 and β_2 receptors and include *timolol*, *levobunolol*, and *carteolol*. The β_1-selective antagonist *betaxolol* is available for ophthalmic use but is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β_2 subtype. However, *betaxolol* is less likely to cause breathing difficulty due to blockade of pulmonary β_2 receptors. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β_2 receptors account for 75% to 90% of the total population. Production of aqueous humor seems to be activated by a β receptor–mediated cAMP-PKA pathway; β blockade blunts adrenergic activation of this pathway and therefore reduces intracellular cAMP. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production.

When there are medical contraindications to the use of PG analogues or β receptor antagonists, other agents, such as an α_2 *adrenergic receptor agonist* (see Table 74–7) or a topical *carbonic anhydrase inhibitor* (*CAI*; Table 74–9), may be used as first-line therapy. The α_2 adrenergic agonists appear to decrease IOP by reducing aqueous humor production and by enhancing both conventional (via an α_2 receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. The α_2 adrenergic agonist and *clonidine* derivative *apraclonidine* is a relatively selective α_2 adrenergic agonist that is highly ionized at physiological pH, does not cross the blood-brain barrier, and is thus relatively free of the CNS effects of *clonidine*. *Brimonidine* is a selective α_2 adrenergic agonist that is lipophilic, enabling easy corneal penetration. Both *apraclonidine* and *brimonidine* reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α_2 receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α_2 receptors, these drugs stimulate the G_i pathway, reducing intracellular cAMP production and thereby decreasing aqueous humor production.

The development of a *topical CAI* was prompted by the poor side effect profile of oral CAIs. *Dorzolamide* and *brinzolamide* both work by inhibiting carbonic anhydrase (isoform II), which is found in the ciliary body epithelium. Inhibition of carbonic anhydrase reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (see Table 74–9).

Rho kinase inhibitors are the most recent class of medication to be used to treat glaucoma and consist currently of *netarsudil* and *ripasudil* (Table 74–10). Rho kinase is a protein serine-threonine kinase involved in the regulation of the cytoskeleton. In the trabecular meshwork and canal of Schlemm, blockade of this pathway can decrease the density of actin stress fibers. The hypothesis is that these agents lower IOP by augmenting outflow via the trabecular pathway (Tanna and Johnson, 2018).

Any of these drug classes can be used as additive second-line or third-line therapy. In fact, the β receptor antagonist *timolol* has been combined with the CAI *dorzolamide* into a single medication and also with the α_2

TABLE 74–7 ■ AUTONOMIC DRUGS FOR OPHTHALMIC USE

DRUG CLASS	FORMULATION	INDICATIONS	OCULAR SIDE EFFECTS
Cholinergic agonists			
Acetylcholine	1% solution	Miosis in surgery	Corneal edema
Carbachol	0.01% solution	Miosis in surgery, glaucoma	Corneal edema, miosis, induced myopia, decreased vision, brow ache, retinal detachment
Pilocarpine	1%, 2%, and 4% solution	Glaucoma, miosis induction, miosis in surgery	Same as for carbachol
Anticholinesterase agents			
Echothiophate	0.03%, 0.06%, 0.125%, 0.25% solution	Glaucoma, accommodative esotropia	Retinal detachment, miosis, cataract, pupillary block, glaucoma, iris cysts, brow ache, punctal stenosis
Muscarinic antagonists			
Atropine	1% solution, 1% ointment	Cycloplegia, mydriasis,[a] cycloplegic retinoscopy,[b] dilated funduscopic exam,[b] iritis, uveitis, myopia	Photosensitivity, blurred vision; long acting (1 week or longer)
Scopolamine	0.25% solution	Cycloplegia, mydriasis, iritis, uveitis, nystagmus[b]	Same as for atropine but the effect lasts several days
Homatropine	2% and 5% solution	Cycloplegia, mydriasis, iritis,[b] uveitis	Same as for scopolamine but does not last as long
Cyclopentolate	Solution (0.5%, 1%, 2%), also with phenylephrine (0.2%/1%)	Cycloplegia, mydriasis[a]	Same as for atropine but effect lasts ~1 day
Tropicamide	0.5% and 1% solution, also with hydroxyamphetamine	Cycloplegia, mydriasis[a]	Same as for atropine but effect lasts several hours; commonly used for office exams
α Adrenergic agonists			
Phenylephrine	2.5% and 10% solution	Mydriasis, vasoconstriction, decongestion,[b] uveitis, glaucoma	α Adrenergic agonist effect lasts several hours; 2.5% used with tropicamide for office exams
Apraclonidine	0.5% and 1% solution	Glaucoma, ocular hypertension, also used for Horner syndrome diagnosis	α Adrenergic agonist; side effects: allergy (conjunctival hyperemia), dry mouth, sleepiness; used for Horner syndrome diagnosis
Brimonidine (α_2 selective)	Ophthalmic gel (0.33%); solution (0.025%, 0.1%, 0.15%, 0.2%); also with timolol or brinzolamide	Conjunctival injection, glaucoma, ocular hypertension	Same as for apraclonidine; causes respiratory depression in young children
Naphazoline	0.1% solution	Decongestant	Contraindicated in closed-angle glaucoma; safety/efficacy not established in the young (neonate to adolescent); use in infants may result in CNS depression, coma, marked reduction in body temperature; use with caution in patients with hypertension, cardiac disease, hyperthyroidism, diabetes, or infection or trauma in eye
Tetrahydrozoline	0.05% solution	Decongestant	Contraindicated in closed-angle glaucoma; safety/efficacy not established in neonates and children <6 years; use with caution in patients with coronary artery disease, hypertension, hyperthyroidism, or diabetes
β Adrenergic antagonists			
Betaxolol (β_1 selective)	0.25% suspension, 0.5% solution	Glaucoma, ocular hypertension	Reduced incidence of respiratory problems compared to timolol
Timolol	Solution, gel (0.25%, 0.5%); also with brimonidine, dorzolamide	Glaucoma, ocular hypertension	Side effects: exacerbation of respiratory problems (asthma and chronic obstructive pulmonary disease), bradycardia, depression, impotence
Carteolol	1% solution	Glaucoma, ocular hypertension	Same as timolol
Levobunolol	0.5% solution	Glaucoma, ocular hypertension	Same as timolol

[a]Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–40 min and 7–10 d; for scopolamine, 20–130 min and 3–7 d; for homatropine, 40–60 min and 1–3 d; for cyclopentolate, 30–60 min and 1 d; for tropicamide, 20–40 min and 6 h. Times to development of maximal cycloplegia and to recovery, respectively, are as follows: for atropine, 60–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h.

[b]Off-label use. Refer to *Physicians' Desk Reference for Ophthalmic Medicines* for specific indications and dosing.

TABLE 74–8 ■ PROSTAGLANDIN ANALOGUES FOR OPHTHALMIC USE

AGENT	FORMULATION	INDICATIONS	SIDE EFFECTS
Latanoprost (the most used glaucoma medication)	0.005% solution; also with netarsudil (0.02%)	Glaucoma, ocular hypertension	Once-daily dosing can cause lash growth; may cause allergic conjunctival hyperemia, permanent ↑ iris pigmentation, orbital fat atrophy
Travoprost	0.004% solution		Same as latanoprost but generally less irritating to corneal epithelium
Bimatoprost	0.01% solution, 0.03% solution 10 μg ophthalmic implant		
Tafluprost	0.0015% solution; preservative-free, single-dose droperettes		
Latanoprostene bunod	0.024%		Same as latanoprost

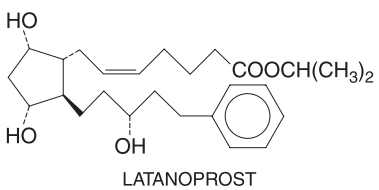
adrenergic agonist *brimonidine*. A *latanoprost/timolol* combination is widely available but not in the U.S. The combination of *brinzolamide/brimonidine* is also an option that is useful when a β receptor antagonist may be contraindicated. More recently, a *latanoprost/netarsudil* combination has become available. Such combinations reduce the number of drops needed and may improve compliance.

Topical miotic agents (see Table 74–7) are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. *Pilocarpine* and *carbachol* are cholinomimetics that stimulate muscarinic receptors and are referred to as having a direct mechanism of action. *Echothiophate*, *an irreversible* organophosphate inhibitor of acetylcholinesterase, enhances muscarinic cholinergic activity by reducing hydrolysis of neurally released acetylcholine (see Chapter 12). *Echothiophate* is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed.

If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with a CAI is an option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is *acetazolamide* in sustained-release capsules (see Chapter 29), followed by *methazolamide*. The least well tolerated are *acetazolamide* tablets.

The main osmotic drugs for ocular use are *glycerin*, *mannitol*, and *hypertonic saline*. Oral *glycerin* and intravenous *mannitol* are used for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of *mannitol* or *acetazolamide* may be preferred over oral administration of *glycerin*. These agents should be used with caution in patients with congestive heart failure or renal failure.

Toxicity of Antiglaucoma Agents. Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. The α_2 agonists, effective in IOP reduction, can cause a vasoconstriction-vasodilation rebound phenomenon, leading to a red eye. Ocular and skin allergies from topical *apraclonidine* and *brimonidine* are common. *Brimonidine* is less likely to cause ocular allergy than *apraclonidine* and therefore is more commonly used. α_2 Agonists can cause CNS depression and apnea in neonates and are contraindicated in children less than 2 years of age. Systemic absorption of α_2 agonists and β adrenergic antagonists can induce all the side effects of systemic administration. Rho kinase inhibitors can have a vasodilating effect that results in conjunctival hyperemia, subconjunctival hemorrhage, blepharitis, and tearing. Rho kinase inhibitors often cause gold-brown pigment deposition in the corneal epithelium (cornea verticillata) and rarely cause reticular corneal epithelial edema. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.



LATANOPROST

Figure 74–3 *Latanoprost.*

Uveitis

Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. *Cyclopentolate*, *tropicamide*, or sometimes even longer-acting antimuscarinic agents such as *atropine*, *scopolamine*, and *homatropine* frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. Various combinations of an α adrenergic agonist and antimuscarinic agent (e.g., 10% *phenylephrine* with 0.3% *scopolamine*; 1% *hydroxyamphetamine hydrobromide* with 0.25% *tropicamide*; 1% *phenylephrine* with 0.2% *cyclopentolate*; and 2.5% *phenylephrine* with 1% *tropicamide*) are available for the induction of mydriasis. Topical steroids usually are adequate to decrease inflammation but sometimes must be supplemented with local steroid injections or systemic steroids.

Strabismus

Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing *diplopia* (double vision), strabismus in children may lead to *amblyopia* (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with *hyperopia*, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest *esotropia* (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about 6 to 8 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. This is a fairly common cause of visual disability. In this setting, *atropine* (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002, 2003). Echothiophate iodide also has been used in the setting of

TABLE 74–9 ■ CARBONIC ANHYDRASE INHIBITORS FOR OPHTHALMIC USE

AGENT	FORMULATION	INDICATIONS	SIDE EFFECTS
Acetazolamide	Tablets (125, 250 mg); extended release (500 mg) Intravenous	Acute ↑ IOP, glaucoma, idiopathic intracranial hypertension	Paresthesias (hands, feet), upset stomach, hypokalemia, allergic rash, kidney stones Rare: aplastic anemia
Methazolamide	Tablets (25, 50 mg)	Glaucoma	Same as acetazolamide but generally lesser paresthesias and upset stomach
Dorzolamide	2% solution; also in combo with timolol (0.5%)	Glaucoma, ocular hypertension	Causes burning, stinging, and a metallic taste
Brinzolamide	1% suspension; also in combo with brimonidine (0.2%)	Glaucoma, ocular hypertension	Causes less burning, stinging, and metallic taste than dorzolamide

accommodative strabismus. Accommodation drives the near reflex, which includes the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as *echothiophate* causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur. It is often used in conjunction with a mydriatic to reduce the formation of iris cysts that are associated with *echothiophate* use.

Myopia

Myopia, or nearsightedness, is a condition in which near objects appear clear, while objects farther away are blurred because light entering the eye is not focused properly onto the retina. This has traditionally been treated with refractive correction such as spectacles, contact lenses, or refractive surgery. The prevalence of myopia has been increasing worldwide and is estimated to reach 5 billion by 2050, while high myopia, defined as more myopia than –5.00 D by the World Health Organization (WHO), will reach a prevalence of 1 billion (Gong et al., 2017). The leading cause of visual impairment worldwide is unaddressed refractive error, and high myopia is associated with sight-threatening complications such as chorioretinal atrophy and choroidal neovascularization; therefore, myopia prevention has become an international effort (WHO, 2017). Low-dose *atropine* ranging from 0.01% to 0.5% can be used to slow and even reverse myopia progression in children, although the exact mechanism of action remains unclear. Ocular side effects are dose dependent and include allergic reactions, dilated pupils requiring sunglasses, and loss of accommodation.

Surgical and Diagnostic Uses

For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (see Table 74–7). Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, *acetylcholine* and *carbachol*. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or eyelid droop (ptosis). Patients with Horner syndrome may present to their ophthalmologist complaining of ptosis, and the reversal of anisocoria that occurs with *apraclonidine* is helpful in diagnosing these patients (see Table 74–2).

Anti-inflammatory, Immunomodulatory, and Antimitotic Drugs

Glucocorticoids

Glucocorticoids have an important role in managing ocular inflammatory diseases (Tables 74–11 and 74–12). The chemistry and pharmacology of glucocorticoids are described in Chapter 50.

Therapeutic Uses. The glucocorticoids formulated for topical administration to the eye are *dexamethasone*, *prednisolone*, *fluorometholone*, *loteprednol*, and *difluprednate*. Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, dry eye syndrome, external eye inflammatory diseases associated with some infections, ocular cicatricial pemphigoid, anterior uveitis, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Steroids commonly are given systemically and by sub-Tenon's capsule injection to manage posterior uveitis. Intravitreal injection of steroids is used to treat diabetic retinopathy and cystoid macular edema. An intravitreal *triamcinolone* formulation is approved for ocular inflammatory conditions unresponsive to topical corticosteroids and for visualization during vitrectomy. Parenteral steroids followed by tapering oral doses is the preferred treatment of optic neuritis. Two ophthalmic implants, *fluocinolone* and *dexamethasone*, are marketed for the treatment of chronic, noninfectious uveitis; a *dexamethasone* implant is also indicated for the treatment of macular edema.

Toxicity. Ocular complications include the development of posterior subcapsular cataracts, secondary infections, and secondary open-angle glaucoma. There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate-to-marked steroid-induced IOP elevations may occur in up to 90% of patients. Some topical steroids (e.g., *loteprednol*) have been developed that reduce, but do not eliminate, the risk of elevated IOP. Certain corneal infections can be worsened by topical steroids, especially from herpes simplex virus, fungus, and acanthamoeba.

TABLE 74–10 ■ RHO KINASE INHIBITORS FOR OPHTHALMIC USE

AGENT	FORMULATION	INDICATIONS	SIDE EFFECTS
Netarsudil	0.02%; also in combination with latanoprost (0.005%)	Glaucoma, endothelial cell repopulation after Descemet stripping only	Conjunctival hyperemia, subconjunctival hemorrhage, blepharitis, tearing, cornea verticillata, rarely reticular corneal epithelial edema
Ripasudil (not available in the U.S.)	0.4%	Glaucoma, endothelial cell repopulation after Descemet stripping only	Same as netarsudil

TABLE 74–11 ■ GLUCOCORTICOIDS FOR TOPICAL APPLICATION TO THE EYE

AGENT	FORMULATION	INDICATIONS
Dexamethasone	0.1% suspension; 0.1% (sodium phosphate) solution; 0.4 mg intracanalicular insert; 0.7 mg intravitreal implant	Steroid-responsive inflammatory conditions of the palpebral and bulbar conjunctiva, cornea, and anterior segment; infective conjunctivitis to reduce edema and inflammation when hazard of steroid use is acceptable; corneal injury from chemical, radiation, or thermal burns or penetration of foreign object; postoperative inflammation
Difluprednate	0.05% emulsion	Ocular pain; postoperative ocular inflammation; uveitis
Fluorometholone	0.1%, 0.25% suspension; 0.1% ointment	Allergic conjunctivitis; giant papillary conjunctivitis; keratitis; ocular burns; postoperative ocular inflammation; uveitis; vernal keratoconjunctivitis
Loteprednol etabonate	0.2%, 0.25%, 0.5% suspension; 0.38%, 0.5% gel; 0.5% ointment	Allergic conjunctivitis; cyclitis; giant papillary conjunctivitis; iritis; keratitis; ocular pain; postoperative ocular inflammation, uveitis[a]
Prednisolone acetate Prednisolone sodium phosphate	0.12%, 1% suspension 1% solution	Allergic conjunctivitis and marginal corneal ulcer; anterior segment inflammation; bacterial conjunctivitis; chorioretinitis; cyclitis; endophthalmitis[a]; Graves' ophthalmopathy; herpes zoster ocular infection (with antiviral therapy); iritis; nonspecific and superficial punctate keratitis; postoperative ocular inflammation; optic neuritis; sympathetic ophthalmia; diffuse posterior uveitis; vernal keratoconjunctivitis; corneal injury from chemical, radiation, thermal burns; or penetration of foreign objects. Commonly used after ocular surgery

[a]Off-label use.

Nonsteroidal Anti-inflammatory Agents

Pharmacological properties of non-steroidal anti-inflammatory drugs (NSAIDs) are presented in Chapter 42. Five topical NSAIDs are FDA-approved for ocular use: *flurbiprofen*, *ketorolac*, *diclofenac*, *bromfenac*, and *nepafenac*.

The NSAIDs are supplied as solutions and suspensions for topical ocular use to reduce ocular inflammation and cystoid macular edema. *Flurbiprofen* is used to counter unwanted intraoperative miosis during cataract surgery. *Ketorolac* is given for seasonal allergic conjunctivitis. A combination *ketorolac/phenylephrine* intraocular solution is available to add to intraoperative ophthalmic irrigation solutions to decrease miosis during cataract surgery. *Diclofenac* is used for postoperative inflammation and pain. Both *ketorolac* and *diclofenac* are effective in treating cystoid macular edema occurring after cataract surgery and in controlling pain after corneal refractive surgery. *Bromfenac* and *nepafenac* are indicated for treating postoperative pain and inflammation after cataract surgery. Topical NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease such as dry eye syndrome or autoimmune conditions affecting the ocular surface.

Antihistamines and Mast Cell Stabilizers

H_1 antagonists (see Chapter 43) and mast cell stabilizers are used to treat the manifestations of ocular allergies. *Pheniramine* and *antazoline* (discontinued in the U.S.) are formulated in combination with *naphazoline*, a vasoconstrictor, for relief of allergic conjunctivitis; *emedastine difumarate* also is used. *Cromolyn sodium* has found some use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. The mast cell stabilizer *lodoxamide tromethamine* is available for ophthalmic use for the treatment of ocular inflammatory states such as vernal conjunctivitis and keratitis. *Nedocromil*, primarily a mast cell stabilizer with some antihistaminic properties, is also used. Likewise, *olopatadine hydrochloride, ketotifen fumarate, bepotastine, azelastine*, and *alcaftadine* are H_1 antagonists with mast cell–stabilizing properties. *Epinastine* antagonizes H_1 and H_2 receptors and exhibits mast cell–stabilizing activity.

Immunosuppressants

Topical *cyclosporine* (Table 74–13) is approved for the treatment of chronic dry eye associated with inflammation. Use of *cyclosporine* is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort. Topical *ifitegrast* (Table 74–13) is approved to treat the signs and symptoms of dry eye disease. *Lifitegrast* inhibits an integrin, lymphocyte function–associated antigen 1 (LFA-1), from binding to intercellular adhesion molecule 1 (ICAM-1), which is thought to downregulate inflammation mediated by T lymphocytes. *Interferon* α_{2b} is used off-label in the treatment of conjunctival papilloma and certain conjunctival tumors.

Antimitotic Agents

In glaucoma surgery, the antineoplastic agents *5-fluorouracil* (5FU) and *mitomycin* (Table 74–13; see details of mechanism in Chapter 70) improve the success of filtration surgery by limiting the postoperative wound-healing process.

Therapeutic Uses. *Mitomycin* is used intraoperatively as a single subconjunctival application at the trabeculectomy site. 5FU may be used intraoperatively at the trabeculectomy site or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1996). Both agents work by limiting the healing process; sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In corneal disease, both *mitomycin* and 5FU are used in the treatment of certain corneal and conjunctival tumors. *Mitomycin* can be used to reduce the risk of scarring after procedures to remove corneal opacities and prophylactically to prevent corneal scarring after photorefractive and phototherapeutic keratectomy. *Mitomycin* also is used to decrease recurrence after pterygium excision. Caution is advocated when using *mitomycin* in light of the potentially serious delayed ocular complications, including limbal stem cell deficiency and corneal or scleral melt.

Agents Used in Ophthalmic Surgery

Presurgical Antiseptics

Povidone iodine is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prepare periocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. *Povidone iodine* can cause local irritation and should be avoided in patients with a history of prior reaction to it. *Hypochlorous acid* is an effective skin preparation agent and can be used for ophthalmic surgery when *povidone iodine* is contraindicated.

Viscoelastic Substances

The viscoelastic substances are agents that assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate and

TABLE 74–12 ■ GLUCOCORTICOIDS FOR SUB-TENON'S, INTRAVITREAL, AND SYSTEMIC USE

AGENT	FORMULATION	METHOD OF ADMINISTRATION	INDICATION
Triamcinolone	Solutions and suspensions for injection, 3–40 mg/mL (only triamcinolone acetonide injectable suspension 40 mg/mL is FDA-approved for intravitreal injection)	Sub-Tenon's,[a] intracameral,[a] intravitreal	Ocular inflammation, ocular surgery, uveitis
Betamethasone	Suspension for IM injection (6 mg/mL)	Sub-Tenon's[a]	Corticosteroid-responsive ophthalmic disorders: allergic conjunctivitis and marginal corneal ulcer, anterior segment inflammation, chorioretinitis, conjunctivitis, endophthalmitis,[a] Graves' ophthalmopathy, herpes zoster ocular infection, iritis, keratitis, postoperative ocular inflammation, optic neuritis, diffuse posterior uveitis, vernal keratoconjunctivitis
Dexamethasone	Oral concentrate (1 mg/mL); tablets (0.5–6 mg); injectable solution (4 mg/mL, 10 mg/mL)	Oral, intravenous, intramuscular	Allergic conjunctivitis, allergic marginal corneal ulcer, anterior segment inflammation, chorioretinitis, cyclitis, endophthalmitis,[a] Graves' ophthalmopathy, giant papillary conjunctivitis, herpes zoster ocular infection, iritis, keratitis, superficial punctate keratitis, postoperative ocular inflammation, optic neuritis, diffuse choroiditis, sympathetic ophthalmia, vernal keratoconjunctivitis, or corneal injury (corneal abrasion)
Dexamethasone	0.4 mg ophthalmic implant	Intravitreal	Ocular inflammation due to macular edema following retinal vein occlusion, including branch retinal vein occlusion or central retinal vein occlusion and for the treatment of noninfectious uveitis affecting the posterior segment of the eye
Fluocinolone acetonide	0.18 mg ophthalmic implant	Intravitreal	Diabetic macular edema in patients who had no clinically significant rise in intraocular pressure when treated with corticosteroids
Fluocinolone acetonide	0.59 mg ophthalmic implant	Intravitreal	For the treatment of chronic noninfectious uveitis affecting the posterior segment of the eye
Methylprednisolone	Tablets (2–32 mg): 20 mg/mL, 40 mg/mL, suspension for IM injection (80 mg/mL); sodium succinate solution for IM/IV injection (40–2000 mg)	Oral, intravenous, intramuscular	For the systemic treatment of ophthalmic disorders, including allergic conjunctivitis, allergic marginal corneal ulcer, anterior segment inflammation, chorioretinitis, endophthalmitis,[a] Graves' ophthalmopathy, herpes zoster ocular infection, iritis, keratitis, postoperative ocular inflammation, optic neuritis, diffuse posterior uveitis, or vernal keratoconjunctivitis
Prednisone	1 mg/mL, 5 mg/mL oral solution; 1, 2.5, 5, 10, 20, 50 mg tabs; 1, 2, 5 mg delayed-release tabs	Oral	Inflammatory conditions such as endophthalmitis,[a] optic neuritis, allergic conjunctivitis, keratitis, allergic corneal ulcer, iritis, chorioretinitis, anterior segment inflammation, uveitis, choroiditis, or sympathetic ophthalmia
Prednisolone	Orally disintegrating tablets (10–30 mg); syrup and oral solution (1–5 mg/mL); injection 125 mg/mL	Oral, injection (IV/IM)	Systemic treatment of corticosteroid-responsive eye disorders

IM, intramuscular; IV, intravenous.
[a]Off-label use.

hydroxypropyl methylcellulose and share varying degrees of the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Complications associated with viscoelastic substances are related to transient elevation of IOP after surgery with retained intraocular material.

Ophthalmic Glue

Cyanoacrylate tissue adhesive, while not FDA-approved for the eye, is widely used in the management of corneal ulcerations and perforations. *Fibrin sealants* are increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

Intraoperative Visualization

Intraoperatively, *trypan blue* is marketed as 0.06% and 0.15% ophthalmic solutions to facilitate visualization of the anterior lens capsule during cataract surgery, for staining of Descemet's membrane that is inserted into the eye during Descemet's stripping endothelial keratoplasty, and

TABLE 74–13 ■ IMMUNOSUPPRESSIVE AND ANTIMITOTIC AGENTS FOR OCULAR USE

AGENT	FORMULATION	INDICATION	COMMENTS
Cyclosporine	0.05% or 0.09% emulsion	Dry eye	Dosed in preservative-free individual droperettes; Can be compounded up to 2%
Lifitegrast	5% solution	Dry eye	Dosed in preservative-free individual droperettes
Interferon α_{2B}[a]	Topical solution (1 million IU/mL); subconjunctival injection (3 million IU/0.5 mL)	Conjunctival tumors Conjunctival papilloma	Used in the treatment of ocular surface squamous neoplasia
5-Fluorouracil (5FU)	50 mg/mL solution	Conjunctival tumors Conjunctival papilloma Glaucoma surgery Epithelial downgrowth	Used intraoperatively and postoperatively to prevent subconjunctival scarring Inhibits corneal epithelial healing; cannot be used if there is corneal abrasion
Mitomycin	0.2 mg/mL for topical application	Conjunctival tumors Glaucoma surgery Pterygium surgery Corneal scarring and surface ablation surgery	Generally used as a subconjunctival application intraoperatively to prevent scarring More commonly used than 5FU in glaucoma surgery; not for injection Used topically on the cornea

[a]Off-label use

for staining the retinal surface during surgical vitrectomy to guide the excision of tissue.

Anterior Segment Gases

Sulfur hexafluoride (SF_6) and *perfluoropropane* (C_3F_8) gases are used as vitreous substitutes during retinal surgery. In the anterior segment, SF_6 is used in a nonexpansile concentration primarily after endothelial keratoplasty to help the lamellar graft adhere to the posterior cornea. Patients are typically advised to lay face up for 3 to 5 days after surgery to maximize graft attachment. SF_6 may also be used to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

Vitreous Substitutes

Several compounds, including gases, perfluorocarbon liquids, and silicone oils, are available as vitreous substitutes (Table 74–14). Their primary use is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. The use of expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for *perfluoropropane*).

TABLE 74–14 ■ VITREOUS SUBSTITUTES[a]

AGENT	DURATION OR VISCOSITY
Gases	
Air	Duration, 3–7 days
Sulfur hexafluoride (SF_6)[b]	Duration, 10–14 days
Perfluoropropane (C_3F_8)[b]	Duration, 55–65 days
Liquids	
Silicone oil (SO)	Viscosity: 1000–5000 cs
SO-PFA combinations	

cs, centistoke (unit of viscosity); PFA, partially fluorinated alkanes
[a]For further information, see Alovisi et al. (2017).
[b]Expansile gas

The liquid perfluorocarbons (specific gravity 1.76–1.94) are denser than vitreous and are helpful in flattening the retina when vitreous is present. Their use is limited to intraoperative settings due to long-term toxicity to the retina. Silicone oil (polydimethylsiloxanes) is used for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity. Combinations of silicone oil and partially fluorinated alkanes have been approved for clinical use, which may have benefit over silicone oil alone for certain types of retinal breaks (Alovisi et al., 2017).

Surgical Hemostasis and Thrombolytic Agents

Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur that can be minimized by thorough irrigation after hemostasis is achieved.

During intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage, *tissue plasminogen activator* (tPA; see Chapter 36) has been used off-label. tPA also has been administered subconjunctivally and intracamerally (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of tPA is bleeding.

Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders

Several botulinum toxin type A preparations are marketed in the U.S. with similar indications: *onabotulinumtoxinA*, *abobotulinumtoxinA*, *prabotulinumtoxinA*, and *incobotulinumtoxinA*. These agents are used for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), bladder dysfunction and urinary incontinence, spasticity, axillary hyperhidrosis, spasmodic torticollis (cervical dystonia), and chronic migraine, among others. By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. Complications related to this toxin include double vision (diplopia), eyelid droop (ptosis), and rarely, potentially life-threatening distant spread of toxin effect from the injection site hours to weeks after administration.

Agents Used to Treat Blind and Painful Eyes

Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye when topical steroids and cycloplegics fail. Retrobulbar *chlorpromazine* also has been used off-label. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged. This may cause paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

Ocular Side Effects of Systemic Agents

Certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening (Li et al., 2008; Pula et al., 2013). Examples are listed in the sections that follow.

IOP and Glaucoma

The antiseizure drug *topiramate* can cause choroidal effusions leading to angle-closure glaucoma. Inhaled, systemic, or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Retina

Numerous drugs have toxic side effects on the retina. The antiarthritis and antimalarial medicines *hydroxychloroquine* and *chloroquine* can cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. *Tamoxifen* can cause crystalline maculopathy, whereas *cisplatin* and *carmustine* cause a pigmentary retinopathy. The antiseizure drug *vigabatrin* causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

Optic Nerve

The phosphodiesterase (PDE) 5 inhibitors *sildenafil*, *vardenafil*, and *tadalafil* inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection (see Chapter 49). They are also used to treat pulmonary arterial hypertension (see Chapter 35). The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina (see Figure 74–9), causing a bluish haze or light sensitivity. Multiple medications, including *ethambutol*, *chloramphenicol*, and *rifampin*, can cause toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss.

Anterior Segment

Steroids have been implicated in cataract formation. *Tamoxifen*, among others, has also been associated with cataracts. *Rifabutin*, if used in conjunction with *clarithromycin* or *fluconazole* for treatment of *Mycobacterium avium* complex opportunistic infections in human immunodeficiency virus–positive persons, is associated with an iridocyclitis and even hypopyon. These conditions resolve with steroids or by stopping the medication.

Ocular Surface

Isotretinoin has a drying effect on mucous membranes and is associated with dry eye and severe dysfunction of the meibomian gland.

Cornea, Conjunctiva, and Eyelids

The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication *amiodarone*. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits disappear slowly when the medication is stopped. Other medications, including *indomethacin*, *atovaquone*, *chloroquine*, and *hydroxychloroquine*, can cause a similar pattern. The phenothiazines, including *chlorpromazine* and *thioridazine*, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Gold- and silver-containing medications can be used to treat rheumatoid arthritis and can cause pigmented deposits in the cornea and conjunctiva. Certain chemotherapeutic agents, such as *cytarabine*, can cause temporary corneal toxicity. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic *minocycline* can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone. *Dupilumab*, a monclonal antibody that inhibits pro-inflammatory signaling by IL-4 and IL-13, is used to treat moderate to severe eczema; its use has been associated with conjunctivitis, keratitis, blepharitis, and dry eye.

Agents Used to Assist in Ocular Diagnosis

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity); to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics); and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed previously. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in the material that follows.

Anterior Segment and External Diagnostic Uses

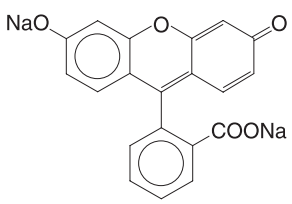
Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes *fluorescein, rose bengal*, and *lissamine green* are used in evaluating these problems. *Fluorescein* (Figure 74–7) is available as 10% and 25% solutions for injection and as an impregnated paper strip, and reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, *fluorescein* is used to determine the patency of the nasolacrimal system. In addition, this dye is used in *applanation tonometry* (IOP measurement) and to assist in determining the proper fit of rigid and semirigid contact lenses. *Fluorescein* in combination with *proparacaine* or *benoxinate* is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. *Fluorexon*, a high-molecular-weight fluorescent solution, is used when *fluorescein* is contraindicated (as when soft contact lenses are in place). *Rose bengal* and *lissamine green* (available as saturated paper strips) stain devitalized tissue on the cornea and conjunctiva.

Posterior Segment Diagnostic Uses

The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either *fluorescein sodium* or *indocyanine green*. These agents commonly cause nausea and pruritis and may precipitate serious allergic reactions in susceptible individuals.

Treatment of Retinal Neovascularization, Macular Degeneration, and Vitreomacular Traction

The medical treatment of retinal neovascularization has been changing rapidly in the past several decades and will likely continue to do so (Agarwal et al., 2015). Current treatment employs agents that inhibit the actions of VEGF (Table 74–15).



FLUORESCEIN SODIUM

Figure 74–7 *The diagnostic dye fluorescein.*

TABLE 74–15 ■ ANTI-VEGF AGENTS FOR OCULAR USE

AGENT	FORMULATION	INDICATION	COMMENTS
Verteporfin	2 mg/mL reconstituted solution for intravenous infusion	Retinal neovascularization associated with macular degeneration	Dosed according to body surface area Activated by a cool laser as it circulates in the retinal circulation Causes photosensitization and propensity for sunburn
Pegaptanib	0.3 mg/0.09 mL intravitreal injection	Same as verteporfin	Binds to the 165 isoform of VEGF
Aflibercept	2 mg/0.05 mL intravitreal injection	Same as verteporfin *plus* DME or for the treatment of diabetic retinopathy in patients with DME	A decoy receptor for VEGF-A
Bevacizumab[a]	1.25 mg/0.05 mL intravitreal injection	Same as aflibercept	First anti-VEGF antibody commercially available; generally used off-label as first-line therapy. Made by compounding pharmacies
Ranibizumab	0.3 mg/0.05 mL intravitreal injection	Same as aflibercept	A variant of bevacizumab
Brolucizumab	6 mg/0.05 mL intravitreal injection	Same as aflibercept	Single-chain antibody fragment Longer duration Rarely, severe inflammatory reaction

[a]Off-label use high risk due to possible contamination in compounding pharmacies.

Verteporfin is approved for photodynamic therapy of the exudative form of age-related macular degeneration (AMD) with predominantly classic choroidal neovascular membranes. *Verteporfin* also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. *Verteporfin* is administered intravenously; once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Activation of the drug in the presence of O_2 generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The $t_{1/2}$ of the drug is 5 to 6 h; it is eliminated predominantly in the feces. Potential side effects include headache, injection site reactions, and visual disturbances. The drug causes temporary photosensitization; patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving *verteporfin*.

Pegaptanib, a selective VEGF antagonist, is approved for neovascular (wet) AMD. VEGF165 induces angiogenesis and increases vascular permeability and inflammation; these actions likely contribute to the progression of the neovascular (wet) form of AMD, a leading cause of blindness. *Pegaptanib* inhibits VEGF165 binding to VEGF receptors. *Pegaptanib* (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported.

Aflibercept is a recombinant fusion protein, consisting of portions of human VEGF receptors 1 and 2, that acts as a soluble decoy receptor for VEGF-A. It is approved for the neovascular (wet) form of AMD as well as macular edema following retinal vein occlusion or associated with diabetic retinopathy. Depending on the underlying disease, *aflibercept* (2 mg) is administered once every month by intravitreal injection into the eye for 3 to 5 months, followed by 2 mg once every 8 weeks. Serious side effects may include eye pain or redness, swelling, vision problems, photosensitivity, headaches, sudden numbness on one side of the body, confusion, and problems with speech and balance. The drug is contraindicated in patients who have an active eye infection or active ocular inflammation.

Bevacizumab is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see Chapter 72). *Ranibizumab* is a variant of *bevacizumab* that has had the Fab domain affinity matured. Both drugs are delivered by intravitreal injection and often are used on a monthly basis for maintenance therapy. Both have been associated with the risk of cerebral vascular accidents. The enormous cost difference between these similar antibodies has sparked a debate about the cost-effectiveness of treatment strategies (Shaikh et al., 2015; Stein et al., 2014), especially in light of recent data indicating similar visual acuity outcomes for each medicine (CATT Research Group, 2011).

Brolucizumab, a more recent therapy for macular degeneration, also targets VEGF-A but is a single-chain antibody fragment and therefore smaller with the potential for increased duration. *Brolucizumab* was shown to be noninferior to *aflibercept* with a similar safety profile, but with a higher incidence of uveitis. It also required less frequent dosing (Dugel et al., 2020), which has significant implications given the cost and frequency of visits associated with treating retinal neovascularization.

Ocriplasmin is a proteolytic enzyme that is used to treat vitreomacular traction. It works to dissolve the vitreous and relieve traction on the macula in the center of the retina. An interesting side effect is the possibility of lens subluxation from zonular dehiscence.

Anesthetics in Ophthalmic Procedures

Topical anesthetic agents used clinically in ophthalmology include *proparacaine* and *tetracaine* drops, *lidocaine* gel (see Chapter 25), and intranasal *cocaine*. *Cocaine* may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. *Lidocaine* and *bupivacaine* are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and inadvertent vascular and subdural injections. Both preservative-free *lidocaine* (1%), which is introduced into the anterior chamber, and ophthalmic *lidocaine* jelly (3.5%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is *ketamine*, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

Treatment of Dry Eye and Corneal Edema

The current management of dry eyes usually includes instilling artificial tears and other ophthalmic lubricants. In general, tear substitutes are

hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film.

Common viscosity agents include *cellulose polymers, polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin*, and *dextran*. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel like. Some tear formulations also are combined with a vasoconstrictor, such as *naphazoline*, *phenylephrine*, or *tetrahydrozoline*. The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision; consequently, they are used primarily at bedtime, in critically ill or sedated patients, or in very severe dry eye conditions. A *hydroxypropyl cellulose* ophthalmic insert that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

Local eye diseases such as blepharitis, ocular rosacea, ocular pemphigoid, or chemical burns may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see Absorption), ophthalmic *cyclosporine*, or ophthalmic *lifitegrast* (see Immunosuppressants). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic *cyclosporine/lifitegrast*, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic *cyclosporine/lifitegrast* can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca. *Doxycycline* (see Bacterial Infections) is often used to treat blepharitis due to its anti–matrix metalloproteinase activity. In severe cases, autologous serum tears are formulated using blood drawn from the patient and prepared in specialty laboratories. Because serum contains a mixture of growth factors, proteins, antioxidants, and lipids, it provides a more effective tear replacement than manufactured tears.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. NaCl is available in either aqueous or ointment formulations. Topical *glycerin* also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to clinical evaluation. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical *glycerin*, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

Rho kinase inhibitors (see Glaucoma), including *netarsudil* and *ripasudil*, promote adhesion, survival, and proliferation of corneal endothelial cells (Macsai and Shiloach, 2019). These medications have been used in conjunction with *Descemet's stripping only* surgery in patients with Fuchs endothelial corneal dystrophy limited to the central 5 mm of the cornea, to stimulate endothelial expansion and possibly proliferation into the area of excised Descemet's membrane/endothelium.

Treatment of the Neurotrophic Cornea

The cornea is the most densely innervated tissue in the human body, and corneal nerves play a critical role in corneal homeostasis. Corneal nerves mediate protective blinking and tearing reflexes and also provide trophic support, releasing neuropeptides to promote corneal epithelial proliferation, migration, and adhesion. Neurotrophic keratopathy can result from multiple underlying causes including herpetic infection, chemical injury, long-term diabetes, prior ocular surgery, long-term contact lens use, or an intracranial mass or neurosurgery. Typical treatment options for nonhealing epithelial defects from neurotrophic disease may include artificial tear lubrication, autologous serum tears, tarsorrhaphy, or amniotic membrane transplantation (Bonini et al., 2018). *Cenegermin*, a recombinant human nerve growth factor topical eye drop, was approved for the treatment of neurotrophic keratopathy in the U.S. in 2018.

Vitamin A and the Visual Cycle

Vitamin deficiencies can alter eye function, especially a deficiency of vitamin A (Table 74–16). In vision, the functional form of vitamin A is *retinal*; its deficiency interferes with vision in dim light, contributing to a condition known as *night blindness* (nyctalopia).

Chemistry

Retinoid refers to the chemical entity *retinol* and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogues that need not have retinol-like (vitamin A) activity. The purified plant pigment carotene (provitamin A) is a protean source of vitamin A. β-Carotene is the most active carotenoid found in plants. The structural formulas for β-carotene and the vitamin A family of retinoids are shown in Figure 74–8.

TABLE 74–16 ■ OPHTHALMIC EFFECTS OF SELECTED VITAMIN DEFICIENCIES AND ZINC DEFICIENCY

DEFICIENCY	EFFECTS IN ANTERIOR SEGMENT	EFFECTS IN POSTERIOR SEGMENT
Vitamin		
A (retinol)	Conjunctiva (Bitot spots, xerosis)	Retina (nyctalopia, impaired rhodopsin synthesis), retinal pigment epithelium (hypopigmentation)
	Cornea (keratomalacia, punctate keratopathy)	
B_1 (thiamine)	—	Optic nerve (temporal atrophy with corresponding visual field defects)
B_6 (pyridoxine)	Cornea (neovascularization)	Retina (gyrate atrophy)
B_{12} (cyanocobalamin)	—	Optic nerve (temporal atrophy with corresponding visual field defects)
C (ascorbic acid)	Lens (? cataract formation)	—
E (tocopherol)	—	Retina and retinal pigment epithelium (? macular degeneration)
Folic acid	—	Vein occlusion
K	Conjunctiva (hemorrhage)	Retina (hemorrhage)
	Anterior chamber (hyphema)	
Zinc	—	Retina and retinal pigment epithelium (? macular degeneration)

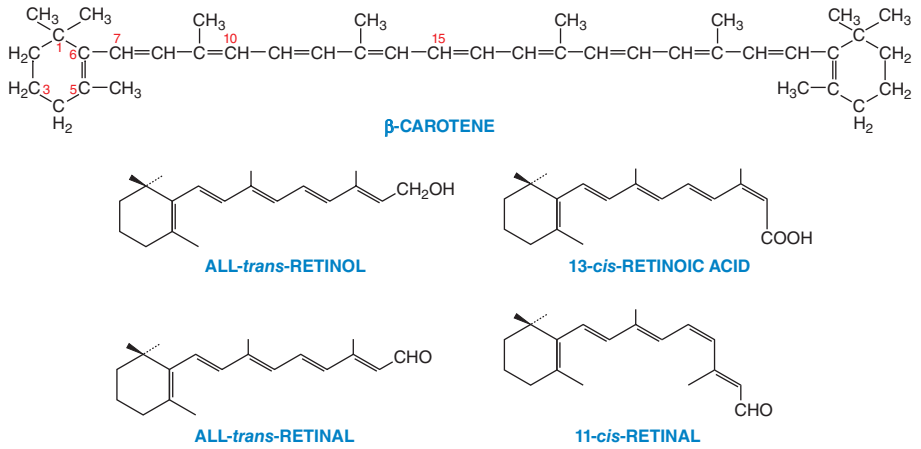


Figure 74–8 *β-Carotene and some members of the vitamin A family of retinoids.*

Retinal Cells and the Visual Cycle

Photoreception is accomplished by two types of specialized retinal cells, *rods* and *cones*. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The chromophore of both rods and cones is 11-*cis*-retinal. The holoreceptor in rods is termed *rhodopsin*—a combination of the protein opsin and 11-*cis*-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related, photoreceptor proteins and respond optimally to light of different wavelengths. This basic scheme was elucidated by Ragnar Granit, Haldan Hartline, and George Wald, who shared the 1967 Nobel Prize in Physiology/Medicine "for their discoveries concerning the primary physiological and chemical visual processes in the eye." Several more recent articles have summarized the process of photoreception (Kefalov, 2012; Saari, 2016). Figure 74–9 summarizes the signaling pathway initiated by absorption of a photon by 11-*cis*-retinal in rods.

Vitamin A Deficiency

Vitamin A is an essential nutrient with multiple functions in the body, including the eye (Sommer and Vyas, 2012). Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. On depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/L (0.70 μM), the concentrations of retinal and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs.

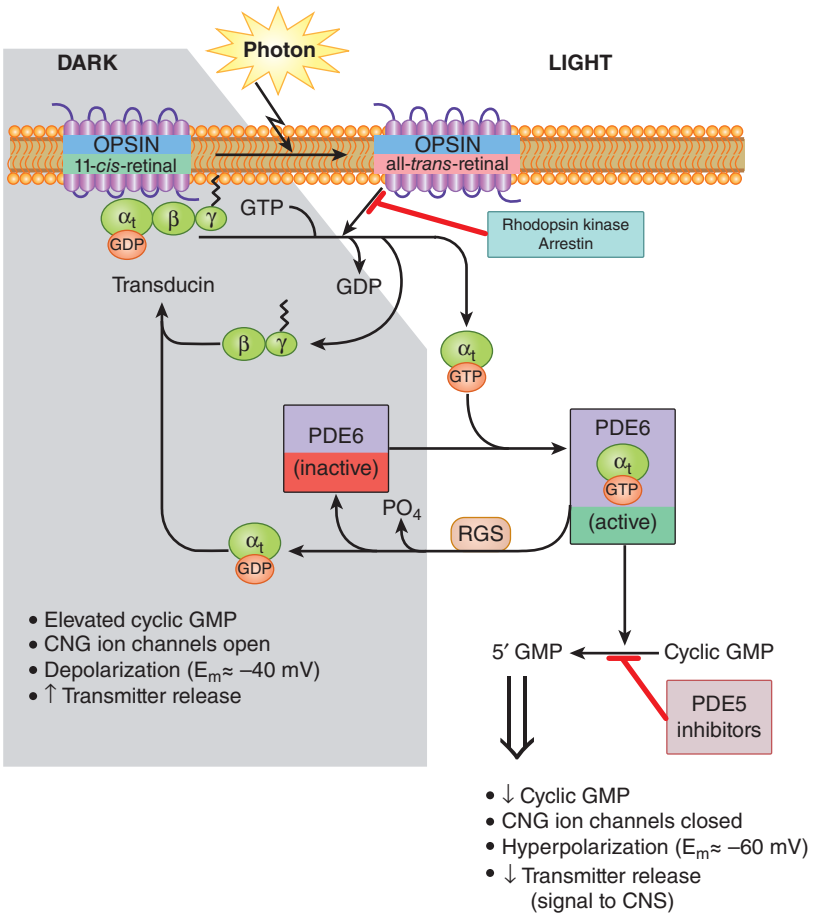

Figure 74–9 *Pharmacologist's view of photoreceptor signaling.* CNG, cyclic nucleotide gated; RGS, regulator of G protein signaling.

Vitamin A and Epithelial Structures

Retinoic acid can influence gene expression via interaction with nuclear receptors. There are two families of retinoid receptors, RARs and RXRs (Figure 3–23 and Table 3–3). In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. Common causes of vitamin A deficiency include malnutrition and bariatric surgery.

Therapeutic Uses of Vitamin A

Nutritional vitamin A deficiency causes *xerophthalmia*, a progressive disease characterized by *nyctalopia* (night blindness), *xerosis* (dryness), and *keratomalacia* (corneal thinning), which may lead to corneal perforation (McLaren and Kraemer, 2012). Vitamin A therapy can reverse xerophthalmia; however, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have a role in corneal epithelial wound healing. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E. Clinical studies suggested a reduction in the risk of progression of some types of AMD by high doses of vitamin C (500 mg), vitamin E (400 IU), β-carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Research Group, 2001a, 2001b; Chew et al., 2014), although substituting lutein/zeaxanthin for β-carotene may be more appropriate (Age-Related Eye Disease Study Research Group, 2007; Age-Related Eye Disease Study 2 [AREDS2] Research Group, 2014).

Chapter 75 Dermatological Pharmacology

Matthew J. Sewell and Dean S. Morrell

Principles of Dermatological Pharmacology

The skin is a biologically active, multifunctional, and multicompartment organ. Medications can be applied to the skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues. Effective and safe use of topical pharmacological therapies requires an understanding of skin physiology and factors influencing percutaneous drug absorption and metabolism (Hwa et al., 2011; Wolff et al., 2008). General features of skin structure and percutaneous absorption pathways are outlined in Figure 75–1.

Nonpharmacological therapy is also used for treatment of skin diseases. This includes the use of parts of the electromagnetic spectrum applied by various sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are also used to decrease the effect of various wavelengths of UV (ultraviolet) light and ionizing radiation on the skin.

Structure of Skin

Stratum Corneum

The stratum corneum is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It may be considered the "nonliving" portion of the epidermis. The stratum corneum differs in thickness at different body sites: The palm and sole are the thickest followed by the general body stratum corneum, the facial and postauricular area, and the eyelid and scrotum.

Abbreviations

APC: antigen-presenting cell
AUC: area under the curve
BCC: basal cell carcinoma
cAMP: 3′,5′-cyclic adenosine monophosphate (cyclic AMP)
CBC: complete blood cell count
CCR4: C-C chemokine receptor 4
CTCL: cutaneous T-cell lymphoma
CTLA4: cytotoxic T lymphocyte–associated protein 4
DEET: diethyltoluamide (*N*,*N*-diethyl-*m*-toluamide)
DHT: dihydrotestosterone
ECP: extracorporeal photopheresis
En1: engrailed-1
EMA: European Medicines Agency
FDA: U.S. Food and Drug Administration
5FU: 5-fluorouracil
GI: gastrointestinal
GM-CSF: granulocyte-macrophage colony-stimulating factor
G6PD: glucose-6-phosphate dehydrogenase
GRASE: generally recognized as safe and effective
HPV: human papillomavirus
HSV: herpes simplex virus
IFN: interferon
IL: interleukin
IVIG: intravenous immunoglobulin
JAK: Janus kinase
MRGPR: Mas-related G protein-coupled receptor
MRSA: methicillin-resistant *Staphylococcus aureus*
mTOR: mammalian (or mechanistic) target of rapamycin
NSAID: nonsteroidal anti-inflammatory drug
ODC: ornithine decarboxylase
OTC: over the counter
PABA: *p*-aminobenzoic acid
PD-1: programmed death-1
PDE: cyclic nucleotide phosphodiesterase
PDT: photodynamic therapy
PUVA: psoralen and UVA
RAR: retinoic acid receptor
REMS: risk evaluation and mitigation strategy
RXR: retinoid X receptor
S1PR1: sphingosine-1-phosphate receptor 1
SPF: sun protection factor
SSD: silver sulfadiazine
SSTI: skin and soft-tissue infection
STAT: signal transducer and activator of transcription
TNFα: tumor necrosis factor α
TPMT: thiopurine S-methyltransferase
TRPV1: transient receptor potential vanilloid type 1
TYK2: tyrosine kinase 2
UV: ultraviolet
VZV: varicella-zoster virus

A drug may partition into the stratum corneum and form a reservoir that will diffuse into the rest of skin even *after* topical application of the drug has ceased.

Living Epidermis

The "living" layers of the epidermis (stratum basale, stratum spinosum, and stratum granulosum) have metabolically active cells and comprise a layer about 100 μm thick (see Figure 75–1). Intercalated in the living epidermis are pigment-producing cells (melanocytes), neuroendocrine cells (Merkel cells), dendritic antigen-presenting cells (APCs) (epidermal Langerhans cells), and other immune cells (γ-δ T cells). In diseased epidermis, many additional immunological cells, including lymphocytes and polymorphonuclear leukocytes, may be present and be directly affected by applied drugs.

Dermis and Its Blood Vessels

The dermis provides mechanical strength and flexibility to the skin. It is composed primarily of fibroblasts and an extracellular matrix, including collagen, proteoglycans, glycoproteins, and, in the upper dermis, elastic fibers. Cells within the dermis that may be targets for drugs include mast cells (permanent residents and producers of many inflammatory mediators) and infiltrating immune cells producing cytokines. The dermis also contains networks of nerves, blood vessels, and adnexal structures. The superficial capillary plexus between the epidermis and dermis is the site of the majority of the systemic absorption of cutaneous drugs (see Figure 75–1). There are large numbers of lymphatics as well. Hair follicles form a lipid-rich pathway for drug absorption but constitute only 0.1% of the total skin area, so follicles are not the primary route of absorption. Sweat glands are not a known pathway for the absorption of drugs, but some drugs (e.g., *griseofulvin*) are excreted to the skin by this route. Below the dermis is the hypodermis or subcutaneous tissue, which provides insulation, cushioning, and an energy reservoir.

Mechanisms of Percutaneous Absorption

Percutaneous absorption occurs primarily through a tortuous intercellular route, with transcellular or appendageal routes playing a much smaller role. Passage through the stratum corneum is the rate-limiting step for percutaneous absorption. Preferable characteristics of topical drugs include:

- Low molecular mass (≤500 Da)
- Adequate solubility in both oil and water
- A high partition coefficient so the drug will selectively partition from the vehicle to the stratum corneum (Hwa et al., 2011; Tran, 2013)

Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical end point (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption. This is often achieved through the selection of drugs formulated in occlusive vehicles such as ointments and through physical occlusive measures such as the use of plastic films, wraps, or bags for the hands and feet or shower or bathing caps for the scalp. Alternatively, medications that are impregnated on patches or tapes may be used. Occlusion may be associated with increased growth of bacteria and resultant infection (folliculitis) or maceration and breakdown of the epidermis. Absorption of most drugs across the skin is a passive process. Percutaneous absorption may be increased using heat, ultrasonic energy, electric currents (iontophoresis), minimally invasive microneedling, and fractional or ablative lasers (Tran, 2013).

Transdermal drug delivery bypasses hepatic first-pass metabolism; however, the epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin (Baron et al., 2001). In addition, transporter proteins that influence influx (OATP [organic anion-transporting polypeptide]) or efflux (MDR [multidrug resistance transporter], P-glycoprotein) of certain xenobiotics are present in human keratinocytes (Baron et al., 2001; also see Chapter 4). Genetic variants of enzymes that regulate the cellular influx and efflux of *methotrexate* have been associated with toxicity and effectiveness in patients with psoriasis (Warren et al., 2008).

Pharmacologic Implications of Epidermal Structure

When proposing topical application of medications, the healthcare practitioner must consider multiple factors, including proper dosage

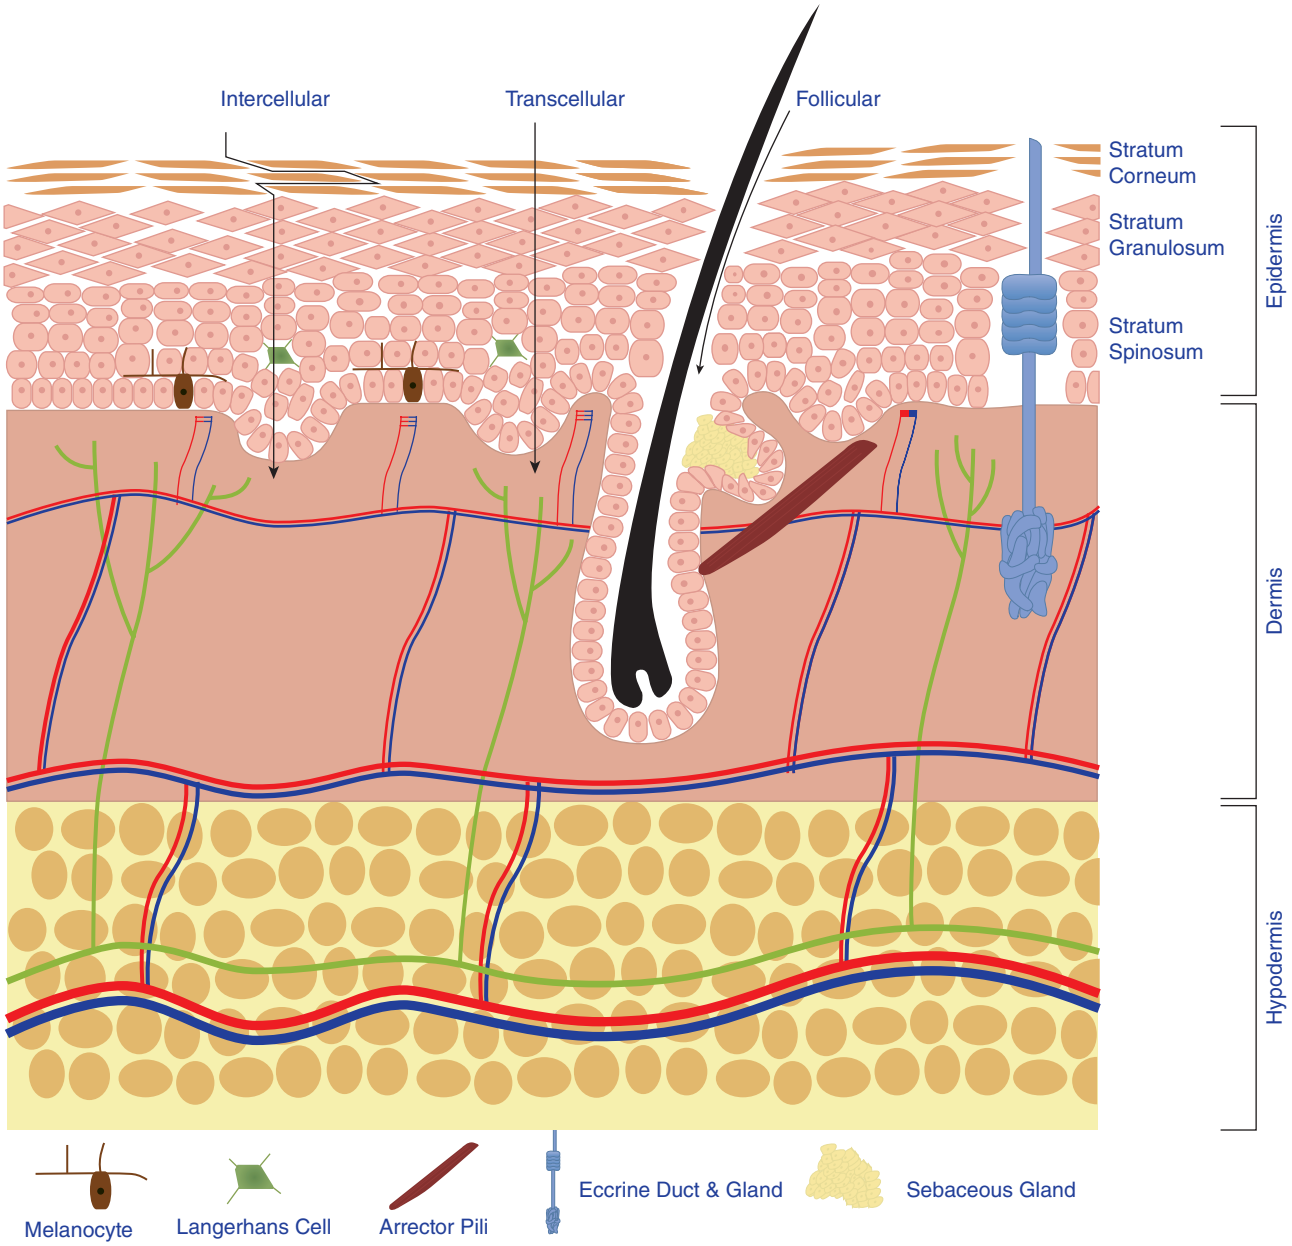

Figure 75–1 *Cutaneous drug absorption.* After application of a drug to the surface of the skin (stratum corneum), evaporation and structural/compositional alterations may occur that affect the drug's ultimate bioavailability. The stratum corneum limits drug diffusion into the lower layers and thence into the body. A number of absorptive routes are possible, singly or in combination: between the cells of the stratum corneum (*intercellular*), across the corneal cellular layer (*transcellular*), and into the concavity of a hair follicle (*follicular*) with its associated sebaceous glandular cells and arrector pili muscle that is innervated by the sympathetic branch of the autonomic nervous system. Melanocytes and Langerhans cells are accessible in the lower epidermis. In the epidermal and dermal layers, drugs may also reach the eccrine glands (sweat glands) and their ducts. Permeation to the dermis brings a drug in contact with lymphatics (in green) and cutaneous vessels carrying arterial and venous blood (red and blue, respectively). These vessels provide an absorptive route into the general circulation. Deeper permeation to the hypodermis may also occur.

and frequency of application, extent and condition of the permeability barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used (Table 75–1). Various drug vehicles have specific advantages and disadvantages (Table 75–2). Newer vehicles or delivery systems, such as liposomes and microgel formulations, can enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy (Rosen et al., 2014). *Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in greater systemic exposure. Preterm infants have a markedly impaired barrier function until the epidermis keratinizes completely* (Hwa et al., 2011). *Many dermatological diseases also compromise barrier function, leading to increased percutaneous absorption.*

TABLE 75–1 ■ IMPORTANT CONSIDERATIONS WHEN A DRUG IS APPLIED TO THE SKIN

What are the absorption pathways of intact and diseased skin?
How does the chemistry of the drug affect the penetration?
How does the vehicle affect the penetration?
How much of the drug penetrates the skin?
What are the intended pharmacological targets?
What host and genetic factors influence drug function in the skin?
What are the predicted adverse effects (local, systemic)?

TABLE 75–2 ■ VEHICLES FOR TOPICALLY APPLIED DRUGS[a]

	OINTMENT	CREAM	GEL	LOTION/SOLUTION/ FOAM/SPRAY
Physical basis	Solid or liquid dispersed in nonaqueous base	Oil-in-water emulsion	Water-soluble emulsion with gelling agent	Lotion—suspended drug Solution/spray—dissolved drug base Foam—drug with surfactant as foaming agent and propellant
Solubilizing medium	Anhydrous to <20% water	20%–80% water	Contains water-soluble polyethylene glycols May have alcoholic solvent	May be aqueous or alcoholic
Pharmacological advantage	Protective oil film on skin	Leaves concentrated drug at skin surface	Concentrates drug at surface after evaporation	
Advantages for patient	Spreads easily Slows water evaporation	Spreads and removes easily No greasy feel	Nonstaining Greaseless Typically clear appearance	Low residue on scalp or other hairy areas May have cooling effect when evaporates
Locations on body	Avoid intertriginous areas	Most locations	Scalp and other hairy locations	Scalp and other hairy locations
Disadvantages	Greasy Stains clothes	Needs preservatives	Needs preservatives Can be drying, especially if high alcohol content	Can be drying May burn if alcohol content Foams tend to be more expensive due to more complex delivery system
Occlusion	Moderate to high Increases skin moisture	Low	None	None
Composition notes	Oleaginous base (e.g., white petrolatum) or absorption base (e.g., hydrophilic petrolatum)	Requires humectants (glycerin, propylene glycol, polyethylene glycols) to keep moist when applied Long-chain alcohol (e.g., stearyl alcohol) in oil phase for stability and smooth feel	Microspheres or microsponges can be formulated in gels	

[a]Some agents may also be supplied on tapes or patches; in powders, emollients, and lacquers; and in liposomes and nanoparticles.

Glucocorticoids

Glucocorticoids have immunosuppressive and anti-inflammatory properties. They are administered locally through topical and intralesional routes and systemically through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are discussed in Chapter 50.

Topical Glucocorticoids

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 75–3). Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses

Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body sites and with the vehicle of the formulation. The steroid is selected based on its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Twice-daily application of topical glucocorticoids suffices; more frequent application does not improve response. Moderately potent to very potent topical corticosteroids are effective with once-daily versus twice-daily application in atopic dermatitis, and patient adherence may be improved with once-daily regimens (Williams, 2007). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin. Intralesional preparations of glucocorticoids include insoluble preparations of *triamcinolone acetonide* and *triamcinolone hexacetonide*, which solubilize gradually and therefore have a prolonged duration of action.

Toxicity

Adverse effects may occur with topical corticosteroid use, including skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Fluorinated compounds should not be used on the face because perioral dermatitis and rosacea can develop after their use. Topical corticosteroid use may induce hypothalamic-pituitary-adrenal axis suppression, especially with high-potency corticosteroids, chronic use, application to large body surface areas, or occlusion.

Systemic Glucocorticoids

Systemic glucocorticoid therapy is used for severe or extensive dermatological illnesses such as allergic contact dermatitis to plants (e.g., poison ivy), vesiculobullous dermatoses (e.g., pemphigus vulgaris and bullous pemphigoid), vasculitis, autoimmune connective tissue diseases, and neutrophilic dermatoses (e.g., pyoderma gangrenosum). Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 50).

TABLE 75–3 ■ POTENCY OF SELECTED TOPICAL GLUCOCORTICOIDS

	CLASS OF DRUG	GENERIC NAME, FORMULATION
Most potent	1	• Augmented betamethasone dipropionate: 0.05% gel, lotion, ointment • Clobetasol propionate: 0.05% cream, ointment, gel, solution, foam, spray, emulsion, lotion • Diflorasone diacetate: 0.05% ointment • Fluocinonide: 0.1% cream • Flurandrenolide: 4 μg/cm² impregnated tape • Halobetasol propionate: 0.05% cream, ointment, lotion, foam
	2	• Amcinonide: 0.1% ointment • Augmented betamethasone dipropionate: 0.05% cream • Betamethasone dipropionate: 0.05% ointment • Clobetasol: 0.025% cream • Desoximetasone: 0.05% gel; 0.25% cream, ointment, spray • Fluocinonide: 0.05% cream, ointment, gel, solution • Halcinonide: 0.1% cream, ointment, solution • Halobetasol propionate: 0.01% lotion
	3	• Amcinonide: 0.1% cream • Betamethasone dipropionate: 0.05% cream • Betamethasone valerate: 0.1% ointment; 0.12% foam • Desoximetasone: 0.05% cream, ointment • Diflorasone diacetate: 0.05% cream • Fluocinonide: 0.05% cream in aqueous emollient base • Fluticasone propionate: 0.005% ointment • Mometasone furoate: 0.1% ointment • Triamcinolone acetonide: 0.5% cream, ointment
	4	• Betamethasone dipropionate: 0.05% spray • Clocortolone pivalate: 0.1% cream • Fluocinolone acetonide: 0.025% ointment • Flurandrenolide: 0.05% ointment • Hydrocortisone valerate: 0.2% ointment • Mometasone furoate: 0.1% cream, lotion • Triamcinolone acetonide: 0.1% cream, ointment
	5	• Betamethasone dipropionate: 0.05% lotion • Betamethasone valerate: 0.1% cream • Desonide: 0.05% gel, ointment • Fluocinolone acetonide: 0.025% cream • Flurandrenolide: 0.05% cream, lotion • Fluticasone propionate: 0.05%: cream, lotion • Hydrocortisone butyrate: 0.1% cream, lotion, solution, ointment • Hydrocortisone valerate: 0.2% cream • Prednicarbate: 0.1% ointment • Triamcinolone acetonide: 0.05% ointment; 0.025% ointment; 0.1% lotion
	6	• Alclometasone dipropionate: 0.05% cream, ointment • Betamethasone valerate: 0.1% lotion • Desonide: 0.05% cream, lotion, foam • Fluocinolone acetonide: 0.01% cream, solution, shampoo, oil • Triamcinolone acetonide: 0.025% cream, lotion
Least potent	7	• Hydrocortisone: 0.5% cream, lipstick; 0.75% lotion; 1% cream, ointment, foam, gel, liquid, lotion, shampoo, spray; 2% lotion; 2.5% cream, lotion, ointment, solution

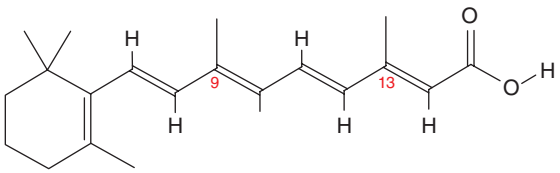
Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing; if chronic therapy is required, prednisone usually is tapered to every other day as soon as practical. Pulse therapy using intravenous doses of *methylprednisolone sodium succinate* is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, dermatomyositis, and linear morphea. When used as high-dose "pulse" therapy, the dose of intravenous *methylprednisolone* is usually 15 to 30 mg/kg/dose (maximum, 1000 mg/dose) daily for 3 days in pediatric patients or 7 to 15 mg/kg/dose (generally 500–1000 mg/dose) in adults daily for 3 to 5 days. The infusion is usually given over 2 to 3 h; more rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

Toxicity and Monitoring

Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 50. Most side effects are dose and duration dependent.

Retinoids

Retinoids comprise natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids. Characteristics of topical and systemic retinoids are summarized in Tables 75–4 and 75–5, respectively.



Tretinoin (all-*trans*-retinoic acid; vitamin A acid)

First-generation retinoids include *retinol* (vitamin A), *tretinoin* (all-*trans*-retinoic acid), *isotretinoin* (13-*cis*-retinoic acid), and *alitretinoin* (9-*cis*-retinoic acid). *Second-generation retinoids*, also known as aromatic retinoids, include *acitretin* and *etretinate*. *Third-generation retinoids* were designed to optimize receptor-selective binding and include *tazarotene*, *bexarotene*, and *adapalene*. A *fourth-generation retinoid, trifarotene*, further optimizes receptor-selective binding.

- ***Mechanism of Action.*** Retinoids exert their effects on gene expression by activating two families of nuclear receptors, *retinoic acid receptors* (RARs) and *retinoid X receptors* (RXRs), which are members of the steroid receptor superfamily. Both retinoid receptor families have three isoforms (α, β, and γ), which are expressed in unique combinations in individual tissues and cells. On binding to a retinoid, RARs and RXRs form heterodimers that subsequently bind specific DNA sequences called retinoic acid response elements (RAREs) that activate transcription of genes whose products produce both the desirable pharmacological effects and the unwanted side effects of these drugs (see Tables 75–4 and 75–5; see also Table 5–5 and Figure 5–13).
- ***Targeted Therapeutic Actions.*** Retinoids that target RARs predominantly affect cellular differentiation and proliferation, whereas retinoids that target RXRs predominantly induce apoptosis. Hence, *tretinoin*, *adapalene*, and *tazarotene*, which target RARs, are used in acne, psoriasis, and photoaging (disorders of differentiation and proliferation), whereas *bexarotene* and *alitretinoin*, which target RXRs, are used in cutaneous T-cell lymphoma (CTCL) and Kaposi sarcoma, respectively, to induce apoptosis of malignant cells.
- ***Retinoid Toxicity.*** Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more physiochemical changes. Because all oral retinoids are potent teratogens, they should not be used during pregnancy and should be used cautiously in females of childbearing potential.

TABLE 75–4 ■ TOPICAL RETINOIDS[a]

DRUG	FORMULATION	RECEPTOR SPECIFICITY	LEVEL OF IRRITATION	INDICATION[b]
Adapalene	Cream: 0.1%, 0.3% Gel: 0.1%, 0.3% Lotion: 0.1%	RAR-β, -γ	+	Acne
Tretinoin	Cream: 0.02%, 0.025%, 0.05%, 0.1% Gel: 0.01%, 0.025% Microsphere gel: 0.04%, 0.06%, 0.08%, 0.1% Lotion: 0.05%, 0.1%	RAR-α, -β, -γ	++	Acne; facial fine wrinkles and mottled pigmentation
Trifarotene[c]	Cream: 0.005%	RAR-γ	+	Acne
Tazarotene	Cream: 0.05%, 0.1% Gel: 0.05%, 0.1% Foam: 0.1% Lotion: 0.045%	RAR-α, -β, -γ	++++	Acne; plaque psoriasis; facial fine wrinkles and mottled pigmentation
Alitretinoin[d] (9-cis-retinoic acid)	Gel: 0.1%	RAR-α, -β, -γ RXR-α, -β, -γ	++	Cutaneous AIDS-related Kaposi sarcoma
Bexarotene[e]	Gel: 1%	RXR-α, -β, -γ	+++	Cutaneous T-cell lymphoma

[a]These agents should not be ingested; oral retinoids should not be used during pregnancy or by females of childbearing potential.
[b]FDA-approved indication may vary for different preparations or brand names.
[c]Human studies have not identified a pregnancy risk with topical use; animal reproduction studies with high doses (exposure 800 times that due to maximal recommended human dose) resulted in fetal adverse effects.
[d]Gel could cause fetal harm if significant absorption were to occur in a pregnant woman.
[e]Gel may cause fetal harm when administered to a pregnant female.

TABLE 75–5 ■ SYSTEMIC RETINOIDS[a]

DRUG	RECEPTOR SPECIFICITY	DOSING RANGE	$t_{1/2}$
Isotretinoin	No clear receptor affinity	Standard or Lidose: 0.5–2 mg/kg/day Micronized Lidose: 0.4–1.6 mg/kg/day	10–20 h
Etretinate[b]	RAR-α, -β, -γ	0.25–1 mg/kg/day	80–160 days
Acitretin	RAR-α, -β, -γ	0.5–1 mg/kg/day	50 h[c]
Bexarotene	RXR-α, -β, -γ	300 mg/m^2/day	7–9 h

[a]These agents must not be used by women who are pregnant, planning to become pregnant, or breastfeeding.
[b]Not currently available in the U.S. Warning in footnote *c* applies.
[c]When combined with ethanol, acitretin is esterified to etretinate, which has a $t_{1/2}$ >80 days. Female patients of childbearing potential should avoid pregnancy for 3 years after receiving acitretin or etretinate to avoid retinoid-induced embryopathy.

Topical Retinoids

Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce *Propionibacterium acnes* counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for noninflammatory (comedonal) acne and are often combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photoaging, are also improved with topical retinoids. Within the dermis, this is believed to result from inhibition of AP-1 (activator protein-1), which normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Thielitz and Gollnick, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia.

Toxicity and Monitoring

Adverse effects of all topical retinoids include erythema, desquamation, xerosis, burning, and stinging (see relative irritancy in Table 75–4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients also may experience photosensitivity reactions (enhanced reactivity to UV radiation) and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, topical retinoids are not recommended for use during pregnancy.

Available Agents; Clinical Use

Tretinoin (all-*trans*-retinoic acid) is photolabile and should be applied once nightly for acne and photoaging. Benzoyl peroxide also inactivates *tretinoin* and should not be applied simultaneously. Formulations with copolymer microspheres or prepolyolprepolymer 2 that gradually release *tretinoin* to decrease irritancy are available and are less susceptible to oxidation by benzoyl peroxide and photodegradation.

Adapalene is approved for the treatment of acne vulgaris. It has similar efficacy to *tretinoin*. Unlike *tretinoin*, it is stable in sunlight or the presence of benzoyl and is also more lipophilic, which allows rapid penetration through follicular openings.

Tazarotene is approved for the treatment of psoriasis, photoaging, facial wrinkles, and acne vulgaris. *Tazarotene* gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with *tazarotene*.

Trifarotene is approved for the treatment of acne vulgaris on the face and trunk. It is a fourth-generation retinoid with selective binding to RAR-γ receptors, which are abundantly expressed in skin.

Alitretinoin is a retinoid that binds all types of retinoid receptors, both RARs and RXRs. It is approved for treatment of cutaneous lesions of Kaposi sarcoma, with its application titrated up from twice daily to three or four times daily as tolerated. *Alitretinoin* should not be applied concurrently with insect repellants containing diethyltoluamide (DEET) because it may increase DEET absorption.

Bexarotene is approved for early-stage (IA and IB) CTCL. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Concurrent application of *bexarotene* with insect repellants containing DEET is not recommended because it may increase DEET absorption.

Systemic Retinoids

Systemic retinoids (see Table 75–5) are approved for the treatment of acne, psoriasis, and CTCL (Desai et al., 2007).

Therapeutic Uses and Contraindications

Off-label uses include ichthyosis, Darier disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus.

Absolute contraindications include use by women who are pregnant, planning to become pregnant, or breastfeeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

Toxicity and Monitoring

Acute toxicities may include mucocutaneous or laboratory abnormalities. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a "retinoid dermatitis" characterized by erythema, pruritus, and scaling. Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines. Bony changes may occur after chronic use at high doses. There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis syndrome, premature epiphyseal closure, and other skeletal abnormalities (Desai et al., 2007).

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Prescribing of *isotretinoin* in the U.S. is restricted via the risk-mitigation iPLEDGE system.

Serum lipid elevation is the most common laboratory abnormality. Less common laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. Laboratory monitoring for *acitretin* and *bexarotene* generally includes a baseline evaluation of serum lipids, serum transaminases, and complete blood cell count (CBC) with subsequent monitoring monthly for the first 3 to 6 months then every 3 months thereafter. Thyroid function testing is also included for *bexarotene*. Less frequent laboratory monitoring is needed during *isotretinoin* use for acne in otherwise healthy patients, and a CBC is not required (Takeshita et al., 2020). Two negative pregnancy tests on separate occasions are required for females of childbearing potential prior to starting *acitretin* or *isotretinoin*; *bexarotene* requires one negative pregnancy test within the week prior to initiating therapy. Monthly pregnancy tests should be obtained for females of childbearing potential.

Available Agents and Clinical Use

Isotretinoin is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce

prolonged remissions after a single course of therapy. Clinical effects generally are noted within 1 to 3 months of starting therapy. Approximately one-third of patients will relapse, usually within 3 years of stopping therapy. Although most relapses are mild and respond to conventional management with topical and systemic antiacne agents, some may require a second course of *isotretinoin*. Systemic absorption is improved when taken with a high-fat meal. An *isotretinoin*-Lidose formulation (a proprietary eutectic mixture of drug and lipids in a hard gelatin capsule) may be given without respect to meals; there is a micronized *isotretinoin*-Lidose formulation available as well. Non-Lidose formulations of *isotretinoin* may be administered with a high-fat meal to achieve higher systemic exposure to the drug.

Acitretin is approved for use in the cutaneous manifestations of psoriasis. Clinical effect may begin within 4 to 6 weeks, with the full clinical benefit occurring at 3 to 6 months. *Acitretin* has a $t_{1/2}$ of about 50 h; however, when combined with alcohol, *acitretin* is esterified *in vivo* to produce etretinate, which has a $t_{1/2}$ of 80 to 160 days. It is not known how much alcohol is required to induce this conversion, and it must be considered that sources of alcohol ingestion may include mouthwash, cough syrup, or other alcohol-based medications. Thus, female patients of childbearing potential should avoid pregnancy for 3 years after receiving *acitretin* to avoid retinoid-induced embryopathy.

Bexarotene is a retinoid that selectively binds RXRs. Formulations of *bexarotene* are approved for use in patients with CTCL (topical for early stage; oral for refractory CTCL). *Bexarotene* reportedly induces apoptosis of malignant cells (Jawed et al., 2014). Because CYP3A4 metabolizes *bexarotene*, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase *bexarotene* plasma levels; conversely, inducers of CYP3A4 (e.g., *rifamycins*, *carbamazepine*, *dexamethasone*, *efavirenz*, *phenobarbital*) will decrease *bexarotene* plasma levels. Side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of thyroid-stimulating hormone gene expression, pancreatitis, leukopenia, and gastrointestinal (GI) symptoms. Thyroid function should be measured before initiating therapy and periodically thereafter.

Vitamin Analogues

Calcipotriene

Calcipotriene is a topical vitamin D analogue that is approved for the treatment of psoriasis.

Mechanism of Action

Calcipotriene exerts its effects through the vitamin D receptor (see Chapter 52). On binding the vitamin D receptor, the drug-receptor complex associates with the RXR-α and binds to vitamin D response elements on DNA, increasing expression of genes that modulate epidermal differentiation and inflammation, leading to improvement in psoriatic plaques (Menter et al., 2009a).

Therapeutic Use

Calcipotriene is generally applied twice daily to psoriasis on the scalp or body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100 g/week limit and resolves within days of discontinuation of *calcipotriene* (Menter et al., 2009a). *Calcipotriene* also causes perilesional irritation and mild photosensitivity. Concomitant administration of topical corticosteroids will reduce the irritation. *Calcipotriene* may be inactivated by concomitant use of acidic topical agents such as salicylic acid or lactic acid. *Calcipotriene* has been used off label for multiple conditions, including morphea, vitiligo, congenital ichthyoses, and in combination with *5-fluorouracil* for actinic keratoses.

β-Carotene

β-Carotene is a precursor of vitamin A that is in green and yellow vegetables; it is used as a nutrient supplement and food coloring agent. Dietary supplementation with β-carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen.

Photochemotherapy

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone (phototherapy) or in the presence of an exogenous photosensitizing drug (photochemotherapy) (Table 75–6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications, such as phenothiazines, thiazides, sulfonamides, nonsteroidal anti-inflammatory drugs (NSAIDs), sulfonylureas, tetracyclines, and benzodiazepines.

The UV radiation region may be subdivided into UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (100–290 nm). UVC radiation is almost completely absorbed by the ozone layer and atmosphere so that measurable amounts do not reach Earth's surface. UVA and UVB exposure can cause sunburns, photoaging, and skin cancer development. UVB is the most erythrogenic and melanogenic, and it is the major action spectrum for sunburn, tanning, skin cancer, photoaging, and cutaneous vitamin D synthesis. UVA is only a thousandth as erythrogenic as UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. UVA is also able to penetrate clouds and glass, so exposure may occur even in the shade or while indoors. Both UVA and UVB cause photoimmune suppression, an effect that is utilized for therapy of certain dermatological conditions.

PUVA: Psoralens and UVA

The PUVA combines UVA light with photosensitizing compounds called psoralens. Orally administered *methoxsalen* (8-methoxypsoralen) followed by UVA (PUVA) is FDA-approved for the treatment of vitiligo and psoriasis. It is also used off label in several other inflammatory or lymphoproliferative cutaneous disorders (Totonchy and Chiu, 2014).

Chemistry and Mechanism of Action

Psoralens are lipophilic, naturally occurring furocoumarins found in some plants. Synthetic versions are also available. The action spectrum for PUVA is between 320 and 340 nm. Psoralens intercalate into the DNA strand, and two distinct photoreactions take place on UVA exposure. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce antiproliferative, immunosuppressive, and anti-inflammatory effects.

Pharmacokinetics

Formulations of solubilized *methoxsalen* in a gel matrix are absorbed rapidly after oral administration, whereas older microcrystalline forms are absorbed slowly and incompletely. Fatty foods slow absorption and decrease peak blood levels. There is significant, but saturable, first-pass elimination in the liver. Peak photosensitivity varies significantly between individuals but typically is maximal 1 to 2 h after ingestion. *Methoxsalen* has a serum $t_{1/2}$ of about 1 h, but the skin remains sensitive to light for 8 to 12 h.

Therapeutic Uses

Oral *methoxsalen* is available as a single 10-mg strength either as soft gelatin capsules (solubilized) or hard gelatin capsules (micronized crystals).

TABLE 75–6 ■ PHOTOCHEMOTHERAPY METHODS

	PUVA	PHOTOPHERESIS	PHOTODYNAMIC THERAPY
Target	Broad cutaneous area	Peripheral blood leukocytes	Focal cutaneous sites
Photosensitizing agent	Methoxsalen (8-methoxypsoralen)	Methoxsalen (8-methoxypsoralen)	Protoporphyrin IX
Method of administration	Oral Topical lotion Bathwater	To isolated plasma within photopheresis device	Topical cream or solution of a prodrug (aminolevulinic acid or methylaminolevulinate)
FDA-approved indications	Psoriasis Vitiligo	CTCL	Actinic keratosis
Activating wavelength	UVA2 (320–340 nm)	UVA2 (320–340 nm)	Blue light (410–420 nm) and red light (630–635) nm
Adverse effects (acute)	Phototoxic reactions Pruritus Hypertrichosis GI disturbance CNS disturbance Bronchoconstriction Hepatic toxicity HSV recurrence Retinal damage	Phototoxic reactions GI disturbance Hypotension Congestive heart failure	Phototoxic reactions Temporary dyspigmentation
Adverse effects (chronic)	Photoaging Nonmelanoma skin cancer Melanoma[a] Cataracts[a]	Loss of venous access after repeated venipuncture	Potential scarring
Pregnancy category	Risk cannot be ruled out	Evidence of risk[b]	Risk cannot be ruled out

[a]Controversial.
[b]Based on fetal toxicity in pregnant rats. No adequate studies in humans.

The dose is 10 to 70 mg, depending on weight (0.4–0.6 mg/kg), taken about 1.5 to 2 h before UVA exposure. Although administration with food can decrease absorption, it may minimize nausea. Topical application of psoralens followed by UVA exposure (topical PUVA) is also used for treatment. A lotion containing 1% *methoxsalen* is available for topical application for vitiligo. The *methoxsalen* lotion or capsules can be diluted in bathwater and used topically for localized palmoplantar (soak PUVA) or more diffuse (bath PUVA) areas to minimize systemic absorption. An extracorporeal solution is available for CTCL (see Photopheresis).

Approximately 70% to 100% of psoriatic patients have clearing or virtual clearing of skin disease within about 24 treatments with PUVA. Remission typically lasts 3 to 6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents. Vitiligo typically requires between 150 and 300 treatments. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa.

Toxicity and Monitoring

The major side effects of PUVA are listed in Table 75–6. Phototoxicity is characterized by erythema, edema, blistering, and pruritus. Ocular toxicity can be prevented by wearing UVA-blocking glasses on the day of treatment. The risk of nonmelanoma skin cancer is dose dependent, with the greatest risk in those receiving more than 200 to 250 treatments (Totonchy and Chiu, 2014). There is a possible association between extensive PUVA exposure and melanoma but the evidence is conflicting.

Photopheresis

Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are separated using a leukapheresis-based method then exposed to UVA radiation in the presence of *methoxsalen* (Perotti and Sniecinski, 2015). *Methoxsalen* is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient, undergoing apoptosis over 48 to 72 h. ECP is used for CTCL and off label for various other T-cell–mediated diseases, including graft-versus-host disease, transplantation rejection, and scleroderma. Patients receive ECP therapy on 2 consecutive days every 2 to 4 weeks, and intervals are increased as the patient improves (Jawed et al., 2014). ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

Photodynamic Therapy

Photodynamic therapy (PDT) combines the use of photosensitizing drugs and visible light for the treatment of dermatological disorders. Two drugs are used for topical PDT: *aminolevulinic acid* is FDA-approved, and *methylaminolevulinate* is approved in a number of other countries. Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 75–2). In the presence of specific wavelengths of light (see Table 75–6) and O_2, protoporphyrin produces reactive oxygen species that oxidize cell membranes, proteins, and mitochondrial structures, leading to apoptosis. The epidermis, sebaceous glands, and neoplastic cells accumulate more porphyrin than other cutaneous cells and structures, providing some preferential targeting of therapy (Rkein and Ozog, 2014). PDT is approved for use on precancerous actinic keratosis. It is also used

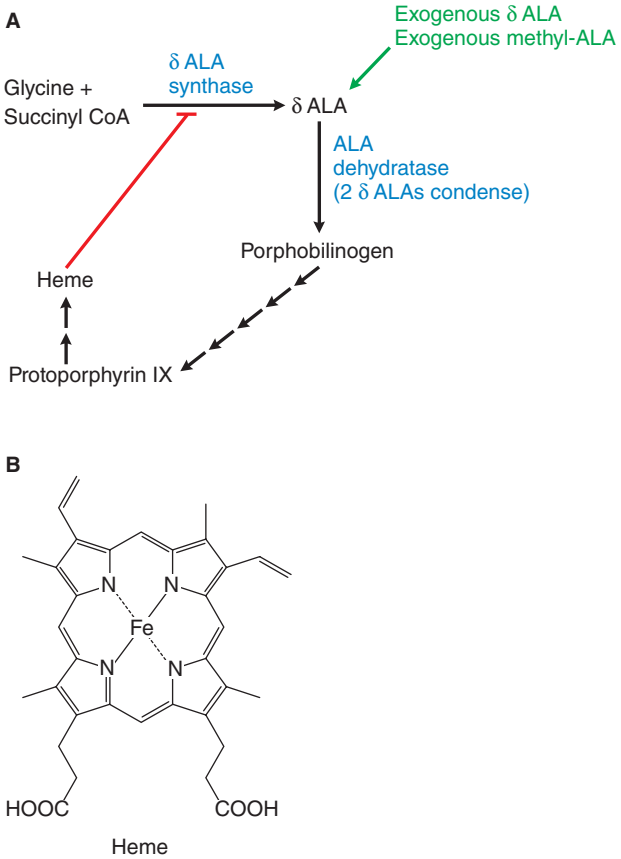


Figure 75–2 *Heme biosynthesis pathway.* **A.** *Under physiological conditions, heme inhibits the enzyme δ-aminolevulinic acid (δ-ALA) synthase by negative feedback.* However, when ALA is provided exogenously, this control point is bypassed, leading to excessive accumulation of protoporphyrin IX and heme. **B.** *Heme.*

off label for superficial nonmelanoma skin cancers, acne, photorejuvenation, and verrucae. Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin (see Table 75–6) and ideally those that permit maximum skin penetration. Light sources currently in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the $t_{1/2}$ of the accumulated porphyrins is about 30 h, patients should protect their skin from sunlight and intense light for at least 48 h after treatment to prevent phototoxic reactions.

Sunscreens

Sunscreens provide temporary photoprotection from the acute and chronic effects of sun exposure. They are an important component of a comprehensive sun protection approach along with minimizing sun exposure and using photoprotective gear. The regular use of sunscreen is efficacious in reducing photocarcinogenesis and photoaging (Mancebo et al., 2014). The sun protection factor (SPF) is defined as the ratio of the minimal dose of incident sunlight that will produce erythema (sunburn) on skin with the sunscreen in place to the dose that evokes the same reaction on skin without the sunscreen. SPF is primarily a measure of UVB protection and does not provide information regarding UVA coverage. In 2011, the FDA published new guidelines for labeling and effectiveness testing of sunscreens (Mancebo et al., 2014). UVA protection is now assessed using the critical wavelength method, and products with a critical wavelength of 370 nm or greater may be labeled as "broad spectrum." Sunscreens providing broad-spectrum coverage with an SPF 15 or greater may include a claim on their labeling that use "decreases risk of skin cancer and early aging caused by the sun." Sunscreens should be applied liberally 15 to 30 min prior to sun exposure and reapplied at least every 2 h. If activities involve swimming or sweating, water-resistant sunscreens are recommended and should be reapplied every 40 or 80 min depending on their labeling.

The major active ingredients of available sunscreens include organic agents ("chemical blockers") that absorb UV radiation in the UVB or UVA ranges and then convert it to heat energy and inorganic agents ("physical blockers") that contain particulate materials that act by scattering or reflecting visible, UV, and infrared radiation to reduce its transmission to the skin. The current FDA-approved active sunscreen ingredients are listed in Table 75–7.

Inorganic Agents

The two inorganic agents available in the U.S. are *zinc oxide* and *titanium dioxide*. They provide UVA, UVB, and visible light protection. Newer microsize and nanosize particle formulations are less opaque and more cosmetically appealing. Both *zinc oxide* and *titanium dioxide* may become classified as non–generally recognized as safe and effective (GRASE) by the FDA.

Organic Filters

Currently available organic filters in the U.S. include benzophenones (*oxybenzone*, *dioxybenzone*, *sulisobenzone*); dibenzoylmethanes (*avobenzone*); anthralates (*meradimate*); camphors (*ecamsule*); aminobenzoates (PABA [*p-aminobenzoic acid*] and *padimate O*); cinnamates (*cinoxate*, *octinoxate*); salicylates (*trolamine salicylate*, *homosalate*, *octisalate*); *octocrylene*; and *ensulizole*. Additional UVA and UVB organic filters are used in other countries but are not currently available in the U.S. PABA and *trolamine salicylate* may become classified as non-GRASE by the FDA. For PABA, risks include allergic and photoallergic skin reactions as well as cross-sensitization with structurally similar compounds. For *trolamine salicylate*, the risks include anticoagulant effects and salicylate toxicity. There is recent concern about potential toxic effects of organic UV filters, including those used in sunscreens, on coral reefs and other marine life (Schneider and Lim, 2019; Mitchelmore et al., 2021), The U.S. National Academy of Sciences has convened a panel to "review the state of science on use of currently marketed sunscreen ingredients, their fate and effects in aquatic environments, and the potential public health implications associated with changes in sunscreen usage" (NAS, 2022); a report will be forthcoming.

Antihistamines

Histamine (see Chapter 43) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors. Additional chemical itch mediators acting as pruritogens on C fibers include *neuropeptides, prostaglandins, serotonin, acetylcholine*, and *bradykinin*. Furthermore, receptor systems (e.g., vanilloid, opioid, and cannabinoid receptors) on cutaneous sensory nerve fibers may modulate itch. Broad classes of pruritogens appear to cause histamine release via their direct interaction with MRGPRX2, a mast cell–specific member of the Mas-related G protein-coupled receptor (MRGPR) superfamily of eight proteins. Two of these proteins in the X family, MRPGRX1 and MRGPRX2, interact with a variety of positively charged compounds, transducing signals that result in itch and pain (McNeil, 2021). These systems, which act independently of the IgE pathway, offer novel future targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H_1, H_2, and H_4 receptors but not H_3 receptors. Both H_1 and H_2 receptors are involved in wheal formation and erythema, whereas only the H_1 receptor agonists cause pruritus (see Chapter 43). However, blockade of H_1 receptors does not totally relieve itching, and combination therapy with H_1 and H_2 antagonists may be superior to the use of H_1 antagonists alone.

Oral antihistamines, particularly H_1 receptor antagonists, have anticholinergic activity and are sedating (see Chapter 43), making them useful for the control of pruritus. *First-generation sedating H_1 receptor antagonists* include *hydroxyzine, diphenhydramine, promethazine*, and *cyproheptadine*. *Doxepin* is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of *doxepin*,

TABLE 75–7 ■ SUNSCREEN ACTIVE INGREDIENTS

CLASS	ACTIVE INGREDIENT	PROTECTIVE SPECTRUM			
		UVB 290–320 nm	UVA2 320–340 nm	UVA1 340–400 nm	VISIBLE 400–800 nm
Inorganic					
	Titanium dioxide	++	++	++	+

[a]In the U.S., these compounds are pending determination of generally recognized as safe and effective status by the FDA.
[b]Sunscreens with this compound are not currently marketed in the U.S.

which can be used in conjunction with low- to moderate-potency topical glucocorticoids, is also available. The antipruritic effect from topical *doxepin* is comparable to that of low-dose oral *doxepin* therapy. Allergic contact dermatitis to *doxepin* has been reported. Topical *diphenhydramine* formulations available over the counter (OTC) also carry a significant risk of allergic contact dermatitis. *Second-generation H_1 receptor antagonists* lack anticholinergic side effects and are described as nonsedating largely because they do not readily cross the blood-brain barrier. They include *cetirizine, levocetirizine, loratadine, desloratadine,* and *fexofenadine*. Second-generation H_1 antagonists are suitable for treating urticaria, cause fewer adverse effects, and are superior in safety compared to older first-generation H_1 antagonists (Fein et al., 2019).

Antimicrobial Agents

Antibiotics

Antibiotic agents are frequently used to treat skin and soft-tissue infections (SSTIs). Several antimicrobial agents, such as tetracyclines, macrolides, and *dapsone*, also have anti-inflammatory properties, which make them useful for noninfectious conditions, such as acne vulgaris, rosacea, granulomatous diseases, neutrophilic dermatoses, and autoimmune bullous diseases (Bhatia, 2009).

Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris (Drucker, 2012). Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VI, *Chemotherapy of Microbial Diseases.* Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne

Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics (Eichenfield et al., 2013). The gram-positive anaerobe *Cutibacterium acnes* (formerly *Propionibacterium acnes*) is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O_2 tension is low. *C. acnes* generates free fatty acids from sebum and interacts with toll-like receptors, thereby promoting microcomedo formation and inflammatory lesions (Das and Reynolds, 2014). Suppression of cutaneous *C. acnes* with antibiotic therapy is correlated with clinical improvement.

Topical antimicrobials commonly used in acne include *benzoyl peroxide*, *clindamycin* (topical preparation not marketed in the U.S.), *erythromycin*, and *benzoyl peroxide–erythromycin* or *benzoyl peroxide–clarithromycin* combinations. Topical monotherapy with *clindamycin* or *erythromycin* is not recommended due to a slower onset of action and potential for development of bacterial resistance; therefore, addition of *benzoyl peroxide* or use of combination antibiotic–*benzoyl peroxide* products is recommended to improve efficacy and decrease emergence of antibiotic-resistant bacteria (Eichenfield et al., 2013). Other topical antimicrobials used in treating acne include *azelaic acid, dapsone, metronidazole, minocycline, sulfacetamide*, and *sulfacetamide/sulfur* combinations.

Systemic therapy is prescribed for patients with acne vulgaris that is more extensive or resistant to topical therapy. There are data to support the use of tetracyclines (*doxycycline*, *minocycline*, *tetracycline*, *sarecycline*), macrolides (*azithromycin, erythromycin*), and *trimethoprim-sulfamethoxazole*. Other antibiotics that decrease the extent of the infection or the inflammatory response to *C. acnes* may be effective as well. After initiation of antibiotic treatment for acne, 6 to 8 weeks are required for visible clinical results, with maximum effect sometimes requiring 3 to 6 months (Eichenfield et al., 2013). Doses are tapered after control is achieved. Concomitant use with topical *benzoyl peroxide* may decrease development of antibiotic-resistant bacteria.

The tetracyclines are the most commonly employed antibiotics. They should not be used during pregnancy or in patients younger than 8 years.

Although agents in the tetracycline class are antimicrobials, efficacy in acne may be more dependent on anti-inflammatory activity. *Minocycline*, *doxycycline*, and *sarecycline* have better GI absorption than *tetracycline* and may be given with food to minimize GI side effects. *Minocycline* and *sarecycline* may be less photosensitizing than either *tetracycline* or *doxycycline*. Adverse effects include vestibular toxicity, hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a potential complication that is readily treated with administration of antifungal drugs. However, *sarecycline* has a more narrow antimicrobial spectrum compared to the other tetracyclines, which may lead to less disruption of the vulvovaginal and GI microbiome.

Cutaneous Bacterial Infections

Numerous organisms may cause cutaneous infections ranging from benign to life-threatening. Clinical presentation and treatment depend on the depth of cutaneous involvement, immune status of the patient, causative organism, and local antibiotic resistance patterns (Rajan, 2012; Stevens et al., 2014). Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of SSTIs. Patients who are diabetic or immunosuppressed are at risk for severe, recurrent, or atypical infections.

Topical Therapy. *Topical therapy* is frequently used for superficial bacterial infections, wounds, and burns. The use of topical antibiotics on clean surgical wounds without signs of infection is not recommended as it does not reduce the rate of infection compared to nonantibiotic ointment or no ointment, and there is a risk of contact dermatitis to topical antibiotics (Levender et al., 2012) and counterproductive selection of resistant bacterial strains.

Mupirocin. *Mupirocin* inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. *Mupirocin* is effective for treatment of *S. aureus* and *S. pyogenes*, but it is inactive against normal skin flora or anaerobes. *Mupirocin* is available as a 2% ointment or cream, applied two or three times daily for 5 to 10 days. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014). A nasal formulation is indicated to eradicate nasal colonization by *methicillin*-resistant *Staphylococcus aureus* (MRSA). It is applied intranasally twice a day for 5 days and often combined with daily *chlorhexidine* or dilute *sodium hypochlorite* washes for the body. Prolonged suppression may be achieved with repeat monthly courses.

Retapamulin. *Retapamulin* selectively inhibits bacterial protein synthesis by interacting at a unique site on the 50S subunit of bacterial ribosomes. It is active against multiple gram-positive organisms, including *S. aureus* and *S. pyogenes*, and against anaerobes. *Retapamulin* ointment 1% is FDA-approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients 9 months or older. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014).

Bacitracin, Neomycin, and Polymyxin B. These agents are sold alone or in various combinations with other ingredients (e.g., *hydrocortisone*, *lidocaine*, or *pramoxine*) in a number of OTC formulations. *Bacitracin* inhibits staphylococci, streptococci, and gram-positive bacilli. *Neomycin* is active against staphylococci and most gram-negative bacilli. *Polymyxin B* is active against aerobic gram-negative bacilli, including *Pseudomonas aeruginosa.* Both *bacitracin* and *neomycin* are relatively common causes of allergic contact dermatitis, especially in patients with stasis dermatitis or otherwise disrupted skin (Drucker, 2012).

Gentamicin. *Gentamicin* is an aminoglycoside that inhibits protein synthesis by binding to the 30S subunit of bacterial ribosomes. It has activity for certain gram-positive bacteria, including *S. aureus*, and gram-negative bacteria, including *P. aeruginosa*. *Gentamicin sulfate* 0.1% cream or ointment may be applied three or four times daily to affected areas.

Ozenoxacin. *Ozenoxacin* is a quinolone with bactericidal activity through inhibition of bacterial DNA gyrase A and topoisomerase IV, thereby inhibiting replication. It is approved for treatment of impetigo due to *S. aureus* or *S. pyogenes* in patients 2 months of age or older. *Ozenoxacin* 1% cream is applied twice a day for 5 days.

Silver Sulfadiazine. *Silver sulfadiazine* (SSD) binds to bacterial DNA and inhibits replication. It is bactericidal against gram-positive bacteria, including MRSA, and gram-negative bacteria, including *P. aeruginosa*. SSD is most frequently used in the treatment of partial-thickness burns or lower extremity venous stasis ulcers. However, recent studies have failed to demonstrate efficacy in these settings (Miller et al., 2012); indeed, SSD may impede re-epithelialization. Rarely, argyria has developed in patients using SSD over extensive areas of the body (Browning and Levy, 2008).

Mafenide. *Mafenide acetate* is a topical sulfonamide, although its mechanism of action may be distinct from other sulfonamides. *Mafenide* is approved as adjunctive therapy for burn wounds and is available as either an 85 mg/g cream or as a 5% topical solution supplied as 50-g packets of powder that must be reconstituted. It exerts broad bacteriostatic action against many gram-positive and gram-negative organisms, including *P. aeruginosa* and some anaerobes. The high solubility of *mafenide* allows it to diffuse easily through eschar and devascularized tissue, which is beneficial for treating subeschar burn wound infection. *Mafenide* and its metabolites inhibit carbonic anhydrase, so treated patients may be at risk for metabolic acidosis, especially if they have renal failure or if *mafenide* is applied to large surface areas. Other potential adverse effects include pain or burning sensation with application, facial edema, allergic contact dermatitis, and rarely, hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Systemic Therapy. Deeper or complicated SSTIs typically require systemic administration of antimicrobials. Superficial infections with diffuse involvement or that are nonresponsive to topical therapy may also require systemic antimicrobials. Because SSTIs are most commonly caused by streptococcal and staphylococcal species, penicillins (especially β-lactamase–resistant β-lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment. A growing concern is the increased incidence of SSTIs with hospital- and community-acquired MRSA and drug-resistant pneumococci. Common outpatient treatment options for MRSA include *clindamycin*, *doxycycline*, and *trimethoprim-sulfamethoxazole*. When coverage for both MRSA and streptococci is needed, *clindamycin* alone or the combination of either *doxycycline* or *trimethoprim-sulfamethoxazole* with a β-lactam may be used (Stevens et al., 2014). *Clindamycin* should not be used as empiric therapy if local resistance rates are greater than 10% to 15% (Stevens et al., 2014). Treatment options for more severe or complicated SSTIs that provide coverage for MRSA include orally administered agents, such as *linezolid*, *tedizolid*, *delafloxacin*, and *omadacycline*, and parenterally administered agents, such as *vancomycin, daptomycin, linezolid, tedizolid, delafloxacin, omadacycline, ceftaroline, dalbavancin, oritavancin*, and *telavancin*.

Antifungal Agents

Fungal infections are among the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 61. This section addresses the management of common superficial cutaneous mycoses. Recommendations for cutaneous antifungal therapy are summarized in Table 75–8. Topical antifungal agents used for superficial mucocutaneous mycoses are listed in Table 75–9.

Dermatophyte Infections of the Skin (Tinea Corporis, Cruris, and Pedis)

The dermatophyte infections (tinea corporis, cruris, and pedis) generally respond to topical antifungals, including allylamines (*naftifine*, *terbinafine*), benzylamines (*butenafine*), azoles (*econazole*, *luliconazole*), and *ciclopirox* (Rotta et al., 2013). Allylamines and benzylamines may provide a more sustained clinical cure compared to azole antifungals (Rotta et al., 2013). Bacterial superinfection of tinea pedis can occur, and antifungal agents such as *econazole* and *ciclopirox* that also provide some bacterial coverage may be useful in those situations. Systemic therapy with

TABLE 75–8 ■ RECOMMENDED CUTANEOUS ANTIFUNGAL THERAPY

CONDITION	TOPICAL THERAPY	ORAL THERAPY
Tinea corporis, localized	Azoles, allylamines, benzylamines	—
Tinea corporis, widespread	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea capitis	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea pedis	Azoles, allylamines, benzylamines	Griseofulvin, terbinafine, itraconazole, fluconazole
Onychomycosis	—	Terbinafine, itraconazole, fluconazole
Candidiasis, localized	Azoles, nystatin	—
Candidiasis, widespread and mucocutaneous	—	Itraconazole, fluconazole
Tinea versicolor, localized	Azoles, allylamines	—
Tinea versicolor, widespread	—	Itraconazole, fluconazole

terbinafine, *fluconazole*, *itraconazole*, or *griseofulvin* is used when there is more extensive cutaneous involvement or a poor response to topical therapy. Systemic therapy with *ketoconazole* carries a risk of severe hepatotoxicity or QT prolongation so it is not a preferred treatment for superficial fungal infections.

Dermatophyte Infections of the Hair and Follicles

Dermatophyte infections of the hair (tinea capitis) or follicularly based infections of the skin (Majocchi granuloma) require systemic therapy. *Griseofulvin* has been the traditional medication for tinea capitis, and treatment failure is often related to inadequate dosage or length of treatment. *Terbinafine* may be more effective for *Trichophyton tonsurans*, which is the most common cause of tinea capitis in the U.S. (Elewski et al., 2008). *Fluconazole* and *itraconazole* are also effective (Gupta and Paquet, 2013).

Onychomycosis

Onychomycosis is a fungal infection of the nails that is commonly caused by dermatophytes or *Candida*. Onychomycosis is most effectively treated with systemic therapy (de Sa et al., 2014). Fungal infection should be confirmed prior to initiating oral therapy. There are other causes of nail dystrophy, and approximately one-third of nails with clinically suspected onychomycosis do not have fungal infection (Mehregan and Gee, 1999).

Terbinafine is the most effective treatment of dermatophyte onychomycosis, with typical adult dosing of 250 mg daily for 6 weeks for fingernails and 12 weeks for toenails. *Terbinafine* remains in the nails for several weeks after medication administration has ceased, and some studies have utilized pulsed dosing of *terbinafine* 500 mg daily for 1 week per month for 3 months based on this finding.

Itraconazole is another effective option for dermatophyte onychomycosis and is more effective than *terbinafine* for candidal onychomycosis. *Itraconazole* persists in the nail for 6 to 9 months after administration has ceased. Traditional adult dosing for *itraconazole* is 200 mg daily for 6 weeks for fingernails and 12 weeks for toenails; however, pulsed dosing is an alternative option because of *itraconazole*'s persistence in the nail after administration has ceased. *Itraconazole* pulsed dosing in adults is 400 mg daily for 1 week per month for 2 months for fingernails and 3 months for toenails, which may minimize adverse effects. *Fluconazole* is an alternative option that may be useful in patients who cannot use *terbinafine* or *itraconazole*.

Griseofulvin, used in the past, is less efficacious and requires much longer treatment courses; it is no longer a preferred option. Topical antifungals approved for onychomycosis include *ciclopirox lacquer*, *efinaconazole*, and *tavaborole*. These topical antifungals require a 48-week treatment course. They may be useful for patients with mild-to-moderate onychomycosis not involving the nail matrix or in patients who are not candidates for systemic therapy (Gupta et al., 2014).

Cutaneous Candidiasis

Cutaneous candidiasis is typically treated with topical azole antifungals or *nystatin* when localized. Systemic azole antifungals such as *fluconazole* or *itraconazole* may be needed for more recalcitrant or severe cases.

Malassezia *Infections*

Pityriasis versicolor and seborrheic dermatitis are caused by *Malassezia* (*Pityrosporum*) species and are frequently treated with azole antifungals in cream or shampoo formulations. Additional topical therapies include *ciclopirox*, *terbinafine*, *selenium sulfide*, *pyrithione zinc*, *sodium sulfacetamide*, and *sulfur* with or without *salicylic acid*. Oral *fluconazole* and *itraconazole* are sometimes used for diffuse or resistant pityriasis versicolor. Oral *terbinafine* does not reach adequate concentrations in the superficial stratum corneum to be effective.

Antiviral Agents

Viral infections of the skin by human papillomavirus (HPV), herpes simplex virus (HSV), molluscum contagiosum virus, and varicella-zoster virus (VZV) are common and produce a variety of lesions, including warts or blisters. *Acyclovir*, *famciclovir*, and *valacyclovir* are often used systemically to treat HSV and VZV infections (see Chapter 62). *Cidofovir* and *foscarnet* are useful for treating *acyclovir*-resistant HSV. Topically, *acyclovir*, *docosanol*, *penciclovir*, and combination *acyclovir/hydrocortisone* are available for treating mucocutaneous HSV; however, they are less effective than systemic therapies (Sarnoff, 2014). *Acyclovir* is also available as a 50-mg buccal tablet for herpes labialis to be applied as a single dose to the upper gum just above the incisor tooth within 1 h of prodromal symptoms.

Cidofovir is used off label topically or intralesionally as treatment of anogenital warts caused by HPV. Topical *cidofovir* 1% gel or cream must be obtained through a compounding pharmacy. It is applied once daily for 5 consecutive days every other week for a maximum of six cycles. Additional treatments for genital warts are nonspecific cytodestructive or immunomodulatory therapies, which are discussed in further detail in other sections. Cytodestructive modalities include topical use of cryotherapy, *podophyllin* (podophyllum resin) or *podofilox* (podophyllotoxin), and *trichloroacetic acid*. Topical immunomodulatory therapies include *imiquimod* and sinecatechins. Intralesional immunotherapy for warts has included *Candida* antigen, measles-mumps-rubella vaccine, bacillus Calmette-Guérin vaccine, tuberculin purified protein derivative, trichophyton antigen, and more recently, HPV vaccine (Nabil et al., 2020). Intralesional or systemic interferons α_{2b}, α_{n3}, and β may be useful for treating refractory or recurrent genital warts, but their use is limited by the pain of multiple injections for intralesional use and by the potential for severe side effects with systemic use (Smith et al., 2007).

Agents Used to Treat Infestations

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and, in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations (Diamantis et al., 2009).

- *Permethrin* is a synthetic pyrethroid that interferes with insect Na^+ transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported and appears to be increasing. A 5% cream is available by prescription for the treatment of scabies, and a 1% lotion or cream rinse is available OTC for the

TABLE 75–9 ■ TOPICAL ANTIFUNGAL AGENTS FOR SUPERFICIAL MUCOCUTANEOUS MYCOSES

TYPE AND GENERIC NAME	FORMULATIONS	FDA-APPROVED INDICATIONS	NOTES
Polyenes			
Nystatin	Topical (0.1 megaunit/g): powder, ointment, cream	Cutaneous and mucocutaneous candidiasis	Orally administered nystatin lacks appreciable systemic absorption; it is used for local treatment of oral cavity and GI tract candidiasis
	Oral (0.1 megaunit/g): suspension, solution, capsule or tablet (0.5 megaunit)	Oral cavity, mucocutaneous, cutaneous candidiasis Nonesophageal GI candidiasis (off-label use)	
Azoles			
Butoconazole	Vaginal cream: 1% and 2%	Vaginal yeast infections	
Clotrimazole	Oral lozenge, 10 mg	Oropharyngeal candidiasis	
	Cream, ointment, solution; 1%	Rx: *Candida albicans*, pityriasis versicolor OTC: tinea	
	Topical: cream, 1%; foam, 1%	Tinea, cutaneous candidiasis, pityriasis versicolor Tinea pedis in patients ≥12 years	
Econazole	Topical: solution, 10%	Toenail onychomycosis	
Efinaconazole	Topical: 2% foam, gel; 1% shampoo; 2% shampoo, gel; 2% cream	Seborrheic dermatitis Pityriasis versicolor Tinea, pityriasis versicolor, seborrheic dermatitis, cutaneous candidiasis	
Ketoconazole	1% cream	Tinea	Shampoo FDA-approved for OTC; other formulations are by prescription
Luliconazole	Topical: 2% cream, lotion, ointment, powder, solution, spray, tincture, paste, liquid	Tinea	
Miconazole	Buccal tablet, 50 mg	Oropharyngeal candidiasis	OTC
	Vaginal suppository, 100 or 200 mg Vaginal cream, 2% or 4% vaginal cream	Vulvovaginal candidiasis	FDA-approved OTC drug
	Topical: 1% cream, lotion	Tinea, pityriasis versicolor	FDA-approved OTC drug
Oxiconazole	Topical: 2% cream, solution	Tinea pedis in patients ≥12 years	
Sertaconazole	Topical: 1% cream, solution	Tinea; pityriasis versicolor	
Sulconazole	Vaginal: 0.4%, 0.8% vaginal cream; 80-mg vaginal suppository	Vulvovaginal candidiasis	
Terconazole	Vaginal: 6.5% vaginal ointment	Vulvovaginal candidiasis	
Tioconazole	Vaginal: 6.5% ointment	Vulvovaginal candidiasis	FDA-approved OTC drug
Allylamines	Topical: 1% or 2% cream, gel	Tinea	
Naftifine	Topical: 1% cream, gel, spray	Tinea; pityriasis versicolor	
Terbinafine	Oral: 250-mg tablet	Onychomycosis	FDA-approved OTC drug
Benzylamines	Topical: 1% cream	Rx: pityriasis versicolor OTC: tinea	
Butenafine	Topical: 1% cream	Rx: pityriasis versicolor OTC: tinea	FDA-approved OTC drug
Hydroxypyridones			
Ciclopirox	Topical: 1% shampoo	Seborrheic dermatitis	
	Topical: 0.77% gel, cream, suspension	Tinea, seborrheic dermatitis	
	Topical: 0.77% gel, cream, suspension	Tinea, seborrheic dermatitis	

(*Continued*)

TABLE 75–9 ■ TOPICAL ANTIFUNGAL AGENTS FOR SUPERFICIAL MUCOCUTANEOUS MYCOSES (*CONTINUED*)

TYPE AND GENERIC NAME	FORMULATIONS	FDA-APPROVED INDICATIONS	NOTES
Oxaboroles			
Tavaborole	5% topical solution	Toenail onychomycosis	
Miscellaneous; available OTC			
Selenium sulfide	Topical: 1% or and 2% topical solutions	Abrasions, minor cuts, surface injuries, superficial fungal infections of the skin	
Gentian violet	Topical: 1% foam, spray, impregnated cloth, gel, liquid, lotion, nail oil, ointment, soap, cream, powder, solution, aerosol	Tinea, pityriasis versicolor	Stains skin and clothing purple
Tolnaftate	Topical: 10%–25% topical powder, cream, solution, soap, others	Tinea	
Undecylenic acid	Topical: 10%–25% powder, cream, solution, soap, others	Tinea	

treatment of lice. *Permethrin* is approved for use in infants 2 months or older. Other OTC agents used in the treatment of lice are pyrethrins plus *piperonyl butoxide* in various formulations and *acetic acid* plus *isopropanol* shampoo.

- *Lindane* is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites. Due to several cases of neurotoxicity in humans, the FDA has labeled *lindane* as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing less than 50 kg and patients with underlying skin disorders such as atopic dermatitis and psoriasis. *Lindane* is contraindicated in premature infants and patients with seizure disorders. *Lindane* carries a boxed warning from the FDA; a Lindane Medication Guide must be given to the patient each time *lindane* lotion or shampoo is dispensed.
- *Malathion* is an organophosphate that inhibits acetylcholinesterase in lice, causing paralysis and death. It is approved for treatment of head lice in children 6 years and older. The current formulation of *malathion* lotion contains 78% isopropyl alcohol and is flammable. Detailed information on *malathion*'s actions and adverse effects may be found in Chapter 12.
- *Benzyl alcohol* 5% lotion is approved for the treatment of lice in patients 6 months and older. *Benzyl alcohol* inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. There may be less potential for development of resistance with this mechanism of action compared to traditional pesticides.
- *Ivermectin* is an anthelmintic drug (see Chapter 68) approved for oral treatment of onchocerciasis and strongyloidiasis. Recently, topical *ivermectin* 0.5% lotion was approved to treat lice in patients 6 months or older, and a 1% cream was approved to treat rosacea. *Ivermectin* is also effective in the off-label treatment of scabies. Because *ivermectin* does not cross the human blood-brain barrier, there is no major CNS toxicity; minor CNS side effects with oral administration may include dizziness, somnolence, vertigo, and tremor. Topical administration may cause local irritant effects, such as conjunctivitis, eye irritation, dry skin, or skin-burning sensation, although these occurred in fewer than 1% of patients during clinical trials. For both scabies and lice, *ivermectin* typically is given at an oral dose of 200 μg/kg, which may be repeated in 1 week. In cases of crusted scabies, longer treatment cycles of oral *ivermectin* may be needed, sometimes in addition to topical keratolytics and scabicides (Ortega-Loayza et al., 2013). It should not be used in children weighing less than 15 kg.
- *Abametapir* is an antiparasitic drug approved for treatment of head lice in patients 6 months or older. The drug exhibits pediculicidal and ovicidal activity through inhibition of metalloproteinases critical for louse survival and egg development. *Abametapir* 0.74% lotion is applied to dry hair and scalp and then left in for 10 min before rinsing. Due to its ovicidal activity, only a single application is needed. Potential adverse effects include skin irritation, eye irritation, pruritus, and hair color changes.
- *Spinosad* 0.9% topical suspension is approved for treatment of head lice in patients 6 months or older. Spinosad causes CNS excitation and involuntary muscle contractions, leading to insect paralysis and death.

Less effective topical treatments for scabies and lice include 10% *crotamiton cream* and lotion and extemporaneously compounded 5% to 10% *precipitated sulfur* in petrolatum. *Precipitated sulfur* may be useful for patients in whom other therapies are contraindicated or not approved; it is typically applied once daily for 3 to 5 consecutive days.

Antimalarial Agents

The antimalarial agents *chloroquine*, *hydroxychloroquine*, and *quinacrine* are used in dermatology to treat dermatoses such as cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light eruption, porphyria cutanea tarda, and sarcoidosis (only *hydroxychloroquine* is FDA-approved for treating lupus erythematosus). The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is uncertain but may involve inhibition of endosomal toll-like receptor signaling, resulting in reduced B-cell and dendritic cell activation (Kalia and Dutz, 2007). The usual dosages of antimalarials are *hydroxychloroquine* 200 mg twice a day (maximum of 6.5 mg/kg per day); *chloroquine* 250 to 500 mg/day (maximum of 3 mg/kg per day); and *quinacrine* 100 to 200 mg/day. Patients with porphyria cutanea tarda require lower doses of antimalarials to avoid severe hepatotoxicity. There is strong evidence that smoking decreases the effectiveness of antimalarials in the treatment of cutaneous lupus erythematosus, so smoking cessation is important (Chasset et al., 2015). Clinical improvement may be delayed for several months. If there is no improvement after 3 months of *hydroxychloroquine*, then *quinacrine* may be added (in the U.S., *quinacrine* must be obtained through compounding pharmacies). Dose-dependent ocular toxicity occurs with *chloroquine* more often than *hydroxychloroquine* and is rare to nonexistent with *quinacrine*. The potential toxic effects of antimalarial agents are described further in Chapter 66.

Cytotoxic and Immunosuppressant Drugs

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, autoimmune blistering diseases, and leukocytoclastic vasculitis. See Table 75–10 for their mechanisms of action...

TABLE 75–10 ■ MECHANISM OF ACTION FOR SELECTED CYTOTOXIC, IMMUNOSUPPRESSIVE, AND IMMUNOMODULATORY DRUGS

Methotrexate	Dihydrofolate reductase inhibitor
Fluorouracil	Blocks methylation in DNA synthesis
Cyclophosphamide	Alkylates and cross-links DNA
Mechlorethamine hydrochloride	Alkylating agent
Carmustine	Cross-links in DNA and RNA
Vinblastine	Inhibits microtubule formation
Podophyllin	Inhibits microtubule formation
Tirbanibulin	Inhibits microtubule formation
Bleomycin	Induction of DNA strand breaks
Azathioprine	Purine synthesis inhibitor
Mycophenolate mofetil	Inosine monophosphate dehydrogenase inhibitor
Cyclosporine	Calcineurin inhibitor
Tacrolimus	Calcineurin inhibitor
Pimecrolimus	Calcineurin inhibitor
Sirolimus	mTOR inhibitor
Everolimus	mTOR inhibitor
Imiquimod	Interferon α induction via toll-like receptor 7
Dapsone	Inhibits neutrophil migration, oxidative burst
Thalidomide	Cytokine modulation

Antimetabolites

Methotrexate is used for moderate-to-severe psoriasis. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen–positive T cells and endothelial cell E-selectin, which may account for its efficacy. *Methotrexate* is useful in treating a number of other dermatological conditions, including atopic dermatitis, pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and CTCL.

Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents. Widely used regimens in adults include 10 to 25 mg orally once weekly as a single dose or as three divided doses given at 12-h intervals, with similar effectiveness using either regimen, or intramuscular administration of 10 to 25 mg injected once weekly (maximum of 30 mg/week) (Menter et al., 2009b). FDA approval allows for oral, intravenous, intramuscular, and subcutaneous administration of *methotrexate*.

Doses must be decreased for patients with impaired renal clearance. *Methotrexate should not be administered with probenecid, trimethoprim-sulfamethoxazole, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression*. Fatalities have occurred because of concurrent treatment with *methotrexate* and NSAIDs. *Methotrexate* exerts significant antiproliferative effects on the bone marrow; therefore, CBCs should be monitored serially. Clinicians administering *methotrexate* should be familiar with the use of *folinic acid* (*leucovorin*) to rescue patients with hematological crises caused by *methotrexate*-induced bone marrow suppression. Careful monitoring of liver function tests is necessary to assess for *methotrexate*-induced hepatotoxicity. Liver biopsy may be recommended after a 3.5- to 4-g cumulative dose in patients without other risk factors versus 1 to 1.5 g in patients with higher risk (e.g., obesity, diabetes) (Menter et al., 2009b). Patients with abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. *Methotrexate* is contraindicated during pregnancy and lactation. Many clinicians routinely administer folic acid to ameliorate side effects of *methotrexate*.

5-Fluorouracil (5FU) is used topically in multiple actinic keratoses, actinic cheilitis, Bowen disease, and superficial basal cell carcinomas (BCCs) not amenable to other treatments (Micali et al., 2014a, b). 5FU is applied once or twice daily for 2 to 8 weeks, depending on the indication. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5FU has been used off label for keratoacanthomas, warts, and porokeratoses (Good et al., 2011).

Alkylating Agents

Cyclophosphamide is an effective cytotoxic and immunosuppressive agent. Both oral and intravenous preparations of *cyclophosphamide* are used in dermatology. *Cyclophosphamide* is FDA-approved for treatment of advanced CTCL (Jawed et al., 2014).

Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener granulomatosis, polyarteritis nodosa, Churg-Strauss angiitis, Behçet disease, scleromyxedema, and cytophagic histiocytic panniculitis. The usual oral dosage is 2 to 2.5 mg/kg per day in divided doses, and there often is a 4- to 6-week delay in onset of action (Meurer, 2012). Alternatively, intravenous pulse administration of *cyclophosphamide* may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer. *Cyclophosphamide* has many adverse effects (see Chapter 70), including the risk of secondary malignancy and myelosuppression, and is used only in the most severe, recalcitrant dermatological diseases.

Mechlorethamine hydrochloride and *carmustine* are used topically to treat CTCL (Jawed et al., 2014). It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. *Carmustine* also can cause erythema and posttreatment telangiectasias.

Microtubule Inhibitors

Vinblastine is approved for systemic use in Kaposi sarcoma and advanced CTCL. Intralesional *vinblastine* also is used to treat Kaposi sarcoma (Regnier-Rosencher et al., 2013).

Podophyllin (podophyllum resin) is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple) that contains podophyllotoxin (podofilox), which binds to microtubules and causes mitotic arrest in metaphase (Fathi and Tsoukas, 2014). In the U.S., it must be obtained through a compounding pharmacy. *Podophyllum resin* 25% is applied topically by a physician and left in place for no longer than 2 to 6 h weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. It is recommended that the use of clinician-administered *podophyllum resin* be replaced by the purified podophyllotoxin (*podofilox*) for patient-administered use. *Podofilox* is available as a 0.5% gel or solution for at-home application two times daily for 3 consecutive days, repeated weekly as needed for up to four cycles.

Tirbanibulin is first-in-class agent that was recently FDA-approved for the topical treatment of actinic keratoses on the face or scalp. The drug inhibits microtubule polymerization and Src kinase signaling (Gilchrest, 2021; Smolinski et al., 2018). It is available as tirbanibulin 1% ointment, which is applied once daily for 5 consecutive days to evenly cover up to a 25 cm^2 area. Adverse reactions may include local skin irritation, application site pain, or pruritus.

Other Cytotoxic Agents

Bleomycin is used off label intralesionally for palliative treatment of squamous cell carcinoma and recalcitrant warts and has cytotoxic and proinflammatory effects. Intralesional injection of *bleomycin* into the digits has been associated with a vasospastic response that mimics Reynaud phenomenon. Other potential adverse reactions include local skin necrosis and flagellate hyperpigmentation. Systemic *bleomycin* has been used off label for Kaposi sarcoma (see Chapter 70) (Regnier-Rosencher et al., 2013).

Liposomal anthracyclines (specifically *doxorubicin*) may provide first-line monotherapy for advanced Kaposi sarcoma (Regnier-Rosencher et al., 2013).

Ingenol mebutate gel, an extract from the plant *Euphorbia peplus*, is FDA-approved for actinic keratosis (Micali et al., 2014a, b). In experimental studies, it was reported to rapidly cause mitochondrial swelling and apoptosis of dysplastic keratinocytes. The gel is applied once daily for 2 to 3 consecutive days. Adverse effects may include local skin irritation, pain, pruritus, and infection at application site; periorbital edema; nasopharyngitis; and headache. Cases of allergic contact dermatitis and reactivation of herpes zoster have been reported.

Azathioprine and Mycophenolate Mofetil

Azathioprine is discussed in Chapter 39. In dermatological practice, the drug is used off label as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet disease.

Azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit *de novo* purine synthesis (see Chapter 70). The level of thiopurine *S*-methyltransferase (TPMT) enzyme activity should be measured before initiating *azathioprine* therapy because low levels of TMPT activity are associated with increased drug toxicity (see Chapter 70). In general, the starting dosage is 1 to 2 mg/kg per day. Careful laboratory monitoring is important, especially in those with diminished TPMT activity.

Mycophenolate mofetil and *mycophenolate sodium* are immunosuppressants approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (see Chapter 39). *Mycophenolate mofetil* is a prodrug that is hydrolyzed to mycophenolic acid by plasma esterases; the salt of the acid, *mycophenolate sodium*, is available in an enteric-coated formulation. Mycophenolic acid functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation through inhibition of inosine monophosphate dehydrogenase, thereby reducing GMP synthesis by the *de novo* purine synthetic pathway. Lymphocytes are vulnerable due to their lack of the salvage pathway for purine synthesis. The drug also may enhance apoptosis.

Mycophenolate mofetil is used off label increasingly to treat inflammatory and autoimmune diseases in dermatology; dosages typically range from 2 to 3 g/day orally in adults or 30 to 50 mg/kg per day in pediatric patients, given in divided doses twice daily. This agent is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders and has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum. Isolated cases of progressive multifocal leukoencephalopathy and pure red cell aplasia have been reported in solid organ transplant patients receiving *mycophenolate mofetil*. The most common side effects of *mycophenolate mofetil* are dose-dependent GI symptoms (e.g., diarrhea, nausea, and abdominal pain). Enteric-coated *mycophenolate sodium* improves GI tolerability; the enteric coating delays absorption until the medication reaches the small intestine rather than occurring in the stomach.

Calcineurin Inhibitors

The mechanisms of action and clinical pharmacology of calcineurin inhibitors are described in Chapter 39. Figure 39–2 shows their sites of action as immunosuppressants

Cyclosporine is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. *Cyclosporine* is FDA-approved for the treatment of psoriasis. A modified microemulsion formulation has increased bioavailability and more consistent absorption than the original formulation. Other cutaneous disorders that typically respond well to *cyclosporine* are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual oral dosage of the modified formulation is 2.5 to 5 mg/kg per day, often given in two divided doses (Menter et al., 2009b; Sidbury et al., 2014).

Hypertension and renal dysfunction are the major adverse effects associated with the use of *cyclosporine*. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regularly monitoring blood pressure. Alternation with other therapeutic modalities may diminish *cyclosporine* toxicity. Patients with psoriasis who are treated with *cyclosporine* are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded in patients who have received phototherapy with PUVA.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations. Systemic *tacrolimus* has shown some efficacy in the off-label treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet disease. When *tacrolimus* is administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia.

Topical formulations (0.03% and 0.1%) of *tacrolimus* ointment are approved for the treatment of atopic dermatitis in adults and in children 2 years or older for 0.03% ointment and 16 years or older 0.1% ointment. Other uses include for treatment of intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. Ointment is applied to the affected area two times daily and generally is well tolerated. Common side effects at the site of application are transient erythema, burning, and pruritus. Other adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia. Systemic absorption generally is very low and decreases with resolution of the dermatitis. Topical *tacrolimus* should be used with extreme caution in patients with Netherton syndrome; these patients may develop elevated blood levels of the drug after topical application (Eichenfield et al., 2014).

Pimecrolimus (as a 1% cream) is approved for the treatment of atopic dermatitis in patients 2 years and older. Its mechanism of action and side effect profile are similar to those of *tacrolimus*. It has low-to-negligible systemic absorption after topical application.

Tacrolimus and *pimecrolimus* are approved as second-line agents for short-term and intermittent treatment of atopic dermatitis in patients unresponsive to, or intolerant of, other treatments. Unlike topical corticosteroids, they do not carry the risk of skin atrophy and may be especially useful as steroid-sparing agents or for use on sensitive skin sites (e.g., eyelids, face, skin folds) or areas with steroid-induced atrophy.

mTOR Inhibitors

Sirolimus causes immunosuppressive and antiproliferative effects through inhibition of mTOR (mammalian target of rapamycin) as part of the PI3 kinase/Akt/mTOR pathway (see Figures 39–2 and 71–5). The mTOR inhibitors are established treatments for posttransplant immunosuppression (see Chapter 39) and as antineoplastic agents for malignancies such as renal and hepatocellular carcinoma (see Chapter 71). Off-label use of mTOR inhibitors in dermatology includes treatment of tuberous sclerosis complex, pachyonychia congenita, complex vascular anomalies, and inflammatory dermatoses such as systemic sclerosis (Fogel et al., 2015). Systemic mTOR inhibitors may be associated with serious side effects, with dermatological side effects among the most common, including stomatitis, myositis, inflammatory cutaneous eruptions, and nail

changes such as paronychia (Fogel et al., 2015). Topical formulations have been used to decrease the risk of side effects associated with systemic therapy. Newer semisynthetic analogues of *sirolimus* such as *everolimus* and *temsirolimus* are available and have improved water solubility and efficacy.

Immunomodulators and Anti-inflammatory Agents

Imiquimod exerts immunomodulatory effects by acting as a ligand at toll-like receptors in the immune system and inducing the cytokines interferon (IFN) α, tumor necrosis factor (TNF) α, and interleukin (IL)-1, IL-6, IL-8, IL-10, and IL-12.

Imiquimod cream is available in 2.5%, 3.75%, and 5% strengths. Approved for the treatment of genital warts, *imiquimod* 5% cream is applied to genital or perianal lesions three times a week until resolution of warts or for up to a 16-week period (and repeated as necessary) (Fathi and Tsoukas, 2014). *Imiquimod* also is approved for the treatment of actinic keratosis, with various regimens used (Micali et al., 2014a, b). No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The 5% cream is also FDA-approved for the treatment of superficial BCCs at a dosage of five applications per week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.

Sinecatechins are partially purified green tea extracts containing a mixture of 85% to 95% catechins and other green tea components. They are approved for the topical treatment of external genital and perianal warts in immunocompetent patients more than 18 years of age. The mechanism of action is unclear but may include a combination of antioxidant, antiviral, antiangiogenic, proapoptotic, and immunomodulatory activities. The *sinecatechin* 15% ointment is applied three times daily for up to 16 weeks until clearance of the warts. The most common side effects are local skin reactions, including erythema, pruritus or burning, pain, superficial ulceration, and edema, with the intensity of local reactions peaking between 2 and 4 weeks of use. Local site reactions may be indicative of a positive clinical response, and patients are encouraged to treat through them as tolerated.

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin (Zhu and Stiller, 2001). *Dapsone* prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects. *Dapsone* is discussed further in Chapter 65.

Dapsone is approved for oral use in dermatitis herpetiformis and leprosy and for topical use in acne vulgaris. It is also particularly useful in the off-label treatment of linear IgA dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey-Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet syndrome, granuloma faciale, relapsing polychondritis, Behçet disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare.

The initial oral dosage is 50 mg/day, followed by increases of 25 mg/day at weekly intervals, titrated to the minimal dosage necessary for effect. Potential side effects of *dapsone* include methemoglobinemia and hemolysis (G6PD level should be checked in all patients). The H_2 blocker *cimetidine* inhibits numerous CYPs and thereby reduces the *N*-hydroxylation of *dapsone* to the hydroxylamine metabolite that causes the methemoglobinemia. Other toxicities of *dapsone* include agranulocytosis, peripheral neuropathy, and psychosis.

Thalidomide is an anti-inflammatory, immunomodulatory, and antiangiogenic agent experiencing resurgence in the treatment of dermatological diseases (Wu et al., 2005). For details of its actions, see Figures 71–8 and 71–9.

Thalidomide is FDA-approved for the treatment of erythema nodosum leprosum. Reports also suggest its efficacy in actinic prurigo, aphthous stomatitis, Behçet disease, Kaposi sarcoma, the cutaneous manifestations of lupus erythematosus, and prurigo nodularis and uremic prurigo. *Thalidomide* has been associated with increased mortality when used to treat toxic epidermal necrolysis. *In utero* exposure can cause limb abnormalities (phocomelia), as well as other congenital anomalies. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. It also may cause an irreversible neuropathy. Because of its teratogenic effects, thalidomide use is restricted and requires both pharmacists and physicians to register in a risk evaluation and mitigation strategy (REMS) program. Newer analogues of thalidomide are available, including lenalidomide and pomalidomide.*

Targeted Immunotherapies for Psoriasis and Atopic Dermatitis

Targeted immunotherapies, including biological agents, are rapidly evolving for the treatment of psoriasis, as the underlying pathogenesis is better understood (Table 75–11). In addition, biological therapy for atopic dermatitis is on the horizon. The appeal of these targeted therapies is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation, whereas traditional systemic therapies are broadly immunosuppressive or cytotoxic. The pathogenesis of psoriasis and atopic dermatitis is discussed briefly next, followed by the relevant targeted therapies. Targeted therapies are discussed in further detail in Chapters 38 and 39.

Psoriasis is a chronic immune-mediated inflammatory disorder involving the innate and adaptive immune systems, with resultant abnormal keratinocyte proliferation (Figure 75–3). Psoriasis is not limited to the skin, as there can be psoriatic arthritis and other systemic manifestations. Previously thought to be primarily T_H1 mediated, more recent developments demonstrate that the T_H17/IL-17 pathway plays the most significant role (Girolomoni et al., 2012). Mediators of inflammation, such as IL-23, TNFα, and IL-17, are key targets for therapy (Girolomoni et al., 2012; Sobell and Leonardi, 2014). In addition, therapies such as inhibitors of Janus kinases (JAKs) and cyclic nucleotide phosphodiesterases (PDEs) are useful to decrease expression or signal transduction of inflammatory cytokines (Sobell and Leonardi, 2014). Sphingosine-1-phosphate receptor 1 (S1PR1) modulators are also being evaluated as potential therapeutic targets for psoriasis through regulation of lymphocyte trafficking from lymphoid tissue into peripheral circulation and the skin; see Figure 39–3 and associated text.

Atopic dermatitis is a chronic skin disorder characterized by epidermal barrier dysfunction and immune-mediated inflammation. Patients often develop asthma and allergic rhinitis as well. Acute atopic dermatitis is T_H2 cell mediated, associated with cytokines IL-4, IL-5, and IL-13, whereas chronic atopic dermatitis also involves T_H1 cell–mediated activity, associated with cytokines IL-12 and IFNγ . Topical corticosteroids, calcineurin inhibitors, and phosphodiesterase-4 (PDE4) inhibitors are commonly used in patients with mild-to-moderate disease. Several of the traditional immunosuppressants have been used for more severe or resistant disease, and more recently, targeted therapy through IL-4/IL-13 inhibition has proven efficacious with a favorable safety profile (Eichenfield et al., 2014; Sidbury et al., 2014). Additional targeted therapies being evaluated for atopic dermatitis include IL-31 inhibitors, IL-13 inhibitors, IL-22 inhibitors, and S1PR1 modulators (Strowd et al., 2020). The FDA has recently approved several JAK inhibitors for treatment of atopic dermatitis (see JAK Inhibitors, below).

Tumor Necrosis Factor Inhibitors

Blockade of TNFα reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions. Because TNFα inhibitors alter immune responses,

TABLE 75–11 ■ BIOLOGICAL AGENTS FOR PSORIASIS

	BINDING SITE	STRUCTURAL CLASS	HALF-LIFE (DAYS)	METHOD OF ADMINISTRATION	ADULT DOSAGE FOR PSORIASIS	PEDIATRIC DOSAGE FOR PSORIASIS
TNFα						
Etanercept	TNFα TNFβ	Human p75 TNF receptor and Fc IgG_1 fusion protein	3–5.5	SC	50 mg twice weekly for 3 months, then 50 mg once weekly thereafter	0.8 mg/kg once weekly (max 50 mg per week)
Adalimumab	TNFα	Human $IgG_{1\kappa}$ mAb	10–20	SC	80 mg at week 0, 40 mg at week 1, then 40 mg every other week thereafter	
Infliximab	TNFα	Chimeric $IgG_{1\kappa}$ mAb	7.7–9.5	IV	5 mg/kg at weeks 0, 2, and 6, then every 8 weeks thereafter	
Certolizumab pegol	TNFα	PEGylated humanized Fab' fragment mAb	14	SC	400 mg every other week If ≤90 kg, alternate dosing of 400 mg at weeks 0, 2, and 4, then 200 mg every other week thereafter may be acceptable	
IL-17						
Bimekizumab*	IL-17A IL-17F	Humanized IgG_1 mAb	17–22	SC	320 mg every 4 weeks for 16 weeks then every 8 weeks thereafter	
Brodalumab	IL-17 receptor A	Human $IgG_{2\kappa}$ mAb	10.9	SC	210 mg at weeks 0, 1, and 2, then every 2 weeks	
Ixekizumab	IL-17A	Humanized IgG_4 mAb	13	SC	160 mg at week 0, then 80 mg at weeks 2, 4, 6, 8, 10, and 12, and then every 4 weeks thereafter	<25 kg: 40 mg at week 0 and then 20 mg every 4 weeks thereafter 25–50 kg: 80 mg at week 0, then 40 mg every 4 weeks thereafter >50 kg: 160 mg at week 0, then 80 mg every 4 weeks thereafter
Secukinumab	IL-17A	Human $IgG_{1\kappa}$ mAb	22–31	SC	300 mg at weeks 0, 1, 2, 3, and 4, and every 4 weeks thereafter For some, maintenance of 150 mg every 4 weeks may be acceptable	
IL-12/23						
Ustekinumab	p40 subunit of IL-12 and IL-23	Human $IgG_{1\kappa}$ mAb	~15–45	SC	If ≤100 kg: 45 mg at weeks 0 and 4, and every 12 weeks thereafter If >100 kg: 90 mg at weeks 0 amd 4, and every 12 weeks thereafter	<60 kg: 0.75 mg/kg at weeks 0 and 4, and every 12 weeks thereafter ≥60 to ≤100 kg: 45 mg at weeks 0 and 4, and every 12 weeks thereafter >100 kg: 90 mg at weeks 0 and 4, and every 12 weeks thereafter
IL-23						
Guselkumab	p19 subunit of IL-23	Human $IgG_{1\lambda}$ mAb	15–18	SC	100 mg at weeks 0 and 4, and every 8 weeks thereafter	
Risankizumab	p19 subunit of IL-23	Humanized IgG_1 mAb	28	SC	150 mg at weeks 0 and 4, and every 12 weeks thereafter	
Tildrakizumab	p19 subunit of IL-23	Humanized $IgG_{1\kappa}$ mAb	23	SC	100 mg at weeks 0 and 4, and every 12 weeks thereafter	

*Approved dosage in European Union; not current FDA-approved.
mAb, monoclonal antibody.

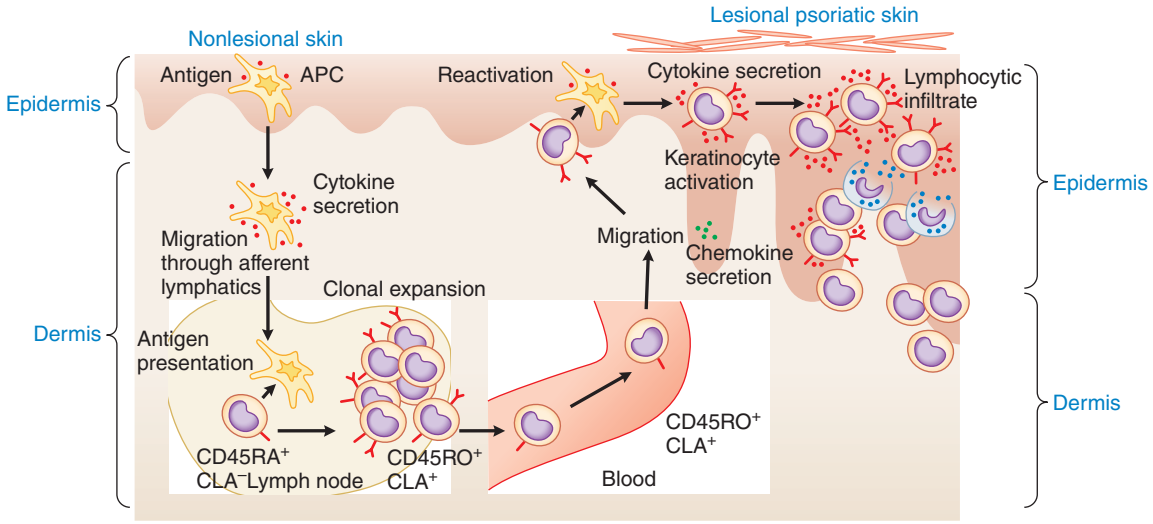

Figure 75–3 *Immunopathogenesis of psoriasis.* Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as-yet-undefined antigen(s) presented by APCs. The dendritic APCs, T cells, keratinocytes, and other cells release proinflammatory chemokines and cytokines, such as TNFα, IFNγ , IL-23, and IL-17, which ultimately induce keratinocyte hyperproliferation and sustain chronic inflammation.

patients on all anti-TNFα agents are at increased risk for serious infection and for malignancies. Other adverse events include exacerbation of congestive heart failure and demyelinating disease in predisposed patients. All patients should be screened for tuberculosis, history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to therapy. TNFα inhibitors include monoclonal antibodies directed against TNFα (*adalimumab, certolizumab, infliximab*) or a soluble TNF receptor that can bind TNFα (*etanercept*) (see Chapter 39). All TNFα inhibitors are able to bind both soluble and membrane-bound TNF, but the monoclonal antibodies against TNFα with an IgG_1 Fc portion are also able to activate complement-dependent cytotoxicity on binding of membrane-bound TNFα. This may explain the increased efficacy of these agents in comparison to *etanercept* for treating granulomatous conditions as well as the higher risk of infection with their use.

Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG_1. It binds both TNFα and TNFβ. *Etanercept* is approved for plaque psoriasis in adults and pediatric patients 4 years or older and for psoriatic arthritis in adults.

Infliximab, a mouse-human chimeric IgG_1 monoclonal antibody directed against human TNFα, is approved for treatment of plaque psoriasis and psoriatic arthritis in adults. The administration of *infliximab* via intravenous infusion can be a limiting factor; however, compared to other TNFα inhibitors, its onset of action may be faster and efficacy greater. Neutralizing antibodies to *infliximab* may develop and lead to decreased efficacy over time. Concomitant administration of *methotrexate* or glucocorticoids may suppress this neutralizing antibody formation.

Adalimumab is a human IgG_1 monoclonal antibody directed against TNFα; thus, the risk for development of neutralizing antibodies is reduced compared to *infliximab*. *Adalimumab* is approved for treatment of plaque psoriasis and psoriatic arthritis in adults. Safety of *adalimumab* in pediatric patients for psoriasis is supported by its use in other conditions, such as juvenile idiopathic arthritis (Bellodi Schmidt and Shah, 2015). *Adalimumab* is also approved for treatment of hidradenitis suppurativa.

Certolizumab pegol is a PEGylated Fab fragment of a humanized monoclonal antibody against TNFα. PEGylation allows for delayed elimination and therefore an extended half-life. Because *certolizumab pegol* lacks the Fc portion, it is not able to activate complement-mediated cytotoxicity. *Certolizumab pegol* has minimal to no placental transfer or transfer into breast milk, which is primarily due to its lack of an Fc portion (Clowse et al., 2017; Mariette et al., 2018). It is approved for the treatment of plaque psoriasis and psoriatic arthritis in adults.

Golimumab is a TNFα inhibitor currently approved for psoriatic arthritis but not psoriasis. However, studies for psoriatic arthritis also demonstrated improvement of plaque psoriasis. *Golimumab* is a fully human monoclonal antibody against TNFα with a longer $t_{1/2}$ than other TNFα inhibitors.

IL-12/23 Inhibitors

Ustekinumab is a human IgG_1 monoclonal antibody directed against the common p40 subunit of IL-12 and IL-23. IL-12 promotes T_H1 activity and related TNFα and IFNγ production, while IL-23 activates T_H17 cells that produce IL-17A, which regulates tissue inflammation and autoimmune responses. *Ustekinumab* is approved for treatment of plaque psoriasis in adults and pediatric patients 6 years or older and of psoriatic arthritis in adults. After initial doses at weeks 0 and 4, it is administered every 12 weeks for the maintenance phase of therapy, which may be ideal for some patients.

IL-17 Inhibitors

Keratinocytes are the major target for IL-17 in psoriasis, with IL-17 stimulation causing increased keratinocyte expression of inflammatory cytokines and other effects that contribute to epidermal hyperproliferation and barrier dysfunction. Clinical trials have demonstrated that IL-17 inhibitors are very efficacious for plaque psoriasis.

Brodalumab, a human IgG2κ monoclonal antibody against the receptor for IL-17A (IL-17RA), is approved for the treatment of moderate-to-severe plaque psoriasis in adults. Through antagonism of the IL-17RA, brodalumab inhibits IL-17 A, C, D, E, and F signaling. There is a boxed warning for *brodalumab* regarding suicidal ideation and behavior, which requires certification through a REMS program prior to dispensing. Patients with psoriasis often have psychiatric comorbidities such as depression: however, studies have not demonstrated a causal relationship between *brodalumab* and suicidal ideation and behavior (Lebwohl et al., 2018).

Bimekizumab, a humanized IgG_1 monoclonal antibody against IL-17A and IL-17F, is EMA-approved for the treatment of moderate-to-severe plaque psoriasis in adults. Dual inhibition of IL-17A and IL-17F may increase efficacy compared to inhibition of IL-17A alone.

Ixekizumab, a humanized IgG_4 monoclonal antibody against IL-17A, is approved for the treatment of moderate-to-severe plaque psoriasis in adults and pediatric patients 6 years or older and of psoriatic arthritis in adults.

Secukinumab is a fully human $IgG_{1κ}$ monoclonal antibody against IL-17A approved for the treatment of moderate-to-severe plaque psoriasis in adults.

The most common adverse effects for IL-17 inhibitors are nasopharyngitis, upper respiratory tract infection, and diarrhea. There is the

potential for increased mucocutaneous candidiasis infections, a risk that is greater with dual IL-17A/IL-17F inhibitors. There are reports of the exacerbation of inflammatory bowel disease by IL-17 inhibitors.

Phosphodiesterase-4 Inhibitors

Phosphodiesterase type 4 (PDE4) hydrolyzes intracellular cyclic adenosine monophosphate (cAMP), which is a critical intracellular messenger in numerous cell types, including immune cells. In both psoriasis and atopic dermatitis, lesional skin has subnormal cAMP levels due to increased PDE4 activity, with a resultant increase in the production of cytokines. Inhibition of PDE4 increases intracellular cAMP levels and thereby decreases expression of inflammatory cytokines such as TNFα, IFNγ, IL-17, and IL-23.

Apremilast is an oral PDE4 inhibitor approved for the treatment of moderate-to-severe plaque psoriasis, psoriatic arthritis, and oral ulcers associated with Behçet disease in adults. It has also been used off-label for atopic dermatitis, alopecia areata, hidradenitis suppurativa, lichen planus, cutaneous sarcoidosis, and discoid lupus erythematosus. The most common side effects are weight loss and depression.

Crisaborole is a PDE4B inhibitor approved for the topical treatment of mild-to-moderate atopic dermatitis in adult and pediatric patients 3 months and older. It is available as a 2% topical ointment, which is applied twice daily. The most common side effect is burning or stinging at the application site. *Crisaborole* is a boron-containing benzoxaborole that mimics the phosphate of cAMP and competitively inhibits PDE4 activity. The use of boron also contributes to the low molecular weight of *crisaborole* (251 Da), which facilitates effective penetration through skin.

Roflumilast is currently approved as an oral PDE4 inhibitor treatment for chronic obstructive pulmonary disease (see Chapter 44). It is being studied as a topical treatment for both psoriasis and atopic dermatitis.

Janus Kinase Inhibitors

Janus kinases (JAKs) are non–receptor tyrosine kinases involved in cytokine receptor signaling. Their interaction with STATs (signal transducers and activators of transcription) leads to activation of the transcription of genes involved in many vital events, such as inflammation, hematopoiesis, wound repair, and apoptosis, among others. As a consequence, inhibition of this pathway offers current and potential treatments for myriad diseases, including dermatological conditions. Dozens of growth factors and cytokines, including ILs, IFNs, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor (GM-CSF), erythropoietin, growth hormone, and leptin, interact with membrane receptors and initiate signaling via the JAK-STAT signaling pathway. There are four JAKs: JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2); they interact selectively with seven STATs (see Figure 3–22A).

JAK inhibitors exhibit variable selectivity for the JAK isoforms; thus, not all JAK inhibitors are approved for identical uses; the approved uses and limitations grow and shift as research, clinical trials, and postmarketing information advance. JAK inhibitors are used, alone or with other agents, to treat chronic and progressive inflammatory conditions such as rheumatoid arthritis and psoriatic arthritis; recently, atopic dermatitis has been added to the FDA-approved indications. A study comparing *tofacitinib* with anti-TNF antagonists noted that the use of the JAK inhibitor was associated with an increased risk of blood clots and death. In response, the FDA has recently issued a boxed warning for oral JAK inhibitors used chronically. The essence of the black-box warning for these agents is:

- Increased risk of serious bacterial, fungal, viral, and opportunistic infections leading to hospitalization or death
- Higher rate of all-cause mortality, including sudden cardiovascular death
- Higher rate of certain cancers
- Higher rate of cardiovascular death, myocardial infarction, and stroke
- Thrombosis

These agents are associated with dose-related increases in total cholesterol, triglycerides, and low-density lipoprotein cholesterol. The varying degrees, these agents also share common side effects, including upper respiratory infection, viral infections (herpes simplex, herpes zoster), headache, nausea, nasopharyngitis, and acne. Combining JAK inhibitors or coadministering them with other strong systemic immunosuppressants is generally not recommended. All age-appropriate vaccinations (see Chapter 40) should be completed prior to therapy, including prophylactic herpes zoster vaccinations, and vaccination with live vaccines immediately prior to, during, and immediately after the course of therapy should be avoided. JAK inhibitors should be used with awareness of the latest information from the FDA and with knowledge of the recommended usages and potential adverse reactions.

Abrocitinib

Abrocitinib is a JAK1 inhibitor that is FDA-approved for the treatment of adults with refractory, moderate-to-severe atopic dermatitis that is not adequately controlled with other systemic agents. The drug is administered orally in doses of 100 and 200 mg, with the 200-mg dose being recommended for patients who are not responding to the 100-mg dose (a 50-mg dose is used in patients with moderate kidney failure). The $t_{1/2}$ of *abrocitinib* and its two major active metabolites is 5 to 6 h but is prolonged by inhibitors of CYP2C19 and in patients who are CYP2C19 poor metabolizers (see Chapter 7); *abrocitinib* should not be used in patients with severe hepatic impairment. There are insufficient data to inform pregnancy risk; the drug may, however, impair fertility (reversible with cessation of the drug). Nursing mothers should not breastfeed while using *abrocitinib* and for 1 day after completing therapy. Antiplatelet therapies (except for low-dose *aspirin* [≤81 mg daily]) are contraindicated during the first 3 months of treatment.

A recent study showed that *abrocitinib*, in combination with topical therapy, was also safe and efficacious in treating atopic dermatitis in adolescents (Eichenfield et al., 2021).

Baricitinib

Baricitinib is JAK1/JAK2 inhibitor EMA-approved for moderate-to-severe atopic dermatitis in adults who are candidates for systemic therapy. For this indication, the drug is administered orally at 2 mg daily (may be increased to 4 mg daily if 2 mg daily proves inadequate). Baricitinb is FDA-approved for the treatment of severe alopecia areata and moderate-to-severe active rheumatoid arthritis. A high-fat meal decreases the area under the curve (AUC) (11%) and the C_{max} (18%). The $t_{1/2}$ of *baricitinib* is approximately 12 h. Modest hepatic metabolism is by CYP3A4; the drug is largely excreted in the urine, predominantly as the unchanged drug. Inhibitors of the OAT3 transporter increase exposure to the drug, which is also a substrate for P-glycoprotein. Use is not recommended in patients with liver or kidney impairment. *Baricitinib* can be used in combination with topical steroids and/or topical calcineurin inhibitors. There are insufficient data to inform pregnancy risk; due to the potential for serious adverse reactions in infants, nursing mothers should not breastfeed while using *baricitinib*. Clinical trials are in progress for other indications (e.g., chronic plaque psoriasis, systemic lupus erythematosus).

Upadacitinib

Upadacitinib is JAK1-selective inhibitor FDA-approved for treatment of rheumatoid arthritis and psoriatic arthritis; its indications were recently extended to include moderate-to-severe atopic dermatitis in patients 12 years (>40 kg) and older who have not responded to previous systemic treatments. Dosage is one 15-mg extended-release tablet, taken orally each day (or one 30-mg tablet daily if an adequate response is not achieved with the lower dose). *Upadacitinib* is a substrate for CYP3A4; thus, strong inhibitors (e.g., *ketoconazole*) and strong inducers (e.g., *rifampin*) of CYP3A4 must be avoided since they will alter the drug's AUC with the possibility of increasing the risk of adverse effects or reducing the blood level below the therapeutic range. The drug's elimination $t_{1/2}$ is 8 to 14 h, with unchanged drug being excreted in urine and feces and about a third excreted as metabolites. *Upadacitinib* may cause fetal harm; females of childbearing potential should use effective contraception during treatment and for 4 weeks following the completion of treatment. Breastfeeding is not recommended during treatment and for 6 days thereafter

Ruxolitinib

Ruxolitinib is a JAK1/2 inhibitor approved for systemic therapy of acute and chronic graft-versus-host disease, myelofibrosis, and polycythemia vera. More recently, it has been approved as a topical treatment for the short-term and non-continuous chronic treatment of mild to moderate atopic dermatitis in immunocompetent patients 12 years and older whose disease is not adequately controlled with topical prescription therapies or when those therapies are not advisable. *Ruxolitinib* is available as a 1.5% cream, which is applied in a thin layer to the affected areas twice daily. The maximum recommended application amount is no more than 60 grams per week and should not exceed 20% of the total body surface area (BSA). Use of *ruxolitinib* in combination with therapeutic biologics, other JAK inhibitors, or potent immunosuppressants is not recommended. There are insufficient data to determine safety of use during pregnancy or with breastfeeding.

Deucravacitinib

Deucravacitinib is an oral, selective TYK2 inhibitor currently in clinical trials for the treatment of psoriasis.

Tofacitinib

Tofacitinib is an oral JAK inhibitor approved for use in rheumatoid arthritis, psoriatic arthritis, ulcerative colitis, and polyarticular juvenile arthritis in adults. It has demonstrated efficacy for psoriasis in clinical trials and for atopic dermatitis in a pilot study.

IL-4 and IL-13 Inhibitors

The cytokines IL-4 and IL-13 are important mediators of the Th2 immune response that is involved in acute atopic dermatitis. Transcriptome data of atopic dermatitis lesional skin demonstrates dominant expression of IL-13 compared to IL-4, which suggests that IL-13 may be the more significant driver of inflammation in atopic dermatitis. Therapies targeting IL-13 or IL-4/IL-13 have emerged and demonstrated efficacy for atopic dermatitis with a favorable safety profile.

Dupilumab is a fully human IgG4 monoclonal antibody against the alpha subunit of IL-4 receptor (IL-4Rα) that inhibits both IL-4 and IL-13 signaling as they each exert their action through binding an IL-4Rα/IL-13Rα1 heterodimer receptor signaling complex (Beck et al., 2014). *Dupilumab* is approved for the treatment of moderate to severe atopic dermatitis in adults and pediatric patients 6 years of age or older whose disease is not adequately controlled with topical prescription therapies or when those therapies are not advisable. *Dupilumab* has shown promising results, demonstrating significant improvement in disease severity and fewer skin infections compared to placebo (Beck et al., 2014). The most frequent adverse effects are conjunctivitis, nasopharyngitis, headache, peripheral eosinophilia, and injection site reactions. Some patients may also develop a drug-associated face and neck dermatitis (also called "*dupilumab* facial redness" or "new regional dermatosis") after initiation of *dupilumab*.

Tralokinumab is a human IgG4 monoclonal antibody that selectively binds to IL-13 and blocks its interaction with the IL-13 receptor a1 and a2 subunits. *Tralokinumab* is approved for the treatment of moderate to severe atopic dermatitis in adults that is not adequately controlled with topical prescription therapies or when those therapies are not advisable. It is administered as a subcutaneous injection of 600 mg on week 0 then 300 mg every 2 weeks thereafter. Patients with a body weight < 100 kg who achieve clear or almost clear skin after 16 weeks of therapy may reduce the dosage to 300mg every 4 weeks. The most common adverse effects were upper respiratory infection, headache, injection site reactions, and conjunctivitis. Conjunctivitis may be less common and less severe with *tralokinumab* than *dupilumab*.

Lebrikizumab is a human IgG4 monoclonal antibody that selectively targets IL-13 and prevents formation of the IL-13Rα1/IL- IL-4Rα heterodimer receptor signaling complex. In comparison to *tralokinumab*, *lebrikizumab* does not inhibit binding of IL-13 to the IL-13Ra2, which may function as a decoy receptor for endogenous regulation of IL-13 levels. The clinical relevance of this is unknown at this time. *Lebrikizumab* is currently in clinical trials for the treatment of atopic dermatitis.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 40). Preparations of IVIG are composed of more than 90% IgG, with minimal amounts of IgA, soluble CD4, CD8, human leukocyte antigen molecules, and cytokines. In dermatology, IVIG is used off label as an adjuvant or rescue therapy for autoimmune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease (Smith et al., 2007).

Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockage of Fas-ligand/Fas-receptor interactions (Smith et al., 2007). IVIG is contraindicated in patients with severe selective IgA deficiency (IgA <0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure.

Targeted Antineoplastic Agents

Recent advances in understanding the molecular pathways and genetic alterations underlying cancer development have allowed for the rapid emergence of oncotherapeutic agents targeted against the specific molecules involved in tumor pathogenesis (Iwasaki et al., 2012; Jawed et al., 2014; John and Cowey, 2015). They are often better tolerated than conventional chemotherapeutic medications; however, adverse effects do still occur, with cutaneous toxicities among the most common. These therapies are discussed in further detail in Chapters 71 and 72.

Targeted Therapies for Basal Cell Carcinoma

Basal cell carcinoma is the most common malignancy in humans, and exposure to UV radiation plays a large role in its development, with intermittent, intense exposure increasing risk more than cumulative exposure. Some genetic disorders, such as nevoid BCC syndrome, predispose to BCC development as well. Typically, BCCs exhibit an indolent growth pattern with local invasion and tissue destruction over time, but metastasis is extremely rare. Nearly all BCCs have aberrant *sonic hedgehog* pathway signaling, which leads to persistent activation and uncontrolled proliferation of basal cells (Iwasaki et al., 2012). Therapies have been developed that inhibit signaling through the sonic hedgehog pathway.

Vismodegib and *sonidegib* are *smoothened* inhibitors, which block activation of the hedgehog pathway (Iwasaki et al., 2012). They are approved for use in patients with locally advanced, metastatic, or recurrent disease that cannot be adequately managed with surgery or radiation therapy. They have also been used in patients with nevoid BCC syndrome. The most common side effects are muscle spasms, dysgeusia, alopecia, and diarrhea. The hedgehog pathway is vital to normal fetal development, so extreme caution is needed in women of reproductive potential, and men should be cautioned regarding potential for exposure and fetal harm through semen.

The antifungal agent *itraconazole* also has an inhibitory effect on the hedgehog pathway (Deng et al., 2020) but has more limited efficacy for treatment-refractory BCC.

Cemiplimab is a recombinant human IgG_4 monoclonal antibody that inhibits programmed death-1 (PD-1) to release PD-1 pathway-mediated inhibition of the immune response (see Figure 38–7). It is approved for

treatment of patients with locally advanced BCC who have previously been treated with a hedgehog inhibitor or for whom a hedgehog inhibitor is not appropriate. The most common side effects are fatigue, musculoskeletal pain, diarrhea, rash, pruritus, and upper respiratory tract infection.

Targeted Therapies for Squamous Cell Carcinoma

Squamous cell carcinoma is the second most common type of skin malignancy. Cumulative exposure to UV radiation plays a large role in its development. Immunosuppression is also a risk factor for development of cutaneous squamous cell carcinoma, such as in organ transplant recipients. The large majority of cutaneous squamous cell carcinomas are treated surgically; however, there may be a need for nonsurgical treatment for those with increased risk for local recurrence or with nodal or distant metastasis.

Cemiplimab and *pembrolizumab* are PD-1 inhibitors approved for the treatment of cutaneous squamous cell carcinoma that is recurrent, metastatic, or locally advanced and is not curable by surgery or radiation.

Additional off-label treatment options for advanced or metastatic cutaneous squamous cell carcinoma include chemotherapy or epidermal growth factor inhibitors.

Targeted Therapies for Cutaneous T-Cell Lymphoma

Histone deacetylase inhibitors approved for treatment of progressive, persistent, or recurrent CTCL refractory to other systemic therapies include *vorinostat* and *romidepsin*. The exact mechanism of antineoplastic effect is not fully characterized; however, inhibition of histone deacetylase may restore expression of tumor suppressor or cell cycle regulatory genes with resultant cell cycle arrest, differentiation, and apoptosis of cancer cells (Jawed et al., 2014). The partial response rate is approximately 30% to 35%, with uncommon complete response. The most common side effects are GI symptoms, fatigue, and hematological abnormalities.

Alemtuzumab is a humanized monoclonal antibody directed against CD52, which is found on immune cells, including T and B cells. Binding of *alemtuzumab* to CD52 causes neutrophil-mediated, antibody-dependent cellular toxicity (Jawed et al., 2014). It has been effectively used off label for CTCL and may be a secondary treatment option for patients with CTCL refractory to other therapies. It is commonly associated with infusion reactions and causes prolonged immunosuppression. Early studies reported opportunistic infections, so antimicrobial prophylaxis is recommended.

Mogamulizumab is a defucosylated humanized $IgG_{1\kappa}$ monoclonal antibody that selectively binds to the C-C chemokine receptor 4 (CCR4) on target cells, targeting them for antibody-dependent cellular cytotoxicity. The CCR4 chemokine receptor is normally expressed on regulatory T and T_H2 cells and highly expressed on many malignant T cells. The defucosylation leads to a 50-fold higher binding affinity for FcγRIIIa, which results in improved activation of antibody-dependent cellular cytotoxicity. *Mogamulizumab* is approved for the treatment of adult patients with relapsed or refractory mycosis fungoides (CTCL) or Sézary syndrome after at least one prior systemic therapy. *Mogamulizumab* must be administered slowly over at least 60 min with monitoring for infusion reactions, some of which can be severe.

Denileukin diftitox is a fusion protein composed of diphtheria toxin fragments A and B linked to the receptor-binding portion of IL-2. In the U.S., *denileukin diftitox* carried a boxed warning from the FDA, alerting practitioners to serious and fatal reactions of the drug, including capillary leak and vision loss. *Denileukin diftitox* is not currently available in the U.S.

Targeted Therapies for Melanoma

Until recently, therapies for metastatic melanoma had low response rates along with either high toxicity or no effect on long-term survival. There has been rapid development of several new therapeutic options for metastatic or unresectable melanoma, primarily geared toward inhibition of mutated, abnormally activated tyrosine kinases that drive growth or enhance immune function to combat malignant cells by inhibiting immune checkpoints (John and Cowey, 2015). These therapies include BRAF inhibitors (*vemurafenib, dabrafenib, encorafenib*), MEK inhibitors (*trametinib, cobimetinib, binimetinib*), inhibitors of cytotoxic T lymphocyte–associated protein 4 (CTLA4) (*ipilimumab*), and PD-1 inhibitors (*pembrolizumab, nivolumab*). These targeted treatments are discussed further in Chapters 71 and 72. An additional novel therapy for unresectable melanoma is *talimogene laherparepvec* (T-Vec), an oncolytic immunotherapy derived from genetically modified attenuated HSV type 1. It is administered by intralesional injection and is designed to selectively replicate within tumors and produce GM-CSF to enhance systemic antitumor immune responses. *Talimogene* is contraindicated in pregnancy and in immunosuppressed patients.

Treatment of Pruritus

Pruritus (itching) occurs in a multitude of dermatological disorders, including xerosis (dry skin), atopic dermatitis, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into one of four clinical categories, as depicted by Table 75–12.

Drugs for Hyperkeratotic Disorders

Keratolytic agents reduce hyperkeratosis through myriad mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

α-Hydroxy acids can reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, thereby facilitating cell separation. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing α-hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun. α-Hydroxy acids used include glycolic, lactic, malic, citric, hydroxycaprylic, hydroxycapric, and mandelic.

Salicylic acid functions through solubilization of intercellular "cement," reducing keratinocyte adhesion, and softening the stratum corneum. Salicylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment. Salicylate toxicity has been reported with application of as little as 1% to 2% *salicylic acid* in neonates when applied multiple times per day over a large body surface area (Madan and Levitt, 2014). *Salicylic acid*, while chemically not a true β-hydroxy acid, often is listed as such on cosmetic labels. Other β-hydroxy acid ingredients in cosmetics include β-hydroxybutanoic acid, δ-tropic acid, and trethocanic acid. Sun protection should accompany the topical application of these agents.

Urea, at low concentrations, increases skin absorption and retention of water, leading to increased flexibility and softness of the skin. At concentrations greater than 40%, *urea* denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

Sulfur is keratolytic, antiseptic, antiparasitic, and antiseborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H_2S). H_2S breaks down keratin, causing dissolution of the stratum corneum.

Propylene glycol (as 60%–100% aqueous solutions) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.

TABLE 75–12 ■ AGENTS USED FOR THE TREATMENT OF PRURITUS

Pruritoceptive pruritus: Itch originating in the skin due to inflammation or other cutaneous disease

- Emollients—Repair of barrier function
- Coolants (menthol, camphor, calamine)—Counterirritants
- Capsaicin—Counterirritant
- Antihistamines—Inhibit histamine-induced pruritus
- Topical phosphodiesterase 4 inhibitors—Anti-inflammatory and antipruritic effects
- Topical steroids—Direct antipruritic and anti-inflammatory effects
- Other topical immunomodulators—Anti-inflammatory
- Phototherapy—Reduced mast cell reactivity and anti-inflammatory effects
- Thalidomide—Anti-inflammatory through suppression of excessive TNFα
- NK-1 inhibitors (aprepitant, serlopitant, tradipitant)—Neurokinin-1 receptor blockade on dermal mast cells and partial agonist of epidermal growth factor receptor (EGFR) on keratinocytes
- Cannabinoids—Modulate peripheral and central neuronal activity; anti-inflammatory through local modulation of keratinocytes and mast cells
- Botulinum toxin—Inhibition of neurotransmitter release including acetylcholine, glutamate, substance P, calcitonin gene-related peptide
- IL-31 inhibitors—Inhibition of IL-31 receptor signaling on peripheral sensory nerves decreases pruritus and improves skin barrier function (effect on keratinocytes)

Neuropathic pruritus: Itch due to disease of afferent nerves

- Carbamazepine—Blockade of synaptic transmission and use-dependent Na^+ channels
- Gabapentin, pregabalin—Mechanism unclear; thought to decrease transmission of nociceptive sensations by binding to the α-2-δ subunit of voltage-dependent Ca^{2+} channels
- Topical anesthetics (EMLA, benzocaine, pramoxine)—Inhibit nerve conduction via decreased nerve membrane permeability to sodium
- Ketamine—NMDA receptor antagonist
- Cannabinoids—Modulate peripheral and central neuronal activity; anti-inflammatory through local modulation of keratinocytes and mast cells
- Botulinum toxin—Inhibition of neurotransmitter release including acetylcholine, glutamate, substance P, calcitonin gene-related peptide

Neurogenic pruritus: Itch that arises from the nervous system without evidence of neural pathology

- Thalidomide—Central depressant
- Opioid receptor antagonists (naloxone, naltrexone)—Decrease opioidergic tone
- Tricyclic antidepressants—Decrease pruritus signaling through alteration in neurotransmitter concentrations
- SSRIs—Decrease pruritus signaling through alteration in neurotransmitter concentrations

Psychogenic pruritus: Itch due to psychological illness

- Anxiolytics (benzodiazepines)—Relieve stress-reactive pruritus
- Antipsychotic agents (chlorpromazine, thioridazine, thiothixene, olanzapine)—Relieve pruritus with impulsive qualities
- Tricyclic antidepressants—Relieve depression and insomnia related to pruritus
- SSRIs—Relieve pruritus with compulsive qualities

NMDA, *N*-methyl-D-aspartate; SSRIs, selective serotonin reuptake inhibitors.

Drugs Affecting Hair Growth

Androgenic Alopecia

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than 40 years. The frequency and severity increase with age and may begin during puberty in some patients. It is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone (DHT) binds to the androgen receptor, and the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair (Varothai and Bergfeld, 2014).

Minoxidil, originally developed as an antihypertensive agent, was noted to be associated with hypertrichosis in some patients. *Minoxidil* enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hair. Treatment must be continued or any drug-induced hair growth will be lost. Patients with increased sulfotransferase enzyme activity are most likely to respond to *minoxidil* treatment; this may be a useful predictive test in the future (Roberts et al., 2014). Topical *minoxidil* is available as a 2% solution and a 5% solution or foam. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying *minoxidil*. Oral low-dose *minoxidil* (0.25 – 5 mg daily) has been used off label for androgenic alopecia with recommended dosages of 0.5 – 2.5 mg daily in females or 2.5 – 5 mg daily in males. The most common side effect with oral low-dose *minoxidil* is hypertrichosis. Additional potential side effects include postural hypotension, lower extremity edema, tachycardia, and headache.

Finasteride inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to DHT (see Chapter 49) and that is found in hair follicles. Balding areas of the scalp are associated with increased DHT levels and smaller hair follicles than nonbalding areas. Orally administered *finasteride* (1 mg/day) variably increases hair growth in men over a 2-year period. *Finasteride* is approved for use only in men but has been used off label for female pattern hair loss (Varothai and Bergfeld, 2014). *Finasteride* use in women is limited by its teratogenicity. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of *finasteride* include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. There have been postmarketing surveillance reports of persistent sexual dysfunction after stopping the medication. As with *minoxidil*, new hair growth will be lost when *finasteride* is discontinued. *Dutasteride* (0.5 mg/day) is a combined type I and type II isozyme 5α-reductase inhibitor that has similar or greater efficacy, but side effects may be more common (Varothai and Bergfeld, 2014).

Spironolactone is an aldosterone antagonist and K^+-sparing diuretic; it also has antiandrogen activity. It is used off label for female pattern alopecia at dosages of 50 to 200 mg/day (Varothai and Bergfeld, 2014). Women of reproductive potential should not receive *spironolactone* without reliable contraception because *spironolactone* can cause feminization of a male fetus.

Other Agents

Eflornithine is an inhibitor of ornithine decarboxylase (ODC) that is approved for the reduction of excessive and unwanted facial hair in women. ODC is the rate-limiting enzyme in the synthesis of polyamines, which are important in cellular migration, differentiation, and proliferation. Levels of ODC activity are higher in proliferating cells, such as in follicular matrix cells in anagen phase, and inhibiting ODC decreases hair

growth. *Eflornithine* 13.9% cream is applied twice daily and is intended to be used along with the patient's preferred hair removal method to slow hair regrowth.

Bimatoprost is a prostaglandin analogue approved for topical treatment of hypotrichosis of the eyelashes by increasing their growth, including length, thickness, and darkness. The prostaglandin-mediated increase in eyelash growth was serendipitously noted during the use of intraocular prostaglandin analogues for glaucoma. The proposed mechanism of eyelash growth is by an increase in the fraction of hairs in, and the duration of, the anagen phase. Increased pigmentation of the hairs is thought to occur due to stimulation of melanin production without an increase in the number of melanocytes. Importantly, brown pigmentation of the iris and eyelid skin may occur, and the increased iris pigmentation may be permanent.

Treatment of Hyperpigmentation

The agents discussed are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on postinflammatory pigmentation within the dermis. Sun protection or avoidance is a vital component of any treatment regimen (Sheth and Pandya, 2011).

Hydroquinone (1,4-dihydroxybenzene) decreases melanocyte pigment production by inhibiting tyrosinase, the initial enzyme in the melanin biosynthetic pathway. In addition, it causes degradation of melanosomes and destruction of melanocytes by production of reactive oxygen radicals. Formulations containing 1.5% to 2% *hydroquinone* are available OTC; 3% to 4% *hydroquinone* formulations are available by prescription. Penetration enhancers and sunscreen ingredients are added to some formulations. A combination prescription product consisting of *hydroquinone* 4%, *fluocinolone* 0.01%, and *tretinoin* 0.05% is available. Adverse effects may include dermatitis and ochronosis.

Azelaic acid, a dicarboxylic acid isolated from cultures of *Malassezia furfur,* inhibits tyrosinase activity but is less effective than *hydroquinone*. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea, especially in patients with postinflammatory hyperpigmentation.

Mequinol (4-hydroxyanisole) is a competitive inhibitor of tyrosinase. It was approved as a 2% prescription product in combination with 0.01% *tretinoin* and *vitamin C* for skin lightening, but it is not currently commercially available.

Monobenzone (monobenzyl ether of hydroquinone) causes *permanent* depigmentation and should *not* be used for routine hormonally induced or postinflammatory hyperpigmentation. A 20% cream is approved for final depigmentation therapy of extensive vitiligo affecting at least more than 50% body surface area; it is rarely used and not currently commercially available.

Glycolic acid is an α-hydroxy acid used in chemical peels for disorders of pigmentation. It is thought to work by inhibiting tyrosinase in a pH-independent manner and to cause exfoliation by decreasing keratinocyte adhesion. Potential side effects are erythema, desquamation, and postinflammatory hyperpigmentation. *Glycolic acid* peels are best used as adjunctive therapy along with other topical therapy in patients with refractory epidermal hyperpigmentation (Sheth and Pandya, 2011).

Tranexamic acid is a synthetic analogue of lysine that exhibits antifibrinolytic activity by competitively inhibiting transformation of plasminogen to plasmin. It is approved for the treatment of heavy menstrual bleeding or to prevent hemorrhage in patients with hemostatic defects undergoing tooth extraction. *Tranexamic acid* is used off label for the treatment of melasma. UV radiation induces plasminogen activator production by keratinocytes, which leads to increased melanogenesis through stimulation of melanocytes by plasmin, arachidonic acid, and fibroblast growth factor, and thence to increased neovascularization via vascular endothelial growth factor stimulation. *Tranexamic acid* mitigates this UV-induced melanogenesis and neovascularization through inhibition of plasminogen activation. *Tranexamic acid* has been used topically as a 2% to 5% formulation twice daily or intradermally at a concentration of 4 mg/mL with injection frequency ranging from once weekly to once monthly. The most common side effect with intradermal injection was injection site burning. *Tranexamic acid* has been used orally at a dosage of 250 to 325 mg twice daily. The most common side effect is abdominal bloating or headache. Patients should be screened for thromboembolic risk factors prior to systemic use.

Miscellaneous Agents

Capsaicin is an alkaloid derived from plants of the *Solanaceae* family (i.e., hot chili peppers). *Capsaicin* interacts with the transient receptor potential vanilloid type 1 (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to *capsaicin* first stimulates and then desensitizes this channel to *capsaicin* and diverse other noxious stimuli. *Capsaicin* also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. *Capsaicin* (cream, lotion, gel, roll-on, and transdermal patch) is FDA-approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis. It is also approved in patch form by prescription for postherpetic neuralgia and is used for off-label treatment of painful diabetic neuropathy and some forms of pruritus.

Bentoquatam (quaternium-18 bentonite) is a mixture of quaternium-18 (quaternary ammonium chloride salts made from the fatty acids of tallow) and bentonite clay. This organoclay mixture is approved for OTC use as a topical barrier to prevent allergic contact dermatitis to the urushiol resin of poison ivy, oak, or sumac. The 5% topical lotion must be applied prophylactically at least 15 min prior to potential risk for exposure to urushiol and reapplied every 4 h.

Coal tar is a distillation product from coal, a mixture of over 10,000 compounds. It is used in dermatology primarily for the treatment of inflammatory skin conditions such as psoriasis, seborrheic dermatitis, and atopic dermatitis or other forms of eczematous dermatitis. The mechanism of action is unknown, although it is known to suppress DNA synthesis. *Coal tar* has anti-inflammatory, antimicrobial, and antipruritic activity. In addition, it has a photosensitizing effect within the UVA and visible light spectrum between wavelengths of 330 and 550 nm. Multiple formulations and products are available commercially or through compounding, including those containing crude coal tar, coal tar extracts, or coal tar solution (Sandhu and Schwartz, 2011). *Coal tar solution*, also known as liquor carbonis detergens, is an alcohol extract of *coal tar* emulsified with polysorbate 80 to yield a more cosmetically acceptable product. *Coal tar* may be used in combination with UVB phototherapy (e.g., Goeckerman regimen), topical *salicylic acid*, or topical corticosteroids. *Coal tar* products are often poorly tolerated by patients due to its unpleasant odor, messiness, and potential for staining of clothing. It can also cause folliculitis or irritant contact dermatitis. Although occupational exposures to *coal tar* have been associated with malignancies (e.g., scrotal cancer), patients with psoriasis or atopic dermatitis who are treated with topical *coal tar* products have not exhibited increased risk of cancer (Menter et al., 2009a).

Anthralin (dithranol), a synthetic version of chrysarobin, is derived from the bark of the Brazilian araroba tree and is used in the treatment of psoriasis and alopecia areata; its mechanisms of action are unclear (Menter et al., 2009a). Use of *anthralin* has been limited by the potential to cause irritant contact dermatitis and to stain skin, hair, nails, fabrics, and household items.

Brimonidine (0.33% topical gel) is an α_2 adrenergic agonist approved for once-daily treatment of persistent erythema of rosacea. It causes temporary vasoconstriction, and rebound erythema has been reported. *Oxymetazoline* (1% cream) is an α_1 adrenergic agonist approved for once-daily treatment of persistent facial erythema of rosacea in adults. It also causes temporary vasoconstriction; rebound erythema occurs in less than 1% of patients.

Propranolol and *timolol* are nonselective β adrenergic antagonists traditionally used for cardiovascular disease. These agents are also effective in treating infantile hemangiomas and have become the preferred treatment of infantile hemangiomas requiring intervention (Chen et al., 2013). Topical *timolol* drops and gel-forming solution are available but do not adequately treat deeper lesions.

Wound Healing and Scar Formation

In normal wound healing, engrailed-1 (EN1) lineage-positive fibroblasts are activated to produce fibrotic scars that lack normal fiber orientation and normal skin components (e.g., sebaceous glands and hair follicles) and that have reduced mechanical strength. The resulting scars can be unsightly and detrimental to function. Tension-activated signaling via mechano-sensors drives EN1 expression and normal scar formation. Inhibitors of mechano-sensitive signaling pathways have been studied for their capacity to alter wound healing. The results with *verteporfin* and *VS-6062*, an inhibitor of focal adhesion kinase, are very encouraging.

Verteporfin is a benzoporphyrin derivative that is approved for use as a photosensitizer in photodynamic therapy for the treatment of subfoveal choroidal neovascularization. However, *verteporfin* has also been studied in vitro for effects wound healing that are mediated via a non-photoactivated mechanism. *Verteporfin* blocks mechano-transduction signaling through the Hippo pathway by inhibition of Yes-1 associated protein (YAP), which results in decreased En1 lineage-positive fibroblast activation in wounds. At appropriate dosage, *verteporfin* permits a response by En1-lineage negative fibroblasts that results in a regenerative response of normal skin with appropriate strength and ultrastructure without scarring (Mascharak et al., 2021).

Focal adhesion kinase (FAK) facilitates the normal linkage of mechanical forces to inflammatory signaling and fibrosis. *VS-6062* inhibits focal adhesion kinase and disrupts the linkage of mechanical stress to profibrotic differentiation of fibroblasts, resulting in faster wound healing/skin regeneration with reduced fibrosis (reduced scarring) and skin with nearly normal mechanical and structural properties (Chen et al., 2021). The detailed molecular pathways of scarring and regenerative healing are currently being delineated (Mascharak et al., 2022). One can imagine that continued progress in this area will prove important not only in wound healing but also in tissue repair and regeneration.

Drug Facts for Your Personal Formulary: *Dermatological Agents*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Glucocorticoids—Table 75–3 and Chapter 50		
Topical glucocorticoids	• Psoriasis • Atopic dermatitis • Other inflammatory skin diseases	• Occlusion increases absorption • May cause skin atrophy, striae, perioricial dermatitis, folliculitis • Limit to ≤2–3 weeks of use • Avoid potent corticosteroids on face and genital areas • *Systemic* glucocorticoids for severe disease; see Chapter 50
Retinoids		
Topical retinoids (see Table 75–4)	• Acne • Facial wrinkling and photodamage • Psoriasis • Cutaneous Kaposi sarcoma (alitretinoin) • CTCL (bexarotene)	• Start every-other-night application to reduce likelihood of skin irritation • Decreased activity in presence of sunlight or BPO except adapalene and tazarotene • Avoid concurrent application of DEET due to potential increased DEET absorption
Systemic retinoids (see Table 75–5)	• Psoriasis (acitretin) • Acne (isotretinoin) • CTCL (bexarotene)	• Teratogenic: pregnancy should be avoided during and for 1 month (3 years for acitretin) after cessation of treatment • Multiple potential side effects, including cheilitis, dermatitis, conjunctivitis, myalgias, arthralgias, epistaxis, decreased night vision, hyperlipidemia
Topical Vitamin D Analogues		
Calcipotriene	• Psoriasis	• Potential hypercalcemia and hypercalciuria • May cause lesional or perilesional irritation
Photochemotherapeutic Agents (see Table 75–6)		
Sunscreen Active Ingredients (see Table 75–7)		
Biological Agents for Psoriasis (see Table 75–11)		
Antihistamines for Urticaria (see Chapter 43)		
Topical Antimicrobial Agents for Acne and Rosacea		
Azelaic acid	• Acne • Rosacea	• Comedolytic, antibacterial, anti-inflammatory • Also useful for postinflammatory hyperpigmentation due to acne
Benzoyl peroxide	• Acne	• Antibacterial, mildly comedolytic • Skin irritation with higher concentrations
Clindamycin	• Acne • Rosacea (off label)	• Antibacterial, anti-inflammatory • Bacterial resistance likely if used as monotherapy, use with benzoyl peroxide
Dapsone	• Acne	• Anti-inflammatory • Use with benzoyl peroxide causes orange-brown staining of skin or hair • G6PD testing not needed
Erythromycin	• Acne • Rosacea (off label)	• Antibacterial, anti-inflammatory • Bacterial resistance likely if used as monotherapy; use with benzoyl peroxide
Metronidazole	• Rosacea	• Anti-inflammatory
Minocycline	• Acne	• Antibacterial, anti-inflammatory
Sulfacetamide ± sulfur	• Acne • Rosacea	• Antibacterial, anti-inflammatory; sulfur also keratolytic • Use with benzoyl peroxide causes orange-brown staining of clothing but not skin • Sulfur may have pungent odor
Topical Antimicrobial Agents for Infection		
Bacitracin Neomycin Polymyxin B Gentamicin	• Superficial bacterial skin infections	• See Section VII, Chemotherapy of Microbial Diseases • Topical use restricted for superficial infections • Not indicated in clean surgical wounds • May cause contact dermatitis (especially bacitracin, neomycin)
Mupirocin Retapamulin	• Superficial bacterial skin infections due to *S. aureus* or *S. pyogenes* • Intranasal decolonization of MRSA	

Drug Facts for Your Personal Formulary: *Dermatological Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Mafenide acetate	• Adjunctive therapy for burn wounds	• Inhibits carbonic anhydrase and can cause metabolic acidosis
Ozenoxacin	• Superficial bacterial skin infections due to *S. aureus* or *S. pyogenes*	
Silver sulfadiazine	• Prevention or treatment in partial-thickness burns or venous stasis ulcers	• Studies have failed to demonstrate efficacy for prevention or treatment in partial-thickness burns or venous stasis ulcers • May impede re-epithelialization
Topical Antifungal Agents (see Table 75–8)		
Oral Antifungal Agents (see Chapter 61)		
Topical Antiviral Agents (see Chapter 62)		
Acyclovir Penciclovir	• Orolabial HSV • Mucocutaneous or genital HSV (acyclovir ointment)	• Inhibits viral DNA synthesis and viral replication
Docosanol	• Orolabial HSV	• Prevents viral entry and replication
Cidofovir	• Off-label treatment for warts	• Inhibits viral DNA synthesis
Oral Antiviral Agents (see Chapter 62)		
Acyclovir Famciclovir Valacyclovir	• VZV • HSV	• Inhibits viral DNA synthesis and viral replication
Agents for Infestations		
Abametapir	• Head lice	• Inhibits metalloproteinases critical for louse survival and egg development
Benzyl alcohol	• Head lice	• Inhibits closure of respiratory spiracles; subsequent obstruction by mineral oil vehicle causes asphyxiation of lice
Ivermectin	• Head lice • Scabies (oral)	• Activates glutamate-gated chloride channels, causing hyperpolarization of nerve or muscle cells of parasite
Lindane	• Scabies • Lice	• Causes neuronal hyperstimulation, eventual parasite paralysis • Potential neurotoxicity with prolonged use or in patients with impaired skin barrier (e.g., atopic dermatitis)
Malathion	• Head lice	• Inhibits acetylcholinesterase, causing neuromuscular paralysis • Flammable due to high alcohol content
Permethrin	• Scabies • Lice	• Interferes with Na^+ transport, causing neurotoxicity and paralysis • Approved for infants ≥2 months • May cross-react with sunflower family plants to cause allergic contact dermatitis
Spinosad	• Head lice	• Causes CNS excitation and involuntary muscle contractions, leading to parasite paralysis
Crotamiton	• Scabies	• Mode of action is unknown • Less effective than other agents but has additional antipruritic effect
Precipitated sulfur	• Scabies	• Mode of action is unknown • Poor odor and mild skin irritation • Considered safe in pregnancy and infants
Systemic Cytotoxic, Immunosuppressant, and Immunomodulatory Agents		
Methotrexate	• Psoriasis • Off label for multiple inflammatory dermatoses	• See Chapter 70
Cyclophosphamide	• CTCL • Off label for severe autoimmune blistering dermatoses	• See Chapter 70
Vinblastine	• Kaposi sarcoma • CTCL	• See Chapter 70
Doxorubicin	• Kaposi sarcoma	• See Chapter 70
Azathioprine	• Off label for inflammatory and autoimmune blistering disorders	• Inhibits *de novo* purine synthesis to decrease T-cell and B-cell activation and proliferation • TPMT enzyme activity should be measured before initiation

Drug Facts for Your Personal Formulary: *Dermatological Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Systemic Cytotoxic, Immunosuppressant, and Immunomodulatory Agents (cont.)		
Mycophenolate mofetil and mycophenolic acid	• Off-label for inflammatory and autoimmune blistering disorders	• Inhibits *de novo* purine synthesis to decrease T-cell and B-cell activation and proliferation • Most common side effect is GI upset
Cyclosporine	• Psoriasis • Off label for multiple inflammatory dermatoses	• Calcineurin inhibitor • Potential side effects: hypertension, renal dysfunction, hypertrichosis, gingival hyperplasia, tremor
mTOR inhibitors Sirolimus Everolimus Temsirolimus	• Off-label use in tuberous sclerosis, complex vascular malformations, and inflammatory dermatoses	• Inhibits mTOR • Potential side effects: stomatitis, mucositis, inflammatory cutaneous eruptions, nail changes
Dapsone	• Dermatitis herpetiformis • Leprosy • Neutrophilic dermatoses (off label)	• See Chapter 65
Thalidomide	• Erythema nodosum leprosum • Off label for prurigo nodularis, cutaneous lupus erythematosus, Behçet disease	• See Chapters 39 and 65
Topical or Intralesional Cytotoxic, Immunosuppressant, and Immunomodulatory Agents		
5-Fluorouracil	• Actinic keratoses • Superficial basal cell carcinoma • Warts (off label)	• See Chapter 70
Bleomycin	• Squamous cell carcinoma (off label) • Recalcitrant warts (off label)	• See Chapter 70
Alkylating agents Carmustine Mechlorethamine	• CTCL	• See Chapter 70
Podophyllum resin and podofilox	• Genital warts	• Inhibits microtubule polymerization, ⇒ mitotic arrest in metaphase • Side effects: irritation and ulcerative local reactions
Ingenol mebutate	• Actinic keratoses	• MOA: mitochondrial swelling and apoptosis of dysplastic keratinocytes
Tirbanibulin	• Actinic keratoses	• MOA: microtubule inhibition
Imiquimod	• Genital warts • Actinic keratoses • Superficial basal cell carcinoma	• Activates toll-like receptor 7 (TLR-7), inducing cytokines and upregulating immune response • Potential local skin reaction or systemic flu-like symptoms
Sinecatechins	• Genital warts	• MOA is uncertain • Potential local skin reactions, including erythema, pruritus, and swelling that peaks between 2 and 4 weeks of use
mTOR inhibitors Sirolimus Everolimus Temsirolimus	• Off-label use in tuberous sclerosis, complex vascular malformations, and some inflammatory dermatoses	• Topical mTOR inhibitors not currently commercially available but may be compounded • Topical use may decrease potential for side effects seen with systemic use
Topical calcineurin inhibitors Pimecrolimus Tacrolimus	• Psoriasis • Atopic dermatitis • Other inflammatory skin diseases	• Decreases T-cell activation • No skin atrophy • Useful in sensitive areas such as face and skinfolds • Common application site reactions (e.g., burning) decrease with continued use
Targeted Immunotherapies for Psoriasis and Atopic Dermatitis		
Inhibitors of TNFα, PDE4, JAKs Inhibitors of IL-12/23, IL-17, IL-23	• Psoriasis	• See Chapter 39 • See Table 75–11
Inhibitors of PDE4, JAKs Inhibitors of IL-4, IL-13	• Atopic dermatitis	• See Chapter 39

Drug Facts for Your Personal Formulary: *Dermatological Agents (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Targeted Antineoplastic Agents		
Smoothened and hedgehog inhibitors Vismodegib Sonidegib *PD-1 inhibitor* Cemiplimab	• Basal cell carcinoma	• See Chapter 72
PD-1 inhibitors Cemiplimab Pembrolizumab	• Squamous cell carcinoma	• See Chapter 72
Alemtuzumab Mogamulizumab Denileukin difitox Histone deacetylase inhibitors	• CTCL	• See Chapter 72
BRAF inhibitors MEK inhibitors CTLA4 inhibitors PD-1 inhibitors Talimogene laherparepvec	• Melanoma	• See Chapters 71 and 72
Topical Agents for Hyperkeratotic Disorders		
α-Hydroxy acids Glycolic acid Lactic acid	• Hyperkeratotic disorders	• Reduces keratinocyte adhesion by promoting degradation of corneodesmosomes • Potential skin irritation
Salicylic acid	• Hyperkeratotic disorders	• Reduces keratinocyte adhesion by affecting desmosomal adhesion proteins • Potential skin irritation • Potential salicylate toxicity with heavy use
Urea	• Hyperkeratotic disorders	• Increases hydration of stratum corneum, enhancing desquamation • Potential skin irritation
Sulfur	• Hyperkeratotic disorders	• May act via interaction with cysteine, causing reduction to hydrogen sulfide with subsequent breakdown of keratin • Pungent odor
Propylene glycol	• Hyperkeratotic disorders	• Increases hydration of stratum corneum, enhancing desquamation
Retinoids	• Hyperkeratotic disorders	• Stimulates keratinocyte turnover • Potential skin irritation
Agents Affecting Hair Growth		
Minoxidil, topical/oral	• Androgenetic alopecia	• Stimulates and prolongs anagen phase • Requires continued use to sustain effect • Oral preparation is used off label
Finasteride, oral Dutasteride, oral	• Androgenetic alopecia • Hirsutism (off label)	• Inhibits 5α reductase to decrease conversion of testosterone to DHT • Side effects: decreased libido, sexual dysfunction, hypotension
Spironolactone, oral	• Hirsutism (off label) • Female pattern alopecia (off label)	• Aldosterone antagonist with antiandrogenic activity • Side effects: breast tenderness, menstrual irregularities, increased urination • Feminization of male fetus
Eflornithine, topical	• Unwanted facial hair in women	• Ornithine decarboxylase inhibitor • Slows hair growth; use in combination with hair removal methods
Bimatoprost, topical	• Hypotrichosis of the eyelashes	• Prostaglandin analogue; increases fraction of hairs in anagen phase • May cause brown pigmentation of eyelid and iris (permanent)

Please note that there are numerous additional off-label uses of medications in dermatological conditions. MOA, mechanism of action.

Chapter 76 Environmental Toxicology

Allison K. Ehrlich

Humans are exposed to chemicals from their environment on a daily basis. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in Chapters 4 to 7. While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The Industrial Revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health; and in occupational toxicology, the study of how chemicals in the workplace affect human health. Many authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, discusses carcinogens and chemoprevention and heavy metal intoxication and chelation therapy, and provides an overview of endocrine disruptors and immunotoxicants. The chapter concludes with emerging data on how microbiome-mediated metabolism contributes to xenobiotic biotransformation and toxicity.

Assessment and Management of Environmental Risk

People are exposed to many environmental *xenobiotics* at low doses over long periods of time, which poses challenges for assessing the risks from those exposures. Thus, the focus of environmental risk assessment is on the low end of the dose-response curve, using experiments based on chronic exposures. Unlike drugs, which are given to treat a specific disease and should have benefits that outweigh the risks, environmental toxicants are usually only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

Epidemiology and *toxicology* provide complimentary approaches to predict the toxic effects of environmental exposures. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stressor, such as a toxicant. Toxicologists perform laboratory studies to examine potential toxic mechanisms of a chemical and to predict whether it is likely to be harmful to humans. These approaches provide complimentary information, necessitating integration of data from both fields to inform *environmental risk assessment*. Risk assessment is used to develop management approaches, such as laws and regulations, with the goal of limiting exposures to environmental toxicants to below a level that is considered safe.

Epidemiological Approaches to Risk Assessment

Epidemiologists use a variety of study designs to look for statistical associations between environmental exposures, including chemical exposures, and health outcomes. This approach has the advantage of examining the effects of real-world exposures to humans but can be expensive, subject to biases, confounding effects, and the inherent difficulties of attributing toxicity to one chemical entity when the exposure includes myriad.

Epidemiological Studies

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses.

- *Ecological studies* correlate frequencies of exposures and health outcomes between different geographical regions. These studies are relatively inexpensive and are effective for generating hypotheses but are subject to confounders and are not effective for establishing causality.

Abbreviations

AhR: aryl hydrocarbon receptor
AR: androgen receptor
ARE: antioxidant response element
ATSDR: Agency for Toxic Substances Disease Registry
BAL: British anti-Lewisite (dimercaprol)
BLL: blood lead level
BPA: bisphenol A
$CaNa_2EDTA$: calcium disodium ethylenediaminetetraacetic acid
CDC: U.S. Centers for Disease Control and Prevention
COX-2: cyclooxygenase 2
DDE: dichlorodiphenyldichloroethylene
DDT: dichlorodiphenyltrichloroethane
DEHP: di-2-ethylhexyl phthalate
DMPS: sodium 2,3-dimercatopropane sulfonate, dimercaprol
EDC: endocrine-disrupting chemical
EDTA: ethylenediaminetetraacetic acid
EPA: U.S. Environmental Protection Agency
ER: estrogen receptor
FSHR: follicle-stimulating hormone receptor
GI: gastrointestinal
GSH: reduced glutathione
Hg^0: elemental mercury
IARC: International Agency for Research on Cancer
LHR: luteinizing hormone receptor
LOAEL: lowest adverse effect level
MCL: maximum contaminant level
$MeHg^+$: methyl mercury
MMA: monomethylarsenic
NF-κB: nuclear factor-κB
NO: nitric oxide
NOAEL: no adverse effect level
NR: nuclear receptor
PAH: polycyclic aromatic hydrocarbon
PCB: polychlorinated biphenyls
PFAS: per- and poly-fluoroalkyl substances
PFOA: perfluorooctanoic acid
PFOS: perfluorooctane sulfonate
PKC: protein kinase C
PM: particulate matter
PPAR: peroxisome proliferator-activated receptor
RfD: reference dose
ROS: reactive oxygen species
TCDD: 2,3,7,8-tetrachlorodibenzo-p-dioxin

- *Cross-sectional studies* examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a health outcome under study might cause someone to eliminate his or her exposure.
- *Case-control studies* start with a group of individuals affected by a disease; this group then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the end point is known. However, case-control studies rely on assessments of past exposures, which can be unreliable and subject to bias.
- *Cohort studies* measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to bias and are better than case-control studies at establishing causality. However, they are expensive, particularly when measuring rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance.
- *Clinical trials* (see Chapter 1) cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposures and disease.

Biomarkers

Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists often rely on biomarkers in risk assessment. Different types of biomarkers provide different information useful for risk assessment. Biomarkers aim to be *specific*, only detecting the change in affected individuals, and *sensitive*, detecting the change in all affected individuals.

- *Biomarkers of exposure* provide information about dose or duration of exposures. Blood and urine concentrations of a chemical or its metabolite measure recent exposures, while levels in hair and toenails can measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead.
- *Biomarkers of toxicity* are used to measure toxic effects at a subclinical level. Examples include measurement of liver enzymes in serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function.
- *Biomarkers of susceptibility* are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single-nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant.
- Some biomarkers simultaneously provide information on exposure, toxicity, or susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B_1 provides evidence of both exposure and a toxic effect (in this case, DNA damage).

Toxicological Approaches to Risk Assessment

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effects on humans. Toxicologists test single chemicals over large dose ranges and at concentrations higher than would be environmentally relevant and over time frames that accommodate laboratory experimentation; this is done in order to get a robust toxic outcome and obtain statistical significance. As a result, there is often uncertainty about the effects of very low doses of chemicals or combinations of chemicals with real-world exposure times measured in decades. To determine the applicability of model systems, toxicologists also study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform *subchronic studies* (3 months of treatment for rodents) and *chronic studies* (2 years for rodents) in at least two different animal models. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in Figure 76–1.

An animal study provides two numbers that estimate the risk from a chemical:

- The *NOAEL* (no adverse effect level) is the highest dose used that does not result in a statistically significant increase in negative health outcomes.
- The *LOAEL* (lowest adverse effect level) is the lowest dose that results in a significant increase in toxicity.

The NOAEL is divided by 10 for each source of uncertainty to determine a reference dose (RfD), which is commonly used as a starting point

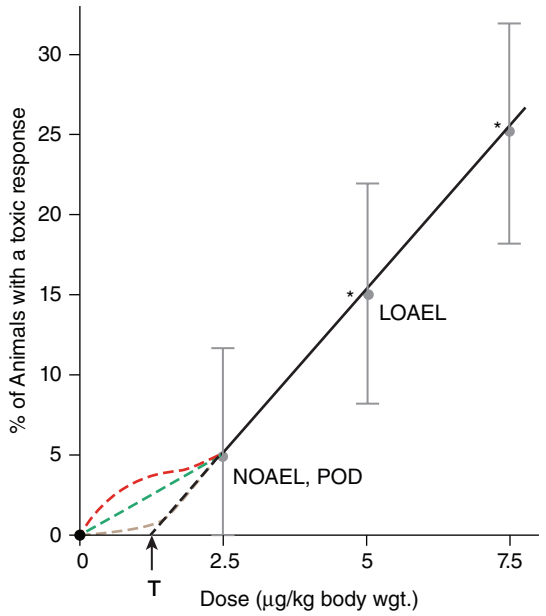

Figure 76–1 *LOAEL and NOAEL.* The theoretical dose-response curve from an animal study demonstrates the *NOAEL* and the *LOAEL*. Below the NOAEL level, there is considerable uncertainty regarding the shape of the response curve; thus, the NOAEL represents the *point of departure* (POD). The dose response could continue linearly below this point to reach a threshold dose (T) where there would be no harmful effects from the toxicant, or it could have a number of different possible inflection points. Each of these curves would have very different impacts on human populations. *Statistically significant toxicity.

for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case RfD = NOAEL/100. Other modifiers can be used to account for specific experimental uncertainties, such as the unavailability of data from chronic studies. The use of factors of 10 in the denominator for determination of RfD is an application of the "precautionary principle," which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable.

A major concern with animal studies is that they do not detect effects at low concentrations. Typically, they are designed to obtain statistical significance with a 10% to 15% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as demonstrated in Figure 76–1. Toxicologists often assume that there is a threshold dose below which there is no toxicity. However, the shape of the dose-response curve below the NOAEL is not known with certainty and represents a point of departure. The existence of a threshold dose assumes that there are cellular defenses that prevent toxicity at concentrations below a given level and that they can be overwhelmed. Some toxicants may not exhibit a threshold, while others, for which detoxification mechanisms exist, do have a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.

Toxicologists perform mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound's three-dimensional structure to determine quantitative structure-activity relationships is commonly performed on both drugs and environmental chemicals. Quantitative structure-activity relationship approaches can predict which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test, which uses strains of *Salmonella typhimurium* and *E. coli* with specific mutations in genes needed to synthesize essential amino acids (Walker et al, 2020). These strains are treated with chemicals in the presence or absence of a metabolic activating system (usually hepatic xenobiotic metabolizing enzymes). If a compound is a mutagen in the Ames test, it reverts the mutation and allows the bacteria to form colonies on plates that lack the specific essential amino acid targeted by the mutation. At the pathway level, RNA sequencing and other "omic" approaches provide a useful tool to identify the molecular targets and pathways altered in cells or tissues from animals exposed to a toxicant. To determine if a toxicant acts through a specific gene target, knockout cell lines or animal models can help to determine whether the specific knocked-out genes are involved in the mechanism of toxicity.

Carcinogens and Chemoprevention

Carcinogenesis

The International Agency for Research on Cancer (IARC) classifies the carcinogenicity of compounds into groups based on risk assessments using epidemiological, human exposure, animal, and mechanistic data. Chemicals in *group 1* are known human carcinogens; *group 2A* chemicals are chemicals that are probably carcinogenic in humans; *group 2B* are chemicals that are possibly carcinogenic in humans; *group 3* are chemicals for which data are lacking to suggest a role in carcinogenesis; and *group 4* are those for which the data indicate that they are unlikely to be carcinogens. Table 76–1 provides examples of group 1 carcinogens.

The transformation of a normal cell to a malignancy is a multistage process, and exogenous chemicals can act at one or more of these stages. A classic model of chemical carcinogenesis is *tumor initiation* followed by *tumor promotion* and *tumor progression*. In this model, an initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A promoter does not directly modify genes but changes signaling pathways or the extracellular environment to increase survival, proliferation, or invasiveness of precancerous cells. Chromosome instability and additional mutations ultimately lead to invasiveness and metastases. Although this model is an oversimplification of the many processes of carcinogenesis, it demonstrates the types of changes that must occur for a normal cell to transform into cancer. Chemical carcinogens cause cancer through genotoxic and nongenotoxic mechanisms (Figure 76–2).

Genotoxic carcinogens initiate tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of reactive oxygen species (ROS), which can oxidize DNA or form lipid peroxidation products that react with DNA. If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it can provide advantages in proliferation or survival. Alternatively, mutations to DNA repair genes can increase the probability that future mutations will occur. With the right extracellular environment, mutations in key genes will allow a cell to proliferate faster than surrounding normal cells and possibly develop into malignant cancer.

Benzo[*a*]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[*a*]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite either can undergo a second oxidation step by a CYP to form a diol epoxide, which readily reacts with DNA, or can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS (Conney, 1982; Penning, 2009).

Nongenotoxic carcinogens increase the incidence of cancer without damaging DNA, and most agents in this category are tumor promoters. Many nongenotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion or angiogenesis. For example, phorbol esters mimic diacylglycerol and activate protein kinase C (PKC) isoforms. This activation in turn stimulates

TABLE 76–1 ■ EXAMPLES OF IMPORTANT GROUP 1 CARCINOGENS[a]

CARCINOGEN CLASS	EXAMPLE	SOURCE	MECHANISM
Genotoxic			
Nitrosamines	Nicotine-derived nitrosaminoketone (NNK)	Tobacco products	Metabolic activation to form DNA adducts
Polycyclic aromatic hydrocarbons	Benzo[a]pyrene	Fossil fuel combustion, tobacco smoke, charbroiled foods	Metabolic activation to form DNA adducts or ROS
Aromatic amines	2-Aminonaphthalene	Dyes	Metabolic activation to form DNA adducts
Fungal toxins	Aflatoxin B_1	Corn, peanuts, and other foods	Metabolic activation to form DNA adducts
Nongenotoxic			
Liver toxicants	Ethanol	Beverages, environment	Toxicity and compensatory proliferation; depletion of GSH
Phorbol esters	Tetradecanoyl phorbol acetate	Horticulture; rubber and gasoline production	Activation of PKC isoforms
Estrogens	Diethylstilbestrol	Drugs, environment	Activation of estrogen receptor signaling
Metals	Arsenic	Environment, occupation	Inhibition of DNA repair; activation of signal transduction pathways
Irritants	Asbestos	Environment, occupation	Stimulation of inflammation; formation of ROS
Dioxins	2,3,7,8-Tetrachlorodibenzop-dioxin (TCDD)	Waste incineration, herbicides, paperpulp bleaching	Activation of the aryl hydrocarbon (Ah) receptor

[a]Compounds in this table are classified as group 1 carcinogens by IARC, with the exception of the phorbol esters, which have not been examined.

mitogen-active protein kinase (MAPK) pathways, leading to proliferation, invasiveness, and angiogenesis (Chapter 3 presents these signaling pathways). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to cell death. Estrogenic carcinogens activate estrogen receptor alpha (ERα) and stimulate proliferation and invasiveness of estrogen-responsive cells. Chronic inflammation is another mechanism of nongenotoxic carcinogenesis. Inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes nongenotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA mutations which can select for cells that proliferate faster or are less sensitive to cell death.

Many compounds can also act as complete carcinogens because repeated exposure can cause tumor initiation and promotion. Examples of complete carcinogens include benzo[*a*]pyrene and ultraviolet radiation.

Tumor initiation also may occur through nongenotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Nongenotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5′-CpG-3′ islands of gene promoters. Methylation can silence tumor suppressor genes, while demethylation of proto-oncogenes can increase their expression. These *epigenetic* effects can occur through sustained transcription or silencing of a gene.

Some chemicals enhance the carcinogenesis of other chemicals and thus act as *cocarcinogens*. These chemicals can increase the absorption or change the metabolism of other chemicals, increasing the probability

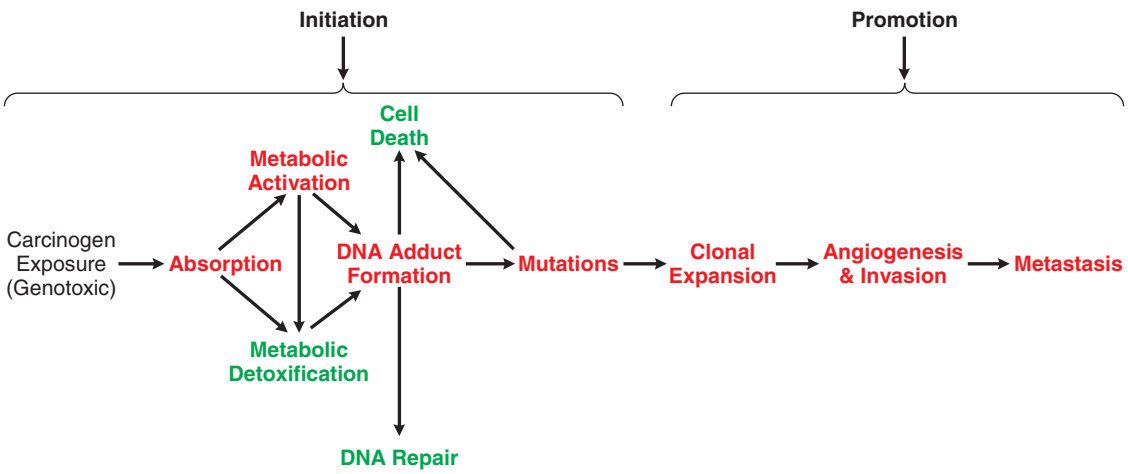

Figure 76–2 *Carcinogenesis: initiation and promotion.* There are multiple steps that occur between the exposure to a genotoxic carcinogen and the development of cancer. Processes in red lead to the development of cancer, while those in green reduce the risk. Nongenotoxic carcinogens act by enhancing steps leading to cancer or inhibiting protective processes. A chemopreventive agent acts by inhibiting steps leading to cancer or by increasing protective processes.

that they form active metabolites in target tissues. Cocarcinogens can also interfere with DNA repair, increasing the occurrence of mutations from a second genotoxic carcinogen. For example, ethanol acts as a solvent and increases the absorption of tobacco carcinogens, increasing the risk of head and neck cancers in people who both smoke and drink. Ethanol also depletes GSH (reduced glutathione), limiting target cells' ability to detoxify reactive metabolites of carcinogens and ROS.

Chemoprevention

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed *chemopreventive agents* (Szabo, 2006; William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as *t*-butyl hydroquinone, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 76–2). Most chemicals tested for chemoprevention have not exhibited a benefit, and in some cases, they have increased the risk of cancer (Potter, 2014). There are currently no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due to endogenous estrogen (*tamoxifen* and *raloxifene*) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents can interfere with initiation or promotion (see Figure 76–2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive genes include γ-glutamylcysteine synthase light chain (which catalyzes the rate-determining step in GSH synthesis) and quinone reductase. Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts.

Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants. For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that also inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and preventing them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. In phase III studies, the cyclooxygenase 2 (COX-2) inhibitor *celecoxib* demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial (William et al., 2009). Studies examining long-term treatment with *aspirin* for cardiovascular benefits found that *aspirin* also reduces the incidence of colorectal adenomas and overall cancer mortality. Naturally occurring compounds such as α-tocopherol have also been hypothesized to exert chemoprevention by reducing inflammation. However, α-tocopherol actually increased the risk of prostate cancer in a phase III trial (Potter, 2014).

Another approach to chemoprevention is disruption of nuclear receptor signaling. Retinoids reduce the incidence of head and neck cancers and represent one of the first successful uses of chemoprevention in

TABLE 76–2 ■ CHEMOPREVENTIVE AGENTS BEING STUDIED IN HUMANS

CHEMOPREVENTIVE CLASS	EXAMPLE COMPOUND	NATURAL SOURCE OR TYPE OF DRUG	CANCER TYPE(S)	MECHANISM	CURRENT STATUS
Isothiocyanates	Phenethyl isothiocyanate	Cruciferous vegetables (broccoli, cabbage, etc)	Liver, lung, breast, etc.	↓ CYP, ↑ GSH, ↑ NQO1, ↑ apoptosis	Phase II clinical trials
Synthetic drugs that modify metabolism	Oltipraz	Antischistosomal drug	Liver, lung	↓ CYP, ↑ GSH, ↑ NQO1	Beneficial effects on biomarkers in phase II clinical trials
Flavonoids and other polyphenols	Catechin	Green tea, red wine, berries, cacao, etc.	Lung, cervical, etc.	↓ ROS, ↓ CYP, ↑ GSH, ↑ NQO1	Phase II clinical trials
Other plant compounds	Curcumin	Turmeric (curry)	Colorectal, pancreatic, etc.	↓ ROS, ↓ CYP, ↑ GSH, ↑ NQO1	Phase II clinical trials
Other plant compounds	Chlorophyllin	All plants	Liver	Reaction with active intermediates, ↓ ROS, ↓ CYP	Beneficial effects on biomarkers in phase II clinical trials
Other antioxidants	α-Tocopherol (vitamin E)	Food	Prostate	Antioxidant, anti-inflammatory	Phase III clinical trials found ↑ prostate cancer with α-tocopherol
Antihormonal therapies	Tamoxifen	Adjuvant for breast cancer	Breast	Inhibit ERα in breast	FDA-approved for chemoprevention
NSAIDs (see Chapter 42)	Aspirin	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase III trials of aspirin for prevention of cardiovascular disease observed ↓ cancer; phase III trials for cancer prevention are ongoing
COX-2 selective inhibitors (see Chapter 42)	Celecoxib	Anti-inflammatory drugs	Colorectal, etc.	Inhibit PG formation	Phase III trial found ↓ cancer but unacceptable side effects for prevention

NSAID, nonsteroidal anti-inflammatory drug; PG, prostaglandin.

humans (Evans and Kaye, 1999; William et al., 2009). Retinoids are also effective for the treatment for acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids increased the incidence of lung cancer, particularly among women, and had other unacceptable toxicities (Omenn et al., 1996).

The selective ER modulators *tamoxifen* and *raloxifene* reduced the incidence of breast cancer in high-risk women in large phase III clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective ER modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions of antipromotion activity can lead to effective drugs for the prevention of cancer.

Aflatoxin B_1

Agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B_1. Aflatoxins are produced in regions with hot and wet climates by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. As a result of exposure to aflatoxin, human hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is rare and not thought to have a significant impact on health (IARC, 2002).

ADME

Aflatoxin B_1 is readily absorbed from the gastrointestinal (GI) tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B_1 is metabolized by CYPs 1A2 and 3A4 to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M_1) or 3 position (aflatoxin Q_1; Figure 76–3). While the hydroxylation products are detoxification products, the 8,9-epoxide reacts with DNA and is responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via nonenzymatic hydrolysis or conjugation with GSH. Aflatoxin M_1 enters the circulation and is excreted in urine and milk.

Toxicity

Aflatoxin B_1 primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

Carcinogenicity

Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and on supporting animal and mechanistic data, IARC has classified aflatoxin B_1 as a known human carcinogen (group 1) (IARC, 2002). Aflatoxin exposure and the hepatitis B virus work synergistically to cause hepatocellular carcinoma. Aflatoxin or hepatitis B exposure alone increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals (Groopman et al., 2005).

Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position (IARC, 2002); the 8,9-epoxide of aflatoxin B_1 readily reacts with amines. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG-to-AGT mutation in codon 249 of the *p53* tumor suppressor gene, resulting in the replacement of an arginine with cysteine (Hussain et al., 2007).

Several mechanisms for the synergistic interaction between hepatitis B and aflatoxin are under investigation (Sylla et al., 1999; Moudgil et al, 2013). The X gene of the hepatitis B virus encodes a protein, HBx, that binds to and inhibits p53, resulting in suppressed nucleotide excision repair of aflatoxin B_1 adducts (Hussain et al., 2007). Hepatitis B also alters the metabolism of aflatoxin B_1 by upregulating CYP genes, including CYP3A4, and decreases GSH *S*-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma

The relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (see Figure 76–3). Inhibiting CYP activity or increasing GSH conjugation will reduce the intracellular concentration of the 8,9-epoxide and prevent DNA adduct formation (Groopman et al., 2008; Kensler et al., 2004). *Oltipraz*, an antischistosomal drug, potently inhibits CYPs and induces genes regulated by the ARE that are involved in GSH synthesis. *Oltipraz* increases the excretion of the *N*-acetylcysteine

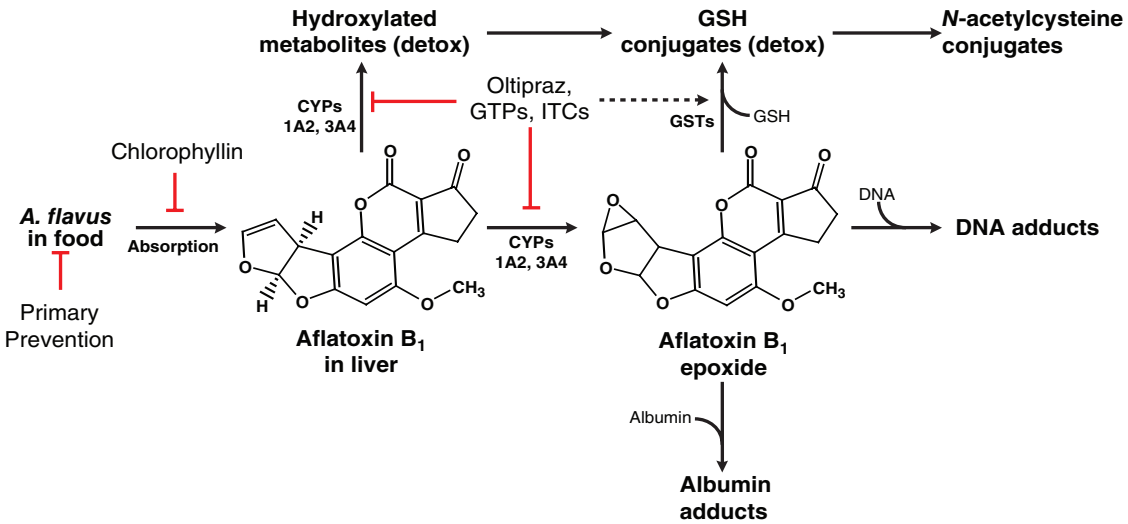

Figure 76–3 *Metabolism and actions of aflatoxin B_1.* Following absorption, aflatoxin B_1 undergoes activation by CYPs to its 8,9-epoxide, which can be detoxified by glutathione *S*-transferases (GSTs) or by spontaneous hydration. Alternatively, it can react with cellular macromolecules such as DNA and protein, leading to toxicity and cancer. *Oltipraz*, green tea polyphenols (GTPs), and isothiocyanates (ITCs) decrease aflatoxin carcinogenesis by inhibiting the CYPs involved in activating aflatoxin and increasing the synthesis of the cofactor GSH for GSTs involved in detoxification.

aflatoxin conjugate, indicating enhanced GSH conjugation of the epoxide. At 500 mg/week, *oltipraz* reduced the levels of aflatoxin M_1, consistent with inhibition of CYP activity.

Green tea polyphenols also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin-albumin adducts and a large increase in the excretion of the *N*-acetylcysteine aflatoxin conjugate, consistent with a protective effect.

Another approach used for the chemoprevention of aflatoxin hepatocarcinogenesis is the use of "interceptor molecules." *Chlorophyllin*, a mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. *In vitro*, *chlorophyllin* inhibits CYP activity and acts as an antioxidant. In a phase II trial, administration of 100 mg of *chlorophyllin* with each meal reduced aflatoxin–N7-guanine adduct levels in the urine. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine reduces the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination also reduces human exposure. A cost-effective primary prevention approach is to improve food storage to limit the spread of *A. flavus*, which requires a warm and humid environment.

Water and Air Pollution

The U.S. Environmental Protection Agency (EPA) protects the public from water and airborne pollutants by enforcing compliance with the Clean Water Act (protects the public and the environment from water pollution); the Safe Drinking Water Act (ensures the quality of the drinking water); and the Clean Air Act (to protect the public from air pollutants). Under these laws, the EPA combines scientific risk assessment with economic analyses and other factors to develop regulations on the release or presence of specific pollutants to limit their effect on human health and the environment.

Toxicity screening of many water contaminants has led to the development of maximum contaminant levels (MCLs) for drinking water. To protect against potential adverse health effects, a primary MCL sets a level for a contaminant that must not be exceeded. The primary MCL is based on consideration of the toxic dose-response curve and on whether a sufficiently sensitive analytical method exists to measure the contaminant for compliance purposes. A secondary MCL is not enforced but is established for aesthetic value (e.g., taste, color, odor) that may not affect health. Currently, there is concern about pharmaceutical waste in the water supply, but MCLs have not been set for these compounds.

The EPA also monitors six priority air pollutants (CO, Pb, NO_x, O_3, particulate matter, and SO_2) that they have determined play the largest role in human health effects from air pollution. The EPA sets National Ambient Air Quality Standards in which local levels of these pollutants may not be exceeded within a given time frame. Measurements made by stationary air monitors provide daily air quality data and also lead to warnings (e.g., ozone awareness days), which advise citizens to stay indoors. Fine particles, smaller than 2.5 μm in diameter (PM2.5), are particularly concerning as they penetrate deep into the lung and can cause or exacerbate respiratory or cardiovascular illness.

Metals

Metals are an important class of environmental toxicants that come from both natural and anthropogenic sources. The U.S. Centers for Disease Control and Prevention (CDC) lists arsenic, mercury, and lead as the top three pollutants of concern, based on their toxicity and levels of human exposure. Although the toxicity of high levels of exposure to metals has long been known, the effects of low-dose chronic exposure to metals have only recently been appreciated. Many of the toxic metals in the environment also are carcinogens (Table 76–3). In addition, several essential metals also are toxic at high concentrations. Copper and iron are associated with toxicities, primarily targeting the liver through generation of ROS.

Lead

Chronic exposure to very low levels of lead has major deleterious effects, particularly for children.

Exposure

Despite substantial improvements over the past four decades, lead exposure remains a major concern, especially for children. In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out between 1976 and 1996. Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains in dust, soil, and the paint of older homes. Young children are exposed to lead by nibbling sweet-tasting paint chips or ingesting dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Removal of lead from gasoline reduced lead levels in air by more than 90% between 1982 and 2002, but lead fallout from air

TABLE 76–3 ■ TOXIC METALS WITH FREQUENT ENVIRONMENTAL OR OCCUPATIONAL EXPOSURE[a]

METAL	CERCLA PRIORITY[b]	COMMON SOURCE OF EXPOSURE	ORGAN SYSTEMS MOST SENSITIVE TO TOXICITY	IARC CARCINOGEN CLASSIFICATION
As	1	Drinking water	CV, skin, multiple other	Group 1, carcinogenic to humans—liver, bladder, lung
Pb	2	Paint, soil	CNS, blood, CV, renal	Group 2A, probably carcinogenic
Hg	3	Air, food	CNS, renal	Group 2B, possibly carcinogenic ($MeHg^+$); group 3, not classifiable (Hg^0, Hg^{2+})
Cd	7	Occupational, food, smoking	Renal, respiratory	Group 1, carcinogenic to humans—lung
Cr^{6+}	18	Occupational	Respiratory	
Be	42	Occupational, water	Respiratory	
Co	49	Occupational, food, water	Respiratory, CV	Group 2B, possibly carcinogenic
Ni	53	Occupational	Respiratory, skin (allergy)	Group 1, carcinogenic (soluble Ni compounds); group 2B, possibly carcinogenic (metallic Ni)—lung

[a]The ATSDR has both detailed monographs and brief summaries for each of these compounds (available at https://www.atsdr.cdc.gov). The IARC also has monographs available (http://monographs.iarc.fr).
[b]CERCLA, Comprehensive Environmental Response, Compensation, and Liability Act.

pollution remains in soils, particularly in urban environments. Lead was also commonly used in plumbing and can leach into drinking water, as evidenced by lead contamination in drinking water in numerous U.S. cities (Fedinick, 2021). As summarized by the Agency for Toxic Substances Disease Registry (ATSDR), lead exposure also has been traced to other sources, such as inhalation of dusts and fumes at firing ranges, retained bullets, artists' paint pigments, ashes and fumes from painted wood, lead-glazed pottery, lead toys, non-Western folk medicines, cosmetics, jewelers' wastes, home battery manufacture, and lead type (ATSDR, 2020). Blood lead levels (BLLs) in children have steadily decreased since the 1970s, when the mean level was 15 µg/dL. Currently, the average BLL in children is 1.3 µg/dL.

The CDC recently updated its recommendations to reflect the modern understanding that *there is no safe level of lead exposure for children* (CDC, 2012). The CDC no longer provides a "level of concern," as any lead exposure to a child is concerning. Instead, the CDC emphasizes primary prevention of lead exposure in all children and recommends that children with a BLL that places them in the top 2.5% (currently ≥5 µg/dL) be identified as in need of exposure reduction and additional screening. They did not change the existing recommendation that physicians consider chelation therapy for children with a BLL above 45 µg/dL.

Occupational exposure to lead also has decreased because of protective regulations. Occupational exposure generally is through inhalation of lead-containing dust and lead fumes. Workers in lead smelters and storage battery factories are at the greatest risk for lead exposure. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2020).

Chemistry and Mode of Action

Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not found naturally. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006), principally zinc and calcium. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function.

ADME

Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divalent metal transporters. The absorption of inhaled lead (~90%) generally is much more efficient than through dietary intake. Tetraethyl lead is readily absorbed through the skin, but transdermal absorption does not occur with inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is found in bone. Growing bones will accumulate higher levels of lead and can form lead lines visible by radiography. Bone lead is slowly reabsorbed into the bloodstream, which can be accelerated when calcium levels are depleted, including during pregnancy. Small quantities of lead accumulate in the brain, mostly in gray matter and the basal ganglia. Lead readily crosses the placenta.

Lead is excreted primarily in the urine. The concentration of lead in urine is directly proportional to its free concentration in plasma (~1% of the total BLL). Lead is excreted in milk and sweat and deposited in hair and nails. The serum $t_{1/2}$ of lead is 1 to 2 months, with a steady state achieved in about 6 months. Lead accumulates in bone, where its $t_{1/2}$ is estimated at 20 to 30 years.

Health Effects

Although the effects of high-dose lead poisoning have been known for more than 2000 years, the insidious toxicities of chronic low-dose lead poisoning (BLL <20 µg/dL) have only recently been discovered. Lead is a nonspecific toxicant; the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems (Table 76–4). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research and the object of considerable public concern.

Neurotoxic Effects. The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2020; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead, with effects persisting down to the lowest measurable levels of lead (Cranfield et al., 2003; Lanphear et al., 2005).

Lead neurotoxicity primarily results from inhibition of Ca^{2+} transporters and channels and altered activities of Ca^{2+} responsive proteins, including PKC and calmodulin (Bellinger and Bellinger, 2006; Garza et al., 2006). These actions limit the normal activation of neurons in response to Ca^{2+} release and cause inappropriate production or release of neurotransmitters. Lead affects multiple neurotransmitter pathways, including the dopaminergic, cholinergic, and glutaminergic systems. At

TABLE 76–4 ■ HEALTH EFFECTS OF LEAD

BLL (µg/dL)	HEALTH EFFECT
Children	
<10	Inhibition of neural development Increased blood pressure Hearing loss Inhibition of hemoglobin synthesis enzymes Short stature Delayed sexual maturation (girls)
>10	Immunological effects (increased IgE)
>15	Increased erythrocyte protoporphyrin Decreased vitamin D
>30	Depressed nerve conduction velocity
>40	Anemia
>45	Chelation therapy warranted
>60	Colic
>70	Encephalopathy
Adults	
<10	Increased blood pressure Inhibition of hemoglobin synthesis enzymes Decreased glomerular filtration
>20	Increased erythrocyte protoporphyrin
>30	Hearing loss Enzymuria/proteinuria
>40	Peripheral neuropathy Reduced fertility Altered thyroid hormone levels Neurobehavioral effects
>50	Anemia
>60	Colic Chelation therapy warranted
>100	Encephalopathy

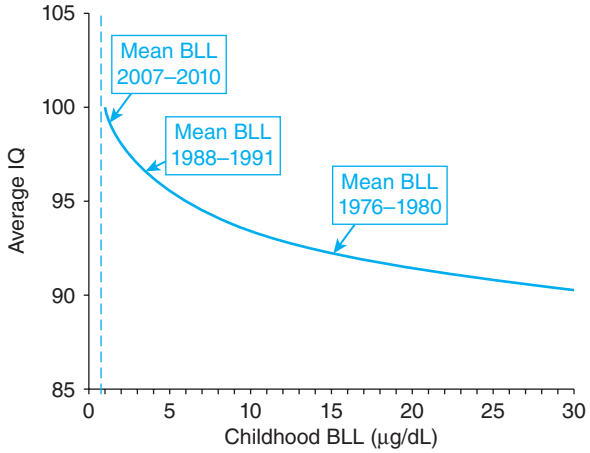

Figure 76–4 *Effect of childhood lead exposure on IQ.* Childhood exposure to lead shows a nonlinear dose-response relationship, with a steeper curve at low concentrations of lead (estimated dose-response curve based on data from Lanphear et al., 2005 and Canfield et al., 2003). For comparison, the average BLL from three iterations of the National Health and Nutritional Examination Survey are shown (Wheeler and Brown, 2013).

high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions.

Lead alters brain development by interfering with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during brain development; this process is disrupted by lead. Lead-induced alterations in brain development can result in decreased IQ, poor performance on exams, language and motor deficits, and behavioral problems such as distractibility, impulsivity, aggression, short attention span, and inability to follow simple sequences of instructions (ATSDR, 2020; CDC, 2014). There is no evidence for a threshold; associations are evident even at the lowest measurable BLL (Figure 76–4). The cognitive and behavioral changes caused by lead vary considerably among children and may depend on the timing of exposure.

Children with very high BLL (>70 µg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are about 25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Adults can also develop encephalopathy from lead exposure, although they are less sensitive than children. Workers chronically exposed to lead can develop neuromuscular deficits, termed *lead palsy*. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2020).

Cardiovascular and Renal Effects. Elevated blood pressure is a lasting effect of low-level lead exposure (BLL <10 µg/dL). Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure (ATSDR, 2020). Lead exposure is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

In the kidney, low-level lead exposure (BLL <10 µg/dL) depresses glomerular filtration. Higher levels (>30 µg/dL) cause proteinuria and impaired transport, while very high levels (>50 µg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2020).

The cardiovascular effects of lead are thought to involve the production of ROS, which react with nitric oxide (NO) to prevent vasodilation (Vaziri and Khan, 2007). It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and interferes with the electron transport chain (ATSDR, 2020).

Other Effects. Lead causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling; these effects can occur at low BLLs in children (Dietert and Piepenbrink, 2006). Lead inhibits the activity of several enzymes involved in the biosynthesis of heme; this effect persists down to very low BLL (<10 µg/dL; Figure 76–5). Chronic high-dose lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. Acute high-dose lead exposure affects the smooth muscle of the gut, producing intestinal symptoms, termed *lead colic*.

Carcinogenesis. The IARC classifies lead in group 2A, "probably carcinogenic to humans" (IARC, 2006). Epidemiological studies show associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. Lead carcinogenesis may result from inhibition of DNA-binding zinc-finger proteins, including those involved in DNA repair and synthesis. Lead is a good example of a nongenotoxic carcinogen.

Treatment

The most important response to lead poisoning is to remove the source of lead exposure. Supportive measures should be undertaken to relieve symptoms.

Chelation therapy is warranted for children and adults with very high BLLs (>45 µg/dL and >60 µg/dL, respectively) or acute symptoms of lead poisoning (Ibrahim et al., 2006). For children with a BLL above 45 µg/dL but below 70 µg/dL, oral chelation is recommended. A BLL above 70 µg/dL in a child is a medical emergency requiring hospitalization and immediate intravenous chelation (American Academy of Pediatrics, 2005).

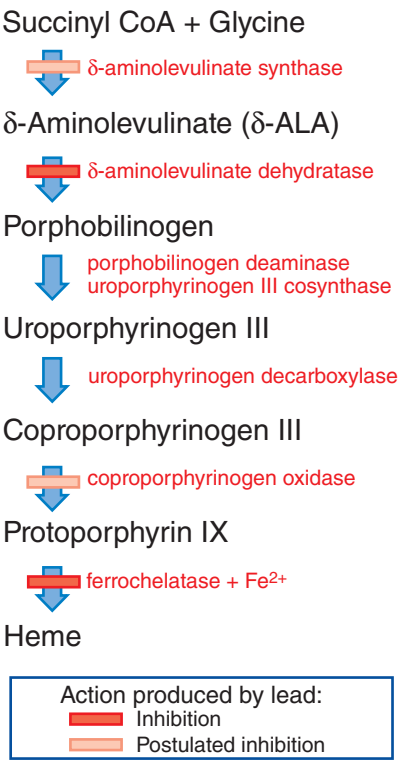

Figure 76–5 *Actions of lead on heme biosynthesis.* CoA, coenzyme A.

Although chelation therapy is effective at lowering BLL and relieving acute symptoms of lead poisoning, it does not reduce the chronic effects of lead beyond the benefit of lead abatement alone (Rogan et al., 2001). In rats, chelators enhance mobilization of lead from the soft tissues to the brain and may increase the adverse neurodevelopmental effects of lead (Andersen and Aaseth, 2002).

Mercury

Mercury is a unique metal in that it is a liquid at room temperature. Mercury has been used industrially since ancient Greece due to its capacity to amalgamate with other metals, and mercury's toxicity was noted by Hippocrates. Mercury also was used as a therapeutic drug for several centuries. Its use for the treatment for syphilis inspired Paracelsus's observation that "the dose makes the poison," one of the central concepts of toxicology, and also gave rise to the cautionary expression: "A night with Venus, a year with Mercury." The phrase "mad as a hatter" originated from the exposure of hatters to metallic mercury vapor during production of felt for hats using mercury nitrate. While the phrase likely inspired the character of the Mad Hatter in *Alice in Wonderland*, his symptoms are not consistent with mercury exposure.

Exposure

Inorganic mercury cations and metallic mercury are found in the Earth's crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities, such as combustion of fossil fuels and gold mining. In 2011, the EPA set the first standards to reduce mercury emissions from coal-fired power plants. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury ($MeHg^+$). $MeHg^+$ concentrates in muscle and other tissues and will bioaccumulate up the food chain (Figure 76–6). As a result, mercury concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are high (ATSDR, 1999).

The primary source of exposure to elemental mercury (Hg^0) in the general population is vaporization of Hg^0 in dental amalgam. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

Workers are exposed to Hg^0 and inorganic mercury, most commonly through exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to Hg^0 from amalgam. Hg^0 can be used to extract gold during mining, which results in substantial occupational exposure. Mercuric salts are used as pigments in paints (ATSDR, 1999).

Thimerosal is an antimicrobial agent used as a preservative in some vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to $MeHg^+$. Some parents have expressed concern that thimerosal might contribute to autism. Even though these concerns were based on a long-discredited report, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for thimerosal's replacement in vaccines to improve the prevalence of vaccination, and thimerosal was removed from childhood vaccines in 2001 (Ball et al., 2001). Concurrently, studies found no association between thimerosal use in vaccines and negative outcomes, and thimerosal is still used in influenza vaccines (Heron and Golding, 2004). The FDA maintains a listing of the thimerosal content in vaccines (http://www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/VaccineSafety/UCM096228).

Chemistry and Mode of Action

There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury (Hg^0) is the liquid metal found in scientific equipment and dental amalgam; it is volatile, and exposure is often to the vapor. *Inorganic mercury* can be either monovalent (*mercurous*, Hg^{1+}) or divalent (*mercuric*, Hg^{2+}) and forms a variety of salts. *Organic mercury* compounds consist of divalent mercury complexed with one or two alkyl groups. *Methyl mercury* ($MeHg^+$), which is formed environmentally from inorganic mercury by aquatic microorganisms, is of most concern. Both Hg^{2+} and $MeHg^+$ readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulfhydryl residues on many proteins and disrupts their functions. Microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

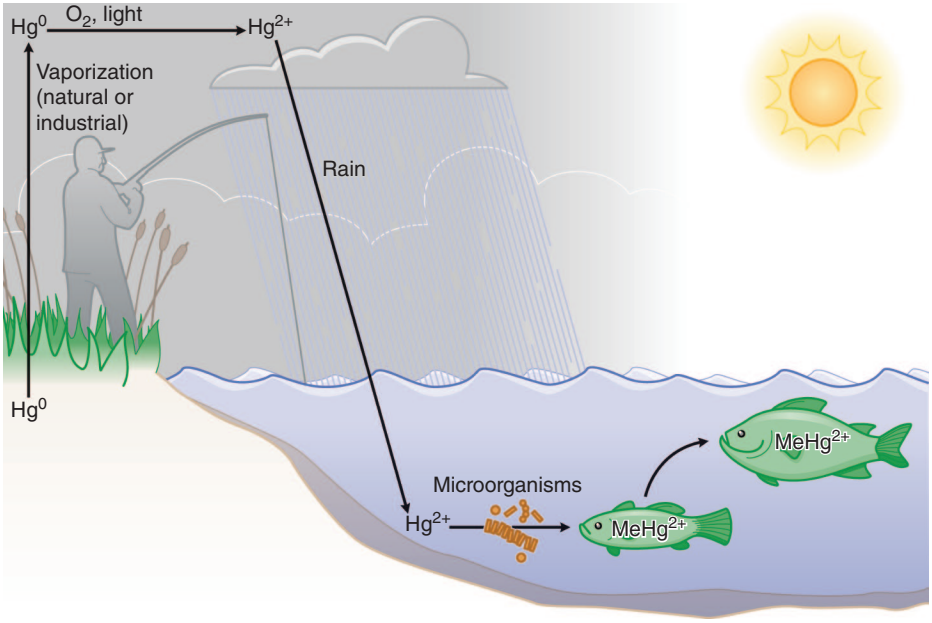

Figure 76–6 *Mobilization of mercury in the environment.* Metallic mercury (Hg^0) is vaporized from Earth's surface both naturally and through human activities such as burning coal. In the atmosphere, Hg^0 is oxidized to form divalent inorganic mercury (Hg^{2+}), which falls to the surface in rain. Aquatic bacteria can methylate Hg^{2+} to form methyl mercury ($MeHg^+$). $MeHg^+$ in plankton is consumed by fish. Because of its lipophilicity, $MeHg^+$ bioaccumulates up the food chain.

ADME

The vapor of Hg^0 is readily absorbed through the lungs (~70%–80%), but GI absorption of Hg^0 is negligible. Once absorbed, Hg^0 distributes throughout the body and crosses membranes, such as the blood-brain barrier and the placenta, via diffusion. Hg^0 is oxidized by catalase in cells to form Hg^{2+}. Shortly after exposure, some Hg^0 is eliminated in exhaled air. After a few hours, distribution and elimination of Hg^0 resemble the properties of Hg^{2+}. Hg^0 vapor can be oxidized to Hg^{2+} in the brain and retained (ATSDR, 1999).

Gastrointestinal absorption of mercury salts varies depending on the individual and on the particular salt and averages about 10% to 15%. Hg^{1+} will form Hg^0 or Hg^{2+} in the presence of sulfhydryl groups. Hg^{2+} is primarily excreted in the urine and feces; a small amount also can be reduced to Hg^0 and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The $t_{1/2}$ for inorganic mercury is approximately 1 to 2 months (ATSDR, 1999).

Complexes between $MeHg^+$ and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes (Ballatori, 2002). Orally ingested $MeHg^+$ is almost completely absorbed from the GI tract. $MeHg^+$ readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999). $MeHg^+$ can be demethylated to form inorganic Hg^{2+}. The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. $MeHg^+$ is excreted in the urine and feces, with the fecal pathway dominating. The $t_{1/2}$ for $MeHg^+$ is about 2 months. The toxicodynamic properties of $MeHg^+$ are thought to result from molecular mimicry.

Health Effects

Metallic Mercury. Inhalation of high levels of Hg^0 vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of Hg^0 exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of Hg^0 is also toxic to the CNS, with symptoms similar to those of chronic exposure (Figure 76–7).

Toxicity to the nervous system is the primary concern with chronic exposure to Hg^0. Symptoms include tremors (particularly of the hands); emotional lability (irritability, shyness, loss of confidence, and nervousness); insomnia; memory loss; muscular atrophy; weakness; paresthesia; and cognitive deficits. These symptoms intensify and become irreversible with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include kidney damage, tachycardia, labile pulse, severe salivation, and gingivitis.

Inorganic Salts of Mercury. Ingestion of Hg^{2+} salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. Acute exposure to Hg^{1+} or Hg^{2+} salts (typically in suicide attempts) leads to renal tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

Organic Mercury. The CNS is the primary target of $MeHg^+$ toxicity. Symptoms of high-dose $MeHg^+$ exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to $MeHg^+$. Children exposed *in utero* can develop severe symptoms, including intellectual disability and neuromuscular deficits, even in the absence of symptoms in the mother. In adults, $MeHg^+$ causes focused lesions in specific areas of the brain, while the brains of children exposed *in utero* sustain widespread damage (Clarkson, 2002).

The effects of low-dose $MeHg^+$ exposure from routine consumption of fish are difficult to assess due to the opposing beneficial effects of ω-3 fatty acids found in fish oils, and studies have produced discrepant results (Grandjean et al., 1999; Myers et al., 2003).

Treatment

Termination of exposure to Hg^0 is critical, and respiratory support may be required. Emesis may be used within 30 to 60 min of exposure to Hg^{1+} or Hg^{2+}, provided the patient is awake and alert and there is no corrosive injury. Maintenance of electrolyte balance and fluids is important for these patients. Chelation therapy is beneficial in patients with acute inorganic or metallic mercury exposure. There are limited treatment options for $MeHg^+$; chelation therapy does not provide clinical benefits, but nonabsorbable thiol resins may be beneficial by preventing absorption of $MeHg^+$ from the GI tract.

Because of the conflicting effects of mercury and ω-3 fatty acids, there is considerable controversy regarding the restriction of fish intake in women of reproductive age and children. The EPA recommends limiting fish intake to 12 oz (two meals) per week. Many experts feel this recommendation is too conservative. The recommendation that women consume fish that is lower in mercury content (i.e., canned light tuna,

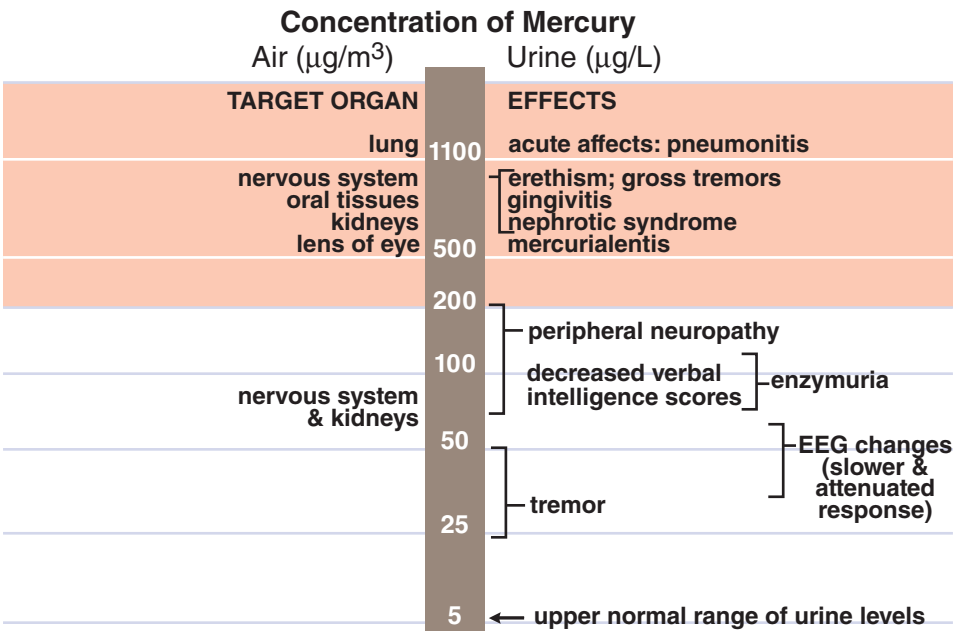

Figure 76–7 *Concentrations of mercury in air and urine are associated with specific toxic effects.*

salmon, pollock, catfish) and avoid top predators, such as swordfish, shark, and tilefish, is not controversial.

Arsenic

Arsenic is a metalloid that is common in rocks and soil. Arsenic compounds have been used for more than 2400 years as both therapeutic agents and poisons. In the late 19th century, Robert Ehrlich coined the terms *magic bullet* and *chemotherapy* to describe his work using the organic arsenic compound *arsphenamine* for the treatment for syphilis. The use of arsenic in drugs has been mostly phased out, but *arsenic trioxide* is still used as an effective chemotherapy agent for acute promyelocytic leukemia (see Chapter 70).

Exposure

The primary source of exposure to arsenic is through drinking water. Arsenic naturally leaches out of soil and rocks into well and spring water (Mead, 2005). Levels of arsenic in drinking water average 2 μg/L (ppb [parts per billion]) in the U.S. but can be more than 50 μg/L (five times the MCL set by the EPA) in private well water. Drinking water from other parts of the world, particularly Taiwan, China, Argentina, Chile, Bangladesh, and eastern India, can be contaminated with much higher levels of arsenic (sometimes several hundred micrograms per liter), and widespread poisonings have resulted (Figure 76–8). Arsenic can enter the environment through human activities, such as the use of arsenic-containing pesticides, mining, and burning of coal. Food, particularly seafood, often is contaminated with arsenic. Arsenic in seafood exists primarily as organic compounds (i.e., arsenobetaine), which are much less toxic than inorganic arsenic. The average daily human intake of arsenic is 10 μg/day, almost exclusively from food and water.

Before 2003, more than 90% of arsenic used in the U.S. was as a preservative in pressure-treated wood, but the lumber industry has voluntarily replaced arsenic with other preservatives. Arsenic-treated wood is thought to be safe unless burned. The major source of occupational exposure to arsenic is in the production and use of organic arsenicals as herbicides and insecticides. Exposure to metallic arsenic, arsine, arsenic trioxide, and gallium arsenide also occurs in high-tech industries, such as the manufacture of computer chips and semiconductors.

Chemistry and Mode of Action

Arsenic exists in its elemental form and trivalent (arsenites/arsenious acid) and pentavalent (arsenates/arsenic acid) states. Arsine (AsH_3) is a gaseous hydride of trivalent arsenic that exhibits toxicities that are distinct from other forms. Organic compounds of either valence state of arsenic are formed in animals. The toxicity of a given arsenical is related to the rate of its clearance from the body and its ability to concentrate in tissues. In general, toxicity increases in the sequence: organic arsenicals < As^{5+} < As^{3+} < AsH_3.

Like mercury, trivalent arsenic compounds form covalent bonds with sulfhydryl groups. The pyruvate dehydrogenase complex is particularly sensitive to inhibition by trivalent arsenicals: The two sulfhydryl groups of lipoic acid that participate in acetate transfer to coenzyme A react with arsenic to form a six-membered ring, effectively inhibiting pyruvate dehydrogenase and other lipoamide-containing enzymes. Inorganic arsenate (pentavalent) inhibits the electron transport chain. It is thought that arsenate competitively substitutes for phosphate during the formation of ATP, forming an unstable arsenate ester that is rapidly hydrolyzed.

ADME

The absorption of arsenic compounds is directly related to their aqueous solubility. Poorly water-soluble compounds such as arsenic sulfide, lead arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed via inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is more than 90% (ATSDR, 2016). At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulfhydryl content, exhibit high concentrations of arsenic. After an acute high dose (i.e., fatal poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (Figure 76–9). Trivalent compounds can be oxidized back to pentavalent compounds, but there is no evidence for demethylation of methylated arsenicals. Humans excrete much higher levels of monomethylarsenic (MMA) compounds than most other animals (ATSDR, 2016). Because the pentavalent methylated arsenic compounds have greatly reduced toxicity, the methylation pathway was long thought to be a detoxification pathway. However, the trivalent methylated arsenicals actually are more toxic than inorganic arsenite due to an increased affinity for sulfhydryl groups, and formation of MMA^{III} now is considered a bioactivation pathway (Aposhian and Aposhian, 2006).

Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly, with a $t_{1/2}$ of 1 to 3 days. In humans, ingested inorganic arsenic that appears in urine is a mixture of 10% to 30% inorganic arsenicals, 10% to 20% monomethylated forms, and 60% to 80% dimethylated forms.

Health Effects

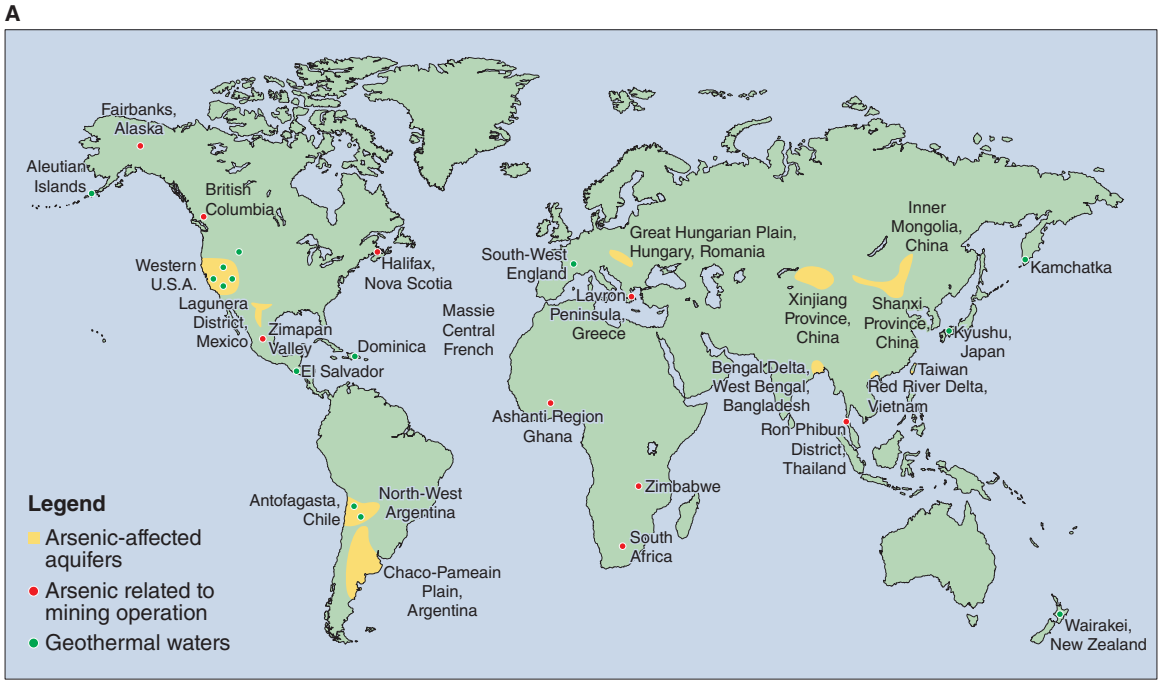
With the exception of arsine gas, the various forms of inorganic arsenic exhibit similar toxic effects. Inorganic arsenic exhibits a broad range of toxicities and has been associated with effects on every organ system tested (ATSDR, 2016). Humans also are exposed to large organic arsenic compounds in fish, compounds that are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70–180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic's combined effect on multiple organs.

Cardiovascular System. Acute and chronic arsenic exposure causes myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of arsenic trioxide for the treatment for leukemia. Chronic exposure to arsenic can cause peripheral vascular disease, the most dramatic example of which is "blackfoot disease," a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Blackfoot disease is endemic in regions of Taiwan, where well water contains arsenic at levels of 170 to 800 μg/L. Arsenic dilates capillaries and increases their permeability; this causes edema after acute exposures and is likely responsible for peripheral vascular disease following chronic exposure. Methylation of DNA may mediate some of arsenic's deleterious effects on the cardiovascular system (Domingo-Relosso et al., 2022) (see *Carcinogenesis*, below).

Skin. Dermal symptoms often are diagnostic of arsenic exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with arsenic concentrations of at least 100 μg/L and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of exposure; hyperkeratinization takes years. Children are more likely than adults to develop these effects (ATSDR, 2016; Mead, 2005).

GI Tract. Acute or subacute ingestion of high-dose arsenic is associated with GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of arsenic.

Nervous System. The most common neurological effect of acute or subacute arsenic exposure is peripheral neuropathy involving both sensory and motor neurons. This effect is characterized by the loss of sensation in the hands and feet, often followed by muscle weakness. Neuropathy occurs several days after exposure and can be reversible following



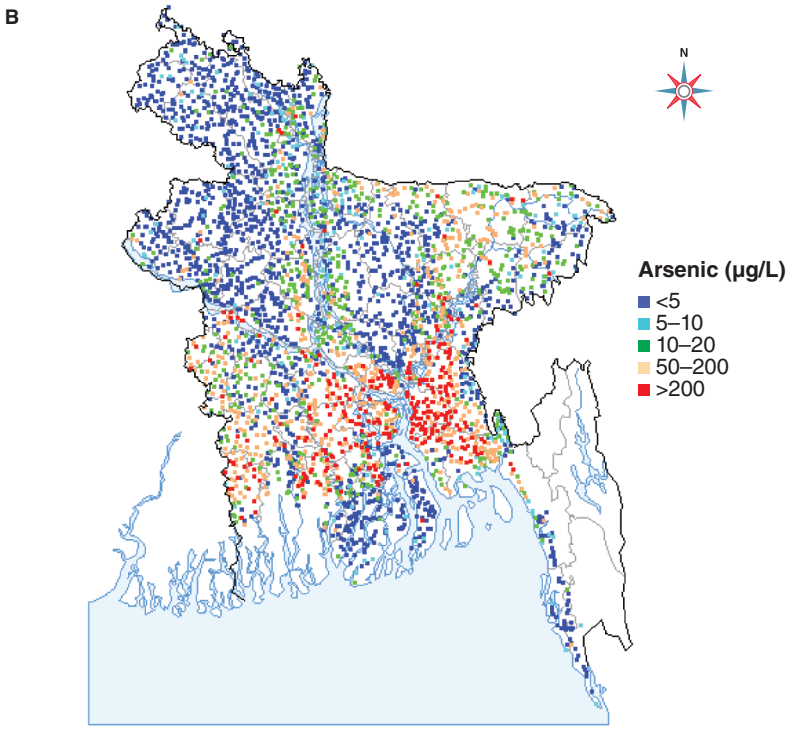


Figure 76–8 *Arsenic in drinking water.* **A.** World map demonstrating regions where there is increased arsenic exposure in drinking water. **B.** Map of Bangladesh demonstrating arsenic concentrations in drinking water in samples from wells across the country. (Adapted from a report produced by the British Geological Survey [2001] and the Department of Public Health Engineering [Bangladesh] undertaking a project funded by the U.K. Department for International Development [DFID]. Any views expressed are not necessarily those of DFID.)

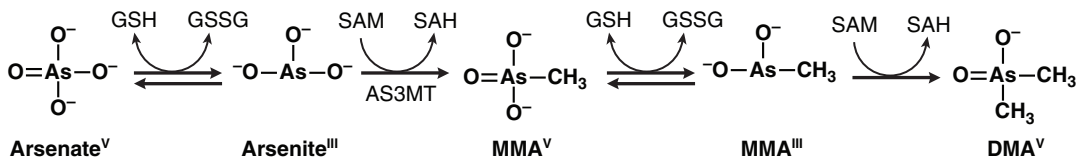

Figure 76–9 *Metabolism of arsenic.* AS3MT, arsenite methyltransferase; DMA^{V}, dimethylarsinic acid; GSH, reduced glutathione; GSSG, oxidized glutathione; MMA^{III}, monomethylarsonous acid; MMA^{V}, monomethylarsonic acid; SAH, S-adenosyl-L-homocysteine; SAM, S-adenosyl-L-methionine.

cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children (Wasserman et al., 2007). Acute high-dose arsenic exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma.

Other Noncancer Toxicities. Acute and chronic arsenic exposures induce anemia and leukopenia, likely via direct cytotoxic effects on blood cells and suppression of erythropoiesis. Arsenic also may inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and ingested arsenic may induce bronchitis, progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

Carcinogenesis. Regions with very high arsenic levels in drinking water consistently have substantially higher rates of skin cancer, bladder cancer, and lung cancer. There also are associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as "carcinogenic to humans (group 1)."

The developing fetus and young children may be at increased risk of arsenic-mediated carcinogenesis and have an elevated risk of developing lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from *in utero* exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalkes et al., 2007).

Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, or altered signal transduction pathways (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic compounds can act as tumor promoters or cocarcinogens in rodents, particularly when combined with ultraviolet light. In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low-arsenic regions (Ferreccio et al., 2000). Arsenic cocarcinogenesis may involve inhibition of proteins involved in nucleotide excision repair (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels.

Arsine Gas

Arsine gas, formed by reduction of arsenic in an industrial setting, is a rare cause of poisonings. Arsine induces rapid and often-fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with O_2. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 h. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsine exposure result in death.

Treatment

Following acute exposure to all forms of arsenic, the patient should be stabilized, and further absorption of the poison should be prevented. Close monitoring of fluid levels is important because arsenic can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to arsenic but has little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic is often warranted following arsine gas exposure (Ibrahim et al., 2006).

Cadmium

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

Exposure

In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 μg. Cadmium also is found in tobacco and tobacco smoke; a cigarette contains 1 to 2 μg of cadmium (Jarup and Akesson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

Chemistry and Mode of Action

Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of ROS, resulting in lipid peroxidation and GSH depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of NO.

ADME

Cadmium is not well absorbed from the GI tract (1.5%–5%) but is absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later the kidney, which together account for 50% of the absorbed dose. Cadmium distributes fairly evenly to other tissues but does not cross the blood-brain barrier or the placenta. Cadmium primarily is excreted in the urine and exhibits a $t_{1/2}$ of 10 to 30 years (ATSDR, 2012b).

Health Effects

Toxicity. Acute cadmium toxicity is due to local irritation along the absorption route. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody.

Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion.

Cadmium bound to metallothionein is transported to the kidney, where it can be released. Renal toxicity results from increased excretion of low-molecular-weight proteins, especially β_2 microglobulin and retinol-binding protein. Cadmium also causes glomerular injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium's effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity, including a reduction in glomerular filtration rate and creatinine clearance (Jarup and Akesson, 2009).

Workers with long-term inhalation exposure to cadmium exhibit decreased lung function. Symptoms include bronchitis and fibrosis of the lung, leading to emphysema. The exact cause of cadmium-induced lung toxicity is not known but may result from inhibition of the synthesis of α_1 antitrypsin. Chronic obstructive pulmonary disease causes increased mortality in cadmium-exposed workers.

When accompanied by vitamin D deficiency, cadmium exposure increases the risks for fractures and osteoporosis. This may be an effect of cadmium interfering with calcium and phosphate homeostasis due to its renal toxicity.

Carcinogenicity. Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; National Toxicology Program, 2021). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (National Toxicology Program, 2021). Cadmium substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks

(Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a nongenotoxic carcinogen.

Treatment

Treatment for cadmium poisoning is symptomatic. Patients who have inhaled cadmium may require respiratory support. Patients with kidney failure as a result of cadmium poisoning may require a transplant. There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2012b).

Chromium

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent (Cr^{III}) and hexavalent (Cr^{VI}) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature. Trivalent chromium was long thought to be an essential metal involved with glucose metabolism and insulin signaling; more recent analyses refute this view (Bailey, 2014; Vincent, 2017). Cr^{VI} is thought to be responsible for the toxic effects of chromium (ATSDR, 2012a).

Exposure

Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chromate production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries. Exposure usually is to a mixture of Cr^{III} and Cr^{VI}.

Chemistry and Mode of Action

Chromium occurs in its metallic state or in any valence state between divalent and hexavalent. Cr^{III} is the most stable and common form. Cr^{VI} is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of Cr^{III} and Cr^{VI} is thought to be differences in their absorption and distribution. Hexavalent chromate resembles sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell, Cr^{VI} undergoes a series of reduction steps, ultimately forming Cr^{III}, which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

ADME

Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are deposited deeper in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50% to 85% of inhaled Cr^{VI} particles (<5 μm) are absorbed. Absorption of ingested chromium is less than 10% and varies depending on water solubility. Cr^{VI} crosses membranes by facilitated transport, while Cr^{III} crosses by diffusion. Cr^{VI} is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr^{VI} is also retained in erythrocytes. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The $t_{1/2}$ of ingested Cr^{VI} is about 40 h; the $t_{1/2}$ of Cr^{III} is about 10 h (ATSDR, 2012a).

Health Effects

Toxicity. Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney. Chronic low-dose chromium exposure causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation (oral ulcers, diarrhea, abdominal pain, indigestion, and vomiting). Cr^{VI} is a dermal irritant and can cause ulceration or burns. Low-dose exposure by any route causes some individuals to become sensitized. These individuals will develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2012a).

Carcinogenicity. The Cr^{VI} compounds are group 1 known human carcinogens (IARC, 1990). There is insufficient evidence for carcinogenesis from metallic and trivalent chromium (classified in IARC group 3). Workers exposed to Cr^{VI} via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to Cr^{VI} in drinking water increases the risk of developing stomach cancer.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). Reduction of Cr^{VI} to Cr^{III} occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including GSH, lipids, proteins, and DNA, also can be oxidized. Cr^{III} forms a large number of covalent DNA adducts, primarily at the phosphate diester backbone. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

Treatment

There are no standard protocols for treatment for acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, GSH, or *N*-acetylcysteine to reduce Cr^{VI} to Cr^{III} after exposure but before absorption to limit bioavailability (ATSDR, 2012a). These compounds and EDTA (ethylenediaminetetraacetic acid) also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

Treatment for Metal Exposure

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator should *be highly soluble in water, be resistant to biotransformation, reach sites of metal storage, form stable and nontoxic complexes with toxic metals, and be readily excreted as a metal-chelator complex.* A low affinity for the essential metals calcium and zinc also is desirable because toxic metals often compete with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in Figure 76–10.

Ethylenediaminetetraacetic Acid

Ethylenediaminetetraacetic acid (EDTA) and its various salts are effective chelators of divalent and trivalent metals. $CaNa_2EDTA$ (*calcium disodium ethylenediaminetetraacetic acid*) is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than calcium has. $CaNa_2EDTA$ is effective for the treatment for acute lead

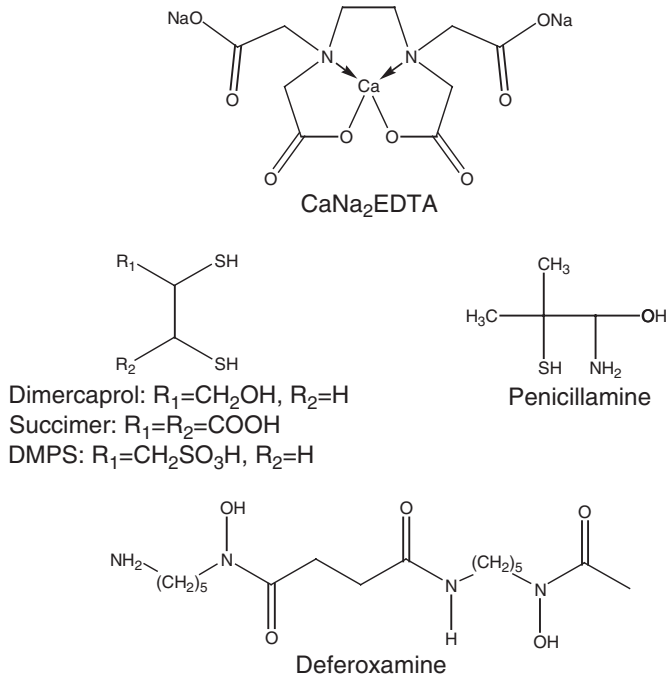

Figure 76–10 *Structures of chelators commonly used to treat acute metal intoxication.*

poisoning, particularly in combination with *dimercaprol*, but is not an effective chelator of mercury or arsenic *in vivo*.

A tetradentate molecule related to EDTA, *ethylene glycol-bis(β-aminoethyl ether)-N,N,N,N-tetraacetic acid (EGTA)*, has greater specificity for Ca^{2+} over Mg^{2+} and is used by researchers to buffer Ca^{2+} concentrations in physiologic solutions. Modifications of EGTA led to research that culminated in a Nobel prize (see Box 76–1).

Chemistry and Mode of Action

The pharmacological effects of $CaNa_2EDTA$ result from chelation of divalent and trivalent metals in the body. Accessible metal ions with a higher affinity for $CaNa_2EDTA$ than Ca^{2+} will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. $CaNa_2EDTA$ mobilizes several endogenous metallic cations, including zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of $CaNa_2EDTA$ is for acute lead intoxication. $CaNa_2EDTA$ does not provide clinical benefits for the treatment for chronic lead poisoning.

$CaNa_2EDTA$ is available as edetate calcium disodium (calcium disodium versenate). Intramuscular administration of $CaNa_2EDTA$ results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, $CaNa_2EDTA$ is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis.

BOX 76–1 ■ From EGTA to a Nobel Prize Via Jellyfish

In the early 1980s, Roger Tsien (1952-2016) published two papers (Tsien, 1980; Tsien, 1981) that described modifications of the tetradentate chelator EGTA that ultimately became a family of fluorophores that were membrane-permeant acetoxy-methyl esters, molecules that were hydrolyzed to ionic forms in the cytosol and thereby trapped within cells, enabling real-time assessment of intracellular Ca^{2+} concentrations. Tsien improved these reporters over the years and also developed a family of genetically encoded indicators for a variety of signaling molecules and protein kinases (Zhou et al. 2021), taking advantage of the discovery that the green fluorescent protein of *Aequorea victoria* jellyfish (Chalfie et al,1994; Shimomura, 2009) can function as a genetically encodeable fluorescent tag (Rodriguez et al, 2017). Osamu Shimomura, Martin Chalfie, and Roger Tsien shared the 2008 Nobel Prize in Chemistry "for the discovery and development of the green fluorescent protein, GFP".

ADME

Less than 5% of $CaNa_2EDTA$ is absorbed from the GI tract. After intravenous administration, $CaNa_2EDTA$ has a $t_{1/2}$ of 20 to 60 min. In blood, $CaNa_2EDTA$ is found only in the plasma. $CaNa_2EDTA$ is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; little gains access to the spinal fluid (5% of the plasma concentration).

Toxicity

The principal toxic effect of $CaNa_2EDTA$ is on the kidney. Repeated large doses of the drug can eventually cause degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with $CaNa_2EDTA$. For patients with lead encephalopathy and cerebral edema, $CaNa_2EDTA$ can lead to a potentially fatal increase in intracranial pressure following intravenous administration. Intramuscular administration is preferred for these patients.

Rapid intravenous administration of a form lacking calcium, such as Na_2EDTA, causes hypocalcemic tetany. However, a slow infusion (<15 mg/min) administered to a normal individual elicits no symptoms of hypocalcemia because of the availability of extracirculatory stores of Ca^{2+}. In contrast, $CaNa_2EDTA$ can be administered intravenously with no untoward effects because the change in the concentration of Ca^{2+} in the plasma and total body is negligible.

Other side effects associated with $CaNa_2EDTA$ include malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. $CaNa_2EDTA$ is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalia and Flora, 2005). Other possible effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B_6 deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

Dimercaprol

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, British anti-Lewisite (BAL). Arsenicals and other heavy metals form a stable and relatively nontoxic chelate ring with *dimercaprol*.

Chemistry and Mode of Action

The pharmacological actions of *dimercaprol* result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of *dimercaprol*-metal complexes and oxidation of *dimercaprol* occur *in vivo*. The sulfur-metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of *dimercaprol* in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL-metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted. *Dimercaprol* is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating

them. *Dimercaprol* limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with $CaNa_2EDTA$ to treat lead poisoning. *Dimercaprol* should not be used in iron, cadmium, or selenium poisoning because the resulting metal complexes are more toxic than the metal alone, especially to the kidneys.

ADME

Dimercaprol is given by deep intramuscular injection as a 100-mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts. Peak *dimercaprol* concentrations in blood are attained in 30 to 60 min. The $t_{1/2}$ is short, and metabolic degradation and excretion essentially are complete within 4 h. *Dimercaprol* and its chelates are excreted in both urine and bile. *Dimercaprol* is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is evidence in laboratory animals that *dimercaprol* mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of *dimercaprol* and is not observed with its more hydrophilic analogues described later in the chapter (see Succimer and Sodium 2,3-Dimercaptopropane-1-Sulfonate).

Toxicity

Side effects occur in about 50% of subjects receiving 5 mg/kg intramuscularly. *Dimercaprol* causes a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The pressure rises immediately but returns to normal within 2 h. *Dimercaprol* also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The *dimercaprol*-metal complex breaks down easily in an acidic medium; production of alkaline urine protects the kidney during therapy. Children react similarly to adults, although about 30% also may experience a fever that disappears on drug withdrawal. *Dimercaprol* is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

Succimer

Succimer (2,3-dimercaptosuccinic acid [DMSA]) has been approved in the U.S. for the treatment of children with BLL greater than 45 μg/dL. Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, *succimer* also is used off label for the treatment of adults with lead poisoning and for the treatment for arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

Chemistry and Mode of Action

Succimer is an orally effective chelator that is chemically similar to *dimercaprol* but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over *dimercaprol*.

ADME

After absorption, *succimer* is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). *Succimer* lowers BLL and attenuates lead toxicity. The *succimer*-lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

Succimer has several desirable features over other chelators. It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, *succimer* exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that *succimer* also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalia and Flora, 2005).

Toxicity

Succimer is much less toxic than *dimercaprol*. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rashes necessitate discontinuation of therapy. Transient elevations in hepatic transaminases have been observed with *succimer* treatment.

Sodium 2,3-Dimercaptopropane-1-Sulfonate

Another dimercapto compound, *sodium 2,3-dimercatopropane sulfonate* (DMPS), is used for the chelation of heavy metals. DMPS is approved for use in Germany. In the U.S., DMPS is available from compounding pharmacies upon physician request.

Chemistry and Mode of Action

DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of *succimer*. DMPS is less toxic than *dimercaprol* but mobilizes zinc and copper and thus is more toxic than *succimer*. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment for chronic arsenic poisoning (Kalia and Flora, 2005), but more thorough clinical studies are needed.

Penicillamine; Trientine

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine. *Penicillamine* is indicated for use in patients with Wilson disease (excess body burden of copper due to diminished excretion) and is used in other heavy metal intoxications. *Penicillamine* is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it often is given at fairly low doses following treatment with $CaNa_2EDTA$ or *dimercaprol* to ensure that the concentration of metal in the blood stays low following the patient's release from the hospital.

ADME

Penicillamine is well absorbed (40%–70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained 1 to 3 h after administration. *Penicillamine* is relatively stable *in vivo* compared to its unmethylated parent compound cysteine. Hepatic biotransformation is responsible for degradation of *penicillamine*; very little drug is excreted unchanged. Metabolites are found in both urine and feces. *N*-Acetylpenicillamine is more effective than *penicillamine* in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

Therapeutic Use

Penicillamine is available for oral administration. For chelation therapy, the usual adult dose is 1 to 1.5 g/day in four divided doses, given on an empty stomach to avoid interference by metals in food. *Penicillamine* is used in Wilson disease, cystinuria, and rheumatoid arthritis (rarely). For the treatment for Wilson disease, 1 to 2 g/day usually is administered in four divided doses. The urinary excretion of copper should be monitored to determine whether the dosage of *penicillamine* is adequate.

Toxicity

Penicillamine induces cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, and dermatomyositis. It also causes dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking *penicillamine*. Hematological reactions may be fatal and include leukopenia, aplastic anemia, and agranulocytosis. Renal toxicity induced by *penicillamine* usually is manifested as reversible proteinuria and hematuria, but it may progress

to nephrotic syndrome with membranous glomerulopathy. Rare fatalities have been reported from Goodpasture syndrome. Severe dyspnea, although uncommon, has been reported from *penicillamine*-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with *penicillamine*. A specific schedule for physical and laboratory monitoring for skin, blood, kidney, lung, liver, and other toxicities is published in the manufacturer's product labeling.

Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson disease, the benefits outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to *penicillamine* therapy include pregnancy in the absence of Wilson disease, renal insufficiency, or a previous history of *penicillamine*-induced agranulocytosis or aplastic anemia. *Penicillamine* increases the requirement for pyridoxine; supplementation with 25 mg daily is advised.

Trientine

Trientine (triethylenetetramine dihydrochloride) is an acceptable alternative for patients with Wilson disease who are intolerant of *penicillamine*. *Trientine* is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Iron deficiency may occur during *trientine* therapy; this can be overcome with short courses of iron therapy, but iron and *trientine* should not be ingested within 2 h of each other.

Deferoxamine; Deferasirox; Deferiprone

Chemistry and Mode of Action

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. *Deferoxamine* (deferoxamine mesylate) has a remarkably high affinity for ferric iron ($K_a = 10^{31}\ M^{-1}$) coupled with a very low affinity for calcium ($K_a = 10^{2}\ M^{-1}$). *In vitro*, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by *deferoxamine*.

ADME and Therapeutic Use

Deferoxamine is poorly absorbed after oral administration, and parenteral (intravenous, intramuscular, or subcutaneous) administration is required. For acute iron toxicity, intramuscular administration is preferred, except for patients in cardiovascular collapse or shock. For patients in shock, the drug is administered intravenously at 10 to 15 mg/kg/h by constant infusion for the first 1000 mg. If additional treatment is needed beyond 1000 mg, it should be administered at a rate not to exceed 125 mg/h. Faster rates of infusion usually are associated with hypotension. For acute iron poisoning without cardiovascular collapse or shock, *deferoxamine* should be given intramuscularly at a dose of 50 mg/kg with a maximum dose of 1 g. Subsequent doses of 500 mg may be given, if needed, every 4 to 12 h. Hypotension also can occur with the intramuscular route. For chronic iron intoxication (e.g., thalassemia), subcutaneous administration is recommended. Continuous subcutaneous administration should be given to achieve a dose of 1 to 2 g/day. The duration of the infusion (8–24 h) should be individualized to the patient. Poorly compliant patients with thalassemia can be given *deferoxamine* by slow intravenous infusion (rate not to exceed 15 mg/kg/h) prior to or after receiving transfusion. *Deferoxamine* may also be administered via an intramuscular dose of 0.5 to 1.0 g/day. *Deferoxamine* is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Off label, *deferoxamine* has also been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized to unknown products by plasma enzymes. The parent drug and its metabolites are readily excreted in the urine.

Toxicity

Deferoxamine can cause a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. *Deferoxamine* may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A "pulmonary syndrome" has been associated with high-dose (10- to 25-mg/kg/h) *deferoxamine* therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of *deferoxamine* include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

Deferasirox; Deferiprone

Deferasirox and *deferiprone* are oral chelators that are FDA approved to treat chronic iron overload in patients receiving transfusions. *Deferasirox* is also indicated for the treatment for chronic iron overload in non–transfusion-dependent thalassemia syndromes. Because of their oral availability, these drugs may allow for better compliance rates for patients with thalassemia. Both drugs form an uncharged chelate with iron and appear to be more effective than *deferoxamine* at reducing cardiac iron. However, both carry FDA black-box warnings (*deferasirox* for renal failure, hepatic failure, GI hemorrhage; *deferiprone* for agranulocytosis, neutropenia), and there are currently insufficient data to recommend replacing *deferoxamine* as the first-line treatment for chronic iron overload.

Endocrine Disruptors

Endocrine-disrupting chemicals (EDCs) include a broad range of compounds that interfere with the endocrine system through modulating hormone production and/or signaling. Key characteristics defining mechanisms through which compounds act as EDCs are outlined in Figure 76–11. These mechanisms include:

- Directly binding or regulating hormone receptors (e.g., ER, androgen receptor [AR], thyroid hormone receptor), their binding partners, or components of their downstream signaling pathways
- Influencing hormone production, secretion, or fate (La Merrill, 2020)

In addition to affecting reproductive function, endocrine disruptors can also negatively influence development, cognitive function, and metabolism. Endocrine disruptors are ubiquitously found in consumer products, including plastics, toys, cosmetics, and food.

Some EDCs have been banned, including the pesticide dichlorodiphenyltrichloroethane (DDT). Such efforts notwithstanding, many putative endocrine disruptors remain in use. The FDA has identified over 1800 manufactured chemicals that are known to have, or are predicted to have, endocrine-disrupting capacity. An exhaustive list of these chemicals can be found in the FDA's Endocrine Disruptor Knowledge Base (FDA, 2019). The following sections will focus on three classes of ubiquitous environmental compounds with well-studied EDC activity: DDT, phthalates, and bisphenol A (BPA).

DDT

Efficacy, low volatility, high lipid solubility, and slow biotransformation and degradtion made organochlorine compounds especially effective insecticides. Their stability, persistence in the environment, and lipid solubility also were the source of concern by environmentalists. In 1962, Rachel Carson published *Silent Spring* (Carson, 1962), which focused on evidence that DDT and other synthetic pesticides persist in the environment, bioaccumulate up the food chain, and cause observable harm to natural ecological systems, notably to avian reproduction. The book incited public outrage against DDT use. Sweden banned DDT in 1970; the U.S. banned its use in 1972. While most countries worldwide have also banned DDT, the persistence of its metabolite, dichlorodiphenyldichloroethylene (DDE), in both humans and the food chain, and its emergency use in controlling mosquito vectors make the health effects of this EDC still relevant today.

Exposure

During its period of active use (1940s to 1970s), DDT exposure occurred through handling or inhaling the chemical during application or interacting with DDT-sprayed surfaces. Today, DDT exposure most often occurs

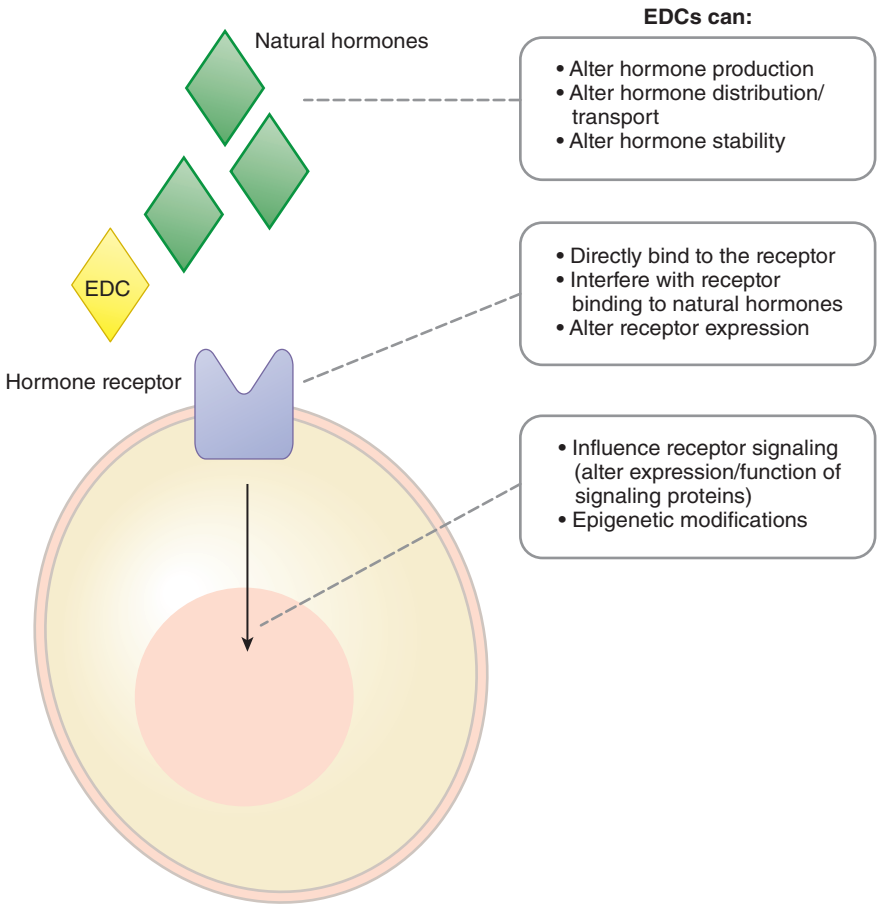

Figure 76–11 *Mechanisms through which chemicals can disrupt endocrine function.* (Adapted from La Merrill et al., 2020.)

through consumption of contaminated food, where DDT or DDE has bioaccumulated. Bioaccumulation of DDT and its metabolites is especially problematic in fish and seafood, although dietary exposure can occur through most lipid-rich foods. In addition to the consumption of food where fat bioaccumulation occurs, leafy vegetables coated with air-deposited DDT and root vegetables grown in contaminated soil can serve as a source of food contamination. DDT exposure can also occur *in utero* and via breastfeeding. In the air, the half-life of DDT is approximately 2 days as it can be broken down by sunlight; however, DDT persists in soil with a half-life of 2 to 15 years. Even though widespread use of DDT ceased decades ago, DDE can still be found in biological samples from most humans worldwide (Koureas, 2019). In regions where DDT is still used, primarily for malaria control, inhalation of contaminated air (from DDT that did not adhere to a surface or that vaporized following application to a surface) serves as an additional source of exposure.

Chemistry and Mode of Action

DDT is a chlorinated ethane derivative and part of the organochlorine pesticide family. In technical grade DDT, p,p′-DDT is the predominant isomer, although it is a mixture of several isomers (o,p′-DDT and p,p′-DDE are the most abundant contaminants). DDT confers its pesticide activity by impairing the nervous system of insects through disruption of voltage-gated ion channels. Likewise, acute toxicity in humans results from prolonged Na^+ channel opening and delayed channel closing. In addition to neurotoxicity, there is evidence that DDT targets several other organ systems, including the endocrine system. The o,p′-DDT isomer, which makes up approximately 15% of DDT, acts as an agonist for both ERα and ERβ. The p,p′-DDE isomer, which makes up approximately 4% of technical grade DDT and is the primary metabolite of p,p′-DDT, acts as an AR antagonist. Additionally, p,p′-DDT interacts with the transmembrane domain of follicle-stimulating hormone receptor (FSHR), positively modulating its downstream signaling (Munier et al., 2016).

ADME

Exposure to DDT, DDE, and dichlorodiphenyldichloroethane (DDD) primarily occurs through ingestion. The percentage of DDT and related isomers that is absorbed via the intestine is high, and the extent of absorption increases when DDT is dissolved in oils. Following absorption, DDT is initially distributed throughout all tissues in the body but ultimately accumulates in tissues proportional to their lipid content. DDE, the primary stable metabolite of DDT, is formed directly by dehydrochlorinase. Alternatively, DDE can be formed from a p,p′-DDD intermediate through reductive chlorination of DDT followed by dehydrogenase conversion of p,p′-DDD to DDE. DDE can persist in the body for decades. DDA [2,2-bis(p-chlorophenyl)acetic acid], an oxidized form of DDT and DDE, is the primary excreted metabolite and is eliminated through the urine; fecal elimination and breast milk serve as additional minor routes of excretion.

Health Effects

The EDC-related health effects of DDT have been determined based on a combination of epidemiological studies and causal studies in animal models (ATSDR, 2019). Using a systematic review approach of published epidemiological studies, there is consistent evidence that serum concentrations of DDT, DDE, and DDD correlate with an increased risk of abortions and preterm births in humans. While correlations with other reproductive effects have also been assessed, including fecundity, reproductive hormone levels in males and females, and early menopause, those data have been inconsistent.

Animal studies have provided more direct evidence of causal EDC activity that has supplemented the limitations of clinical studies. In rodent models, the health effects of p,p′-DDT, DDE, and DDD have mostly involved their antiadrenergic activity, whereas the health effects of o,p′-DDT are related to its estrogenic activity. DDT exposure in males led to a decrease in reproductive tissue weights, and in females, it led

to increased uterine weight, decreased fertility, and decreased estradiol levels. Although mild effects on thyroid function have been observed in animal studies, there is less direct evidence for an involvement of DDT in thyroid function (T_3, T_4, and thyroid-stimulating hormone levels) in humans. The health effects of DDT exposure may be dependent on timing and could explain some of the inconsistencies in the epidemiological data. DDT exposure during development has been shown to impact health effects later in life, which is relevant today for older adults who were born prior to the ban of DDT. In this regard, there is evidence that DDT developmental exposure is associated with an increase in type 2 diabetes, obesity, and liver cancer (Russ and Howard, 2016; vonderEmbse et al., 2021).

Phthalates

Phthalates are a group of chemicals that are commonly used as plasticizers to increase flexibility of polyvinyl chloride (PVC) and in consumer industries for the production of personal care products, medical tubing, and pharmaceuticals.

Exposure

The prevalence of phthalates in plastics and personal care products and the increase in plastic waste make exposure unavoidable in daily life. Accordingly, exposure routes to phthalates predominately occur through ingestion, inhalation, and dermal absorption. Animal meats, cooking oils, and dairy products consistently reportedly have high levels of phthalates such as di-2-ethylhexyl phthalate (DEHP). Consumption of food wrapped in plastic packaging is also a source of ingestion-based exposure. Individuals who live in proximity to plastic manufacturers may be exposed through air, contaminated water, dust, and soil. Since phthalates are capable of crossing the placental barrier, exposures also occur at the embryonic and fetal developmental stages.

Chemistry and Mode of Action

Phthalates are esters of phthalic acid with the basic structure and predominant derivatives shown in Figure 76–12. Depending on the modifications of the two side chains, phthalates are grouped into two categories: long-chain, high-molecular-weight phthalates and short-chain, low-molecular-weight phthalates. The side chains can be linear, branched, or cyclic, but generally, structures with greater than a six-carbon backbone are considered high-molecular-weight phthalates; DEHP and diisononyl phthalate (DINP) predominate and are used as plasticizers. In contrast, the low-molecular-weight compounds (e.g., dimethyl phthalate [DMP], diethyl phthalate [DEP]) are more often used in the manufacturing of personal care products. Phthalates impose their EDC activity through multiple mechanisms, including modulating hormone levels, altering hormone receptor expression, direct binding to receptors, and epigenetic modifications of genes involved in hormone signaling pathways (Hlisníková, 2020). In rodent studies, the impact of phthalate exposure is not monotonic. Exposure at high concentrations of individual phthalates or in mixtures led to increased FSHR, gonadotropin-releasing hormone, and luteinizing hormone receptor (LHR), whereas lower levels of exposure resulted in decreased FSHR and LHR. Phthalates directly bind nuclear receptors (NR) by mimicking the steroid A ring of hormones. As a result, phthalates can influence AR, ER, and peroxisome proliferator-activated receptor (PPAR) signaling by either activating or inhibiting these receptors depending on the phthalate side chain, the size of the ligand-binding domain of the NR, and interactions between NRs and coactivators. Phthalates also affect cell-signaling pathways that converge with NRs, including the MAPK, nuclear factor-κB (NF-κB), and PI3K/Akt pathways, which can result in altered cell proliferation and apoptosis.

ADME

Absorption, bioavailability, and elimination of phthalates are dependent on the route of exposure and hydrophobicity of the specific compound. Metabolites eliminated in the urine are similar across exposure routes (Domínguez-Romero and Scheringer, 2019). Absorption after dermal exposure can range from 1% to 60%; absorption is higher by the oral route. Following oral and dermal exposure, phthalates undergo first-pass metabolism; diesters are hydrolyzed into monoester metabolites by lipases and esterases. Low-molecular-weight phthalates and monoesters are excreted in the urine, whereas high-molecular-weight phthalates undergo phase II conjugation prior to elimination. Approximately 60% of total phthalates are eliminated in the urine and feces after dermal exposure, whereas 80% are eliminated following oral exposure. In general, the elimination of total phthalates increases with decreasing hydrophobicity of the parent phthalate compound. Phthalates are rapidly metabolized, with the plasma half-life of most phthalates being less than 24 h. Therefore, acute exposure to phthalates is often determined by measuring metabolites in the urine.

Health Effects

Research in human and animal models has established the developing reproductive system as a particularly sensitive target of phthalates. In adults, phthalate exposure is associated with reduced reproductive ability (reduced semen quality in males, increased pregnancy loss in females) and increased risk of type 2 diabetes, obesity, and inflammation. In epidemiological studies of children, phthalate exposure is associated with decreased luteinizing hormone and testosterone, reduced anogenital distance, thyroid dysfunction, and precocious puberty (Hlisníková, 2020; Sedha et al., 2021).

Bisphenol A

Bisphenol A (BPA) is another prevalent synthetic compound used as a plasticizer in the manufacturing of polycarbonate plastics and epoxy resins.

Exposure

Bisphenol A is commonly used in the manufacturing of food and beverage packaging including water bottles, protective coatings in food cans, and bottle tops. The primary route of exposure to BPA is through ingestion by direct contact with packaging, or indirectly by consuming water and food contaminated by plastic leaching. The rate that BPA leaches into the environment increases with heat, interactions with liquids of nonneutral pH, harsh detergents, and physical disruption of BPA-containing plastics. BPA can cross the placenta and has been measured in the umbilical cord,

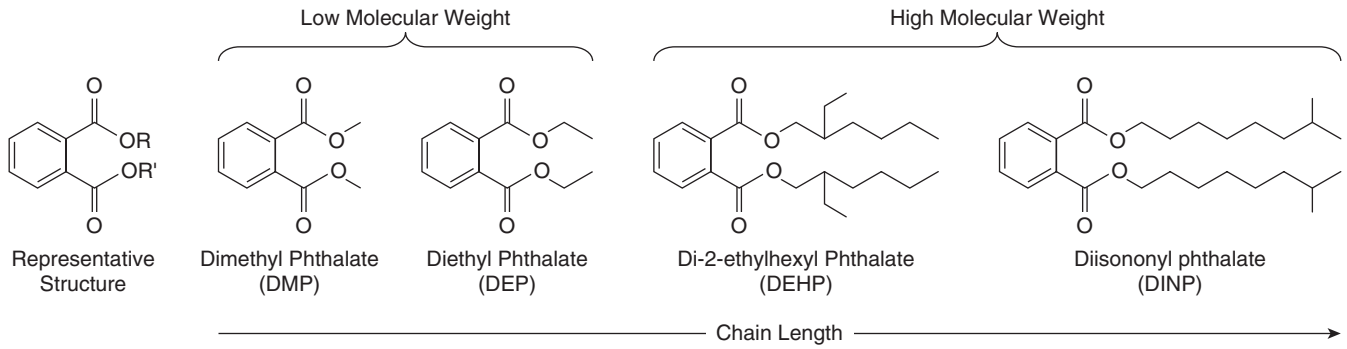

Figure 76–12 *Representative phthalate structures.*

amniotic fluid, and fetal plasma. BPA has also been measured in breast milk, which serves as an additional route of exposure in infants.

Chemistry and Mode of Action

Bisphenol A is generated from a reaction between phenols and acetone and is structurally composed of two phenols connected by an alkyl group. Because of its structural similarity to estrogen, BPA can bind to both ERα and ERβ, and has weak estrogenic activity (~1000-fold lower affinity than estradiol). BPA can activate ERα signaling but differentially interacts with the ERβ ligand-binding domain, preventing the conformational changes needed for productive signaling. As a result, BPA serves as a selective ER modulator and can act as both an agonist and antagonist. Most studies focus on the effects of high doses of BPA on ER transcriptional activity; however, at low concentrations, BPA can interfere with nongenomic ER pathways, including the formation of extranuclear complexes and Ca^{2+} release (Acconcia et al., 2015).

ADME

Following ingestion, BPA undergoes first-pass metabolism in the intestines and liver. BPA is primarily metabolized by the CYP2C subfamily and undergoes glucuronidation and, to a lesser extent, sulfation. BPA-monoglucuronide lacks estrogenic activity and is the primary metabolite found in bile and urine.

Health Effects

Bisphenol A has been identified in the urine of nearly all adults and children, as well as in the serum of pregnant women, breast milk, follicular and amniotic fluid, cord blood, and placental tissue. Even though it is difficult to form causal links with epidemiological studies, the evidence supports the hypothesis that BPA exposure is harmful to the human endocrine system (Abraham and Chakraborty, 2020). In regard to fertility and sexual function, higher urinary BPA levels were associated with lower serum E2, poorer oocyte yield, reduced maturation of oocytes, higher implantation failure, and a decrease in male sexual function. Males exposed to BPA have lower daily sperm production, sperm count, and motility. For women of childbearing age, higher BPA levels are associated with a shorter luteal phase. Urinary BPA correlates with other diseases involving endocrine disruption such as type 2 diabetes and thyroid dysfunction. Despite compelling associations, limitations to these studies include small sample sizes, confounding variables, and study designs that make it difficult to predict causations. Because of the inconclusive evidence in humans, regulation of BPA differs across countries, although bans of BPA in baby bottles have been enacted. Based on consumer demand, BPA has been phased out of food packaging with containers labeled as "BPA free," although replacement chemicals are often less studied.

In laboratory studies, mice exposed to BPA have impaired reproductive organ development, sperm development, and testosterone excretion (Adegoke et al., 2020). BPA exposure alters the function and structure of the brain via neurohormone receptors and the expression of the genes involved in thyroid hormone synthesis (Bansal and Zoeller, 2019; Kim and Park, 2019). Dams exposed to BPA gave birth to offspring with decreased insulin secretion. BPA has its greatest effect on health outcomes during critical stages of development such as embryonic development, gestational stages when BPA crosses the placental barrier, the neonatal period, childhood, and the peripubertal and pubertal periods (Eckstrum et al., 2018; Tuduri et al., 2018).

Chemicals That Target the Immune System

Immunotoxicants encompass a broad category of xenobiotics that interfere with or modulate the function of the immune system. In general, immunotoxicants act through one or more of the following mechanisms that target the immune system:

- Functional changes
- Structural changes
- Compositional changes

Changes secondary to other target organ toxicities

Chemicals that induce functional changes modulate the ability of immune cells to perform their effector functions, such as antibody production, release of cytokines, processing and presentation of antigen, and cell proliferation or differentiation. Chemicals that lead to structural changes alter the expression of cellular receptors and their ligands or damage lymphoid organ architecture. Chemicals that induce compositional changes may lead to alterations in the proportion or number of immune cell populations and subsets. Since the immune system has significant crosstalk with other organ systems, chemicals such as EDCs that target other organs can indirectly impair immune system function. Immunotoxicants can interfere with immune homeostasis or appropriate immune responses, which can lead to immunosuppression or immune overactivation. Immunosuppressive chemicals increase the risk of infection and cancer, whereas immunostimulants can increase the risk for autoimmunity and allergic reactions/hypersensitivity, especially in genetically susceptible individuals.

The following section covers 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the most potent immunotoxicant. TCDD mediates its toxicity through the aryl hydrocarbon receptor (AhR), and immunotoxicity of other persistent organic pollutants adsorbed to ambient particulate matter will also be briefly covered. Finally, emerging data on the immunotoxicity of per- and poly-fluoroalkyl substances (PFAS) are discussed.

TCDD

TCDD is a by-product or contaminant formed in the manufacturing of 2,4,5-trichlorophenol (TCP), a chemical once used as an herbicide and fungicide and that is also a combustion product in the burning of organic matter. Due to its resistance to breakdown, it is a persistent environmental pollutant. TCDD gained notoriety following three well-known exposure incidents:

- As a contaminant of Agent Orange, an herbicide that was used during the Vietnam War
- As the chemical accidentally released following a pressure tank incident in Seveso, Italy
- As the agent used in an assassination attempt of the Ukrainian presidential candidate, Viktor Yushchenko (Kerkvliet, 2012)

Exposure

TCDD, a lipophilic chemical, is resistant to metabolism and accumulates within the food chain. Today, greater than 90% of exposure is through the ingestion of contaminated food, with TCDD particularly soluble in fat-rich foods (e.g., dairy products, meat, and fish). Exposure also occurs occupationally from municipal, medical, and hazardous waste incineration and through natural combustion reactions.

Chemistry and Mode of Action

TCDD is part of a family of chemicals known as dioxins. There are greater than 400 structurally similar chemicals including polychlorinated dibenzo-para-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and dioxin-like polychlorinated biphenyls (PCBs). TCDD is the most potent of the congeners, based on its high affinity for the AhR and resistance to metabolism by CYPs, a profile that ensures a strong sustained AhR activation. Immunotoxicity of TCDD is mediated through AhR, which is expressed either constitutively or upon activation in most cells of the immune system. T cells are the primary target of AhR-mediated immunosuppression, with TCDD promoting the differentiation of newly activated $CD4^+$ T cells toward a regulatory T-cell phenotype (Ehrlich et al., 2017). TCDD also influences antiviral responses in $CD8^+$ T cells, induces tolerogenic dendritic cells, and inhibits antibody production in B cells (Franchini et al., 2019; Rothhammer and Quintana, 2019).

ADME

Following oral exposure, approximately 90% of TCDD is absorbed when dissolved in oil and approximately 50% to 60% is absorbed when administered in the diet. TCDD initially distributes through blood, liver,

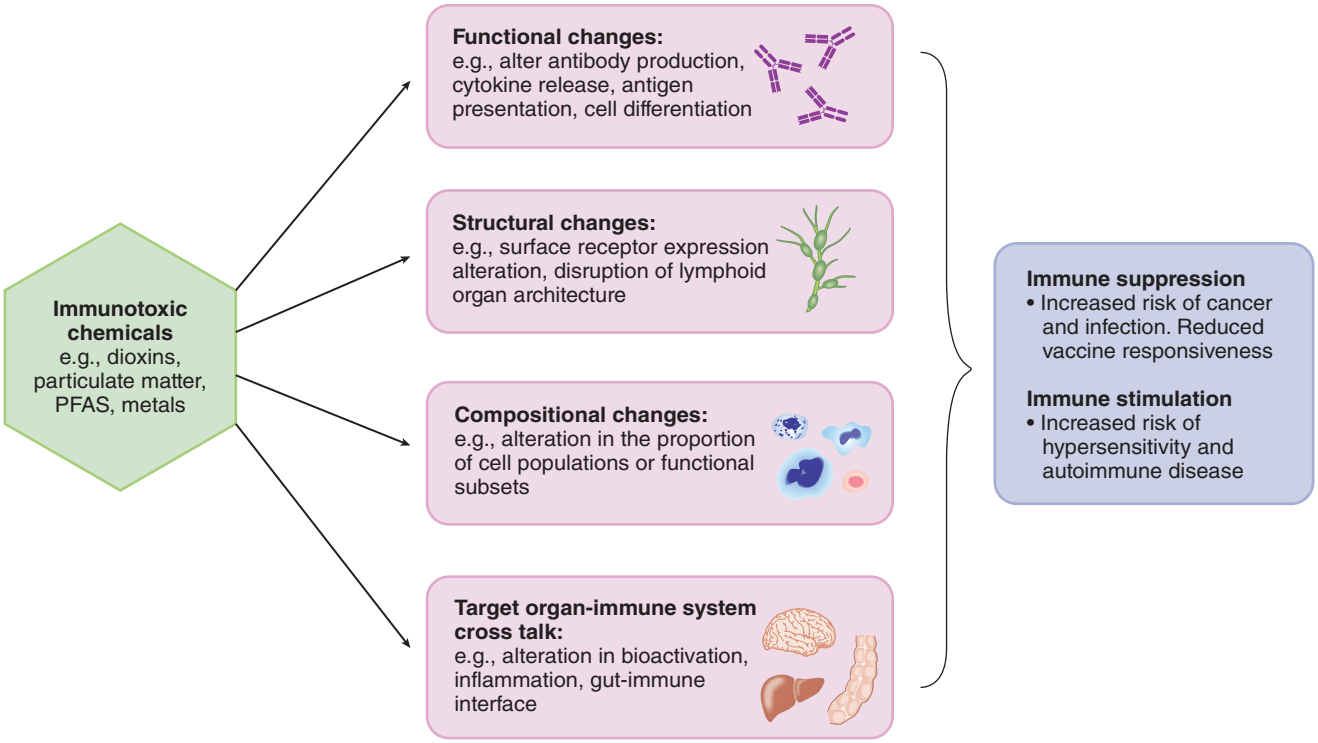

Figure 76–13 *Mechanisms through which chemicals can cause immunotoxicity.*

muscles, skin, and adipose tissue, and ultimately bioaccumulates in the liver and adipose tissue. TCDD is generally resistant to metabolism, although there are differences in metabolism across species. In humans, the half-life of TCDD is 7 to 11 years, and elimination primarily occurs through the feces.

Health Effects

The toxic effects of TCDD are mostly garnered from occupational and accidental exposure incidents, with the most consistent findings being the development of chloracne and increased risk of certain cancers. Most consistently, a reduction in $CD4^+$ T helper cell subsets has been reported in several studies and confirmed in nonhuman primates. In animal models, TCDD exposure results in thymic involution or atrophy (Harris et al., 1973). Additionally, rodents become more susceptible to influenza infection, *Trichinella spiralis* infection, and systemic (but not respiratory) *Streptococcus pneumoniae* infection (Lawrence and Vorderstrasse, 2013). Notably, exposure to TCDD does not render animals more susceptible but even is protective in certain infection paradigms. Collectively, these studies highlight the multitude of (often contradictory) roles AhR plays in different cell types and pathways, which can be impacted by ligand dose, exposure route, tissue location of AhR activation, and timing/duration of AhR activation (Boule et al., 2018; Ehrlich et al., 2017).

AhR Ligands and Particulate Matter

Aryl hydrocarbon receptor signaling is now known to play a role in immune cell development, maintenance, and function, and in the absence of AhR or its ligands, immune homeostasis is interrupted. AhR has been shown to play a key role in T_H17 differentiation, innate lymphocyte development, and the production of the cytokine interleukin-22. The health effects of AhR-driven proinflammatory pathways is highlighted by studies with air pollution and ambient particular matter (PM) (Vogel, 2020).

Air pollution can trigger or exacerbate asthma, allergies, and chronic obstructive pulmonary disease and increase risk of cancer and autoimmune diseases. Indeed, air pollution is a major cause premature deaths worldwide, estimated by the World Health Organization at millions per year (World Health Organization, 2021).

The physiological consequences of PM depend on both physical properties (e.g., size, mass, shape) and properties of the chemicals absorbed to the particulates (e.g., polyaromatic hydrocarbons [PAHs], PCBs, metals). PAHs and dioxin-like PCB-bound PM can activate AhR in both *in vivo* and *ex vivo* assays and induce downstream signaling as measured by induction of CYPs 1A1, 1A2, and B1. Unlike immunosuppression associated with systemic TCDD exposure, AhR activation by PM is associated with an increase in ROS and oxidative stress, interactions with NF-κB and Nrf2 signaling pathways, and an increase in inflammation. PM2.5 alters dendritic cell differentiation toward a T_H17-promoting phenotype in an AhR-dependent manner (van Hooris et al., 2013). The proinflammatory outcomes of PM were also observed in the Seveso, Italy, cohort, where exposed individuals were twice as likely to develop chronic obstructive pulmonary disease (Baccarelli et al., 2004). The inflammatory consequences of AhR activation by PM are of particular interest with overlap between the severe acute respiratory distress syndrome coronavirus-2 (SARS-CoV-2) pandemic, wildfires, and climate change emergencies impacting air quality and environmental health outcomes.

PFAS

Per- and poly-fluoroalkyl substances (PFAS) are a class of anthropogenic chemicals commonly used in aqueous firefighting foams and in the manufacture of commercial surfactants (Figure 76–14). PFAS are often referred to as "forever chemicals" because of their long half-life in environmental and biological matrices.

Exposure

Due to their hydrophobic and oleophobic properties, PFAS are used in food packaging, cookware, furniture, and carpeting. Exposure occurs through consumer use of these products as well as through contaminated drinking water. PFAS contamination is highest near airports and chemical manufacturing plants. In addition to ingestion, PFAS exposure can occur through inhalation of indoor dust and, to a much lesser extent, through dermal exposure. PFAS do not readily degrade in the environment; therefore, these compounds have been accumulating since they were first introduced in the 1940s. While legacy PFAS such as perfluorooctane sulfonate (PFOS) have been voluntarily phased out of products in the U.S., these compounds are still used globally, and next-generation replacement

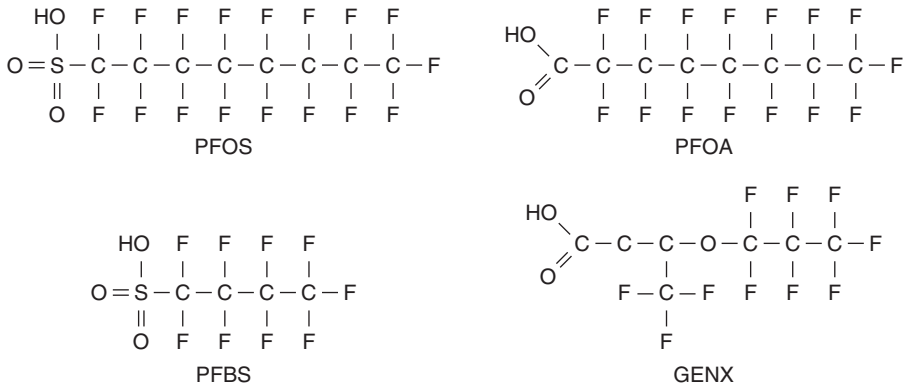

Figure 76–14 *Per- and poly-fluoroalkyl substances (PFAS).* PFAS are fully fluorinated carbon chains with a substituent as a functional head group. Their properties vary with chain length and head group. They have the general formula R-C_nF_{2n+1} (R, head group, e.g., carboxylate, sulfonate, amine, phosphate). Long-chain PFAS, n ≥ 6, have a greater tendency to bioaccumulate than PFAS with shorter chain lengths. There are also branched-chain PFAS, such as GenX, an industrial environmental toxin introduced as a replacement for PFOS. GenX is now found in drinking water drawn from the Cape Fear River around Wilmington, North Carolina (EPA, 2021; NC Policy Watch, 2021).

compounds with shorter chain lengths are continually developed. More than 4000 PFAS have been synthesized, and more than 100 have been measured in environmental samples.

Chemistry and Mode of Action

Per- and poly-fluoroalkyl substances contain at least one perfluoroalkyl moiety of the formula C_nF_{2n+1-} and a functional head group R. PFAS with fully fluorinated carbon chains are referred to as polyfluoroalkyl substances; those with incomplete replacement of the hydrogen atoms with fluorine are called perfluoralkyl compounds. The fluorinated carbon chain renders PFAS hydrophobic and oleophobic, although the specific chemical properties of PFAS are dependent on chain lengths and the functional head group. Perfluoroalkyl carboxylic acids and perfluoroalkane sulfonates with a chain length greater than 7 and 6, respectively, are considered long-chain PFAS and have a greater tendency to bioaccumulate. Perfluorooctanoic acid (PFOA) and PFOS are the most extensively manufactured and widely studied compounds. PFAS can interfere with endocrine function through disruption of lipid metabolism and steroid hormone biosynthesis, inducing ER stress and ROS, and directly interfering with PPAR (α and γ), Nrf2, and NF-κB signaling pathways (Corsini et al., 2012; Sant et al., 2021).

ADME

Following exposure by ingestion, greater than 90% of PFAS are absorbed and tend to partition to biological matrices with high protein content due to their hydrophobic nature. In the blood, most PFAS are bound to serum albumin. PFOA and PFOS preferentially partition to the liver; distribution of the next-generation PFAS, perfluorohexanesulfonic acid (PFHxS), favors the serum. PFAS are highly resistant to metabolism and bioaccumulate. The primary route of elimination is through the bile and urine, although menstruation and lactation serve as additional elimination routes. Serum concentrations tend to be higher in males than females, with elimination by menstruation partly explaining this sex difference. In humans, the half-lives of PFOA and PFOS are estimated to be 2 to 5 years.

Health Effects

Based on a combination of epidemiological and animal model studies, PFOS and PFOA are presumed to be an immune hazard to humans (National Toxicology Program, 2016). This conclusion is largely based on studies showing a negative correlation between PFAS levels and antigen-specific antibody responses. Several studies have shown that developmental exposures to PFAS are correlated with a reduction in antibody responses to childhood vaccines and with a decrease in antibodies to tetanus and diphtheria vaccines to below the clinically protective levels (Timmermann et al., 2022). Epidemiological studies are supported by murine studies showing that exposure to PFAS suppresses the T-cell–dependent antibody response, a robust *in vivo* assay of immunosuppression. There is also evidence in both human and mouse models that PFAS exposures can increase hypersensitivity responses, although the data are inconsistent and likely dependent on dose, timing, and duration of exposures (DeWitt et al., 2019). Understanding the mechanisms by which PFAS can induce its immunosuppressive and immunostimulant effects may help design epidemiological studies that can tease out these separate immunotoxic outcomes.

GI Microbiome and Environmental Toxicants

Exposure to environmental toxicants can lead to structural and functional changes in the gut microbiome. Consequences of gut microbiome toxicity include loss of bacterial diversity, changes in bacterial metabolites, and alterations in energy metabolism and balance (Tu, 2020). The loss of diversity due to toxicants can increase the susceptibility of invasion by pathogenic bacteria. Metabolites of the microbiome act as signaling molecules, and alterations of these pathways can have serious consequences on host physiology and homeostasis. The presence of specific bacterial species in the microbiome is critical for proper energy metabolism (see Chapter 6), and disturbances of these species are linked to obesity and malnutrition.

Dysbiosis, which can be generated by environmental chemicals, is linked to a broad range of diseases including inflammatory bowel disease, obesity, diabetes, cardiovascular disease, liver disease, colorectal cancer, and neurological disorders (Honda and Littman, 2016; Yuan et al., 2019). Pesticides can exert toxicity by disturbing bacterial communication through quorum sensing bacteria (Gao et al., 2018). Heavy metals can cause changes in the composition of the microbiome and alter the metabolic capabilities of the bacterial species (Li et al., 2019)

The gut microbiota can also mediate the toxicity of environmental chemicals (Claus et al., 2016). The gut flora express enzymes able to bioactivate or detoxify environmental compounds. Several key enzymes involved in bacteria-mediated metabolism of chemicals of concern include azoreductases, nitroreductases, β-glucuronidases, sulfatases, and β-lyases. These enzymes contribute to the metabolism of PAHs, nitrotoluenes, pesticides, PCBs, metals, azo dyes, melamine, and artificial sweeteners.

Drug Facts for Your Personal Formulary: *Metal Chelators*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Heavy Metal Chelators		
$CaNa_2EDTA$ (calcium disodium ethylenediaminetetraacetic acid)	• Acute lead poisoning	• IV or IM administration • Not effective for chronic lead poisoning • Nephrotoxic • IV administration can increase intracranial pressure in patients with lead encephalopathy and cerebral edema • Zinc supplementation may be beneficial
Dimercaprol	• Acute arsenic, gold, and mercury poisoning • Acute lead poisoning (in combination with $CaNa_2EDTA$)	• Administered IM • Not effective for chronic intoxication • Increases toxicity of iron, cadmium, and selenium • Toxicity profile is worse than for succimer
Succimer	• Treatment of children with blood lead >45 µg/dL • Off label for adults with lead poisoning and for arsenic and mercury poisoning	• Orally bioavailable • Improved toxicity profile over dimercaprol • Reduced mobilization of lead to brain • May cause allergic reactions
Copper Chelators		
Penicillamine	• Treatment of copper intoxication due to Wilson disease • Chelates heavy metals, but more toxic, less potent, and less selective than other options	• Orally bioavailable • Allergenic • Nephrotoxic • Causes hematological toxicities • Causes a variety of other side effects
Trientine	• Treatment of Wilson disease in those intolerant of penicillamine	• Orally bioavailable • Less potent than penicillamine
Iron Chelators		
Deferoxamine	• Treatment of acute iron intoxication • Treatment of chronic iron overload due to transfusion	• IV, IM, or SC administration required • SC administration preferred for chronic iron overload • IV use for cardiovascular collapse or shock • IM administration for other acute iron intoxication cases
Deferasirox	• Treatment of chronic iron overload due to transfusion • Treatment of non–transfusion-dependent iron overload	• Orally bioavailable • Renal failure, hepatic failure, and GI hemorrhage are concerns • Not recommended over deferoxamine
Deferiprone	• Treatment of chronic iron overload due to transfusion	• Orally bioavailable • Causes agranulocytosis and neutropenia • Not recommended over deferoxamine

This appendix provides a summary of basic pharmacokinetic information pertaining to small-molecule drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic dosing regimen design. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs). In some instances, sufficient pharmacokinetic data are not available.

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutically equivalent. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the top 200 selling drugs in 2020 for usage data. Drugs that fall into that list and meet the criteria above are generally selected. We have also consulted all new FDA drug approvals between 2016 and 2020. As mentioned above, a less used drug may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side effect profile. Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

With rare exceptions (e.g., interferons), recombinant therapeutic proteins have been excluded from this compilation. In many cases, the therapeutic protein interacts with specific tissue or cellular targets with exquisite affinity; as a result, clinical efficacy seldom correlates with circulating drug concentration and pharmacokinetics are not considered critical in guiding dosing. For example, for a number of therapeutic antibodies, the antibody is administered at a fixed dose and at prolonged intervals that allow for its near-complete clearance (e.g., *infliximab*). There is also the constraint of space in the book; hence, the appendix focuses on small-molecule drugs.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table AI-1 contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of some disease states, age, pregnancy, and sex on these processes, where significant; and the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 2. Their application using the data in Table AI-1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some kinetic measures of drug absorption and distribution. The text below defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both healthy subjects and patients with renal or hepatic impairment. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table AI-1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation (mean ± SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval or a coefficient of variation (in percentage). When sufficient data were available, a range of mean values obtained from different studies of similar design is presented: these ranges are in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule is needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g., *G* (V) indicates a parameter for *ganciclovir* after administration of the prodrug, *valganciclovir*].

A number of approved drugs are actually the active metabolite or stereoisomer of an earlier marketed drug. For example, *desloratadine* is the *O*-desmethyl metabolite of *loratadine*, and *esomeprazole* is the active *S*-enantiomer of *omeprazole*. Unless the parent drug and the active

Abbreviations

AUC: area under the plasma drug concentration-time curve
NDA: New Drug Application

metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has permitted us to include more drugs in the Appendix, hopefully without undue confusion. The only exception is with *prednisone* and *prednisolone* which are both included as individual drugs and which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states or due to physiological variables is noted below the average value. In previous editions, we have included disease states where studies have shown no change or clinically insignificant change for a particular pharmacokinetic measure. For the sake of space and consistency, we have eliminated the results of negative studies; hence, when a disease state is not listed, it implies no significant change due to the disease or that no information is available. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or a web-based drug database; the latter two secondary sources provide a broader range of papers for the interested reader. In some instances (e.g., many new drug approvals), we have relied on unpublished data provided by the drug sponsor in its New Drug Application (NDA) files or product labeling submitted to the U.S. Food and Drug Administration (FDA). This information can be accessed at *Drugs@FDA: FDA-Approved Drugs* (https://www.accessdata.fda.gov/scripts/cder/daf/index.cfm). After searching by drug name, pharmacokinetic data are found most often in the *Clinical Pharmacology and Biopharmaceutics* section. Recent standardization in the presentation of data supporting the NDA in this section makes this an increasingly valuable resource.

Tabulated Pharmacokinetic Parameters

Each of the eight parameters presented in Table AI-1 has been discussed in detail in Chapter 2. The following discussion focuses on the format in which the values are presented.

Bioavailability

The *extent of oral bioavailability* (F) is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation–the fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0%–100%). T_{max} as a measure of the *rate of availability* is also presented in the table under peak time in hours after dosing. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of area under the plasma drug concentration–time curve (AUC) between the oral dose and an intravenous reference dose. For those drugs where intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [–]). A dash also will appear when a drug is given by parenteral administration only.

A low oral bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid, degradative loss of drug in the gastrointestinal fluid, poor mucosal permeability including active efflux transport of drug back into the gut lumen, first–pass metabolism during transit through the intestinal epithelium, or first–pass hepatic metabolism or biliary excretion (see Chapter 2). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases and/or because vascular shunts develop around the liver.

Urinary Excretion of Unchanged Drug

The second parameter in Table AI-1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance (CL_{cr}) ≥100 mL/min). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the fractional contribution of renal clearance (CL_R) to total body clearance (CL) irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways (nonrenal clerance CL_{NR}) of elimination are available; thus, as renal function decreases, a greater fraction of the dose is eliminated via other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with pK_a values within the normal range for urine pH, changes in urine pH will affect their urinary excretion.

Binding to Plasma Proteins

The tabulated value is the percentage of drug in plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed *in vitro* (rather than from *ex vivo* measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percent bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic and renal impairment, and inflammatory diseases that alter the concentration of albumin, α_1-acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the apparent binding affinity of albumin for some drugs. Disease-induced changes in plasma-protein binding can dramatically affect the volume of distribution (V), clearance (CL), and elimination $t_{1/2}$ of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

Plasma Clearance

Systemic clearance of total drug from plasma or blood is given in Table AI-1. Clearance varies as a function of body size and most frequently is presented in the table in units of mL/min/kg of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimates, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is conventionally used. When unit conversion was necessary, individual

or mean body weight or body surface area (when appropriate) from the cited study were used, or if this was not available, a body mass of 70 kg or a body surface area of 1.73 m^2 for healthy adults was assumed.

For the few drugs that exhibit saturation kinetics following therapeutics doses, the Michaelis Menten constant, K_m, and the maximum velocity of drug elimination, V_{max}, are given if available. These values represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached in units of mass/volume and the maximal rate of elimination in units of mass/time/kg of body weight. K_m must be in the same units as the concentration of drug in plasma (C_p).

In almost all cases, clearances based on plasma (or serum) concentration data are presented in Table AI-1, because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by a footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the blood cells.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of *CL/F* is given; values offset by the fractional availability (*F*) are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is known to be a substrate for a cytochrome P450 (CYP) or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions (see Appendix II).

Volume of Distribution

The volume of distribution at steady state (V_{ss}) is given in Table AI-1 and is expressed in units of L/kg or in units of L/m^2 for some anticancer drugs. Again, when unit conversion was necessary, individual or mean body weights or body surface area (when appropriate) from the cited study were used; if such data were not available, a body mass of 70 kg or a body surface area of 1.73 m^2 for healthy adults were assumed.

When estimates of V_{ss} were not available, values for V_{area} (also known as V_β or V_z) were provided; V_{area} represents the volume at equilibrated distribution during the terminal elimination phase. Unlike V_{ss}, V_{area} varies when drug elimination changes, even though there is no change in extravascular distribution. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of V_{ss}, a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript (shown as *V*).

As with clearance, V_{ss} usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate, V_{ss}/F or V_{area}/F, was reported.

Half-Life

Half-life ($t_{1/2}$) is the time required for the plasma concentration to decline by one-half *when elimination is first order*. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, etc. Determination of $t_{1/2}$ is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multiexponential pattern of decline over time. The mean value listed in Table AI-1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this $t_{1/2}$ refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the $t_{1/2}$ of an earlier phase is presented, even though a prolonged $t_{1/2}$ may be observed later at very low plasma concentrations when very sensitive analytical techniques are used. If the latter component accounts for 10% or less of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer $t_{1/2}$ is ignored. The effective $t_{1/2}$ that predicts time to steady state for multicompartmental drug kinetics is given in Table AI-1.

Half-life usually is independent of body size because it is a function of the ratio of two parameters, volume of distribution and clearance, each of which is proportional to body size. It also should be noted that the $t_{1/2}$ is preferably obtained from intravenous studies, if feasible, because the $t_{1/2}$ of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow-release formulations are given. If the $t_{1/2}$ is derived from an oral dose, this will be indicated in a footnote of Table AI-1.

Time to Peak Concentration

Because clearance concepts are used most often in the design of multiple dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration (i.e., peak (C_{max}) and trough (C_{min}) concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table AI-1.

When more than one type of drug formulation is available commercially, we have provided absorption information for both the immediate- and extended-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and extent of drug availability. We have indicated with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

Peak Concentration

There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect parameter or effective concentration is difficult. This is particularly true for antimicrobial agents because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action is (are) expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations or the plasma concentration at which 50% of the maximum effect is observed (EC_{50}) for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 10 years, it is rare to find a declaration of an *effective concentration range*, even in the manufacturer's product label. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following *effective dosage* regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., $\overline{C}_{ss}$ as estimated by dividing the mean AUC by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, $\overline{C}_{ss}$ does not take

into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for specific populations sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most reported parameter, C_{max} (peak concentration), rather than effective or toxic concentrations, is presented in Table AI-1. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval, C_{max} can be related to the trough concentration (C_{min}) through appropriate mathematical predictions (see Chapter 2). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak concentration can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations, about concentrations at which toxicity occurs or the EC_{50} value for a specific effect they have been incorporated in a footnote.

It is important to recognize that significant differences in C_{max} will occur when comparing similar daily-dose regimens for an immediate-release and extended-release product. Indeed, the extended-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report C_{max} for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect have been included, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, information on concentrations of the individual enantiomers or the active enantiomer that contributes most to the drug's efficacy is presented.

Alterations of Parameters in the Individual Patient

Dose adjustments for an individual patient should be made according to the manufacturer's recommendation in the FDA-approved product label when available. This information generally is available when disease, age, or genetics have a significant impact on drug disposition. In some cases, a significant difference in drug disposition from the "average" healthy adult can be expected but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available.

Unless otherwise specified, the values in Table AI-1 represent mean values for populations of healthy adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available (F) and clearance (CL) would need to be adjusted to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated $t_{1/2}$ is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent $t_{1/2}$ following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than approximately 30 kg, it is best to consult textbooks of pediatrics or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as "↓ LD," which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the product label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

Plasma-Protein Binding

Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as *propranolol*, often bind to other plasma proteins (e.g., α_1-acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma-protein concentrations. Significant pharmacokinetic effects from a change in plasma-protein binding will be denoted under clearance or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of *unbound drug* that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the time-averaged unbound plasma concentration over a dosing interval at steady state will not change with reduced or elevated plasma-protein binding, despite a significant change in time-averaged total drug concentration. If so, no adjustment of daily maintenance dose is needed.

Clearance

For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient's estimated or measured creatinine clearance (CL_{cr}) to a normal value (100 mL/min/1.73 m^2). Creatinine clearance is often estimated from standardized serum creatinine concentration (C_{cr}) using the Modification of Diet in Renal Disease (MDRD) Study equation for CL_{cr} less than 60 mL/min/1.73 m^2 and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation.

Except for certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in individuals with obesity or malnourishment. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area. In the tabulation, if the literature reported dose per body surface area, we present the data in the same units. If the cited clearance data were not normalized, but the preponderance of the literature used body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m^2 for a healthy adult.

Volume of Distribution

Volume of distribution should be adjusted for the modifying factors indicated in Table AI-1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual is generally proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends

critically on whether the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

Half-Life

Half-life may be estimated from the adjusted values of clearance (CL_{pt}) and volume of distribution (V_{pt}) for the patient: $t_{1/2} = 0.693 * V_{pt} / CL_{pt}$. Because $t_{1/2}$ has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

Drug-Drug Interactions

Appendix II, Table AII-1, and Table AII-2 provide information on drug-drug interactions that can lead to large changes in drug exposure, with special reference to drugs included in Table AI-1, the large table of pharmacokinetic data.

TABLE AI–1 ■ PHARMACOKINETIC DATA

Key: Unless otherwise indicated by a specific footnote, the data are presented for the study population as a mean value ± 1 standard deviation (SD), a mean and range (lowest-highest in parentheses) of values, a range of the lowest-highest values, or a single mean value. ACE, angiotensin-converting enzyme; Aged, aged; AIDS, acquired immunodeficiency syndrome; CHF, congestive heart failure; C_{max}, peak concentration; CYP, cytochrome P450; F or Fem, female; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous; LD, chronic liver disease; M, male; MAO, monoamine oxidase; NAT, *N*-acetyltransferase; Neo, neonate; Obes, obesity; *PDR*58, *Physicians' Desk Reference,* 54th ed. Montvale, NJ, Medical Economics Co., 2000; *PDR*58, *Physicians' Desk Reference,* 58th ed. Montvale, NJ, Medical Economics Co., 2004; Pneu, pneumonia; PO, oral administration; Preg, pregnant; Prem, premature infants; Rac, racemic mixture of stereoisomers; RD, chronic renal disease; SC, subcutaneous; Smk, smoking; ST, sulfotransferase; $T_{max,}$ peak time; UGT, UDP-glucuronosyl transferase. Other abbreviations are defined in the text section of this appendix.

Alendronate[a]							
<0.7[b]	44.9 ± 9.3	78	1.11 (1.00–1.22)[c]	0.44 (0.34–0.55)[c]	~1.0[e]	IV: 2[f]	IV: ~275 ng/mL[f]
↓ Food			↓ RD[d]				PO: <5–8.4 ng/mL[f]

[a]Pharmacokinetic values reported are for doses <2 g; drug exhibits concentration-dependent kinetics above this dose. [b]Acetaminophen is eliminated predominantly via glucuronidaion and sulfation with a minor pathway via CYP2E1-mediated metabolism. [c]Mean concentration following a 20-mg/kg oral dose. Hepatic toxicity associated with levels >300 μg/mL at 4 h after an overdose.

References: Forrest JA, et al. Clinical pharmacokinetics of paracetamol. *Clin Pharmacokinet,* **1982**, *7*:93–107; van Rongen A, et al. Morbidly obese patients exhibit increased CYP2E1-mediated oxidation of acetaminophen. *Clin Pharmacokinet,* **2016**, *55*:833–847.

[a]Decreases with increasing dose. [b]Range of steady-state concentrations following a 400-mg dose given orally every 4 h to steady state.

Reference: Laskin OL. Clinical pharmacokinetics of acyclovir. *Clin Pharmacokinet,* **1983**, *8*:187–201.

[a]Oral albendazole undergoes rapid and essentially complete first-pass metabolism to albendazole sulfoxide (ALBSO), which is pharmacologically active. Pharmacokinetic data for ALBSO in male and female adults are reported. [b]The absolute bioavailability of ALBSO is not known but is increased by high-fat meals. [c]*CL/F* following twice-daily oral dosing to steady state. Chronic albendazole treatment appears to induce the metabolism of ALBSO. [d]$t_{1/2}$ reportedly shorter in children with neurocysticercosis compared with adults; may need to be dosed more frequently (three times a day) in children, rather than twice a day, as in adults. [e]Following a 7.5-mg/kg oral dose given twice daily for 8 days to adults.

References: Marques MP, et al. Enantioselective kinetic disposition of albendazole sulfoxide in patients with neurocysticercosis. *Chirality,* **1999**, *11*:218–223. *PDR*58, **2004**, p. 1422. Pharmacokinetic optimisation of the treatment of neurocysticercosis. *Clin Pharmacokinet,* **1998**, *34*:503–515.

[a]Data from healthy subjects for *R*- and *S*-enantiomers. No major sex differences. No kinetic differences in asthmatics. β-Adrenergic activity resides primarily with R-enantiomer. PO, oral; IH, inhalation. Oral dose undergoes extensive first-pass sulfation at the intestinal mucosa. [b]Median (range) following a single 4-mg oral dose of racemic albuterol.

References: Boulton DW, et al. Enantioselective disposition of albuterol in humans. *Clin Rev Allergy Immunol,* **1996**, *14*:115–138. Mohamed MH, et al. Effects of sex and race on albuterol pharmacokinetics. *Pharmacotherapy,* **1999**, *19*:157–161.

[a]Data from healthy postmenopausal female subjects. [b]Based on urinary recovery; reduced when taken <1 h before or up to 2 h after a meal. [c]*CL* and V_{ss} values represent mean and 90% confidence interval. [d]Mild to moderate renal impairment. [e]The $t_{1/2}$ for release from bone is ~11.9 years. [f]Following a single 10-mg IV infusion over 2 h and a 10-mg oral dose daily for >3 years.

Intra- and inter-individual variation in pharmacokinetics of intravenously infused amoxicillin and ampicillin to elderly volunteers. *Br J Clin Pharmacol,* **1986**, *27*:171–181.							
Amphotericin B[a]							
<5	2–5	>90	0.46 ± 0.20[b]	0.76 ± 0.52[c]	18 ± 7[d]	—	1.2 ± 0.33 μg/mL[e]
[a]Data for amphotericin B shown. [b]Data for eight children (ages 8 months to 14 years) yielded a linear regression, with *CL* decreasing with age: *CL* = −0.046 · age (years) + 0.86. Newborns show highly variable *CL* values. [c]Volume of central compartment. V_{ss} increases with dose from 3.4 L/kg for a 0.25-mg/kg dose to 8.9 L/kg for a 1.5-mg/kg dose. Also available as liposomal encapsulated formulations (ABELCET and AMBISOME). Amphotericin distribution and *CL* properties of these products are different from the nonencapsulated form; they have a terminal $t_{1/2}$ of 173 ± 78 and 110–153 h, respectively; however, an effective steady-state concentration can be achieved within 4 days. [d]$t_{1/2}$ for multiple dosing. In single-dose studies, a prolonged dose-dependent $t_{1/2}$ is seen. [e]Following a 0.5-mg/kg IV dose of amphotericin B given as a 1-h infusion, once daily for 3 days. Whole blood concentrations (free and liposome encapsulated) of 1.7 ± 0.8 μg/mL and 83 ± 35 μg/mL were reported following a 5-mg/kg/day IV dose (presumed 60- to 120-min infusion) of ABELCET and AMBISOME, respectively.

[a]Data from healthy adult male and female subjects. No clinically significant sex differences. Atorvastatin undergoes extensive CYP3A-dependent first-pass metabolism. Metabolites are active and exhibit a longer $t_{1/2}$ (20–30 h) than parent drug. [b]Mean *CL/F* calculated from reported *AUC* data at steady state after a once-a-day 20-mg oral dose, assuming a 70-kg body weight. [c]AUC following oral administration increased; mild-to-moderate hepatic impairment. [d]Following a 20-mg single oral dose oral dose. Following once daily 20mg oral dosing for 14 days the C_{max} of atorvastatin equivalents that include pharmacologically active metabolites is 14.9 ± 1.8 ngEq/mL[d].

References: Gibson DM, et al. Effect of age and sex on pharmacokinetics of atorvastatin in humans. *J Clin. Pharmacol,* **1996**, *36*:242–246. Lennernas H, Clinical Pharmacokinetics of Atorvastatin, *Clin Pharmacokinet,* 2003, 42:1141-1160. Mazzu AL, Lasseter KC, Shamblen EC, Agarval V, Lettieri J, Sundaresen P. Itraconazole alter the pharmacokinetics of atorvastatin to a greater extent than either cerivastatin or pravastatin *Clin Pharmacol Ther* 2000, 68:391-400.

[a]Value reported when taken with food. [b]Cleared from blood primarily by biliary excretion; undergoes enterohepatic cycling, with eventual fecal elimination. [c]Population estimates of *CL/F*, *V/F* and $t_{1/2}$ in Black, Asian, and Malay patients, respectively, treated for malaria. [d]Longer T_{max} values also reported, possibly because of enterohepatic recycling. [e]Following a 250-mg oral dose (Malarone) given once a day for 4 days.

References: Hussein Z, et al. Population pharmacokinetics of atovaquone in patients with acute malaria caused by *Plasmodium falciparum*. *Clin Pharmacol Ther,* **1997**, *61*:518–530. [a]Data from healthy adult male subjects. [b]Bioavailability estimate based on urine recovery of unchanged drug after oral dose. [c]*CL/F* and V_{area}/F reported for intestinal infusion of drug. [d]Limited data suggest *CL/F* reduced with renal impairment. [e]Following a single 10-mg oral dose.

References: Kochak GM, et al. The pharmacokinetics of baclofen derived from intestinal infusion. *Clin Pharmacol Ther,* **1985**, *38*:251–257. Wuis EW, et al. Plasma and urinary excretion kinetics of oral baclofen in healthy subjects. *Eur J Clin Pharmacol,* **1989**, *37*:181–184.

[a]Data from male and female subjects undergoing surgery. Buprenorphine is metabolized in the liver by CYP3A4 to an active metabolite, norbuprenorphine, and via conjugation. Majority of the dose is excreted into feces. [b]*CL,* 60 ± 19 mL/min/kg; V_{ss}, 3.2 L/kg; $t_{1/2}$, 1.03 ± 0.22 h; children 4–7 years of age. [c]Following 8-mg sublingual solution (SL) or 4-mg buccal (BC) dose.

[a]Bupropion is administered as a racemic mixture of *R* and *S* bupropion that can interconvert. Data from healthy adult male volunteers. Bupropion is metabolized by CYP2B6 to hydroxy-bupropion and by 11β-hydroxysteroid-dehydrogenase and aldo-ketoreductases to threo- and erythrohydrobupropion. All three metabolites accumulate in blood and are active. [b]*CL/F,* V_{ss}/F, and $t_{1/2}$ reported for oral dose. Percent coefficient of variation shown in parentheses. [c]Following oral dosing of 150-mg XL (sustained release) tablet to 42 healthy subjects for 7 days (steady state). 95% confidence interval shown in brackets.

References: Benowitz NL, et al. Influence of CYP2B6 genetic variants on plasma and urine concentrations of bupropion and metabolites at steady state. *Pharmacogenet Genomics,* **2013**, *23*:135–141. Chiral plasma pharmacokinetics and urinary excretion of bupropion and metabolites in healthy volunteers. *J Pharmacol Exp Ther*, **2016**, *358*:230–238.

[a]Data from healthy adult male subjects. No significant sex differences. Undergoes extensive CYP3A-dependent first-pass metabolism. The major metabolite (l-pyrimidinyl piperazine) is active in some behavioral tests in animals (one-fifth potency) and accumulates in blood to levels severalfold higher than buspirone. [b]Bioavailability increased ~84%; appears to be secondary to reduced first-pass metabolism. [c]*CL/F* reduced, hepatic cirrhosis. [d]*CL/F* reduced, mild renal impairment; unrelated to CL_{cr}. [e]Following a single 20-mg oral dose.

[a]Data from young (15–22 years) patients on peritoneal dialysis. Metabolized by 23-, 24-, and 26-hydroxylases and also excreted into bile as its glucuronide. [b]Calcitriol $t_{1/2}$ is 5–8 h in healthy adult subjects. [c]Oral dose $t_{1/2}$ = 27 ± 12 h, children 2–16 years. [d]Following a single 60-ng/kg IV, intraperitoneal (IP) dialysate, or PO dose. Baseline plasma levels were <10 pg/mL.

Cannabidiol[a]							
<10	—[b]	>94	PO: 265–455[c,d]	PO: 300–612[e]	PO: 56–61	PO: 2.5–5	PO:292 ± 88 ng/mL[d]
			IV:17.7 ± 3.4[f]	IV: 32.7 ± 8.6[f]	IV: 24 ± 6[f]		IV: 686 ± 239 ng/mL[f]
↑ Food			↓ LD		↑ LD, ↓ Food		

[a]Data from male and female healthy subjects. Cannabidiol exposure increases less than dose proportionally over the range of 5 to 25 mg/kg/day in patients. Cannabidiol is metabolized in the liver and the gut (primarily in the liver) by CYP2C19 and CYP3A4. It also undergoes glucuronidation by UGT1A7, UGT1A9, and UGT2B7 isoforms. After repeat dosing, the active metabolite of cannabidiol, 7-hydroxycannabidiol (equipotent with parent), has a 38% lower AUC than the parent drug. The 7-hydroxycannabidiol metabolite is metabolized to 7-carboxycannabidiol (pharmacologically inactive), which has an approximately 40-fold higher AUC than the parent drug. [b]After oral administration, cannabidiol is eliminated predominantly in feces, with metabolites found in urine. [c]*CL/F* reported. [d]After a 1500-mg single oral dose (approximately equal to the 20 mg/kg/day dosage). [e]V_{ss}/F reported. [f]Following 20 mg cannabidiol given IV to five male volunteers (infrequent to frequent cannabis smokers).

Capecitabine[a]							
—	3	<60	145 (34%) L/h/m^{2}[c,d]	270 L/m^{2} [c,d]	C: 1.3 (146%)[c]	C: 0.5 (0.5–1)[e]	C: 6.6 ± 6.0 μg/mL[e]
↓ Food[b]			↓ LD[e]		5-FU: 0.72 (16%)[c]	5-FU: 0.5 (0.5–2.1)[e]	5-FU: 0.47 ± 0.47 μg/mL[e]

[a]Data from male and female patients with cancer. Capecitabine (C) is a prodrug for 5-fluorouracil (5-FU; active), listed later in this table. It is well absorbed, and bioactivation is sequential in liver and tumor. [b]AUC for C and 5-FU decreased. [c]Geometric mean (coefficient of variation). [d]*CL/F* and V_{area}/F reported for oral dose. [e]Following 1255 mg/m^2.

References: Dooley M, et al. Capecitabine. *Drugs,* **1999**, *58*:69–76; discussion 77–78. Reigner B, et al. Effect of food on the pharmacokinetics of capecitabine and its metabolites following oral administration in cancer patients. *Clin Cancer Res,* **1998**, *4*:941–948.

Carbamazepine[a]							
78 ± 24[b]	3	74 ± 6	0.73± 0.3[b]	1.1 ± 0.3[b]	20 ± 9[b]	—	11.2–11.7 (2–18) μg/mL[c]

[a]A metabolite, carbamazepine-10,11-epoxide, is equipotent in animal studies. Its formation is catalyzed primarily by CYP3A and secondarily by CYP2C8. [b]Data from 92 patients receiving carbamazepine oral therapy for treatment of epilepsy and given stable isotope-labeled carbamazepine intravenously. Carbamazepine induces its own metabolism; for a single dose, *CL/F* = 0.36 ± 0.07 mL/min/kg and $t_{1/2}$ = 36 ± 5 h. [c]Mean steady-state C_{max} is similar following either dosing of immediate-release carbamazepine four times a day or extended-release carbamazepine once daily (800–1600 mg/day). Concentration following a daily 200-mg oral dose (immediate release) given to adult patients with epilepsy reported.

[a]Active metabolites, 7-hydroxychlorpromazine ($t_{1/2}$ = 25 ± 15 h) and possibly chlorpromazine *N*-oxide, yield AUCs comparable to the parent drug (single doses). [b]After a single dose. Bioavailability may decrease to ~20% with repeated dosing. [c]*CL/F*, V_{area}, and terminal $t_{1/2}$ following IM administration. [d]Following a 100-mg oral dose given twice a day for 33 days to adult patients. Neurotoxicity (tremors and convulsions) occurs at concentrations of 750–1000 ng/mL.

Reference: Dahl SG, et al. Pharmacokinetics of chlorpromazine after single and chronic dosage. *Clin Pharmacol Ther,* **1977**, *21*:437–448.

[a]Value is for 50- and 100-mg doses; renal *CL* is decreased at an oral dose of 200 mg, and there is a concomitant decrease in the percentage excreted unchanged. [b]Chlorthalidone is sequestered in erythrocytes. $t_{1/2}$ is longer if blood, rather than plasma, is analyzed. Parameters reported based on blood concentrations. [c]Following a single 50-mg oral dose (tablet) given to healthy male adults.

Reference: Williams RL, et al. Relative bioavailability of chlorthalidone in humans: adverse influence of polyethylene glycol. *J Pharm Sci,* **1982**, *71*:533–535.

[a]Data from patients with HIV infection and positive for cytomegalovirus. Cidofovir is activated intracellularly by phosphokinases. For parenteral use. [b]Parameters reported for a dose given in the presence of probenecid. [c]*CL* reduced, mild renal impairment (cleared by high-flux hemodialysis). [d]Following a single 5-mg/kg IV infusion given over 1 h, with concomitant oral probenecid and active hydration.

							PM: 18 ± 14 ng/mL
							AM[d]
							EM: 39 ± 15 ng/mL
							IM: 26 ± 11 ng/mL
							PM: 24 ± 6 ng/mL
[a]Clopidogrel (Clo) is a prodrug that is converted to a minor unstable active metabolite (AM) via two sequential CYP dependent reactions. The majority of the dose gets converted rapidly to an inactive hydrolytic product by esterases. Although multiple CYP isoforms contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotype status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for ≤10% of the administered dose and may be dose dependent due to saturable metabolism. [b]The absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. [c]The reported value may represent disappearance of high levels of metabolite formed during first pass and not the terminal $t_{1/2}$, which should be formation limited. [d]Following a single 300-mg loading dose of Clo. IM, intermediate metabolizer.

[a]Codeine is metabolized by CYP2D6 (polymorphic) to morphine. Analgesic effect is thought to be due largely to derived morphine. [b]Oral/IM bioavailability reported. [c]CL/F and V_{area}/F reported. [d]Data for codeine (C) and morphine (M) following a 60-mg oral codeine dose given three times daily for 7 doses to healthy male adults.

Reference: Quiding H, et al. Plasma concentrations of codeine and its metabolite, morphine, after single and repeated oral administration. *Eur J Clin Pharmacol,* **1986**, *30*:673–677.

[a]Decreased bioavailability after multiple doses has been reported. [b]Colchicine is a substrate of P-glycoprotein, which may contribute to its renal and biliary excretion and enterohepatic recirculation. Colchicine is also metabolized by CYP3A4. [c]Colchicine displays multicompartment kinetics with an initial central distribution volume of 0.26 L/kg. [d]Reported after administration of a single 1-mg tablet.

Reference: Ferron GM, et al. Oral absorption characteristics and pharmacokinetics of colchicine in healthy volunteers after single and multiple doses. *Eur J Clin Pharmacol,* **1996**, *36*:874–883.

[a]Cyclophosphamide is activated to hydroxycyclophosphamide primarily by CYP2C9. The metabolite is further converted to the active alkylating species, phosphoramide mustard ($t_{1/2}$ = 9 h) and nornitrogen mustard (apparent $t_{1/2}$ = 3.3 h). Kinetic parameters are for cyclophosphamide. [b]Following a 600-mg/m^2 IV (bolus) dose given to breast cancer patients.

[a]Data from patients with HIV infection. No significant sex differences. [b]Absolute oral bioavailability is unknown. Oral AUC increased 50% with high-fat meal. [c]Metabolized primarily by CYP2B6 and to a lesser extent by CYP2A6 and through *N*-glucuronidation. [d]Single-dose (SD) data reported for *CL/F* and both SD and multiple-dose (MD) data for $t_{1/2}$. Efavirenz is a weak inducer of CYP3A4 and its own metabolism. [e]Following a 600-mg oral dose given daily to steady state.

References: Adkins JC, et al. Efavirenz. *Drugs,* **1998**, *56*:1055–1064. *PDR*54, **2000**, p. 981. Villani P, et al. Pharmacokinetics of efavirenz (EFV) alone and in combination therapy with nelfinavir (NFV) in HIV-1 infected patients. *Br J Clin Pharmacol,* **1999**, *48*:712–715.

[a]Data from non–HCV-infected subjects unless otherwise specified. [b]The primary route of elimination of elbasvir and grazoprevir is through feces, with >90% of radiolabeled dose recovered in feces compared to <1% in urine following oral administration. Elbasvir and grazoprevir are partially eliminated by oxidative metabolism, primarily by CYP3A. No circulating metabolites of either elbasvir or grazoprevir were detected in human plasma. Elbasvir and grazoprevir are substrates of P-glycoprotein, but the role of intestinal P-glycoprotein in the absorption of elbasvir and grazoprevir appears to be minimal. Grazoprevir is a substrate of OATP1B1/3. [c]From population pharmacokinetic analysis. [d]In HCV-infected subjects. [e]Median (range) measured in HCV subjects. [f]Steady-state concentrations following administration of Zepatier (elbasvir 50 mg and grazoprevir 100 mg) once a day for 12 weeks in non-HCV subjects. Steady-state is reached within approximately 6 days; values are mean (90% confidence intervals) and estimated based on population pharmacokinetic modeling. Elbasvir pharmacokinetics are similar in healthy subjects and HCV-infected subjects, while grazoprevir oral exposures are approximately 2-fold greater in HCV-infected subjects when compared to healthy subjects. Elbasvir pharmacokinetics were approximately dose-proportional over the range of 5–100 mg once daily. Grazoprevir AUC increased more than dose proportionally over 10–800 mg once-a-day dosing in HCV-infected subjects.

[a]Hydrolyzed by esterases to the active metabolite, enalaprilic acid (enalaprilat); except when noted, pharmacokinetic values and disease comparisons are for enalaprilat, following oral enalapril administration. [b]For IV enalaprilat. [c]*CL/F* and V_{ss}/F after multiple oral doses of enalapril. Values after single IV dose of enalaprilat are misleading because binding to ACE leads to a prolonged $t_{1/2}$, which does not represent a significant fraction of the *CL* upon multiple dosing. [d]Estimated from the approach to steady state during multiple dosing. [e]Mean values for enalaprilat following a 10-mg enalapril oral dose given daily for 8 days to healthy young adults. The EC_{50} for ACE inhibition is 5–20 ng/mL enalaprilat.

[a]Enoxaparin consists of low-molecular-weight heparin fragments of varying lengths. [b]43% is recovered in urine when administered as ^{99}Tc-labeled enoxaparin; 8%–20% anti–factor Xa activity. [c]*F, CL/F,* and V_{area}/F for SC dose measured by functional assay for anti–factor Xa activity. [d]Measured by functional assay of anti–factor Xa activity. Using anti–factor IIa activity or displacement binding assay gives a $t_{1/2}$ of ~1–2 h. [e]Following a single 40-mg SC dose to healthy adult subjects. High-affinity antithrombin III molecules: ACLM, above-critical-length molecules (anti–factor Xa and IIa activity); BCLM, below-critical-length molecules (anti–factor Xa activity).

References: Bendetowicz AV, et al. [a]Eplerenone is converted (reversibly) to an inactive ring-open hydroxy acid. Both eplerenone (E) and the hydroxy acid (EA) circulate in plasma; concentrations of E are much higher than EA. Irreversible metabolism is catalyzed predominantly by CYP3A4. Data for E in healthy male and female volunteers reported; no significant sex differences. [b]Recovered as E and EA following an oral dose. [c]Protein binding is concentration dependent over the therapeutic range; lower at the highest concentration. [d]*CL/F* and V_{ss}/F reported. [e]Following a 50-mg oral dose given once daily for 7 days.

[a]Value for enteric-coated erythromycin base. [b]Decreased concentrations in pregnancy possibly due to decreased bioavailability (or increased *CL*). [c]Erythromycin base. [d]Erythromycin is a CYP3A substrate; *N*-demethylation. It also is transported by P-glycoprotein, which may contribute to biliary excretion of parent drug and metabolites. [e]Range of mean values from studies following a 250-mg oral enteric-coated free base in a capsule (B) given four times daily for 5–13 doses or a 250-mg film-coated tablet or capsule of erythromycin stearate (S) given four times daily for 5–12 doses.

[a]Escitalopram is the active *S*-enantiomer of racemic citalopram. Pharmacokinetic data after dosing of escitalopram (Es) and citalopram racemate (Rac) are reported. No significant sex differences. Citalopram is metabolized by CYP2C19 (polymorphic) and CYP3A4 to desmethylcitalopram. [b]Data from CYP2C19 extensive metabolizers. CYP2C19 poor metabolizers exhibit a lower (~44%) *CL/F* and longer $t_{1/2}$ than extensive metabolizers. [c]*CL/F* and *V/F* for Es reported. [d]Following a single 40-mg (Rac) or 20-mg (Es) oral dose.

[a]Esomeprazole is the *S*-enantiomer of omeprazole. Both esomeprazole (Es) and racemic omeprazole (Rac) are available. Data for both formulations are reported. [b]Bioavailability determined after multiple dosing. Lower Es values 64% (54%–75%) reported for single dose. [c]The metabolic *CL* of the Es is slower than that of the *R*-enantiomer. Both Es and Rac are metabolized by CYP2C19 (polymorphic) and CYP3A4. *CL* of Es and Rac is decreased and $t_{1/2}$ increased in CYP2C19 poor metabolizers. [d]Following a single 40-mg IV dose. *CL* of Es decreases and $t_{1/2}$ of Es increases with multiple dosing. [e]Reduced *CL* and increased $t_{1/2}$ in patients with severe (Child-Pugh class C) hepatic impairment. [f]Following a 40-mg oral dose of Es given once daily for 5 days to healthy subjects of unspecified CYP2C19 phenotype. [g]Following a 20-mg oral dose of Rac given twice daily for 4 days to healthy subjects phenotyped as CYP2C19 extensive metabolizers (EM) and poor metabolizers (PM).

[a]Eszopiclone is the (*S*)-isomer of zopiclone. Pharmacokinetic data after dosing of eszopiclone (Es) is shown. Es is metabolized extensively by CYP3A4 and CYP2E1. [b]*CL/F* following a 15-mg oral dose of zopiclone is 2.7 mL/min/kg for Es and 4.4 mL/min/kg for racemic zopiclone. [c]*V/F* following a 15-mg oral dose of racemic zopiclone is 1.4 L/kg for eszopiclone and 2 L/kg for racemic zopiclone. [d]In patients with severe hepatic impairment. [e]Following 3 mg Es given once daily to steady state.

[a]Exenatide is a synthetic peptide cleared primarily by the kidney through filtration, reabsorption, and proteolytic degradation. [b]*CL/F* after SC injection reported. [c]V_{area}/F after SC injection reported. [d]Following a 10-μg SC injection.

Reference: Linnebjerg H, et al. Effects of renal impairment on the pharmacokinetics of exenatide. *Br J Clin Pharmacol*, **2007**, *64*:317–327.

[a]Ezetimibe is extensively metabolized to a glucuronide, which is more active than ezetimibe in inhibiting cholesterol absorption. Clinical effects are related to the total plasma concentration of ezetimibe and ezetimibe–glucuronide, with ezetimibe concentrations being only 10% of the total. [b]For ezetimibe and ezetimibe–glucuronide. [c]*CL/F* and a volume for the central compartment (V_c/F) for total (unconjugated and glucuronide conjugate) ezetimibe reported. [d]Ezetimibe undergoes significant enterohepatic recycling, leading to multiple secondary peaks. An effective $t_{1/2}$ is estimated. [e]Total (unconjugated and glucuronide conjugate) ezetimibe following a 10-mg oral dose given once daily for 10 days.

[a]Racemic mixture; *S*-(−)-enantiomer is an active Ca^{+2} channel blocker; different enantiomer pharmacokinetics result in *S*-(−)-enantiomer concentrations about 2-fold higher than those of *R*-(+)-isomer. [b]Undergoes significant CYP3A-dependent first-pass metabolism in the intestine and liver. [c]May be age related rather than CHF related. [d]Following a 10-mg oral immediate-release (IR) or extended-release (ER) tablet given twice daily to steady state in healthy subjects. EC_{50} for diastolic pressure decrease is 8 ± 5 nM in patients with hypertension.

Reference: Dunselman PH, et al. Felodipine clinical pharmacokinetics. *Clin Pharmacokinet,* **1991**, *21*:418–430.

[a]Fenofibrate is a prodrug that is hydrolyzed by esterases to fenofibric acid, the pharmacologically active compound. All values reported are for fenofibric acid. [b]Absolute bioavailability is not known. Recovery of radiolabeled dose in urine as fenofibric acid, and its glucuronide is 60%. Immediate-release (IR) tablet and micronized (Mic) capsule are bioequivalent. Bioavailability is increased when taken with a standard meal. [c]Recovery following oral dose. [d]*CL/F* and *V/F* reported. [e]Following a 300-mg IR fenofibrate tablet given once daily to steady state. [f]Following a 200-mg Mic capsule given once daily to steady state.

TABLE AI–1 ■ PHARMACOKINETIC DATA (*CONTINUED*)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (h)	PEAK Time (h)	PEAK CONCENTRATION
Flecainide[a]							
70 ± 11	43 ± 3	61 ± 10	5.6 ± 1.3[b]	4.9 ± 0.4[c]	11 ± 3[b]	~3 (l–6)[d]	458 ± 100 ng/mL[d]
			↓ RD, LD,	↑ LD	↑ RD, LD,		
			↑ Child		↓ Child		

[a]Racemic mixture; enantiomers exert similar electrophysiological effects. [b]Metabolized by CYP2D6 (polymorphic); except for a shortened elimination $t_{1/2}$ and nonlinear kinetics in extensive metabolizers, CYP2D6 phenotype had no significant influence on flecainide pharmacokinetics or pharmacodynamics. [c]V_{area} reported. [d]Following a 100-mg oral dose given twice daily for 5 days in healthy adults. Similar levels for CYP2D6 extensive and poor metabolizers.

Reference: Funck-Brentano C, et al. Variable disposition kinetics and electrocardiographic effects of flecainide during repeated dosing in humans: contribution of genetic factors, dose-dependent clearance, and interaction with amiodarone. *Clin Pharmacol Ther,* **1994**, *55*:256–269.

Fluconazole							
>90	75 ± 9	11 ± 1	0.27 ± 0.07	0.60 ± 0.11	32 ± 5	1.7–4.3[a]	10.6 ± 0.4 μg/mL[a]
			↓ RD, Prem	↑ Prem, Neo	↑ LD, RD, Prem		
					↓ Child		

[a]Following a 200-mg oral dose given twice a day for 4 days to healthy adults.

References: Debruyne D, et al. Clinical pharmacokinetics of fluconazole. *Clin Pharmacokinet,* **1993**, *24*:10–27. Varhe A, et al. Effect of fluconazole dose on the extent of fluconazole-triazolam interaction. *Br J Clin Pharmacol,* **1996**, *42*:465–470.

Fludarabine[a]							
—	24 ± 3	—	3.7 ± 1.5	2.4 ± 0.6	10–30	—	0.57 μg/mL[b]
			↓ RD				

[a]Data from adult male and female cancer patients following IV administration. Fludarabine is rapidly dephosphorylated to 2-fluoro-arabinoside-A (F-ara-A), transported into cells, and phosphorylated to the active triphosphate metabolite. Pharmacokinetics of F-ara-A are reported. [b]Following a single 25-mg/m^2 IV dose of fludarabine (30-min infusion); no accumulation after five daily doses.

References: Hersh MR, et al. Pharmacokinetic study of fludarabine phosphate (NSC 312887). *Cancer Chemother Pharmacol,* **1986**, *17*:277–280. *PDR*54, **2000**, p. 764. Plunkett W, et al. Fludarabine: pharmacokinetics, mechanisms of action, and rationales for combination therapies. *Semin Oncol,* **1993**, *20*:2–12.

5-Fluorouracil (5-FU)							
28 (0–80)[a]	<10	8–12	16 ± 7	0.25 ± 0.12	11 ± 4 min[b]	—	11.2 μM[c]

[a]Higher *F* with rapid absorption and lower *F* with slower absorption, due to a saturable first-pass effect. [b]A much longer (~20 h) terminal $t_{1/2}$ has been reported, representing a slow redistribution of drug from tissues. [c]Steady-state concentration following a continuous IV infusion of 300–500 mg/m^2/day to cancer patients.

Reference: Diasio RB, et al. Clinical pharmacology of 5-fluorouracil. *Clin Pharmacokinet,* **1989**, *16*:215–237.

Fluoxetine[a]							
—[a]	<2.5	94	9.6 ± 6.9[b,c]	35 ± 21[d]	53 ± 41[e]	F: 6–8[f]	F: 200–531 ng/mL[f]
			↓ LD		↑ LD		NF: 103–465 ng/mL[f]

[a]Active metabolite, norfluoxetine; $t_{1/2}$ of norfluoxetine is 6.4 ± 2.5 days (12 ± 2 days in cirrhosis). Absolute bioavailability is unknown, but ≥80% of the dose is absorbed. [b]Reduced *CL* with repetitive dosing (~2.6 mL/min/kg) and with increasing dose between 40 and 80 mg. [c]*CL/F* reported; fluoxetine is a CYP2D6 and CYP2C19 substrate and inhibitor, but steady-state elimination is not dependent on these enzymes because of autoinhibition. [d]V_{area}/F reported. [e]Longer $t_{1/2}$ with repetitive dosing and with increasing doses. [f]Range of data for fluoxetine (F) and norfluoxetine (NF) following a 60-mg oral dose given once daily for 1 week. NF continues to accumulate for several weeks.

[a]Gentamicin clearance declines in proportion to a decline in CL_{CR}. [b]Gentamicin has a very long terminal $t_{1/2}$ of 53 ± 25 h (slow release from tissues), which accounts for urinary excretion for up to 3 weeks after a dose. Majority of the dose is eliminated during the distribution phase. [c]Following a single 100-mg IV infusion (1 h) or IM injection given to healthy adults.

References: Schentag JJ, et al. Gentamicin disposition and tissue accumulation on multiple dosing. *J Pharmacokinet Biopharm*, **1977**, *6*:559–577. Regamey C, et al. Comparative pharmacokinetics of tobramycin and gentamicin. *Clin Pharmacol Ther,* **1973**, *14*:396–403.

[a]Data from healthy male subjects. No significant sex differences. Glimepiride is metabolized by CYP2C9 to an active (approximately one-third potency) metabolite, Ml. [b]CL/F and V_d/F increased and $t_{1/2}$ unchanged, moderate to severe renal impairment; presumably mediated through an increase in plasma-free fraction. Ml AUC also increased. [c]Following a single 3-mg oral dose.

References: Badian M, et al. Determination of the absolute bioavailability of glimepiride (HOE 490), a new sulphonylurea. *Int J Clin Pharmacol Ther Toxicol,* **1992**, *30*:481–482. *PDR*54, **2000**, pp. 1346–1349. Rosenkranz B, et al. Pharmacokinetics and safety of glimepiride at clinically effective doses in diabetic patients with renal impairment. *Diabetologia,* **1996**, *39*:1617–1624.

[a]CL/F and V_{ss}/F reported. [b]Following a single 5-mg oral dose (immediate-release tablet) given to healthy young adults. An extended-release formulation exhibits a delayed T_{max} of 6–12 h.

Reference: Kobayashi KA, et al. Glipizide pharmacokinetics in young and elderly volunteers. *Clin Pharm,* **1988**, *7*:224–228.

[a]Data for GLYNASE PRESTAB micronized tablet (G) and MICRONASE tablet (M). [b]$t_{1/2}$ for micronized formulation reported. $t_{1/2}$ for nonmicronized formulation is 6–10 h, reflecting absorption rate limitation. A long terminal $t_{1/2}$ (15 h), reflecting redistribution from tissues, has been reported. Longer $t_{1/2}$ in patients with type 2 diabetes mellitus also reported. [c]Following a 3-mg oral GLYNASE tablet taken with breakfast or a 5-mg oral MICRONASE tablet given to healthy adult subjects.

References: Jonsson A, et al. Slow elimination of glyburide in NIDDM subjects. *Diabetes Care,* **1994**, *17*:142–145. *PDR54,* **2000**, p. 2457.

[a]Undergoes reversible metabolism to a less active reduced haloperidol. [b]Represents net *CL* of parent drug; reduced haloperidol $CL = 10 \pm 5$ mL·min^{-1}·kg^{-1} and $t_{1/2} = 67 \pm 51$ h. Slow conversion from reduced haloperidol to parent compound probably responsible for prolonged terminal $t_{1/2}$ (70 h) for haloperidol observed with 7-day sampling. [c]Following a single 20-mg oral or 10-mg IM dose. Effective concentrations are 4–20 ng/mL.

Reference: Froemming JS, et al. Pharmacokinetics of haloperidol. *Clin Pharmacokinet*, **1989**, *17*:396–423.

[a]Renal *CL* reported, which should approximate total plasma *CL*. [b]V_{area} calculated from individual values of renal *CL*, terminal $t_{1/2}$, and fraction of drug excreted unchanged; 70-kg body weight assumed. [c]Longer terminal $t_{1/2}$ of 8 ± 2.8 h has been reported with a corresponding increase in V_{area} to 2.8 L/kg. [d]Following a single (SD) or multiple (MD) 12.5-mg oral dose of hydrochlorothiazide; MD given once daily for 5 days to healthy adults.

[a]Data from healthy male and female subjects. The metabolism of hydrocodone to hydromorphone (more active) is catalyzed by CYP2D6. Subjects were phenotyped as extensive metabolizers (EM) and poor metabolizers (PM). [b]CL/F and $t_{1/2}$ reported for oral dose. [c]Following a 10-mg oral dose (syrup). Maximal hydromorphone concentrations are higher in EM than in PM (5.2 vs. 1.0 ng/mL). Hydromorphone is metabolized extensively to principal metabolite 3-glucuronie, which accumulates to much higher (27-fold) levels that hydromorphone. Hydromorphone half-life is 2.4 ± 0.6 h, CL 14.6 ± 7.6 mL/min/kg, and V_{area} 2.90 ± 1.31 L/kg.

[a]Hydroxychloroquine is marketed as a racemic mixture of *R*- and *S*-hydroxychloroquine. Data for the racemic mixture are reported. [b]Plasma clearance is reported. Hydroxychloroquine accumulates in red blood cells with an average blood-to-plasma ratio of 7.2. Blood clearance of hydroxychloroquine is 1.3 mL/min/kg. [c]Following oral administration of a single 155-mg tablet.

References: Tett SE, et al. A dose-ranging study of the pharmacokinetics of hydroxychloroquine following intravenous administration to healthy volunteers. *Br J Clin Pharmacol,* **1988**, *26*:303–313. Tett SE, et al. [a]Data from male and female patients treated for solid tumors. A range of mean values from multiple studies is shown in parentheses. [b]Nonrenal elimination of hydroxyurea is thought to exhibit saturable kinetics through a 10- to 80-mg/kg dose range. [c]Following a single 2-g, 30-min IV infusion or oral dose.

References: Gwilt PR, et al. Pharmacokinetics and pharmacodynamics of hydroxyurea. *Clin Pharmacokinet,* **1998**, *34*:347–358. Rodriguez GI, et al. A bioavailability and pharmacokinetic study of oral and intravenous hydroxyurea. *Blood,* **1998**, *91*:1533–1541.

[a]Hydroxyzine is metabolized to an active metabolite, cetirizine. Plasma concentrations of cetirizine exceed those of the parent drug; its $t_{1/2}$ is similar to that of hydroxyzine when formed from parent drug. Hydroxyzine data for adults (A) and children (C) are reported. [b]CL/F, V_d/F, and $t_{1/2}$ after oral dose reported. [c]$t_{1/2}$ increases with increasing age (1–15 years of age). [d]Following a single 0.7-mg/kg oral dose given to healthy adults and children.

References: Paton DM, et al. Clinical pharmacokinetics of H_1-receptor antagonists (the antihistamines). *Clin Pharmacokinet,* **1985**, *10*:477–497. Simons FE, et al. Pharmacokinetics and antipruritic effects of hydroxyzine in children with atopic dermatitis. *J Pediatr,* **1984**, *104*:123–127. Simons FE, et al. [a]Cleared primarily by the kidney. [b]Exposure increases 50%–100% in patients with moderate and severe renal impairment. [c]Following a single 50-mg oral dose.

References: Barrett J, et al. Ibandronate: a clinical pharmacological and pharmacokinetic update. *J Clin Pharmacol,* **2004**, *44*:951–965. Bergner R, et al. Renal safety and pharmacokinetics of ibandronate in multiple myeloma patients with or without impaired renal function. *J Clin Pharmacol,* **2007**, *47*:942–950.

[a]Racemic mixture. Kinetic parameters for the active *S*-(+)-enantiomer do not differ from those for the inactive *R*-(−)-enantiomer when administered separately; 63 ± 6% of the *R*-(−)-enantiomer undergoes inversion to the active isomer. [b]Unbound percent of *S*-(+)-ibuprofen (0.77% ± 0.20%) is significantly greater than that of *R*-(−)-ibuprofen (0.45% ± 0.06%). Binding of each enantiomer is concentration dependent and is influenced by the presence of the optical antipode, leading to nonlinear elimination kinetics. [c]CL/F and V_{ss}/F reported. [d]Following a single 800-mg dose of racemate. A level of 10 μg/mL provides antipyresis in febrile children.

Basel, Switzerland, Novartis, **2004**.

[a]Formulated as a 1:1 (mg/mg) mixture for parenteral administration; cilastatin inhibits the metabolism of imipenem by the kidney, increasing concentrations of imipenem in the urine; cilastatin does not change imipenem plasma concentrations appreciably. [b]Plasma C_{max} of imipenem following a single 1-g IV infusion over 30 min or 750-mg IM injection.

Reference: Buckley MM, et al. Imipenem/cilastatin. A reappraisal of its antibacterial activity, pharmacokinetic properties and therapeutic efficacy. *Drugs*, **1992**, *44*:408–444.

[a]Undergoes significant enterohepatic recycling (~50% after an IV dose). [b]Following a single 50-mg oral dose given after a standard breakfast. Effective at concentrations of 0.3–3 μg/mL and toxic at >5 μg/mL.

Reference: Oberbauer R, et al. Pharmacokinetics of indomethacin in the elderly. *Clin Pharmacokinet*, **1993**, *24*:428–434.

[a]Values for recombinant interferon alfa-2a (I) and its 40-kDa pegylated form (PI_{40kD}) and the 12-kDa pegylated form of interferon alfa-2b (PI_{12kD}) are reported. [b]I undergoes renal filtration, tubular reabsorption, and proteolytic degradation within tubular epithelial cells. Renal elimination of PI forms is much less significant than that of I, although not negligible. [c]*CL* values in four patients with leukemia were more than halved (1.1 ± 0.3 mL/min/kg), while V_{ss} increased more than 20-fold (9.5 ± 3.5 L/kg) and terminal $t_{1/2}$ changed only minimally (7.3 ± 2.4 h). [d]A terminal $t_{1/2}$ of 5.1 ± 1.6 h accounts for 23% of the *CL* of I. [e]Following a single 36 × 10^6 units SC dose of I. [f]Following 4 weeks of multiple SC dosing of 1 μg of PI_{12kD}. [g]Following 48 weekly SC doses of 180 μg/kg of PI_{40kD}.

[a]Data from male and female patients with malignant solid tumors. No significant sex differences. Irinotecan (I) is metabolized to an active metabolite, SN-38 (100-fold more potent but with lower blood levels). [b]Following a 125-mg/m^2 IV infusion over 30 min.

References: Chabot GG, et al. Population pharmacokinetics and pharmacodynamics of irinotecan (CPT-11) and active metabolite SN-38 during phase I trials. *Ann Oncol,* **1995**, *6*:141–151. *PDR*54, **2000**, pp. 2412–2413.

[a]Metabolized by NAT2 (polymorphic). Data for slow acetylators (SA) and rapid acetylators (RA) reported. [b]It is usually stated that isoniazid is completely absorbed; however, good estimates of possible loss due to first-pass metabolism are not available. Absorption is decreased by food and antacids. [c]Recovery after oral administration; assay includes unchanged drug and acid-labile hydrazones. Higher percentages have been noted after IV administration, suggesting significant first-pass metabolism. [d]*CL*/*F* and V_{ss}/*F* reported. [e]Decrease in CL_{NR}/*F* as well as CL_R. [f]Following a single 400-mg oral dose to healthy RAs and SAs.

[a]Loratadine (L) is converted to a major active metabolite, desloratadine (DL). Almost all patients achieve higher plasma concentrations of DL than of L. DL (CLARINEX) is approved for similar clinical indications as L. DL is eliminated by metabolism. DL is eliminated by metabolism to an active metabolite, 3-hydroxydesloratidine (HDL). Approximately 7%–20% of patients are slow metabolizers of DL; frequency varies with ethnicity. [b]Bioavailability of L and DL is not known; L is probably low due to extensive first-pass metabolism. [c]Plasma protein binding of HDL is 85%–89%. [d]*CL/F* and V_{area}/F reported. For DL, oral *CL/F* calculated from AUC data following a single 5- to 20-mg oral dose given to healthy adults. [e]Mean for L and DL following a 10-mg oral L dose (CLARITIN-D 24 HOUR) given once daily for 7 days to healthy adults. [f]Mean for DL and HDL following a 5-mg oral DL dose (CLARINEX) given once daily for 10 days to healthy adults.

[a]Data from healthy male subjects. Losartan (L) is metabolized primarily by CYP2C9 to an active 5-carboxylic acid metabolite (LA). [b]*CL/F* for L but not LA decreased in severe renal impairment (L/LA not removed by hemodialysis). No dose adjustment required. [c]*CL/F* for L reduced in mild to moderate hepatic impairment. LA AUC also increased. [d]Following a single 50-mg oral dose (tablet). Higher plasma levels of L (but not LA) in female subjects than in male subjects.

[a]Lovastatin is an inactive lactone that is metabolized to the corresponding active β-hydroxy acid. Pharmacokinetic values are based on the sum of 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibition activity by the β-hydroxy acid and other less potent metabolites. [b]The lactone (in equilibrium with β-hydroxy acid metabolite) is metabolized by CYP3A. [c]Following an 80-mg oral dose given once daily for 17 days. Peak levels represent total active inhibitors (AI) and total inhibitors (TI) of HMG-CoA reductase.

[a]Inactive prodrug is metabolized intracellularly to 6-thioinosinate. Pharmacokinetic values for mercaptopurine are reported. [b]Increases to 60% when first-pass metabolism is inhibited by allopurinol (100 mg three times daily). [c]Metabolically cleared by xanthine oxidase and thiopurine methyltransferase (polymorphic). Despite inhibition of intrinsic *CL* by allopurinol, hepatic metabolism is limited by blood flow, and *CL* is thus little changed by allopurinol. [d]Following an IV infusion of 50 mg/m^2/h to steady state in children with refractory cancers or a single oral dose of 75 mg/m^2 with (+) or without (–) allopurinol pretreatment.

TABLE AI–1 ■ PHARMACOKINETIC DATA (*CONTINUED*)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (h)	PEAK TIME (h)	PEAK CONCENTRATION
Methylphenidate[a]							
(+): 22 ± 8	(+): 1.3 ± 0.5	(+/−): 15–16	(+): 6.7 ± 2.0[b]	(+): 2.7 ± 1.1	(+): 6.0 ± 1.7[c]	(+): 2.4 ± 0.8[c,d]	(+): 18 ± 4.3 ng/mL[d]
(−): 5 ± 3	(−): 0.6 ± 0.3		(−): 12 ± 4.7[b]	(−): 1.8 ± 0.9	(−): 3.6 ± 1.1	(−): 2.1 ± 0.6[d]	(−): 3.0 ± 0.9 ng/mL[d]

[a]Methylphenidate is available as a racemate and the active (+)-dextro-enantiomer, dexmethylphenidate. Methylphenidate and dexmethylphenidate are extensively metabolized, primarily through ester hydrolysis to ritalinic acid. Data for individual enantiomers following racemate administration to healthy adult male subjects. No significant sex differences. [b]The (+)-enantiomer exhibits dose-dependent kinetics at high doses of racemate, with an ~50% reduction in *CL/F* between a 10- and 40-mg dose. [c]When dexmethylphenidate is given alone, its $t_{1/2}$ is 2.2 h, and T_{max} is 1–1.5 h. [d]Following a single 40-mg oral dose (immediate release). Longer T_{max} (3–5 h) and lower C_{max} reported for sustained-released oral formulation.

Metoprolol[a]							
38 ± 14[b]	10 ± 3[b]	11 ± 1	15 ± 3[b]	4.2 ± 0.7	3.2 ± 0.2[b]	EM: ~2[c]	EM: 99 ± 53 ng/mL[c]
↑ LD			↑ Preg		↑ LD, Neo	PM: ~3[c]	PM: 262 ± 29 ng/mL[c]
↓ Preg			↑ Fem	↑ Fem			

[a]Data for racemic mixture reported. Metabolism of less active *R*-(+)-enantiomer (*CL/F* = 28 mL/min/kg; V_{area}/F = 7.6 L/kg; $t_{1/2}$ = 2.7 h) is slightly faster than that of more active *S*-(−)-enantiomer (*CL/F* = 20 mL/min/kg; V_{area}/F = 5.5 L/kg; $t_{1/2}$ = 3 h). [b]Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers (EM), individuals who are poor metabolizers (PM) have a lower *CL/F* and a longer $t_{1/2}$ (7.6 ± 1.5 vs. 2.8 ± 1.2 h) and excrete more unchanged drug in urine (15% ± 7% vs. 3.2% ± 3%) due to reduced hepatic metabolism. [c]C_{3h} following a single 100-mg oral dose in CYP2D6 EM and PM patients with hypertension. Plasma concentrations of the more active *S*-enantiomer are ~35% higher than the *R*-antipode in CYP2D6 EM. No stereochemical difference was observed in PM subjects. EC_{50} for decreased heart rate during peak submaximal exercise testing was 16 ± 7 ng/mL; EC_{50} for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/mL.

[a]Active hydroxylated metabolite accumulates in renal failure. [b]Bioavailability is 67%–82% for rectal suppositories and 53% ± 16% for intravaginal gel. [c]Following a single 100-mg dose of vaginal (VA) cream, a 100-mg IV infusion over 20 min three times daily to steady state, or a 100-mg oral dose three times daily to steady state.

Reference: Lau AM, et al. Clinical pharmacokinetics of metronidazole and other nitroimidazole anti-infectives. *Clin Pharmacokinet*, **1992**, *23*:328–364.

[a]Undergoes arylsulfatase-dependent metabolism and biliary excretion. [b]Following a 100-mg IV infusion administered over 1 hour.

Reference: Hebert MF, et al. Pharmacokinetics of micafungin in healthy volunteers, volunteers with moderate liver disease and volunteers with renal dysfunction. *J Clin Pharmacol*, **2005**, *45*:1145–1152.

[a]Undergoes extensive first-pass metabolism by intestinal and hepatic CYP3A. Bioavailability appears to be dose dependent; 35%–67% at 15-mg, 28%–36% at 7.5-mg, and 12%–47% at 2-mg oral dose, possibly due to saturable first-pass intestinal metabolism. [b]Metabolically cleared by CYP3A. [c]Increased *CL* due to increased plasma free fraction; unbound *CL* is unchanged. [d]Following a single 5-mg IV bolus or 10-mg oral dose.

References: Garzone PD, et al. Pharmacokinetics of the newer benzodiazepines. *Clin Pharmacokinet*, **1989**, *76*:337–364. Thummel KE, et al. Oral first-pass elimination of midazolam involves both gastrointestinal and hepatic CYP3A-mediated metabolism. *Clin Pharmacol Ther*, **1996**, *59*:491–502.

[a]Data from female and male healthy subjects. [b]No unchanged drug was found in the urine after oral administration. Midostaurin is primarily metabolized by CYP3A4 to CGP52421 (hydroxyl metabolite) and CGP62221 (*O*-demthylated metabolite), both active metabolites. CGP62221 and CGP52421 account for 28% ± 2.7% and 38% ± 6.6% (mean ± SD), respectively, of the total circulating radioactivity. [c]Mean (CV%) reported in healthy subjects. [d]Median (range) reported in healthy subjects. [e]Following 50-mg single dose orally to healthy subjects. Midostaurin exhibits time-dependent pharmacokinetics with an increase in trough concentrations during the first week of dosing followed by a decline to a steady state after ~28 days. [f]Midostaurin AUC increased 1.2-fold when coadministered with a standard meal and 1.6-fold when coadministered with a high-fat meal compared to a fasted state. Midostaurin maximum concentrations (C_{max}) were reduced by 20% with a standard meal and by 27% with a high-fat meal compared to a fasted state.

[a]Data from healthy adult male subjects. [b]Moxifloxacin is metabolically cleared by ST and UGT. [c]Following a single oral 400-mg dose.

Reference: Stass H, et al. Pharmacokinetics and elimination of moxifloxacin after oral and intravenous administration in man. *J Antimicrob Chemother*, **1999**, *43*(suppl B):83–90.

[a]Data from healthy adult male and female subjects and organ transplant patients. No significant sex differences. Mycophenolate mofetil (MM) is rapidly converted to the active mycophenolic acid (MPA) after IV and oral doses. Kinetic parameters refer to MM and MPA after a dose of MM. MPA is metabolized by UGT to MPA-glucuronide (MPAG). MPA undergoes enterohepatic recycling; MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. [b]Accumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. [c]*CL/F* and V_{area}/F reported for MPA. [d]Range of mean MPA C_{max} and T_{max} from different studies following a 1- to 1.75-g oral dose given twice daily to steady state in renal transplant patients.

[a]Naltrexone has an active metabolite, 6β-naltrexol, that circulates at greater concentrations than naltrexone and has a 10-fold higher AUC than naltrexone after oral administration of naltrexone. [b]The oral AUC of naltrexone was significantly increased in patients with liver impairment, whereas the AUC of 6β-naltrexol was not changed. [c]A $t_{1/2}$ of 2.7 h after IV administration also reported. [d]Following a single 100-mg oral dose.

[a]Estimated bioavailability. [b]Saturable plasma protein binding yields apparent nonlinear elimination kinetics. [c]No change in total *CL*, but a significant (50%) decrease in *CL* of unbound drug; it is thus suggested that dosing rate be decreased. A second study in elderly patients found a decreased *CL* and increased $t_{1/2}$ with no change in percent bound. [d]Metabolically cleared by CYP2C9 (polymorphic) and CYP1A2. [e]*CL/F* and V_{area}/F reported. [f]Following a single 250-mg dose of suspension (S) given orally to pediatric patients or a 250-mg immediate-release tablet (T-IR) or a 500-mg controlled-release tablet (T-CR) given to adults.

Reference: Wells TG, et al. Comparison of the pharmacokinetics of naproxen tablets and suspension in children. *J Clin Pharmacol,* **1994**, *34*:30–33.

[a]Data from healthy adult and HIV-infected subjects. No significant sex differences. Metabolized by CYP3A. [b]Range of *CL/F* and *V/F* reported. Nevirapine appears to autoinduce its own metabolism. *CL/F* increases and $t_{1/2}$ decreases from a single dose (SD) to multiple doses (MD). [c]Patients <8 years. [d]Following a single 200-mg oral dose (SD), and 200 mg, twice a day, to steady state (MD).

[a]Following a single 50-mg oral dose (tablet) given to fasted healthy adults. No changes when taken with a meal.

Reference: Hoener B, et al. Nitrofurantoin disposition. *Clin Pharmacol Ther,* **1981**, *29*:808–816.

[a]Dinitrate metabolites have weak activity compared to nitroglycerin (<10%), but because of a prolonged $t_{1/2}$ (~40 min), they may accumulate during administration of sustained-release preparations to yield concentrations in plasma 10- to 20-fold greater than parent drug. [b]Following sublingual (SL) dose rinsed out of mouth after 8 min. Rinse contained 31% ± 19% of the dose. [c]Following a 40- to 100-min IV infusion. [d]V_{area} reported. [e]Steady-state concentration following a 20–54 μg/min IV infusion over 40–100 min or a 0.4-mg SL dose. Levels of 1.2–11 ng/mL associated with a 25% drop in capillary wedge pressure in patients with CHF. T_{max} for topical (Top) and transdermal (TD) preparations also reported.

[a]Oxaliplatin is an organoplatinum complex; Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxaliplatin (Ox) undergoes nonenzymatic biotransformation to reactive derivatives, notably $Pt(DACH)Cl_2$ (PtDC). Antitumor activity and toxicity are thought to relate to the concentration of Ox and PtDC in plasma ultrafiltrate (i.e., unbound concentration). [b]For IV administration only. [c]Approximately 54% of the platinum eliminated is recovered in urine. [d]Binding to plasma proteins is irreversible. [e]CL of total platinum is much lower; ~2–4 mL/min/kg. [f]The elimination of platinum species in plasma follows a triexponential pattern. The quoted $t_{1/2}$ reflects the $t_{1/2}$ of the first phase, which is the clinically relevant phase. The $t_{1/2}$ for the slower two phases are 17 and 391 h. [g]Steady-state plasma ultrafiltrate concentration of Ox and PtDC after an 85-mg/m^2 IV infusion over 2 h during cycles 1 and 2.

[a]Data from healthy adult male subjects. No significant sex differences. Oxcarbazepine (O) undergoes extensive first-pass metabolism to an active metabolite, 10-hydroxycarbamazepine (HC). Reduction by cytosolic enzymes is stereoselective (80% *S*-enantiomer, 20% *R*-enantiomer), but both show similar pharmacological activity. [b]CL/F for O reported. HC eliminated by glucuronidation. [c]AUC for HC increased, moderate to severe renal impairment. [d]AUC for HC decreased, children <6 years of age. [e]Following a 300-mg oral oxcarbazepine dose given twice daily for 12 days.

[a]Data from healthy female subjects. No significant sex differences. Racemic mixture; anticholinergic activity resides predominantly with *R*-enantiomer; no stereoselectivity exhibited for antispasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to *N*-desethyloxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. [b]Data reported for a 1-mg IV dose, assuming a 70-kg body weight. A larger volume (2.8 L/kg) and longer $t_{1/2}$ (5.3 h) reported for a 5-mg IV dose. [c]Exhibits a longer apparent $t_{1/2}$ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) $t_{1/2}$ = 9 ± 2 h; extended-release (XL) $t_{1/2}$ = 14 ± 3 h. The apparent $t_{1/2}$ for DEO was 4.0 ± 1.4 h and 8.3 ± 2.5 h for the IR and XL formulations, respectively. [d]Following a dose of 5-mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/mL for IR and XL, respectively.

TABLE AI–1 ■ PHARMACOKINETIC DATA (*CONTINUED*)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (h)	PEAK Time (h)	PEAK CONCENTRATION
Oxycodone[a]							
CR: 60–87[b]	—[c]	45	12.4 (9.2–15.4)	2.0 (1.1–2.9)	2.6 (2.1–3.1)[d]	CR: 3.2 ± 2.2[e]	CR: 15.1 ± 4.7 ng/mL[e]
IR: 42 ± 7[b]						IR: 1.6 ± 0.8[e]	IR: 15.5 ± 4.5 ng/mL[e]
[a]Oxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated *O*-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. [b]Values reported for OXYCONTIN (oxycodone controlled release [CR]) and immediate-release (IR) tablets. [c]Up to 19% excreted unchanged after an oral dose. [d]The apparent $t_{1/2}$ for the CR oral formulation is ~5 h; this most likely reflects absorption-limited terminal elimination kinetics. [e]Following 10 mg of OXYCONTIN (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 h to steady state.

Paliperidone[a]							
28 (oral ER)[b,c]	59 (51–67) (oral ER)	74	3.70 ± 1.04[d]	9.1[d] (oral ER)	28.4 ± 5.1[d] (oral ER)	22 (2.0–24)[d] (oral ER)	10.7 ± 3.3 ng/mL[d] (oral ER)
		↓ LD	↑ LD[e]		25–49 days (IM PP)[f]	13 days (IM PP)	
[a]Paliperidone, otherwise known as the 9-hydroxy active metabolite of risperidone, is marketed as an oral extended-release (ER) tablet (INVEGA) or in the form of its water-insoluble palmitate ester as a once-monthly long-acting IM injection (INVEGA SUSTENNA). Paliperidone is a racemate; its enantiomers have similar pharmacological profiles. The (+) and (–)-enantiomers of paliperidone interconvert, reaching an AUC (+) to (–) ratio of ~1.6 at steady state. [b]High-fat/high-caloric meal increased C_{max} and AUC by 60% and 54%, respectively. [c]No data on the absolute bioavailability of IM paliperidone palmitate (IM PP). The initiation regimen for INVEGA SUSTENNA (234 mg/156 mg in the deltoid muscle on day 1/day 8) produces paliperidone concentrations matching the range observed with 6–12 mg oral ER paliperidone. [d]At steady-state during once-daily doses of 3 mg, assuming an average body weight of 73 kg. V_{area} is estimated from *CL/F* and $t_{1/2}$. [e]Patients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. [f]The apparent long terminal $t_{1/2}$ of paliperidone following IM depot injection reflects the slow dissolution of paliperidone palmitate and release of active paliperidone.

FDA. Drugs@FDA. Invega label approved on 4/27/07; Invega Sustenna label approved on 7/31/09. Available at: http://www.accessdata.fda.gov/Scripts/cder/DrugsatFDA/. Accessed on January 1, 2010.							
Pantoprazole[a]							
77 (67–89)	—[b]	98	2.8 ± 0.9	0.17 ± 0.04	1.1 ± 0.4	2.6 ± 0.9	2.5 ± 0.7 μg/mL[c]
			↓ LD		↑ LD		
[a]Pantoprazole is available as a racemic mixture of (+) and (–) isomers. Pantoprazole is cleared primarily by CYP2C19 (polymorphic)-dependent metabolism. Poor metabolizers (PM) exhibit profound differences in *CL* (lower) and $t_{1/2}$ (higher) compared to extensive metabolizers (EM). In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (–) pantoprazole were observed, whereas in CYP2C19 PM, the *CL* of (–) pantoprazole was significantly greater than that of (+) pantoprazole. [b]No unchanged drug recovered in urine. [c]Following a single 40-mg oral dose.

Pharmacokinetics of pantoprazole following single intravenous and oral administration to healthy male subjects. *Eur J Clin Pharmacol,* **1993**, *44*:575–578. Tanaka M, et al. Stereoselective pharmacokinetics of pantoprazole, a proton pump inhibitor, in extensive and poor metabolizers of S-mephenytoin. *Clin Pharmacol Ther*, **2001**, *69*:108–113.							
Paroxetine							
Dose dependent[a]	<2	95	8.6 ± 3.2[a,b]	17 ± 10[c]	17 ± 3[d]	5.2 ± 0.5[e]	EM: ~130 nM[e]
			↓ LD, Aged		↑ LD, Aged		PM: ~220 nM[e]
[a]Metabolized by CYP2D6 (polymorphic); undergoes time- and dose-dependent autoinhibition of metabolic *CL* in extensive metabolizers (EM). [b]*CL/F* reported for multiple dosing in EM. Single-dose data are significantly higher. In CYP2D6 poor metabolizers (PM), *CL/F* = 5.0 ± 2.1 mL/min/kg for multiple dosing. [c]V_{area}/F reported. [d]Data reported for multiple doses in EM. In PM, $t_{1/2}$ = 41 ± 8 h. [e]Estimated mean C_{max} following a 30-mg oral dose given once daily for 14 days to adults phenotyped as CYP2D6 EM and PM. There is a significant disproportional accumulation of drug in blood when going from single to multiple dosing due to autoinactivation of CYP2D6.

[a]Phenobarbital is a weak acid (pK_a = 7.3); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. [b]Mean steady-state concentration following a 90-mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 μg/mL provide control of tonic-clonic seizures, and levels of at least 15 μg/mL provide control of febrile convulsions in children. Levels >40 μg/mL can cause toxicity; 65–117 μg/mL produce stage III anesthesia—comatose but reflexes present; 100–134 μg/mL produce stage IV anesthesia—no deep tendon reflexes.

[a]Data from healthy male and female subjects and patients with type 2 diabetes. Pioglitazone (P) is metabolized extensively by CYP2C8, CYP3A4, and other CYP isozymes. Two major metabolites (M-III and M-IV) accumulate in blood and contribute to the pharmacological effect. [b]*CL/F* and V_{area}/F reported. *CL/F* is lower in women than in men. [c]Steady-state $t_{1/2}$ of M-III and M-IV is 29 and 27 h, respectively. [d]Following a 45-mg oral dose given once daily for 10 days.

[a]Pramlintide is a synthetic peptide analogue of amylin for the treatment of both type 1 and type 2 diabetes. It is metabolized in the kidneys to at least one primary active metabolite: des-lys(1)pramlintide (2-37 pramlintide) with a $t_{1/2}$ similar to that of the parent drug. [b]SC administration with greater variability in response when the injection is into the arm compared to into the abdomen or thigh. [c]Not extensively bound to blood cells or albumin. [d]Based on IV infusion of a low dose of 30 μg for type 1 diabetes and a high dose of 100 μg for type 2 diabetes. [e]Following a low SC dose of 30 μg and a high SC dose of 100 μg.

[a]Although renal *CL* decreases with reduced renal function, no significant changes in *CL/F* or $t_{1/2}$ are seen following oral dosing as a result of the low and highly variable bioavailability. [b]A longer $t_{1/2}$ = 1.8 ± 0.8 h reported for oral dosing; probably rate limited by absorption. [c]Range of mean values from different studies following a single 20-mg oral dose.

Clinical pharmacokinetics of pravastatin. *Clin Pharmacokinet,* **1994**, *27*:94–103.

[a]Data from male and female patients with schistosomiasis. [b]Absolute bioavailability is not known. Praziquantel is well absorbed (80%) but undergoes significant first-pass metabolism (hydroxylation), the extent of which appears to be dose dependent. [c]*CL/F* and V_{ss}/F reported; *CL/F* and $t_{1/2}$ are dose dependent. [d]*CL/F* reduced, moderate to severe hepatic impairment. [e]Range of mean values from different studies following a single 40- to 60-mg/kg oral dose.

[a]Prednisolone and prednisone are interconvertible; an additional 3% ± 2% is excreted as prednisone. [b]Extent of binding to plasma proteins is dependent on concentration over range encountered. [c]Total *CL* increases as protein binding is saturated. *CL* of unbound drug increases slightly but significantly with increasing dose. [d]Changes are for unbound drug. [e]*V* increases with dose due to saturable protein binding. [f]Following a 30-mg oral dose given twice daily for 3 days to healthy adult male subjects. The ratio of prednisolone/prednisone is dose dependent and can vary from 3–26 over a prednisolone concentration range of 50–800 ng/mL.

[a]Measured relative to equivalent IV dose of prednisolone (PL). [b]An additional 15% ± 5% excreted as PL. [c]In contrast to PL, there is no dependence on concentration. [d]Kinetic values for prednisone (P) often are reported in terms of values for PL, its active metabolite. However, the values cited here pertain to P. [e]Range of mean data for P and PL following a single 10-mg oral dose given as different proprietary formulations to healthy adults.

TABLE AI–1 ■ PHARMACOKINETIC DATA (*CONTINUED*)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (h)	PEAK TIME (h)	PEAK CONCENTRATION
Pregabalin							
≥90[a]	90–99	0	0.96–1.2[b,c]	0.5	5–6.5	1[a]	8.5 μg/mL[e]
			↓ RD[d]				

[a]Bioavailability does not vary with dose up to 600 mg. T_{max} is delayed from 1 h to 3 h and C_{max} decreased by 25%–30% when pregabalin is given with food. No change in AUC or extent of absorption is noted. [b]Pregabalin undergoes minimal metabolism; an *N*-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. [c]Mean renal clearance in healthy young subjects ranges from 67 to 81 mL/min and assuming 70-kg body weight. Pregabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. [d]Pregabalin clearance is proportional CL_{cr}; hence, dosage can be adjusted in accordance to CL_{cr} in renal dysfunction. Plasma pregabalin decreased by ~50% after 4 h of hemodialysis. [e]Steady-state concentration in healthy subjects receiving 200 mg pregabalin every 8 h.

Procainamide[a]							
83 ± 16	67 ± 8	16 ± 5	$CL = 2.7\ CL_{cr} + 1.7$	1.9 ± 0.3	3.0 ± 0.6	M: 3.6[d]	M: 2.2 μg/mL[d]
	↓ LD		+ 3.2 (fast)[b] or + 1.1 (slow)[b]	↓ Obes	↑ RD[c]	F: 3.8[d]	F: 2.9 μg/mL[d]
			↑ Child		↓ Child, Neo		

[a]Active metabolite, *N*-acetylprocainamide (NAPA); CL = 3.1 ± 0.4 mL/min/kg, V = 1.4 ± 0.2 L/kg, and $t_{1/2}$ = 6.0 ± 0.2 h. [b]CL calculated using units of mL/min/kg for CL_{cr}. CL depends on NAT2 acetylation phenotype. Use a mean value of 2.2 if phenotype unknown. [c]$t_{1/2}$ for procainamide and NAPA increased in patients with RD. [d]Least square mean values following 1000-mg oral dose given twice daily to steady state in male (M) and female (F) adults. Mean peak NAPA concentrations were 2.0 and 2.2 μg/mL for male and female adults, respectively; T_{max} = 4.1 and 4.2 h, respectively.

Propofol[a]							
—[b]	—	98.3–98.8[c]	27 ± 5	1.7 ± 0.7[f]	3.5 ± 1.2[f]	—	SS: 3.5 ± 0.06 μg/mL[g]
			↑ Child,[d]	↑ Child[d]			
			↓ Aged[e]	↓ Aged[e]			
							E: 1.1 ± 0.4 μg/mL[g]

[a]Data from patients undergoing elective surgery and healthy volunteers. Propofol is extensively metabolized by UGTs. [b]For IV administration only. [c]Fraction bound in whole blood. Concentration dependent; 98.8% at 0.5 μg/mL and 98.3 at 32 μg/mL. [d]CL and central volume increased in children 1–3 years of age. [e]CL and central volume decreased in elderly patients. [f]V_{area} is much larger than V_{ss}. A much longer terminal $t_{1/2}$ was reported following prolonged IV infusion. Concentration producing anesthesia after infusion to steady state (SS) and at emergence (E) from anesthesia.

Propranolol[a]							
26 ± 10	<0.5	87 ± 6[b]	16 ± 5[c,d]	4.3 ± 0.6[c]	3.9 ± 0.4[c]	P: 1.5[e]	P: 49 ± 8 ng/mL[e]
↑ LD		↑ Preg, Obes	↑ LD	↑ Obes, Fem	↓ LD	HP: 1.0[e]	HP: 37 ± 9 ng/mL[e]
		↓ LD	↓ LD, Obes, Fem				

[a]Racemic mixture. For *S*-(−)-enantiomer (100-fold more active) compared to *R*-(+)-enantiomer, CL is 19% lower and V_{area} is 15% lower because of a higher degree of protein binding (18% lower free fraction); hence, there is no difference in $t_{1/2}$. Active metabolite, 4-hydroxypropranolol (HP). [b]Drug is bound primarily to α_1-acid glycoprotein, which is elevated in a number of inflammatory conditions. [c]Based on blood measurements; blood-to-plasma concentration ratio = 0.89 ± 0.03. [d]CYP2D6 catalyzes the formation of HP; CYP1A2 is responsible for most of the *N*-desisopropyl metabolite; UGT catalyzes the major conjugation pathway of elimination. [e]Following a single 80-mg oral dose given to healthy adults. Plasma accumulation factor was 3.6-fold after 80 mg was given four times daily to steady state. A concentration of 20 ng/mL gave a 50% decrease in exercise-induced cardioacceleration. Antianginal effects manifest at 15–90 ng/mL. A concentration up to 1000 ng/mL may be required for control of ventricular arrhythmias. P, propranolol.

References: Colangelo PM, et al. Age and propranolol stereoselective disposition in humans. *Clin Pharmacol Ther,* **1992**, *57*:489–494. Walle T, et al. 4-Hydroxypropranolol and its glucuronide after single and long-term doses of propranolol. *Clin Pharmacol Ther,* **1980**, *27*:22–31.

Pseudoephedrine[a]							
~100	43–96[b]	—	7.33[b,c]	2.64-3.51[c]	4.3-8[b,c]	IR: 1.4–2[d]	IR: 177–360 ng/mL[d]
						CR: 3.8–6.1[d]	CR: 265–314 ng/mL[d]

[a]Data from healthy adult male and female subjects. [b]At a high urinary pH (>7.0), pseudoephedrine is extensively reabsorbed; $t_{1/2}$ increases, and CL decreases. [c]CL/F, V/F, and $t_{1/2}$ reported for oral dose. [d]Range of mean values from different studies following a single 60-mg immediate-release tablet or syrup (IR) or 120-mg controlled-release capsule (CR) oral dose.

[a]Pyrazinamide is hydrolyzed in the liver to an active metabolite, 2-pyrazinoic acid. Reported peak 2-pyrazinoic acid concentrations range from 0.1- to 1-fold that of the parent drug. Pyrazinamide data reported are for male and female adults with tuberculosis. [b]Absolute bioavailability is not known, but the drug is well absorbed based on recovery of parent drug and metabolites (70%). [c]Recovery unchanged following an oral dose; the recovery of pyrazinoic acid is 37% ± 5%. [d]*CL/F* and V_{area}/F reported. [e]Following a 15- to 53-mg/kg daily oral dose to steady state.

[a]Raltegravir undergoes *O*-glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with *UGT1A1*28/*28* genotype compared to **1/*1* genotype. [b]The absolute oral bioavailability of raltegravir has not been determined. This minimum extent of oral absorption is based upon recovery of radioactivity in urine following oral administration of ^{14}C-labeled raltegravir in healthy human subjects. [c]Geometric mean (95% confidence interval) of pharmacokinetic parameters following a single 400-mg oral dose. Apparent oral clearance (*CL/F*) is listed. [d]Plasma concentration time course of raltegravir exhibits multiphasic washout kinetics. Initial (α) and terminal (β) $t_{1/2}$s are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. [e]Median for T_{max} and geometric mean (95% confidence interval) for C_{max} following a 400-mg twice-daily monotherapy regimen for 10 days in treatment-naive patients with HIV-1 infection.

[a]Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C_{max} and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. [b]Poor systemic availability of ramelteon is due to extensive first-pass metabolism. C_{max} and AUC are elevated by a high-fat meal; T_{max} is slightly delayed. [c]Intersubject variability is notably large. [d]Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. [e]P = parent drug; M = M-II metabolite. [f]C_{max} following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination $t_{1/2}$.

[a]Hydrolyzed to its active metabolite, ramiprilat (RT). Pharmacokinetic data for ramipril (R) and RT following oral and IV R administration are presented. [b]Based on plasma AUC of R and RT after IV and oral R administration. [c]Following an oral dose of R. [d]*CL/F* of R calculated from reported AUC data. [e]No data available; mean renal *CL* of RT is ~1.1 mL/min/kg. [f]$t_{1/2}$ for the elimination phase reported. A longer terminal $t_{1/2}$ of ~120 h most likely corresponds to the release of drug from ACE; contributes to the duration of effect but does not contribute to systemic drug accumulation. [g]Following a single 10-mg oral dose.

[a]Data from patients with advanced cancer unless otherwise specified. [b]Following 600-mg single oral dose administration in healthy subjects. Ribociclib was the major circulating drug-derived entity in plasma (44%). The major circulating metabolites included metabolite M13 (CCI284, *N*-hydroxylation), M4 (LEQ803, *N*-demethylation), and M1 (secondary glucuronide), each representing an estimated 9%, 9%, and 8% of total radioactivity, and 22%, 20%, and 18% of ribociclib exposure, respectively. Clinical activity (pharmacological and safety) of ribociclib was due primarily to parent drug, with negligible contribution from circulating metabolites. Ribociclib is extensively metabolized in the liver mainly via CYP3A. [c]Mean (CV%) in cancer patients. [d]*CL/F* reported. [e]V_{ss}/F reported. [f]Steady-state concentrations following 600 mg once a day for 21 days of a 28-day cycle; steady-state was generally achieved after 8 days. Ribociclib exhibited more than dose proportional increases in exposure (C_{max} and AUC) across the dose range of 50–1200 mg following both single dose and repeated doses.

[a]Active desacetyl metabolite. [b]Absolute bioavailability is not known, although some studies indicate complete absorption. Such reports presumably refer to rifampin plus its desacetyl metabolite because considerable first-pass metabolism is expected. [c]$t_{1/2}$ is shorter (1.7 ± 0.5) and *CL/F* is higher after repeated administration. Rifampin is a strong enzyme (CYP3A and others) inducer and appears to autoinduce its own metabolism. [d]Not observed with 300-mg doses but pronounced differences with 900-mg doses. $t_{1/2}$ is longer with high single doses. [e]Following a 600-mg dose given once daily for 15–18 days to patients with tuberculosis.

Reference: Israili ZH, et al. Pharmacokinetics of antituberculosis drugs in patients. *J Clin Pharmacol,* **1987**, *27*:78–83.

[a]High-fat meal. [b]Eliminated primarily by CYP1A2-dependent metabolism; metabolites are inactive. Involvement of CYP1A2 may contribute to ethnic (lower *CL/F* in Japanese) and sex (lower *CL* in women) differences and inductive effects of smoking (higher *CL* in smokers). [c]Following a 50-mg oral dose given twice daily to steady state.

Single- and multiple-dose pharmacokinetics of riluzole in white subjects. *J Clin Pharmacol,* **1997**, *37*:820–827. *PDR*58, **2004**, p. 769. Wokke J. Riluzole. *Lancet,* **1996**, *348*:795–799.

[a]The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a $t_{1/2}$ of 20 ± 3 h. In extensive metabolizers, 35% ± 7% of an IV dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. [b]Parameters reported for extensive metabolizers. In poor metabolizers, *F* is higher; ~20% of an IV dose is excreted unchanged, 10% as the 9-hydroxy metabolite; *CL* is slightly <1 mL/min/kg, and $t_{1/2}$ is similar to that of the active metabolite, ~20 h. [c]77% for 9-hydroxyrisperidone. [d]Changes in elderly subjects due to decreased renal function affecting the elimination of the active metabolite. [e]Mean steady-state C_{min} for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

References: Cohen LJ. Risperidone. *Pharmacotherapy,* **1994**, *14*:253–265. Heykants J, et al. The pharmacokinetics of risperidone in humans: a summary. *J Clin Psychiatry,* **1994**, *55*(suppl):13–17.

[a]Absolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral AUC for capsule formulation. [b]Ritonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own *CL* with single-dose (SD) to multiple-dose (MD) administration. [c]*CL/F*, V_{area}/F, and $t_{1/2}$ reported for oral dose. [d]*CL/F* reduced slightly and $t_{1/2}$ increased slightly, moderate liver impairment. [e]Following a 600-mg oral dose given twice daily to steady state.

References: Hsu A, et al. Ritonavir. Clinical pharmacokinetics and interactions with other anti-HIV agents. *Clin Pharmacokinet,* **1998**, *35*:275–291. *PDR*54, **2000**, p. 465.

[a]The oral bioavailability is lower (~60%) at doses >10 mg; food increases the fraction absorbed at those higher doses. [b]Rivaroxaban is cleared from blood by both renal and multiple biotransformation routes, including CYP3A-dependent metabolism. [c]Mean (range) following a single 10-mg oral dose in the fasted stated.

References: FDA. Drugs@FDA: FDA-approved drug products. Rivaroxaban (Xarelto). Available at: http://www.accessdata.fda.gov/scripts/cder/daf/. Accessed April 26, 2022. Mueck W, et al. Clinical pharmacokinetics and pharmacodynamics profile of rivaroxaban. *Clin Pharmacokinet,* **2014,** *53*:1–16.

[a]Following a 6-mg oral dose. Bioavailability increases with dose; following a 3-mg dose, the median bioavailability is 36%. [b]Rivastigmine is metabolized by cholinesterase. No apparent sex differences. [c]IV dose of 2 mg. [d]The pharmacodynamic $t_{1/2}$ is ~10 h due to tight binding to acetylcholinesterase. [e]Following oral administration of a 6-mg capsule. C_{max} increases more than proportionally at doses >3 mg.

[a]Data from patients with cancer. [b]Mean (range) absolute bioavailability of rucaparib immediate-release tablet. [c]Following 600-mg single dose oral administration. [d]*CL/F* measured at steady state after 600 mg twice-a-day dosing. [e]Following a single IV dose of 12–40 mg. [f]Mean (CV%) measured in cancer patients. Based on population pharmacokinetic analyses, steady-state concentrations following rucaparib 600 mg twice a day did not differ significantly across CYP1A2 or CYP2D6 genotype subgroups.

[a]Absolute bioavailability is not known (>44% absorbed); undergoes extensive first-pass metabolism to essentially inactive metabolites; catalyzed by multiple CYP isoforms. [b]*CL/F* reported. [c]Following a dose titration up to 200 mg given once daily for 30 days to healthy male (M) and female (F) adults.

References: van Harten J. Clinical pharmacokinetics of selective serotonin reuptake inhibitors. *Clin Pharmacokinet*, **1993**, *24*:203–220. Warrington SJ. Clinical implications of the pharmacology of sertraline. *Int Clin Psychopharmacol*, **1994**, *6*(suppl 2):11–21.

[a]Data from healthy male subjects. Sildenafil is metabolized primarily by CYP3A and secondarily by CYP2C9. Piperazine *N*-desmethyl metabolite is active (~50% parent) and accumulates in plasma (~40% parent). [b]*CL/F* reduced, mild to moderate hepatic impairment. [c]*CL/F* reduced, severe renal impairment. Increased unbound concentrations. [d]Following a single 50-mg oral (solution) dose.

[a]Data from male and female renal transplant patients. All subjects were on a stable cyclosporine regimen. Sirolimus is metabolized primarily by CYP3A and is a substrate for P-glycoprotein. Several sirolimus metabolites are pharmacologically active. [b]Cyclosporine coadministration increases sirolimus bioavailability. *F* increased by high-fat meal. [c]Concentrates in blood cells; blood-to-plasma concentration ratio ~38 ± 13. [d]Blood *CL/F*, V_{ss}/F, and $t_{1/2}$ reported for oral dose. [e]Following a single 15-mg oral dose (SD) in healthy subjects and 4- to 6.5-mg/m^2 oral dose (with cyclosporine) given twice daily to steady state (MD) in renal transplant patients.

[a]Cleared primarily by the kidney. Renal clearance is ~350 mL/min, which indicates active tubular secretion, possibly mediated by human organic anion transporter-3 (OAT3) and P-glycoprotein (ABCB1). [b]Apparent oral clearance increased by a respective 2.3-, 3.8- and 4.5-fold in patients with moderate (CL_{cr} = 30–50 mL/min) and severe (<30 mL/min) renal insufficiency and in patients with end-stage RD requiring hemodialysis. [c]Following a single 100-mg oral dose. Plasma AUC increased by ~14% following daily doses of 100 mg at steady state compared to the first dose.

[a]Sofosbuvir is sequentially metabolized to a pharmacologically active nucleoside analogue triphosphate; the active metabolite is undetected in plasma. The first hydrolytic step appears to be rapid (much of it may occur during first pass), yielding the intermediate metabolite, GS566500, which can either be fully activated by kinases to GS-461203 or inactivated by phosphatase activity to GS-331007. [b]The absolute oral bioavailability of sofosbuvir in humans is not known. Administration with a high-fat meal increases systemic sofosbuvir exposure by 67%–91%, although this is not thought to be clinically meaningful. [c]3.5% of the oral dose is recovered as unchanged sofosbuvir in urine; the true fraction excreted unchanged may be much higher, depending on the absolute bioavailability. [d]Also reported to be 62%–65% based on *in vitro* ultrafiltration experiments. [f]Systemic exposure (AUC) of sofosbuvir and GS-566500 increased 171% and 244%, respectively, in patients with severe renal impairment; smaller increases seen with less severe disease. [e]Mean (25th and 75th quartiles or CV%) reported following administration of 400-mg oral sofosbuvir, given once a day for 27 days.

Pharmacokinetic, pharmacodynamics and drug interaction profile of the hepatitis C virus NS5B polymerase inhibitor sofosbuvir. *Clin Pharmacokinet,* **2015**, 54:677–690.

[a]Solifenacin is extensively metabolized by CYP3A. The 4*R*-hydroxy-solifenacin metabolite is pharmacologically active but not likely to contribute to the therapeutic efficacy of solifenacin because of low circulating levels. [b]Primarily bound to α_1-acid glycoprotein. [c]Dosage reduction is advised in patients with severe renal impairment (CL_{cr} <30 mL/min), in whom a 2-fold reduction in clearance and prolongation in $t_{1/2}$ are expected. [d]At steady state following 21 days of dosing with 10 mg once daily.

Pharmacokinetics, safety, and tolerability of solifenacin in patients with renal insufficiency. *J Pharmacol Sci*, **2007**, *103*:67–74.

[a]The absolute bioavailability is not known, and a significant fraction of the oral dose is recovered in feces as unchanged drug, suggesting either poor absorption or significant biliary excretion. [b]Sorafenib is cleared by CYP3A4- and UGT1A9-dependent metabolism. [c]*CL/F*, V_β/F, and $t_{1/2}$ calculated following a single 400-mg oral dose assuming 70-kg body weight. [d]Mean (CV%) following a 400-mg oral dose given twice daily to steady state in cancer patients.

References: FDA. Drugs@FDA: FDA-approved drug products. Sorafenib (Nexavar). Available at: http://www.accessdata.fda.gov/scripts/cder/daf/. Accessed April 26, 2022. van Erp NP, et al. Clinical pharmacokinetics of tyrosine kinase inhibitors. *Cancer Treat Rev,* **2009,** *35*:692–706.

[a]Sotalol is available as a racemate. The enantiomers contribute equally to sotalol's antiarrhythmic action; hence, pharmacokinetic parameters for the total enantiomeric mixture is reported herein. β-Adrenoreceptor blockade resides solely with *S*-(–)-isomer. [b]Following 80-mg, twice-a-day dosing to steady state.

The pharmacokinetics of d-sotalol and d,l-sotalol in healthy volunteers. *Eur J Clin Pharmacol,* **1990**, *38*:579–582.

[a]Spironolactone (S) is extensively metabolized; it has three known active metabolites: canrenone (C), 7α-thiomethylspironolactone (TS), and 6β-hydroxy-7α-thiomethylspironolactone (HTS). [b]Absolute bioavailability is not known; old values reported in the literature were based on nonspecific assays for C; likely to exhibit first-pass metabolism. AUC of parent drug and metabolites increased when S taken with food. [c]Measured after an oral dose. [d]Binding of S and its active metabolites. [e]*CL/F* and V_{area}/F; calculated from reported AUC and $t_{1/2}$ data. [f]Following a single 200-mg oral dose of S. C accumulates 2.5-fold with multiple S dosing. [g]$t_{1/2}$ of parent drug and metabolites increased in patients with cirrhosis.

[a]An apparent $t_{1/2}$ of ~2 h reported for SC and oral doses. [b]Following a single 6-mg SC or 100-mg oral dose given to healthy young adults.

References: Scott AK. Sumatriptan clinical pharmacokinetics. *Clin Pharmacokinet*, **1994**, *27*:337–344. Scott AK, et al. Sumatriptan and cerebral perfusion in healthy volunteers. *Br J Clin Pharmacol,* **1992**, *33*:401–404.

[a]Drug disposition parameters calculated from blood concentrations. Data from liver transplant patients reported. Metabolized by CYP3A; also a substrate for P-glycoprotein. [b]A similar bioavailability (F = 21% ± 19%) reported for kidney transplant patients; F = 16% ± 7% for normal subjects. Low oral bioavailability likely due to incomplete intestinal availability. [c]Different values for plasma protein binding reported. Concentrates in blood cells; blood-to-plasma concentration ratio = 35 (12–67). [d]Slightly higher V_{ss} and $t_{1/2}$ reported for kidney transplant patients. Because of the very high and variable blood-to-plasma concentration ratio, markedly different V_{ss} values are reported for parameters based on plasma concentrations. [e]Following a single 7-mg oral dose given to healthy adults. Consensus target C_{min} at steady state is 5–20 ng/mL.

References: Bekersky I, et al. Dose linearity after oral administration of tacrolimus 1-mg capsules at doses of 3, 7, and 10 mg. *Clin Ther*, **1999**, *27*:2058–2064. Jusko WJ, et al. Pharmacokinetics of tacrolimus in liver transplant patients. *Clin Pharmacol Ther*, **1995**, *57*:281–290. *PDR*54, **2000**, pp. 1098–1099.

[a]Eliminated primarily by CYP3A4-dependent metabolism. [b]*CL/F* and *V/F* reported. [c]AUC increased in patients with mild or moderate (2-fold) and severe (4-fold) renal insufficiency. [d]Following a single 20-mg oral dose.

References: Curran M, et al. Tadalafil. *Drugs*, **2003**, *63*:2203–2212; discussion 2213–2214. Product labeling: Cialis® (tadalafil tablets). Lilly Icos, Bothell, WA, **2004**.

[a]Data from female and male heathy subjects. [b]Tafenoquine was administered as an investigational capsule formulation with a high-calorie, high-fat meal. [c]After single oral dose administration of tafenoquine, the only circulating component is unchanged tafenoquine, with no major systemic metabolites observed in blood or plasma. Over a 6-day collection period, renal elimination of unchanged tafenoquine was negligible. [d]CL/F reported. [e]The apparent volume of distribution after oral dose (V/F) reported. [f]Mean (CV%) measured in healthy subjects following 300-mg single oral dose to healthy subjects.

References: FDA. Product labeling: Krintafel (tafenoquine oral tablets). Drugs@FDA: FDA-approved drugs. Available at: https://www.accessdata.fda.gov/scripts/cder/daf/index.cfm. Accessed April 2, 2021.

[a]Has active metabolites; 4-hydroxytamoxifen and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen) are minor metabolites that exhibit affinity for the estrogen receptor that is greater than that of parent *trans*-tamoxifen. The $t_{1/2}$ of all metabolites are rate limited by tamoxifen elimination. [b]*CL/F* and V_{area}/F reported. [c]The major pathway of elimination, *N*-demethylation, is catalyzed by CYP3A. Polymorphic CYP2D6 catalyzes the 4-hydroxylation step key to metabolite activity. [d]$t_{1/2}$ consistent with accumulation and approach to steady state. Significantly longer terminal $t_{1/2}$s are observed. [e]Average C_{ss} following a 10-mg oral dose given twice daily to steady state.

[a]Data from female and male adult healthy subjects. [b]Administration of tecovirimat with a moderate-fat meal increased tecovirimat AUC by 49% compared to the fasted state. [c]Tecovirimat is extensively metabolized, predominantly by hydrolysis of the amide bond and glucuronidation. After a single oral dose administration of [^{14}C]-tecovirimat in mass balance study, 73% of the dose was excreted in urine, predominantly as metabolites. [d]*CL/F* at steady state reported following 600-mg oral daily dose for 14 days. [e]The apparent volume of distribution during the terminal phase (V_{area}/F) reported, after oral administration of 600-mg daily dose. [f]Value reflects administration of drug with food. [g]Mean (CV%) measured in healthy subjects. [h]Steady-state concentrations at the recommended dosage of 600 mg twice a day for 14 days in adults; steady-state AUC is achieved by day 6.

[a]Temsirolimus, a water-soluble ester analogue of sirolimus or rapamycin, is available for IV use. Following IV administration, temsirolimus is converted to sirolimus; blood AUC of sirolimus is 3-fold higher than that of temsirolimus at the recommended dose of 25 mg for the treatment of advanced renal cell carcinoma. Both temsirolimus and sirolimus inhibit mTOR kinase activity and undergo oxidative metabolism mediated by CYP3A. [b]Recovery of radioactivity after a single IV dose of [^{14}C]-temsirolimus. [c]Both temsirolimus and sirolimus partition extensively into blood cells; a major fraction of temsirolimus and sirolimus in plasma is bound to plasma proteins. [d]Based on *CL* of 16.1 ± 2.5 L/h and V_{ss} of 232 ± 36 L at a dose of 25 mg, assuming an average body weight of 70 kg. All pharmacokinetic assessments are based on whole blood concentration. [e]Following the first dose of a 25-mg/wk regimen.

[a]Tenofovir is formulated as an ester prodrug, VIREAD (tenofovir disoproxil fumarate), for oral administration. [b]Bioavailability under fasted state reported; increased to 39% with high-fat meal. [c]Data reported for steady-state 3-mg/kg IV dose given once a day for 2 weeks to HIV-1–infected male and female adults. Slightly higher *CL* with single IV dose. [d]Longer apparent plasma $t_{1/2}$ (17 h) reported for steady-state oral dosing; this may reflect a longer duration of blood sampling; also, phosphorylated "active" metabolite exhibits a longer intracellular $t_{1/2}$ (60 h). [e]Following a 300-mg oral dose given once a day with a meal to steady state.

[a]Data from healthy adult male subjects. No significant sex differences. Tolterodine (T) is metabolized primarily by CYP2D6 to an active (100% potency) metabolite, 5-hydroxymethyl tolterodine (5-HM), in extensive metabolizers (EM); $t_{1/2}$ 5-HM = 2.9 ± 0.4 h. Also metabolized by CYP3A to an *N*-desalkyl product, particularly in poor metabolizers (PM). [b]*CL/F* reduced and AUC 5-$HM_{unbound}$ increased, hepatic cirrhosis. [c]Following a 4-mg oral dose given twice daily for 8 days. C_{max} of 5-HM was 5 ± 3 ng/mL for EM.

[a]Tramadol (T) is available as a racemic mixture. At steady state, the plasma concentration of (+) (*1R,2R*)-tramadol is ~30% higher than that of (−) (*1S,2S*)-tramadol. Both isomers contribute to analgesia. Data reported are for total (+ and −) T. T is metabolized by CYP2D6 to an active *O*-desmethyl metabolite (M1); there are other CYP-catalyzed metabolites. [b]Recovery following an oral dose was reported. [c]Following a 100-mg immediate-release tablet given every 6 h for 7 days.

Valproic Acid[a]							
100 ± 10[b]	1.8 ± 2.4	93 ± l[c]	0.11 ± 0.02[d,e]	0.22 ± 0.07	14 ± 3[d,e]	L–4[f]	34 ± 8 μg/mL[f]
		↓ RD, LD, Preg, Aged, Neo	↑ Child	↑ LD, Neo	↑ LD, Neo		
					↓ Child		

[a]Valproic acid is available either as the free acid or stable coordination compound comprised of sodium valproate and valproic acid (divalproex sodium). [b]Systemic availability of valproate ion is the same after molar equivalent oral doses of free acid and divalproex sodium. [c]Dose dependent; value shown for daily doses of 250 and 500 mg. At 1 g daily, percent bound = 90% ± 2%. [d]Data for multiple dosing (500 mg daily) reported. Single-dose value: 0.14 ± 0.04 mL/min/kg; $t_{1/2}$ = 9.8 ± 2.6 h. Total *CL* is the same at 100 mg daily, although *CL* of free drug increases with multiple dosing. Valproate is eliminated mainly by glucuronidation. [e]Increased *CL* and decreased $t_{1/2}$ from enzyme induction following concomitant administration of other antiepileptic drugs. [f]Average concentration following a 250-mg oral dose (capsule, DEPAKENE) given twice daily for 15 days to healthy male adults. A therapeutic range of 50–150 μg/mL is reported. T_{max} is 3–8 h for divalproex tablets and 7–14 h for extended-release divalproex tablets.

[a]Very poorly absorbed after oral administration but used by this route to treat *Clostridium difficile* and staphylococcal enterocolitis. [b]Following a dose of 1000 mg IV (1-h infusion) given twice daily or 7.5 mg/kg IV (1-h infusion) given four times daily to adult patients with staphylococcal or streptococcal infections. Levels of 37–152 μg/mL have been associated with ototoxicity.

Reference: Leader WG, et al. Pharmacokinetic optimization of vancomycin therapy. *Clin Pharmacokinet,* **1995**, *28*:327–342.

[a]Vardenafil is primarily metabolized by CYP3A with minor involvement of CYP2C9. The major oxidative metabolite (M1), a product of *N*-desmethylation at the piperazine ring, is a less potent PDE5 inhibitor and circulates at a level 28% that of the parent drug. It contributes only 7% of the *in vivo* activity of vardenafil. [b]V_{ss} of 208 L, assuming 70-kg body weight. [c]Following a single 20-mg dose. There is no change in pharmacokinetics between single and multiple dosing.

[a]Data from patients with relapsed or refractory chronic lymphocytic leukemia or non-Hodgkin lymphoma. [b]Administration with a low-fat meal increased venetoclax exposure by approximately 3.4-fold and administration with a high-fat meal increased venetoclax exposure by 5.1- to 5.3-fold compared to fasting conditions. [c]Venetoclax is extensively metabolized, predominantly by CYP3A4/5, to the major circulating metabolite M27, which is also mainly metabolized by CYP3A4/5. After a single oral dose of radiolabeled [^{14}C]-venetoclax 200 mg to healthy subjects, >99.9% of the dose was recovered in feces (21% as unchanged drug) and <0.1% in urine within 9 days. The major metabolite identified in plasma, M27, is considered inactive, and its AUC represented 80% of the parent AUC. [d]CL/F measured at steady state following 400 mg orally once a day with low-fat meal. [e]The apparent volume of distribution (V_{ss}/F) reported. [f]Following multiple oral administration under fed conditions. [g]Steady-state concentrations following administration of 400 mg orally once a day with a low-fat meal. Venetoclax steady-state AUC increased dose proportionally over the dose range of 150–800 mg (0.25–1.33 times the maximum approved recommended dosage).

Venetoclax NDA and label. NDA approved in 2016; label revised 11/2020. Available at: https://www.accessdata.fda.gov/drugsatfda_docs/label/2020/208573s023lbl.pdf. Accessed April 2, 2021. Salem A, et al. Pharmacokinetics of venetoclax, a novel BCL-2 inhibitor, in patients with relapsed or refractory chronic lymphocytic leukemia or non-Hodgkin lymphoma. *J Clin Pharmacol,* **2017**, *57*:484–492.

[a]Venlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the *l*-(–)-enantiomer and its equipotent *O*-desmethyl metabolite (formation catalyzed by CYP2D6—polymorphic). Parameters for the derived *O*-desmethylvenlafaxine (ODV) are included. [b]*O*-Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a T_{max} of 7.5 h. Desvenlafaxine has a much lower CL (3.5 mL/min/kg) and a smaller V_{ss} (3.4 L/kg). Its reported $t_{1/2}$ matches that observed for metabolite derived from V. [c]Values for ODV after V dosing. [d]CL/F and V_{ss}/F reported. [e]Mean data for V and ODV, following a 75-mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. T_{max} for an extended-release formulation is 5.5 (V) and 9 (DV) h.

Warfarin[a]							
93 ± 8	<2	99 ± 1[b]	0.045 ± 0.024[c,d,e]	0.14 ± 0.06[b,d]	37 ± 15[f]	<4[g]	*R*: 0.9 ± 0.4 μg/mL[g]
		↓ RD					*S*: 0.5 ± 0.2 μg/mL[g]

[a]Racemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower *CL* (10 ± 2 vs. 18 ± 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. [b]Active metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or PR interval. At steady state (oral dosing), AUC is equivalent to that of parent drug ($t_{1/2}$ = 9 ± 3 h). [c]Multiple dosing causes a greater than 2-fold decrease in *CL/F* and prolongation of $t_{1/2}$ in some studies, but no change of $t_{1/2}$ in others. [d]Verapamil is a substrate for CYP3A4, CYP2C9, and other CYPs and for the efflux transporter P-glycoprotein. [e]Mean data following a 120-mg oral conventional tablet (IR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once daily, both for 7–10 days to healthy adults. EC_{50} for prolongation of PR interval after an oral dose of racemate is 120 ± 20 ng/mL; the value for IV administration is 40 ± 25 ng/mL. After oral administration, racemate concentrations >100 ng/mL cause >25% reduction in heart rate in atrial fibrillation, >10% prolongation of PR interval, and >50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/mL (after IV administration) was found to terminate reentrant supraventricular tachycardias.

The pharmacokinetics of vincristine in man: Reduced drug clearance associated with raised serum alkaline phosphatase and dose-limited elimination. *Cancer Chemother Pharmacol*, **1982**, *8*:215–219.

[a]For liquid-filled gelatin capsules. [b]Elimination kinetics of vinorelbine follow a three-compartment model with extensive tissue distribution. Values for the terminal elimination phase are reported. [c]Following a single 100-mg/m² oral dose (gel capsule). [d]Following a single 30-mg/g IV infusion over 15 min.

Reference: Leveque D, et al. Clinical pharmacokinetics of vinorelbine. *Clin Pharmacokinet,* **1996**, *37*:184–197.

[a]Metabolized mainly to an inactive *N*-oxide by CYP2C19 (major), CYP3A4, and CYP2C9. [b]Elimination is dose and time dependent. Pharmacokinetic parameters determined at steady state are reported. Mean *CL* was reduced (64%), V_{ss} reduced (32%), and $t_{1/2}$ increased (16%) with 12 days of twice-daily 3-mg/kg IV administration. Also, *CL* decreased 41% when dose was increased from 200 to 300 mg twice daily. [c]*CL* reduced in patients with mild to moderate hepatic insufficiency. [d]Following a 3-mg/kg oral dose given twice daily for 12 days. [e]Following a 3-mg/kg IV infusion over 1 h given twice daily for 12 days.

Voriconazole, a novel wide-spectrum triazole: oral pharmacokinetics and safety. *Br J Clin Pharmacol,* **2003**, *56*(suppl):10–16.

[a]Values are for racemic warfarin; the *S*-(–)-enantiomer is 3- to 5-fold more potent than the R-(+)-enantiomer. [b]No difference between enantiomers in plasma protein binding or V_{area}. [c]*CL* of the *R*-enantiomer is ~70% of that of the antipode (0.043 vs. 0.059 mL · min^{-1} · kg^{-1}). [d]Conditions leading to decreased binding (e.g., uremia) presumably increase *CL* and *V*. [e]The *S*-enantiomer is metabolically cleared by CYP2C9 (polymorphic). [f]$t_{1/2}$ of the *R*-enantiomer is longer than that of the *S*-enantiomer (43 ± 14 vs. 32 ± 12 h). [g]Mean steady-state, 12-h postdose concentrations of warfarin enantiomers following a daily oral dose of 6.1 ± 2.3 mg of racemic warfarin given to patients with stabilized (1–5 months) anticoagulant therapy.

Reference: Chan E, et al. Disposition of warfarin enantiomers and metabolites in patients during multiple dosing with rac-warfarin. *Br J Clin Pharmacol,* **1994**, *37*:563–569.

Appendix

Drug-Drug Interactions

Isabelle Ragueneau-Majlessi, Jingjing Yu, and Nina Isoherranen

Tables AII–1 and AII–2 present a perspective on drug-drug interactions as examined by the effect that one drug (the perpetrator) can have on the area under the plasma concentration versus time curve (AUC) of another drug (the victim). The cutoff value of 5-fold change in the AUC of the victim drug was chosen in order to focus these tables on clinically significant drug-drug interactions that would generally contraindicate the coadministration of the drugs or at least require dosage adjustment.

Table AII–1 lists *sensitive substrates,* which are drugs for which at least a 5-fold increase in their AUC is observed in humans when coadministered with an inhibitor of drug metabolism or transport.

Table AII–2 lists *strong inhibitors* and *strong inducers*, which are drugs that cause at least a 5-fold increase or 80% decrease in the AUC of a victim drug, respectively. The therapeutic classes for the substrates and inhibitors are also provided.

The *enzyme/transporter implicated* section refers to the main clearance pathway of the victim drug that is likely impacted by the drug-drug interaction. In the majority of cases, this assignment is based on information collected from *in vitro* experiments demonstrating metabolism of the victim drug via the implicated pathway or inhibition or induction of the target enzyme or transporter.

TABLE AII–1 ■ DRUG-DRUG INTERACTIONS WITH AT LEAST 5-FOLD CHANGE IN EXPOSURE OF VICTIM DRUG: SENSITIVE SUBSTRATES

SENSITIVE SUBSTRATE (victim drug)	THERAPEUTIC CLASS	CYP or TRANSPORTER IMPLICATED	AUCR[a]	INHIBITOR	ORAL DOSE[b] of INHIBITOR (perpetrator)	REFERENCE
Alosetron	Gastrointestinal agents	CYP1A2	6.0	Fluvoxamine	50–200 mg/day	1
Atazanavir	HIV protease inhibitors	CYP3A	25.9	Ritonavir	100 mg QD	2
Atorvastatin	Statins	CYP3A	5.6	Itraconazole	200 mg QD	3
		OATP1B	8.5	Rifampin	600 mg SD	4
Buspirone	Anxiolytics	CYP3A	19.2	Itraconazole	100 mg BID	5
Duloxetine	SNRIs	CYP1A2	5.6	Fluvoxamine	100 mg QD	6
Eletriptan	Triptans	CYP3A	5.9	Ketoconazole	Not available	7
Lopinavir	HIV protease inhibitors	CYP3A	≤30	Ritonavir	Not available	8
Lovastatin	Statins	CYP3A	36.4	Itraconazole	200 mg QD	9
Metoprolol	β adrenergic antagonists	CYP2D6	5.1	Pridopidine	45 mg BID	10
Midostaurin	Protein kinase inhibitors	CYP3A	10.4	Ketoconazole	400 mg QD	11
Quetiapine	Antipsychotics	CYP3A	6.2	Ketoconazole	200 mg QD	12
Ramelteon	Hypnotics-sedatives	CYP1A2	189.9	Fluvoxamine	100 mg BID	13
Repaglinide	Meglitinides	CYP2C8	8.3	Gemfibrozil	900 mg SD	14
Rosuvastatin	HMG-CoA reductase inhibitors (statins)	OATP1B, BCRP	7.1	Cyclosporine	75–200 mg BID	15
Sildenafil	Erectile dysfunction treatments	CYP3A	9.9	Ritonavir	300–500 mg BID	16
Simvastatin	Statins	CYP3A	16.1	Grapefruit juice	200 mL TID	17
Sirolimus	Immunosuppressants	CYP3A	10.9	Ketoconazole	200 mg QD	18
Tacrolimus	Immunosuppressants	CYP3A	78.0	Telaprevir	750 mg TID	19
Tolterodine	Muscarinic Antagonists	CYP2D6	14.9	Fluoxetine	20 mg/day	20
Valsartan	AngII receptor blockers	OATP1B	5.5	Rifampin	600 mg SD	21
Vardenafil	Erectile dysfunction treatment	CYP3A	49.1	Ritonavir	300–600 mg BID	22
Venetoclax	Cancer therapy	CYP3A	7.9	Ketoconazole	400 mg QD	23
Venlafaxine	SNRIs	CYP2D6	0.17 (CL ratio)	Quinidine	100 mg BID	24

AngII, angiotensin II; CL, clearance; HIV, human immunodeficiency virus; SNRIs, serotonin-norepinephrine reuptake inhibitors.

[a]AUCR is the ratio of the AUC of the sensitive substrate in the presence of inhibitor to the control AUC (absence of inhibitor):

$$AUCR = \frac{AUC_{inhib}}{AUC_{control}}$$

[b]QD, once daily; BID, twice daily; TID, three times daily; SD, single dose.

The magnitude of the alteration in the AUC of the victim drug AUC is provided in the column labeled AUCR, the *AUC ratio* (mean $AUC_{inhibited}$ divided by the mean $AUC_{control}$). In this column, the most severe observed drug-drug interaction magnitude is listed (worst-case scenario). In reports in the biomedical literature, the magnitude of drug-drug interactions varies considerably for the same perpetrator (inhibitor) with different victim drugs and with the same victim with different perpetrators.

For sensitive substrates (Table AII-1), the inhibitor listed refers to the coadministered inhibitor that resulted in the *AUCR* provided for the sensitive substrate. For strong inhibitors/inducers (Table AII-2), the substrate listed refers to the victim drug that was coadministered in the clinical studies to observe the *AUCR* provided. The *oral dose of the perpetrating inhibitor or inducer* is listed in order to provide some context to the reported findings, since the magnitude of a drug-drug interaction is often dependent on the dose of the perpetrator and its circulating concentrations.

TABLE AII–2 ■ DRUG-DRUG INTERACTIONS WITH AT LEAST 5-FOLD CHANGE IN EXPOSURE OF VICTIM DRUG: STRONG INHIBITORS AND INDUCERS

INHIBITOR OR INDUCER	THERAPEUTIC CLASS	CYP or TRANSPORTER IMPLICATED	AUCR[a]	VICTIM DRUG	ORAL DOSE[b] of INHIBITOR or INDUCER	REFERENCE
Strong Inhibitors						
Ciprofloxacin	Antibiotics	CYP1A2	9.7	Tizanidine	500 mg BID	25
Clarithromycin	Antibiotics	CYP3A	8.4	Midazolam	500 mg BID	26
Clopidogrel	Anticoagulants/antiplatelets	CYP2C8	5.1	Repaglinide	300 mg SD	27
Fluconazole	Antifungals	CYP2C19	13.5	Omeprazole	200 mg QD	28
Fluoxetine	SSRIs	CYP2D6	27.2	Dextromethorphan	60 mg QD	29
		CYP2C19	7.1	Omeprazole	60 mg QD	29
Gemfibrozil	Fibric acid derivatives	CYP2C8	11.3	Dasabuvir	600 mg BID	30
		CYP2C8	8.3	Repaglinide	900 mg SD	31
Itraconazole	Antifungals	CYP3A	10.8	Midazolam	200 mg QD	32
		Pgp	6.9	Dabigatran	200 mg QD	33
Nelfinavir	HIV protease inhibitors	CYP3A	5.3	Midazolam	1250 mg BID	34
Paroxetine	Antidepressants	CYP2D6	14.4	Dextromethorphan	20 mg (2 doses)	35
Posaconazole	Antifungals	CYP3A	6.2	Midazolam	400 mg BID	36
Ribociclib	Protein kinase inhibitors	CYP3A	5.2	Midazolam	600 mg QD	37
Rifampin	Antibiotics	OATP1B	7.25	Atorvaststin	600 mg SD (IV)	38
Ritonavir	HIV protease inhibitors	CYP3A	26.4	Midazolam	100 mg TID	39
Telithromycin	Antibiotics	CYP3A	6.2	Midazolam	800 mg QD	40
Voriconazole	Antifungals	CYP3A	9.6	Midazolam	200 mg BID	41
Strong Inducers						
Carbamazepine	Anticonvulsants	CYP3A	0.13	Quetiapine	200 mg TID	42
		CYP2B6	0.10	Bupropion	942 ± 254 mg/day	43
Phenytoin	Anticonvulsants	CYP3A	0.10	Nisoldipine	200–450 mg/day	44
Rifampin	Antibiotics	CYP2C19	0.07	Omeprazole	600 mg QD	45
		CYP3A	0.003	Budesonide	600 mg QD	46
Ritonavir	HIV Protease Inhibitors	CYP2C19	0.16	Voriconazole	400 mg BID	47

Pgp, P-glycoprotein; SSRI, selective serotonin reuptake inhibitor.

[a]AUCR is the ratio of the AUC of the sensitive substrate in the presence of inhibitor or inducer to the control AUC (absence of inhibitor/inducer):

$$AUCR = \frac{AUC_{inhib/inducer}}{AUC_{control}}$$

[b]QD, once daily; BID, twice daily; TID, thrice daily; SD, single dose.
